## Abstract

Statisticians have calculated probabilities for most of the circumstances of everyday life, including the chances that an individual will become ill, have an accident, or die. The danger profile for a single individual is divided into a multitude of individual risks, which are unequally distributed, sometimes starting from birth. For example, 2% of all diseases are genetically determined. Even people who arrive in the world healthy, however, have disadvantages, but factors such as success in an occupation and high income are protective against early death. Statistically high risks are associated with smoking and poor nutrition, whereas the risk of death from viruses, radiation, or chemicals is low.

The calculation of risks is difficult and dangers often arise. Experts as well as laypeople may fall victim to “cognitive dissonance,” where knowledge that disturbs established beliefs and habits is not perceived. Risk assessment thus becomes difficult, as seen by the following phenomena:

e-mail: [reichl@lmu.de](mailto:reichl@lmu.de)

- The occurrence of rare hazards (e.g., snake bite) is overestimated, whereas that of frequent hazards (e.g., death caused by cardiac infarct resulting from obesity) is underestimated.
- People are subject to an imperfect assessment of probabilities; for example, driving in a car is more dangerous than flying in a plane, but the fear of flying is common compared with the fear of driving.
- People tend to overestimate their own abilities (e.g., they believe they are immune from disease).
- Fears are minimized for things people believe they can control (e.g., smoking).
- Fears are maximized for things people believe they cannot control (e.g., a toxic waste repository).

Psychological studies show that events with a high “horror factor” (e.g., being eaten by a shark) are particularly feared, even if they occur extremely rarely. Human behavior is less determined by numbers and facts than by faith, desires, and fears.

## Introduction

Insurance companies and security specialists define risk as the product of probability of occurrence and level of damage, and calculate premiums accordingly. So, the risk remains the same, regardless of whether minor damage occurs frequently or major damage occasionally. According to this principle the risk for 1,000 road accidents, each with one adult killed, is exactly the same as that of a school fire in which 1,000 children die. In general, however, the word “risk” encompasses both danger and chance. It describes both the objective threat which cannot be avoided and also the subjective gamble which is assumed voluntarily. A danger survived can therefore also become a chance for a better and safer life.

The idea that each person holds his fate in his or her own hand did not emerge until after the Middle Ages. While prior to this many people believed in evil or good-natured gods, who at least partly determined fate, in modern times each individual rose to become important producers of dangers and chances. And because at that time, there was no term for this concept, a new word had to be coined. The word “risk” derived etymologically in the sixteenth century from the Italian word *risco* (gamble, hazard), which was in turn probably derived from the Greek *rhiza* (root; secondary meaning: cliff) or from the Arabic *rizq* (livelihood which depends on God and fate).

---

## Definitions

- *Absolute risk* in an equally affected group of persons is the ratio of the number of illnesses to the total number of persons.
- *Relative risk* is the ratio of the absolute risk of the affected group to the unaffected group.
- *Risk appraisal* (risk description) is the quantitative determination of possible health risks due to chemicals or radiation depending on efficacy, length of exposure, and level of exposure or the dose absorbed.
- *Risk assessment* is the evaluation of a risk with regard to its tolerability under social and health political aspects.

---

## Risk Structures

Statisticians have calculated the probabilities for all possible circumstances of everyday life that an individual will, e.g., contract an illness, have an accident, or die. Their calculations of the risk of illness (“morbidity”) and the risk of dying (“mortality”) are, however, applicable only to an imaginary being: the statistical average person.

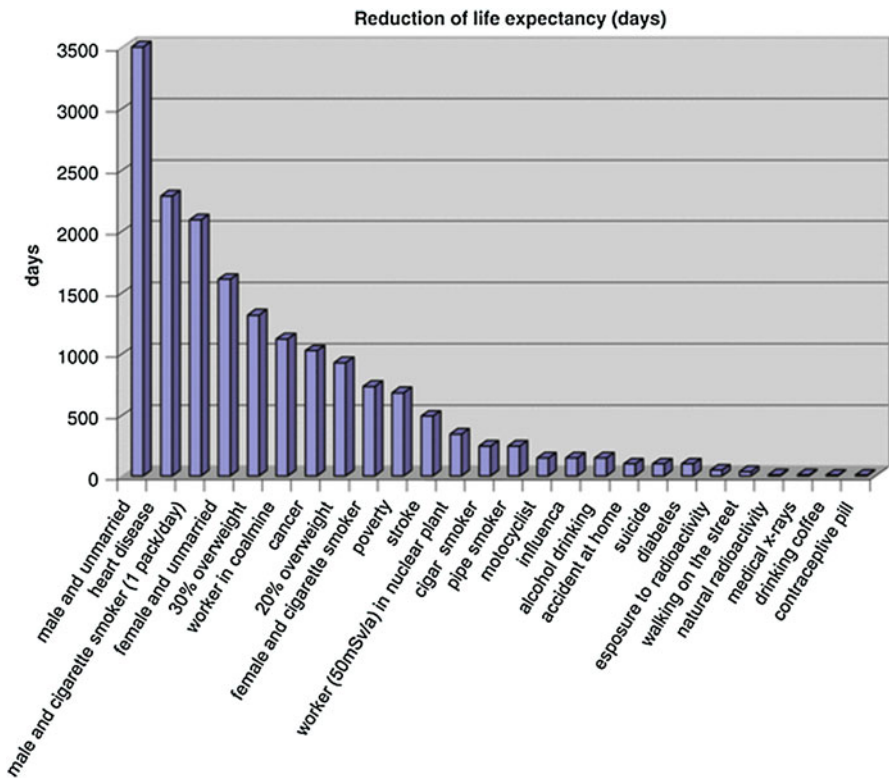

His existence follows a risk profile which changes dramatically with age. Already on the first day after birth, one in every 600 newborns dies in Germany, as the result of, for instance, having too low a birth weight or pregnancy complications (Cawley et al. 2020). In the first year of life, the rate increases to one in 125 babies. After the first birthday, survival odds then rise steeply. Ten years after birth and survival of childhood diseases, the safest phase of life is reached. The annual risk of death reduces to the lowest level of 1 in 6,000, before increasing again between the ages of 15 and 20 for the average male teenager to 1 in 1,000 due to the propensity to take risks (e.g., driving). In addition, the willingness to take their own lives increases: Around one in five men who die around the age of 30 commit suicide. Diseases (e.g., cardiac and circulatory diseases, cancer) (Samet et al. 2020), which are the cause of death for 95% of people, only dominate from the age of 40, and in the decade before retirement bring the mortality rate back up to the level of infants.

This basic risk structure has not changed for thousands of years. Already in the Paleolithic Age, death claimed mainly infants and old people and granted security in late childhood. Equally, young people took risks, although in those times not on the roads but perhaps in hunting.

But any attempt to derive one’s personal destiny from these figures is senseless. The **risk profile** for the individual is made up of millions of individual risks which are often unequally distributed right from birth. Two percent of all diseases are, for instance, genetically determined. And a child born healthy but male already has a disadvantage. In their very first year of life, around one third more boys die than girls. Women are less likely to commit suicide and do not have as many accidents on the road or at work. They also used to drink and smoke less than men – an advantage which is, however, diminishing in the name of emancipation.

Professional success, high income, and a good education are on the other hand factors which protect men in particular against an early death. According to an US study, rich men, for instance, in Canada live four-and-a-half years longer than the poorest ones there. Background, poverty, poor living conditions, unemployment, and contaminated food (de Boer 2019) reduce **life expectancy**. This becomes particularly clear in the New York district of Harlem which is populated almost entirely by non-whites, almost 50% of whom live below the poverty line. In this area, mortality rates in women between 25 and 34 and in men between 35 and 44 are six times higher than the US average. The likelihood of reaching the age of 65 in Harlem is less than it is in Bangladesh.

Other various risks also contribute to reducing life expectancy, e.g., the life expectancy of men who smoke cigarettes reduces on average by almost 7 years (Fig. 1). One way to reduce personal risk slightly (on a purely statistical basis) is a trip to the registry office. But whether marriage really offers more security is not certain. Perhaps single people between the ages of 35 and 45 have a riskier way of life. Divorce and even more so the death of a partner drive many to an early grave – although women cope with the loss considerably better.

**Fig. 1** Reduction of life expectancy through various risks in the population of Europe

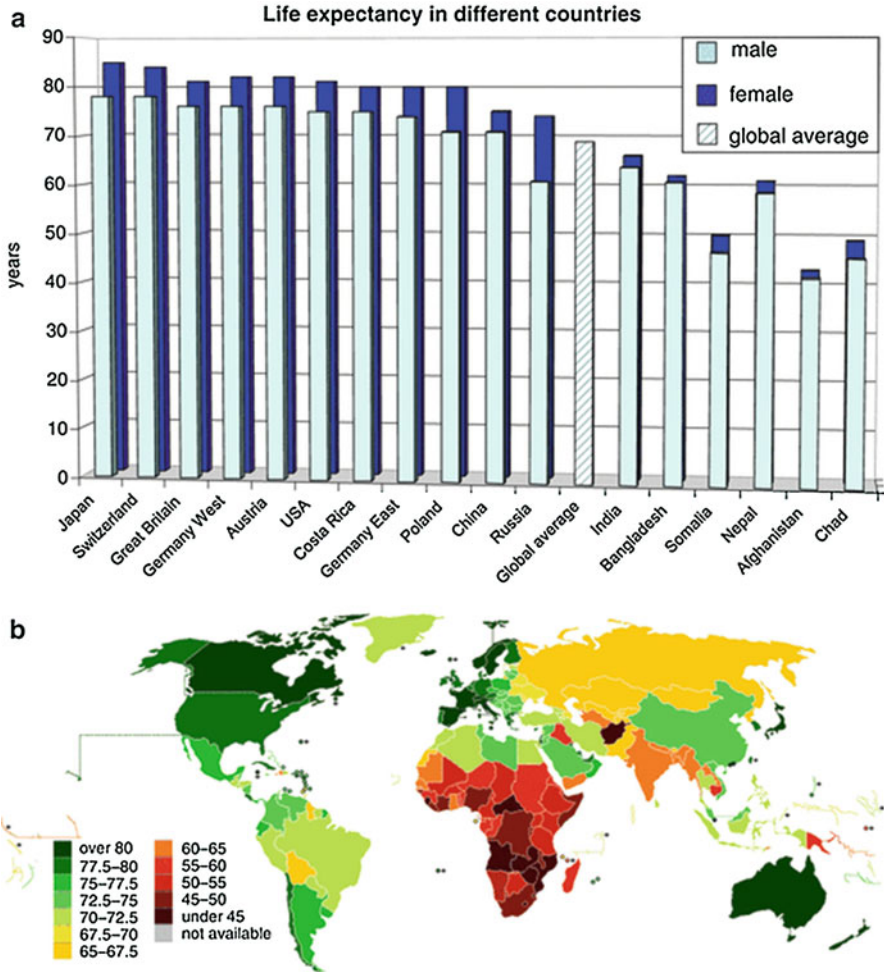

**Fig. 2** Development of life expectancy in Germany (years; average of men and women)

Today, statistically speaking, Germans are getting around three times as old as they were 300 years ago at 85 years (women) and 79 years (men) (Fig. 2). The main reason for this is the decline of infant mortality. For the year 2040, in Germany, a life expectancy of 86 years (women) and 81 years (men) and for 2060 89 (women) and 85 (men) is forecast (Fig. 2). The life expectancy of persons in Afghanistan has up to now not got beyond 45. Almost all over the world, women live longer than men, with the exception of countries such as Afghanistan or Bangladesh, in which they are severely disadvantaged (Fig. 3).

## Future Risks

Compared to smoking and nutrition, today, **radiation** and **chemicals** (still) represent relatively minor risks. In the future, however, four risks from the environment and biology could be a particular threat:

- Damaging ultraviolet (UV) radiation: according to US calculations by 2100, skin cancer will claim the lives of an additional 10,000 people as a result of increased UV radiation on the Earth due to the reduced (protective) ozone layer.
- In the USA, it is estimated that passive smoking causes up to 8,000 deaths a year.

**Fig. 3** (a) Life expectancy in various countries. (b) World map indicating Life expectancy at birth in UN member states

- The radioactive gas radon, which comes up through the ground and penetrates natural building materials, today also already claims the lives of around 20,000 Americans.
- Viruses may kill thousands of people worldwide and may cause long-term economic damages of trillions US-dollars as already happened for the virus SARS-Covid2 in the year 2020.

The risk of contracting cancer from the more than 60,000 chemicals is relatively low. According to the most recent studies, this contributes a total of only around 1–2% of the overall cancer risk to humans. However, 50,000 materials have still not even been tested

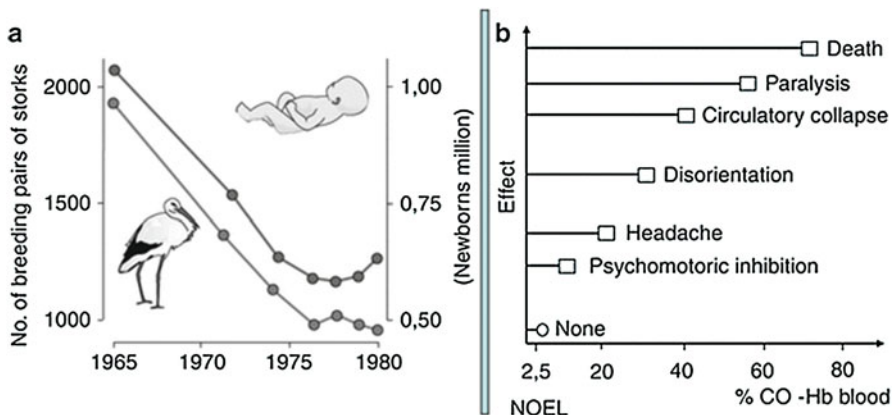

for their carcinogenic potential. It is still disputed just how dangerous these over 600 substances are which have proved carcinogenic in animal experiments. What induces cancer in a rat may have no effect on a mouse and vice versa.

Another problem still unresolved is the effect of carcinogens in combination. The effect of radon contaminated inside air, asbestos, or alcohol must not simply be added to the risk factor of smoking. In combination, these substances may even exponentiate the risk of lung cancer.

Patients are also increasingly complaining of the onset of symptoms after a tooth restoration, because they believe they are being slowly poisoned by the substances released from the inserted dental materials in combination with other (environmental) pollutants. What risk actually exists for these patients can be established by a recognized international toxicological dental advice center (e.g., at the Ludwig-Maximilian University of Munich: [www.dentaltox.com](http://www.dentaltox.com)).

Because the analysis of health risks is fraught with many uncertainties, statisticians tend to resort to averages calculated from many individual findings. This does, however, have its pitfalls: Risks which are meaningless for the general public can be a major threat to those in certain risk groups, e.g., children who sit in classrooms contaminated with asbestos. Although in the average population of the USA, 100 times more schoolchildren die at football games than from asbestos poisoning, anyone who is exposed to the deadly dust at relevant concentrations bears a high individual risk.

Comparisons such as “asbestos versus football” are intended to put risks into perspective. But one risk is not like any other, and not every relation is useful. This becomes particularly clear by considering, for instance, the correlation between the reduction of breeding pairs of storks in Germany and the reduction of the birth rate in Germany in the years 1965–1980 (Fig. 4): An accurate correlation, but not a useful one!

**Fig. 4** Useful and senseless correlations. (a) Statistically significant correlation, but no causal link: decline of breeding pairs of storks and decline of birth rate in the Federal Republic of Germany from 1965 to 1980. (b) Statistically significant correlation, causal link: effect of an increasing carbon monoxide content in the blood

## Mortality Risks in the Population

The calculation of risks is very difficult and often involves dangers. Experts are, namely, just as susceptible as lay people to what is known as **cognitive dissonance** (Reichl and Ritter 2011). The phenomenon by which knowledge which disrupts long-established habits is simply not perceived. Thus, for instance, in the USA in 1985, NASA published a risk assessment on the Space Shuttle, according to which the probability of crash for the shuttle was 1: 100,000. Studies by other committees, however, assumed a risk ranging from 1: 270 to 1: 57. In fact, the shuttle “Challenger” exploded on its 25th flight and the shuttle “Columbia” broke up on its 28th flight.

According to more recent studies, being killed by lightning is around 650 times more unlikely than dying as a consequence of alcohol – but dying as a result of cigarette smoking is almost 10 times more likely (Fig. 5). The risk of being killed by a meteorite crash is in fact greater than that of dying in a plane crash. Although the likelihood of being hit by a celestial body is astronomically small, if it did happen millions of people could die – so the result is an increased risk.

The probability for the average citizen of dying in a terrorist attack or a natural disaster is infinitesimal. It remains infinitesimal even though the number of, e.g., major natural disasters has been increasing globally since 1980 (Fig. 6).

It is this increase which is often the reason for escalating fear in the population, although in fact this is not justified. But escalating fears would be justified if you consider the indirect consequences of terror attacks or natural disasters, which affect every one of us, i.e., even the unaffected average citizen, and could thus precipitate

**Fig. 5** Mortality risks in the population of Europe

**Fig. 6** Number of natural catastrophes. Number of natural catastrophes from 1980 to 2018 (worldwide; source: Münchener Rückversicherungs-Gesellschaft/GeoRisikoForschung, NatCatSERVICE 2020). **Geophysical events:** General terms having their origin in the earth crust like earthquake, tsunami, volcanic activity, and mass movement dry. **Meteorological events:** General term for loss events caused by all kinds of storms such as tropical storm, winter storm, convective storm, and local windstorm. **Hydrological events:** General term for loss events covering all kinds of floods and rain triggered mass movements (Tsunami is not included). **Climatological events:** General term for loss events covering all kinds of extreme temperature, drought, and wild fire

his downfall. Because the national economic damage caused by disasters has in fact increased dramatically over the last 60 years (Table 1), bringing some countries to the brink of ruin and even causing some reinsurance companies to topple (Fig. 7) (just the terrorist attack on the World Trade Center on 11 September 2001 caused national economic damage of almost half a billion Euros). The loss of immense sums of money (Fig. 7) means that there is then no longer enough funding available for necessary projects. Whole population groups can thus be thrust suddenly into economic poverty, which is in turn a factor for a shorter life.

## Acceptance of Risks

The risk acceptance in the population is a complex and unpredictable phenomenon.

1. Rare risks (e.g., a snake bite) are overestimated, common threats (e.g., fatal heart attack due to excess weight and lack of exercise) are underestimated.

**Table 1** Comparisons across decades of the number of major natural disasters occurring, the damage to the national economy, and the insured damage in billions of US dollars (worldwide; values from 2006; source: Münchener Rückversicherungs-Gesellschaft/GeoRisikoForschung, NatCatSERVICE 2020)

Major natural catastrophes 1950 -2006						
	Dekade 1950-1959	Dekade 1960-1969	Dekade 1970-1979	Dekade 1980-1989	Dekade 1990-1999	last 10 1997-2006

**Fig. 7** Percentage distribution for relevant natural loss events worldwide from 1980 to 2018 (worldwide; source: Münchener Rückversicherungs-Gesellschaft/GeoRisikoForschung, NatCatSERVICE 2020). Explanation to the types of events: See legend to Fig. 6

2. People are liable to falsely evaluate probabilities (e.g., driving a car is more dangerous than flying, but we always talk about a fear of flying and never a fear of driving). People do not worry because the possibility of dying in each individual car journey is one in four million and thus lower than the chance of having a fatal

accident when mowing the lawn. But if you consider that in the course of your life you undertake several 1000 car journeys, the actual risk increases. One in 100 Germans dies as the result of a road traffic accident.

3. People overestimate their own abilities (e.g., they believe they are immune to disease or will have a long life).
4. Things which we believe are under our control minimize fear (e.g., smoking, drinking alcohol, driving, or climbing).
5. Things which we obviously cannot control ourselves increase fear (e.g., toxic waste facilities, invisible toxins in foodstuffs, atomic power plants).

Psychological studies show that events with a high “gruesomeness factor” (e.g., plane crashes, death by lightning, or being eaten by a shark) are especially feared, even though they are extremely rare. This is made particularly clear by the following study: When asked to choose between two forms of treatment, patients, and even doctors, preferred the treatment with a 90% chance of survival over that with a 10% mortality rate, although both figures express exactly the same thing: one in ten dies.

Thus, human behavior is steered less by facts and figures than by beliefs, desires, and anxieties. That is why in the future too, acceptance of risks will remain a fascinating and unpredictable social psychological phenomenon for us all.

## Abstract

If an action involves risk, the outcome is not completely predictable in advance. This raises the question as to whether there are decision-making tools that could help to identify the consequences as much as possible and then to evaluate them and weigh them. Both positive consequences (benefits) and negative consequences (risks) are considered together. The evaluation depends on being able to quantify the risks and benefits using the same units, such as monetary value or length and quality of life.

## Introduction

When governments and agencies decide to take a risk, they should do so after considering formal risk-benefit and cost-benefit analyses and a utility analysis.

There are *known knowns* (those well-characterized and quantified risks and benefits), *known unknowns* (effects that can be identified but not quantified), and *unknown unknowns* (risks or benefits not known at the time of the evaluation). Risk-benefit analysis is an attempt to quantify known knowns and known unknowns, with, for the known unknowns, an attempt to quantify the uncertainties involved. It cannot address unknown unknowns, which may be risks or benefits. It is not unknown for a drug or other chemical developed for one purpose to have a much more important use discovered later – and therefore not taken into account in the original risk-benefit analysis. Also, sometimes a new toxicity is described after a drug or other chemical has been marketed that changes the risk-benefit equation. In the case of a drug, this often results in its withdrawal from the market. Thus, there is always a residuum of risk that cannot be included in a risk-benefit assessment.

## Risk-Benefit Assessment

The **risk-benefit analysis** compares the identified risks with the identified benefits. A variety of methods can be used (Fig. 1). From an economic perspective, the benefit/utility of an object is based on a subjective judgment of the value of the benefit gained or the risk foregone. Both the object itself and the estimation of its value are considered. As no useful universally valid measure exists for the determination of a benefit, a benefit can only be measured indirectly. Care must be taken to

**Fig. 1** Ways of carrying out a risk-benefit analysis (examples)

identify whether the property that should result in a benefit is intrinsic or whether it depends on further conditions which are not dependent on the risk decision or whether it appears just accidentally to be advantageous.

Simultaneously, both the benefits and the consequential risks must be allowed for, although these consequential risks will need to be tolerable. Household disinfectants are a good example. The aim of using the material to be evaluated is to disinfect. Disinfectants have the purpose to reduce germs. However, they can cause irritation of the skin, eye, and respiratory tract of the user if not handled appropriately. Besides the desired benefits, that is, “reducing the germs,” other features, i.e., the corrosive/irritant properties of the substance, must also be taken into account. In the present example, the benefits are evident, and warning labels identifying the hazardous properties and some basic precautions inform users so that they can minimize their exposure. However, if the hazardous properties of the active ingredient are identified as an unavoidable concomitant to achieving the objective of disinfection, and serious, such a product may either be banned or some limitation as to user (e.g., “for professional use only”) imposed.

From an economic perspective, there are fundamental concerns with such considerations, since the evaluation of the benefits is determined by the market and includes the question as to whether there is a demand for such a material.

**Risk comparison** is one method by which substitute products can transparently be evaluated. As stated in ► [Chap. 50, “Current Role of the Risk Concept in Regulatory Toxicology,”](#) a comparison of risks is only possible if the assessable parameters of the various risks are realistically comparable, i.e., sufficiently similar in terms of their combination, chronologic order, and the distribution of advantages and disadvantages. A risk comparison can lead to a transparent identification of the critical parameters. When interpreted competently, the comparison of risks is an adequate evaluation framework in which the individual decision to take a specific risk can be made. It is important for the regulatory toxicologists that all information, including information concerning the different ways in which risks are perceived, is considered in the risk comparison. The risk comparison will only be convincing, when the underlying preconditions are clearly presented and possible shortcomings of the comparison are explained (see ► [Chap. 58, “Risk Comparison in Toxicology”](#)).

Risk comparison may allow decision takers to communicate the decision more effectively. If the comparison shows that the risk posed by a substance or an action is less than a similar risk that has previously been accepted by society, then it is likely that the decision will be generally acceptable.

Risk comparisons are appropriate when they are based on a solid safety assessment. If however the uncertainty is high and/or variable, the risk comparison will not be convincing.

---

## Cost-Benefit Analysis

While the risk-to-benefit analysis generally requires a more qualitative approach, a cost-benefit analysis contributes a quantitative component to the overall assessment. Here, the risks and the benefits of an action or of a substance/use are set out

quantitatively, usually in monetary terms, i.e., the risks and benefits are monetized. Consider the costs and benefits to the state of a premature death caused by a chemical exposure. The direct costs are reduced productivity and cost of treatment of any illness/infirmity. An earlier death is likely to reduce the costs of treatment of diseases of the elderly and cost of pensions. Funeral expenses will arise in both cases. Generally, possible psychological/psychiatric costs for those affected and their family are not monetized. The valuation shows here an extreme case of how profits and losses for society can be estimated. It should be noted that moral and ethical considerations may result in considerable disproportionation occurring, i.e., that the benefits gained by society may have to grossly exceed the risks taken by the individual before that risk is deemed tolerable. In some cases, moral/ethical considerations may completely override any cost-benefit analysis.

**Value of a Human Life:** Four different methods have been used to calculate the value of a human “life.” If the costs that arise to eliminate effects of a substance or an action from which a person suffers are determined, we talk about “**regeneration cost.**” This approach can be applied in connection with such accident damages that result from a risky decision. The costs can be estimated on the basis of statistical data. The monetary benefits that might result from a professional development of the person (e.g., a promotion) can however only partially – if at all – be considered.

A system which is based on years of life lost assesses the productive contribution of the individual to society. This method calculates the costs (residual working lifetime, employment rate, and national income) and the benefits which can no longer be taken advantage of (consumption, services, medical expenses). A cost calculation is based on this so-called human capital approach.

A fundamentally different method for rated human life uses neither statistical data about recovery costs nor the contribution of the individual to the productivity of the society but personal judgment. A **willingness to pay** analysis is conducted where a court awarded compensation or the amount of a life insurance serves as the base. The costs identified using this technique depend heavily on the tradition and the ethical values of the society in which the individual lives. Examples are the different levels of compensation in the USA and Europe.

Furthermore, appropriate questioning/survey techniques allow us to estimate those costs which the individual would be willing to bear in order to compensate for the consequences of an action or the application of a substance. The acceptance of such “compensation cost” depends not only on the social environment of the respondents but also on the individual’s concern at the loss and the availability of alternatives, as demonstrated by the example of the marketing of so-called organically grown food.

Each method can give very different results, and the actual results obtained are country specific. In the Federal Republic of Germany, the Federal Highway Research Institute calculated the annual economic cost of road accidents. Therefore, apply in 2009 following personal accident costs: for a slightly injured person 4416 €, for a seriously injured person 110,571 €, and for a fatal outcome 996,412 €. Although the range of values is extremely broad, UK and US Governmental organizations appear to be similar. The mean values for the UK were given as 2281 million US dollars, and the USA is predictably higher, at 3472 million US dollars (Miller 2000).

## Utility Analysis

Monetization is often rejected not only for ethical reasons but also because of methodological shortcomings. The utility analysis provides a quantification of values independent of money. It does not balance out cost of alternatives, but this analysis captures the benefits/utility as dimensionless value, derived from priorities, ideas, and experience of the decision-maker. The focus is on possible consequences of the decision and the probability of their arrival. If the benefits can be subdivided, the various cost-benefit values are weighted and combined to a total benefit.

It is also possible within the frame of a given plausible and/or politically legitimate objective and precondition to summarize individual cost-benefit values, determined by various decisions, and include them in the total analysis. Risk managers may choose between different courses of action, and they then have to seek widespread acceptance for the measures taken. This is best sought through a description of the decision parameters. Advantages and disadvantages should be distributed as evenly as possible among the affected individuals or interest groups. Since no pecuniary settlement is involved, even nonmonetary parameters (e.g., improved quality of life) can adequately be used for decision-making.

In utility analysis, the initial objectives and requirements in the decision-making process can continuously be questioned. If considered desirable, these objectives can be modified following appeals from stakeholders, and this should result in the greatest possible consensus (even though that may still be a very limited consensus in the case of some projects, such as new airport capacity around London!).

## Abstract

The control of potential health hazards to humans due to the production, use, and disposal of chemicals is a major issue of concern. The concern arises from the increasing numbers of chemicals in production and use and the increasing numbers of chemicals demonstrated to exert toxic effects in sensitive toxicity testing systems. This situation has afforded growing legislative control of the production and application of chemicals. Control measures may limit the presence of hazardous chemicals in the environment or regulate the use of hazardous chemicals.

## Introduction

The assessment of potential human *health risks* resulting from the exposure to chemicals provides the basis for appropriate regulatory and control measures (Table 1). The *health risk assessment* determines whether a chemical may cause adverse health effects, at what level, duration and frequency of exposure, and the probability that adverse health effects will occur. Risk assessment considers the available data on the toxicology of a specific chemical when judging which agents potentially pose a significant risk to the human population. Tolerable exposure levels for humans are derived from the results of animal studies by using margins of safety or defining “acceptable” incidences of adverse health effects in exposed humans.

Health risks due to contact with potentially toxic chemicals are dependent on the conditions of exposure, since not only the intrinsic toxicity of a chemical determines the magnitude of the adverse effect but also the dose. In toxicological terms, risk therefore is the product of the intrinsic toxicity of a chemical and the exposure characteristics.

## Acceptable Risk, Comparison of Risks, and Establishing Acceptable Levels of Risk

In earlier phases of risk assessment, the basic belief was that few chemicals are toxic and all of these toxic chemicals are derived from synthetic processes. To achieve a zero risk, chemical exposure must be reduced below a threshold level under which it does not cause risk. However, where such a threshold cannot be demonstrated, one must assume that a finite risk may occur at any exposure level. These considerations resulted in the *zero-risk concept*. However, the more widespread testing of chemicals

**Table 1** Possible measures to reduce *human exposure to hazardous chemicals*

Application of or exposure to chemical in question	Measures to reduce exposure
Industrial chemicals	Reduction or cessation of application, protective measures in the workplace, alternative chemicals with lower hazard
Pharmaceuticals	Definition of optimal dosing and dose limits, cost–benefit analysis
Alcohol, smoking, pharmaceuticals of abuse	Education
Environmental chemicals	Quantitation of exposure, strategies for avoidance, or reduction of environmental pollution

for toxicity, the increased sensitivity of analytical instruments to determine chemicals, and the developments in the science of toxicology put the basic assumption of the zero-risk concept into question.

These developments led to the recognition that zero risk was unachievable and, perhaps, unnecessary for the regulation of chemicals. This was based mainly on a few facts: (1) all chemicals, both of synthetic and natural origin, are toxic under *specific exposure conditions*; (2) most of the hazardous chemicals routinely encountered by humans are of natural rather than synthetic origin; (3) most of the exposure to hazardous synthetic chemicals cannot be avoided entirely or be eliminated from the environment without profoundly changing the way of life in many countries; and (4) in the case of cancer risk assessment, DNA damage and mutations, assumed to be of major significance in the process of carcinogenesis, occur spontaneously, albeit at a low rate.

Given these facts, the *acceptable risk concept* was developed as an alternative. The acceptable risk concept realizes that it is not possible to eliminate all potential health risks associated with chemical exposure due to the lifestyle. According to the concept of acceptable risk, safety – the reciprocal of risk – is no longer an absolute term but is redefined as a condition of certain but very low and thus acceptable risk. This conceptual change improves the ability to deal with potentially very low risks identified by the increased sensitivity of analytical instrumentation and with increasingly sensitive scientific methods to detect *potential adverse effects*. The concept of acceptable risk also permits the definition of limits for the exposure to toxic chemicals that can be considered to have a negligible impact on the incidence of adverse effects in an exposed population. Risk assessment therefore is unavoidable.

In different regulatory frameworks, while the general approaches to risk assessment are used in an identical approach – *hazard assessment*, *exposure assessment*, and *dose–response evaluation* – a number of specific factors and circumstances are influencing *risk characterization*. These are outlined in the following for some major application of chemicals. For most of the areas of applications of chemicals, the responsible authorities or scientific bodies have developed specific guidance documents which in detail define the approaches to be used and are frequently updated to include scientific progress and societal demands.

---

## Pharmaceuticals

The marketing and application of pharmaceuticals is most highly regulated as compared to other application areas of chemicals. *Unwanted effects* play a major role in risk assessment. In contrast to other regulations concerning chemicals, which often attempt to avoid any negative health effects due to exposure, *risk–benefit considerations* are specifically integrated in the *evaluation*. Risk–benefit considerations are important since any therapeutically active chemical may have unwanted effects even at optimal *therapeutic dosage*. While unwanted effects may be mitigated by specific molecular design and optimized therapeutic schemes, they usually

cannot be completely avoided, specifically when treating life-threatening diseases. Risk assessment aims to reduce the incidence of unwanted effects to a tolerable extent. The necessary evaluation therefore includes *risk–benefit analysis*. Benefit is the *beneficial therapeutic effect* for a patient; *risk in this context is the type, frequency, and intensity of unwanted effects*. The relation between risk and benefit will then be translated in a scientifically supported relation; performing risk–benefit analysis is implied in legal regulations. However, due to the complexity of the disease processes and the potentially different responses of a disease to treatment options (from complete curability to mitigation of severe symptoms and improvement of life quality), the criteria for risk–benefit analysis in different areas of pharmaceutical treatment differ widely. For normative purposes and harmonization, science-based consensus by highly experienced expert groups and scientific societies has been developed both on a national and an international scale. *Risk assessment of pharmaceuticals* is performed at two levels, at the *level of authorization* and at the *level of supervision* of the incidence of unwanted effects when the pharmaceutical is on the market and applied to a large number of patients.

*Authorization of Pharmaceuticals.* Authorization of pharmaceuticals is regulated by national, European, Japanese, and US laws. Authorization by the *US Food and Drug Administration (US- FDA)* is often also used as the basis for authorization of pharmaceuticals by national authorities of other countries. Authorization is based on three pillars: pharmaceutical quality, measurable clinical effects, and aspects of “safety.” Definition of “safety” of pharmaceuticals implies risk–benefit assessment.

The applicant, usually a pharmaceutical producer, has to submit a detailed dossier in a defined format, the *Common Technical Document (CTD)*, to apply for authorization. All information has to be collected according to predefined protocols and to be reported in harmonized format. This common format is requested in Europe, the USA, and Japan. The CTD dossier has to contain all relevant information regarding production, research, and development of the pharmaceutical. In addition, a major focus are the results of the non-clinical, pharmacologic, and toxicological studies and all data from clinical studies investigating efficacy and frequency and intensity of unwanted effects.

Regarding toxicology, harmonization and standardization of the required toxicological testing has been developed by international harmonization between the US-FDA, the *European Medicines Agency (EMA)*, and Japanese authorities in the *International Committee on Harmonization (ICH)*. Most of the requested study designs developed by ICH are considered mandatory by these regulatory agencies.

Authorization within the European Union may be performed by a centralized application at the EMA or in a decentralized procedure by application to a regulatory authority of a member state. The regulatory authority evaluates the submitted dossier and may request additional information in case of uncertainties or specific issues. After authorization, effects of pharmaceuticals are further monitored to detect potential risks in larger populations. Low incidence effects with severe health impact or unwanted effects under certain conditions will only be evident after use of a pharmaceutical in large populations.

## Occupational Health

Protection of worker health when handling chemicals is one of the oldest areas of regulation where a science-based risk assessment served as a basis for regulatory decisions. The major protective measures are reduction of exposure due to technical improvements of the work situation and *maximum tolerated concentrations of chemicals* in workplace air. Regarding reversible effects, *threshold limit values (TLVs)* are developed; for chemicals with irreversible modes of action such as carcinogens, *quantitative risk assessments* are performed. TLVs for reversible modes of action are based on thresholded dose–responses for adverse effects; concentrations below the thresholds should not result in health effects in the exposed workers. TLVs are derived from observations in occupationally exposed humans or based on animal toxicity testing using appropriate routes of exposure (usually inhalation). *Safety factors (SFs)* as used in risk assessment for food additives and food contaminants are not mandatory in deriving TLVs; if used, they are much smaller than those used for regulation of food additives (SFs of 5–10 as compared to 100). *Surveillance* of TLVs is performed by analytical determination of the air concentration of the respective chemical at the workplace; periodic health surveillance of exposed workers will assure that the aim of health protection is reached. TLVs are usually derived for an exposure of 8 h per day, 5 days a week, and 40-year work life, but a variety of values for shorter duration exposures or specific situations have been developed in the different regulatory frameworks. Deduction of TLVs may consider specific *individual susceptibilities* if procedures to detect such predisposing factors are available. *Sensitizing properties of a chemical* are not generally considered, but such properties will require specific labeling. Issues of costs of compliance and technical measures for compliance are not considered.

TLVs presently are also derived for chemicals with irreversible modes of action, which usually are genotoxic carcinogens. Based on the *basic concept of carcinogen risk assessment*, even very low exposures to genotoxic carcinogens may result in an increased incidence of tumors (although often in extremely low incidences); thus, the aim of complete health protection cannot be reached when exposure to a genotoxic carcinogen at the workplace may occur. Therefore, the basis for the TLVs for carcinogens is a comparison of the calculated tumor risk of an exposure (over the whole work life) with that of other occupational health risks not related to chemical exposures (such as accidents). Such a comparison requires a quantitation of the tumor risk, which is usually done by *extrapolation* of the dose–response curve from animal experimentation to render concentrations expected to result in an acceptable risk. Previously, TLVs for carcinogens were not derived since the risk assessment process has not been considered sufficiently precise. However, in Germany, since 2005, the former “Technische Richtkonzentrationen (TRK)” for genotoxic carcinogens has been formally replaced by TLVs, which need to be developed over time. Driving force for the decision was the intent to base a value for a TLV for a carcinogen on a scientific evaluation instead of relying on technical capacities, analytical surveillance, and socioeconomic issues, which were drivers for TRKs.

Risk assessments for TLVs are performed by independent scientific committees such as the “Senatskommission zur Prüfung gesundheitsschädlicher Arbeitsstoffe (MAK-Kommission)” or the EU Scientific Committee on Occupational Limits (SCOL). In analogy, TLVs in the USA are also derived by the TLV Committee. Members of the committees are recruited from independent toxicologists, occupational physicians, and analytical chemists. A public consultation period regarding the derived TLV is often integrated in the process, and all TLVs are justified in detailed written reports.

---

## Indoor and Ambient Air

In contrast to occupational exposures which usually only occur for 8 h per day, exposure to indoor and ambient air contaminants occurs for 24 h per day and the whole population is affected. Risk assessment for ambient and indoor air contaminants often is also based on inhalation toxicity studies, but often needs to integrate higher *extrapolation factors* to cover potentially sensitive groups such as infants, the aged population, and predisposed individuals. However, besides a risk assessment-based approach using animal test data, many regulatory tolerance values regarding air contaminants are derived based on observations in large-scale epidemiology studies in humans. In addition, some values are using a precautionary approach or may be oriented regarding socioeconomic considerations and natural background of the contaminant.

---

## Food

*Food additives* and *food contact materials* have become important over the past 50 years to preserve food or improve appearance and taste and shelf life. More and more contaminants present in low concentrations in food are detected by the increased food surveillance and the significantly improved analytical capabilities. Risk assessment for these types of compounds is performed on national and international levels. In the European Union, the *European Food Safety Authority (EFSA)* is responsible for setting tolerable concentrations of contaminants and food contact materials in different food items and for evaluation of maximum content of food additives. EFSA uses the classical risk assessment process integrating safety factors for contaminants with reversible mode of action and quantitative approaches for carcinogens, decisions on the limits are made by advisory panels of independent scientists, and detailed justification documents are published. Tolerable limits for food additives, which require authorization, are also assessed using safety factor methodology. Chemicals with genotoxic properties will not be authorized for these purposes.

Human exposures to food additives are estimated by using maximum addition levels of the additive to food items and surveillance data regarding consumption of food items containing the additive. A similar approach using concentration data for

contaminants in different food items and European consumption data are derived to define tolerable intakes for contaminants. Regarding genotoxic contaminants, the *margin-of-exposure (MoE) concept* is applied. The MoE represents the difference between the estimated human exposure to a genotoxic contaminant and a dose descriptor (usually a benchmark dose, BMD05) from animal testing. An MoE of >10,000 is considered to be of “low concern” for regulatory action or mitigation. Food contact materials are usually regulated based on *migration testing* by standardized procedures and intended uses of the food contact material with certain food items and its consumption pattern. Similar approaches as used by EFSA are used by the US-FDA and national authorities worldwide and by international organizations such as the *Joint FAO/ WHO Expert Committee on Food Additives (JECFA)*.

---

## Cosmetics and Consumer Products

Due to the increased awareness regarding potential risks of synthetic chemicals, risk assessment for chemical ingredients in cosmetics and consumer products is also performed. On the one hand, intentionally added ingredients are systematically assessed regarding potential health risks based on information requests by scientific advisory bodies; in addition, assessment of contaminants may be requested by regulatory authorities. Exposure assessments are performed based on the concentration of the chemical to be added to the consumer product and anticipated frequencies of use and use levels. When oral exposure is involved, migration testing determining the release of the agent from the product under predefined conditions (e.g., plasticizers from toys) is used as a major basis for exposure assessment. Regarding cosmetics, where the major exposure to ingredients is likely dermal uptake and inhalation, oral toxicity data are used as a basis for hazard assessment integrating consideration of toxicokinetics. It should be noticed that animal experiments regarding hazard assessment of cosmetic ingredients are banned in Europe after 2013 and new ingredients in cosmetics subjected to animal testing will not be permitted. Non-animal methods for hazard assessment, however, do at present not have the capacity to predict potential toxicities. A solution to this dilemma is not expected in the near future.

---

## General Chemical Safety

The new European legislation regarding *Registration, Evaluation, Authorization of Chemicals (REACH)* attempts to establish “safe uses” for all chemicals available on the market and used in products. Within REACH, the producer or importer of a chemical has to file a registration dossier containing all available hazard data, anticipated exposures, and a risk assessment for the intended and foreseeable uses. The general approach therefore shifts responsibility for risk assessment from a *regulatory agency* to industry. Due to the large number of chemicals to be registered,

it is expected that only a limited number of the submissions will be checked for correctness and scientific soundness. In addition, chemicals of “very high concern” may need to be authorized for specific applications. Specific assessments of priority chemicals are made by a scientific committee (*Committee for Risk Assessment, RAC*) consisting of a limited number of independent scientists and mostly of representatives of national regulatory agencies. In addition, socioeconomic consequences of restrictions or bans of certain chemicals will be evaluated by a specific group. Detailed guidance regarding approaches to be used in REACH has been developed over the past decade.

---

## Radiation Protection

*Radiation protection* aims at limiting the number of people exposed and the probability of exposure to be “as low as reasonably achievable” (*ALARA*); if exposed, exposure should also be as low as reasonably achievable. In the process to set exposure limits, social and economic factors are taken into consideration and risk comparisons are performed. Risk assessment for ionizing radiation for the general population is based on a comparison of the natural background radiation and its variation with that of the radiation source to be assessed. Since radiation protection assumes low-dose linearity for risk assessment with the main focus on cancer prevention, risk comparison is performed. The radiation dose expressed in Sv represents the amount of radiation energy deposited in tissue. As Sv is a large unit of measurement, the millisievert (mSv) is frequently used. The average human dose from background radiation is about 2 mSv per year. In many cases of radiation exposures, including background radiation, the radiation dose is evenly distributed throughout the body. Exposure may also be directed to a limited area of the body (radiation therapy) or single organs (e.g., radioactive iodine in the thyroid). As some organs are more sensitive to radiation, tissue weighing factors ( $W_T$ ) are used to determine the equivalent risk of locally limited exposure. When the tissue weighing factor has been applied, the term “effective dose” is used. *The International Commission on Radiological Protection (ICRP)* recommends tissue weighing factors. The effective dose puts all ionizing radiation on an equal basis in terms of their potential to cause damage. In the EU, the upper limit for the ionizing radiation is 20 mSv/year in occupational scenarios and 1 mSv for the general population regarding technical sources.

## Abstract

Differences in testing requirements in different countries, which were not based on scientific grounds, resulted in barriers to international trade and created a financial burden for the industry. Therefore, in 1981 the major industrial nations agreed to harmonize the requirements for safety testing of industrial chemicals under the leadership of the OECD (Organization for Economic Cooperation and Development). OECD Test Guidelines (TGs) are under constant review and new guidelines being adopted. Following this encouraging example, also the guidelines for safety testing of drugs and medicinal products hormones and biologicals were harmonized by the International Conference of Harmonisation (ICH) and the EU & US pharmacopoeias and safety testing of vaccines and immunologicals was harmonized by the WHO. All testing for human safety was conducted in animals and regulatory agencies wanted to accept new nonanimal tests only, if

they allow to classify and label chemicals in the same way as the animal tests. The OECD has, therefore, decided to accept new in vitro toxicity tests, for example, for cosmetics, for regulatory purposes only after successful experimental validation. Therefore, in 1990 the European Centre for the Validation of Alternative Methods (EURL ECVAM) developed a concept for the experimental validation of toxicity test and conducted several successful validation studies with in vitro test for local toxicity on eye and skin to meet the requirements of the EU Cosmetics Directive. Since these validation studies proved successful, in 2005 the OECD published a “guidance document on the validation and international acceptance of new or updated test methods for hazard assessment.” As a result, today there 16 validated OECD nonanimal toxicity test guidelines for local toxicity eye and skin toxicity and 5 for endocrine disruptors, most of them using human cells and tissues.

**Introduction**

Toxicity testing for regulatory purposes began after the Thalidomide (Contergan<sup>®</sup>) tragedy in Germany around 1960, when unexpectedly the hypnotic drug caused severe limb malformations in newborns whose mothers had taken the drug during pregnancy. This accident initiated in the first place regulatory testing for drugs, while safety testing of other chemicals, for example, pesticides, industrial chemicals, cosmetics, and food ingredients, has become mandatory at the international level about 20 years later. Meanwhile regulatory safety testing of chemicals is mandatory in all OECD (Organization for Economic Cooperation and Development <http://www.oecd.org/>) member states, which are the major industrial countries except Brazil, China, and India.

Initially test requirements as well as individual tests were developed at the national level and, therefore, they differed quite significantly due to experience at the national level in industry and regulatory agencies. Consequently, international industry had to conduct different sets of safety tests to meet the legal requirements in each of these countries. Differences in test requirements created a considerable financial burden for the industry, and for patients and consumers, who in the end must pay for testing. Thus, the differences in testing requirements, which were not based on scientific grounds, resulted in barriers to international trade.

Finally, the major industrial nations agreed to harmonize the requirements for safety testing. At the OECD industry and regulatory agencies took the lead in this activity, since regulatory testing has a higher priority for them than for academic

institutions. Since it was the goal of the harmonization activity to achieve **mutual acceptance of data** (MAD) by OECD all member countries, testing requirements had to be standardized. Today harmonization of test guidelines has been achieved for regulatory testing in all areas of toxicology. In addition, the criteria for development and validation of new test methods are harmonized by the OECD, since test guidelines must be updated continuously according to scientific progress and to include newly emerging endpoints.

In this chapter the concept of the international acceptance of standardized and harmonized toxicity tests (MAD concept of the OECD) is described and the criteria for developing, validating, and achieving international acceptance of new tests methods by the OECD.

---

## International Harmonization of Guidelines for Toxicity Testing

For historical and economic reasons, standardization and harmonization of test guidelines for the major areas of toxicology, for example, safety testing of drugs, cosmetics, industrial chemicals, pesticides/biocides, and nanomaterials, were developed separately. This is due to differences in regulatory requirements, which must cover differences in use and exposure of humans and the environment. The most important step was in 1981 the international agreement on the “OECD Guidelines for the Testing of Chemicals” (OECD TGs) <http://www.oecd.org/chemicalsafety/testing/oecdguidelinesforthetestingofchemicals.htm>, which are mandatory today for testing of all chemicals except human and veterinary drugs. It is important to note that OECD TGs for safety testing of chemicals have not only been accepted for health effects (toxicity) but also for physico-chemical properties, and environmental safety including accumulation and degradation of biotic and abiotic systems. Guidelines are numbered with three-digit numbers, for example, for the health section “4” is the first number. Guidelines are under constant review, with guidelines being periodically updated, new guidelines being adopted, and guidelines being withdrawn. Previous guidelines are maintained on the website for reference purposes. To provide better understanding and faster implementation of the OECD TGs, Guidance documents (GDs) have continuously been published for specific areas of toxicity. To ensure animal welfare concerns, animal tests are only permitted where necessary.

The most important consequence of the adoption of harmonized OECD TGs by OECD member states is the concept of “**mutual acceptance of data**” (MAD) that are generated by testing according to OECD TGs by regulatory agencies of all OECD member countries. Another important requirement for MAD is that testing must be conducted according to **good laboratory practice** (GLP), which is an accepted measure to enforce quality assurance. If a toxicity test has been conducted according to an OECD TG and to GLP, the test *must* be accepted by other OECD countries for assessment purposes. This is the concept of “*tested once, accepted for assessment everywhere*,” which saves the chemicals industry the expense of duplicate testing for products marketed in more than one country.

The harmonization of TGs by the OECD has not only financial advantages for industry and consumers, but it also improves ethical standards from the animal welfare perspective, which is a major driving force in OECD member countries. Finally, from the scientific perspective harmonization of TGs is most welcome, since data for specific endpoints of toxicity must now be produced according to the same TG, which provides for a better comparison of the results of different chemicals for the same endpoint.

It has been criticized that OECD TGs are quite rigid and it is time-consuming and laborious to update them once they have been accepted, since at the OECD decisions are not made by majority vote, but all OECD member states have to agree. Although progress may be delayed by unanimous agreement, this has not really happened during the past 40 years, since the procedure for submitting new TGs and for updating existing TGs has continuously been improved.

When the EU legislation was changed in 2007 from the EU Directive 76/769/EEC on the regulation of dangerous substances and preparations to the EU Directive 1907/2006 on the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), the European Chemicals Agency (ECHA), was established in Helsinki, which is only accepting data from testing according to OECD TGs (<https://echa.europa.eu/guidance-documents/guidance-on-reach>).

Since the concept of using standardized OECD TGs for toxicity testing has proven successful and also the MAD concept, OECD TGs are now used or safety testing of all chemical substances and products except drugs, for example, biocides, pesticides, cosmetics, as well as food and feed additives. The OECD TGs also provide the basis for the international transport of chemicals (i.e., transport regulations), although there are some variations relating to specific needs at the local level.

Considering the successful implementation of the OECD TGs into regulatory practice, in 1990 the national and international agencies that are responsible for the regulation of drug safety agreed on an international harmonization of the test guidelines for human and veterinary drugs. They were harmonized by the ICH (International Conference on Harmonisation, <http://www.ich.org/>), which is formed by regulatory agencies and the drug industry of the major economic regions Europe, Japan, and USA. ICH Test guidelines (TGs) are not only used for toxicity testing but also for all other areas of preclinical drug testing, for example, efficacy testing and pharmaceutical quality control. As described for OECD TGs, results of tests that were conducted according to ICH guidelines will only be accepted internationally according to MAD, if testing has been conducted according to “GLP” and produced according to “**good manufacturing practice (GMP)**.” Again, the harmonization of TGs has led to significant reduction of testing in animals, since all regulatory agencies around the world are now accepting the results of a test that was conducted according to ICH guidelines.

Table 1 summarizes the progress achieved in the international harmonization of TGs for regulatory safety testing in animals. It shows that in addition to drugs, industrial chemicals, and pesticides, TGs have also been harmonized for hormones and biologicals by the pharmacopoeias and for vaccines and immunologicals by the

WHO. So far, the harmonization of international TGs for safety and toxicity testing has been the most successful approach to reduce animal testing for regulatory purposes.

---

## **Validation and Acceptance of New Toxicity Test Methods by the OECD**

Regulators will only accept new nonanimal tests, also termed “alternative tests” (e.g., in vitro or in silico tests), if the new tests allow to classify and label chemicals in the same way as the current animal tests. The OECD has, therefore, decided that in vitro toxicity tests can be accepted for regulatory purposes only after a successful experimental validation study has been conducted. To approach this problem scientifically, European and American scientists agreed in 1990 on a definition of experimental validation and the essential steps in this process. At this workshop, *validation* was defined as “the process by which reproducibility and relevance of a toxicity testing procedure are determined in vitro or in vivo.” The essential steps of the experimental validation process were defined in the following manner: 1. test development in one or several laboratories, 2. experimental validation under blind conditions in several laboratories in a ring trial, 3. independent assessment of the results of the validation trial, and 4. regulatory acceptance.

Steps 2 and 3 are the essential part of a formal validation study conducted for regulatory purposes. The report of this workshop (Balls et al. 1990) encouraged scientists to initiate several international validation studies. Since the Draize eye test has been the most widely criticized toxicity test, a world-wide validation study on nine nonanimal alternatives to the Draize eye irritation test was co-ordinated by the EU Commission’s Centre for the Validation of Alternative Methods (ECVAM, <https://ec.europa.eu/jrc/en/eurl/ecvam>) and the British Home Office. However, this and other extensive international validation attempts have failed (Balls et al. 1995b).

Therefore, the leading scientists recommended the inclusion of three additional elements into the validation process (Balls et al. 1995a), which had not sufficiently been identified in the ECVAM validation concept. The following three essential elements were added:

1. The definition of a biostatistical based “*prediction model*” (PM).
2. The inclusion of a *prevalidation* stage between test development and formal validation under blind conditions.
3. Well-defined *management structures*.

The PM of an in vitro test should allow the prediction of in vivo endpoints in animals or humans from the endpoints determined. The PM must be defined mathematically in the standard operation procedure (SOP) of the test that must undergo experimental validation under blind conditions with coded chemicals (Balls et al. 1995a). In order to assess the limitations of a new test before it will be evaluated in a formal validation study, the test should be standardized in a pre-validation study with a few test chemicals in a few experienced laboratories (Curren et al. 1995). This will ensure that the in vitro test method, including the PM, is robust and that the formal validation study under “blind” conditions with coded chemicals is likely to be successful.

The improved concept of experimental validation for regulatory purposes was accepted by ECVAM in 1995 and in 1996 by USA and by the OECD (OECD 1996). The improved validation concept was immediately introduced into ongoing validation studies, for example, an ECVAM/COLIPA validation study of in vitro phototoxicity tests and the ECVAM validation study of in vitro skin corrosivity tests. Since these two validations studies proved successful, in 2005 the OECD has published a “guidance document on the validation and international acceptance of new or updated test methods for hazard assessment” (OECD 2005).

---

### **Example of Successful Validation and Regulatory Acceptance of New Test Methods**

Since in 1991 no standard guideline existed for the testing of photo-irritation potential for regulatory purposes, either in vivo or in vitro, the OECD, the European Commission (EC) and the European Cosmetics, Toiletry and Perfumery Association (COLIPA) established a joint program to develop and validate in vitro photo-irritation tests. In the first phase of the study, in vitro phototoxicity tests established in laboratories of the cosmetics industry were evaluated and also a new assay, the 3T3 NRU PT test, which is a photo-cytotoxicity test using the mouse fibroblast cell line 3T3 and neutral red uptake (NRU) as endpoint of cytotoxicity.

In the prevalidation study conducted with 20 test chemicals, the 3T3 NRU PT in vitro phototoxicity test was the only in vitro test, in which 20 test chemicals were correctly identified as phototoxic or nonphototoxic. Quite independently, a laboratory in Japan obtained the same results in the 3T3 NRU PT with the same 20 test chemicals. In the formal validation study, which was funded by ECVAM, the 3T3 NRU PT test was validated with 30 carefully selected test chemicals in 11 laboratories in a blind trial. The results obtained in the 3T3 NRU PT in vitro test under blind conditions were reproducible, and the in vitro–in vivo correlation of the data was almost perfect (Spielmann et al. 1998a). In a subsequent blind trial on UV filter

chemicals the phototoxic potential of all test chemicals was predicted correctly in the 3T3 NRU PT (Spielmann et al. 1998b). Therefore, in 1998, the EU, having accepted the 3T3 NRU PT test as the first experimentally validated *in vitro* toxicity test for regulatory purposes, officially applied to the OECD for world-wide acceptance of this *in vitro* toxicity test. In 2000 the European Commission officially accepted and published the 3T3 NRU PT phototoxicity test in Annex V of Directive 67/548 EEC on the Classification, Packaging and Labelling of Dangerous Substances (EU Commission 1983) and in 2004 the OECD accepted the 3T3 NRU PT phototoxicity test at the world-wide level as the first *in vitro* toxicity test into the OECD Guidelines for the testing of chemicals (TG 432, OECD 2004).

---

### **Implementing of New Concepts for Developing Toxicity Tests During the Last Decade**

Recent EU legislation, as, for example, the 7th Amendment of the EU Cosmetics Directive (EU Commission 2003), has enforced the use of nonanimal methods to replace toxicity testing in animals. Since this initiative was quite successful, for this specific field of toxicology, *in vitro* tests were developed, validated, and accepted by regulators, and the full ban on animal testing for cosmetic products manufactured or marketed within the EU finally came into force in 2013 (EC 2013).

The past two decades have seen unprecedented scientific and technological advances, including the birth of functional genomics, the fast-paced growth of computing power and computational biology/bioinformatics, the establishment of robotic platforms for high-throughput screening of chemicals, and the sequencing of the human genome. Together, these advances have triggered a revolution in molecular biology and have made available a wide range of new tools for studying the effects of chemicals on cells, tissues, and organisms in a rapid and cost-efficient manner.

This convergence of factors, coupled with increased recognition of the limitations of conventional *in vivo* tests and the need to evaluate the safety of an increasingly large number of chemical substances and mixtures, has led authorities such as the US National Research Council and other to call for shift in toxicity testing towards the elucidation of “toxicity pathways” at the cellular level – an approach commonly referred to as “Toxicity Testing in the 21st Century” (US National Research Council 2007). According to this concept, an “Adverse Outcome Pathway” (AOP) delineates the documented, plausible, and testable processes by which a chemical induces molecular perturbations and the associated biological responses which describe how the molecular perturbations cause effects at the subcellular, cellular, tissue, organ, whole animal, and population levels of observation (Ankley et al. 2010). The AOP can then be used to form categories by integrating knowledge of how chemicals interact with biological systems (i.e., the molecular initiating events) with knowledge of the biological responses. Meanwhile, the AOP concept has been accepted by the international scientific community, and the OECD launched a new program on the development of AOPs in 2013 (OECD 2013).

Accepted by the OECD for regulatory purposes (classification and labelling) ([http://www.oecd-ilibrary.org/environment/oecd-guidelines-for-the-testing-of-chemicals-section-4-health-effects\\_20745788](http://www.oecd-ilibrary.org/environment/oecd-guidelines-for-the-testing-of-chemicals-section-4-health-effects_20745788))

Complex endpoints cannot be predicted by a single stand-alone nonanimal test as it will never be possible to reproduce a whole organism, mainly due to the lack of kinetic relationships and crosstalk among cells, tissues, and organs. It is

instead necessary to use **integrated approaches to testing and assessment (IATA)**, where information and evidence from a battery of tests can be incorporated (OECD 2017b). Data can then be integrated by means of modeling. The IATA approach has been used successfully to replace skin sensitization testing in animals: the first three *in vitro* AOP-based OECD Test Guidelines (TGs) have been adopted, covering the MIE of the skin sensitization AOP (protein binding, TG 442C; OECD 2015a), as well as the intermediate key events of keratinocyte activation (TG 442D; OECD 2015b) and dendritic cell activation (TG 442E; OECD 2016). As a consequence, testing of new chemicals for local toxicity can now be conducted according to the following OECD *in vitro* toxicity tests methods shown in Table 2.

Table 2 summarizes OECD non-animal toxicity Test Guidelines (TGs), that have been validated according to the OECD Guidance Document 34 “*On the validation and international acceptance of new or updated test methods for hazard assessment*” (OECD 2005). Among the 16 TGs for “*local eye and skin irritation*,” there are three more complex tests for skin sensitization, which are based on the recently developed AOP and IATA concept. The 5 TGs for endocrine disruptors are addressing the interaction of test chemicals with specific hormone targets and pathways.

---

## Outlook

In Table 2 Tests No 442C and 442D illustrate quite nicely that the new AOP concept of “*toxicity pathways*,” which are facilitating integrated approaches to testing and assessment (IATA), can successfully be used to develop and validate new test guidelines for complex endpoints of toxicity. Therefore, the OECD is proposing that the all new tests methods should be based on the new AOP/IATA concept and it should also be considered when existing test are updated.

## Abstract

A risk cycle in toxicology typically consist of repetitive steps, consisting of hazard- and risk evaluation, risk perception, risk reduction, monitoring, and review. Risk cycles can lead to promotion of an existing risk or its reduction. Risk-reduction cycles are an effective means to stepwise minimize toxic exposures of man and the environment. Critical risk perception is an essential motor for risk-reduction efforts.

## Keywords

Risk cycle · Risk reduction · Risk management · Risk perception · Whistleblower · Pollutant

## Introduction

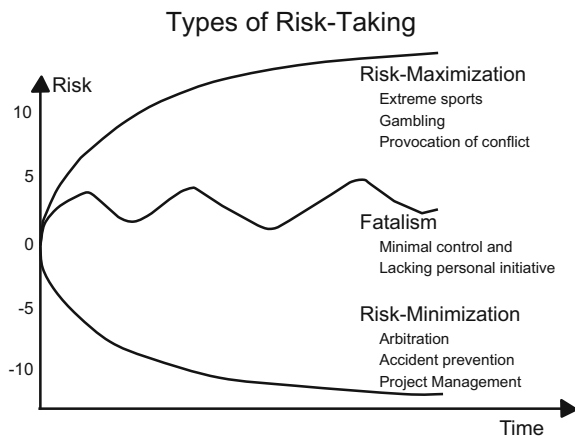

The risk cycle involves the interplay of activities belonging to the three basic components of risk assessment, risk management, and risk communication (see “[Cross-References](#)” at the end).

Risk cycles can occur in two contrasting forms. “Risk enhancement cycles” show themselves in the form of enhanced pesticide performance (in terms of removing the pest) and enhanced levels of risk associated, e.g., with stock market speculation, willingness to partake in dangerous sports, and preparedness to escalate armed conflicts. When human behavior is involved, Adams (1995) has called this group “*Homo aleatorius*” – dice man, gambling man, or risk-taking man. They are willing to take risks, and they may be driven by mass psychological phenomena, such as a “spiral of violence.”

“Risk-reduction cycles,” however, are, in Adams’ terms, undertaken by “*Homo prudens*” – those who strive to avoid “accidents.” The aim is to reduce risk, based on a factual analysis and willingness to find technical solutions. This approach is rarely spectacular but is usually considered to be essential for sustainable and positive development. It occurs, for example, in the form of security measures, dispute settlement, and prevention measures. It also plays an important role in project management of companies and chemical safety.

A third variant involves no real change in risk. It is **fatalism**. Fatalists believe they have minimal control over their lives. They accept risks, are resigned to their fate and see no point in trying to change it. Thus, they are unlikely to modify the risks to which they are exposed to (Fig. 1).

**Fig. 1** Contrasting forms of risk modulation

Generally, risk taking is seen as “good” (“nothing ventured – nothing gained” or “no risk – no reward”) and a necessary part of “progress.” Nevertheless, the propensity to take risks, when combined with human fallibility, is often asserted to be the root causes of dangerous exposures, i.e., human error due to miscalculation, lapse of concentration, or ignorance concerning the dangers leads to inappropriate exposure. When society imposes risk management measures that reduce risk, the individual may seek to restore the balance of risk by behavior that accepts higher risks (including so-called macho behavior). Human nature often leads individuals toward *Homo aleatorius* when society as a whole wants to encourage the behavior associated with *Homo prudens*. Understanding the sociological and psychological background concerning how risks are perceived is essential if risks are to be reduced.

---

## A Framework for Risk Evaluation

The Royal Society study group put forward a risk evaluation framework (Royal Society 1983, 1992). Essentially, this is concerned with “objective risk” – the probability that a particular adverse event occurs during a stated period of time or results from a particular challenge. It was originally developed to handle engineering risk, but it is equally applicable to health risks from chemicals. Illing and Marrs (2009) have discussed the application of this framework to the evaluation of health risks arising from exposure to chemicals.

Criteria for reaching decisions can be classified according to three “pure” criteria (UK Health and Safety Executive 2001). These are:

- An **equity-based** criterion, which starts from the premise that all individuals have unconditional rights to certain levels of protection. This leads to standards, applicable to all, held to be usually acceptable in normal life. In practice, this leads to fixing a limit to represent the maximum level of risk above which no individual can be exposed. If the risk characterization indicates that the risk is above this limit, the risk is held to be unacceptable – whatever the benefits.
- A **utility-based** criterion, which applies to the comparison between incremental benefits of measures to prevent the risk of injury or detriment (for health effects, ill-health) and the cost of the measures. The utility-based criterion compares the relevant benefits (e.g., statistical lives saved, life years extended, reduced ill health, and better quality of life) obtained by adoption of a particular risk prevention measure with the net cost of introducing it and requires that a balance be struck between the two. This balance can be deliberately skewed toward risk reduction by ensuring gross disproportion between costs and benefits.
- A **technology-based** criterion, which essentially reflects the idea that a satisfactory level of risk prevention is attained when “state of the art” control measures (technological, managerial, organizational) are employed to control risks, whatever the circumstances.

These criteria underlie the regulatory process first outlined by the Royal Society (1983). The scheme is based on:

- An upper limit of risk which should not be exceeded for any individual (“unacceptable”)
- Further control, so far as is reasonably practicable, making allowances if possible for aversions to the higher levels of risk or detriment (“tolerable”)
- A cutoff in the deployment of resources below some level of exposure or detriment judged to be trivial (“broadly acceptable”)

This approach to risk evaluation can be applied to health effects, both to the target species and to incidentally affected species. For many health effects, the risk evaluation is concerned only with determining what constitutes a “broadly acceptable” risk and hence with the equity criterion. This is the case if any equity criterion for “safe” (the “broadly acceptable” level of risk), such as a residue level in a foodstuff, is exceeded, thus resulting in its immediate withdrawal from the market. It is also applied to the indirect risks to the environment and to humans mediated via the environment.

---

## Risk-Reduction Cycles

The aim of risk reduction is to reduce risk levels to those regarded as “broadly acceptable” or, if this is not possible and the benefits to society are required, at least to keep risks within “tolerable” levels while seeking improvements aimed at eventually achieving the “broadly acceptable” level of risk. Measures to mitigate risks are found in many areas of human activity. Such risks can be detected early through effective project management, which includes periodical simulation of risk-reduction cycles. Here are some examples:

---

## Product Development Risk

Different types of risks may arise during the development and use of new materials and products such as new chemicals, pharmaceuticals, and medical devices. Appropriate management can be critical for the economic success of a company:

1. The technical risk that the desired product (or the process for its manufacture) has problems and cannot be produced economically
2. The regulatory risk, that the product does not receive approval
3. The market risk that the intended sales success does not happen
4. The risks arising from litigation when a product is perceived by a consumer as having caused damaged or ill health

Reduction of product-development risks is often a consequence of product optimization.

---

## Life Cycle Cost Risk

The life cycle cost risk is the risk of a producer or customer or their insurer. Especially for long-lived and fragile products, the long-term costs can be much higher than the purchase price. That can be considered before purchase, making a life cycle cost risk estimation. It includes not only the purchase price but also the maintenance and repair costs, disposal costs, and the possible cost for unforeseeable events (“force majeure” risks). Such a life cycle cost assessment can help to make decisions between alternative products.

---

## Health Risks

Risk-reduction cycles have made possible the safe use of new techniques in many areas of modern life. For example, in the field of car accident prevention, the periodic improvement of occupant safety of modern cars includes introduction of crumple zones, seat belts, headrests, airbags, and antilock brakes. Comparable cycles existed in the protection of the chemical worker from harmful exposures in the workplace (occupational safety), the reduction of pollutants in consumer goods (consumer protection), and the attempts toward clean environmental media (environmental protection). Thus, in the twentieth century, the consequent reduction of uncontrolled emissions into the ambient air led to a drastic decrease of air pollution. Initially, this was through the reduction of dust emissions. Later, the emissions of sulfur dioxide, nitrogen oxides, chlorofluorocarbon propellants, lead, chlorinated hydrocarbons, dioxin, benzene, and cigarette smoke were systematically reduced. The effort is not over yet. Future tasks include the reduction of carbon dioxide, diesel particles, domestic heating emissions, garbage management, and the management of new sources of emissions.

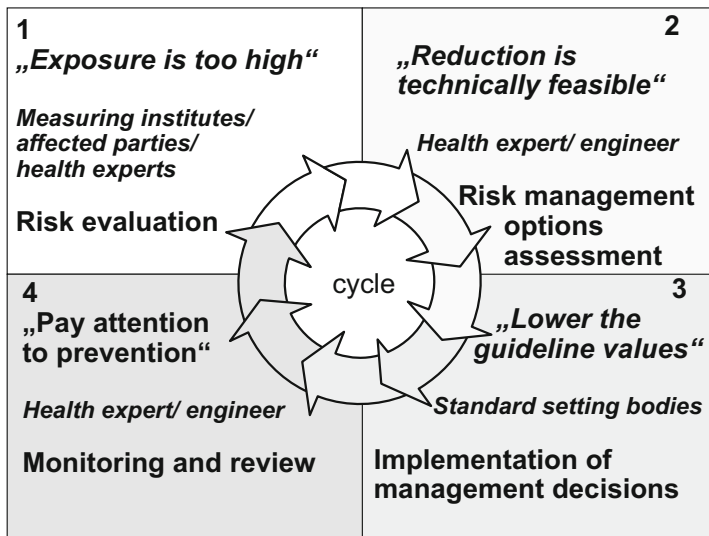

---

## The Risk Cycle in Toxicology

Risk-reduction cycles in the field of workers protection, consumer protection, and environmental protection typically can be divided into steps. An EU expert scientific committee has divided the cycle into four stages (EU 2000): risk evaluation, risk management options assessment, implementation of management decision, and monitoring and review (Fig. 2).

IPCS (2004) identified that risk management consists of risk or risk-benefit evaluation, emission and exposure control, and risk monitoring, with the risk options assessment being implicit in the process and risk options implementation being the decisions taken concerning emission and exposure.

In the EU scheme, phase 1, measurement organizations detect elevated levels of pollutants in the air, soil, water, or housing and suggest that this may represent a health hazard. Residents are shocked and proclaim that such a high risk is unacceptable. Health experts get involved and conclude that the risk should be avoided or

**Fig. 2** The four steps of risk cycles

reduced. In EU phase 2, a range of control options are identified and an appropriate option is selected. For EU phase 2, engineers and other experts offer technical solution, leading to an emission/exposure reduction or sanitation improvement. In EU phase 3, the chosen solutions are implemented. For EU phase 4, the new level of exposure is measured and the effects evaluated. A new, and almost always tougher criterion for the exposure (normally called a standard), may be developed and the lowered guideline levels monitored. This new criterion is considered as acceptable until, some years later, new findings and insights lead again to concern, initiating a second risk-reduction cycle. Many existing limit values and guideline values were developed in the context of such cycles. When multiple cycles occur in a row, one can talk of a risk-reduction spiral.

In the environmental context, risk-reduction cycles often start in an unplanned and chaotic “scandal.” They can be promoted by “concerned” people, whistleblowers or lobbying groups, including citizens’ groups and environmental organizations. Because these groups usually demand zero risk quite aggressively (possibly combined with attempts to denigrate the experts), they initially are considered by experts (including toxicologists) with skepticism. Whenever possible, this difference between perceived risk and objective risk should be resolved as, usually, cooperation is required between all involved parties to achieve an acceptable solution.

Sometimes cycles end with an unsatisfactory result. This may be the case when the claim is too high or the solution too expensive or technically not feasible. It is also the case when obvious opportunities for improvement are ignored or when the “precautionary principle” is misapplied and a control measure introduced that is ineffective or, possibly, harmful.

---

## Future of Risk-Reduction Cycles

Risk reduction has contributed a great deal to the steadily decreasing pollution in many parts of the world in the past decades. It has reduced the exposures of workers, consumers, and the living environment. As a beneficial side effect, the development of environmental protection technology has become an important economic benefit. The potential for further improvements is almost endless, especially when considering the global dimensions.

Sustainable development (development that meets the needs of the present without compromising the ability of future generations to meet their own needs) can and must be the way forward. But this is only possible when society considers the maintenance of a clean and healthy environment as an important goal. Experts will be required who support this idea and its implementation, both technically as well as at the regulatory level. Thus, it is likely that risk-reduction cycles will continue to play an important role in the future.

**Abstract**

Risk minimization plays a central role in different areas of regulatory toxicology. Extremely complex and time-consuming methods are applied for risk minimization in drug development with the aim to exclude potential health risks for humans as far as possible. Therefore, the nonclinical and clinical drug development comprises a program whose results shall ensure a maximum amount of safety for each phase of clinical development (risk-benefit assessment).

---

**Keywords**

Drug development · Clinical trials · Nonclinical testing · ICH guidelines · Risk assessment

---

**Introduction**

Drug development rests on two important pillars. On the one hand, a drug has to be identified which shows efficacy in fighting or preventing a disease. On the other hand, such a drug has to be safe when administered to humans. To ensure the safe use of a drug during clinical development and later after market approval, different regulatory steps have to be taken into consideration. These steps are based on the specific drug development phase, on the patient population treated, and on the various toxicity endpoints investigated to assess potential risks for humans. This chapter tries to give an overview of the different strategies to minimize the risk during drug development.

---

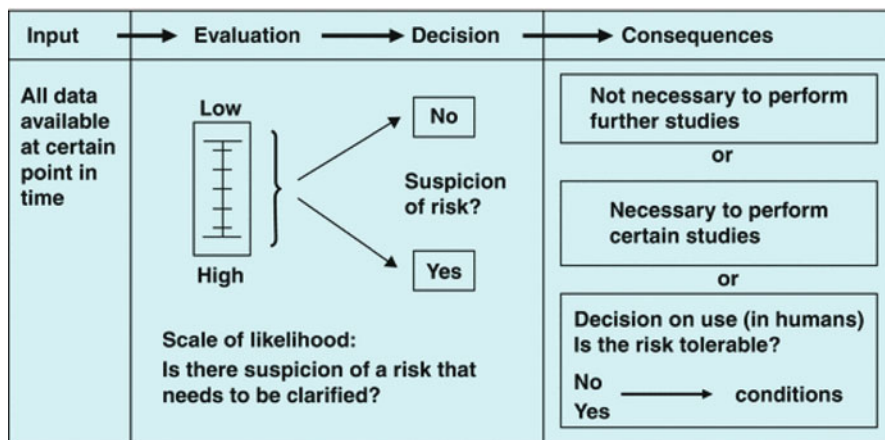

**Risk and Risk Minimization**

“Risk” means that something undesirable may occur. “Probable” means that the occurrence of a risk cannot be evaluated with absolute certainty but that it will remain relative, i.e., it can be classified anything from “low” to “high,” but can never be fixed at “zero” or a “100%.” Therefore, nothing can ever be excluded or anticipated with certainty.

Risk minimization in the framework of drug development implies that the probability of occurrence and the extent of a possible damage caused to the health of a volunteer or patient should be kept as low as possible. Opposed to that may possibly be the entrepreneurial risk to stop the further development of a compound out of safety reasons although the compound might be generally safe and efficacious (low risk).

**Risk Level**

Experience and knowledge are indispensable for risk identification. If the assessment of a graded risk shows that the probability of the risk occurring is too high to be considered irrelevant (i.e., the suspicion having arisen requires clarification), then a

**Fig. 1** Nonclinical testing strategy for risk identification

suitable nonclinical experiment must precede studies in humans. It is understandable that during medicinal product development, there will be a continuous increase in the amount of data available, which suggest a certain degree of suspicion that can only be clarified by an additional experiment or study.

The question whether there is a risk leading to such a degree of suspicion that would require scientific clarification must be answered on the basis of all available information. The assessment of the degree of risk, which ranges from “low” to “high,” can only lead to one of the following decisions:

No, there is no suspicion for a risk requiring (experimental) clarification.

Yes, there is suspicion for a risk requiring (experimental) clarification.

The impact of this assessment on the requirement for particular nonclinical studies as well as on the decision about the use of the developmental compound in humans will become evident and can be categorized with the help of special flowcharts covering all typical areas of possible damage to humans. The different experimental areas are usually of interest during various phases of drug development, i.e., they will be dealt with earlier or later during drug development (Fig. 1).

## Unknown Risks

Unknown risks cannot be investigated scientifically. The effects of chlorofluorocarbons (CFCs) on the stratospheric ozone layer are a well-known example. The risk from the ozone-destroying activity was discovered not until 1974, resulting in a stepwise reduction in CFC use up to complete abandonment. An analogous principle applies to medicinal uses.

## **Strategies for Risk Minimization in Nonclinical Development**

### **Adaption of Trial Protocols to the Stages of Drug Development**

The nonclinical development of drugs includes studies on toxicology and safety pharmacology in animals and *in vitro*. These studies are performed to minimize the risk for the use of a new drug substance in humans from the first orienting administration to volunteers/patients up to the broad therapeutic use in practice.

Due to average drug development times of 5–15 years, the nonclinical development program inevitably ranges over a period of several years. This program does not represent an isolated sequence of different studies but is embedded in the whole process of drug development. During drug development, a constant adaptation of both individual study plans and the whole study program to the constantly changing progress in knowledge is needed. The same applies for its execution, which happens stepwise and is coordinated with the clinical studies.

### **Chronological Order**

Chronologically, certain nonclinical studies usually precede certain clinical trials. The required contents of nonclinical studies can be deduced from the scientific questions arising from the planned clinical trials. Generally, the characterization of the pharmacodynamic effects is followed by an investigation into toxicodynamic effects before the substance can be used in humans at all. Findings from the use in humans usually have an effect on the kind and content of further nonclinical studies and their logical and chronological position in the development process. Thus, a cycle of accumulating knowledge and its influence on the design of the remaining nonclinical program is completed. This sequence gives only an extremely rough guidance for the course of the development process for a new drug substance, regarding its contents and chronological order. However, it clearly indicates that the cycle in question can be – and usually is – repeated as development progresses.

### **Potential Areas of Risk for Humans**

In an attempt to cover all relevant areas of potential risks, it is necessary to consider an exhaustive list of adverse reactions that are generally expected to occur and to compare them with the risks observed in the clinical trial situation. Consequently, identified and potentially meaningful risks have to be as far as possible investigated experimentally.

Typical areas of possible damage to humans are the following:

Acute toxicity

Repeated-dose toxicity

Adverse effects on reproduction (male and female fertility, embryo-fetal development, pre-/postnatal development)  
Genotoxicity  
Tumorigenicity  
Sensitization/immune suppression and stimulation  
Local or other particular adverse events

Drug development is a stepwise process where information about safety from animal as well as human studies is assessed. The aims of nonclinical studies comprise characterization of toxic effects on target organs, dose-effect relationship, relation to exposure, and potential reversibility. Such information is important regarding the evaluation of the safe starting dose in humans and to determine which parameters have to be monitored to detect possible adverse effects during the clinical trial.

### **Extrapolation to Humans**

Before a potential medicinal product is used in humans for the first time, there are, with regard to risk assessment, only results available from nonclinical investigations and possibly some hints on potential effects in humans derived from experience with related compounds. Based on this knowledge and considering particular results from nonclinical or clinical areas under investigation, it can be stated which relation exists, e.g., between substance-related effects and amounts of bioavailable substance. It may be possible to make assumptions, whether effects were provoked by the applied substance itself or by its biotransformation products. However, at this point of time, no reliable statement can be made about the degree of similarity of the experimental models to the situation in humans.

As a result, the investigator is forced to use the potential medicinal product in a variety of testing models (various models of animal species, application forms and experimentation, and different duration of studies) in order to increase the chances of having included relevant models for the situation in humans.

### **Feedback of the Results from Early Clinical Trials**

If this was the case can only be stated after the first studies in humans have been performed. With an increase in scientific knowledge resulting from various steps of the clinical development, certain findings obtained in the nonclinical stage will invariably lose their meaning for risk assessment.

On the other hand, through the flow of information from clinical studies, those nonclinical models can be identified that are particularly appropriate for risk assessment on the basis of their similarity to the human situation. Results from these studies together with those from early clinical trials form the basis of risk assessment, which must always be carried out before the next phase of clinical trials can be entered.

## **Role of Clinical Development**

Clinical trials are performed in humans with the objective to show the safety and efficacy of the respective medicinal product. The first phase starts with a safe low exposure in a small number of volunteers to investigate compatibility. In the following clinical trials, exposure will generally be increased in relation to dose, duration, and/or size of the exposed patient population. Clinical trials will be extended if appropriate safety was proven in prior clinical trials plus additional safety information from nonclinical studies, which will be obtained during clinical development.

## **Prerequisites for Use in Humans**

Prior to use in humans, it is necessary to build up a risk assessment using the most sensitive nonclinical testing model following medicinal-ethical and also legal aspects. This rule remains valid until it can be convincingly shown that the models have no or only limited biological impact on risk assessment.

The depicted approach, i.e., drawing conclusions from nonclinical test results with a view to potential results and risks for humans, and the feedback from relevant information obtained from clinical trials, turns the development and application of nonclinical testing strategies into a complex and dynamic process beyond fixed plans or checklists.

A reasonable approach implies the possibility for a critical analysis of planning, performance, interpretation, and assessment of nonclinical and clinical studies. It is acknowledged that any individual kind of investigation may be of limited relevance. One should be aware that results obtained can influence the type and extent of subsequent nonclinical and clinical studies. The design of testing strategies must, therefore, be accompanied by a high sense of responsibility reconciling the volunteers', patients', and doctors' requests for new safe medicines and the need to protect laboratory animals. Adhering to this principle will reveal, after thorough evaluation, which practical steps should be taken for each step of drug development.

## **Harmonization of Drug Assessment**

The European Union's (EU) strive for harmonization with a view to a common market for medicinal products and the trilateral negotiations between Japan, the United States, and the EU led in October 1989 to the initiation of the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH). ICH is hosted by the International Federation of Pharmaceutical Manufacturers & Associations (IFPMA). The ongoing program has, among others, the following objectives:

**Table 1** Nonclinical ICH guidelines: checklist

ICH code	Topic
S1A	Need for Carcinogenicity Studies of Pharmaceuticals
S1B	Testing for Carcinogenicity of Pharmaceuticals
S1C (R2)	Dose Selection for Carcinogenicity Studies of Pharmaceuticals
S2 (R1)	Guidance on Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use
S3A	Note for Guidance on Toxicokinetics: The Assessment of Systemic Exposure in Toxicity Studies
S3B	Pharmacokinetics: Guidance for Repeated-Dose Tissue Distribution Studies
S4	Duration of Chronic Toxicity Testing in Animals
S5 (R3)	Detection of Reproductive and Developmental Toxicity for Human Pharmaceuticals
S6 (R1)	Preclinical Evaluation of Biotechnology-Derived Pharmaceuticals
S7A	Safety Pharmacology Studies for Human Pharmaceuticals
S7B	The Nonclinical Evaluation of the Potential for Delayed Ventricular Repolarization (QT-Interval Prolongation) by Human Pharmaceuticals
S8	Immunotoxicity Studies for Human Pharmaceuticals
S9	Nonclinical Evaluation for Anticancer Pharmaceuticals
S10	Photosafety Evaluation of Pharmaceuticals
S 11	Nonclinical Safety Testing in Support of Development of Paediatric Pharmaceuticals
M3 (R2)	Guidance on Nonclinical Safety Studies for the Conduct of Human Clinical Trials and Marketing Authorization for Pharmaceuticals

To identify and eliminate the differing technical requirements in the three states/regions

To avoid repetition of all kind of tests

To accelerate drug development, thus giving patients quicker access to new medicinal products without negatively affecting quality, safety, and efficacy

In the field of nonclinical testing of drugs, 15 guidelines have been adopted since the initiation of the ICH process (Table 1).

### **Carcinogenicity Studies (ICH S1)**

Carcinogenicity studies are generally not required to be completed prior to the conduct of clinical trials except there is a cause of concern. For pharmaceuticals, which are developed for certain life-threatening diseases, carcinogenicity studies, if applicable, may be completed after market approval.

### **Reproduction Toxicity Studies (ICH S5)**

Reproduction toxicity studies should be conducted as is appropriate for the population that is to be exposed.

## **Criteria for Inclusion of Volunteers/Patients in Clinical Trials (ICH M3 (R2))**

### **Men**

Men (volunteers/patients) can be included in phase I trials and phase II clinical trials before the conduct of the male fertility study in rodents since an evaluation of the male reproductive organs is performed in the repeat-dose toxicity studies. Repeated-dose toxicity studies of at least 2 weeks are considered to be adequate for evaluation of male reproductive organs.

### **Women Not of Childbearing Potential**

Women of not childbearing potential (i.e., permanently sterilized, postmenopausal) can be included in clinical trials without reproductive toxicity studies if the relevant repeated-dose toxicity studies (which include an evaluation of the female reproductive organs) have been conducted; again repeated-dose toxicity studies of at least 2 weeks are considered appropriate.

### **Women of Childbearing Potential**

For women of childbearing potential, there is a high level of concern for the unintentional exposure of an embryo or fetus before information is available concerning the potential benefits versus potential risks. The recommendations on timing of reproduction toxicity studies to support the inclusion of women of childbearing potential in clinical trials are similar in the EU, United States, and Japan.

It is important to characterize and minimize the risk of unintentional exposure of the embryo or fetus when including women of childbearing potential in clinical trials. One approach to achieve this objective is to conduct reproduction toxicity studies to characterize the inherent risk of a drug. A second approach is to limit the risk by taking precautions during exposure of women of childbearing potential in clinical trials. Testing for pregnancy during the trial and subject education should be sufficient to ensure compliance with measures designed to prevent pregnancy during the period of drug exposure. To support these approaches, informed consent should be based on any known pertinent information related to reproduction toxicity. If no relevant reproductive information is available, the potential for unidentified risks to the embryo or fetus should be communicated.

In all three regions, women of childbearing potential can be included in early clinical trials without nonclinical development toxicity studies (e.g., embryo-fetal studies) in certain circumstances. One circumstance could be intensive control of pregnancy risk over a short duration (e.g., 2 weeks) clinical trials. Precautions to prevent pregnancy include pregnancy testing, use of highly effective methods of birth control, and study entry only after a confirmed menstrual period.

Generally, where appropriate preliminary reproduction toxicity data are available from two species, and where precautions to prevent pregnancy in clinical trials (see above) are used, inclusion of women of childbearing potential (up to 150) receiving investigational treatment for a relatively short duration (up to 3 months) can occur before conduct of definitive reproduction toxicity testing. This is based on the very low rate of pregnancy in controlled clinical trials of this size and duration.

In the United States, assessment of embryo-fetal development can be deferred until before phase III for women of childbearing potential using precautions to prevent pregnancy in clinical trials (see above). In the EU and Japan, other than the situations described above, definitive nonclinical developmental toxicity studies should be completed before exposure of women of childbearing potential.

In all three regions, women of childbearing potential can be included in repeated-dose phase I and II trials before conduct of the female fertility study since an evaluation of the female reproductive organs is performed in the repeated-dose studies. Nonclinical studies addressing female fertility should be completed to support inclusion of women of childbearing potential in large-scale or long duration clinical trials (e.g., phase III trials).

In all three regions, the pre-/postnatal development study should be submitted for marketing approval. All female reproductive toxicity studies and the standard battery of genotoxicity tests should be completed before inclusion, in any trial, of women of childbearing potential not using highly effective birth control or whose pregnancy status is unknown. Further details on the inclusion of women of childbearing potential in clinical trials are given in ICH M3 (R2).

## **Pregnant Women**

Before the inclusion of pregnant women in clinical trials, all female reproductive toxicity studies and the standard battery of genotoxicity tests should be conducted. In addition, safety data from previous human exposure should be evaluated.

## **Clinical Trials in Pediatric Populations**

When pediatric patients are included in clinical trials, safety data from previous adult human experience would usually represent the most relevant information and should generally be available before initiation of pediatric clinical trials. The appropriateness and extent of adult human data should be determined on a case-by-case basis. Extensive adult experience might not be available before pediatric exposures (e.g., for pediatric-specific indications).

Results from repeated-dose toxicity studies of appropriate duration in adult animals, the core safety pharmacology package, and the standard battery of genotoxicity tests should be available before initiation of trials in pediatric populations. Reproduction toxicity studies relevant to the age and gender of the

pediatric patient populations under study can also be important to provide information on direct toxic or developmental risks.

The conduct of any juvenile animal toxicity studies should be considered only when previous animal data and human safety data, including effects from other drugs of the pharmacological class, are judged to be insufficient to support pediatric studies.

The appropriateness of carcinogenicity testing should be addressed before long-term exposure in pediatric clinical trials. However, unless there is a significant cause for concern, carcinogenicity studies are not recommended to support the conduct of pediatric clinical trials. Further recommendations for clinical trials in the pediatric population are depicted in ICH M3 (R2) and ICH S 11.

---

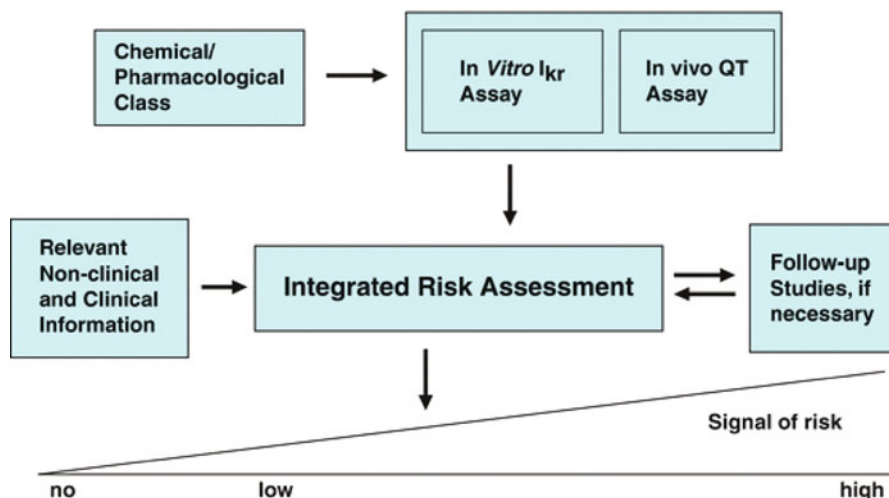

## **Tolerable/Non-tolerable Risks Using the Example of Safety Pharmacology**

Additionally to the characterization of the desirable pharmacodynamic effects of a drug, studies investigating secondary pharmacodynamic effects are requested. Pharmacodynamic effects relevant for safety fall into the category of “safety pharmacology.” Safety pharmacology studies concerning effects of the medicinal product on vital functions like the cardiovascular, central nervous, and respiratory system should be performed prior to first administration in humans. If not covered by results from previous toxicology studies, supplemental safety pharmacology studies may be necessary for the renal/urinary system, the autonomic nerve system, the gastrointestinal system, etc. with respect to further drug development.

### **Example QT Interval Prolongation**

A relatively recent finding is that drugs intended for a non-antiarrhythmic indication may lead to an abnormal QT interval prolongation displayed in the electrocardiogram (ECG). In this context, potential life-threatening cardiac arrhythmias belonging to the type of torsade de pointes may occur. At international level, this potentially serious adverse reaction raised a question: How can the data material collected for assessment of the arrhythmogenic potential of a drug in nonclinical studies be improved, and how can a more precise risk assessment be guaranteed?

The QT interval of the ECG is a measure of the duration of ventricular depolarization and repolarization. Repolarization of the heart ventricle is mainly influenced by the activation of the delayed rectifier  $K^+$  current ( $I_K$ ) which is composed of a rapidly ( $I_{Kr}$ ) and a slowly ( $I_{Ks}$ ) activating component. The rapidly activating component ( $I_{Kr}$ ) is encoded by hERG (human ether-a-go-go-related gene). Substances which block the  $I_{Kr}$  prolong the action potential of the heart. Whether the medicinal product under investigation belongs to a chemical/pharmacological class with the potential to prolong the QT interval should be assessed prior to first administration in humans.

**Fig. 2** Nonclinical testing strategy for assessing risk for QT interval prolongation (Refer to ICH 7B)

Nonclinical methodologies address investigations using hERG-encoded  $K^+$  channels, action potential parameters, as well as ECG parameters taken from non-rodent species. Follow-up studies might also be necessary which, e.g., comprise investigations on different other cardiac ion channels. All data available are included in an “integrated risk assessment” to detect a potential risk for a potential to prolong the QT interval (refer to Fig. 2). The result “no risk,” “low risk,” or “high risk” can be crucial for further drug development. A new medicinal product with QT interval-prolonging properties has to be clearly defined concerning its therapeutic significance especially in comparison to drugs with similar or comparable indications.

## Abstract

If the risk resulting from an event, including an event involving exposure to a defined chemical substance, is known and characterized, measures preventing the event or mitigating the damage (including ill-health) can be set up. These may include land use and emergency planning and restrictions on use, including the ultimate restriction, which is prohibition. Such measures can have major socio-economic impacts. In a democratically organized society, these measures must be acceptable to the public as a whole; thus, effective multidirectional communication between stakeholders (interested parties) is essential.

**Introduction**

The term risk management includes those measures which must be taken by individuals or society to cope with an identified risk. The regulatory toxicologist may be asked to suggest measures that are used to control, reduce, or regulate risk. The general objective of risk management is to select appropriate tools to reduce the likelihood or size of risks and thus to prevent or minimize damage, but it may include maximizing risk to a target species with the aim of minimizing damage from, for example, a crop pest. Toxicological risk management includes standard setting, i.e., defining and setting limit values for exposure that represent the maximum acceptable or tolerable risk. Exposure standards exist within a process of risk management, which, when followed, should ensure the safe handling of the relevant substance. *Classification and labeling* draws attention to the inherent properties without defining a risk. For a risk to exist, there must also be sufficient exposure to the substance. Exposure monitoring can then serve as management tool.

Important measures to limit the impact of unavoidable damage are appropriate land use planning, proper design of manufacturing plants, restriction on use (e.g., for certain applications or in specified processes or to specified users – often combined with the use of protective equipment) or sales outlets, and, in extreme cases, prohibitions on the marketing of certain substances. The range of these instruments shows that these measures must be decided politically. Usually there is some actual or potential benefit foregone when manufacture or use of a substance is restricted. Since the acceptability of the risk depends on attitudes to risk and in the majority of cases there is no clear, generally accepted solution, management decisions often require detailed discussion. Here, the preferences for *risk-friendly*, *risk neutral*, or *risk averse* options must be weighed against each other. Bans may ultimately lead society into a foregone of opportunities. Therefore, such a drastic measure must be carefully justified. The choice of policy instruments for risk control is not arbitrary. The regulatory toxicologist may have to explain the basis of the acceptability of a risk in a way that is both intelligible to the public and well founded. The widest acceptance can be achieved if all stakeholders are affected similarly by the management decision. Ideally, when an individual's choice creates extra risk burdens, those burdens should be to that individual rather than to others in society or society in general.

**Chemical Risk Assessment**

There are two main streams of chemical risk assessment. The first is in terms of substances and their uses, and the second is in terms of risk assessment for pollution

prevention and control. The latter includes “major accident hazards,” such as those seen at industrial manufacturing plants, and land use planning. Associated with the last named is the “cleanup” (remediation) for preexisting pollution.

Within the EU substances are now dealt with through the REACH (Registration, Evaluation, Authorisation and Restriction of Chemicals) regulation (Regulation EU No 1907/2006, as amended) and a variety of use-specific schemes (for medicines, veterinary products, food additives and contaminants, plant protection products, biocides, personal care products [“cosmetics”], etc.). Closely associated with this regulation is that for classification, labeling, and packaging of substances (CLP Regulation, Regulation 1272/2008). REACH and CLP replace older regulatory schemes, notably those associated with “new” and “existing” substances. REACH also subsumes the control requirements set out in former “Marketing and Use” Directives. The CLP regulation introduces the UN Globally Harmonized classifications into EU law. This classification system is intended to be utilized worldwide.

REACH requires that a chemical safety assessment is conducted for chemicals registered in quantities of 10 tons or more and chemicals identified as causing certain types of toxicity. The guidance to the REACH regulation identifies that the chemical safety report (produced as a result of the assessment) should include an assessment of any hazards that the substance may present (to human health, to physical chemical hazards [fire and explosion, etc.], and to the environment). When the substance meets classification criteria or is persistent, bioaccumulative and toxic, or very persistent and very bioaccumulative, the assessment is likely to be conducted by the regulatory authority. In all cases it includes an attempt to identify the conditions under which the risks can be controlled and therefore requires an examination of exposures and risk management procedures.

Pollution prevention and control involves both prevention and control of incidental and accidental releases of chemicals. Therefore, both land use planning and emergency planning are important. At the base of such prevention is the identification of chemicals and processes that cause harm to human health and the environment, modeling their dispersion and monitoring emitted levels of the substances to ensure that the exposures do not exceed acceptable levels. Incidental exposures are dealt with through processes such as “integrated pollution prevention and control.”

In the EU, **major accident hazards** are subject to the “Seveso Directives” – Seveso 1 is Directive 82/501/EEC, Seveso 2 is Directive 96/82/EC, and Seveso 3 is Directive 2012/18/EU. This major accident hazards legislation was the result of chemical exposures following accidents at Seveso (Italy) and Flixborough (UK). The current Directive is Seveso 3 which came into effect in 2015. The legislation is concerned with both planning for the prevention of major incidents and emergency planning should a major accident occur. It should be noted that many of these major accidents are the result of fire or explosion, but others (e.g., dioxins at Seveso or methyl isocyanate at Bhopal) are due to direct health hazards of chemicals released to the atmosphere. Again, underpinning the assessment for releases of chemicals capable of causing damage to human health and to the environment is identification and characterization of the hazards (i.e., the toxicology and ecotoxicology) as well as the exposure pathways.

In certain parts of the world, “contaminated land” is an issue, i.e., land that contains substances in or under the land that are actually, or potentially, hazardous to health or the environment. This land may have been contaminated by human activities such as mining, railways, industry, chemical and oil spills, or waste disposal. Contamination can also occur naturally as a result of the geology of the area (e.g., arsenic contamination) or through agricultural use. Human exposure to contaminants can be through inhaling dust or gasses, contact with soil, or eating food grown on the land. In some cases, sites are so contaminated that they present an unacceptable risk to human health or the environment. When such contamination is identified, the land concerned requires remediation. Identification of contaminated land involves identification of the health effects of potential contaminants as well as modeling the pathways by which the contaminants are likely to be taken to the target.

---

## Risk-Reduction Strategy

The creation of a risk-reduction strategy involves several steps, namely, risk assessment and risk or risk-benefit evaluation, identification of management options, and monitoring both of the risks and of the effectiveness of the risk management measures.

The *risk assessment*, which the risk manager receives from independent risk assessors, must be “fit for purpose.” The assessment may include information on whether the statements are based on collected information or assumptions, whether extrapolation steps were included (inter- and intraspecies, route of exposure, exposure period), and, if so, what the extrapolation procedure was. Ideally, it should include an identification of any specific group within a population at higher risk. *Risk-benefit* evaluations have to take into account whether, and to what extent, benefits will be foregone as a result of the proposed risk management procedures. Occasionally, risk (or risk-benefit) evaluations will also have to take into account public opinion or, at least, opinions of affected persons (“stakeholders”), which may, in turn, be derived from controversial risk evaluations based mainly on nonscientific factors.

If the initial risk assessment results indicate to legislators that they should look further and, possibly, reduce the risk, further evaluations and adequate risk-reduction measures must be sought. A preliminary step may be to determine whether existing legislation is adequate or can be extended to cover the problem.

In REACH, the normal first step in the risk-reduction process is to perform a more specific evaluation of the risks and current management measures and, if the risks cannot be minimized to an acceptable level, a risk-benefit analysis. Technical control measures include replacement by substitution for either the chemical or the process, engineering controls – either at the design stage or by retrofitting – and use of personal protective equipment, often combined with the setting of maximum exposure standards or restricting users or outlets. Finally, in the risk-benefit analysis, socioeconomic aspects must be borne in mind. This

socioeconomic analysis requires economic and sociological expertise and includes a consideration of costs and benefits to all stakeholders of health benefits and detriments, harm to competition, and job loss. Socioeconomic analysis reduces everything to a common, usually monetary basis and is in its infancy. Possible alternative solutions can create new markets (e.g., the use of wind energy, photovoltaics).

Any decision taken must be transparent and comprehensible even though, given the complexities and inconsistencies in the available data, this may be extremely difficult. There is always a need to review and complement existing data. The adequacy and quality of the risk management measures must be checked in time in order to confirm that the required mitigation has occurred. Decisions on classification and labeling on basis of the inherent toxicity of the substance are clearly within the realm of the regulatory toxicologist. In Europe, this is done in laid down procedures in the course of chemical assessment. The decisions in this area may be subjective or a matter of judgment when qualitative factors affect the decision (e.g., extent of dermal effects) or when the relevance of animal data to humans has to be assessed (e.g., specific cancer site, molecular characteristics, and morphology).

Universally accepted decision-making patterns are emerging, even if some of these approaches are pragmatic rather than fully justified on the basis of the science.

## **Voluntary Agreements and Regulatory Actions**

Measures concerning restrictions or even prohibitions are usually controversial. Here, two different approaches are available: *voluntary agreements* or *regulatory actions* of the legislature. It is assumed that the voluntary agreement has the advantage that it is usually considered “common sense” and shows rapid effects, while a legislative process takes a comparatively much longer time and leaves those affected without the required protection during this period. Voluntary agreements can be made, e.g., between the specific producing industry and the responsible state agency. Although historically voluntary agreements were often preferred, they have almost universally been succeeded by regulatory actions. Examples of historically important regulatory schemes are given below.

## **Thalidomide and Drug Legislation**

In combination with other agents, thalidomide was used to treat cold, cough, anxiety, migraine, and asthma and for calming children. Very quickly it reached the largest market share in its class. At the time of its introduction, regulatory requirements were minimal, and sales in Germany and the UK increased rapidly. In 1960–1961, it became obvious that an increase in malformations in children was associated with maternal thalidomide intake, and the drug was withdrawn. The USA did not approve the drug because a theoretical possibility of

reproductive toxicity had not been evaluated experimentally. In the UK, this disaster led to an inquiry by Sir Derek Dunlop and, both in Germany and the UK, more stringent national legislation concerning the safety of medicines.

As a consequence of the thalidomide case, the UK Medicines Act of 1968 and the German Medicines Act of 1976 were enacted in order to increase drug safety. Switzerland has set up an inter-cantonal agreement in 1971. Austria followed in 1983. In recent years, the national approval systems for medicines have been subsumed into an EU-wide scheme. Generally, the legislation sets up license requirements for medicines and their producers, introduces an authorization procedure, and requires adequately conducted clinical trials. For many products, a prescription is mandatory. Recent EU legislation has introduced pharmacovigilance requirements to ensure that safety in use is properly monitored.

## **Smoke Control and Air Quality Legislation**

The improvement of air quality with its far-reaching implications for the regulation of chemicals provides an example of successful claims regulation by new legislation.

As early as 1306, King Edward I (of England) had banned the burning of coal in furnaces in London. Almost 600 years later, the death of 1000 inhabitants of London was reported, which was caused by “smog.” The smog was caused by sulfur dioxide accumulation in the air during combustion of coal. In December 1952, there was such a dense fog for 4 days (“Killer Smog”) that the busses could operate only when an officer walking with a lantern showed the direction. There were 4000 extra fatalities in London hospital. It was clear from the weekly deaths registrations in the UK that the smog was the cause of death. Based on the analysis of this incident, the “Clean Air Act” was enacted in 1956 in the UK, unfortunately not soon enough to prevent further 1000 deaths in a smog period in 1955. The “Clean Air Act” set up “smoke control zones” within which emission of smoke was prohibited and controls were introduced on the fuels that could be burnt and on appliances used for burning. This Act was reinforced with the Clean Air Act of 1968 after another smog period in 1962, which cost 750 additional lives. These were consolidated into a Clean Air Act of 1993. Since 1968, there have been no similar smog episodes in London, and, as a result, chronic bronchitis and related disease clearly decreased and the number of sunny days increased. In the urban area of London, flora and fauna recovered, and there was a significant improvement in the quality of life of the citizens.

In New York, USA, there was also a smog period in 1953 which resulted in 170–260 additional casualties, and there were 405 additional cases in 1963 and 168 cases in 1966. This led to the founding of the EPA (Environmental Protection Agency, US EPA) in 1970 and the adoption of the American “Clean Air Act.” The success of this law led in 1976 to the ratification of the “Toxic Substances Control Act,” which authorizes the US EPA to control the use of toxic substances. In Germany, similar legislation was made possible in 1986.

## DDT, Malaria Control, and Wildlife

DDT (dichlorodiphenyltrichloroethane) belongs to the class of chlorinated hydrocarbons. Its insecticidal effect was discovered in 1939 by Paul Mueller, who was honored with the Nobel Prize in 1948. Because of its low toxicity to humans – a dose of 18 g was survived – but very good efficiency against flies, lice, and mosquitoes, which transmit malaria and other diseases, its versatility, and low manufacturing and application costs, DDT quickly became the world's most important insecticide, used extensively against the vector for malaria, the anopheles mosquito. In Sri Lanka (Ceylon), some 2.8 million people suffered from malaria in 1946, i.e., before DDT spraying was used to control the vector, but only 17 cases were reported in 1963, after DDT spraying. The worldwide production and application of DDT amounted to almost 100,000 t in 1963. At this time, results were published according to which DDT is toxic to fish and causes a thinning of eggshells in birds of prey, preventing their successful reproduction. This was made public in the book *Silent Spring* by Rachael Carson in 1962. There appeared also reports that DDT generated liver cancer in mice. This together with the accumulation of the compound in human adipose tissue and breast milk resulted in attempts to ban DDT in various countries such as the USA and Germany in 1972.

In Sri Lanka, the 2.8 million cases of malaria and more than 12,500 deaths in 1946 fell to 17, and the number of deaths fell to 1 in 1963, i.e., after spraying was introduced. But 5 years after spraying ceased, i.e., in 1969, the number of deaths had climbed to 113, and the number of cases to 500,000. Selective house spraying with DDT has restored some of the control on malaria. The WHO estimates that during the 20 years of widespread use of DDT, the lives of some 100 million people living in Africa, Asia, and South America were saved.

The DDT example shows the dimensions and the dilemma of risk management decisions. Proven and assumed chronic damage of humans and animals, especially in the USA and Europe, led to a ban, which, while it may have been appropriate for the first world where malarial treatments and expensive alternative insecticides are available, caused disease and death of people in poorer, less developed countries for whom costs are critical.

It also illustrates that, generally, prevention is better than cure when examining risk management measures. Meanwhile, the situation is further complicated by the observation that DDT-resistant insects have developed.

The outbreak of the corona virus (SARS-CoV-2) pandemic in 2020 provides an example for the difficulty of reasonable risk management in a situation of unknown knows. It was known that the virus type has a high danger potential, but its routes of infection and infectivity were initially largely unknown. The preventive actions resulted in a rapid worldwide lockdown of international traffic and new regulations, often on state or regional level, with quarantines, enforced contact restriction, and severe restriction of human freedom, sometimes in a nonproductive way. Moreover and ironically, the lockdown resulted in improvements of air quality and reduction of carbon dioxide emissions at a rate which has never been achieved by attempts of climate protection.

## Preventive Measures

Preventive measures include the assessment of possible environmental and health impacts during the planning stage of projects involving potential exposure to chemicals and deciding on the acceptability or otherwise of the proposal, either for the projected facility or for the surrounding population. These may include possible considerations as to where to site a manufacturing or storage facility that is a potential major accident hazard (e.g., a chemical plant) and/or whether a (usually brownfields) site is contaminated by chemicals and requires remediation. Prevention measures (e.g., “stay indoors” while the toxic chemical disperses) may also be a part of emergency planning aimed at mitigating effects should an incident involve release of substantial amounts of a hazardous chemical. It is worth noting that farm wastes, notably those from animal housing facilities, require particular care as they can result in poisonous gasses and vapors (hydrogen sulfide, carbon monoxide, and carbon dioxide) being emitted in confined spaces (e.g., animal housing containing slurry tanks), yet agricultural buildings may be subject to less onerous planning requirements.

A **health impact assessment** (HIA) should be performed when major construction projects involving toxic agents are planned, such as town, traffic, or airport projects, waste incineration plants, wind farms, or tanks containing chlorine, ammonia, and phosgene.

Generally, the public health and environmental services are responsible for the assessment of health effects on humans. Health and environmental impact assessments are effective in the context of planning. Although they do not prevent preexisting dangers, they can also help in developing emergency procedures.

It is understandable that questions about scientific methods and administrative procedures used in toxicological risk analysis conducted by regulatory authorities are often controversial. Many of the methods used involve judgments. Topics of dispute may be the judgments concerning the quality of the data and its interpretation, judgments involved in the qualitative or quantitative risk characterization, judgments concerning the prognosis, and, especially, judgments in the risk-benefit evaluation and the attitudes to risk of the stakeholders. Many of the methods must be worked out on an international level and harmonized without increasing the administrative overhead. Actual criteria should be based on local conditions. Clearly, the people carrying out the risk assessment and management need to be properly educated and trained.

## Abstract

Limit values are legal concentration limits for chemical compounds at work, in the environment, in food, in cosmetics, in medicinal products, and so on. There are different rationales for each, but all are equally binding, both negatively and positively, for concerned persons and interest groups. These values are in constant danger of being attacked as either too stringent or too lax. For this reason, only concentration limits that have gained a maximum of societal consent by means of a transparent, politically organized process should become legally enforced. Such consent is most likely to be reached on the basis of the three-dimensional rule of environmental hygiene (REH): Avoid useless exposure, optimize functional exposure, and prevent adverse exposure.

By applying this rule, this chapter explains how to find a science-based societal consent between all interest groups when managing functional, avoidable, and natural exposure.

## Keywords

Environmental hygiene · Exposure · Protection goals · Limit values · Maximal values · Precaution · Societal consent

## Introduction: Types of Exposure

The criterion of “avoidability” primarily involves anthropogenic contaminants, whereas “unavoidability” concerns geogenic/biogenic exposure. With respect to tolerability (tolerance threshold  $T$ ), the following regulatory differentiations must be made: on the one hand, there are the avoidable = anthropogenic exposures  $B$  and  $C$ , with their – if functional – threshold concentration  $F_B > 0$  for optimal on-site technical function and  $F_C \geq 0$  (remote environmental), representing the minimum concentration required to guarantee a compound’s  $B$  desired on-site technical functionality (list of abbreviations for this chapter is at the end of this essay). Such exposure, provided that it is kept below a (presumed) threshold  $E_a$  of health concern about adverse effects, is either accepted at  $F_B > 0$  or at  $F_C = 0$ , respectively, but only tolerated at levels of  $T_B \geq F_B$  and  $T_C \geq F_C$ .

The situation is different for the virtually unavoidable = geogenic/biogenic exposure  $A$  from the use of natural resource. Here, the ratio between upper limit of expected background exposure ( $BG_A$ ) and  $E_a$  is the main criterion for whether a resource  $A_1$  (with  $E_a \geq BG_{A1}$ ) might either be usable without treatment up to a  $F_{A1} \leq E_a$  or, with  $E_a$  being  $< BG_{A2}$  ( $A_2$ ), only after reducing the compound’s  $A_2$

concentration in the raw material or resource down to its technical avoidability (by elimination) and hence a tolerance threshold of  $T_{A2} < E_a$ .

The following conditions for *maximum* limit values LV (maximum legal concentration limits) accepted by society as a whole can therefore be derived from the rule of environmental hygiene (REH):

- *Compound class A (geogenic/biogenic):*
  - *Class A1 ( $E_a \geq BG_{A1}$ )*  
LV = threshold of the resource's usability or  $LV = F_{A1} = E_a$  (A1)
  - *Class A2 ( $BG_{A2} > E_a$ )*  
LV = threshold of technical avoidability (elimination) or  $LV = T_{A2} \leq E_a$  (A2)
- *Compound class B (anthropogenic, functional,  $F_B > 0$ ):*  
LV = threshold of functionality or  $LV = T_B \leq E_a$
- *Compound class C (anthropogenic, nonfunctional,  $F_C = 0$ ):*  
LV = threshold of tolerability or  $LV = T_C \leq E_a$  (any remote  $T_C$  ought to be fixed as closely as possible to  $F_C = 0$ )

This classification from A to C also helps to rationalize how intensely a final product needs to be surveyed on constituents (A), residues (B), and contaminants (C). Class A compounds rarely need short-time interval surveillance. On the other hand, class B compounds need continuous surveillance at the point of on-site functional and intended addition/effect, and C compounds are preferably surveyed at more or less remote points of their unintended environmental penetration.

The concept of consensual legal limit values outlined here is not only a tool for a responsible environmental policy and surveillance. It is also an instrument that may help avoid "adverse effects" at the societal level by enabling the different interest groups to communicate with each other in a civilized and organized manner.

---

## Criteria to Limit Exposure

Limit values (LV) are legally binding limit concentrations for chemical or other parameters in technical compartments and environmental media including food and drinking water. They have proved to regulate use and handling of chemicals and of many other noxa within all compartments of the environment and human life. They eventually quantify the *societal readiness to pay* when reducing, minimizing, or avoiding useless risks or loads on a *maximum level* and admitting functional ones on a minimal but functionally unavoidable and, hence, *minimum* technical level.

Toxicologists, health professionals, ecologists, environmental technicians, and engineers propose to legislators' options on how to substantiate necessity, nature, and numerical amount of legal limit values in the form of:

- Maximal values as derived based through science (e.g., toxicology, medicine, ecology)
- Maximum values as derived technically (functional technology and to avoid useless loads)

An ideal, politically set limit value:

- Represents the regulatory equivalent of a science-based maximum value
- Originates from a societal process of decision that is transparent and knowledge directed

When trying to scientifically find or define tolerable or acceptable maximum values for potentially harmful exposure (or to find minimum values for functional exposure), the following protection goals and corresponding options for management of their protection should be considered:

- Health of humans and their protection from illness
- Nonhuman organisms/intact ecosphere or compartments thereof
- Technical devices and equipment
- Cultural monuments and cultural traditions/customs
- Usability of natural resources
- Sensorial and expected aesthetic quality

It is clear that, within these different domains, different options are conceivable to support a maximum value for exposure towards a single compound. Any concrete numerical value (concentration) will vary in correspondence. As a consequence, in different compartments, numerically diverse limit values to trigger regulatory interventions for the same noxa are reasonable not only from the point of politics but also of science. Moreover, the nature and numerical value of a maximum value as well as the density and quality of knowledge to support it is defined by four categories of protection (see section “[Categorization of Legal LVs in Terms of General Precaution, Early Warning, Control of Concern, or Control of Hazard](#)”):

1. General precaution to prevent any possible concern
2. Early warning about possible concerns in the near future
3. Control of present concerns
4. Control of imminent hazards

If a maximum value is on the way of being established within one of these categories as a legal limit value (LV), its concrete setting as such should have brought together:

- the *scientific information* contained in that maximum value (background, warning about concern, threshold of concern, threshold of imminent hazard)with

- the corresponding *political-regulatory interpretation* and need of surveillance (precaution, early indication of possible concern, control of concern, control of hazard).

Any scientific and politically interpreted (or misinterpreted) maximum value is open to becoming judicially binding in the form of a legal limit value (LV).

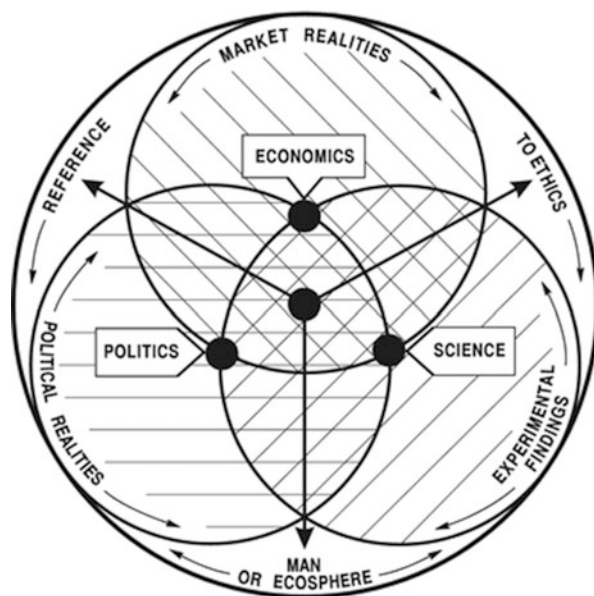

## Spheres of Interest When Setting Legal Limit Values

Only those maximal and minimal levels referring to societal acceptance of quality and quantity should be fixed as LVs. Such acceptance is only reached by relying on a transparent and knowledge-based societal process on how to decide which chemical or parameter must be regulated and what the subject (precaution/repair, intended/unintended, voluntary/involuntary exposure) of its regulation should be.

The central field of tension of Fig. 1 is the location of dispute and argument between:

- Political experts (e.g., members of parliament), representing the public interest for avoiding any load above socially (legally) an accepted  $T = \textit{tolerance threshold}$ .
- Scientific experts, representing the interest of science to specify *concern about adverse-effect thresholds* =  $E_a$  (or corresponding risks) only if supported by correspondingly sufficient database(s). In human toxicology, as a rule, the  $E_a$  represents defined fraction of an ADI or TDI value (see section “[Threshold of Concern for Adverse Effects,  \$E\_a\$](#) ”).

**Fig. 1** Common and separated spheres of interest (overlapping areas of circles) represented by politics, the private sector, and science regarding protection of humans (health and environment) and/or ecosphere (protection of nature and its diversity). The success of consensual societal setting of LVs is possible only in the central field of tension between experimental realities (scientific considerations), market realities (beneficial and economic considerations), and political realities (consideration of democratic minorities and majorities) (Dieter et al. 1997)

- Experts from the private sector, representing the latter's interest for public acceptance of private benefit at technically consensual or optimized *functional thresholds* =  $F$ .

This complex situation was summarized by the European Environment Agency (2002): “Compartmentalised science, no matter how erudite, is an insufficient base for knowing enough to anticipate or mitigate the impacts of such systems: integrated and synthesised knowledge, which pools the wisdom from many natural and social sciences, is a necessary condition for being *Homo sapiens*.”

Therefore, within the dynamics of expert panels, often only lower than purely *scientifically based and effect-related thresholds of concern* are open for societal consent or acceptance in form of a LV. Such “lower” limit values then serve (not only) to protect human health but also to reach more ambiguous technical, aesthetic, or even non-anthropocentric protection goals (Dieter 2017).

An optimal agreement in favor of an as-low-as-possible load on humans and the environment would correspond with the actual level of technical-scientific knowledge (LK) to avoid useless exposure or loads as a precaution. Less ambiguous limit values would reflect the state of technology (StT) or at least the generally accepted rules of technology (gaRT). Any LV should be set referring to three-dimensional rule of environmental hygiene (REH) as explained in the following.

---

## Rule of Environmental Hygiene (REH)

- *Minimize useless load/exposure*. Its upper limit is *tolerated* up to  $T$  = tolerance threshold.
- *Optimize functional load/exposure*. The minimal level to guarantee intended function be  $F$  = functional threshold.  $F$  is *accepted* if set according to LK; any higher  $F$  (StT, gaRT) is *tolerated* only.
- *Prevent harmful load/exposure*. Its upper limit is  $E_a$  = threshold of concern about adverse effects (adverse-effect threshold).

Observance of the REH not only helps to define precautionary limit values below any  $E_a$ , thus promising not only minimal necessary or even zero exposure, but also provides a perspective on a holistic social management of environmental noxa to enable “acceptable” societal consents to protect society as well from harmful social consequences.

---

## REH-Based Criteria for Evaluating Exposure from Chemical Loads

### Framework or Conditions of Social Evaluation: Prevention, Optimization/Acceptance, and Minimization/Tolerance of Exposure

The regulatory framework to apply the REH and its evaluation criteria are:

1. The (social or technical) avoidability

2. The (technical or beneficial) functionality
3. The (ecological, technical, aesthetic, or health-related) concern over adverse effects as (potentially) caused by the environmental load under question.

This framework must be delimited early on, before the factual risk assessment process.

Loads, if avoided, put aside the necessity to assess their risks. The first step before any balancing of social, beneficiary, or scientific interests when quantifying a limit value would be, at best, a decision on whether the load or exposure under question seems avoidable or not. Avoidable loads are rejected; unavoidable ones are either accepted or (temporarily) tolerated.

The decision on the tolerability of a useless load or the acceptance of a functional load should never be dramatized or trivialized by science nor be forced or prevented by economy. Each decision should follow a political rationale and be publicly defensible by referring to proven facts, functionalities, and identified opinions of majorities and minorities.

*Scientists and technologists*, for example, provide input to politicians with analytical data on natural background loads, on technical or other options for avoiding exposure, or on the slope and shape of a dose/response relation.

*Sociologists or psychologists*, on the other hand, have to determine what is the best way in a democratic society to make informed decisions that then may possibly be recognized and followed by as many (but rarely all) members of society as possible. From this societal view, that is to say, not so much the potential harmfulness of a load but much more its origin and concurrent avoidability at the point of exposure give reason for conflict, although the clashing parties often prefer to look desperately for (mostly arguable) scientific arguments to favor their specific view(s).

## **Holistic Concept for Evaluating Chemical Loads or Exposure in a Triangle of Precautionary Prevention, Rejection, and Acceptance/Tolerance**

The point of origin or source of any anthropogenic load is always bound to a functional value or intention “on-site” in close proximity of its source. The same load, after its environmental transport to a point “off-site” or distant from the source, will have lost its functional aspect there, seeming dispensable at its place of detection. In contrast, this observation does not apply on unavoidable geogenic and/or biogenic loads, independent of any functional value or intentional context.<sup>1</sup>

This *first step* of evaluating or identifying a load’s origin opens the option to principally reject any dispensable anthropogenic load but to principally accept or at least tolerate any geogenic/biogenic load.

However, in a *next step*, it is necessary to ask immediately for or define the possible net functional value of any load from an anthropogenic origin since, from case to case, albeit principally avoidable, such load may have been already accepted on-site at an optimized = hopefully minimized yet fully functional level.

Neither of these two decision steps is formally regulated at the societal level. Instead, the corresponding decisions on which potentially dangerous load may appear as avoidable and which one as functional as a rule are arbitrarily forced by economy and are underlined later by science, although consensual answers on which load might be “avoidable” very often could be found much easier than (often speculative) scientific answers on concerns over the adversity of a load or exposure which could or should have been avoided. Such scientific decisions are sought (but not always found) in a *third step*, called risk assessment.

This step, although often done too late (EEA 2002), is well established at the societal level. It describes and quantifies the harm (lessness) of two classes of compounds:

- *Class C of anthropogenic compounds*: These are found in “off-site” compartments, mostly environmental and distant from their primary functional use. They are therefore called *environmental contaminants*, minimized down to what are hoped are precautionary level(s) by LK or ALARA, respectively, of emission control and treatment/elimination. Examples of class C compounds are plant protection products if present in *drinking water*, HAMR if present in *surface water*, or industrial chemicals if present in *waste water*.
- *Class B of anthropogenic compounds*: These are found in “on-site” compartments, mostly technical, being close to their primary functional/intentional use. They comprise *workplace agents and additives, including their residues and side products*, hopefully minimized to a still fully functional level  $F_B > 0$  by LK of functional optimization or (in case of side products) respecting such level. Examples of class B compounds are additives to conserve *food* and chlorine to disinfect *drinking water*, including unavoidable side products from disinfection or conservation/storage.

In both classes, load or exposure are bound to *never exceed an adverse effect threshold*  $E_a = \text{threshold of (health-related) concern}$  or to exceed an *accepted risk*, respectively. Exposure is neither allowed to damage the goal of protection nor to violate it at any possible lower level, the only exemption being a situation where a hopefully extremely high, mostly individual functional exposure is deemed to outweigh any corresponding health or functional damage or annoyance.

Close to the concrete place of their functional use and depending on the concrete binding force of exposure levels referring to LK, StT, or gaRT, respectively, *class B compounds* are tolerated by society at different minimized limits of tolerance, called *tolerance thresholds*  $= T_B \geq F_B > 0$ . The lowest yet still technically feasible  $T_B = F_B > 0$  does conform with LK and would be *accepted* as functional by society instead of being tolerated only as would be the case if  $T_B > F_B$ . In any case, on this second step (see above) of the societal decision process, regulators or managers would have to allow for implementing the same or a similar functional idea only if not linked with any “unacceptable” exposure  $T_B > 0$ .

*Class C compounds*, despite being often structurally identical or closely related to those that are also found in class B, by definition are ascribed or linked only to places

and compartments where they are devoid of any functional value ( $F_C = 0$ ). This is the reason why they never can be *accepted* there. At best, according to the binding force of levels to be defined by LK, StT, or gaRT, they may or may not even be *tolerated* at minimized limits *called tolerance thresholds*  $T_C > 0$  or even  $T_C = 0$  at/in such places and compartments.

A third class of compounds that should be clearly differentiated by management criteria from classes B and C with regard to their avoidability in a given raw material or resource are geogenic/biogenic loads or exposure. They are encompassed in the following as:

- *Class A compounds*, comprising natural constituents and their technically unavoidable transformation products.

Natural constituents, if identified or proven as potentially harmful and present at levels  $> E_a$ , are reduced by treatment down to a (technical) *tolerance threshold*  $T_A < E_a$ . The numerical value of  $T_A$ , however, depends strongly on societal readiness to pay either for applying LK, StT, or simply gaRT. Examples are the elimination of inorganic arsenic from drinking water to levels far below its  $E_a = 10 \mu\text{g/l}$ , measures to avoid, by appropriate storage and preparation of food, the formation there of analytically detectable levels of aflatoxins, nitrosamines, or acrylamide, or the minimization of natural radioactivity, especially radon, in buildings by technical or structurally engineered measures. The *functional threshold*  $F_A = \text{threshold of usability}$  of such resource or space is reached at the latest if  $T_A = E_a = F_A$ ; values of  $F_A > E_a$  are then rejected together with the corresponding resource.

The definitions material to understanding the process of defining and quantifying precautionary limit values are assembled in Table 1.

## **Concrete Evaluation of Annoyances, Loads, and Risks Within the Triangle of Prevention, Rejection, and Tolerance/Acceptance**

The numerical amount for the adverse effect threshold  $E_a = \text{threshold of concern}$ , in contrast to numerical amounts of the different categories of F and T, should, in principle, be based on strictly scientific data. This is why  $E_a$ , if either the societal tolerance of a load or exposure or the acceptance of its functional value would cease to exist, never shifts downwards nor upwards, whereas such shifting of  $E_a$  could happen by its own when reevaluating either the protection goal's sensitivity or the underlying database.

It is to be noted here that individual perception and evaluation of any "objective" risk, be this a merely supposed or an actually measured one, varies strongly with the absence or presence of a personal benefit from the same exposure and its subjective evaluation. Any *subjectively* "correct" genic  $E_a$  would vary accordingly, more so in cases where its scientific database appears vulnerable for being denounced as not sufficient. Therefore, if a load needs to be evaluated on an insufficient or "patchy"

**Table 1** Decisive maximal (max) and minimal (min) concentrations or doses of chemicals to be considered when setting precautionary limit values

Designation of maximal or minimal value	Symbol	Differentiation according to class of origin A, B, or C (see text)			Definition
		A	B	C	
<b>Threshold (max or min) to functionality</b>	<b>F</b>		$F_B$		Anthropogenic <i>on-site</i> concentration $F_B > 0$ of a functional chemical or its technically unavoidable residues in a final product
				$F_C$	Anthropogenic <i>remote</i> concentration $F_C \geq 0$ of a contaminant C or its metabolites in a final product (a) <b>Max:</b> <i>above</i> which a corresponding B compound could not be allowed for use <i>on-site</i> even when applying there StT (b) <b>Min:</b> <i>below</i> which a corresponding B compound would be excluded for use <i>on-site</i> even when applying there StT, the lowest desirable $F_C$ being 0
<b>Threshold (max) to non-usability</b>		$F_A$			Geogenic concentration of a natural constituent A <i>above</i> which a resource would not be usable prior to treatment since $BG_A > Ea$
<b>Threshold (max) to non-tolerability</b>	<b>T</b>				Tolerated and/or accepted
		$T_A$			<i>Supraregional</i> geogenic background concentration of a natural constituent ( $T_A \geq BG_A > 0$ ) <sup>a</sup>
			$T_B$		anthropogenic <i>on-site</i> ( $T_B \geq F_B > 0$ ) concentration of a functional chemical or residue from it
				$T_C$	anthropogenic <i>off-site</i> ( $T_C > F_C \geq 0$ ) concentration of a functional chemical or its metabolites/transformation products if presenting, e.g., at the same time as a contaminant of drinking water
<b>Threshold (max) for concern about adverse effects<sup>b</sup></b>	<b>Ea</b>	No differentiation between classes of origin A, B, and C			Concentration or dose threshold above which the usability of a chemical B or of a natural resource containing a constituent A or a contaminant C would give reason for concern about adverse effects within the respective protection goal <sup>b</sup>

<sup>a</sup> $BG_A$  represents a background concentration below  $T_A$  in any *regional* resource under specific consideration. In order to become usable, such regional resource would need elimination of a class A compound down to  $\leq Ea$  only if  $BG_A > T_{A1}$  with  $T_{A1} = Ea$ . As long as treatment down to at least  $T_{A2} = Ea$  would not seem possible or affordable, respectively, such resource remains not usable

<sup>b</sup>This chapter deals preferentially with potentials of adversity by threshold of effect as quantified by human toxicology. There exist, however, other thresholds whose exceedance could result in technical or aesthetic (color, odor, taste, purity) adversity or impairments/discomfort/annoyances

database, the only consensual way to proceed is to look for a level of  $E_a$  being not higher (albeit possibly lower) than a level seeming eventually quantifiable later on a then-sufficient database.

In most cases, exposure to class B compounds results in relatively high levels that are similar to exposure to class A compounds. In the absence of legal requirements to evaluate class A compounds, their toxicological database as a consequence, similar to class C, is often incomplete. Possible A risks are correspondingly often difficult to quantify but accepted more easily than B and C risks inasmuch as they appear more difficult to avoid than the latter.

Moreover, surveillance of compliance of LVs for A compounds is not necessary at the same (and high) frequency as advisable for B compounds. If the raw material or resource has been selected properly, concentrations of A compounds can be supposed to be constant, whereas concentrations of B compounds in a final product may easily be subject to technical change and failure. Finally, surveillance of C compounds should preferably be performed at the point of their environmental input and be eliminated there and not “end of pipe” having reached there a critical raw material or resource.

In any case,  $E_a$  turns out to be the only but at the same time also the maximal point of reference (health-related guide value, HRGV) to be considered when looking for a decision about which numerical amount of the different lower and much lower  $F_A$ ,  $T_A$ ,  $F_B$ ,  $T_B$ ,  $F_C$ , or  $T_C$  might appear as acceptable or tolerable to be set and surveyed in whichever frequency as a legal limit value. The numerical amount of  $E_a$  is the only merely scientific one of all these levels. It depends neither on an exposure's or loads' anthropogenic or geogenic/biogenic origin nor on whether such load or exposure may be functionally accepted or just tolerated as nonfunctional but (temporarily) unavoidable.

---

## Definition of Precautionary Limit Values According to Origin A–C of Compounds

### Class A, Geogenic/Biogenic: Natural Constituents Without (A1) or After Treatment (A2) of the Resource

Group A compounds or “constituents,” according to their natural (perceived or analyzed) background concentration  $BG_A$ , the defensible effort for treatment, and the technical or health-related benefit resulting from such effort, are either eliminated from a natural resource or tolerated and even accepted, respectively.<sup>2</sup>

By using the respective conceptual definitions from Table 1, two relations are obtained to define precautionary limit values (LV) for class A compounds in a natural raw material or resource: one relation A1 for geogenic/biogenic compounds in resources without treatment and a second one (A2) after their treatment to eliminate class A compounds.

*Definition of precautionary limit values  $LV_{A1}$  for class A1 compounds = constituents without treatment:*

$$0 < BG_{A1} \leq F_{A1} = T_{A1} \equiv LV_{A1} = Ea$$

The sign “ $\equiv$ ” in this relation denominates the conceptual and numerical identity of  $T_{A1}$  from remark a) under Table 1 with the compound’s legally tolerated (politically set) and mainly *natural background/health-related* limit value  $LV_{A1} = Ea$  in the untreated final product. The compliance of the compound’s natural concentration  $T_{A1}$  in the final product with  $LV_{A1}$  indicates social acceptance ( $T_{A1} = BG_{A1}$ ) or at least tolerance ( $T_{A1} = F_{A1}$ ) for utilization of natural raw material or resource, even if not treated to eliminate the critical compound.

The maximum admissible load, that is to say, the *highest possible limit value*  $LV_{A1}$  for accepting the exploitation of a natural resource without treatment, is reached if  $T_{A1} = F_{A1} = LV_{A1} = Ea$ .

On the other hand, by scaling the environmental quality of the  $LV_{A1}$  using the criteria offered by the REH, the decisive maximal concentration to be consensually chosen for  $LV_{A1}$  from this relation is the lowest possible concentration placed left from the sign “ $\equiv$ .” Therefore, only if  $LV_{A1} = BG_{A1}$ , may the former be denominated the *lowest possible precautionary limit value*  $LV_{A1}$  to limit legally the compound’s concentration in the untreated resource on its natural 50-, 90-, or any other percentile of background level (percentiles to be calculated by science and set by politics).

If weighting the relations “ $<$ ” and “ $\leq$ ” and “ $=$ ” left from any LV by 2 or 1 or zero points, respectively,<sup>3</sup> the weighting sum  $WS_{A1}$  takes a fraction of 3/3. This 100% *WS fraction*, if evaluating class A1 compounds according to the REH, as a rule anticipates numerical identity with  $Ea$  of a REH-compatible *precautionary*  $LV_{A1}$ .

*Definition of precautionary limit values  $LV_{A2}$  for class A2 compounds = constituents after treatment:*

$$0 \leq F_{A2} = T_{A2} \equiv LV_{A2} \leq Ea < BG_{A2}$$

The sign “ $\equiv$ ” in this relation denominates the conceptual and numerical identity of  $T_{A2}$  from remark a) under Table 1 with the compounds legally tolerated (politically set) and mainly *technical/treatment-related* limit value  $LV_{A2} \leq Ea$  in the treated final product. The compliance of the compound’s concentration  $T_{A2}$  after treatment in the final product with  $LV_{A2}$  indicates social acceptance ( $T_{A2} = 0$ ) or at least tolerance ( $T_{A2} = F_{A2}$ ) for the latter’s utilization only if treated to eliminate the critical compound down to  $T_{A2}$  or lower.

The maximum admissible load, that is to say, the *highest possible limit value*  $LV_{A2}$  for accepting the exploitation of a treated natural resource, is  $T_{A2} = F_{A2} = LV_{A2} \leq Ea$ . On the other hand, by scaling the environmental quality of the  $LV_{A2}$  using the criteria offered by the REH, the decisive maximal concentration to be consensually chosen for  $LV_{A2}$  from this relation is the lowest

possible concentration placed left from the sign “ $\equiv$ .” Therefore, only if  $LV_{A2} = 0$ , may the former be denominated the *lowest possible precautionary limit value*  $LV_{A2}$  to limit legally the compound’s concentration in the treated resource, the technically lowest possible value of  $T_{A2}$  being a function of whether the raw material or resource was treated according to *accepted* LK or *tolerated* StT and gART, respectively.

The *rule of weighting* (see with definition A1) results in a  $WS_{A2}$  – fraction of  $1/4 = 25\%$ . This *very low fraction of WS*, if evaluating A2 compounds by applying the REH and LK for their technical elimination, anticipates only a rare numerical identity with  $E_a$  of a REH-compatible *precautionary*  $LV_{A2}$ .

## **Class B, Anthropogenic: Additives and Their Technically Unavoidable Residues and Side or Transformation Products**

Class B compounds or “residues” deliver or delivered in their intentional and mostly technical target compartments either an *accepted* function or the presence of their transformation products, there is linked with such function in a technically unavoidable manner.

By using the respective conceptual definitions from Table 1, the following relation to define precautionary limit values  $LV_B$  for class B compounds = **residues** in their functional technical target compartments is obtained:

$$0 < F_B \leq T_B \equiv LV_B \leq E_a$$

The sign “ $\equiv$ ” in this relation denominates the conceptual and numerical identity of  $T_B$  from Table 1 with the compound’s legally tolerated (politically set) and mainly *technical = function-related* limit value  $LV_B \leq E_a$  in the final product or technical compartment. The compliance of the compound’s concentration  $T_B$  with its  $LV_B \leq E_a$  in the final product or technical compartment implies social *tolerance* for the compound’s functional use if  $T_B > F_B$  and *acceptance* if  $T_B = F_B$ .

The maximum admissible load, that is to say, the *highest possible limit value*  $T_B = LV_B \leq E_a$  for tolerating the functional value of a class B additive/residue/side product, is reached if  $T_B = E_a$ . On the other hand, by scaling the environmental quality of the  $LV_B$  using the criteria offered by the REH, the decisive maximal concentration to be consensually chosen for  $LV_B$  from this relation is the lowest possible concentration placed left of the sign “ $\equiv$ ”; hence,  $F_B = T_B \leq LV_B \leq E_a$ . The  $F_B$  below which the compound’s *accepted* function would no longer be realizable corresponds to LK. An  $LV_B = F_B$  is the *lowest possible precautionary limit value* to limit a B compound’s concentration in the final product. Values between  $F_B$  and  $E_a$  are called  $T_B$  and *tolerated* in case of applying only StT or gART.

Applying the *rule of weighting* (see with definition A1) results in a  $WS_B$  – fraction of  $3/4 = 75\%$ . This *high WS fraction*, if evaluating class B compounds by applying the REH and LK for their functional use on-site, anticipates a frequent numerical identity (between  $F_B$  and  $T_B$ ) with  $E_a$  of a REH-compatible *precautionary*  $LV_B$ .

## Class C, Anthropogenic: Environmental Contaminants and Their Transformation Products

Group C compounds or environmental “contaminants” and their transformation products deliver in their mostly environmental yet unintentional target compartments neither an *accepted* function nor is their presence linked there directly with such function.

By using the respective conceptual definitions from Table 1, the following relation to define precautionary limit values  $LV_C$  for class C compounds = environmental *contaminants* is obtained:

$$0 = F_C \leq T_C \equiv LV_C \leq E_a$$

The sign “ $\equiv$ ” in this relation denominates the conceptual and numerical identity of  $T_C$  from Table 1 with the compound’s legally tolerated (politically set) limit value  $LV_C \leq E_a$ . The compliance of the compound’s concentration  $T_C$  with its  $LV_C \leq E_a$  in the environmental yet unintentional target compartment implies only social *tolerance* for the compound’s presence there ( $T_C > F_C = 0$ ) and *acceptance* only for its absence ( $T_C = F_C = 0$ ).

The maximum admissible load, that is to say, the *highest possible limit value*  $T_C = LV_C \leq E_a$  for tolerating the presence of a class C compound in a “remote” environmental compartment, is reached if  $T_C = E_a$ . On the other hand, by scaling the environmental quality of the  $LV_C$  using the criteria offered by the REH, the decisive “off-site” maximal concentration to be consensually chosen for  $LV_C$  from this relation is the lowest possible concentration placed left of the sign “ $\equiv$ ”; hence,  $F_C = 0 = LV_C \leq E_a$ . If, with a  $LV_C = 0$  in a remote compartment, the compound’s *accepted* on-site function would no longer be realizable even by using LK, any values of  $T_C$  between  $F_C$  and  $E_a$  may be *accepted* as precautionary limit values if applying on-site LK, but would be *tolerated* only if StT or gaRT would be applied on-site.

Applying the *rule of weighting* (see with definition A1) results in a  $WS_C$  – fraction of  $1/3 = 33\%$ . This *low WS fraction*, if evaluating class C compounds by applying the REH and LK for their functional use on-site as B compounds, anticipates only an occasional numerical identity with  $E_a$  of an REH-compatible *precautionary*  $LV_C$ .

## Setting and Evaluation of Legal Limit Values by Means of the REH

### Drinking Water Limit Values from the EU as an Example

Using drinking water as an example, Table 2 demonstrates how to become informed on whether or not a legal limit value was set and quantified directly as a precautionary value by using the REH-based relations above. The legal limit values in column 4 represent a society's eventual expression of tolerance or acceptance ( $LV \equiv T$ , column 4) of exposure (column 1). These  $LV \equiv T$  are compared respectively and in accordance with the compounds' class of origin, with their  $E_a$  in column 5 and the author's proposal for their numerical  $F_B$  or their  $F_C$  in column 6. Two partial evaluations in columns 5a and 6a of the LV in column 4 are obtained, their absolute amount depending on whether the LV under evaluation is (much) larger, similar, or (much) smaller than the respective compound's value of  $E_a$  and of  $F_B$  or  $F_C$ . Each sign ">" ("<<") counts for 2 negative (positive) weighting points, each " $\geq$ " (" $\leq$ ") for 1 negative (positive) point, and " $=$ " counts for  $\pm 0$ . The net  $WS =$  weighting sum of all partial evaluations in column 7 eventually gives the information on whether the LV under question is a precautionary limit value ( $WS > 0$ ) or whether it stands merely for nothing better than simply to defend the integrity of human health or of a technical device ( $WS < 0$ ).

The method presented here to evaluate, from the aspect of environmental hygiene, legal limit values for any environmental or technical medium could easily also be applied at the beginning of any societal discourse between science, politics, and the private sector to define in advance the precautionary character of limit values to be sought by societal consent.

### Categorization of Legal LVs in Terms of General Precaution, Early Warning, Control of Concern, or Control of Imminent Hazard

The expression *limit value* ( $LV$ ) should only be used to denominate legally binding maximum values/concentrations. Legal LVs for a specific compound exhibit a strong numerical variance in correspondence with the underlying societal consensus about which goal of protection should be considered and to what extent it should be eventually protected as early as possible.

With increasing numerical ratio (hazard index) between an actual LV and an  $E_a$  value of the same compound, the setting and observation of the former departs step by step from the (1) precautionary principle over (2) early warning to enable (3) control of concern and, eventually, (4) control of imminent hazard (see section "[Criteria to Limit Exposure](#)").

This means that risk management, in case a LV would be exceeded, should be organized in accordance with the motivation underlying this LV to safeguard the goal of protection when allowing for overexposure during the LV's exceedance.

**Table 2** Examples of REH-based evaluation (col. 7) of parametric values = limit values LV (col. 4) from EU “Drinking-Water” Directive 98/83/EEC. For details, see definition A, A1, B, and C of LVs in the text and remarks at end of table. Numbers for T- and F-values as proposed by author

Evaluation →	Evaluation of LV ≡ T from column 4							Column 7	
	Column 2 highest allowable threshold = Ea (here: health- related guide value <sup>a</sup> ) for drinking- water)	Column 3 lowest possible threshold F according to LK and class of compounds <i>Dimension:</i> <i>col. 1</i> $F_{A2}^b = Ea = 10$	Column 4 tolerance threshold T as given by EU- Directive in form of $LV \equiv T$ <i>Dimension:</i> <i>col. 1</i> $T \equiv LV = 10^e$	Column 5 comparison of Ea (col. 2) with LV (col. 4) $Ea \equiv T \rightarrow$	Column 5a +bonus/- malus for LV in col. 4 by comparison with T in col. 5 $\pm 0$	Column 6a +bonus/- malus for LV in col. 4 by comparison with F in col. 6 $\pm 0$	Column 6 comparison of F (col. 3) with LV (col.4) $\leftarrow F = T$	Column 7 Bonus <i>plus</i> Malus from summing col.s 5a and 6a $\pm 0$	corresponding qualitative evaluation of the LV in col. 4 LV ✓/?
↓ Compound (class of origin)									
Arsenic (A2)	10 µg/l		$T \equiv LV = 10^e$	$Ea \equiv T \rightarrow$	$\pm 0$	$\pm 0$	$\leftarrow F = T$	$\pm 0$	LV ✓?
Lead (B)	10 µg/l	$F_B = 40$	$T \equiv LV = 40^d$	$Ea << T \rightarrow$	-2	$\pm 0$	$\leftarrow F = T$	-2	LV ↓, ↓ <sup>d</sup>
Bromate (B)	0.3 µg/l	$F_B = 10$	$T \equiv LV = 10$	$Ea < T \rightarrow$	-2	$\pm 0$	$\leftarrow F = T$	-2	LV ↓ ↓!
Cadmium (A1)	3 µg/l	$F_{A1}^b = Ea = 3$	$T \equiv LV = 5^a$	$Ea < T \rightarrow$	-1	-1	$\leftarrow F < T$	-2	LV ↓ ↓! <sup>a</sup>
Cyanide (A1)	50 µg/l	$F_{A1} = BG_{A1}^c < Ea$	$T \equiv LV = 50$	$Ea = T \rightarrow$	$\pm 0$	-1	$\leftarrow F < T$	-1	LV ↓!
1,2-Dichloro- ethane (C)	3 µg/l	$F_C = 0.00$	$T \equiv LV = 3$	$Ea = T \rightarrow$	$\pm 0$	-1	$\leftarrow F < T$	-1	LV ↓!
Fluoride (A1)	1.5 mg/l	$F_{A1}^b = Ea = 1.5$	$T \equiv LV = Ea$	$Ea = T \rightarrow$	$\pm 0$	$\pm 0$	$\leftarrow F < T$	$\pm 0$	LV ✓?
Copper (B)	2 mg/l	$F_B = 2$	$T \equiv LV = 2$	$Ea = T \rightarrow$	$\pm 0$	$\pm 0$	$\leftarrow F = T$	$\pm 0$	LV ✓?
Chlorinated solvents (C)	20 ← → 100 µg/l	$F_C = 0.00$	$T \equiv LV = 10.0$	$Ea > T \rightarrow$	+1	-1	$\leftarrow F < T$	+0	LV ✓?

<b>Manganese</b> (Mn <sup>2+</sup> ) (A2)	1.0 mg/l (E) 0.2 mg/l (Ea)	$F_{A2} = E_a^f = 0.05$	$T \equiv LV = 0.05^c$	$E_a = T \rightarrow$	$\pm 0$	$\leftarrow F = T$	$\pm 0$	LV✓?
<b>Nitrate</b> (C)	50 mg/l	$F_C = 20$	$T \equiv LV = 50$	$E_a = T \rightarrow$	$\pm 0$	$\leftarrow F < T$	-1	LV ↓ <sup>g</sup>
<b>PAH</b> (A1; B) <sup>h</sup>	$\geq 0.1 \mu\text{g/l}$	$F_{A1} = 0.1^e \leq E_a$	$T \equiv LV = 0.10$	$E_a \geq T \rightarrow$	$+0.5$	$\leftarrow F = T$	$\pm 0$	LV✓!
<b>Pesticides</b> (C)	$1 \leftarrow \rightarrow 1,000 \mu\text{g/l}$	$F_C = 0.00$	$T \equiv LV = 0.10$	$E_a >> T \rightarrow$	$+2$	$\leftarrow F < T$	-1	LV✓!
<b>THMs</b> (B)	60–200 $\mu\text{g/l}$	$F_B = 10^i$	$T \equiv LV = 10^j$	$E_a > T \rightarrow$	$+1$	$\leftarrow F = T$	$\pm 0$	LV✓!

✓! means: **Bonus + Malus** > 0. The actual LV  $\equiv$  T for these compounds may be evaluated without any restriction as a precautionary maximal value far below any  $E_a$

! means: **Bonus + Malus** < 0. The actual LV  $\equiv$  T for these compounds is not a precautionary maximal value. It is even too high (↓↓!) if interpreted as adverse effect-related LV (its lowering seems necessary)

✓? means: **Bonus + Malus** = 0. LV  $\equiv$  T for these compounds may yet be interpreted as a precautionary maximal value but also to be adverse effect related. Its compliance therefore needs regular short-time interval surveillance

<sup>a</sup>From WHO (2017), LV  $\equiv$  T for cadmium should be lowered for health reasons to  $E_a = 3 \mu\text{g/l}$  (health-related guide value of WHO 2017)

<sup>b</sup>Threshold to usability of a raw water if not treated accordingly to eliminate potentially harmful geogenic/biogenic constituents.

<sup>c</sup>After treatment

<sup>d</sup>EU-LV since November 1998 (with moratorium): 10  $\mu\text{g/l}$ , to be met only after exchange of lead pipes by pipes made from better adapted materials

<sup>e</sup>Upper limit of geogenic load (cyanide) or of geogenic background (PAH) plus unavoidable load from using old coal tar-coated pipes (numbers estimated by author)

<sup>f</sup>Threshold to technical adversity

<sup>g</sup>The LV for nitrate is the only one (!) for an environmental contaminant C in drinking water with an exclusively health-related rationale

<sup>h</sup>Sum of four polycyclic aromatic hydrocarbons (PAH, without benzo[a]pyrene) originating from old coal tar-coated pipes and/or geogenic/biogenic background

<sup>i</sup>To be complied with at outlet of waterworks

### General Precautionary Maximal Values, $PV_g$

*General precautionary maximal values* are the numerically lowest of all possible LVs. They help to avoid from the start loads and annoyances, not just when looking at specific protection aims but rather in general for present and future generations. For compounds of classes A1 and C, such PVs ideally ask for not exceeding a compound's natural (regional?) background concentration. For class C compounds, this condition mostly would mean a (analytical) level "zero," realizable at best by LK or ALARA, whereas precautionary LVs for class B or A2 compounds, as a rule, are to be found between classes C and A1 since they are situated close to or are identical with the lowest level of technical feasibility (of treatment or function, respectively).

The best rationale of a broadly accepted PV would be an equal balance between scientific quantification, technical/functional benefit, and political acceptance/tolerance of any corresponding risk or load. Their scientific part, as a rule, is confined to quantifying natural background concentrations or high-quality analytical criteria to allow for reliable detection or definition, now and in future, of any deviation of load/exposure from a legally accepted (e.g., "background")  $PV_g$ .

Only a few of the LVs in Table 2 for A1 and C compounds or A2 and B compounds, respectively, are close to their ideal (optimal precautionary) maximal contaminant level as described by this condition.

Sustainable repair of a precautionary LV's exceedance to achieve legal recompliance normally is not adequately feasible by means of short-time measures to protect persons or technical devices from immediate hazards or risks. Instead, such sustainable repair ought to be considered on a medium to long-term time scale by using the scope of sustainable action, as it should be part of any precautionary LV concept. For the time of repair, so-called health-related "maximal action values" may be functional to rationalize and avoid risks from possible but temporarily limited exposure  $> LV$ .

Within the framework of this discussion, general PVs are conceptually and numerically identical, respectively, with  $F_C$ ,  $F_B$ , or  $BG_{A1}$ .

### Warning Values, $WV$

The next higher and, from a scientific point of view, sounder category of maximum values is the category of *warning values*,  $WVs$ . Their exceedance should indicate as early as possible, on the basis of scientific data, that the normal state of a system or organism could be undergoing a switch to instability or non-normality. The database of a  $WV$  is more informative than that of a general precautionary value; therefore,  $WVs$  are also called specific (health related, technical, sensorial/aesthetic) precautionary values. As such, they do not need to be "LK," but should at the same time never be higher than any science-based threshold of concern as possibly derived later on a sufficient database to replace such warning value.

Within the context of this discussion,  $WVs$  are conceptually and numerically identical, respectively, with any  $T_C$ ,  $T_B$ , or  $T_{A1}$ . For the special case of human toxicology, such  $WVs$  have been denominated in Germany as  $GOW = \text{Gesundheitlicher Orientierungswert}$  (in English,  $HRIV = \text{health-related indication value}$ ). The scientific basis of this pragmatic regulatory approach was outlined by Dieter (2014).

### Threshold of Concern for Adverse Effects, Ea

The exceedance of a scientifically based *threshold of concern for adverse effects*, Ea, would not just warn about a possible health concern for adverse effects in the future but should also directly trigger such concern. Toxicologists derive an Ea in a way that the selected protection goal is unlikely to be harmed as long as the measured load/exposure is in compliance with the same compounds' Ea.

In human toxicology, an Ea, as a rule, is derived from an ADI or TDI value by allocating a certain percentage from the latter to the amount in kilograms or liters of daily personal consumption (e.g., 2 l of drinking water or 1 kg of food). In the case of drinking water, such aliquot concentration normally represents 10% of an ADI or TDI and is usually called a compound's health-related guide value, HRGV, for drinking water (in German LW = *gesundheitlicher Leitwert*).

### Hazard-Linked Action Values, AV

Scientifically based maximum values whose exceedance in a standard scenario would trigger with sufficient probability an imminent hazard from toxic exposure are called *hazard-linked action values*, AV. They are higher by a compound-specific "interpolation factor" (IF) than the scientific Ea of the same compound.

In Germany, as a rule, AVs are calculated as being threefold to tenfold higher than a corresponding Ea. On a quasi logarithmic scale, the interpolation into the margin of safety, which is the space of adverse effect extrapolation from experimental conditions on humans, places the AV halfway between the selected PoD = point of departure of extrapolation and the protection goal's Ea (Dieter and Konietzka 1995; Konietzka and Dieter 1998; Dieter 2011).

---

## Summary: A Short Directory to Quantify and Survey Precautionary LVs

The REH helps to organize the following steps to fix socially consensual (tolerated or accepted) limit values and criteria for their surveillance:

- A: Geogenic/biogenic constituents (hardly avoidable):
  - A1: If no single threshold of concern Ea is exceeded in the raw material or resource, respectively, treatment to eliminate class A compounds would neither be necessary nor indicated. Any  $LV_{A1}$  to be chosen accordingly would appear as tolerable, if representing rather an "upper" percentile, or as acceptable, if representing rather a "lower" percentile of regional  $BG_{A1}$  levels. As a rule, any  $LV_{A1} \equiv BG_{A1}$  would need only a longtime interval surveillance to safeguard compliance.
  - A2: If one or more threshold(s) of concern Ea are exceeded in the raw material or resource, respectively, treatment(s) to eliminate class A compounds down to a technically tolerable (gaRT) or acceptable (StT or LK) level of

$LV_{A2} \equiv T_{A2} \leq Ea$  is indicated only if a resource to need no such treatment would not be readily (e.g., regionally) available.

As a rule, any  $LV_{A2} \equiv T_{A2}$  would need a short-time interval surveillance in the treated resource to safeguard compliance.

- B: Anthropogenic additives with intended function in specific compartments with their residues and unavoidable transformation products:

B compounds ought to exert their intended function as far as possible below their on-site threshold of concern  $Ea$ . Any  $LV_B$  to be chosen accordingly would appear as being tolerable at a level of  $LV_B \equiv T_B \leq Ea$  (gaRT) or as acceptable as a precautionary maximal value at a level of  $LV_B \equiv T_B = F_B < Ea$  (StT or LK). The societal readiness to *accept* any levels  $T_B > F_B$  below  $Ea$  increases with optimization of functional efficiency and increasing readiness to pay for them.

As a rule, any  $LV_B \equiv T_B$  would need a short-time interval surveillance in the finished product to safeguard compliance.

- C: Anthropogenic environmental contaminants and degradation products in remote places and compartments where they are devoid of intended function and potentially harmful:

C compounds may dissipate unintentionally from the on-site use of B compounds onto remote places or compartments of the environment (resources or raw materials). If there is no single or sum threshold of concern  $Ea$  exceeded, their treatment to eliminate class C compounds would neither be necessary nor indicated. An  $LV_C$  to be chosen accordingly would appear as tolerable at a level of  $LV_C \equiv T_C < Ea$  (gaRT) and as acceptable as a precautionary maximal value only at the level  $0 = F_C = T_C \equiv LV_C$  (StT or LK). The societal readiness to *tolerate* any remote levels  $T_C > F_C$  below  $Ea$  increases with optimization of functional compartmentalization of the use on-site of the respective class B compounds and increasing readiness to pay for.

As a rule, any  $LV_C \equiv T_C$  would ask for a longtime interval surveillance to safeguard compliance in any remote contaminated raw material or resource if this is done in alliance with the respective class B compound's short-time interval on-site surveillance of emission and degradation/dissipation.

---

## Conclusions

The three-dimensional *rule of environmental hygiene* (REH) as outlined here serves to ascertain in each individual case whether a limit value is, in fact, necessary to avert contamination and, if so, which component of the overall rationale determines or should determine where and at which level at which it should be fixed. This assessment has to take place by way of a rational public discourse befitting democratic forms of government, with the participation of all societal players (cf. AdW 1992; EEA 2002; Dieter 2017). Only such procedure opens the way to avoid exposure inequities, differences in acceptance, and uncertainty as to the conditions governing economic activities within society. Violators of limit values coming from such procedure rightfully face society's sanctions.

Limit values also serve to establish an overall social compatibility of exposure whose implementation is useful to one party, of no particular interest to another, and possibly detrimental to a third. This compatibility should best be cleared before questions of whether an adverse effect threshold is reached or exceeded can or must be answered by science in a reliable manner.

The three-dimensional concept to fix limit values outlined here is an instrument that may also be helpful in limiting “adverse effects” at the societal level by enabling different interest groups to communicate with each other in a civilized, organized, tolerant, and, hence, acceptable manner.

Those who permanently or temporarily withdraw from such rational, civilized discourse in order to push through, out of self-interest, highly specific protection goals aside from general acceptability deliberately act in an anti-democratic or a politically short-sighted manner and are in danger of losing their credibility.

On the other hand, it is only in rare cases that the temporary exceedance of a limit value directly results in an immediate hazard. Information on such “dangerous” values can be obtained from toxicologists and ecologists, who should have no reservations about divulging it. The overwhelming majority of limit values, however, have been found and fixed on the basis of criteria relating to the functional value of useful exposure and the avoidability of unnecessary exposure – at levels usually far below those based on the criterion of “imminent hazard.”

Thus, the often-heard slogan of “poisoning sanctioned by limit values” is quite out of place. All the more care must be taken to ensure that limit values are complied with and that remedial measures are performed where necessary, because carelessness spreads when there is no threat of impending or immediate danger.

Even farther off the mark is the common claim that the application of StT and gaRT (LK usually plays a role in pilot projects only) and the concomitant limit values would be a threat to the industrial base of high-tech nations and meaningful employment for millions of people. Many of the case studies in EEA (2002) suggest that wider use of the precautionary principle can help stimulate both innovation and science, replacing nineteenth-century technologies and the simple science of the first industrial revolution with the “eco-efficient” technologies and systems science of the third.

More important than the negotiation of and the compliance with limit values is, however, to never stop questioning the necessity and/or functional value of pollution-, resource- and exposure-intensive use concepts. It is the exposure that is avoided that is the most compatible with human health, its environments, and nature as a whole. Given this, the observance of the four categories of protection and the three-dimensional rule of environmental hygiene to find and fix goal-specific precautionary limit values are two efficient conceptual tools to sustain environmental hygiene and human health.

### **Signs and Abbreviations** ... ≡ ... “defined/fixed as” or “identical with”

*A* Class of biogenic/geogenic compounds

*ADI* See TDI

*B* Class of functional loads/exposure (compounds with intended function on-site)

- BG** (Natural) background load/exposure
- C** Class of nonfunctional loads/exposure (mostly environmental contaminants with no function where detected)
- Ea** Adverse-effect threshold
- F** Functional threshold = Threshold of optimized functionality (class B compounds; class C compounds)/threshold of usability (class A) compounds
- gaRT** Generally accepted rules of technology
- LK** Level of technical-scientific knowledge
- LV** Limit value (a maximum concentration fixed by law)
- PoD** Point of departure = Threshold (dose or concentration) of adverse effect chosen for being extrapolated on humans as part of toxicological evaluation of experimental or epidemiological data to derive an ADI or TDI
- REH** Three-dimensional rule of environmental hygiene
- StT** State of technology
- T** Tolerance threshold
- TDI** (ADI) Tolerable (acceptable) daily intake of a chemical, mostly given in mg/kg of body mass as considered safe for lifelong exposure
- WS** Weighting sum

## Notes

1. Culturally conserved or protected loads or exposure (e.g., from natural foodstuffs, certain habitualities of feeding, or from processing of food) occupies a complicated medium position and will not be discussed here.
2. The criteria for whether and how to perceive geogenic/biogenic loads as harmful or harmless refer not only to their scientific evaluation but also to value systems coming from society or cultural history.
3. This “rule of weighting” implies the condition that in this and the following relations, the total weighting sum WS of all signs left and right from the LV is set on 100%, respectively. The differential distribution of the signs left and right the

LV describes the range of expected numerical difference between the respective concentrations of exposure if regulated according to the REH.

## Abstract

Standards for the protection of human health are important tools used for risk management of chemical substances. They represent the limit value, the maximum level of exposure deemed acceptable or tolerable, under the particular exposure circumstances for which they are set. Usually, there is a formal assessment process by which the standard is set. From a toxicological point of view, limit values reflect a risk characterization for an available data base. Because assessments by individual scientists can differ, limits are usually based on a consensus. Although they must meet a scientific rationale, limit values also have to take into account political considerations, technical feasibility, and economic consequences.

**Introduction**

The setting of limit values has to be seen in the context of the general regulatory framework. According to the NAS/NRC (2009) (and IOMC/WHO (2010)) risk assessment/management paradigm, the risk characterization (the qualitative and, wherever possible, quantitative determination of the probability of the occurrence of known and potentially adverse effects of chemical substances under defined exposure condition) is the final stage of the risk assessment. The risk characterization is preceded by the steps hazard identification, hazard characterization, and exposure assessment. The development of alternative regulatory options and the weighing of their economic, social and political consequences are elements of risk evaluation (IOMC), which is the first stage of risk management. The US NAS/NRC report was concerned principally with risk assessment and the EPA does not break down risk management into the three components identified by IOMC, namely, risk evaluation, emission and exposure control, and risk monitoring.

A principle way to regulate harmful substances involves managing exposures in order to prevent their exceeding an exposure considered to represent the maximum acceptable/tolerable level of risk. For the regulator this includes setting and enforcing limit values. In this context, risk assessment and risk management are two related but independent processes. The risk assessment is based exclusively on scientific principles while risk management (and, in particular, the risk evaluation) has to balance problems of socioeconomic costs and benefits, technical feasibility, societal perception, and public policy. The risk management process includes identification of the procedures that should be adopted to control exposure (engineering controls, use of protective equipment, remediation, etc.), the setting of limits, and the enforcement of the procedures and limits. Decoupling of political management and scientific analysis ensures clear responsibilities. It should be emphasized that environmental health policy decisions should be based on established links among emission sources, human exposures, and adverse health effects, i.e., on scientific evidence.

In the narrowest sense limit values are measurable, quantitative thresholds representing uptake at the receptor or site of action within the body for hazardous substances. In practice either the human's body burden of toxic chemical compounds, elements or their metabolites is measured in biological samples (exhaled air, blood, urine, sweat, hair), or by extrapolation from measurements on exposure in various media such as air, water, soil, or food. The limit values have been recommended by the regulatory body established under the appropriate legal framework. Legal limits represent "tolerable" or "acceptable" risks, depending on their definition and the framework within which they are utilized.

The general public uses a very general understanding of the generic term *limit value*. Its scope is extended to guidance values, threshold values, ceiling values, etc., many of which are not enforceable. In contrast, if limit values are treated as values set within a legal framework established by the state, binding thresholds are defined and exceeding these thresholds triggers specific consequences. On the other hand, normally adherence to guidance values (whether from nongovernmental organizations or from government) is voluntary.

The approach used for establishing limit values generally distinguishes between populations. It may also distinguish different levels of protection. A clear definition of the group “at risk” and of the type and level of risk being addressed is one of the most important requirements when setting limits. Thus, health-based limit values can protect different groups of people (to different extents) depending on the circumstances of the exposure; these include:

- Workers
- Consumers
- The general public via environmental exposure (including human health-based standards aimed at protection the environment on the whole or specific compartments (soil, groundwater/surface water, ambient air) within the environment).

The general methodology for establishing health-based limits should be equally applicable both in workplace and non-workplace scenarios. There should be a clear distinction between scientific and other aspects in the practice of setting limit values. Transparency of derivation, flexibility and ease of use, and defined rules for re-evaluation and updating all help to build public acceptance of governmental limit values for the regulation of toxic chemicals. It should be noted that, although apparently different approaches for the risk assessment of chemical substances in the workplace and in other scenarios have emerged on the international and the national level, these differences are due to, *inter alia*, the standards being for different populations (healthy workers, without children or the elderly and with the possibility of excluding the more susceptible individuals, versus everyone), often with different attitudes to risk, and different exposure scenarios (8 h workplace shifts versus continuous).

---

## **The Setting of Occupational Exposure Limits**

Occupational Exposure Limit values (OELs) are set by national authorities or national institutions as limits for concentrations of hazardous compounds in the workplace air. Most of the industrialized countries establish and maintain OEL lists that regulate hazardous substance concentration levels to which workers may be exposed via inhalation, ingestion, or skin contact for specified time periods without being at risk over a working lifetime. These limits can be binding or indicative. For workplace airborne exposures to gases, vapors, and particulates, there are three

principal limits in widespread use. They are based on different durations of exposure:

- The 8-h Time-Weighted Average Exposure Limit (TWA): The maximum average concentration of a chemical in air for an 8-h working day and a 40-h week.
- The Short-Term Exposure Limit (STEL): The maximum average concentration to which workers can be exposed for a short period (usually 15 min).
- The Ceiling Value (STEL-C): A concentration that should not be exceeded at any time.

In addition, Biological Exposure Indices (BEIs) represent the body burden, i.e., the concentration of chemicals in the body that would correspond to inhalation exposure at a specific concentration in air. Theoretically, biological effects indices are also possible, but they are unlikely to be set on the grounds that the aim is to prevent harmful effects occurring, and harmful effects are occurring if the measure is one of minimal harm.

Fundamental work to develop a comprehensive approach to setting occupational exposure limits was done by the American Conference of Governmental Industrial Hygienists (ACGIH). The conception of the ACGIH to derive Threshold Limit Values (TLVs) for chemical substances and Biological Exposure Indices (BEIs) is one of the earliest developments aimed at managing workplace exposures. The ACGIH first published Maximum Allowable Concentrations (MACs) from 1946. These were later renamed TLVs, and are republished annually by the ACGIH. TLVs are subject to a health-based view only and are not legally binding. The US Occupational Safety and Health Administration (OSHA), which is a regulatory body, adopts mandatory limits, the Permissible Exposure Limits (PELs), and OSHA is supported in this process by the National Institute for Occupational Safety and Health (NIOSH). NIOSH develops its own health based Recommended Exposure Limits (RELs). Together with ACGIH's TVLS, the RELs of NIOSH contribute to the setting of PELs by the OSHA, however, OSHA makes its own independent judgment regarding the final value of PEL. PELs arise from a comprehensive and well documented rule-making that takes into account significant health risks, sampling and analytical procedures as well as technological and economic feasibility.

Similar approaches to that of ACGIH and NIOSH were adopted by the *Deutsche Forschungsgemeinschaft* (DFG) in Germany (non-enforceable maximum workplace concentration, MAK), the Netherlands and Scandinavia.

The UK Health and Safety Executive (HSE, a regulatory authority with enforcement responsibilities) pursued a dual system of maximum exposure limits (MELs) and occupational exposure standards (OESs), each of which carried different exposure management requirements, until 2005. In 2005, UK's two-OEL system has nominally been replaced by a single OEL system of workplace exposure limits (WELs), in which most of the existing MELs and OELs have been converted to WELs, but the different management approaches previously applicable to MELs and OESs have been maintained using EU classification and labelling requirements to identify which management approach is appropriate. The list of WELs for use with

the Control of Substances Hazardous to Health Regulations 2002 (as amended) (COSHH) is legally binding. Recently, the Health and Safety Executive has approved new and revised WELs that came into force on 17 January 2020 (EH40/2005 Workplace exposure limits, Fourth Edition 2020) (HSE 2020).

On the EU level, there are two principal types of OELs, the so-called Indicative Occupational Exposure Limit Values (IOELVs) and the Binding Occupational Exposure Limit Values (BOELVs). IOELVs are health-based nonbinding values, derived from the most recent scientific data available and taking into account the availability of reliable measurement techniques. EU Member States are obliged to take IOELVs into account when implementing national limits for the chemical agents in question. Risk-based BOELVs are established for, e.g., carcinogens, mutagens, and airway sensitizers, for which a threshold mechanism is not known. For chemicals for which a BOELV is established at Community level, Member States have to introduce a corresponding national binding limit based on the BOELV. National OELs for both IOELVs or BOELVs may be equal to or lower than the EU OELs. OELs are used to facilitate the regulatory initiatives on occupational exposure limit values for the protection of workers from chemical agent risks, to be set at Union level pursuant to the Chemical Agents Directive (Directive 98/24/EC) and to the Carcinogens and Mutagens Directive (Directive 2004/37/EC).

The European Commission set up the *Scientific Committee for Occupational Exposure Limits to Chemical Agents* (SCOEL) for the work on the scientific evaluation of the health risks posed by exposure to chemical agents in the workplace (Decision 95/320/EC, updated by Decision 2014/113/EU). The major task of the SCOEL has been to advise on the setting of OELs based on scientific data and, where appropriate, propose values (SCOEL 2017). SCOEL's regulatory approach is documented in its *Methodology for the Derivation of Occupational Exposure Limits* (revised 2017). The SCOEL has recommended OELs, which can be supplemented by further notations as:

- Eight-hour time-weighted average (TWA - 8 h)
- Short-term exposure limits (STEL).

If skin penetration of a chemical agent is likely to make a significant contribution to the total body burden and consequently to possible health effects (in general, amounting to 10% or more of the uptake from inhalational exposure at the 8-h TWA), SCOEL assigned a "skin" notation in addition to the establishment of the OEL. A "sensitization (dermal and/or respiratory)" notation may be assigned based upon availability of evidence on either dermal or respiratory sensitization. For respiratory sensitizers, the SCOEL evaluated data on a case-by-case basis. Furthermore, SCOEL may assign a "noise" notation if ototoxicity may occur even at exposures below or close to the established OEL if there is also exposure to excess noise.

The SCOEL aimed to give health-based OELs that can be recommended when the available scientific data suggest that a clear threshold value can be identified as point of departure (PoD) for the adverse effects of the substance in question. For

some adverse effects (in particular genotoxic carcinogenicity, respiratory sensitization, and genotoxicity), it is deemed according to current knowledge that it is not possible to identify thresholds. In these cases, the SCOEL recommended a pragmatic OEL, which is established at levels considered implying sufficiently low risk. Since the late 1990s, SCOEL has developed the concept of “Practical Thresholds” in the derivation of OELs for carcinogens (Bolt and Huici-Montagud 2008). For some carcinogens, health-based OELs have been recommended, while a quantitative assessment of the substance-related carcinogenic risk is made for others. Non-genotoxic carcinogens and/or non-DNA-reactive carcinogens are deemed to have a true threshold associated with a clearly founded NOAEL.

Under certain circumstances, biological monitoring offers advantages over air monitoring in assessing risk to workers' health. This particularly concerns substances with a skin notation, which are well or predominantly absorbed through the skin in addition to inhalation absorption. Furthermore, biological monitoring should be considered in operations where:

- Oral intake of hazardous substances may be important.
- Workers are exposed to hazardous substances with long biological half-lives.
- An exposure to substances classified as carcinogenic, mutagenic, or toxic for reproduction takes place.
- The hazardous substances are difficult to measure in the air due to strongly fluctuating concentrations.
- Exposure is greater than 8 h per day and 5 days per week.
- An accidental exposure took place.

Where appropriate, SCOEL recommended a *biological limit value* (BLV) which indicate that concentrations equivalent to the BLV are unlikely to result in adverse effects on worker's health. In the case where the available data do not allow to establish a health-based BLV SCOEL may establish a *biological guidance value* (BGV). BGVs are exposure-related guidance values. They represent the upper concentration of the chemical agent or one of its metabolites in any appropriate biological medium corresponding to the 90th or 95th percentile in a defined reference population. Normally, the reference population is a non-occupationally exposed working age population.

When carrying out an assessment of human health effects for the chemical safety assessment under Regulation (EC) No 1907/2006 (REACH), the regulation requires the derivation of a “*Derived No Effect Level*” (DNEL) or “*Derived Minimal Effect Level*” (DMEL) for each relevant human population (e.g., workers, consumers, and humans liable to exposure indirectly via the environment) and possibly for certain vulnerable subpopulations (e.g., children, pregnant women) by the registrant. DNEL or DMEL should be derived for all relevant routes of exposure (inhalation, dermal or oral). Inhalation is usually considered an important potential route of exposure in the workplace. A (generic) maximum “safe” inhalation exposure level can be developed from the appropriate DNEL/DMEL using the recommended (in Guidance from ECHA) standardized procedure and assessment factors. If no OEL is available, the

adequacy of the protective measures used in the workplace can be assessed by comparing the predicted or actual exposure levels with the maximum “safe” exposure level derived from this REACH-based procedure.

In the past, the derivation of an OEL or a DNEL by SCOEL or by using the ECHA guidance quite frequently resulted in numerically different workplace air concentrations for the same substance. Therefore, a “Joint Task Force of the ECHA Committee for Risk Assessment (RAC) and Scientific Committee on Occupational Exposure Limits (SCOEL)” (2017a, b) was engaged in a critical evaluation of scientific aspects and methodologies related to the exposure of chemicals at the workplace to improve mutual understanding of the different approaches and to work towards agreed common scientific approaches including through the further development of existing and new concepts as necessary in relation to workers’ exposure to chemicals.

Since January 2019, the scientific evaluation of health effects of hazardous chemical agents in the workplace and derivation of safe levels of occupational exposure (OELs, BVLs) is performed by ECHA’s Risk Assessment Committee. The findings of the ECHA/RAC-SCOEL Joint Task Force on alignment of methodologies related to the exposure of chemicals at the workplace, including the inhalation, dermal routes, and in particular carcinogens with or without a threshold mechanism were considered in ECHA’s recent “Guidance for preparing a scientific report for health based exposure limits at the workplace” (ECHA 2019).

---

## Health-Based Limit Values for Environmental Contaminants

### Air Pollutants

The World Health Organization (WHO) defines air pollution as “contamination of the indoor or outdoor environment by any chemical, physical or biological agent that modifies the natural characteristics of the atmosphere.” Effects of air pollutants can impair human health either directly via inhalation exposure or indirectly via atmospheric deposition on edible plants and thus entering the food chain. The dimension of air pollution is a global one. Recent data of WHO (2019) show that over 90% of the world’s population lives in places, where air quality exceeds WHO guideline limits.

Outdoor (ambient) and indoor air quality are usually considered separately by WHO. WHO’s air quality guidelines (for ambient air quality) were first published in 1987 as “Air Quality Guidelines for Europe” (WHO 1987), followed by the second edition in 2000. WHO emphasizes that these guidelines are not intended as standards. In moving from guidelines to standards, the prevailing exposure levels and environmental, social, economic, and cultural conditions in a country or region should be taken into account. The guideline setting process has been described in detail in the “Guidelines for Air Quality” (WHO 2000). In short, toxic effects are considered to be of two types, threshold and non-threshold. For substances where the critical effect is considered to have a threshold (including non-genotoxic

carcinogenesis for which there is adequate mechanistic data), a *Tolerable Intake* (TI) expressed as airborne concentrations (i.e.,  $\mu\text{g}$  or  $\text{mg}/\text{m}^3$ ) is developed usually on the basis of a NOAEL. A range of safety or uncertainty factors was used but not a rigid framework; these represented the expert judgment of the scientists involved in derivation of WHO's air quality guidelines. The derivation of guidance values for compounds present in other environmental media than air will require the allocation of proportions of the TI to such as air, food, and water, which will be based on sound information on relative exposure via different routes. A default approach, low-dose risk extrapolation, was conducted for carcinogens of IARC classification groups 1 and 2A, and an uncertainty factor approach applied in the case of substances in groups 2B and 3. The mechanism of action was the determining factor for the method of assessment. Hence, it was decided that compounds classified under 1 or 2A could be assessed using uncertainty factors, if evidence for a threshold mechanism of carcinogenicity existed. In contrast, compounds classified under 2B could be assessed by low-dose extrapolation methods, if a nonthreshold mechanism of carcinogenicity in animals was proven.

WHO has revised its air quality guidelines in 2005 for key parameters of contamination (particulate matter, ozone, nitrogen dioxide, and sulfur dioxide). Whereas the previous guidelines (published in 1987 and 2000) concentrated on Europe, the 2005 revision included information from low- and middle-income countries worldwide (WHO 2005). They are designed to offer global guidance on reducing adverse health impacts of air pollution. WHO air quality guidelines are not legally binding, but constitute an important basis for the regulation of air pollution. National air quality *standards* will vary from country to country. They depend on each country's attitude to health risk and its specific approaches to balancing risks to health and technological feasibility. They also take into account economic considerations and political and social factors.

In 2010, WHO proposed its guidelines for selected indoor air pollutants. The substances considered, i.e., benzene, carbon monoxide, formaldehyde, naphthalene, nitrogen dioxide, benzo(a)pyrene, radon, trichloroethylene, and tetrachloroethylene, have indoor sources or sources subadjacent to the building, and are often found indoors in concentrations of health concern (WHO 2010). WHO's guidelines for indoor air quality provide the scientific basis for legally enforceable standards. The WHO guidelines for indoor air quality on household fuel combustion published in 2014 represent a risk-management tool designed to provide guidance and support for people in low- and middle-income countries that still rely on solid fuels burned in inefficient and highly polluting stoves or open fires for cooking and heating. The intervention options, strategies, and recommendations were mainly based on the WHO guidelines for indoor air quality from 2010. WHO's guidelines for indoor air quality on household fuel combustion were the first one developed following the procedures outlined in the WHO handbook for guideline development (WHO 2012 and 2014) that aims at ensuring that WHO guidelines are of high methodological quality and are developed through a transparent, evidence-based decision-making process. It is expected that the coming revision of WHO's global air quality guidelines, started from 2016, will provide updated numerical concentration limits

and, where possible, an indication of the shape of the concentration–response functions for PM<sub>10</sub>, PM<sub>2.5</sub>, ozone, NO<sub>2</sub>, SO<sub>2</sub>, and CO, for short- and/or long-term exposure.

The US *National Ambient Air Quality Standards* (NAAQS) are standards established by the US EPA under authority of the Clean Air Act (CAA) that apply to outdoor air. EPA has set NAAQS for the following principal pollutants (also known as “criteria air pollutants”): Carbon monoxide, lead, nitrogen dioxide, ozone, particulate matter (PM), and sulfur dioxide. The standards are listed in Title 40 of the Code of Federal Regulations Part 50. CAA established two types of national air quality standards. *Primary standards* set limits to protect public health with an adequate margin of safety to allow for the health of vulnerable populations such as individuals suffering from respiratory disorders, children, and the elderly. *Secondary standards* set limits to protect public welfare, including protection against visibility impairment, damage to animals, crops, vegetation, and buildings. When establishing a new NAAQS or revising an existing standard for each criteria air pollutant, US EPA must designate areas as in compliance or not in compliance with the standard. The CAA requires states to develop *State Implementation Plans* (SIPs) to attain and maintain the standards in all areas of the country and a specific plan to attain the standards for areas designated nonattainment.

With the Air Quality Framework Directive 96/62/EC, the European Union (EU) has created the legal framework for future air quality development. Directive 2008/50/EC of 21 May 2008 on ambient air quality consolidated as much existing legislation on objectives for ambient air quality in relation to sulfur dioxide, nitrogen dioxide, and oxides of nitrogen, particulate matter (PM<sub>10</sub>, PM<sub>2.5</sub>), lead, benzene, carbon monoxide, and ozone and Directive 2004/107/EC (which was not included in the consolidation) set objectives for arsenic, cadmium, mercury, nickel, and polycyclic aromatic hydrocarbons (PAHs) in ambient air. Under EU law, a *limit value* is legally binding from the date it comes into force subject to any exceedances permitted by the legislation. In contrast, a *target value* is to be attained as far as possible by the attainment date. Target values are less strict than limit values. Member States are required to ensure that limit values are met. Where limit values are not met, EU Member States must take all necessary measures and prepare an *air quality plan* to address the problems identified. EU’s legislative instrument to achieve the ambitious 2030 objectives of the Clean Air Programme is the Directive 2016/2284/EU on the reduction of national emissions for the five pollutants sulfur dioxide, nitrogen oxides, volatile organic compounds, ammonia, and fine particulate matter.

## Water Quality Criteria and Standards

Quality standards for ground and surface water may reflect either or both ecological criteria and quality criteria for drinking water. Either water resources used as sources of drinking-water, and their related water ecosystems should be protected from pollution or they have to be purified during supply.

The European Union has implemented the Water Framework Directive (EU Directive 2000/60/EC) establishing a framework for Community action in the field of water policy (<http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2000:327:0001:0072:EN:PDF>). Its ultimate objective is to achieve a “good ecological and chemical status” for all Community waters by 2015. The Directive establishes a list of 33 priority substances, including cadmium, lead, mercury, nickel, and its compounds, benzene, PAHs, and DDT for action. The corresponding *Environmental Quality Standards* (EQS) for priority substances and certain other pollutants have been laid down in Annex I of the Directive 2008/105/EC on environmental quality standards in the field of water policy. EQS are derived as an annual average value providing protection against long-term exposure, and maximum allowable concentrations to protect against short-term exposure in order to ensure that the aquatic environment and human health are adequately protected. Generally, groundwater is the most sensitive and the largest body of freshwater and, in particular, is a main source of public drinking water supplies. The Directive 2006/118/EC on the protection of groundwater against pollution and deterioration comprises *groundwater quality standards* for nitrates and active substances in pesticides, including their relevant metabolites, degradation, and reaction products. It also requires Member states to establish threshold values for groundwater pollutants and indicators of pollution on the basis of a minimum list of pollutants and their indicators (arsenic, cadmium, lead, mercury, ammonium, chloride, sulphate, trichloroethylene, tetrachloroethylene, and conductivity [which is indicative of saline or other intrusions]) considering the guidelines outlined in Annex II/Part A.

Section 304(a) (1) of the US Clean Water Act is the legal basis for the development of criteria for ambient water quality for the protection of aquatic life as well as for human health (including organoleptic effects) in the USA. US EPA’s (2020) *National Recommended Water Quality Criteria* defines the human health criterion as the highest concentration of a pollutant in water that is not expected to pose a significant risk to human health (<https://www.epa.gov/wqc/national-recommended-water-quality-criteria-human-health-criteria-table>). The criteria that were revised in 2015 for 94 chemical pollutants consider human health for the consumption of water and organisms or organisms only. The methodology for deriving *Ambient Water Quality Criteria for the Protection of Human Health* has been revised in 2000 with revisions in the assessment of exposure to carcinogens, exposure to noncarcinogens, exposure assessment, and bioaccumulation. For noncarcinogens, the effective EPA guidance on assessing noncarcinogenic effects of chemicals and for the Reference Dose (RfD) derivation should be used. More sophisticated methods are recommended for cancer risk assessment, including identification of the likely mechanism of human carcinogenicity and use of the most appropriate low-dose extrapolation.

WHO’s water related activities cover a broad range of activities, including water and drinking water quality and infectious agents, toxic chemicals, and radiological hazards and general aspects of water supply and sanitation as well (WHO 2017). Since 1984, a comprehensive framework, the *Guidelines for Drinking-water Quality* (GDWQ), has been published periodically by the WHO. The last

(4th) edition dates from 2017 incorporating the 1st addendum. Two approaches to derive guideline values are used: one for “*threshold chemicals*” and the other for “*non-threshold chemicals*” (mostly genotoxic carcinogens). In establishing GDWQ, the IARC evaluation of carcinogenic compounds, where available, is taken into consideration. The principles in the derivation of ADIs (acceptable daily intakes) developed by FAO, JECFA, and JMPR have been adopted, where appropriate, in the derivation of TDIs used in developing guideline values for drinking-water quality. GDWQ are kept up-to-date through an ongoing “*rolling revision*” process. Increasingly the preferred approaches for the derivation of TDIs/ADIs for threshold chemicals include the benchmark dose (BMD) or the benchmark dose lower confidence limit (BMDL) and chemical specific adjustment factors. In order to make the distinction with respect to the underlying mechanism of carcinogenicity, compounds that have been shown to be a carcinogen (i.e., chemicals classified in group 1 or group 2A by IARC) are evaluated on a case-by-case basis. The evidence of genotoxicity, the range of species affected, the relevance of the tumors observed in experimental animals to humans and the toxicokinetics of the substance are considered when determining the mode of action, and therefore the approach taken. For carcinogens for which there is evidence to suggest a non-genotoxic mechanism or to suggest that detoxification mechanisms require to be overwhelmed by high doses, guideline values are derived using the threshold chemicals approach. WHO’s normal allocation of 20% of the TDI/ADI to drinking-water has changed from the allocation of 10% used in the third edition of the GDWQ. The latter was found to be excessively conservative, and the new value will be incorporated in new guidelines and revisions of existing guidelines.

The current EU binding framework for Member State national standard setting for the quality of *water intended for human consumption at the point of deliver* is contained in the Council Directive 98/83/EC (Drinking Water Directive), last amended by Commission Directive (EU) 2015/1787 of 6 October 2015. The numerical values for chemical parameters in Annex I are generally those of WHO’s GDWQ; the opinion of the Commission’s Scientific Advisory Committee is a further scientific basis for the quality standards (*parametric values*) in drinking water. The Commission must review Annex I at least quinquennially and has to make proposals for amendments in the light of scientific and technical progress. Member States can include in their own national legislation additional requirements, e.g., regulate additional substances that are relevant or set higher standards but are not allowed to set lower standards as the level of protection of human health should be the same within the whole EU. Temporary derogations from the chemical quality standards as specified in Annex I can be granted, provided it does not constitute a potential danger to human health and provided that the supply of drinking-water in the area concerned cannot be maintained by any other reasonable means.

Under the Safe Drinking Water Act (SDWA), US EPA (2018) evaluates substances that may be found in drinking water by developing Contaminant Candidate Lists contaminants to regulate in drinking water and sets regulatory limits. *Drinking Water Standards* and *Health Advisories* (DWSHA) are issued periodically by US EPA (current tables of drinking water standards and health advisories as of March,

2018). The Health Advisory (HA) Program publishes concentrations of drinking water contaminants at Drinking Water Specific Risk Level Concentration for cancer ( $10^{-4}$  Cancer Risk) and concentrations of drinking water contaminants at which noncancer adverse health effects are not anticipated to occur over specific exposure durations: 1-day, 10-day, and Lifetime. The *Lifetime HA* for the drinking water contaminant is calculated from its associated *Drinking Water Equivalent Level* (DWEL), obtained from its Reference Dose (RfD), and incorporates a drinking water Relative Source Contribution (RSC) factor of contaminant-specific data or a default of 20% of total exposure from all sources. *1-day HAs*, *10-day HAs*, and *Lifetime HAs* are not to be construed as legally enforceable Federal standards. In contrast, an enforceable *Maximum Contaminant Level* represents the highest level of a contaminant that is allowed in drinking water. MCLs are set as close as feasible to the *Maximum Contaminant Level Goal* (MCLG) using the best available analytical and treatment technologies and taking cost into consideration.

### Soil Values (Contaminated Land)

Land contamination may occur naturally or through anthropogenic activities. A distinction is often made between soil contamination originating from clearly confined sources (local or point source contamination, e.g., abandoned hazardous sites) and that caused by diffuse sources. In general, land contamination and remediation is a newer field of environmental legislation and control is currently mainly through land use planning legislation. Different policies (e.g., on water, waste, chemicals, industrial pollution prevention, pesticides, agriculture) have contributed to preventing land being contaminated. However, as these policies have other aims, they are not sufficient to ensure an adequate level of soil protection. On the European scale, a proposal for a framework Directive (COM (2006) 232) exist which sets out common principles for protecting soils across the EU (European Commission 2006). Taking note that the proposal for a Soil Framework Directive has been pending for almost 8 years without a qualified majority in the Council in its favor, the Commission withdrew this proposal on 30 April 2014. Aspects of EU's soil protection continued to be addressed in the Decision No 1386/2013/EU on a General Union Environment Action Programme to 2020.

Specific soil trigger values have been set in recent times at the national level, notably in Canada, Germany, Netherlands, Switzerland, and United Kingdom. The US EPA developed the Soil Screening Guidance to help standardize and accelerate the evaluation and cleanup of contaminated soils. This guidance provides a methodology to calculate risk-based and site-specific *Soil Screening Levels* (SSLs) for contaminants in soil. To calculate SSLs, the exposure equations and pathway models are run in reverse to back calculate an "acceptable level" of a soil contaminant. For ingestion, dermal, and inhalation pathways, toxicity criteria are used to define an acceptable level of contamination in soil, based on a  $10^{-6}$  individual excess cancer risk for carcinogens and a hazard quotient (HQ) of 1 for noncarcinogens. SSLs are back calculated for migration to ground water pathways using ground water

concentration limits (MCLGs, MCLs, or health-based limits (HBLs) ( $10^{-6}$  cancer risk or a HQ of 1, where MCLs are not available). Generic SSLs are not national cleanup standards.

---

## Future Perspectives

Increasingly, scientific quantitative risk assessment succeeds in identifying and reducing uncertainties that are inherent in all stages of the risk analysis. For substances with adverse health effects, alternative methods such as the Benchmark Dose method are being incorporated into the determination of dose-response relationships. These alternatives can reduce the shortcomings of the classical concept of determining tolerable body doses based on a NOAEL or LOAEL. Recent assessments of carcinogenicity are based on the complete analysis of all available biological information, including that on the mechanism of action. This is an improvement on the older risk quantification in the low doses range using the linearized multistage model, which often led to an overestimation of risk. Exposure assessment methods are beginning to allow a more realistic description of exposure. However, better exposure models require an expanded data base. Current issues include the use of multiple “worst case” (or “reasonable worst case”) assumptions by regulatory authorities, leading to unrealistically precautionary overall risk assessments. Probabilistic approaches, such as Monte Carlo analysis, yield more realistic overall risk assessments. Emerging issues include approaches to considering the extrapolation to low doses in a sound manner, low-dose effects in toxicology/non-monotonic dose-response, and the development of scientific state of the art approaches to mixtures of chemicals. Future challenges will be the regulatory acceptance of alternatives to animal testing and the use of toxicogenomics data in human health limit value setting.

## Abstract

Consumers are exposed directly or indirectly to all kinds of chemical substances by using products and articles in daily life. Products and articles are regulated in different ways and with various processes depending on the intended uses to ensure the safety of man and environment.

Specific application areas in which consumers are exposed to chemical substances are subject to regulations and approvals. Such areas are chemicals in general for professional and private uses e.g. pesticides, plant protection products, biocides, consumer goods, e.g., cosmetics and toys as well as areas for human

health, e.g., medical devices and medicines. These areas are some of the most important and most relevant regulated fields.

The requirements for approval and legally placing the product on the market depend on the intended uses and the appropriate regulation. The key point of every approval process is the evaluation of the potential risk and/or hazard for man and the environment. A risk-benefit analysis has to be performed in order to evaluate if the correlated risk or hazard occurring from the use of the substance, the product, or the article is acceptable. The authorization, registration, or notification of substances, products, or articles for the various application areas is different from country to country and from region to region. The regions with the most advanced and developed registration requirements are Europe, the USA, Canada, and Japan. However, especially Asian countries are implementing more and more regulation processes. Very often are these requirements a mixture of the US and the European system combined with some national demands.

It is the aim to harmonize the requirements and standards for the regulations between the different regions and countries. On an international level, OECD standards bring a certain level of harmonization. In Europe, the EU directives and EU regulation are aiming for a harmonization between the European Member States. Europe is the region with the fastest development in harmonization of the various regulated areas. European regulations and directives of the abovementioned areas are the focus of the following outlines.

**Chemical Regulations**

Relevant regulations:

- Regulation (EC) No. 1907/2006 of the European Parliament and of the Council of 18 December 2006 concerning the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), establishing a European Chemicals Agency, amending Directive 1999/45/EC and repealing Council Regulation (EEC) No. 793/93 and Commission Regulation (EC) No. 1488/94 as well as Council Directive 76/769/EEC and Commission Directives 91/155/EEC, 93/67/EEC, 93/105/EC and 2000/21/EC
- Regulation (EC) No. 1272/2008 of the European Parliament and of the Council, of 16 December 2008, on classification, labelling and packaging of substances and mixtures, amending and repealing Directives 67/548/EEC and 1999/45/EC, and amending Regulation (EC) No. 1907/2006

## Introduction

Chemicals are regulated through national chemical inventories. The requirements for inclusion of chemicals in the different national chemical inventories vary greatly from country to country. The chemical regulation in the EU went through a dramatic and fundamental change in the past years. The new chemical regulation in the EU is probably the one with the deepest impact on chemical-related industries since the existence of the EU.

REACH: The chemical regulation in the EU is now known as REACH with the official number EC No. 1907/2006. REACH stands for Registration, Evaluation, Authorisation and Restriction of Chemicals. It replaces the former EINECS (European Inventory of Existing Commercial Substances) and the ELINCS (European List of Notified Chemical Substances) lists.

REACH had a tremendous impact on manufactures and importers as well as on the so-called downstream users of chemicals. REACH is a very complex registration system; only the basic points and the frame idea are outlined below.

The REACH regulation became effective on 1 June 2007. The aim of this regulation is to control all manufactured or imported chemicals into the EU in order to improve the protection of human health and environment. The European Chemicals Agency (ECHA), located in Helsinki, is appointed to organize and manage the registration processes and to handle a central database where all necessary data are stored and which is accessible for national competent authorities, professionals, as well as consumers.

REACH affects all chemicals manufactured or imported with a quantity over 1 t/year per producer or importer. The regulation differs between phase-in and phaseout substances. Phase-in substances are chemicals already listed in the EINECS or “no long polymers” as well as chemicals produced 15 years before REACH was in force but were never sold in the market, e.g., internal production. Not under the scope of REACH are polymers (not the monomers); radioactive substances; substances for research; substances in transit; substances which are controlled by other regulations, e.g., medicines for human and animal health and plant protection and biocide active substance, which are considered as registered; substances for food and feed; reimported substance into the EU; as well as substances mentioned in Annexes IV and V, e.g., water, limestone, and natural substances classified as not dangerous.

The whole REACH system is divided into different notification and registration phases with different deadline. In principle, since 1 December 2008, only registered chemicals are allowed on the market. The basic principle is no data – no market. However, if a manufacturer or importer has preregistered the chemical, transitional periods will apply. Only the “phase-in” chemicals are under the scope of the preregistration. The advantage of the preregistration is the extended timelines depending on the amount of chemicals placed on the market (Table 1) and the participation in a so-called SIEF forum. SIEF stands for “Substance Information Exchange Forum.” In this forum, different manufacturers and

**Table 1** Timelines according to article 23 of the REACH regulation

Amount placed on the market	Timelines
$\geq 1,000$ t/a	1 December 2010
CMR substances $\geq 1$ t/a	1 December 2010
Substances dangerous to the environment $\geq 100$ t/a	1 December 2010
Notification Art 7 (4)	1 June 2011
$\geq 100$ t/a	1 June 2013
$\geq 1$ t/a	1 June 2018

importers can exchange data about the same chemicals and can also share costs for the data needed for the registration.

ECHA has published a list with the preregistered chemicals. The list can be downloaded on the ECHA website (<http://echa.europa.eu/web/guest/information-on-chemicals/pre-registered-substances>). Under certain circumstances, even if the preregistration phase is over, it is still possible for a late preregistration, e.g., if an importer decides to import a certain chemical.

The requirements for submission of data to a certain timeline depend on the total amount of the chemical placed on the EU market. The higher the amount of chemical manufactured or imported, the more data are required for the registration, and the shorter is the deadline to submit the data. All chemicals above 1 t/year on the EU market are under the scope of the regulation and need to go through the REACH processes. Chemicals classified as carcinogenic, mutagenic, or reproduction toxic (CMR) have special more strict requirements in respect of registration timelines and requested data. For all phase-in and non-phase-in substances, a submission of a technical dossier is required. Besides the physical/chemical properties and toxicological and ecotoxicological properties, the dossier must also include information on classification and labeling, manufacturing, and intended uses as well as instructions for the safe usage of the substance. The technical dossier needs to be submitted via the latest IUCLID (<http://iuclid.eu>) (International Uniform Chemical Information Database) database software version.

Substances may be recognized as substances of very high concern, so-called SVHCs (substances of very high concern). If a substance is identified as a SVHC, because of its potential negative impacts on human health or the environment, a substance may be included on the authorization list (Annex XIV of the REACH regulation) and become subject to authorization. If a SVHC is placed on the authorization list, the use of this substance needs an authorization by ECHA. Candidates for authorization are included on the candidates list of the SVHC. This list is continually updated and can be downloaded from the ECHA website (<https://echa.europa.eu/candidate-list-table>). From 1 June 2011, the ECHA must be notified of the presence of SVHCs in articles if the total quantity used is over 1 t/year and the SVHC is present on more than 0.1% of the mass of the object.

An additional important REACH element is the communication along the user downstream. Manufactures as well as users need to communicate and exchange data on the use of the chemical. In this sense, the whole industry is affected from the big chemical industry to the medium-sized and small-sized companies using the chemical.

The REACH regulation is complemented by the GHS (Globally Harmonized System) regulation or also called CLP regulation (EC No. 1272/2008) on classification, labeling, and packaging of substances and mixtures. The CLP regulation became effective on 20 January 2009 and substitutes the EU Directives 67/548/EEC and 1999/45/EC for labeling, classification, and packaging of substances and mixtures.

Information on REACH is available on the ECHA website (<http://echa.europa.eu>), in particular in the guidance documents. Also national helpdesks provide support for REACH and CLP questions (<https://echa.europa.eu/support/helpdesks/>). A special situation occurs in Switzerland. Switzerland, not a member of the EU, has an own regulation for chemicals described in the national “Chemikalienverordnung” under the chemical law “Chemikaliengesetz (ChemG).” Switzerland has adapted some parts of the REACH regulation, e.g., the CLP regulation, but Switzerland has not adapted the general REACH regulation, and there are essential differences between the Swiss legislation and the REACH regulation. Information is available on the Swiss Chemical website (<https://www.bag.admin.ch/bag/de/home/das-bag/organisation/direktionsbereiche-abteilungen/direktionsbereich-verbraucherschutz/ anmeldestelle-chemikalien.html>).

---

## Pesticides

Pesticides are essential for agriculture and high hygiene standards in our society. Pesticides are chemical compounds intended to kill, repel, and control pests, to protect crops before and after harvest, to destroy weeds preventing their growth, as well as to influence and preserve plant products. Pesticides cover a broad range of specific protection products like insecticides, acaricides, herbicides, fungicides, plant growth regulators, rodenticides, biocides, and veterinary medicines.

The EU regulates pesticides strictly to ensure safety of humans and environment and to ensure the efficacy of the used products.

The EU established an approval and authorization system on pesticides, especially on plant protection products and biocidal products in a two-step approach:

### Step 1.

The Commission approves the active substances contained in the products.

### Step 2.

EU Member States authorize the products on their territory and ensure compliance with EU rules.

## Plant Protection Products

Relevant regulations:

- Regulation (EC) No. 1107/2009 of the European Parliament and of the Council of 21 October 2009, concerning the placing of plant protection products on the market and repealing Council Directives 79/117/EEC and 91/414/EEC

The Plant Protection Products Directive was introduced in 1991 with the Council Directive 91/414/EEC, regulating the placing of plant protection products on the EU market. The directive lays down rules and procedures for approval of active substances at EU level and for the authorization at Member State level of plant protection products (PPPs) containing these active substances. The Directive 91/414/EEC was replaced by Regulation (EC) No. 1107/2009.

The regulation intends to ensure a high level of human, animal, and environmental protection and to provide clear rules to make the approval process for plant protection products more effective.

A plant protection product contains one or usually more active substances. Before companies can use an active substance in a plant protection product, the active substance needs to be approved by the responsible EU Committee. The EU Regulation 1107/2009 regulates the approval and use of plant protection products and active substances. An active substance will only be approved if the criteria according to Annex II No. 2 and No. 3 are fulfilled. The criteria consider efficacy of the active substance, available analytical methods, and effects on human health and environment. The approval of an active substance is not equivalent with the approval of a plant protection product (formulation). The plant protection products need to be also approved by the concerned Member States.

To find out which active substances are approved in the European Union, a database can be consulted on the website of the European Commission (<http://ec.europa.eu/food/plant/pesticides/eu-pesticides-database>). For each substance, there is a reference to the EU legislation, including the relevant toxicological information and the maximum residue levels in food and feed.

More general information concerning active substances and plant protection products and different guidance documents can be found on the EU website ([http://ec.europa.eu/food/plant/protection/evaluation/index\\_en.htm](http://ec.europa.eu/food/plant/protection/evaluation/index_en.htm)).

In correlation to Regulation (EC) No. 1107/2009, two related topics need to be mentioned: one is the Regulation (EC) No. 396/2005 which regulates the residues of pesticides in food and the Directive 2009/128/EC which regulates the sustainable uses of pesticides.

In Switzerland, not an EU Member State, plant protection products are regulated by the “Pflanzenschutzmittelverordnung” (PSMV). This regulation has many similarities to the EU regulation. Further information is available at the website of the BAG (Bundesamt für Gesundheit) ([http://www.admin.ch/ch/d/sr/c916\\_161.html](http://www.admin.ch/ch/d/sr/c916_161.html)).

## Biocides

Relevant regulations:

- Regulation (EU) No. 528/2012 of the European Parliament and of the Council of 22 May 2012, concerning the making available on the market and use of biocidal products

Biocides are essential for the health and hygiene standards in our societies. Biocides are used in various application fields like disinfections and pest control or as preservatives to protect perishable materials. Biocides are regulated in the EU under the Biocidal Products Regulation (BPR) EU No. 528/2012, which replaced the initial Biocidal Products Directive (BPD) 98/8/EC. Before the BPD, biocides were regulated individually by the national Member States with different registration or notification systems or were not regulated at all. With the BPD (98/8/EC), the EU tried to implement a harmonized framework on biocidal products.

Essential for understanding of the authorization processes is the differentiation between an active substance, a biocidal product, and a treated article. A chemical or a microorganism that has an action on or against harmful organisms is defined as an active substance. Formulations with an active substance are defined as biocidal products, which are usually used for various biocidal purposes. The definition, according to the Biocidal Products Regulation (EU) No. 528/2012, of a biocidal product includes all substances or mixtures containing or generating active substances with the intention to destroy, deter, render harmless, prevent the action, or exert otherwise a controlling effect on any harmful organism by any means other than mere physical or mechanical action. A treated article is a substance, mixture, or article which has been treated with, or intentionally incorporates, one or more biocidal products.

The BPR determines a two-step approach for the authorization of a biocidal product. In the first step, the approval of the active substances takes place at EU level. The assessment of the single active substance for the intended uses, the so-called product type (PT), has been allocated to the competent authorities of an EU Member State. The appointed EU Member State reports the results of the evaluation, which is then discussed at the competent authority meetings. It is the task of the responsible EU Committee to decide on the inclusion in the positive list for active substances (union list). In the second step, the subsequent authorization of the biocidal product is on the single EU Member State, meaning that an application for authorization needs to be submitted to the Member State in which the biocidal product is planned to be marketed. Also a union authorization, covering all EU Member States, is a possible path. In this case the ECHA takes an administrative and organization role.

One key point of the BPR is the assignment of an active substance to 1 of the 22 different application fields for the intended uses outlined in the 22 product types (PTs) as described in Annex V of the BPR.

There are four main groups of PTs, which are further divided in subgroups adding up to 22 PTs. The four main PTs are:

- Disinfectants and general biocidal products, e.g., human hygiene, private and public health area, veterinary hygiene, food and feed area, and drinking water disinfectants
- Preservatives, e.g., in-can or film preservatives; wood preservatives; preservatives for leather, plastics, rubber, and masonry; preservatives for liquid-cooling and liquid-processing systems; slimicides, e.g., for paper production; and metal-working fluid preservatives, as well as bad odor protection (e.g., on textiles)
- Pest control, e.g., rodenticides, avicides, molluscicides, piscicides, insecticides, repellents, and attractants
- Other biocide products, e.g., preservatives for food or feedstock and antifouling products (e.g., for marina uses)

With the assignment to a PT, a clear intended use and application field is defined. Any uses in other applications are clearly separated. Other uses are not under the scope of the BPR if these intended uses are controlled by their own regulations, e.g., pharmaceuticals for human and animals, plant protection, cosmetic, medical devices, and food and feed.

Active substances already placed on the market before 14 May 2000 are considered as “existing active substances,” active substances placed on the market after that date are considered as “new active substances.” Manufactures, formulators, or importers could notify active substance which they wanted to support until 28 March 2002. All identified existing active substances are listed in Annex 1 of Regulation EU 1451/2007. All notified active substances are listed together with the assigned PT in Annex 2 of the Regulation 1451/2007. The EU Commission updates the ongoing evaluation and decisions on the approval or non-approval of the active substances for the assigned PTs. The current status can be checked on the ECHA web page for biocides (<https://echa.europa.eu/information-on-chemicals/biocidal-active-substances>).

New elements in the BPR are also exclusion and substitution criteria for active substances. If a substance meets the exclusion criteria, the substance will not be approved. Exclusion criteria are, e.g., carcinogens, mutagens, and reprotoxic substances category 1A or 1B according to CLP classification; endocrine disruptors; persistent, bioaccumulative, and toxic (PBT) substances; as well as very persistent and very bioaccumulative (vPvB) substances. Active substances falling under the substitution criteria will be candidates for substitution during the approval processes.

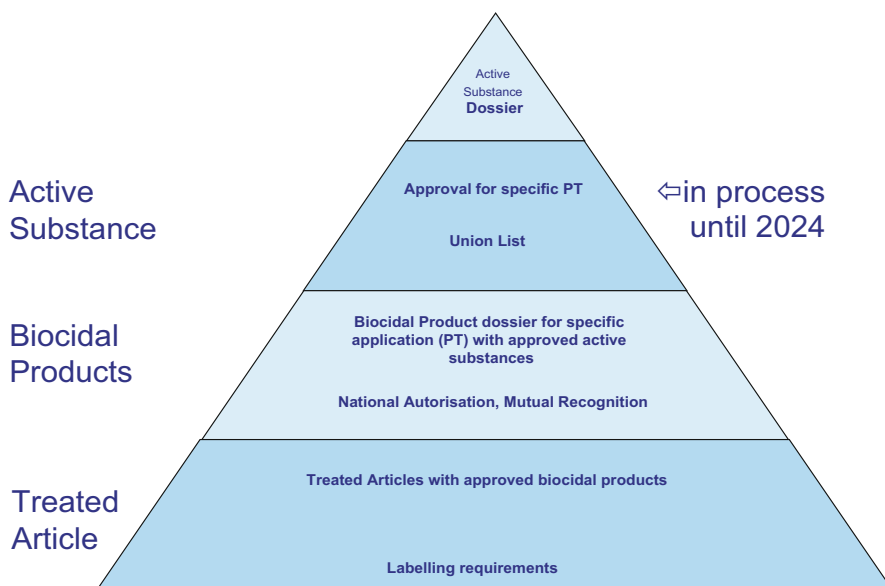

Under the BPR, the authorization of the biocidal product is still mainly at the national competent authority level. That means if an active substance is approved and a company is using the approved active substance for a biocidal product, the company needs to apply for authorization in a Member State. However, if an authorization is granted in a Member State, the applicant has the possibility to ask for recognition of the authorization in another Member State. This so-called mutual-recognition procedure can be performed in sequence or in parallel.

In addition to the mutual recognition of an authorization, a union authorization for all Member States is now possible under the BPR. The union authorization is organized by the ECHA and is only possible for single PTs currently.

A new tool of communication is a database for biocidal products, the so-called Register for Biocidal Products (R4BP). The R4BP database will be maintained by ECHA and is used as a submitting and exchanging platform between applicants, ECHA, Member States, competent authorities, and the European Commission.

Another main new subject under the BPR is the regulation of so-called treated articles. Treated articles are articles which have been treated with or intentionally incorporated one or more biocidal products. Treated articles do not fall under the definition of a biocidal product and do not need an authorization. However, it will be required to label the article with certain information, e.g., that the article was treated with a biocidal product and the name of the active substance the article includes. Treated articles are widely spread in articles used by consumers in daily life, e.g., treated wood, plastic, and leather products, as well as in technical textiles and apparel, furniture, and building material. The correlation between active substances, biocidal products, and treated articles is shown in Fig. 1.

Under the BPR transitional periods still exist and will continue to exist especially for active substances, which are still in the evaluation phase for inclusion in the union list. The evaluation of active substances is planned to be finalized by 2024 (EU Regulation 736/2013). Existing active substances, still in the evaluating phase, can be marketed until a decision is taken. This situation reveals in transitional period for those substances. Biocidal products containing substances still in the evaluation

**Fig. 1** BPR, correlation between active substances, biocidal products, and treated articles (*PT* product types)

phase are subject to national regulations. The nation regulations are very different from Member State to Member State. In some Member States, a simple notification is requested, e.g., Germany. In other Member States, a complete BPR dossier is required, e.g., in the Netherlands, or a time-consuming complex notification and registration system was implemented, e.g., in Belgium.

It needs to be mentioned that active substances registered or in the evaluation phase under the BPR are excluded from the REACH requirements. These substances are considered as registered. However, other chemical substances included in the biocidal products, e.g., solvents, stabilizers, and emulsifiers, are still subjects to REACH.

Information about biocides is available on the EU Commission biocide website (<https://echa.europa.eu/regulations/biocidal-products-regulation>) or on the website of the national authorities usually under the chemical section. Switzerland, not a member of the EU, adapted fully the EU legislation for biocides and has implemented the “Biozidprodukteverordnung” (VBP) under the chemical law. Information is available on the chemical website of the BAG. Therefore, Switzerland has the same status as regular EU Member States and can act as a RMS (Reference Member State) as well as a CMR (Concerned Member State) in the approval process under the BPR in the EU (<https://www.anmeldestelle.admin.ch/chem/de/home/themen/pflicht-hersteller/zulassung-biozidprodukte.html>).

---

## Food Contact Materials

Relevant regulations:

- Regulation (EC) No. 1935/2004 of the European Parliament and of the Council of 27 October 2004, on materials and articles intended to come into contact with food and repealing Directives 80/590/EEC and 89/109/EEC
- Commission Regulation (EU) No. 10/2011 of 14 January 2011, on plastic materials and articles intended to come into contact with food
- Commission Regulation (EC) No. 2023/2006 of 22 December 2006, on good manufacturing practice for materials and articles intended to come into contact with food
- Commission Regulation (EC) No. 450/2009 of 29 May 2009, on active and intelligent materials and articles intended to come into contact with food
- Commission Regulation (EC) No. 282/2008 of 27 March 2008, on recycled plastic materials and articles intended to come into contact with foods and amending Regulation (EC) No. 2023/2006
- Commission Directive 2007/42/EC of 29 June 2007 relating to materials and articles made of regenerated cellulose film intended to come into contact with foodstuffs
- Council Directive of 15 October 1984 on the approximation of the laws of the Member States relating to ceramic articles intended to come into contact with foodstuffs
- Further substance specific regulations

Food contact materials are intended to come into contact with food, e.g. packaging material, containers, cutlery and dishes, material in contact with water for human consumption, but it does not cover fixed public or private water supply equipment. The regulation of food contact materials in the EU is a complex system of regulations and directives. The frame Regulation EU No. 1935/2004 describes the general requirements for all food contact materials. In principle, material intended to come into contact with food shall not release chemicals into food in unacceptable quantities. Furthermore, the material shall not change the food in composition and in quality, and it shall not impact taste, smell, or appearance of the food.

The overall migration limit for plastic materials is set to 10 mg of substances/dm<sup>2</sup> of food contact surfaces, which is equivalent to 60 mg/kg foodstuff for all substances that can migrate from the contact material into food. Specific migration limits (SML) are also established for individual substances based on ADI (acceptable daily intake) or TDI (tolerable daily intake) values established by the European Food Safety Authority (EFSA). At EFSA's website opinions can be searched for substances to be used in food contact materials (<http://www.efsa.europa.eu/en/topics/topic/food-contact-materials>). Regulation EU No. 10/2011 regulates plastic materials and articles intended to come into contact with food, replacing the EU Directive 2002/72/EC, and includes a list of approved substances (Annex I) for food contact materials. This regulation also outlines the test methods and conditions for the measurement of migration.

An overview of the related regulations and directives for food contact materials is outlined and illustrated in Fig. 2.

Frame legislation:

Regulation EC No. 1935/2004: Frame regulation on materials and articles intended to come into contact with food

Regulation EC No. 2023/2006: Good manufacturing practice

Legislation on specific materials:

Regulation EU No. 10/2011, updated by Regulation EU No. 1282/2011: Plastic materials and articles intended to come into contact with food

Regulation EC No. 450/2009: Active and intelligent materials and articles intended to come into contact with food

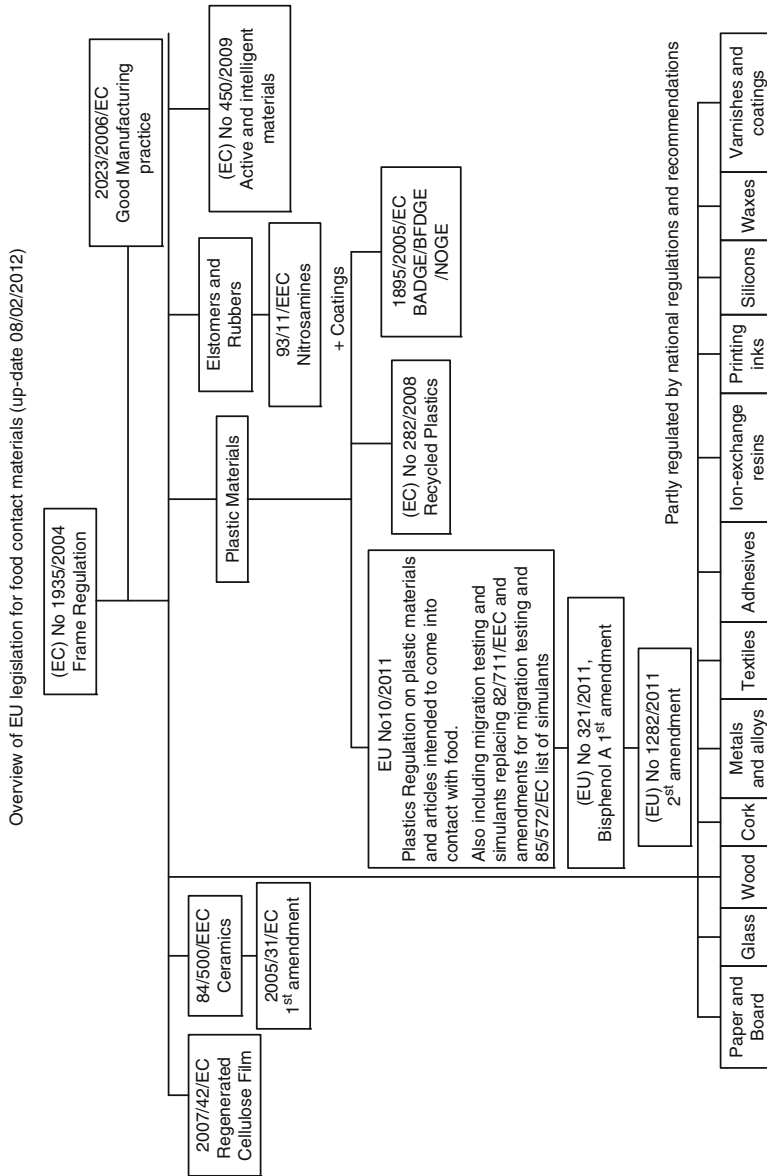

Regulation EC No. 282/2008: Recycled plastic material and articles intended to come into contact with food

Directive 2007 /42/EC: Materials and articles made of regenerated cellulose film intended to come into contact with food

Directive 84/500/EEC, amended by Directive 2005/31/EC: Sets migration limits for cadmium and lead which might be released from decoration or glazing

Legislation on specific substances:

Regulation No. 1895/2005/EC: Restriction of use for certain epoxy derivatives

**Fig. 2** Overview of EU legislation on food contact material. (Source: References of the European and National Legislations, European Commission 2012)

Regulation EU No. 321/2011: Restriction on bisphenol A use in plastics for infant feeding

Regulation EU No. 284/2011: On import procedures for polyamide and melamine plastic kitchenware from China and Hong Kong

Directive 93/11/EEC: Release of N-nitrosamines and N-nitrosatable substances from rubber teats and soothers

Further information can be found on the EU website ([http://ec.europa.eu/food/food/chemicalsafety/foodcontact/index\\_en.htm](http://ec.europa.eu/food/food/chemicalsafety/foodcontact/index_en.htm)).

---

## Toys

Relevant regulations:

- Directive 2009/48/EC of the European Parliament and of the Council of 18 June 2009, on the safety of toys

Toys are a source for exposure of chemicals to the consumer. Therefore, toys must meet high safety standards to ensure the safety of consumers in general and for children in specific. Toys are regulated by the “Toy Safety Directive” 2009/48/EC, which replaces the old Directive 88/378/EEC.

The directive lays down the basic safety criteria toys must meet before being placed on the market. Technical details are described in technical harmonized standards which are suitable to ensure the safety of toys, e.g., Standard EN 71-2 for flammability or Standard EN 71-3, and migration of certain elements, e.g., metals.

Toys are not subject to registration processes. However, toys underlie the conformity assessment in which the conformity with the applicable safety standard needs to be confirmed. The conformity is identified by the CE mark on toy articles.

Details and further information can be found on the EU website ([http://ec.europa.eu/growth/sectors/toys/safety/legislation\\_en](http://ec.europa.eu/growth/sectors/toys/safety/legislation_en)).

---

## Cosmetics

Relevant regulations:

- Regulation (EC) No. 1223/2009 of the European Parliament and of the Council of 30 November 2009 on cosmetic products

Cosmetic products are products only intended to be used for contact with the various external parts of the human body, e.g., epidermis, hair system, nails, lips, or teeth, and the mucous membranes of the oral cavity with the intention of cleaning

them, perfuming them, changing their appearance, and/or correcting body odors and/or protecting them or keeping them in good condition.

In comparison with the already discussed previous regulated areas, substances used for cosmetic products are intended for the exposure to consumers. Cosmetic products are regulated by the EU Regulation No. 1223/2009. This Cosmetic Regulation came into force in January 2010 and was effective on 1 July 2013, replacing the older Cosmetic Council Directive 76/768. The general structure of the former Cosmetic Directive is also reflected in the new Cosmetic Regulation. There is no registration requirement for cosmetic products before placing them on the market. However, substances included in cosmetic products are regulated depending on their function. The Cosmetic Regulation has included positive and negative lists of substances for specific uses.

On the negative list are substances that are not allowed in cosmetic products, e.g., CMR substances. On the positive list are substances for the specific intended use as preservatives, UV filters, and dyes with concentration limits. An update of the different lists is done regularly by amendments to the regulation by Commission Regulations.

Substances, which are not regulated by negative or positive lists, are permitted as ingredients in cosmetic products as long as they are safe for consumers. Therefore, a key element of a cosmetic product is the dossier with the safety assessment that needs to be available on demand for the competent authority.

Responsible for the safety of cosmetic products is the importer, manufacturer, or distributor placing the product on the market.

More information is provided at the EU website for cosmetics ([http://ec.europa.eu/consumers/sectors/cosmetics/index\\_en.htm](http://ec.europa.eu/consumers/sectors/cosmetics/index_en.htm)). Switzerland, not a Member State of the EU, adapted the EU Cosmetic Regulation 1223/2009. The new Swiss Cosmetic Regulation came into force by 01 May 2017 (<https://www.admin.ch/opc/de/classified-compilation/20143407/index.html>).

---

## Medical Devices

Relevant regulations:

- Regulation (EU) 2017/745 of the European Parliament and of the Council of 5 April 2017 on medical devices, amending Directive 2001/83/EC, Regulation (EC) No. 178/2002 and Regulation (EC) No. 1223/2009 and repealing Council Directives 90/385/EEC and 93/42/EEC
- Regulation (EU) 2017/746 of the European Parliament and of the Council of 5 April 2017 on in vitro diagnostic medical devices and repealing Directive 98/79/EC and Commission Decision 2010/227/EU

Medical devices are instruments, apparatuses, implants, in vitro reagents, or related articles that are used to diagnose, prevent, or treat disease or other conditions and do not achieve their purposes through chemical action within or on the body.

Medical devices act by physical, mechanical, or thermal means. Medical devices vary greatly in complexity and application. They cover a vast range of equipment from simple tongue depressors to hemodialysis machines and pacemakers.

Rules that relate to safety and performance of medical devices were harmonized in the EU. The core legal framework consists of three basic directives:

Directive 93/42/EEC regarding medical devices (MDD)

Directive 90/385/EEC regarding active implantable medical devices (AIMD)

Directive 98/79/EC regarding in vitro diagnostic medical devices (IVDD)

The aim of a harmonized Medical Device Directive in the EU is to ensure a high level of protection of human health and safety. These three main directives have been supplemented and amended over time by several modifying and implementing directives. Directive 2007/47 EC introduced the last bigger technical revision.

Two new revisions of the regulatory framework for medical devices in the EU were adopted by the EU Parliament 5 April 2017.

- Regulation(EU) 2017/745 (regulation on medical devices, MDR)
- Regulation (EU) 2017/746 (regulation on in vitro diagnostic medical devices, IVDR)

The new regulations came into force on 26 May 2017 and replace the old directives in several graduated transition periods. Several elements of the new rules come into force after 6 months. After the transitional period of 3 years, the regulation on medical devices will be completely mandatory (May 2020), and after 5 years, the regulation on in vitro diagnostic medical devices (May 2022) will be mandatory.

The new regulations shall improve the safety for patients and ensure a high quality and safety level of the products.

The main changes and improvements of the new rules among others are:

- Stricter ex ante control for high-risk devices
- Reinforcement of criteria for the designation and processes for oversight of Notified Bodies.
- The inclusion of certain aesthetic devices
- The introduction of a new risk classification system for in vitro diagnostic medical devices
- The introduction of an implant card
- The reinforcement of rules on clinical evidence
- Strengthening of post-marketing surveillance
- Improvement of coordination between EU countries in the field of vigilance and market surveillance

Medical device regulations are based on a compliance system. The responsibility for safety and compliance with the EU regulations is on the side of the medical device manufacturer or importer. Manufacturers guarantee the authorization of

medical devices through a Declaration of Conformity. Medical devices belonging to class I can be marketed by self-certification of the manufacturer. Certification of higher-risk products (class IIa, IIb, or III) must be verified by a Certificate of Conformity issued by a Notified Body. A Notified Body is a public or private organization that has been accredited to validate the compliance with the according regulations. All medical devices must be identified with the CE mark.

Medical devices are divided into different classes based on their design complexity, their use characteristics, and their potential for harm if misused. A combination of medical devices and drugs, so-called combination products, needs to follow a special regulatory process before being marketed.

The classification of medical devices in the European Union is outlined in the Regulation (EU) 2017/745 or in the former Directive 93/42/EEC. There are basically four classes, ranging from low risk, class I, to high risk, class III:

Class I (e.g., wound bandages)

Class IIa (e.g., surgical suture)

Class IIb (e.g., lung ventilator)

Class III (e.g., pacemaker)

The European classification depends on rules that involve the medical device duration of body contact, invasive character, use of an energy source, effect on the central circulation or nervous system, diagnostic impact, or incorporation of a medicinal product.

More detailed information and guidance (MEDDEV Guidance) are available on the EU website:

---

## Medicines

Relevant regulations:

- Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the community code relating to medicinal products for human use
- Regulation (EC) No. 726/2004 of the European Parliament and of the Council of 31 March 2004 laying down community procedures for the authorisation and supervision of medicinal products for human and veterinary use and establishing a European Medicines Agency

Medicine products, also called medicinal products or pharmaceuticals, are chemical substances that achieve their principal action by pharmacological, metabolic,

or immunological means. The mode of action is different than for medical devices. Medicines are intended to have an effect on humans and animals. An exposure of the chemical substance on humans or animals is intended. The authorization of medicines is the most complex and most expensive regulated field compared to other regulated areas.

To ensure a high safety standard and an acceptable risk-benefit ratio, medicines need to pass a complex authorization process.

The requirements for medicines are basically very similar in all countries with an authorization system for medicines and are very much harmonized in Europe, North America, and Japan. The basic requirement for an authorization of a medicine is the acceptable pharmaceutical quality, pharmaceutical efficacy, safety for the patient, and an acceptable risk-benefit ratio.

The medicine must have an acceptable quality according to pharmaceutical rules. The guidelines and rules of pharmaceutical quality are described, e.g., in the pharmacopeia monographs. The pharmaceutical quality covers the composition of a medicine, the manufacturing processes, and the quality control of the raw materials, the intermediates, and the final product as well as storage stability studies. The manufacturing processes need to comply with the rules for “good manufacturing practice” (GMP).

The efficacy of a medicine is a basic requirement for the authorization. The efficacy is the intended effect to heal diseases or improve the health of a patient. Safety can only be considered in relative terms. All medicines carry a certain degree of risk and could cause problems in specific circumstances. The safety of a medicine needs to be demonstrated by nonclinical and clinical studies. In order to obtain a complete safety profile of the medicine, observations of the continuously collected “pharmacovigilance” reports are included in the safety evaluation of the competent authorities. In this way also long-term effects, which could not be discovered during the clinical studies, can be recognized. Pharmacovigilance is the pharmacological science relating to the detection, assessment, understanding, and prevention of adverse effects particularly long-term and short-term side effects of medicines (<http://apps.who.int/medicinedocs/en/d/Js4893e/>). The risk-benefit ratio reflects the possible benefit of the medicine for the human or the animal in relation to the possible risks, which could occur, e.g., possible side effects. The benefit risk is also constantly under observation using the pharmacovigilance reporting.

For the authorization of a medicine, all necessary data and studies need to be submitted to the competent authorities for evaluation. In order to harmonize the submitted data, a standard application format dossier was developed by the ICH (International Conference on Harmonization). The standard application format is known as the Common Technical Document (CTD). The CTD dossier consists of five modules, which include all the necessary information.

Module 1 is about regional and specific information, not part of the CTD dossier.

Module 2 includes an overview and summary of modules 3, 4, and 5.

Module 3 includes the quality part, describing manufacturing and analytics of the medicines.

Module 4 includes the preclinical pharmacological and toxicological studies. Module 5 includes the clinical studies.

Detailed information is available on the ICH website (<http://www.ich.org>).

The approval procedures are regulated by national regulations, international regulations, and international mutual-recognition procedures. In the EU, the authorization of medicines was regulated in the beginning by Directive 65/65/EEC, which has been replaced by the Directive 2001/83/EC; in addition EU Regulation No. 726/2004 describes the procedure for centralized procedures authorization. The directive is integrated in the different national laws for the authorization of medicines.

The regulation in the EU offers several different ways of how a company can apply for the authorization of medicines. The national procedure was the only way in the EU until 1995. Since then the European procedure gained importance, and the national procedures were preplaced by the European ones. Nowadays the national procedure is only possible in one Member State. Multiple national procedures are not possible anymore. Nevertheless, national competent authorities still play a major role in the authorization process.

The centralized authorization procedure for human and veterinary medicine is managed by the EMEA (European Medicines Agency) in London, and the EU Commission grants the authorization. The authorization is valid in all EU Member States as well as in Iceland, Lichtenstein, and Norway. The centralized procedure is mandatory for human medicines for the treatment of cancer, diabetes, HIV/AIDS, neurodegenerative diseases, autoimmune and other immune dysfunctions, and viral diseases; veterinary medicines for use as growth or yield enhancers; medicines derived from biotechnology processes, e.g., genetic engineering, gene therapy, and somatic cell therapy or tissue-engineered medicines officially designated “orphan medicines” (medicines used for rare human diseases).

Decentralized procedure is used when an authorization is intended simultaneously in several EU Member States if the medicine does not already have an authorization in an EU Member State.

**Table 2** Different ways of authorization in the EU

	Centralized procedure	Decentralized procedure	National procedure	Mutual- recognition procedure
Procedure	Authorization in all EU Member States	Authorization in several EU Member States simultaneously	Only national authorization	Authorization on the base on an existing authorization in another Member State
Competent authority (CA)	EMA	EMA and national CA	National CA	National CA
Validity	All EU Member States including Iceland, Norway, Lichtenstein	All Member States in which the authorization is accepted	In the concerning national state	In the Member States who accepted the application

Mutual-recognition procedure needs to be used if a national authorization has already been granted and additional authorization in other Member States is intended (Table 2).

Further and more detailed information is available on the websites of the EMEA (<http://www.ema.europa.eu>, [https://ec.europa.eu/health/authorisation-procedures\\_en](https://ec.europa.eu/health/authorisation-procedures_en)) and the national competent authorities responsible for medicinal products.

criteria and communication elements for substances and mixtures are worldwide harmonized by the United Nations Globally Harmonized System of Classification and Labelling of Chemicals (UN-GHS). In the European Union, the UN-GHS is implemented by the Regulation on Classification, Labelling and Packaging of Substances and Mixtures (EC) No. 1272/2008 (CLP Regulation). Professional users have access to more comprehensive information (including safe use scenarios) in the Safety Data Sheets (SDS) as required by the REACH Regulation (EC) No. 1907/2006, Article 31.

In case of a medical incident, i.e., an unsafe exposure or an exposure with poisoning concern, product labelling information and SDS are the starting points for adequate medical management, but more detailed information is needed in many cases.

## Introduction

Several regulations of the European Union (EU) aim to ensure a high level of protection of human health from the risks that can be posed by chemical substances on the EU market. Classification and labelling of hazardous substances and mixtures are important in communicating the hazards and providing the basis to describe and plan for safe use. Furthermore, classification supports the poisoning risk assessment if persons have been exposed in an unsafe way. In the past, different systems for the classification and labelling of chemicals were used around the world. A substance or mixture could be classified as hazardous in one country and not classified as hazardous in another country. This led to diverse problems on the industrial or professional side but also to misunderstandings among consumers. To harmonize hazard classification criteria and communication elements worldwide, the United Nations Globally Harmonized System (UN-GHS) of Classification and Labelling of Chemicals (UNCED 1992; UNECE 2003) was developed. The Regulation on Classification, Labelling and Packaging of substances and mixtures (EC) No. 1272/2008 (CLP Regulation) implements UN-GHS in the EU (EC 2008). CLP Regulation entered into force on 20 January 2009 and became valid for classification, labelling, and packaging of substances on 1 December 2010 and for mixtures on 1 June 2015.

Due to the Regulation on Registration, Evaluation, Authorisation and Restriction of Chemicals (EC) No. 1907/2006 (REACH), industry is responsible for assessing and managing the risks of chemicals and for gathering all relevant substance information for registration at the European Chemicals Agency (ECHA). REACH (see [Cross-References](#), below) incorporates requirements for the Safety Data Sheet (SDS), an important document informing professionals on safe use of a substance or mixture (“product”).

## Health Hazard Classification

The three elements structuring the CLP Regulation are hazard classification, labelling, and packaging. An overview of classification and labelling is presented here.

The classification describes substances or mixtures in terms of their physical, health, or environmental hazards. The manufacturers, downstream users (e.g., formulators, professional end users), and importers are responsible for providing appropriate classification for most substances and all mixtures. As an exception, substances with fixed classification according to Annex VI have to be classified as indicated in this Annex. To perform the classification, companies have to identify all hazard-related data available and evaluate its quality (weight of evidence). The CLP Regulation defines the criteria according to which the hazardous properties of a substance or a mixture are determined and offers the following options for obtaining the relevant information:

- Animal experiments with the substance or mixture with regard to its hazardous properties
- Other animal experiment-free methods for substances such as (Q)SAR
- Evaluation by applying a weight of evidence determination using expert judgment, including experience on humans, such as epidemiological data, data from accident databases and occupational data, all new scientific information, and any other information obtained from internationally recognized chemical programs

For mixtures, data indicating the health hazard profile is only rarely available. If no hazard data on the mixture is available, then procedures listed in Annex I of the CLP Regulation can be used to evaluate its hazard. Furthermore, official calculation methods allow deduction of the mixture classification from classification of its ingredients if insufficient data were available for hazard evaluation of the mixture.

The framework of the CLP health hazard classification (CLP, Annex I, Part 3) is based on ten health hazard classes, describing the quality of action of the hazard in focus (e.g., “acute toxicity,” “carcinogenicity”). The quantity measure (strength or potency) of a hazard quality is described using numeric hazard categories, where higher category numbers (1 to a maximum of 4) indicate lower strength or potency. For some hazard classes, only one category is defined, while for some classes, category 1 is subdivided into 1A, 1B, and 1C. An overview of CLP health hazard classes and categories is presented in Table 1.

## Health Hazard Labelling

The second element within the CLP Regulation is the labelling of substances and mixtures. The labelling is used for hazard communication and is based on hazard classification. It informs the user about the hazard(s) of a substance or mixture and

**Table 1** CLP health hazard classes

CLP Annex I chapter	CLP health hazard class	Differentiation
3.1	Acute toxicity	Oral, dermal, inhalation
3.2	Skin corrosion/irritation	
3.3	Serious eye damage/eye irritation	
3.4	Respiratory or skin sensitization	Airways, skin
3.5	Germ cell mutagenicity	
3.6	Carcinogenicity	
3.7	Reproductive toxicity	Sexual function and fertility, development of the offspring
3.8	Specific target organ toxicity (STOT): single exposure	
3.9	Specific target organ toxicity (STOT): repeated exposure	
3.10	Aspiration hazard	

the need to control the associated risks. Manufacturers, importers, downstream users, or in certain cases distributors have to label the classified packaged substance or mixture before placing it on the market (Article 4 (4) of the CLP Regulation).

For the consumer, the label is usually the only source of information about the product hazards. For professional users, a Safety Data Sheet is available in addition that contains all labelling elements and substantially more hazard-related information (see section “[Safety Data Sheet](#)”).

Each hazard class and category is linked to four groups of specific hazard communication elements:

- Signal word
- Hazard pictogram
- Hazard statement (“H-statements”)
- Precautionary statements (“P-statements”)

There are two signal words: “DANGER” with classes and categories of higher concern, strength, or potency while “WARNING” with those of lower concern, strength, or potency.

Four hazard pictograms are used in the health hazard communication: the “skull and crossbones” pictogram, the “corrosion” pictogram, the “health hazard” pictogram, and the “exclamation mark” pictogram (Fig. 1).

An overview of the links between health hazard classes/categories and signal words and hazard pictograms is presented in Fig. 2.

Hazard statements describe the character and strength of the hazard, for some classes differentiated according to the route of exposure (see Table 2 for some examples).

Precautionary statements advise about the correct handling of chemical substances and mixtures. Statements give:

**Fig. 1** Pictograms for health hazards according to the CLP Regulation (EC) No. 1272/2008 (with kind permission from UNECE 2012). (a) Skull and crossbones, (b) corrosion, (c) health hazard, (d) exclamation mark

- General advices (P1xx)
- Prevention-related advices (P2xx)
- Emergency-response-related advices (P3xx)
- Storage-related advices (P4xx)
- Disposal-related (P5xx) advices (with x indicates numeric digits)

A complete list of hazard and precautionary statements and official statement combinations (with translations in all EU languages) is included as Annex III and Annex IV to the CLP Regulation, respectively.

The system of precautionary statements is complex. For different reasons, precautionary statements are of very limited value in regulatory toxicology and therefore not further elucidated here.

All classifications of substances shall be reported to the European Chemicals Agency (ECHA). These classification and labelling information on substances are made available online in the Classification and Labelling Inventory (maintained by ECHA). This database includes all substances with a harmonized (and thus legally

binding) hazard classification as listed in Annex VI of the CLP Regulation and substances registered under REACH for which the manufacturer or importer is responsible for correct classification and labelling.

## Safety Data Sheet

For a more detailed risk assessment, especially in emergency situations and for development of scenarios for safe use of hazardous substances and mixtures at workplace, the communication elements on the label are not sufficient. Additional

**Table 2** Hazard statements for acute toxicity (selected examples for oral and dermal exposure)

Category of acute toxicity	Route	Hazard statement code	Hazard statement
1	Oral	H300	Fatal if swallowed
2	Oral	H300	Fatal if swallowed
3	Oral	H301	Toxic if swallowed
4	Oral	H302	Harmful if swallowed
1	Dermal	H310	Fatal in contact with the skin
2	Dermal	H310	Fatal in contact with the skin
3	Dermal	H311	Toxic in contact with the skin
4	Dermal	H312	Harmful in contact with the skin

**Table 3** Structure of Safety Data Sheet according to REACH: sections important for emergency response

Section number	Content
1	Company name and address and emergency telephone number
2	Description of the hazards of the substance or mixture and the appropriate warning information associated with those hazards
3	Composition/information on hazardous ingredients. Listing all ingredients classified as hazardous (above specified concentration thresholds) and their concentration (either exact or ranges)
4	First aid measures by relevant routes of exposure
11	A description of the various toxicological (health) effects and the available data used to identify those effects, including, where appropriate, information on toxicokinetics, metabolism, and distribution

information is provided in the Safety Data Sheet (SDS). The SDS has a fixed structure with 16 sections, as described in Annex II of the REACH Regulation (EC) No. 1907/2006 (EC 2006). The content of the sections with important data relevant for emergency health response is listed in Table 3.

The toxicological information in Section 11 shall apply to the substance or mixture as placed on the market. If available, the relevant toxicological properties of the hazardous substances in a mixture shall also be provided. For every relevant health hazard class, toxicological information should be included, and if available, human data should be provided.

For substances, Section 11 of the SDS will include (a summary consistent with) the toxicological information which is supplied for the registration of the substance according to the REACH Regulation.

For some substances, a Chemical Safety Report (CSR) is compiled for the REACH registration which includes Exposure Scenarios describing how the substance will be used by professional users or consumers (e.g., duration and frequency) and – if needed – risk management measures to be implemented to reduce or avoid direct and indirect exposure. These exposure scenarios will be made available as an Annex to the SDS.

## Poisons Centres' Perspective

As described above, consumers are informed about the hazards and safe use of a product by communication elements on the product label only, while professional users have access to additional information on the SDS. In case of incidents (unsafe exposures), the SDS information is only a starting point, and more detailed information is necessary for medical management in many cases.

When exposure cases are treated in the medical system, most often in a hospital, poisons centres are frequently consulted for professional toxicological support. Poisons centres often deal with unusual exposures, e.g., intake of large doses, untypical exposure pathways (e.g., ingestion, intravenous application), patient groups with high sensitivity to specific toxic substance (e.g., pregnant, child, immunosuppressed patients) or unusual expose pattern (patients with reduced taste, smell, or mental capacity).

An important general shortcoming of the SDS for poisons centres' practice is that only substances that are classified as hazardous have to be mentioned and only if exceeding threshold concentrations. Furthermore, as guidelines on the notification of the concentration of ingredients are not available in practice, wide concentration ranges are often used. To perform a clinical risk assessment in individual poisoning cases, poisons centres need to have access to the detailed product formula of all hazardous products.

**Abstract**

The last century has seen huge advances in chemistry. It has been estimated that more than 300,000 substances are on the market. It is hardly possible to keep an overview of the entire complex situation. Evidently, substances that pose a risk to human health and the environment must get regulated. Even substances with low toxic risks are often restricted with regard to application fields or maximal limits.

This chapter mentions as historic example the alcohol prohibition in the United States in the 1920s. It discusses several types of prohibition and restriction, like the prohibition of chemical weapons, prohibition of certain addictive drugs, prohibition of smoking in public rooms, banning of persisting organic pollutants, and regulation of mercury. This contribution also deals with some terms used in regulatory toxicology and risk management, the praxis of prohibition, and potential disagreements and conflicts.

**Introduction**

Considering the large number of 350,000 chemicals and mixtures that have been registered (Wang et al. 2020), each with an individual physicochemistry, reactivity, application field, life cycle, and toxicity, effective regulations and global harmonization are mandatory. Most chemicals on the market are restricted in some way, others are prohibited, usually because of toxicity to health and environment. Prohibition or banning is the most restrictive tool. They grant safety, but may affect the liberty of those who discovered, produce or use the substance.

Prohibition (from Latin *prohibere* = to forbid) is ordering that something not be done or used. Prohibition in regulatory toxicology is the act of banning the production, distribution, possession, or use of a chemical substance or items containing the substance. It may also be prohibited to delete a chemical from a product, where its presence guarantees quality and safety. “Prohibition” in a narrow sense refers to the period of alcohol prohibition in the USA from 1920 to 1933 (see also below).

Restriction (from Latin *restrictio* = limitation) in regulatory toxicology is the act of limiting and controlling the production, distribution, possession, or use of a chemical, by defining specific conditions where usage is allowed or forbidden.

Today, toxicological regulations commonly include some type of prohibition or restriction. We describe some anecdotal examples of well-known chemicals that were prohibited and restricted and the preceding, often time-consuming negotiations. Regulations may vary from country to country and change over time.

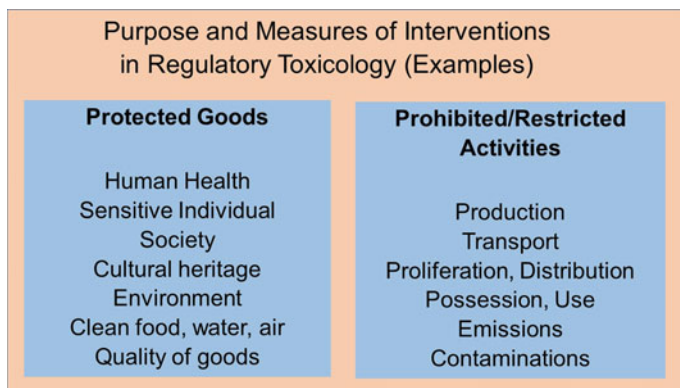

**Fig. 1** Schematic visualization depicting the scopes of prohibition and restriction in regulatory toxicology

Even when a substance is prohibited, there may exist defined exemptions, allowing a specific application (Fig. 1). For example, the insecticide lindane is banned in the Stockholm Convention, but an exemption exists for (second line) medical treatment of scabies. Likewise, a substance may have a wide application, but nevertheless there may be limitations with regard to transport, ceiling levels, application fields, and others. Finally, some chemicals are believed to have no or only minimal toxicology-based regulatory limitations, like pure water. But even in such cases, there tend to exist some restrictions or recommendations (e.g., “don’t spill water over metallic sodium”). The right panel of Fig. 1 may appear somewhat hypothetical.

## Purpose of Prohibition in Toxicology

Prohibition in toxicological regulations can have varying targets, just to name a few:

- Prohibition concerning distribution, possession, and use of a substance outside its determined usage. This is, for example, the case for addictive drugs, some of which are on the legal market as essential pharmaceuticals when administered under the supervision of a medical doctor, but illegal for street users.
- Prohibition under any condition. Examples are chemical weapons that are prohibited in the lists of the Organization for the Prohibition of Chemical Weapons (OPCW 2021).
- Prohibition to emit or dispose hazardous substances in a way that is not approved.
- Prohibition of animal experiments, for example, in the development of cosmetics. This is incisive, considering that equivalent alternative safety-test possibilities do

**Fig. 2** Schematic presentations of protected assets and prohibited/restricted activities related to chemicals and drugs

not provide all the required information. But it reflects the intention to respect nature and life.

Examples for purpose and measures are shown in Fig. 2.

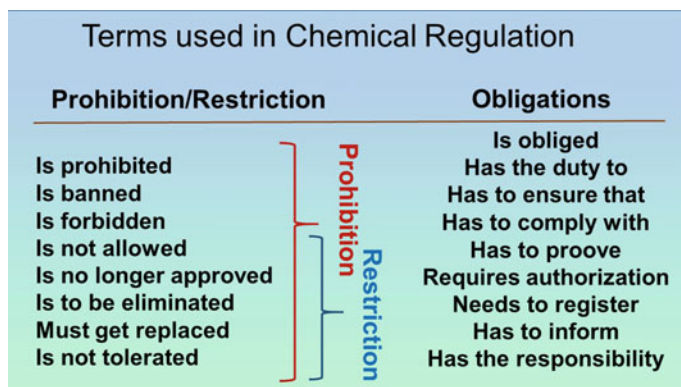

## Levels and Origins of Prohibitions and Restrictions

Countries may have different governmental structures according to national laws; however, decreasing decision-making power is common when moving from national, to regional, to local regulatory authority. Prohibitions and restrictions can be proclaimed on any hierarchical level, but compliance may be better, if based on national law. An example for prohibition by local administrations is the banning of alcohol during big events in order to avoid aggressive behavior, or the interdiction to enter a danger zone after a chemical accident.

Initiatives that ultimately result in prohibition may come from scientific evidence, NGOs, whistleblowers, or court decisions. Some prohibitions are not based on secular laws, such as the prohibition to drink alcohol as a religious principle.

Decisions on the international level have the highest level of competence. International conventions are usually preceded by intensive, time-consuming international negotiations and based on scientific evidence. National interests will also be taken into account. These processes are usually very complex, resulting in an agreement of all signatory bodies. The agreements need to be adopted and incorporated into national laws.

Prohibition and restrictions both affect the freedom of individuals and industry. The problem can often get solved by replacing restricted chemicals with novel substances that fulfill the same purpose but exhibit less adversity. Chemical regulations contain prohibitions and restrictions, but also obligations, for example, to prove

**Fig. 3** Prohibitions and obligations in regulatory toxicology. The terms in the two lists are examples for expressions used by authorities. The brackets depict that there may be overlapping that may vary from case to case

the quality and safety of a product and to keep authorities informed. Figure 3 shows terms that are commonly used in regulation.

Conflicts among related regulations exist. For example, the EU cosmetic regulation bans animal testing, whereas EU REACH requires or allows animal testing of chemicals under restricted conditions to study risks to health and environment (ECHA 2017).

## Drugs

Phenylbutazone was a very effective analgesic, but associated with the life-threatening side effect of agranulocytosis. In 1985, it lost its approval in Germany, meaning that a larger number of commonly used phenylbutazone-containing pharmaceutical preparations were banned from the market. In 1986, metamizol, a substance with similar pharmacological and toxic features, became restricted as well. Thereafter, medical doctors were not allowed to prescribe metamizol for common pain, but only for specific orthopedic indications, or as second line medication, when other medication was not effective. Then, over the years and decades, metamizol experienced a revival and became a major analgesic, contrary to the official recommendation. The prescribing doctors now argue that metamizol has advantages over other analgesics in having no relevant unwanted effects on blood coagulation, kidney function, and gastric mucosa and that the risk of agranulocytosis, although not exactly known, was estimated higher in the past, than it actually is. During this period, many other pharmaceuticals were restricted as well; they could usually get replaced by newer pharmaceuticals that are more effective and have less side effects.

Thalidomid came to the market in 1957. It was advertised as anti-nausea drug for pregnant women. It tragically produced malformations in newborns, by interfering with specific steps of morphogenesis during fetal tissue differentiation. This ended in a big

drug scandal. The drug became a prototype, showing the need for better drug testing, notably in developmental toxicology. The further use was prohibited. However, it was later detected that thalidomide has a therapeutically useful antiangiogenic effect, and the agent experienced a revival in the treatment of leprosy, as second-line therapeutic for multiple myelomas and treatment of various other diseases. It must be administered under the strictest conditions to avoid its use by women in child-bearing age. This exemplifies that new knowledge can reverse a prohibition.

---

## Addictive Drugs

The UN “Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances” of 1988 by the United Nations Office on Drugs and Crime (UNODC) made it mandatory for the signatory countries to prohibit production, trafficking, sale, and distribution of certain addictive drugs that were listed in the Single Convention on Narcotic Drugs 1961 and Convention on Psychotropic Substances 1971. It also includes provisions against money laundering and related crimes.

Some current examples show the dilemma of prohibition: Carfentanyl is a synthetic opioid that is very effective as sedative and widely approved for anesthesia in large animals. It is under strict regulation. Having opioid-like psychoactive effects, it is illegally consumed by drug users. Due to its very high pharmacological/toxic potency, it is a hazardous substance in humans resulting in life-threatening inhibition of respiration.

Methamphetamine is a stimulating drug, used in some medical applications, but also misused as prohibited addictive drug. It is cheap to produce. It gets illegally pushed by the drug mafia into the international drug-user markets with a huge margin of profit. The international and national networks of prosecutors, analytical laboratories, and toxicology centers do a very good job in detecting this criminality.

This shows that the illicit drug problem has many aspects, including risks to health and socioeconomic situations of users. The authorities have difficulties to successfully eliminate these drugs and to discourage their consumption. It is difficult to find a balance between prohibition/prosecution and legalization/liberalization.

Considering the increasing influence of the drug mafia and transnational criminal activities, and the ever increasing number of novel psychoactive drug analogues sold on the black market, some people come to the conclusion that the regulations of addictive drugs according to UNODC lists (UNODC 2013) should be liberalized and decriminalized. However, it is difficult to estimate the consequences. In any case, liberalizations, such as happened with cannabis, should have several preconditions, such as:

- Mandated labels with dosage and medical warnings
- Ban on advertising
- Access to clinical setting and medical support
- Accompanying scientific control studies

## Doping Drugs

Based on the world antidoping code of the year 2004 (WADA 2021) signed by the Olympic movement, national antidoping organizations and other movements, various drugs that may increase the athletic performance (e.g., stimulants, testosterone, EPO), are prohibited in sports in the annual list of substances released by the World Anti-Doping Agency (WADA). There are three categories.

1. Prohibited all times (e.g., anabolic agents)
2. Prohibited in competition (e.g., stimulants)
3. Prohibited in particular sports (beta-blockers)

Any misuse is closely controlled by WADA and its adhering national organizations; data are published. Athletes who violate these rules are publicly denounced. In general, WADA is very successful in its efforts to keep sports free of doping. It thus provides equality among athletes and breaks the spiral of performance enhancement and dose-increase of doping agents. Finally it is a necessary measure to protect the athletes from doping-induced damage to their health.

---

## Example Alcohol

### US Prohibition

Around the year 1915, various countries started to ban alcohol drinking. The best known example is that of the United States. Due to the increasing consumption of strong alcoholic beverages like whisky and rum and the expansion of breweries, alcohol consumption had increased in the preceding years. The temperance movement had the aim to ban alcohol with the arguments that alcohol disabled drinkers due to drunkenness, aggressive behavior, increasing poverty, and destruction of societal cooperation. People expected that a restriction of alcohol would concern only the liquor bars and heavy consumers. Then in 1919, the Eighteenth Amendment to the United States Constitution established that alcohol was prohibited with the following words (US law 1917):

*After one year from the ratification of this article the manufacture, sale, or transportation of intoxicating liquors within, the importation thereof into, or the exportation thereof from the United States and all the territory subject to the jurisdiction thereof for beverage purposes is hereby prohibited*

Initially the country experienced a decline of alcohol consumption. But illegal alcohol producers soon started their work, mafia-like structures consolidated, methanol intoxication occurred, and finally the public opinion increasingly objected to the prohibition, which was finally repealed by the twenty-first amendment in 1933. Thereafter many US states issued their own regulations and restrictions. The State

of Utah is known to have preserved some strict alcohol regulations until today: Only persons older than 21 years are allowed to buy and to consume alcoholic drinks. In supermarkets, only beer with limited alcohol content is offered. Packaged liquor, wine, and beer are sold in liquor stores.

## General Situation Today

It is primarily the psychoactive effects of alcohol that cause societal problems. With rising dose, alcohol induces sedation, subsequently activation, and finally – depending on personality – aggressiveness. Another risk concerns the drinking pregnant woman, because alcohol is transferred to the fetus and provides a serious dose-dependent risk to the developing fetal brain (fetal alcohol syndrome). It may have been unclear 100 years ago to which extent alcohol has chronic toxicity. Excessive chronic ethanol consumption is associated with dependency, peripheral neuropathy, brain damage, liver disorders, and increased cancer risk. When consumed by poor people in large quantities, alcohol may serve as major energy source, with the risk of malnutrition. Alcohol is associated with injuries, traffic accidents, and suicides.

Considering these adverse effects of alcohol, it may appear reasonable even today, to prohibit its use. But many people use alcohol moderately, without serious risk of dependency. And prohibition might again not be successful in many societies. According to the World Health Organization (WHO), countries have a responsibility of implementing and monitoring public policies to reduce the harmful use of alcohol and to apply evidence-based reduction measures (WHO 2018, 2021). The WHO program offers skillful tools with elaborate and evidence based indicators on reducing the negative consequences of drinking and alcohol intoxication and reducing the public health impact of illicit or informally produced alcohol. So this approach is more differentiated than a plain prohibition.

---

## Smoking, Tobacco

In the 1970s, smoking was common in the public. Smoking was considered by smokers as a sign of independence and emancipation. Smoking was normal at the workplace, in restaurants, in airplanes even in hospitals. Few exceptions existed where smoking was not allowed, for example, near fuel stations.

Over time, individuals and NGOs who felt annoyed by cigarette smoke and restricted in their right for clean air started to organize campaigns against smoking. Initially this was not very successful, not least because the tobacco industry supported research projects related to cancer studies, with the consequence that numerous experts in the field had no interest to oppose tobacco industry; some of them were smokers themselves.

Advertisements for tobacco products continued to be obtrusive, like the depiction of a young woman saying “I like smoking.” This was not tolerable, considering the

increasing knowledge about the adverse health effects on smokers, female smokers, and pregnant smokers.

A tough battle between a powerful tobacco industry and nonsmoking campaigns started. The nonsmokers argued that active smoking should be forbidden, considering tobacco is the number one toxic agent in daily use, causing atherosclerosis, lung cancer, and many other disorders. Smoking should also be forbidden because even passive smoking leads to adverse health effects in nonsmokers. In addition, many people suffer from the irritating effects of tobacco smoke on eyes and respiratory tract.

Over time, the freedom of smoking gradually became more restricted. Initially, it was prohibited to smoke at the workplace, in restaurants, and in public buildings. At the beginning of the 2000s, many countries had introduced laws that led to relevant reductions of tobacco-related risks. The debate continues, and pediatricians want to prohibit smoking in cars and homes in the presence of children.

In Europe, the Tobacco Products Directive (2014/40/EU) entered into force in 2014 and became applicable in EU countries in 2016 (EU 2021). It prohibits cigarettes and roll-your-own tobacco with characterizing flavors (that might seduce young people to start smoking because of a pleasant scent), requires health warnings on tobacco-products, allows EU countries to prohibit Internet sales of tobacco and related products, and contains many more restrictions.

---

## Chemical Weapons

In World War I, the German army was the first to use in 1915, vaporized chlorine, a lung-toxic gas, and in addition, from 1917 on, the vesicant sulfur mustard, a corrosive agent that produces burns of the skin, irritation of airways, and lung destruction. This use of a chemical weapon was in violation of the Geneva Convention of 1864 and the Hague convention of 1899. Following World War I, the Geneva conference (1925) banned the use of all forms of chemical weapons.

In 1932, the neurotoxic action of organophosphates was detected. This led to the development of a large group of substances used as insecticides, but also to the development of very highly toxic nerve agents, such as sarin, tabun, and soman. These were produced in Germany during World War II, but not used. These nerve gases, and some newer analogues, are acutely debilitating when inhaled, often with fatal outcome or long episodes of recovery under intensive care conditions, with atropine being administered as an antidote.

The invention of these new types of agents was one of the reasons for the Chemical Weapons Convention that entered into force in 1997, headed by the Organization for the Prohibition of Chemical Weapons (OPCW) in The Hague, Netherlands (OPCW 2021). It has the mandate to stop development, production, stockpiling, transfer, and use of chemical weapons; ultimately to eliminate chemical weapons and to prevent their re-emergence. Its international inspection teams visit facilities, where chemicals are produced that might be either precursors or the final chemical weapon products. The prohibition of chemical weapons is a great step

## Prohibition in International Conventions and Organizations (Examples)

Conventions on Narcotic and Psychoactive Drugs (UNODC 2013)  
Stockholm Convention On Persistent Organic Pollutants (UNEP 2004)  
Paris Agreement on Limitation of Global Warming (UN 2016)  
Minamata Convention on Mercury (UNEP 2017)  
Basel Convention on ... Hazardous Waste movement... (UNEP 2019)  
Rotterdam convention on... hazardous chemical / pesticides in trade (UN 2019)  
Treaty on the Prohibition of Nuclear Weapons (UNODA 2021)  
Organisation for the Prohibition of Chemical Weapons (OPCW 2021)  
World Anti-Doping Agency (WADA 2021 )  
REACH legislation (ECHA 2006)

**Fig. 4** Examples for International conventions, agreements and organizations, that focus on prohibition and restriction of hazardous chemicals, chemical weapons, and/or drugs

forward towards international cooperation and humanity. OPCW received the Nobel Prize in 2013. In addition to OPCW, there exist various other international conventions and agreements that focus on prohibition (Fig. 4).

---

## Mercury

The metals mercury, lead, and cadmium had wide applications in the past. All of them were already known in antiquity. Lead, for example, was used for lead pipes, pigments and since about the 1920s as antiknocking gasoline additive. As a consequence of human intoxications and environmental contaminations, the use of these metals was gradually restricted. Mercury will serve as example for a continuing process of restrictions and prohibitions.

Mercury sulfide (cinnabar) is the predominant mercury-containing ore, from which mercury is released by heating. Metallic mercury and most mercury compounds are very toxic, notably to the brain. However, in the past, mercury and mercury compounds had many applications.

## Technical Uses

Mercury was historically used in large amounts for gold and silver extraction and until today it is used in small-scale gold mining, often under terrible hygienic conditions.

Mercury is a component of thermometers, manometers and many other measuring instruments, calomel electrodes, and in mercury batteries (widely prohibited after the 1990s). It is used as catalyst in chemical processes.

Mercuric chloride solution has been used as timber preservative (kyanizing). The soil of the treatment areas became mercury-contaminated and the sites are considered as Brownfields.

Methylmercury has fungicide activity and was used among others to preserve seeds. In 1971, a large tonnage of wheat and barley seed, treated this way, was accidentally consumed in Iraq. Hundreds of people died, survivors suffered from chronic neurologic disorders. Methylmercury is toxic to the developing brain. It is transferred via the placenta to the developing fetus. This was one of the catastrophic events that later led to the ban on mercury for such applications.

## Medical Uses Earlier and Now

Elemental mercury, when ingested, is poorly absorbed. Elemental mercury was previously used to treat acute intestinal obstruction. Mercury was also the main component of “beauty cream” used to lighten the skin and is still found in the markets of some regions in the world (FDA 2016).

Mercury(I)chloride ( $\text{Hg}_2\text{Cl}_2$ , calomel) is poorly soluble and less toxic. It was used as laxative and diuretic.

Mercury(II)chloride  $\text{HgCl}_2$  (corrosive sublimate) is water soluble, tends to sublime, and is very toxic. It has been in use as antiseptic and to treat syphilis for 500 years. The mercury therapy often led to chronic inhalative mercury poisoning. It was abandoned, when the first effective antimicrobial agent, salvarsan, became available in 1910.

Mersalyl is an organomercury compound that was formerly used as diuretic as it acts on renal tubules and decreases blood pressure and edema. Today it is still used in biochemistry as an agent that protects sulfhydryl groups in proteins.

Merbromin, a mercury- and bromine containing red-colored organic substance, was used in aqueous solution as powerful disinfectant for wounds and burns. When analytical methods became available for measuring mercury in blood, it was noticed that merbromin treatment increases mercury levels in the blood. This was a major reason for the US FDA to declare it not safe for general use in 1998. It was thereafter withdrawn from the markets in several countries, partly without the need for explicit prohibition, because the producers were not able to proof the safety in comparison to alternative disinfectants.

Thiomersal, an organochlorine compound, is used in small concentrations as a preservative in vaccines. Near the end of the last century, there was some concern that it might induce autism. However, WHO came to the following conclusion: “Based on the current evidence, GACVS considers that no additional studies of the safety of thiomersal in vaccines are warranted and that available evidence strongly supports the safety of the use of thiomersal as a preservative for inactivated vaccines” (WHO 2012).

Mercury amalgam tooth fillings were state of the art until the 1990s. They have the advantage of not requiring sophisticated technical equipment and being cheap for people who cannot afford more elaborate fillings. Tooth amalgam is very insoluble, but corrodes over time and releases tiny amalgam particles that may be swallowed. Because of their low solubility and rapid passage through the gastrointestinal tract, these are believed not to contribute in relevant amounts to the internal load. Nonetheless, people with amalgam fillings tend to have elevated mercury levels in the blood, dependent on the amount, quality, and age of the fillings. This is thought to occur via the inhalative pathway. This finding, together with the risk of exposure for dentists and their coworkers and the problem of environmental contamination, led to the initiation of campaigns against dental amalgam, which resulted in restrictions. These may differ between countries. A recommendation in the Minamata convention suggests to prefer mercury-free dental restoration (UNEP 2017).

## Mercury and the Environment

Metallic mercury that is spilled indoors and not removed will evaporate and result in long-lasting elevated indoor air concentrations, a risk for those who live or work in these rooms.

Environmental mercury in soil and water is gradually converted by plankton and microorganism to methylmercury. This is a very lipophilic substance that accumulates in the nutrition chain, typically in fish of mercury-contaminated waters, ultimately constituting a relevant source of mercury for fish-consuming humans. Some countries have developed recommendations for pregnant women, to reduce consumption of larger fatty fish, in order to minimized exposure to methylmercury (and POP).

## Mercury Regulations

As outlined, mercury had widespread applications until the middle of the last century when evidence for adverse mercury contaminations and mercury levels in the human body and the environment could be analyzed with increasing precision. Decades followed when mercury containing products were prohibited or restricted step by step. Mercury may serve as an example for multiple regulations (restriction and prohibition) on national and international levels. For example, the EU set maximum levels for mercury and many other contaminants in foods (EU 2006). The Minamata Convention on mercury provides insight into the dimensions of the mercury problem and its suggested regulations (UNEP 2017). The convention is a global treaty to protect human health and the environment. It is named after the mercury incidents in Minamata Bay, Japan. It was adopted in 2013 and entered into force in 2017. It includes a ban on new mercury mines, the phasing-out of existing mines, and reduction of mercury-containing products, processes, and waste, as well as surveillance of emissions and exposures.

The Global Mercury Assessment (UNEP 2018) is a collection of worldwide data on mercury emissions and exposures. It provides a departing point, which will allow to estimate the effects of prohibitions and restrictions in the future.

---

## Persistent Organic Pollutants (POP)

The Stockholm Convention (UNEP 2004) is a global treaty to protect human health and the environment from persistent organic pollutants (POPs). POPs are chemicals that remain intact in the environment for long periods, become widely distributed geographically, accumulate in the fatty tissue of living organisms, and are toxic to humans and wildlife. POPs circulate globally and can cause damage wherever they travel. In implementing the convention, governments will take measures to eliminate or reduce the release of POPs into the environment. Over 152 countries ratified the Convention and it entered into force in 2004.

The Stockholm Convention has elements of prohibition and of restriction for each of the persistent organic pollutants (POPs), listed in the Annexes of the convention. DDT, PCBs, and PCDDs are members of the original list of 12 regulated substances. Many other organochlorine substances and nonchlorinated substances are currently on the list (UNIDO 2021).

We take here lindane (hexachlorocyclohexane) as an example. Lindane was formerly widely used in many countries as insecticide to eliminate mosquitos and bugs. Production and agricultural use is now banned in the countries that are Parties to the Stockholm Convention. However, lindane may be used as second-line medical treatment for ectoparasites on and in the human skin (lice and scabies) when other agents are ineffective or not tolerated. In most countries, today, the first choice insecticide for this application is permethrin. Lindane should be used with caution, notably in children, because of absorption via the skin, accumulation in tissues, long half-life, and neurotoxicity of the agent.

DDT (dichlordiphenyltrichlorethane) was synthesized already in the nineteenth century. Its insecticidal action was discovered in 1939 by the Swiss chemist Müller, who was awarded the Nobel prize for discovering this very efficient contact poison against insects. DDT came to market in 1942 and was rapidly found to eliminate malaria by killing the anopheles mosquito.

DDT is a chlorinated organic compound that is very lipophilic and resistant to degradation in the environment and indoors, meaning that it persists for a long time, once sprayed on surfaces. This is an application-advantage. In humans, it is subject to metabolic transformation to DDE and DDD, which then both accumulate in the body fat and in milk fat and are thus transferred to babies. DDT also induces cytochrome P450 and is a tumor promotor.

Already in 1962, Rachel Carson wrote in her book “Silent Spring” about the dangers of chemical pollution. She argued that the number of fish eating birds decreased, because DDT accumulated in fish through the food chain which seemed to make the eggshells thinner and more fragile. Carson wrote just a booklet not a high-level publication. Nevertheless, her argumentation received much attention

**Fig. 5** Formation of the by-product 2,3,7,8 tetrachlorodibenzodioxine. The herbicide 2,4,5-trichlorophenoxyacetic acid is synthesized in a reaction of 2,4,5-trichlorophenol with 3-chloropropionic acid, where two molecules of 2,4,5-trichlorophenoxyacetic may combine to the minor by-product 2,3,7,8-tetrachloro-dibenzodioxine, which occurred as a contaminant of the herbicide

among environmentalists at the time, and the DDT-dilemma resulted in a ban of DDT for agricultural uses in the United States in 1972 and was one of the arguments that led to bans in many other countries.

However, at the same time, DDT was still considered an important agent for fighting insect-borne disease in various countries. Although basically banned in the Stockholm Convention, it received an exemption for disease vector control in specific circumstances. Meanwhile there is some evidence that the thinning of eggshells may be due to the hormonal effect of DDT.

TCDD is not an industrial chemical. It has never been produced for an application, but became known as an unintentional by-product of certain chemical reactions. It occurred as contamination in the defoliation agent “agent orange,” a mixture having 2,4,5-T and 2,4-D as active herbicides (Fig. 5) that was used in the Vietnam war and resulted in TCDD contaminations of plants, fields, domestic animals, adults, and babies (via mother milk). TCDD is also a very common side product of incineration processes when chlorine-containing organic material is heated in the presence of oxygen. TCDD is the most toxic and best known congener in the family of polychlorinated dibenzodioxines.

## Biocides

The group of insecticides includes chlorinated organic compounds, organophosphates, carbamates, pyrethroids, and neonicotinoids. All of them are neurotoxic to insects and to humans. Many members of these biocides have been prohibited for different reasons, including residues on edible crops, persistence in the environment, contamination of ground water, unintended extinction of useful insects like honey bees, as well as risks of acute neurotoxicity to workers and elevated risks of suicidal application.

**Fig. 6** Structures of the natural substrate phosphoenolpyruvate of the plant-enzyme 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase and of the competitive inhibitor glyphosate. EPSP synthase has as a second substrate shikimate-3-phosphate (not shown). The reaction product is a precursor of essential aromatic amino acids in plants

Neonicotinoids are a comparatively new group of insecticides. They are very effective in insects. There was an extensive discussion about their negative effects on honey bee colonies. Neonicotinoids are widely banned in the European Union from 2020 on, but there are exemptions for certain applications (EU 2020b).

Another group of biocides are the herbicides, intended to suppress growth of weed. One of the most controversial biocides is glyphosate. It was introduced in 1975 as herbicide that is specifically toxic to plants, bacteria, and fungi, but not to animals. Glyphosate inhibits competitively the enzyme 5-enolpyruvylshikimate-3-phosphate synthase, which does not occur in animals, but is member of an essential biochemical pathway in bacteria, fungi, and plants (Fig. 6). Its inhibition leads to a deficiency of aromatic amino acids, and thus, to death of plants. Glyphosate is widely used in agriculture to combat weeds that compete with cultivated crops, but also for other reasons like keeping railway tracks free from overgrowth. Glyphosate is usually applied before crops are sown and/or in combination with genetically modified, glyphosate-resistant crops. Glyphosate minimizes the need to use ploughing machines.

The International Agency for Research on Cancer (IARC) classified glyphosate as “probably carcinogenic to humans” in 2015. Thereafter, a never ending dispute between those, supporting this classification, on the basis that very high exposures of humans has been found to be associated with multiple myeloma and others, who found no evidence for carcinogenicity (Andreotti et al. 2018). This situation led to diverse regulatory responses in different countries. The situation for regulatory agencies is complex because, first, the risk assessment results of IARC are usually not put in question, and second, because some see a major risk of glyphosate in the concomitant use of genetically altered crops and a risk for the future of global agriculture. They oppose the use of genetically resistant crops and anticipate damage

to biodiversity (no wild plants = no bees and insects = no animals that would feed on insects. ...) and contamination of soils and ground water.

Glyphosate is currently approved in the European Union until December 2022. It can be used by member states until this date, subject to each plant protection product being authorized by national authorities following an evaluation of its safety. Thereafter, it is intended to initiate a renewal process for future approval of glyphosate in the European Union (EU 2020a). Germany intends to prohibit glyphosate from end of 2023 (BMU 2021).

---

## Food, Drinking Water

Food is a potential source for chronic intake of toxic substances. These can occur as natural ingredients of a food (lectins in beans), contaminants (aflatoxin on poorly stored rice), pesticide residues, food additives, or intentionally added substances, used to adulterate a food (e.g., melamine addition to milk in order to imitate a high protein level). Numerous prohibitions and restrictions exist, often defining maximum levels (EU 2006, 2011). A network of controlling agencies with well-equipped analytical laboratories was established in many countries which are specialized in detecting substances that are prohibited or regulated in foodstuff.

An example for the regulation of natural plant products is the pyrrolizidine alkaloids that occur in many plants and to which humans may be exposed via certain teas and leaves. When ingested, they are metabolized via reactive intermediates that are genotoxic and hepatotoxic. Maximal levels of pyrrolizidine alkaloids were defined in various foodstuffs, notably tea and some herbal products (EU 2020c).

Similarly, drinking water may become contaminated in various ways, including geogenic substances (e.g., arsenic), contaminants (such as nitrate from agricultural activity), residues (from plant protection agents), disinfection side products (from reactions of chlorine with organic substances in the raw water), or released materials from water pipes. The drinking water guidelines of the World Health Organization (WHO) provide toxicologically derived limit values (WHO 2017). In addition, technological aspects require consideration. Although drinking water is a relevant source for calcium in humans, it is common to limit the calcium content of drinking water in order to prevent calcification of pipes and washing machines.

---

## Regulations of Emissions and Waste

Since the Great Smog of London (1952), there were continuous technical improvements to reduce harmful emissions from industrial activities, homes, and automobiles based on effective filtering techniques. Regulations attempt to limit emissions and thus keep the outdoor air quality within reasonable levels. The standards differ from country to country. More recently, a focus of regulation has been nitrogen oxide emissions from diesel engines, ultrafine particles, photo-smog, and volatile organic substances.

Unresolved is the problem of carbon dioxide emissions. Carbon dioxide is not toxic at the still low atmospheric levels, but emissions contribute to the elevation of atmospheric temperature. Carbon dioxide is considered to be the most relevant anthropogenic factor that influences climate. The Paris agreement on climate change aims at reducing carbon dioxide emissions to an extent that would not result in further warming of the atmosphere (UN 2016). The concepts aim at replacing natural oil, gas, and coal by other energy producing technologies that do not emit carbon dioxide. However, this is a big challenge that will require lots of innovations in climate-friendly energy production with global cooperation.

Hazardous waste, environmental plastic, and electronic waste provide an ever increasing problem, notably in the high-throughput, throw-away societies that accumulate endless masses of waste. The Basel convention on transboundary hazardous waste control (UNEP 2019) attempts to find ways out of some of these dilemmas.

---

## Nuclear Weapons

The treaty on the prohibition of nuclear weapons entered into force in 2021 (UNODA 2021). The treaty aims at sustainability and prevention of nuclear wars. Though physical aspects are in the focus, it also is of radio-toxicological relevance, considering possible exposures during isotope enrichment and separation, or, in the case of an incident, the acute- and chronic exposures to radio nucleotides by inhalation (iodine) or ingestion (cesium). By 2021, those countries that possess nuclear weapons and some of their partners did not sign the convention. Nevertheless, it is the hope that the convention will develop into a general agreement that results in the step-wise elimination of nuclear weapons.

---

## REACH and Restrictions

REACH is a regulation of the European Union that stands for Registration, Evaluation, Authorization and Restriction of Chemicals (ECHA 2006). It entered into force in 2007. It is very voluminous and considered one of the stricter regulations.

REACH has the aim to protect human health and the environment from risks, posed by chemicals. It also aims at reducing tests in animals. The most hazardous substances should be substituted with priority by less dangerous ones. The standard process is via registration. Substances of very high concern (notably carcinogenic, mutagenic, reprotoxic) may require an authorization in order to be placed on the market (ECHA 2021).

The British government has issued in connection with the EU exit, the domestic UK-REACH Regulations (UK 2020), which are largely congruent with EU REACH (ECHA 2006), with changes to make it operable in a domestic context. The key principles of the EU REACH Regulation have been retained. From 2021 on, the EU REACH and UK REACH work independently from each other. This demonstrates that regulations are in a continuous, dynamic flow.

---

## Summary

A huge number of laws and conventions aimed to prohibit chemicals and drugs have been established since the 1980s, many of them after 2000. The word prohibition may sound authoritarian to some, and related terms are often used such as “banned,” “not allowed,” “forbidden.” The setting of rules for chemicals is extremely complex. It restricts essential interests, such as protection of property, freedom of trade, and freedom of individuals, in the interest of human health and preservation of the global environment. Toxicology as a basic and applied science is of imminent importance for the management of these processes. With the definition of limit values, toxicology provides the basis for safe and acceptable solutions. These processes have to continue, considering the upcoming new challenges, like biopharmaceuticals, nanoparticulate matter, waste accumulation, and global pollution.

## Abstract

Awareness has increased that subgroups in the population may exist which respond with a higher susceptibility than the majority of the population when setting health-based threshold values or assessing MOS (margin of safety) values. It is not an easy task to take increased susceptibility into consideration. Even if we know or at least have some indications that, for example, new-borns might be more susceptible than adults, it is hard to account for the difference in terms of numeric figures because of incomplete data.

**Keywords**

Specific subgroups in the population · Neonates · Elderly · Unborn child

---

**Introduction**

When assessing substances or exposure situations, for example, accidental release of dangerous chemicals, it has to be considered whether in the remit of the assessment, susceptible subpopulations may exist. If so their specific situation has to be reflected in the assessment and the measures taken. Potential sensible subgroups are the unborn child, the neonates, the elderly, and the subjects with allergic conditions.

**Are Susceptible Subgroups Protected by the Default Safety Factors?**

Intraspecies variability and susceptibility has to be taken into consideration when setting health-based threshold levels like ADI (accepted daily intake) values for pesticides. The conventional default value of 10 has been introduced by JECFA (Joint Food and Agriculture Organization – World Health Organization Expert Committee on Food Additives) in the 1950s and was taken up by Joint Food and Agriculture Organization – World Health Organization Meetings on Pesticide Residues (JMPR). The default factor of 10 was subdivided in a factor covering variability in toxicokinetics and a subfactor covering variability in toxicodynamics. It has been proposed to allocate equal factors of 3.14 for both parts of the total factors. Other scientists proposed to use a subfactor of 4 for the toxicokinetic and a subfactor of 2.5 to cover variability in toxicodynamics. Retrospective analysis of data from clinical studies shows that the factor of 10 is sufficient to cover intraindividual variability with the exception of cases in which the drug is metabolized by a polymorphically expressed enzyme (e.g., CYP 2D6 or CYP 2C18). As the data were mainly from phase-I studies in which health young adults with predefined body weight and body height take part, the variability of the general population may be greater than in the population of young healthy adults.

**Specific Groups and Regulations**

The need to consider special subpopulations is laid down in several guidances for risk assessment and for the use of the TTC (threshold of toxicological concern) concept (EFSA et al. 2012, 2019). However, there is no general factor to be used and a case-by-case consideration is recommended.

When deriving the ADI, consideration is given to population groups above 16 weeks of age only. It is only recently that a specific risk assessment is performed for infants below 16 weeks concerning food additives which are allowed to be used in formulas such as modified starch.

**Table 1** Examples for specific regulation for children

Regulation	Specific parameter
Ordinance on toys for children	Heavy metals
Order on dietetic foodstuff	Organochloro- compounds
Protection of minors	Alcohol
Drug law	Specific doses for children, contraindications

In Germany, the protection of children is explicitly expressed in several regulations. Table 1 gives some examples.

A second group which is often mentioned as being specifically sensitive is the group of pregnant women. It should be born in mind that it is not the pregnant women who is the sensitive subject but the unborn child whose development when exposed to environmental may be impaired.

Other groups are the elderly which are mentioned when discussing about specific sensitivity towards exposure against chemicals, the female population in general, and asthmatics. The drug legislation foresees specific trials for children. Elderly and women have to be included into the trial population and their data may be requested to be analyzed separately. In the following part, we will discuss the state of the knowledge including also subjects with impaired excretory organ function.

---

## Specific Sensitivity in Different Life Periods

### Prenatal Period

Birth defects due to prenatal exposure towards chemical substances, drugs, infections, and other environmental influences are the main causes for mortality in early life. Drugs which are known to cause birth defects are among the groups of cytostatic drugs, sex hormones, anticonvulsives (such as valproic acid), and antipsychotics. Intrauterine infections which can cause birth defects are rubella, cytomegalovirus infections, syphilis, and toxoplasmosis. Radiation at higher doses may cause structural abnormalities of the brain and the eye. Exposure against some chemicals and environmental agents during pregnancy has been described as causing birth defects. Organic solvent sniffing may cause craniofacial abnormalities, similar to the syndrome after alcohol abuse in pregnancy. Further defects are associated with glycol ethers and alcohol abuse such as microcephalus and intellectual impairment. Some other agents have been imputed. The data are however inconclusive including pesticides exposure and arsine exposure. Also, the exposure of the father has been imputed to be causally related to birth defects without clear results (tobacco, grass, pesticides, anesthetics, and lead).

It is however beyond doubt that smoking, even secondary smoke during pregnancy, is related with low birth weight.

The influence of intrauterine exposure towards chemicals on the development of cancer is controversial in most of the cases. Diethylstilbestrol is known as causing vaginal carcinoma in young adults, 20 years after intrauterine exposure.

## Age up to Six Months

In this period starting at birth, toxicokinetic differences are well documented. The activity of most of the CYP enzymes is lower at birth, maturing during the first 6 months and reaching the level of the adult within the first year. The enzyme proteins for phase-II conjugation reactions are expressed whereby for some glucuronyl transferases, the levels at birth are at the adult level, for others a reduced capacity is known (e.g., UTG 1A1 or UTG1B15). As far as known today, sulfation is fully expressed at birth, whereas activity of acetyltransferase may reach adult levels only at the age of 2. Absorption through skin is enhanced due to the reduced thickness. Distribution of substances is different because of the lower relation between fat and body weight and the higher relation between water and body weight. In the first weeks, the blood/brain barrier is not anatomically developed which plays a role in the development of “kernicterus” in the newborn where physiologically a high turnover of erythrocytes containing the fetal hemoglobin in newborns leads to high bilirubin levels. In cases of different blood groups between mother and child, the incompatibility leads to lysis of erythrocytes. The high bilirubin levels in conjunction with the impaired ability to conjugate bilirubin to bilirubin glucuronide and the impaired blood/brain barrier are components of the enrichment of bilirubin in cerebral structures such as basal ganglia and brainstem nuclei. The status “kernicterus” may lead to severe neurological deficit and even death.

The renal function as measured by glomerular filtration rate is reduced up to 50% in early life and is gradually increasing to the normal level within the first 6 months. The physiological changes are all in the direction that the elimination and excretion of xenobiotics is prolonged which at the same level of exposure leads to higher internal exposure when compared with the adult. Depending on whether the parent compound or the metabolite is the toxic agent, this may result in a high (parent compound is the toxic agent) or lower (metabolite is the toxic agent) sensitivity. Brain, bones, immune system, and endocrine and reproductive organs are developing in the postnatal period over years. Thus, specific susceptibility can be present also after the first months in life. In particular the development of the brain is a highly susceptible physiological process which might be critical. In this respect, lead and also PCBs may play a role in negatively influencing intellectual capacity. The specificities of this age group and how to consider them in the risk assessment are explained in detail in the EFSA Guidance on the risk assessment of substances present in food intended for infants below 16 weeks of age (EFSA SC et al. 2017).

## Child and Youth

The kinetics in these age groups is not much different from the kinetics in the adults. In school-aged kids, the metabolizing enzymes are rather highly expressed so that the clearance is somewhat higher than in adults. It is to be noted that windows of development exist during which exposure towards chemicals may have negative influences. Continuously developing organs are the brain (influence of marijuana?) and bones. Closure of epiphyses can be influenced by chinolones. The immune system is developing until the age of young adults. Exposure towards some chemicals might negatively influence the development of the immune system. Among the chemicals imputed to cause immunotoxicity are organotin compounds, pesticides (methoxychlor, heptachlor), and polyhalogenated aromatic hydrocarbons (e.g., 2,3,7,8-tetrachlordibenzo-p-dioxine). A special awareness has been raised for the exposure towards compounds exhibiting sexual hormonal activity, so-called endocrine active substances. There is no doubt that high exposure levels can influence the sexual development in animals; the effect of much lower exposure levels in the human population is not yet finally assessed.

## Elderly (>70 Years of Life)

Physiological functions may be caning with increasing age whereby the variability of these processes is extremely high. Generally, the excretory functions are declining with age. Liver mass as well as liver blood flow are slightly reduced in high age (mass, reduction of 17% between the age of 20 and the age of 80 years; liver blood flow, reduction of 0.3–1.5%/year). Reduced liver mass and liver blood flow may cause a reduced metabolic clearance of chemical compounds. Depending on whether the parent compound or the metabolite is the toxic agent, this may result in a high (parent compound is the toxic agent) or lower (metabolite is the toxic agent) sensitivity. The renal function measured by glomerular filtration rate is also a function of age. The physiological change is a reduced renal blood flow (2%/year) and a reduced renal organ mass (up to 30% in the very elderly). Substances which are excreted by the kidneys (e.g., perfluorooctanoic acid, PFOA) are much slower excreted. It should be noted that at the same external exposure level, a twofold higher internal exposure will result if the renal function is reduced to 50%.

On the toxicodynamic field, there are some observations showing a reduced number of receptors. This concerns beta-receptors, alpha-2 receptors, and insulin-, glucagon-, steroid-, dopamine-, and prolactin-receptors. The results, if transferred to the *in vivo* situation, should result in a lower susceptibility. Whereas for some effects (effect of beta-blockers, effect of insulin), data in humans and animals are available, no generalization can be made, and for chemicals this field is not yet studied in detail.

---

## **Pregnancy**

It is well known that the body of the pregnant woman undergoes physiological changes with an increased blood volume, body weight, and hormonal changes. Nevertheless, the difference between pregnant women and nonpregnant women for three substances (caffeine, midazolam, and metoprolol) is not more than a factor of two. Hence, major and important changes are not present.

---

## **Influences of Diseases**

### **Impairment of Excretory Organs**

Impairments of excretory function in liver or renal diseases are the same as described for the very elderly. At the same level of external exposure, the level of internal exposure is several times higher as compared with healthy subjects, potentially causing an increased effect. Theoretically, in patients with reduced lung surface such as in emphysema patients, the reduced surface should lead to a reduced internal exposure. On the other hand, substances which are excreted by exhalation should accumulate in these patients. However, there are no data confirming the theoretical considerations. It is known that in emphysema patients and in patients with asthma, chemicals acting on the airways have an increased effect (“higher sensibility” of these patients).

### **Other Organs**

Systematic studies are not found in the literature. It is to be inferred from biology that patients with impaired bone marrow due to pretreatment with cytostatic drugs may have an increased effect from chemicals acting on the blood and bone marrow such as benzene. Likewise, patients with impaired immune function either inborn or due to treatment with immunosuppressive drugs may be at a greater risk than healthy subjects exposed towards immunotoxicants. In the current risk assessment, no special considerations apply for subgroups with preexisting conditions.

---

## **Gender-Specific Aspects**

Physiological differences are obvious between males and females. Different chromosomal status and hormonal levels determine the phenotypic body appearance, in particular in the adult life. Men do have higher mean body weights and higher mean height when compared with the mean values for women. The body composition differs in such that men have a greater muscle mass in terms of proportion of their body weight, whereas women do have a greater proportion as fat mass.

The hormonal situation in women is characterized by cyclic changes in the estrogens and gestagens in the lifetime between menarche until menopause; in a great number of women using hormonal contraception, the situation is changed. During pregnancy the level of hormones increases from about 50 pg/ml (ovulation) to 25 ng/ml in week 40 of pregnancy; this is a factor of 500. In the menopause, the sex hormonal levels are declining. In males extreme changes in sex hormonal levels are not known.

Gender-related differences of metabolizing enzymes are known; they are, however, not impressive. The activity of CYP3A4 is some 20% higher in women as compared to men. There are subtle changes of hormonal influences on CYP 1A2 activity as the half-life of theophylline and caffeine may be different within the cycle, and men do have a bit higher activity of CYP1A2. As the changes and differences are rather small, they are covered in the intraspecies factor of 10.

In animal studies, we know some sex-specific reaction and the results of studies have to be assessed cautiously. Renal tubular damage related to  $\alpha$ 2-microglobulin excretion is found in male rats only, and the finding is without relevance for the human, males, as well as females. On the other hand, breast tumors in female rats are difficult to assess with respect to the relevance for humans as it is the leading tumor in females. It may also occur in men, however, only in rare cases. Carcinoma of the prostate and mesothelioma of the testes are clearly only occurring in males. Thus, findings in animals are difficult to interpret.

Although physiological differences and sex differences in susceptibility and findings in animals exist, we do not know similar differences towards chemicals, with the notable difference of sex hormones. At present, the effect of endocrine active substances is hotly debated. The question remains unresolved until now whether these substances in environmental concentration may negatively impact male fertility. Also the increase in breast cancer in females has been discussed in the context of exposure towards chemicals with estrogenic activity present in the environment.

Recently, gender-specific aspects are taken up in developing drugs and treatment of diseases (Legato 2017).

**Abstract**

The question of whether or not a substance should be classified as toxic could in certain cases be a question of life or death. Despite or because of this importance, this critical question is surprisingly hard to answer, since many different aspects, which may influence the toxicity of a compound, have to be considered. In addition, scientist or authorities with a differential expert knowledge and years of experience might differently interpret registered compound-related effects. Thus, writing of an unbiased toxicology report might be the best way of evaluating the toxicological significance of a given compound. Such a report should aim at presenting all collected raw data, the way of calculating the statistical significance, an evaluation of the potential health risks associated with the exposure to a defined compound, and the complete related literature. Then, in the best case, such a toxicological report answers the question about a possible toxic effect of a given substance or at least is the basics of further analysis or investigations. Although every toxicological report is unique and requires adjustment to the predefined study design, one has to keep in mind that such a report in some cases represents the base of legislation or in the worst case can make the difference between life and death. In this review, we give an overview of scientific, industrial, and consumer-related toxicological reports; summarize essential knowledge and key changes regarding exposure, poisons, and poisoning; and indicate contents, which are required to evaluate the toxicity of a tested compound.

---

**Key Points**

*Toxicologists may be asked for their expertise in academic, criminal, labor, social, and civil affairs.*

*Typical starting points for expert reports are private or public service remits, sometimes also a court direction for evidence, which is mandatory and specific to the expert.*

*An expert report has to meet typical requirements in form and content as outlined below.*

---

**What's New?**

Since the release of the first edition, several changes have gained impact on how we discuss, communicate, and report toxicology-related findings and conclusions. However, in spite of almost a decade of scientific advance, there is still no generally

consented standard on what should be included in the Toxicology Report and how it should be presented. Some organizations have implemented their own layouts, and we will present a few of them.

This chapter summarizes essential knowledge and key changes regarding scientific, industrial, and consumer-related reports on exposure, poisons, and poisoning. The revision of several regulations dealing with classified and public information has reshaped the typical way to write and comment on toxicological findings and health hazards. A great deal of toxicological expertise is required in court. However, this extensive field of forensic toxicology is mostly beyond the scope of this chapter, and the inclined reader is referred to special publications outlined in the “[Further Reading](#)” section.

---

## Expert Requirements

A toxicologist is a respected expert. Advanced education is required, and several years of professional expertise is the typical outset to become a toxicologist. Former training programs saw many adepts emerging from medical specialties like pharmacology, occupational health, and hygiene, but a web article by Jennifer Alyson (<https://work.chron.com/duties-toxicologist-16885.html>) states that a bachelor’s degree in biology, biochemistry, chemistry, or environmental science currently characterizes the majority of applicants. Not surprisingly, according to a recent publication of the Society of Toxicology (SOT), the world’s leading group of toxicologists, most graduates specializing in toxicology find their jobs in industry, academia, and agencies that are government-related or work for nonprofit organizations dealing with environmental health or workplace and consumer safety (Fig. 1).

Toxicologists working in various fields after graduation often join one or more of the major societies, associations, and networks worldwide, where they find early information on emerging issues and support to organize their Reports according to specific needs. Table 1 lists the major associations (and their websites) where experts gather to communicate, discuss, and elaborate on the latest toxicology challenges and controversies. These communities are also best places where to get the most recent information about report requirements, standard layouts, and citation conventions. Apart from a deep understanding of the scientific foundations, a fundamental knowledge of the specific field of law is another important expert requirement. The expert should approach the subject and its related terms from the point of view of a lawyer, in order to be able to explain any investigations, methods, and results and communicate these findings in court. The dictionary of toxicological terms has been growing rapidly over the past 40 years, and even experts sometimes miss the mark when a concise distinction of terms is necessary. Another requirement is clear and unambiguous presentation – in written and oral form – of the details and facts pertaining to the case. Expert witnesses may be challenged by critical questions posed by the scientific community and legal authorities. Outside of academia, it is not the expert’s primary goal to come up with new hypotheses or to forward suspicions outside the realm of toxicology but to communicate the corroborated

findings in light of existing regulations. Finally, it is the duty of judges, attorneys, and lawyers to find out the truth.

Like any other expert in a field, a toxicologist must be independent, neutral, and honest. After receiving a formal, often legal request for a statement, toxicologists have to ensure that the issue falls within their scientific and technical competence. If this is not the case, a prompt informative reply to the client is mandatory. Once the toxicologist has accepted a request for a statement, she/he is responsible for the unbiased fulfilment of the job and is solely obliged to provide sound scientific reasoning based on the state of the art. An agreed expert's mandate is generally not negotiable.

---

## Report Types

The past years of toxicological practice have prompted the division of Toxicological Reports into parts: important types are the Toxicological Analysis Report and the Toxicological Assessment Report.

The Analysis Report deals with some specific results, usually of an experimental analysis, but increasingly also of *in silico* predictions, when computer simulations substitute for expensive, time- and resource-consuming measurements in the laboratory or on-site. When based on experimental data (measurements, observations), the report starts with a short description of the mandate. Next, it includes the (i) circumstances of sampling and specimen conservation; (ii) transport to the analytical site, if appropriate; (iii) handling and preparation steps for analysis; (iv) the analytical method and/or technique applied including negative and positive controls; (v) experimental data of various measurements and observations; and (vi) their statistical significance. Reports are typically prepared by the staff and laboratory experts who performed the analyses and who have a profound knowledge of the applied methodology and potential pitfalls.

The Assessment Report is typically based on various analytical findings or an epidemiological survey on the topic of interest. It starts with a description of the task and elaborates on the circumstances, which prompted mandating of the report. Since toxicological assessment mostly deals with hazards and risks related to human and environmental health, the report usually includes a list of identified hazards and their relevance for the underlying assessment. It then weighs the analytical findings or survey results in the context of available evidence and carefully cites relevant sources and rules.

It is considered good practice if Analysis Report and Assessment Report come from different sites in order to minimize conflicts of interest.

---

## Report Essentials

Traditionally, expert reports consist of at least two parts. Part I is the prologue in which the expert details all the facts that were known to him when arriving at the final statement. These facts include (i) the relevant parts of the disclosed file as received from the court or client, (ii) known facts of the medical history if individuals are involved, and (iii) obtained laboratory results with analytical data and/or specimens, clinical findings, testimonies, and any other relevant evidence.

Part II is the expert's assessment, which is based solely on evidence and findings that were elaborated on in Part I. It is a good habit to begin Part II with the question(s) that were asked to the expert. Any assessment should not come as a plain repeat of evidence and findings presented in Part I. It should also not only reiterate the contents of the filed information. Instead, it should contain the detailed reasoning – step by step – as to how the expert arrived at the

presented conclusions. These conclusions may be given as a statement followed by the relevant arguments and should be based on logical and scientific reasoning.

An optional third part that is highly recommended for complicated or large reports is a short summary in which the essential arguments and conclusions are presented as a concise fact sheet, preferably by repeating each interrogatory issue against the backdrop of the expert's answers.

Toxicological reports should be written in plain language that non-professionals are able to understand. The text should be comprehensible without sacrificing precision. Any special medical or scientific terms should be avoided or should be explained and referenced. This may be accomplished in parentheses or footnotes. For large reports, a glossary may be appropriate, and references should be made to it in the text.

---

## Required Basic Information for Experts

The toxicologist will be asked as an expert about relationships between exposure of one or more individuals to an identified or suspected health hazard or environmental situation. That is why any information about exposure is of utmost importance. It may already be included in the file of the court or client, or it will be determined by the toxicologist, based on his/her own investigations that are clearly presented in the report.

Of similar importance is the determination and assessment of any suspected toxic effects. These may be symptoms, diseases, epidemiologic findings, or environmental abnormalities. If the filed data include observations, statements, expert statements of medical specialists, environmental scientists, etc., these may be included in the toxicologist's reasoning. It is common practice to rank any relationship or association of identified causes and observed effects according to probability. Unfortunately, the English language uses different terms to measure certainty, and toxicologists face a dilemma in putting scientific data into the context of the official language used in court (Brodsky 2009). This is reflected in the three terms "likeliness," "likelihood," and "probability." Table 2 lists the various expressions that are being used to describe any causative or plausible link between an exposure and its outcome.

**Table 2** Degrees of likelihood

Impossible	0%
Possible	≤50%
Somewhat probable	60%
Probable	70%
Very probable	80%
With high probability	90%
With utmost probability	99%
With certainty	100%

## Reporting Toxicities

One of the most prominent tasks for a toxicologist is reporting toxicities. Whether you think of a new drug or a new consumer product one of the key questions is “How toxic is it?” Considering that a product might consist of several single compounds, the toxicologist faces the challenge to distinguish between the toxicity of each compound alone, any possible combination effects and of course of the entire product itself. Screening for toxic effects has many faces as overt toxicity may occur when the compound is ingested once in sufficient amount, but often repeated doses are required – sometimes in combination with the consumption of other food, e.g., grapefruit – to bring up hidden dangers for human health. In other instances, it turns out that it is not the chemical ingested which causes toxicity but a metabolite that arises from biotransformation in the liver – sometimes only after a critical induction period. Protective regulations have now been implemented in Western countries, which require that one has a rough estimate of the toxicity of the new substance before entering the market. In the USA, two governmental agencies, the Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA), take care that new materials are characterized regarding their toxicity before patients and consumers may benefit from their commercial availability. In Europe, the European Union and Switzerland have enforced standards for informing and protecting patients and consumers from various health risks that might ensue from the marketing of new materials. For the EU, the responsible authorities are the European Chemicals Agency (ECHA) and the European Medicine Agency (EMA), while the Federal Office of Public Health (FOPH) oversees new materials in Switzerland. In Canada, the government has Health Canada and the Chemicals Management Plan to protect its citizens, whereas Australia has implemented its National Industrial Chemicals Notification and Assessment Scheme (NICNAS) for similar purposes. Protective regulations are also effective in China, India, and many other countries. So, depending in which country one is to deliver a Toxicology Report, it is wise to contact local experts who are familiar with the effective regulations prior to writing up the Report. In this context, it might be noteworthy that toxic substances “do not know” borders or areas of jurisdiction. Hence, if distinct countries judge the putative harm of a substance differently, the less restrictive jurisdiction might allow the production/release of this substance, which could raise the concentration of this substance in adjoining areas above the limit acceptable to the responsible authorities. Thus, in times of globalization the Toxicology Report should not only address the needs of one jurisdiction but could also consider potential differences with adjoining authorities. This is where global standards come in handy.

ISO 10993 is an important harmonized international standard which regulates the amount and depth of toxicity screening required for approval or certification of medical devices. ISO 10993 lists several endpoints for a comprehensive screening (Table 3) of various devices. Be sure to comply with these regulations before performing and reporting on any testing procedures. In the European Union, all

**Table 3** Toxicological endpoints considered in ISO 10993

Cytotoxicity (in vitro)	Sensitization
Acute systemic toxicity (single dose)	Irritation/intracutaneous reactivity
Subacute/subchronic toxicity	Material-mediated pyrogenicity
Chronic toxicity (repeated dose)	Hemocompatibility
Genotoxicity	Implantation
Carcinogenicity	Degradation
Reproductive/developmental toxicity	

knowledge about toxicity of chemical substances is thought to be compiled in the REACH (= Registration, Evaluation, Authorization and Restriction of Chemicals) database which was put into effect in 2007.

ECHA may waive one or more toxicity data from the REACH dossier of a specific substance depending on the annual production and consumption figures, but usually the registrant must include data on various environmental risks (water, soil, air).

A special case of report is the toxicological characterization of natural and synthetic chemical substances in mixtures. This topic is discussed elsewhere in this book.

## Reporting Standards for Omics in Regulatory Toxicology

In recent years, it became increasingly important that toxicity, as described in a Toxicology Report, is not a physicochemical attribute of a given substance or mixture but the result of a more or less intense interaction between the substance and a biological organism. Work on 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), one of the most toxic industrial pollutants worldwide, has made this point very clear. TCDD may kill guinea pigs at a single dose of 1–2 µg/kg, whereas almost half of a hamster population may tolerate up to 3000 µg/kg and more (Hengstler et al. 1999). Modern omics (genomics, transcriptomics, proteomics, metabolomics) set out to incorporate that information and put it into perspective. It probably will not be long before qualified Toxicology Report will have to include a section on metabolic profiles to cover these interactions and their implications for human health and consumer safety. Only recently has the OECD Extended Advisory Group on Molecular Screening and Toxicogenomics (EAGMST) initiated a project to develop an Omics Reporting Framework specifically for regulatory toxicology issues. The metabolomics guidelines in the METabolomics standaRds Initiative in Toxicology (MERIT) are being advanced in coordination with expert groups to develop the OECD Transcriptomics Reporting Framework and Metabolomics Reporting Framework (Viant et al. 2019).

---

## Cause and Effect Relationships

There are different concepts of cause in various areas of science and jurisprudence. Essentially, jurisdiction and the theory of law differentiate between the theory of equivalence (in criminal law), the theory of adequate causation

(in general civil law), and the theory of essential conditions (social and insurance law). The theory of equivalence describes an action as causal with respect to its success, i.e., the intended action or observed effect, if and only if it cannot be omitted without obviating the specific success. In contrast, general civil law defines an action as causal with respect to its success if the specific circumstances would normally lead to this success, and not some rare, odd, or unlikely peculiarities that are not generally adequate and would have been ignored given the normal (natural) course of things or events. Additionally, the theory of essential conditions requires that a specific cause or event has substantially contributed to the observed “success,” e.g., a specific disability.

An example of forensic toxicology may clarify this issue. On a workbench, in his shed, a 60-year-old gardener has kept an aqueous solution of paraquat, a herbicide, in a glass bottle that would normally contain sparkling water. The original labels were removed, and there is a handwritten warning sign, but no other hint of the toxic content. In the absence of the gardener, a 16-year-old neighbor who by chance is the son-in-law of the gardener’s sister broke into the secured shed and by mistake took a great mouthful of the toxic water to satisfy his thirst. The ensuing lung edema, followed by a permanent pulmonary damage, eventually caused the death of the boy. The criminal trial is now to investigate the accident in order to determine if a case of familial homicide or a bodily harm with fatal consequences has occurred. The judge may decide that the gardener’s action was grossly negligent, because the paraquat solution caused the fatality, and gardener ignored necessary protective measures. Any civil court will approach the case in terms of due compensation, e.g., when asked whether the boy’s parents should compensate the gardener for the broken shed door, but may arrive at a similar decision since the break-in is a minor delict that would not normally lead to death, while the toxic drink does. Had the boy survived with a permanent disability, any social court would have attested a reduction in earning capacity. Again, the toxic drink was directly causal and not the illegal break-in.

## **Occupational and Workplace Issues**

Within a forensic framework, the court will define the precise questions that the Toxicology Report must deal with. Therefore, it is mandatory that the expert strictly adheres to these specific questions. A rather complicated issue is the elaboration of a causal medical assessment in terms of the social law. Quite often, this question arises if the underlying cause is an occupational illness. In such cases, insurance companies, e.g., the Accident Prevention and Insurance Association, may be obliged to provide fair compensation for health care and rehabilitation. Recognized occupational diseases are overseen by the International Labour Organization (ILO 2010). An occupational disease is accepted if the medical diagnosis has been confirmed, the exposure conditions have been unequivocally verified, and the medical evidence confirms cause and effect. The latter is usually agreed on if the causal relationship between exposure and disease has been assessed as probable. That is, there is more reason to argue in favor than against the assumed relation of cause and effect. Any

Toxicology Report that deals with occupational and/or workplace issues must reflect these considerations and provide a provisional answer about the likelihood that identified hazards and observed damages of health and safety are linked.

With regard to liability, law systems are quite different among countries of the European Union and may even be more different between the so-called G8 nations and other countries of the world. Employees may be protected against health injuries from workplace exposure, but to varying degrees. In the USA, the Division of Federal Employees' Compensation (DEFC) at the US Department of Labor will oversee compliance with the Federal Employees' Compensation Act (FECA) through its district offices, which are located throughout the country. In principle, the act treats permanent and temporary employees alike. However, the employee must provide medical and factual evidence to establish the essential elements of the claim, i.e., that the claim was filed within the statutory time requirements of the FECA, the injured or deceased person was an employee within the scope of the FECA, the employee suffered from an injury or disease, the employee was in the performance of duty when the injury occurred, and the condition in question resulted from the injury. If the injury has not been reported, no benefits will be paid. The restrictions on these reports are rather strict: If medical treatment is required, a special form has to be submitted – usually within 4 h of the request. Retroactive issuance is not permitted under any circumstances. If the damaging event was a toxic substance, the toxicologist will have to fill in the gaps and answer the questions put forward by the district officers. In Germany, for example, social courts have to decide if an employee will receive compensation for an acquired disease that has been linked to workplace exposure. If the disease is on the list of known occupational health problems, the Accident Prevention and Insurance Association (“Berufsgenossenschaft” in Germany) will cover any illness-related expenses (for therapy and rehabilitation, if appropriate). If the disease is not on the list, the worker's health insurance would have to pay the costs to restore the worker's health. Once a causal relationship between a toxic exposure and an observed disease has been established, but the disease is not (yet) covered by the International Labour Organization, there is an exemption clause that will allow the worker's condition being treated as an occupational disease although it has been shown that notification of an occupational disease may increase the risk of work disability (Kolstad et al. 2013). In order to do so, four criteria have to be met: (i) a special group of workers or employees has to be identified that will be exposed to certain influences at the workplace more seriously than the general population and the affected person, i.e., the patient, must be a member of that group; (ii) the claimed influences must be able – according to the state of the art and the medical science – to cause the observed health injury; (iii) scientific knowledge about the newly suspected influences was not available or insufficient, when the last revision of the list of known occupational disease was made, or has not been thoroughly checked; and (iv) a causal relationship between worker's or employee's duties and the ensuing illness must be a “deemed-to-satisfy” provision. Once again, the toxicological expert will have to provide evidence or deny such a link, before the patient will be promoted to an applicant for compensation. The expert has to deliver his/her scientific opinion for each of the four points, and the

statements must respect the available literature in the fields of occupational and social medicine. If the expert fails at any point, chances are that the whole report with all its arguments will be dismissed in court. Conversely, a carefully written report with convincing data and evidence may provide enough reason to resume hearings and discussions that may eventually lead to the filing of the newly discovered condition as an occupational disease.

## Adverse Drug Effects and Drug-Related Disease

For a long time, adverse drug effects have been recognized as inevitable sequelae of certain medical treatments. Modern drug safety requirements and consumer protection regulations require that such information be provided to the patient on a case-by-case basis. But drug makers continue to collect data even after their products enter the market and such data-on-file dossiers may provide an important source for keeping the quality of information up-to-date. Consequently, Toxicology Reports in special formats, e.g., Warning Letters, Rote-Hand-Briefe, and others, continue to be an essential part of drug surveillance, which reflects the progress being made with an increasing number of observations (Fig. 2). It should be noted here that data integrity, i.e., the inclusion and labelling of info data according to the ALCOA principle (= attributable, legible, contemporaneously recorded, original (or a true copy), accurate), has become increasingly important for audits and reports, likewise (Food and Drug Administration 2018).

**Fig. 2** Global drug manufacturing letters by data integrity. The issue of data integrity (DI) has become increasingly important over the years as shown by this North America survey. (Modified from: de la Torre 2019, available from: <https://govzilla.com/blog/2019/05/pharma-medical-devices-data-integrity-breaking-down-keywords-and-citation-trends-from-the-fda/>)

The physician who prescribes a certain drug is usually held responsible for informing the patient. It should be emphasized that despite potentially severe adverse effects, drug treatment is warranted if the benefits for an individual outweigh the risks. Recent trends appear to enforce the patients' rights of clear and understandable information about the most frequent and (or) most serious adverse drug effects. Failure to provide this clarification at the beginning of treatment may be sued as medical malpractice. Nowadays, toxicologists may be asked for their scientific opinion in court. In such cases, it is mandatory that the expert is unbiased and independent, scientifically sound and has no personal history that might be deemed a conflict of interest.

---

## **Work Disability and Reduction in Earning Capacity**

One of the issues most often dealt with in Labor Courts is the reduction of earning capacity. Even minor shifts in the granted percentage will have great repercussions on the patient's compensation and benefits. However, the toxicological expert should be aware that clinicians and specialized physicians generally provide such an assessment. Only in exceptional cases will the toxicological expert be asked for some scientific statement. The most notable exception is occupational cancer and carcinogenesis when the toxicologist should provide his/her expertise and give an estimate of likely sequelae and prognosis, based on the most recent research and study results in the field of interest.

---

## **Historical Crosslinks to Regulatory Affairs**

The above given examples should have made clear that Toxicology Reports may have a strong impact on later amendments of jurisdiction. For example, a new entity may be added to the list of occupational diseases if an increasing number of expert reports emphasize its relevance and the experts communicate the need for such a revision. In Germany, the Contergan Trial (1968–1970) was the most prominent example of how toxicological experts might take part in the decision-making processes in politics and public opinion and thus trigger a fundamental revision of the country's law (Stephens and Brynner 2001). The German Medicines Law, which became effective in 1971, was significantly influenced by the science of toxicology, by toxicologists and other experts in the field, and reciprocally stimulated toxicological research in Germany and elsewhere.

---

## **Recommended Internet Sources**

As stated above, there is no generally agreed standard on how to report the various aspects of toxicological screening for scientific and forensic purposes. But there are several resources in the worldwide web from various organizations, which strive for the improvement of report quality, and standards provide suggestions and templates

to harmonize reports. The entries that are listed in the paragraph “Resources” are by no means complete but provide a starting point for everyone who is in the need of making contributions in scientific meetings, to regulatory authorities, and in court. Many sources do not only outline how to report but rather focus on the conduction of proper toxicity screening procedures for which the report is a final step when presenting the results to the public.

---

## Resources

- (i) Templates for reporting various aspects of toxicology screening of chemical substances have been formulated already in 2003 and can be found at <https://www.fda.gov/regulatory-information/search-fda-guidance-documents/guidance-industry-templates-reporting-toxicology-data>.
- (ii) Recommendations for reporting forensic content have been published as drafted ASB Standard 053, First Edition 2018 by the AAFS Standards Board (available at [https://asb.aafs.org/wp-content/uploads/2018/09/053\\_Std\\_Ballot01.pdf](https://asb.aafs.org/wp-content/uploads/2018/09/053_Std_Ballot01.pdf))

**Abstract**

Toxicological disasters, such as industrial accidents or the use of highly toxic compounds in terroristic attacks or civil wars, are rare, but more frequently occurring events with high impact to health and environment. Medical preparedness in such situations requires policy, planning, and a preorganized response system on a cross-ministry basis. This chapter briefly describes the main parts of the planning process and the needed legal framework to support this process. Production, storage, transport, use, etc., should be monitored to prevent or minimize the chance of release of hazardous substances. Knowledge about toxicological profiles, characteristic symptoms of poisoning (so-called “toxidromes”), and medical countermeasures (including stockpiling and availability of antidotes) should be readily accessible. The response system has to provide detailed plans for the management of toxicological events and exercise the procedures on a regular basis involving all levels of command. Financial support is mandatory to support continuous toxicological research, to build up and maintain the working capacity of poison control centers and specialized medical response teams. These efforts taken together should form an efficient risk management system.

Toxicological disasters · Terroristic attacks · Framework · Preparedness

---

**Introduction**

The release of poisonous substances, either accidentally or intended, can cause severe health effects in a huge number of people and can result in disaster. For example, ergotalkaloids caused mass poisoning during the middle ages. More recently, the extensive use of chemical warfare agents during World War I and the Iraq–Iran war (1980–1988) caused hundreds of thousands of soldiers to be injured. Terrorists from the Aum Shinrikyo Cult released sarin in Matsumoto and Tokyo in 1994 and 1995. The Tokyo subway attack resulted in 12 fatalities and 980 injured persons. More than 5,000 people thought they might have been poisoned (so-called “worried wells”) and consequently sought medical help. In 1984, 42 tons of methyl isocyanate leaked into the air from reservoirs of a local chemical plant in Bhopal. There were 5,000 fatalities and more than 200,000 long-term injuries counted within an area of 20 km<sup>2</sup>. The confirmed use of chemical weapons in the Syrian Civil War is the most recent incident that documents the deliberate use of chemical warfare agents against the civilian population. These examples clearly demonstrate the urgent need for preparedness, including planning and organization, as well as availability of appropriate medical countermeasures.

The onset of acute clinical symptoms after the release of toxic substances may vary between seconds and days depending on the nature of the poison. In addition to

acute health effects, symptoms with a delayed onset may occur. Moreover, even a single exposure event may provoke long-term effects.

From a medical perspective, a disaster situation has to be expected in mass casualty events that either overwhelm the local community's medical services and/or result in contamination of relevant medical infrastructure. This means that the relationship between the capacity of local response teams and their need for external aid is more important to qualify an incident as a disaster than is the total number of intoxicated persons or fatalities.

---

## Characteristics of Toxicological Disasters

The release of a toxic chemical may only be realized when a high number of patients present with comparable clinical symptoms. Initially, the exact toxic compound may be unknown. In this phase, risk assessment and patient treatment are based on clinical signs and symptoms. However, unambiguous identification as fast as possible by using appropriate detectors or test systems may help to readjust risk estimation and medical countermeasures. Especially the release of complex mixtures of toxic gases (e.g., during fire accidents) necessitates rapidly available analytical methods close at hand. A contamination of the ambient atmosphere, soil, buildings, and persons has to be considered unless proven otherwise. For this reason, personal protective equipment is essential to enable rescue operations within the contaminated area. However, wearing personal protective equipment (PPE) significantly limits the action time and requires replacement of personnel dependent on the environmental condition. In the worst case, the action time may be limited to less than 1 hour. Thus, medical treatment of injured and (or) intoxicated patients is severely impaired.

Secondary contamination of medical personnel and infrastructure may be accelerated by the evacuation of contaminated patients, animals, or traffic through the hot zone. Thus, all potentially contaminated persons and materials have to be thoroughly decontaminated before leaving the hot zone. In order to avoid uncontrolled trafficking, it may be required to control and secure the hot zone by security forces.

A decontamination line in front of hospitals or other relevant infrastructure is mandatory to protect these.

---

## Preparedness, Regulatory, and Legal Frameworks

Massive release of toxic substances affects both environment and infrastructure. Thus, a wide range of capabilities is necessary to cope with a toxicological disaster. Local authorities and communities are responsible to provide the required plans of operation. There are legal requirements to ensure proper planning and training of local public health service, agencies for technical relief, fire and ambulance services, police force, and homeland defense to respond to and to manage the incident scene in its early phases. In later phases, more specialized help (both civilian and military) is needed to provide more sophisticated expertise. The legal framework to manage this kind of disaster differs

from nation to nation and even within a nation. Because of this, delays may occur that may complicate the situation. Continuous political leadership is the only chance to prevent these issues. In times where homeland defense is reduced in several countries due to tight budgets, it is important to enhance risk perception so that the high-risk areas are given priority for appropriate control measures to be taken (OECD 1994).

A consistent legal framework of responsibilities, tasks, procedures, alarm plans, and communication lines is crucial for the successful management of disasters or catastrophes. The availability of points of contact and key personnel 24 hours and 7 days a week is essential.

---

## **Training, Drill, and Exercises**

Efficient collaboration between different agencies, governmental (GO) and non-governmental organizations (NGO) depends on their current knowledge and practical skills. Regular exercises including the highest political levels are necessary to achieve an appropriate level of preparedness and understanding. All participants must be aware and prepared for their tasks. Such preparation necessitates a profound understanding of toxicological risks and available countermeasures. Appropriate protective equipment must be available in sufficient quantity to deal with any possibility of a major disaster. Personnel must be trained on a regular basis to ensure safe handling of protective equipment.

---

## **Identification of Potential Hazard Sources**

To counteract potential terrorism, integrated intelligence systems with interagency activities are essential to recognize threats as early as possible. This includes not only knowledge about the capabilities of a potential antagonist, but also identifying industrial facilities that store and produce substances that might be of interest for terrorists. Additionally, transport routes should be known and analyzed for potential risks. Regulatory approaches that may be applied include the UN Recommendations on the Transport of Dangerous Goods, Dangerous Goods Emergency Action Code List 2011, and Canadian Transportation of Dangerous Goods Regulation. To supplement the above activities, an epidemiological surveillance system should be introduced for early detection of the effects of any hazardous substances that may be released into the community.

---

## **Identification of Hazards Through Emergency Forces**

Toxic chemicals (solids, liquids, or gases) that can harm people, other living organisms, property, or the environment are classified as dangerous goods. Regulation of such chemicals should be enforced by local regulatory agencies. Proper labeling of chemicals is essential for the safety of emergency forces and to

ensure proper countermeasures. The Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) is a European Union regulation to enforce the safe use of chemicals. A comparable law is the US Toxic Substances Control Act. As described in the previous section, the transport of dangerous goods is strictly regulated at both international and national level. Especially first responders must be familiar with the legal framework and the labeling system. In addition, an analytical task force should be available to identify unknown chemicals and to ensure that the correct measures are taken to minimize their potential to cause harm.

---

## Detection

Various devices are available for the rapid detection of unknown chemicals. However, detection systems have been optimized for a number of civil or military scenarios, and unfortunately, there are always new and unforeseen events occurring. Thus, it is essential to have available first-class and up-to-date analytical chemists and a well-equipped laboratory in order to devise and apply new methods which may be necessitated as new problems are presented. To ensure reliable results, sample collection and preservation (e.g., with refrigeration and lightproof containers) must be properly carried out. Transportation to the analytical laboratory must be as quick as possible. In addition to the addresses of the laboratories that are involved in normal emergency response, emergency response units should also keep a list of addresses of laboratories with special knowledge and skills (e.g., universities, industry, and the armed forces).

---

## Information on Toxic Substances

Companies that use highly toxic substances should develop a risk management program (RMP). Information, including material safety data sheets, should be available for protective, diagnostic, and medical countermeasures. Poison control centers should have this information available because they have a central role in the initial planning of medical countermeasures. Specialized knowledge about chemical warfare agents will be available from military sources. Specialized internet databases may also provide detailed information. Regulatory laws under the European REACH regulation should eventually ensure the availability of all relevant data regarding industrial chemicals.

---

## Limits of Exposure

A number of exposure limits have been defined for the safety of human beings, workplace, buildings, and environment. These limits are of minor importance during the emergency management of toxic catastrophes. However, they are helpful to estimate limits for acute short-time exposure for emergency personnel during the initial phase of disaster management. Additionally, they are useful for information of exposed

population about possible hazards (OECD 1994). These limits become highly relevant in the aftermath of the accident in ensuring that harmful consequences are kept to a minimum.

---

## Physical Protection

Toxic contamination of air and body surfaces requires physical protection of airways, eyes, and skin. Without certain knowledge of the nature of the released toxic substance, it is necessary to wear whole body protection and a self-contained breathable air supply. Airway protection may be sufficient in some cases if the potentially toxic substance involved has been identified. Masks, suits, gloves, and overshoes should be made of appropriate material with a high protection factor. In order to choose the right equipment, it is necessary to have data readily available defining relevant protective properties (Gupta 2020).

---

## Decontamination

Contaminated persons have to be decontaminated before leaving the hot zone. It is crucial that intoxicated persons do not contaminate hospitals or other critical infrastructure. The preparedness of hospitals and the public medical service is a legal requirement in some nations. Sufficient amounts of clean water and decontamination equipment should be available. Management of wastewater must be considered as well. Hospital emergency plans should contain information about the traffic routes to and from the medical facility, and hospitals should have sufficient stockpiles of antidotes, beds, and blankets (WHO 2004).

---

## Drugs

Life-threatening poisoning is a rare event. Usually, stockpiles of specific drugs and antidotes to treat intoxicated patients are small and not sufficient to cope with a mass casualty situation. Lifesaving antidotes should always be kept available for emergency personnel to treat contaminated patients but also for self-treatment after self exposure, e.g., by damage to their protective equipment. Further stockpiles of antidotes and other drugs must be available at short notice. Distribution depots should be established, and their location must be known to ensure short transportation times. Pharmaceutical companies should participate in planning for the rapid supply of necessary drugs.

## Centers of Expertise

Centers of expertise for the management of toxicological catastrophes are rare. They may be part of a ministry, university, company, or even of the military. Laws should ensure that a sufficient quantity and quality of toxicological expertise are available on a national level. This expertise is especially needed after a toxicological incident and should be responsible for human biomonitoring to follow up exposed patients.

## Research and Development

Risk assessment, preparedness, and strategic planning are the responsibilities of national authorities. However, basic scientific expertise is needed as well as capability to respond to an incident. In order to sustain toxicological research, adequate financial support has to be secured as well as the establishment of research institutes at the medical faculties of leading universities. Medical students and doctors should be supported to participate in toxicological research programs. These programs are mandatory to support the education of new scientists with a medical background. This future scientific expertise is necessary to support ongoing research. Currently, a small number of scientists have to deal with a plethora of urgent toxicological problems:

- Development of new antidotes
- Development of a system to decontaminate injured patients
- Development of a decontamination treatment which can be applied to eyes and mucous membranes
- Development of new methods to analyze and monitor toxicological exposures

**Table 1** Management in toxicological disaster – some essentials

Preparedness	Incident management	
Legal framework	<i>Hazard identification</i>	<i>Protection measures</i>
Training, drill, and exercise		
Key stakeholder organizations	Support by emergency forces	Physical protection
Analytical equipment	Support by poison centers	Decontamination
Stockpiles	Source identification	Antidotes & medical countermeasures
Access to toxicity data & guidelines	Sampling	Evacuation procedures
Documentation SOPs	(Forensic) Analysis	Documentation SOPs

---

## Risk Management

WHO suggests the implementation of a structured planning process to meet the needs of effective risk management. The following step-by-step approach is suggested:

1. Identify the hazards
2. Evaluate the hazards to determine the probability and severity of the initial risk
3. Introduce risk-reduction strategies
4. Quantify the residual risk, and decide what risk is acceptable
5. Monitor the risk management program and repeat the process as required

---

## Summary

Some major elements of toxicological disaster management are shown in Table 1.

## Abstract

Public participation in risk management decisions has a sound legal base in Europe. In democracy it replaces the authoritarian top-down risk management. Participation of the public changes the role of scientific toxicology. Toxicologists should state clearly their models, assumptions, and resulting uncertainties and strictly separate scientific analysis from extrapolation and opinion. Participatory risk management is based on the notion of the emancipated citizens, who are capable of informed risk appraisal and enable them to contribute their interests,

beliefs, and values. The rationale and supposed benefits of public participation in decisions about environmental health risks are discussed, and different models applied so far are presented.

---

**Keywords**

Public participation · Risk management

---

## Introduction

The *Aarhus Convention* of 1998 (UNECE 1998), signed by 40 countries and the European Union, guarantees the rights of the public to participate in decision-making in environmental matters. Substantial evidence shows clearly that an adequate involvement of *stakeholders* and persons concerned in environmental health decisions achieves more effectively better and enduring results. Goals of participation should be to de-emotionalize conflicts, to reconcile different points of view, and to develop a common basis of assessment and consensual strategies for solutions, which do justice to the distinct interests of the different stakeholders. Participation enables better acceptance of decisions. The unsolvable points of conflict may be unearthed, and last not least the transparency of political decisions increased.

---

## Why Participation?

In the classic concept of “*top-down*” *risk management*, public administration regulates risks for the public or for single individuals using adequate measures, which in their discretion best suits the problem. The background of the decision, such as the scientific facts and their *uncertainties*, the *conflicts of interest*, the accepted compromises and weighing processes, and the remaining residual risk, remains hidden to the public. The role of the toxicologists as a scientific expert is to propose suiting treatment policies to the administration. Their expert statements serve to justify decisions that are founded on scientific facts, but depend as well on *normative values*. The underlying assumption of this risk management model is as follows: The administration well intentioned represents public welfare whereas stakeholders want only to enforce their special interests.

In the 1970s and 1980s, sensational incidents and in hindsight obviously wrong risk assessments by governmental policy makers scandalized by the media put public confidence in the ability of the administration to regulate risks for the benefit of the general public seriously in question. People’s trust in the impartiality and objectivity of scientific risk statements was lost. Affected parties demanded loudly a participation in risk decisions. The political implementation of controversial techniques, such as genetic engineering or waste incineration, got almost impossible if they were felt threatening, justified or not. Small risks were overregulated, large neglected. A rethink was strongly indicated.

---

## Participatory Risk Management

Social science risk research indicates that the *rating of environmental risks* on human health depends not only on its height but at least equally on the uncertainty of the scientific facts and on the values the rating persons have. In a society, in which pluralism of values prevails, risk assessment and management must be democratically legitimized. The paradigm of risk management as a participatory process in mutual faith replaces the “top-down” model of risk management. It is characterized by a broad participation of all people concerned, the so-called stakeholders.

In this counter-model of a *participatory risk management*, the authorities provide basically the framework for process-oriented regulations. Decision processes take place as locally as possible, if possible at the local level where the risks occur. Science is not presented anymore as the single factor determining the decisions about risks, but as one factor among others, such as economic criteria and value-led trade-offs. Science is accessible to all people involved.

Participatory risk management changes the role of scientific toxicology. Toxicology is required to adhere strictly to scientific data and to refer only to facts that are proven according to sound scientific methodology. On the other side, scientists have to be explicit about the extent and limits of their knowledge. They should state clearly their models, assumptions, and resulting uncertainties and strictly separate scientific analysis from extrapolation and opinion. For the public, it is critical to know not only what definite knowledge is but also what is still ambiguous.

Participatory risk management is based on the notion of the emancipated citizen, who is capable of informed risk appraisal. The concept means being in a position to make an informed risk appraisal on the basis of knowing the objectively demonstrable consequences of risk-generating events or activities, the residual uncertainties, and other risk-relevant factors and to rate the risks according to the individual's values for shaping his own life and in correspondence to his personal criteria for assessing the acceptability of these risks for society as a whole. Once this capacity for *informed risk appraisal* on the part of the citizen is acknowledged, it is the task of the authorities to build up and maintain the communication base necessary for this purpose. In the context of risk communication, there is a need for all forms of communication, from simple documentation of results, through targeted information offerings, to forms of dialog and of participation in the decision-making process.

---

## Legal Background of Participation

In democracies the participation of each person in decisions that affect them is viewed as a fundamental right. In 1989 all the Ministers of the Environment and of Health of the European region of WHO signed the *European Charter on Environment and Health* (WHO-Euro 1989), which states: Every individual is entitled to . . . information and consultation on the state of the environment, and on plans, decisions and activities likely to affect both the environment and health (and to) participation in the decision-making process.

*Principle No. 10 of the Rio Declaration* (UNEP 1992) declares that environmental issues are best handled with participation of all concerned citizens, at the relevant level. At the national level, each individual shall have appropriate access to information concerning the environment that is held by public authorities, including information on hazardous materials and activities in their communities and the opportunity to participate in decision-making processes.

These fundamental rights were materialized in the UN/ECE Convention on Access to Information, Public Participation in Decision-Making and Access to Justice in Environmental Matters (UNECE 1998), signed 1989 in Aarhus, Denmark, by more than 40 states and the European Union, the so-called *Aarhus Convention*. For the EU, the institutions (European Commission, European Parliament, European Council, etc.) are bound by the convention through the so-called Aarhus Regulation. In the framework of EU legislation, rights of the public to be informed and to participate in decisions are guaranteed in the *EU Strategic Environmental Assessment Directive 2001/42/EC* (EU 2001) and the *EU Public Participation Directive 2003/35/EC* (EU 2003). Both directives are binding on the Member States and accordingly have been implemented into national law.

However, in 2017, the Compliance Committee of the Aarhus Convention ruled that the Aarhus regulation of the EU does not give people and NGOs enough rights, and in many EU-countries there are too many constraints that limit proper participation (Pánovics 2017). Lately a tendency is observed to restrict public participation in order to speed up planning processes.

On the other side the European Food Safety Authority established in 2003 a specific Stakeholder Forum to include contributions of consumers and industry into their decisions and the European Chemical Agency launches calls for comments and evidence in the preparatory phase of the restriction proposal and on the different documents under preparation in ECHA in relation to restrictions, such as reports on substances in articles and guidelines on restriction entries. Anyone can submit comments.

---

## **Rationale and Benefits of Public Participation in Risk Decisions**

The benefits of *stakeholder participation* in risk decisions are obvious (Table 1). The participation of people concerned by risks or generally interested in risk issues should eliminate the widespread suspicion of the public towards authorities and established science. It should ensure the transparency of the foundation, framework, and underlying assumptions of the decision and finally promote their acceptance. For the authorities, participation of the public provides opportunity to become acquainted with the fears and worries of the citizens and their specific concerns, which they can take into account. Local experience and knowledge can be utilized for risk management. Finally, public participation encourages the participants to focus on arguments rather than on ideological contradictions. Timely involvement of the persons concerned may possibly avoid time-

**Table 1** Benefits of stakeholder participation in risk management

Democratization of the decision processes
Inclusion of different values in society
Promotion of a better understanding of administrative decisions by the public
Improvement of the knowledge base
Saving of time and costs
Trust building
Supporting acceptance of decisions by the public

consuming legal disputes and heavy conflicts fought out in the media or in the political arena. However, participation is no panacea. Objective clash of interests cannot always be settled, and unsolvable conflicts must ultimately be decided at the political level.

Participation adjusts to the three key challenges of rational risk management. What issue dominates a specific process and defines what type of participation is most useful. If the complexity of scientific data as to the cause-effect relationship prevails, then the main issue will be clarification and explanation of difficult-to-understand scientific facts to lay people. Main conflicts arise at interprofessional level. The objective of public participation in this case is to inform about the scientific facts and make the scientific debates transparent to the public. Thus, it serves the understanding between experts and laymen.

If predominantly the *uncertainty* about the level of risk is under debate on account of methodological uncertainties, statistical variability or limitations, and uncertainty of scientific knowledge, then it will be important to find the narrow path between excessive caution and irresponsible negligence. Risk benefit considerations may be the remedy of choice (see ► Chap. 59, “Risk-Benefit Considerations in Toxicology”). A balance must be struck between the burdens of those who have to bear the risk and the benefit of those who create the risk.

If *ambiguity of risk*, which means different interpretation and evaluation of scientific facts according to differences in values, is the issue, then the acceptability of risks has to be negotiated and finally decided. Cultural, social, and ethical values have to be taken into account. In this case participation serves to improve understanding of different positions and to guarantee a fair and equitable procedure.

---

## Who Should Participate?

The process should include credible representatives of the full spectrum of parties, who are interested in or will be affected by a decision (Table 2). It should be structured to encourage their voluntary commitment. Basically, anyone who feels affected by a specific risk has the right to participate. In practice only few people will have such an immediate interest to sacrifice time and money required to fully participate in the decision process. Such people feel personally affected in their

**Table 2** Stakeholders in participatory risk management

lifestyles, their health, their economic interests, or their values and organize themselves in grassroots initiatives. But this must not lead to the fallacy that grassroots initiatives represent only the interests of a small minority. Experience has shown that risk managers often be wrecked, if they doubt whether these initiatives represent the general public and if they try to play the so-called silent majority against them.

In order to decide, who has to be involved, authorities have to ask the questions: Who is affected by the risks (but also of the measures to eliminate the risks)? Who has additional information or expertise? Who was affected by similar risks in the past? Who could be upset if not invited?

---

## Models of Participation

In the past various *models of a public participation* have been applied.

### Publication of Decision with a Set Period to Submit Objections

The decisions of the authority are made accessible to the public. Everyone can raise written objections within a prescribed period. The authority must deal with them. Participation is aimed mainly at professionals and associations.

### Hearing

Similar to the previous model, arguments from interested parties could be raised and publicly discussed with the authority. In this and the previous model, the objective is to bring arguments to the authority's notice, which was not considered in the initial decision. According to all experience, the effect on the final decision is low, because the authorities are not bound to take additional arguments into account. Usually the participation takes place at a time, at which the cause has largely decided and authorities hate to revise once taken decisions. Hearings are legally prescribed in a

**Table 3** Five key principles for effectively melding scientific analysis and public participation

1. Ensuring transparency of decision-relevant information and analysis
2. Paying explicit attention to both facts and values
3. Promoting explicitness about assumptions and uncertainties
4. Including independent review of official analyzes and/or engage in a process of collaborative inquiry with interested and affected parties
5. Allowing for iteration to reconsider past conclusions on the basis of new information

number of European environmental laws. Participation is typically restricted to persons or institutions with a “legitimate” interest on the issue.

## Round Table

The experience that hearings in practice contribute little to a de-escalation of risk-related conflicts leads to the establishment of so-called round tables in particular settings. The objective of this exercise is to negotiate with as many opponents, as possible, at an early stage of the decision process with the hope that the final decision will be accepted by most of the stakeholders. Critical for the success of a round table is the inclusion of all people concerned, a collaborative formulation of the problem, a good faith communication, and last not least the transparency of all decision-relevant information. Specifically the role of scientific expertise has to be considered carefully and accessible to all participants. As put by the Panel on Public Participation in Environmental Assessment and Decision Making of the US National Research Council generally (NRC 2008), it should be wise for responsible agencies to follow the five key principles shown in Table 3.

From (NRC 2008)

## Advisory Board

An Advisory Board is made up of representatives of the interested parties and experts and accompanies a planned project from the beginning. The Board must have clearly predetermined competences to interfere with the decision process. In practice the delegated members of the advisory board are endangered to decouple themselves increasingly over time from the interest of their base.

## Mediation

In addition to the participating interest groups of the “round table,” an impartial arbitrator (mediator) is appointed to guarantee a fair deliberation. Its role is to promote the integration of diverging positions. So to speak, the mediator should act as a catalyst for consensus. Mediation is indicated, where conflicts between stakeholders are evident in the run-up of risky projects.

**Table 4** Models of public participation in risk management: pros and cons

Participatory models	Pros	Cons
<b>Publication with objections</b>	Transparency	Minor influence on decision
<b>Hearing</b>	Transparency, platform for diverging arguments	Minor influence on decision, no settlement of conflicts
<b>Round table</b>	Fairness	Time-consuming questionable legitimacy
<b>Advisory board</b>	Anticipated settlement of conflicts, expertise, competence to decide	Limited participation, questionable legitimacy alienation from public
<b>Mediation</b>	High potential to settle conflicts, fairness	Time consuming, low efficiency
<b>Cooperative discourse</b>	Adequate to the problem, effective, efficient	Costly

### Cooperative Discourse

This model, proposed by (Renn 1999), consists of three steps: identification and selection of concerns and values of the stakeholders, identification of impacts and consequences of different policy options by experts, and finally evaluation of potential solutions by a panel of randomly selected citizens. In the last step, the stakeholders and the experts contribute only as witnesses. They provide their arguments and scientific evidence to the panel, which ultimately decides on the various options. In this model the phases of elicitation of scientific facts, elaboration of deviant values of people concerned, and weighing of facts and values are clearly separated into three panels with varying participants.

Pros and cons of the different participatory models are summarized in Table 4.

### Evaluation of Participation

In spite of the legal establishment of public participation, its application in practice has been criticized repeatedly (SRU 2002; NRC 2008; Pohjola and Tuomisto 2011). But the evaluation of public participation has been focused on process and access rather than on outcomes. But what is important from the point of view of participation in risk assessments and management is the influence allowed for the stakeholders in the different settings. The framing of a risk assessment approach can be a significant constraining factor for potential effectiveness of participation. For example, the commonly applied approach to environmental health assessment treats stakeholder involvement and public participation rather as an add-on brought about by legal requirements than as an essential aspect of risk assessment or decision-making. The common current practices of participation are not necessarily always in line with the latest

discourses in the literature, and the law seldom requires very high degrees of openness to public participation. It is usually built on the conventional frameworks of administrative decision-making. Professional risk assessors and policy makers fear losing their power, although they should see themselves as feeding an open collaborative process with their expertise. Pohjola et al. addressing the issue of effective participation developed a concept of five dimensions of openness of risk management, which include the scope of participation, access to information, timing of involvement of the public, aspects of the issue the participants are allowed to contribute, and the weight given to the contributions in the final decision. The framework of openness provides a context for evaluation and constructive criticism of contemporary institutions and practice of public participation in risk assessment, and policy making, and a basis for developing new models. Openness should not, however, be considered as an end in itself, but rather a means for advancing societal development through creation and use of broadly distributed collective knowledge upon issues of great societal relevance (Pohjola and Tuomisto 2011).

---

## Conclusions

Participation in risk assessment and policy making upon issues of environment and environmental health has become a commonplace. There are numerous good examples of public participation to manage risks at the local level. At the national or international level, specifically for the management of toxic substances in consumer-relevant products, they are scanty or completely missing. Existing experience with participatory risk management shows that participation can be an invaluable part of risk assessment and decision-making. There are no simple “best practices” that provide universal guidance (NRC 2008). Therefore, the creativity of risk managing authorities is challenged.

The strength of participation is that aided by discursive methodology, it is possible to weigh arguments by rational and political legitimized criteria before deciding. A formally structured and organized deliberate procedure takes notice of scientific expertise, laws, norms, social interest, and people’s values. If it is conducted in a fair and representative manner, it will integrate rational, emotional, and normative statements and opens a perspective to solve conflicts of interest. Prerequisite is the willingness to debate, to learn, and to compromise.

It is not possible to predict in advance how effective a particular participation process will be to avoid or lessen conflicts. Participation has limitations. It is reasonable only if there is still something to decide and if willingness to compromise exists on the side of all parties involved and last not least if the public is supported by trustworthy scientific experts. Participation is not effective, if it depraves to unlimited debating. Besides well-intended openness, the majority of concerned citizens will always remain bystanders.

## Abstract

This chapter is primarily written for scientists concerned with the assessment of risks for human health or the environment and involved in communicating and explaining scientific risk issues to the public. Besides following basic rules of

---

W. Lilienblum (✉)

Former: Faculty of Social and Behavioural Sciences, University of Amsterdam, Amsterdam, Netherlands

good communication, *risk experts* have to find solutions to overcome specific barriers in the dialogue with differently educated protagonists of the public, i.e., laymen, stakeholders, well-informed citizens, other experts, and also with public media. This includes adapting the dialogue to the audience, to explain complex scientific facts and their legal context perspicuously, and to achieve trust and a truthful dialogue atmosphere when discussing with citizens or stakeholders. Eventually, the risk expert should contribute to reach agreements or other options (including disagreements) when discussing risks. For the interaction with public media, the risk expert should keep particular rules in mind. *In conclusion*, awareness of obstacles in communication and acquiring special communication skills and training are mandatory for scientists in the role of risk experts before discussing risks in a public setting.

Institutions involved in risk communication issues, such as many authorities and enterprises, should develop concepts and long-term strategies to build up confidence as an indispensable basis of successful risk communication. Essential prerequisites of such confidence are i) scientific competence and legal independence of the risk experts within the institution (as far as possible by contract) and ii) transparency and a two-way communication between the institution, stakeholders, and the public.

---

## Introduction: Issues and Objectives of Good Risk Communication

*Risk communication* has been defined as “an interactive process of exchange of information and opinions on risk among risk assessors, risk managers, and other interested parties” (FAO and WHO 2016). Consequently, basic objectives of good risk communication are:

- The *exchange of information* on facts, in particular features, extent, and probabilities of risks discussed
- *Exchange of opinions* about appraisals, concerns, fears, and anxieties about these risks

One major issue in risk communication is that risks, perceived by individuals or groups, are *perceived risks associated with emotions* and corresponding responses. Table 1 provides an overview on some of the factors that influence the perception of risks. Predominantly, these factors are associated with *risk aversion* presumably triggered by spontaneous emotional responses deeply fixed in our behavioral repertoire of survival when the individual is faced to risk or threat (*flight or fight*).

Another major issue of risk communication is the recipient's cognitive bias and consequently misevaluation of risk, often caused by the context of information. Factors favoring cognitive biases are, e.g., the public information flood from different sources or distorted information. In addition, information that is manipulated, overstated, incomprehensible, unfamiliar, ambiguous, or even contradictory raises the concern or the feeling of threat.

**Table 1** Factors influencing risk perception

Factor	Increase of perceived risk	Decrease of perceived risk
Perceived catastrophic potential	1000 people affected at the same time	1000 people affected over a greater period of time
Perceived naturalness	Unnatural/human-made hazard	Natural hazard
Perceived controllability	Uncontrollable	Personal controllability
Severity of consequences	Severe consequences (regardless of likelihood of occurrence)	Consequences not severe
Immediacy of consequences	Immediate consequences	Delayed consequences
Affected sub-population	Susceptible groups by age, pregnancy, genetic or acquired susceptibility	None of these groups
Scientific knowledge	Risks unknown to science	Risks known to science
Familiarity of risk	New risk	Familiar risk
Voluntariness of exposure	Involuntary exposure	Choice about exposure
Perceived distribution of risks and benefits	Unequal distribution of risks and benefits	Equal distribution of risks and benefits
Ethical and moral concerns	Risk considered as ethically or morally wrong (e.g., fraudulent acts)	No ethical or moral concerns

From FAO/WHO 2016 (modified)

Ignoring individual emotions or personal values connected to the risk issue would be like talking about the visible part of an iceberg while disregarding the major part below the water surface. With regard to the exchange of opinions, it is often difficult for scientists to deal with the expectations beyond the factual level: Scientists in the role of risk experts usually evaluate risks in a different manner than individuals or public media do (see Table 2). Nonetheless, risk experts may behave similarly to laymen when faced to risks in areas where they are laymen themselves.

Risk management in short is a decision-making process involving considerations of political, social, economic, and technical factors with relevant risk assessment information on a hazard (WHO 2004). Important aims for the *risk management* are mutual understanding in the communication and agreement, e.g., about the implementation of measures for the reduction of risks. Whether such objectives can be achieved, strongly depends on the opinions and interests of the protagonists and stakeholders concerned. The role of the risk expert in such a situation may become difficult in case his opinion is attributed to particular interests; consequently, his objectiveness and credibility may be doubted by individuals or parties with different interests or opinions.

Involved parties in risk communication are as follows:

Risk experts from different institutions (engineers' offices, industry, authorities, scientific institutions)

Citizens with diverse levels of knowledge and education

**Table 2** Risk perception and risk appraisal by risk experts and citizens

Risk experts	Citizens
High degree of abstraction	Real and subjective observations
Strict application of scientific methods/procedures	Preference of intuitive approaches
Application of statistical or probabilistic methods	Expectation of inevitable (deterministic) developments
Determination of acceptable risk values/limit values as basis for measures by risk management	Striving for 100% safety
Comparison of different risk scenarios by mathematical/abstract figures	Consideration of single/separate incidents; refusal of the comparison of different risk scenarios
Statistical average person as a reference, e.g., 70 kg average bodyweight	Personal or social relationship to (potential) victims, sympathy, dismay/shock

Ref.: German Advisory Council on the Environment (SRU), 1999 (modified)

Public media (television, broadcast, print media)  
 Action groups (citizens), consumer councils  
 Companies and associations of industry  
 Other administrative authorities, bodies, agencies  
 Political lobby groups  
 Other protagonists or stakeholders

Some of these different parties have in common that, when confronted with warning messages about hazards or risks, they have diverse and often little previous knowledge about the issues. Hence it is important for risk assessing institutions to integrate risk communication as a permanent discourse in their external communication in order to reduce information deficits and to promote a realistic perception of risks in the general population (see ► [Chap. 58, “Risk Comparison in Toxicology”](#) in this book). Especially government agencies and industrial companies and associations should feel their responsibility to this invitation.

The larger the differences between the groups of the target audience, the more difficult it will be to manage the risk communication process and the higher will be the potential for conflicts. Elements with a conflict potential are:

Previous knowledge of risks and level of information about particular risks  
 Risk perception  
 Acceptance of certain risks  
 Distribution of benefits and expenses of a risk-reduction measure  
 Extent and kind of the exposure to a risk  
 Particular interests

Particular interests may be of economic nature including suspected decrease in value (e.g., lower costs for the industry, gain or loss of employment, residential sites close to a planned industrial plant) or of, e.g., political, moral, or ideological interests.

## Elements of Effective Risk Communication

*Every message is only as credible as the source that tells it!* When important decisions have to be taken, the success of the parties depends on their credibility and the trust that other parties have in them. When an obvious charlatan appears more credible than a risk expert, something went wrong in the debate.

Criteria for the trust of citizens in scientific statements are as follows:

Trust in a message

Trust in the person that states it (personal reputation)

Credibility and trust in the information source

Credibility and trust in the scientific institution

Social climate which may ease or constrain the confidence building

## Basic Rules of Good Communication

Being proficient in the basics and rules of communication is a requirement for effective risk communication. There is much information easily available in guidebooks and on the Internet about how to achieve and to perform good and efficient communication. It is recommended to join advanced training courses additional to the study of appropriate literature. Taking courses of rhetoric may also be useful but will cover only a subarea.

A message is a basic element of communication. In the following, some background and practical rules are provided on the components of a message: *Every message is only as good as the part of it which is reaching the recipient!* This does not only apply to the factual content but also to three other layers of a message. Based on the psychological work of Paul Watzlawick on communication, (“We talk even when we’re not saying anything” is just one of Watzlawick’s five axioms on communication), Schulz von Thun (1998) developed the *four-sides model of communication* (also known as *communication square* or *four-ears model*). The four sides have the function to clarify the four layers of a message:

*Layer of matters and facts* of a message

*Self-revealing and self-disclosure* by the sender

*Layer of relationship* between sender and recipient of the message

*Layer of appeal* from sender to recipient

The simple example of the four sides of the communication square is used just to illustrate that communication is multilayered. Consequently, risk experts would be well advised to look more closely at the basics of communication in order to avoid blunders in communication, to practice one’s abilities, and (similarly important) to detect attempts of manipulation by stakeholders.

On the *layer of matters and facts*, the recipient gets information about the communicated issues. Clear structure, logical order of factual arguments, and

comprehensible wording (inclusive explaining of technical terms) can help the recipient to encode the message the way it is intended. The sender's request for feedback about how the message has been perceived can help to detect any misunderstanding and provides the opportunity for correction.

On the *layer of self-revealing and self-disclosure*, the sender gives information about themselves, e.g., about their role in the process of communication, competence, points of view, ideals, other parts of their personality, or about their actual mental state. This partly happens as an intentional self-revealing but also as an unconscious disclosure.

On the *layer of relationship*, the sender communicates openly or subliminally what they think about the recipient or about the way they define the relationship. The way of talking (wording, body language, intonation, etc.) may express, e.g., respect, friendliness, disinterest, or contempt toward the recipient.

On the *layer of appeal*, the sender openly or subliminally attempts to influence the recipient in order to think, feel, or act in the way intended by the sender.

On each of the four levels of a message, each perceived signal triggers a sensation or a reaction of the recipient. On the level of self-disclosure and on the level of relationship, unintended effects of subliminal or unconscious signals of the sender might be particularly problematic.

Risk experts in particular have to take into account that protagonists of other parties, as being recipients, critically compare the factual information with their sensations of the other three levels for incongruities. A message consistent on all of the four levels of communication is one of several important requirements for credibility and trust; another term, which means the same, is authenticity. If all of these four levels of a message reach the receiver and are encoded in the intended way, the risk expert has successfully resolved one of several obstacles with regard to credibility and trust.

## **Important Requirements for Effective Risk Communication**

Additionally to being proficient of the basics of good communication, the risk expert is expected to translate technical terms into a language comprehensible for everybody (including citizens unversed in the risk issue) and to arrange mutual understanding.

Important tools and techniques for this challenging task are as follows:

- Translating technical language into everyday language
- Simplifying circumstances and line of thought to the essential, without omitting relevant information
- Illustrating complex matters with examples and comparisons of everyday life

Useful strategies to gain trust and credibility are as follows:

- Disclosure of all relevant factual information and transparency with regard to the expert's personal role/function

Dynamic communication policy, rapid and comprehensive information, e.g., immediately after accidents happened (important for institutions involved)

Reliable adjustment of information

Acknowledging ambiguities and uncertainties

Responding to emotions of the public

Showing presence and leadership skills

Also, the risk expert has to consider that abstract determinism and reductionism, often inherent to a scientific approach, can be rarely reconciled with the thinking of citizens in social relations. Furthermore, good risk communication is not a one-way communication: Sending a message does not mean that the receiver passively absorbs the message like a sponge. It is a two-way communication with both an active sender and active receivers with their own opinions and own perceptions (including contrary positions).

And finally, all parties have to be conscious about the fact that good risk communication is an important requirement, but not a guarantee for comprehension or agreement.

---

### **Contact with *News Media* (Press, Television, Broadcast)**

Risk experts are in great demand, especially when accidents in the field of chemistry, scandals around food, etc. have happened because of the public attention focused on these issues. However, they are also consulted for less big issues.

There are different reasons why risk experts are getting consulted by the media. It might be pure interest in information, but journalists could also already have a certain idea of how to present a particular issue and which statements (or headlines) ought to be supported by means of an expert. In the latter case, the risk expert would provide a scientific disguise for the story the journalist has in mind; only certain parts of the interview would appear in the article/interview, utilized to support the journalist's idea of the story. Before agreeing to the interview, catch up on the background of the request! Clarify, *in advance*, that you can have a look at the final material for correcting gross errors of reporting before it gets published. However, this request might not always be embraced by the journalist.

Furthermore, the following is recommended:

#### Preparation

Think about and prepare *in advance* how you can formulate in a few words what you want to say. It is important to keep it simple so that laypeople can follow it. Also illustrate your statements with examples to make abstract things comprehensible. Besides, illustrations are often better understood, maintained, and reproduced than abstract explanations.

#### Comprehensibility

Journalists are busy people and therefore are often only superficially informed. If you leave the translation of your complicated technical wording to the journalist

(because everyday language is necessary for a broad public), the risk of an incorrect reproduction increases. Keep in mind and take care about your statements being clear and comprehensible to laypeople. Also avoid jargon; the meaning of terms has to be (made) clear to non-insiders.

#### Statements

Time on air or space in articles is restricted: be short and concise. Be aware of the fact that journalists often omit details when editing the material in order to create a clearer picture or to enhance comprehension. Also, the public's ability to maintain information is limited (and reproduction of information even more).

While listening to you, journalists often already listen and think in an editing mode:

Which sentences are short and concise; what is an expedient quotation in the context?

Provide the journalist with appropriate (short and clear) statements which are "ready for use"; this increases the probability that the statement will get published correctly (because the journalist can easily use it), and it decreases the risk of an incorrect report due to subsequent need for editing (shortening or simplification).

In certain cases, you can consider a media training session to practice how to appear in front of a camera, how to react on critical or delicate questions, and how to communicate your message effectively in a convincing and intelligible way (*perceived* competence).

---

## Preventive Risk Communication

### Basic Rules for Institutions Involved in Risk Management and Risk Communication

Institutions involved in risk management and risk communication should implement a program on good risk communication. Besides the rules and elements described in other sections, some additional rules should be followed to ensure successful risk communication and to achieve building up credibility and trustworthy (EFSA 2017; OECD 2002):

#### Openness

Openness is crucial to good risk communication and the reputation of an organization. It is important that risk assessments are published in a timely way and that information can be scrutinized how and which decisions have been made. Open dialogue with stakeholders and interested parties is also critical to building trust in the risk assessment process.

#### Transparency

Transparency is closely linked to openness and is equally important in building up trust and confidence. Transparent decision-making and a transparent approach explaining how an organization works and how it takes its decisions are also crucial.

### **Preparedness for crisis situations**

In the real world, occurrence of fraud, misuse of chemicals, chemical accidents, etc. cannot be excluded. Therefore, institutions involved in risk assessment and risk management need structures and networks for rapid and adequate response in case of crisis situations. As an example, the European Food Safety Authority (EFSA 2011) describes in a guidance how the urgent advice structures are activated, which steps must be followed, and who the actors are and their tasks.

### **Public Hearings for Preparing Decisions by Authorities or in Politics**

The preparation of an official decision, e.g., a public hearing, is a typical case where risk communication is necessary. Due to the legal frame, particular rules should be considered for risk communication. It is necessary to distinguish between public hearings and expert hearings for preparing changes of legislation (laws, ordinances, etc.). The former are based on existing law, e.g., in connection with the approval of hazardous industrial plants, whereas the latter provides more space for different scientific opinions, options, and political debate. It is inherent for legal procedures such as approval that the competent authority is bound by law to approve any submission if the applicant fulfills the legal requirements. In such a case, the authority often has only a small margin of decision, contrary to expectations of citizens concerned. Therefore, it is important for a successful progress of the procedure to provide detailed and clear explanations of the frame of legislation to the public or citizens involved, already at the beginning of the hearing. This may help to restrain unrealistic expectations of citizens with regard to the realization, prevention, or substantial limitations of the project.

A dilemma of risk regulation is that zero exposure of humans to chemical substances is often not possible due to practical reasons or is in conflict with important socioeconomic considerations. Therefore, the concept of acceptable risk has been developed. This concept requires the setting of limits for the exposure to toxic chemicals, i.e., acceptable limit values or other measures that can be considered to have no or a negligible impact on the incidence of adverse effects in an exposed population. Setting the acceptable risk and adequate measures is a risk regulation issue case by case: According to WHO (2004), the acceptability of a risk depends on scientific data, social, economic, and political factors and the perceived benefits arising from exposure to an agent. In complex situations, potential remaining risks (although considered presumably small and in general not measurable) often cannot be excluded and are inherently also part of the accepted risk.

Similarly important is the detailed explanation of basic but often undetermined legal terms by the management of the hearing such as the *principle of proportionality*. This principle is being anchored in the Treaties of the European Union and in the constitutions of the EU Member States and has the function to limit the

extent of restrictions the authority can impose, e.g., because technical measures reducing risks may be expensive. In risk management discussions, the principle of proportionality is often closely connected to the *precautionary principle*. The precautionary principle may be applied in special cases, when scientific uncertainties prevent a full risk or cost-benefit analysis and severe or irreversible adverse effects for a part of the population or for the environment cannot be excluded. For details, the reader is referred to a Communication of the European Commission (COM 2000). In addition, other important legal terms should be explained to the audience such as the *generally recognized codes of practice* or the *current state of scientific knowledge and practice*, if applicable. This kind of hearings is normally managed by a leading official of the competent authority, who is often a lawyer specialized in administrative law. The risk expert should be familiar with such legal terms.

The risk expert in such hearings usually has the role of an appraiser. Often the applicant proposes an accredited or well-respected expert to be appointed by the authority.

The following criteria are essential for generating credibility and acceptance of the appraiser by citizens or stakeholders involved:

*Perceived independence*

*Perceived competence*

Consistency of scientific reasoning

Fairness

Willingness and the competence of responding to different opinions or contradictory arguments

Perception of independence is as important as independence itself, but it is subjective. Independence and zero tolerance of conflicts of interest (CoI) are driven by societal organizations. An important criterion of independence is the affiliation of the risk expert. Risk experts from industry are normally not regarded as independent although they often strive to be. A consultant or appraiser, dependent on mandates from industry because of a high degree of specialization, may be generally regarded as independent; however, he should preferably demonstrate his independence and credibility by consistency of reasoning and persuasiveness. Competent authorities and other public scientific institutions often have introduced a passage in their rules of internal procedure which assures that the scientist is independent from instructions with regard to scientific appraisal issues he is responsible for. Usually this does not apply to risk managing authorities such as ministries where often hierarchy and political considerations predominate. In case the risk scientist acts the role of an appraiser in public hearings or at other public occasions, he should explain his role in the procedure as detailed as necessary and also comment on the issue of his scientific independence, if applicable.

Public hearings intended for the preparation of regulatory changes may leave more scope for discursive procedures and external moderation. Also for this kind of hearings, the above-described role of the risk expert applies.

## **Risk Communication and Training Preventing Hazardous Incidents and Transport Accidents with Release of Dangerous Substances**

The life cycle of many risk issues can be divided into four phases: In the *latency phase*, the risk issue is not yet a matter of public discussion but only known to insiders. In the *emergency phase*, slowly or fast, the risk issue arises in public discussions and media and may develop into a “problem.” In case of a critical event such as a plant accident with release of dangerous substances, the emergency phase is very short and the problem may develop toward a *crisis*. In the subsequent *regulation phase*, the risk issue becomes the matter of regulatory actions (Wiedemann et al. 2011). Therefore, all organizational and communicative actions are primarily focused on warding off any damage or on limiting the extent of damage. However, good risk communication starts far in advance to hazardous incidents, namely, by specifying procedures for approval/authorization of industrial plants with intrinsic dangerous potentials. Required information and communication includes scenarios of accidents, emergency (management) plans, and appropriate practice and exercises on a regular basis (SFK 1997; OECD 2002; Wiedemann et al. 2011).

By information and training in advance, the emergency staff is usually familiar with the local conditions and also with possible accidental releases and will arrive immediately in case of an incident.

With regard to the transport of hazardous goods on roads, rails, or shipping lanes, the focal point is concentrated on safety-related provisions on the means of transportation in order to prevent accidents. This applies also to the transport company’s reliability, aiming to reduce the probability of technical or human failure and to limit the impact of an accident on human health or the environment, respectively.

If hazardous incidents happen, a smooth and rapid interaction with adequate communication lines between the responsible institutions and authorities is crucial for the conduct of emergency plans, in particular when substance release exceeded the plant boundary. This requires careful planning and coordination in order to limit damage to a minimum.

In addition to the elucidation of the cause(s) of an accident, extensive information of the public on hazards or risks, which may have existed or may still exist, has to be carried out. The necessity of medical diagnostic examination or treatment of exposed individuals has to be decided case by case. Such decisions require adequate scientific justification and knowledge of the adequate chemical and medical investigation methods available but also some (political) flair in order to avoid public criticism.

---

## **Risk or Hazard Information on Chemical Substances and Products**

Last but not least, an important area of preventive risk communication is the design of written product information for consumers and for workers handling hazardous materials. Form and extent of such product information is partly stipulated by laws,

by regulations, or by nonlegislative technical rules and standards intended as technical minimum requirements.

Some typical examples of important product information (see also ► [Chap. 68, “Health Hazard Classification and Labelling”](#) Author Desel of this book) are as follows:

Labeling of dangerous substances, preparations, articles with regard to their dangerous properties by hazard pictograms, hazard statements (risk phrases), precautionary statements, and safety data sheets (SDS) according to the Globally Harmonized System of Classification and Labeling of Chemicals (GHS)

Labeling of ingredients, e.g., additives in food, often listed as codes (E numbers) or the list of ingredients in cosmetic products

Instructions for use and warning notes of medicinal products or articles of daily use

Beyond the official legally provided requirements, the written information has to be short but complete and comprehensible. Editorial review by laypersons is recommended. Especially in case of complex information, graphic images may be more comprehensible than pure text. Readability (the fine print!) is often more important than the handiness of the package insert; not everybody can be expected to have as good eyes as the designer of the leaflet.

**Abstract**

The cause behind the so-called MCS or IEI (Idiopathic Environmental Intolerance) is a mental or psychogenic or psychosomatic disorder.

Although the regulated threshold values in environmental media are aimed at virtually eliminating adverse health effects due to toxic substances, there are patients who attribute their illnesses to pollution. Only rarely is it possible to construct causality between the symptoms complained of and an exposure to toxicants. The communication between the physician and the patient is often disrupted. Only close cooperation between the family doctor and the doctors of environmental medicine can alleviate the suffering of these patients.

---

**Introduction**

Patients presenting themselves to the doctor as being environmentally ill often complain of a strong feeling of being unwell, the cause of which had not been medically explained so far. The symptoms can include listlessness, fatigue, disturbed concentration, muscle pain, and irritation of mucous membranes. Patients attribute the cause to pollution and/or an increased sensitivity to ubiquitous pollutants. They hope for identification of the contaminant, either by having the specific symptoms pertaining to that contaminant or by means of pollutant analysis (Staudenmayer et al. 2003a, b; Bornschein et al. 2006). This vague clinical picture is also referred to as *multiple chemical sensitivity* (MCS). This concept is based on the notion that sensitization to various chemicals is triggered by previous exposure to pollutants, as a rule usually accompanied by odor intolerance.

*Regulatory aspects* are present in two ways. Firstly, patients demand more stringent threshold values so that they, with their hypersensitivity, are protected. Secondly, with its human biomonitoring, environmental medicine has a method of investigation, the results of which can be assessed on the basis of scientifically derived values (reference values, HBM values).

---

**Environmental Health Investigation**

The examination of the environmental health patient consists, as is common, of taking a medical history, a physical exam, and – if necessary and useful – apparatus-based diagnostics and laboratory tests. Consultations with specialists should be requested if the symptoms are outside the specific area of expertise of the examining doctor. The following disciplines are required: internal medicine, clinical toxicologist, dermatologist, allergist, neurologist, occupational medicine, laboratory medicine, and – last but not least – the psychosomatic specialist and/or

psychiatrist. When it concerns prevention and counseling, Public Health specialists and doctors from the Public Health Service are involved.

---

## Medical History

While this statement reportedly made by a wise physician certainly still holds true: “Whoever does not have a diagnosis after taking the medical history, is badly off,” apparatus- or laboratory-based examinations are often given precedence. But as experience has shown, patients with ailments associated with environmental health issues are often not helped by these kinds of diagnostic investigations, and so taking the medical history is of utmost importance. This serves not so much the purpose of inquisitorial questioning of the patient, but rather of creating a *basis of trust* from the very beginning. Although time consuming, the patient should be allowed to express himself and should be listened to.

However, in order not to miss or forget important symptoms or associations, giving patients a *questionnaire* to answer beforehand has proved invaluable. As these questionnaires cover all possible symptoms and associations imaginable connected to living and working areas and are therefore very extensive, it makes sense to let the patient have a questionnaire well in advance of the consultation and to give oneself enough time to study it before seeing the patient.

The following categories are covered in the questionnaire:

1. Symptoms, with information about the time of onset, the duration, intensity, and the frequency
2. The disposition of the subject regarding familial clustering of diseases, hypersensitivities, allergies, and certain diseases
3. Potential exposure due to lifestyle factors such as natural stimulants, smoking, drugs, medication, sport, and leisure activities

Furthermore, *exposure possibilities* within the living accommodation, the surroundings, the household furniture, the use of domestic chemicals, and potential exposure in the workplace, by means of traffic, food, animal contact, and travel have all to be elicited.

Should suspicion fall and harden on a particular exposure, the search for possible vectors must be carried out. To this end, air, water, dust, food, utensils, products, and clothing are called into question. Of course, the maximum concentration that can be present in these vectors also plays a significant role. It is important to ask about first-time exposure and a one-off acute event. The doctor taking the history should not get too set in any one direction, but should remain open. He has to accept the patient's explanations, but must not overlook any symptom complex that might indicate a non-environment-related disease. That is why a doctor well trained in internal medicine with a broad subject knowledge and who has possibly come across many, even rare, diseases is predestined to be especially suitable for taking patient case histories.

---

## Uncommon Somatic Disorders

In our department, for example, some uncommon diseases have been diagnosed in these patients, such as acromegaly, hyperthyroidism, hypothyroidism, Wilson's disease, Mediterranean fever, cardiomyopathy, diabetes mellitus, insulinoma, pheochromocytoma, chronic lymphocytic leukemia, sarcoidosis, and various connective tissue diseases. In the neurological department, we came across Parkinson's disease, amyotrophic lateral sclerosis, multiple sclerosis, and meningioma with disturbance of the sense of smell. Chronic carbon monoxide poisoning accompanied by nausea and headache, usually due to faulty flues and chimneys, are among these misattributions. Uncovering medical or neurological disorders despite the aforementioned diagnoses is still somewhat rare.

---

## Disorders Not Able to Be Diagnosed by Conventional Medicine

As a rule, none of the somatic disorders defined by conventional medicine are diagnosed. In the case of somatic disorders, when the medical history is being taken, very often quite specific indicators are mentioned, for example, pain at very typical locations such as the stomach, gall bladder, kidneys, lower abdomen, or thorax, after meals, during exercise, climbing stairs, in the night, or a loss of appetite with weight loss, bloody stools, blood in the urine; however, patients with environmental disorders do not present in the same way. Rather, they complain of pain that cannot be exactly localized, and their presenting signs are vague but manifold. Such patients specify muscular pain that migrates and is not precisely localized. Reports of occurrences of feelings of numbness without exact localization and constancy arise repeatedly. Problems such as indigestion with nausea but without vomiting or increased stool frequency are also often specified. Nervousness, fatigue, dizziness, a burning feeling on the skin or mucous membranes, palpitations, dyspnea without cyanosis, or spasticity are also complained of frequently. Disturbed sleep patterns are also included, but without specifying whether the problem lies in falling asleep or sleeping through the night.

---

## Social History

Besides taking the medical history and asking about all the presenting signs and symptoms, care should be taken to enquire after the social environment. It is to be noted that most of the patients appear dissatisfied with their social environment, but not because money is short, or the employer is putting on the pressure, or the partner is being difficult, but rather because they are experiencing problems due to their symptoms that were there in the first place.

---

## Previous Findings

Before patients visit a clinic for environmental medicine, as a rule they have already been seen by doctors from various disciplines. Many of these patients keep a special file folder that they bring with them to the consultation, usually containing files of numerous previous examinations. Mostly, the previous examiners could not decide on a common diagnosis. Such patients lay great importance on receiving original copies of the findings as quickly as possible in order to store them in this folder. Included in these investigations, besides laboratory screening and human biomonitoring tests, there are investigations of their surroundings. These had usually been carried out by institutions specialized in measuring minute concentrations of chemicals in the air, in dust, and in materials to be found in the home environment. Upon exceeding the background values or reference values of one method, a whole host of complaints are then specified that could match the chemical that has exceeded the reference value.

---

## Findings

A complete physical examination, which should have an internal medicine focus as well as a neurological focus, is essential! One works from top to bottom. In addition to the reflex test, the neurological exam incorporates the extended-hand test, Romberg's test, Babinski, Hackengang, evaluation of superficial and deep sensibility, and testing the diadochokinesis.

---

## Blood Sampling

At a time of cost constraints within health care, some restrictions on laboratory tests should be in place. They should be selective and targeted at searching out any organ pathologies that may already have been indicated in the examination. As a rule, electrolytes, serum liver values, serum kidney values, blood sugar, and blood count with leukocytes, erythrocytes, and platelets are determined, along with an inflammatory parameter, preferably CRP. In respect of the biomonitoring, according to laboratory guidelines either blood or urine should be collected, depending on the pollutant. The urine should be checked at the same time for bacteria and erythrocytes.

---

## Monitoring in Environmental Medicine

The patients' hypothesis is that a pollutant has caused their suffering. Case history and chronological sequence of the complaints should indicate the direction the search has to take to find the source. Basically, one can distinguish between

**environmental monitoring** (ambient (bio)monitoring) and human biomonitoring. Environmental monitoring, in connection with patients, only makes sense if a suspected source is known. Often, this is the dwelling place. A possible increase in pollution in the dwelling place can be ascertained by measuring the ambient air, preferably preceded by a specialized tour of the dwelling and history taking with respect to any potential sources of contamination. Nowadays, only rarely and usually only temporarily following any new fittings or renovations, can an increased concentration of pollutants be found within the dwelling that are likely to induce ailments. In this connection, odor nuisance can be a relevant factor.

*Human biomonitoring* can be divided into exposure biomonitoring, effect biomonitoring, and susceptibility biomonitoring. With **exposure biomonitoring**, the substances absorbed from the environment are registered in body materials, mostly in blood/plasma/serum and/or urine. Biomonitoring of hair, saliva, breast milk, or fatty tissue rarely makes sense. It is not correct to determine formaldehyde contamination on the basis of the identification of formic acid in urine, because formic acid accumulates during metabolism even without exposure to formaldehyde. One speaks of **effect biomonitoring** if the poison itself can be measured less well than one of its effects, which thereby do not have to be toxic yet. A classic example of effect biomonitoring is determining plasma cholinesterase (PChE) to assess a contamination with organophosphates (also see ► [Chap. 42, “Assessment of Background Exposure and Additional Exposure by Human Biomonitoring”](#)). **Susceptibility monitoring** is served by measuring biomarkers that indicate the individual susceptibility to toxic influences. An example of this is determining the expression of detoxification enzymes, or, in the field of allergology, the determination of immunoglobulin E.

---

## Specimen Collection and Processing Procedure

The first thing to consider is what the appropriate materials to use for exposure biomonitoring are. As a rule, blood is a suitable medium to determine an exposure occurring within the near past, while urine covers a somewhat longer time period and especially because most substances are found in higher concentrations in urine than in blood. For some substances, hair can provide evidence of an exposure that took place up to several months previously. However, in the case of hair, it is difficult to distinguish between internal and external exposure. Blood fat provides a suitable medium to determine lipophilic substances. For this purpose, larger amounts of blood are needed. Teeth or bones allow for gauging exposures lying further in the past, even over the course of years.

In order to choose the most suitable material for biomonitoring, it is important to know about the metabolism of a particular substance. So, for material with low renal excretion and high metabolism in the liver, blood/plasma/serum are better and more suitable for analysis than urine. The insecticide lindane is a classic example of this. Unaltered lindane appears in urine in only the slightest amounts, making plasma the more suitable material for ascertaining lindane.

As a rule, 10 ml of EDTA blood and/or 50 ml of urine are required. It is important to ensure that no contamination occurs. As a matter of principle, venous blood, for example, should not be drawn via metal cannulae when ascertaining levels of metals, but rather by means of polyethylene cannulae in situ. This is particularly critical when drawing blood for aluminum, chromium, and nickel analysis, because for these metals there is a high risk of contamination from the surroundings. Urine samples are collected as a random specimen or timed collection specimen. In turn, the most suitable collection vessels for this purpose are made of polyethylene or polystyrene. For determining organochlorine biocides (e.g., DDE, HCB, PCB) in blood, glass tubes should be used throughout the procedure.

---

## Evaluation of Results of Human Biomonitoring

The assessment of the results can be done in two ways. On the one hand, in comparison to the reference value that reflects the background level to be found nowadays in the population, and on the other hand, by means of toxicologically derived values such as the BAT values for the workplace or the HBM values for the environmental area (see “[Cross-References](#)”).

---

## Reference Values for Human Biomonitoring

The comparison of the measured level of contamination of the patient with the reference value provides information about whether a greater than average concentration is present. Excess above the reference value has per se no toxicological relevance.

---

## Toxicologically Derived Human Biomonitoring Values

A comparison of the measured level of contamination of the patient with the toxicologically derived HBM value provides information about the degree of health risk. Unfortunately, HBM values are only available for a few substances.

---

## Limitation of Biomonitoring

Many patients who visit an environmental medical clinic are not aware of which pollutant is causing their ailments. This can lead to an ineffectual, very broadly based biomonitoring. From this, one might conclude that biomonitoring does not have a good cost-benefit ratio at a time when savings are called for in health care. This contrasts with legal concerns: If a patient feels that a certain substance is poisoning him, he has the right to demand clarity. A common problem lies in the interpretation of results. Doctors often certify that, when a reference value is exceeded, then a

patient has a health-related risk. This is pure nonsense, because the reference value is not derived toxicologically. Announcing such erroneous findings results in patients being frequently misdiagnosed as “poisoned.” If everything is unclear, further help can be obtained via ambient monitoring. If under ambient monitoring increased exposure to a specific toxicant is established, under certain circumstances this can be specifically searched for by human biomonitoring. Ambient biomonitoring is, however, not a medical service and, as a rule, must be paid for by the patients themselves.

---

## **Dealing with Environmental Patients from a Psychological and Psychiatric Perspective**

With the present state of knowledge, one must assume that a psychological component (toxicophobia, nocebo effect, phantom risk) plays a role with many patients. In order to meet patients’ needs, in addition to the somatic-orientated and well-trained doctors such as general practitioners or internists, there should be doctors trained in psychosomatic medicine or psychiatry.

---

### **Psychiatric Diagnostics**

Before the therapy, the “gods” have made the diagnosis. As already pointed out above, all known serious somatic disorders must be excluded. Once this is done, the patient has to be examined by a psychiatrist/psychosomatic doctor. As a large-scale study done by us on 308 patients in cooperation with the toxicology and psychiatry departments has shown, in 35.3% of them the presenting symptoms can be completely explained as belonging to a mental disorder. In 21.6%, there was an underlying physical condition that could explain the symptoms adequately. In 22.2%, the simultaneous presence of a mental disorder and a somatic disorder could justify the symptoms. In 1.6%, the patients’ ailments could be explained by the impact of a pollutant. This leaves a group of 14.1% remaining where the ailments could neither be explained somatically nor mentally. These patients were suffering from an impairment of well-being that was neither mental nor psychosomatic.

For an experienced psychiatrist or doctor of psychosomatic medicine, it should not normally be difficult to narrow down the type of mental dysfunction, so long as the patient is prepared to undergo one or more verbal consultations. However, if one wants as scientific and comprehensible a diagnosis as possible, a battery of psychological and/or psychiatric tests is essential. In our study of over 300 patients, of course, not all environmental patients were found to have the same personality or psychiatric disorder, but rather virtually any kind of distinctive personality type or known psychiatric diagnose could be found (Fig. 1). In these studies, we used as test batteries the Symptom Check-List (SCL-90) which is measuring the recent psychological stress and the Structured Clinical Interview following the Diagnostic and Statistical Manual of Mental Disorders (SCID-DSM-IV) Axe I and Axe II.

**Fig. 1** Psychiatric diagnoses in patients with environmental disorders ( $n = 308$ ) (some of the patients have multiple diagnoses)

What they all have in common is simply the belief that the perceived ailments are the result of environmental pollutants. Under somatoform disorders, we understand psychosomatic diseases; under affective disorder, depression and/or manic depression; under anxiety disorders, the phobias; and under psychotic disorders, the schizophrenias.

Others like Skovbjerg et al. (2012) from Denmark used a revised SCL-test the SCL-92 and compared the found symptoms with a healthy control group. Their results confirmed a positive association between symptoms of depression and symptoms of IEI-patients. These depressive patients exhibited significant more CNS and mucosal symptoms. A further association was given between the symptoms and the lack of social support whereas recent severe life events did not influence the symptoms. Nearly 70% of the patients belong to a low occupational social class.

## Further Models of the Origin of IEI

An intensive literature review by Viziano et al. (2018) from Italy including 34 studies with the emphasis on sensory perception concluded that in IEI-patients a multisensory perception disruption is prevailing. In a study by Chiaravalloti et al. (2015) comparing IEI-patients with healthy controls by (18) F-FDG PET/CT the cortical activity in IEI-patients differed from that in healthy individuals. Micarelli et al. (2016) found in IEI-patients a defective central and peripheral vestibular processing by a battery of otoneurological tests. In a study by Andersson et al. (2009), patients with IEI were compared with healthy subjects using a chemosomatosensory, olfactory, and auditory

event-related potentials. The IEI subjects did not get habituated to the stimuli. The results indicate an attention bias, an enhanced sensitization, and a different cognitive response to chemical exposure.

---

## Therapy

Treatment is determined by the diagnosis, of course. If indeed a relevant pollutant exposure can be proved, then the avoidance of this exposure is the decisive therapy. However, if a pollutant exposure is only suspected on the basis of a psychiatric disorder, then psychotherapy comes into play. In the case of *anxiety disorders*, behavior therapy brings fast and good results. In a few of these anxiety disorders, treatment can also be supported by use of psychotropic drugs. The *depressive* disorders usually require a combination of psychotherapy and antidepressant pharmacotherapy. Depending on the severity of the depression, treatment with antidepressants can stand in the foreground (major depression), or a balanced combination therapy consisting of medication and psychotherapy as in the case of milder forms of depression (dysthymia).

*Substance abuse* necessitates detoxification and then withdrawal treatment in an appropriate, specialized clinic that works particularly with group therapy and sociotherapy. Following on from this, self-help groups are particularly meaningful. Schizophrenic disorders require treatment with predominantly high-potency neuroleptic drugs and social therapeutic measures after resolution of the productive symptoms. *Personality disorders* are unfortunately difficult to treat. Sociotherapy, psychotherapy (dialectic behavioral therapy DBT; Transference focused therapy TFP), and psychotropic drug therapy can lead to improvement.

There is repeated emphasis on not taking patients with environmentally associated disorders seriously, and that they should not be unnecessarily *psychiatrically treated*. Which normal-thinking, emphatic-feeling doctor would not take such a patient seriously? On the other hand, psychiatry is part of conventional medicine; "psychiatrization" is not done by doctors. Rather, this is more a phenomenon of society, and it is actually time to overcome stigmatization by means of education. To this end, long years of positive public relations are needed, as has long been the case for other kinds of impairment. Of course, it is useless to try to talk the patient out of his notion that his symptoms are related to environmental toxicants. Letting go of these symptoms is only possible at the end of treatment. Especially in the case of somatic disorders, symptom-orientated psychotherapeutic measures seem sensible. One begins with relaxation training, such as autogenic training, progressive muscle relaxation, or hypnosis. This is combined with deep psychologically orientated focal therapy and cognitive behavioral therapy. The aim is to reduce social isolation and symptoms.

Mechanisms need to be found to help other things become more meaningful rather than just *dealing with the toxicant* (coping strategies). This way, quality of life is improved. Forces, that is healthy aspects of the psyche, are reactivated. In individual cases, there are reports of success in the aforementioned therapy forms

with these kinds of environmentally related somatic disorders. Patients that exclude any psychogenesis – and they are many – cannot be reached at this point in time. Patients who are ambivalent about accepting a psychosomatic illness are treatable with patience. Patients who accept psychotherapy are to a large extent capable of improvement and in about 40% (personal experience) of cases can be cured.

It is interesting that even though patients seek help from alternative medicine therapy forms, they mostly do not break off contact with conventional medicine and carry on expecting help from that quarter, too. This may be an indication that alternative therapies such as chelation agent therapy, antioxidant therapy, electro-acupuncture, or cleansing methods by means of hydrotherapy or Ayurveda therapy do not always lead to success. The psyche needs a valve in order to stabilize itself. Only if changes are possible can the symptoms be minimized. Suppressed conflicts or guilt is often the reason for externalizing, which means that the blame (the toxicant) for a particular plight is sought for in the outside world, because otherwise the burden of internal tensions would be unbearable. It is my wish that such patients may be helped, but this will only work with interdisciplinary cooperation and patience.

## Abstract

This chapter intends to illustrate the general framework of the European Chemical Regulation “REACH” (Registration, Evaluation, Authorization, and Restriction of Chemicals). Special focus will be on the aspects which are important for a regulatory toxicologist. Objectives, scope, and basic rules are explained. The most famous REACH principle is “no data – no market.” So-called “Klimisch reliability criteria” are decisive to determine whether data are suitable for a hazard assessment under REACH. Non-animal-testing approaches such as in vitro methods or weight-of-evidence approaches are encouraged by the regulation.

Registration entails broad-scale derivation of no effect levels for Man and the environment. Exposure scenarios serve as standardized communication tools along the supply chain to convey information on chemical safety under intended use.

Since its implementation more than 10 years ago REACH continued to adjust dynamically to new developments in regulatory toxicology. Several new alternative methods became part of the registration package. They aim at reducing, refining, and replacing animal tests. However, a reverse trend can be observed as well: a reduced acceptance of weight-of-evidence assessments by evaluating authorities. This could lead to even more animal tests in the future for hazard identification.

The 2006 European REACH regulation set a precedence for the world. It established a standard which is increasingly taken as a role model for the chemical regulation in other countries and economic areas.

### Keywords

European Regulation · ECHA · Registration · Evaluation · Authorization · Restriction · DNEL · exposure scenarios · Klimisch criteria · Weight-of-evidence approach

### Abbreviations

BfR	Federal Institute for Risk Assessment (Bundesinstitut für Risikobewertung)

SME	Small or Medium Enterprise
SVHC	Substances of Very High Concern
vPvB	very Persistent very Bioaccumulative

## Introduction

In its 1999 “White paper” the European Union published the result of an analysis of the existing chemical legislation identifying several problems. The paper challenged the existing allocation of resources applying different approaches for new and existing substances. For new substances, even at low tonnage levels, a burdensome and expensive notification was required. On the other hand, producers were not obliged to submit similar data packages for existing substances. Moreover, the systematic evaluation of existing chemicals had turned out inefficient.

After an intensive dialogue with all stakeholders, the “REACH” regulation was adopted in 2006. The acronym “REACH” stands for *Registration, Evaluation, Authorization, and Restriction of Chemicals* (European Union 2006a).

---

## Objectives, Scope, and Implementation of REACH

REACH aims to ensure a high level of protection of human health and the environment, while at the same time enhancing competitiveness and innovation with the focus on less hazardous materials. The regulation applies to substances on their own, substances in mixtures and in articles and is directly applicable in all member states of the European Union.

For the management of the technical, scientific, and administrative aspects of REACH at the Community level, a new institution was founded. This is the European Chemicals Agency (ECHA) in Helsinki, Finland. In order to support industry and authorities to meet their obligations under REACH, technical guidance documents were developed involving experts from various stakeholders (e.g., industry, member states and non-governmental organizations). These documents aim to facilitate the implementation of REACH. They are not prescriptive, but summarize generally acknowledged good practice (ECHA 2013–17). It should be kept in mind that these guidance documents are not legally binding.

In order to maintain the workability of the system, reduced requirements from the obligation to register exist for intermediates under strictly controlled conditions, as well as some exemptions for selected groups of substances (e.g., polymers). Compared to the previous system, an important change is the shift in responsibility for the risk management of substances, which now resides with the industry. Depending on its role as a manufacturer, importer or downstream user (e.g., formulator) industry must comply with specific duties and obligations. A major task for industry is to provide data by filing registrations to ECHA.

At this point in time it is noteworthy that REACH was not the only major change in the regulatory landscape. At about the same time the Globally Harmonized System (GHS) was introduced in the European Union with the adoption of the “CLP-Regulation” (European Union 2008). The regulation sets the ground for classification, labeling, and packaging in the European Union. The idea of GHS goes back to the United Nations Conferences on Environment and Development in

1992 and 2002 (Johannesburg Earth Summit) which decided to develop globally harmonized criteria for classification and labeling.

There are many close links between CLP and REACH. Both regulations make use of a uniform terminology and definitions in order to ensure maximum consistency in the application of chemical legislation within the European Union in the context of global trade. The infrastructure used is basically the same. Both regulations are steered by the same legislative body, the European Chemicals Agency (ECHA). National helpdesks have been established to provide advice to suppliers and any other interested parties, particularly small and medium sized enterprises (SMEs), on their respective responsibilities and obligations under both regulations. The same applies to the technical guidance document for the application of the CLP criteria. It is included in the compendium of supporting documents for REACH on the ECHA website.

---

## **Registration of Chemical Substances: “No Data – No Market”**

The review programs on existing chemicals had indicated that safety data were often lacking even for high production volume chemicals. To overcome this issue, REACH obliges manufacturers and importers of chemicals to systematically compile safety information in a registration dossier.

Tonnage per year manufactured or imported serves as a crude indicator for exposure of Man and the environment, which triggers the extent of information that must be filed in the registration.

---

## **Information Gathering and Closing of Knowledge Gaps**

A registrant who manufactures or imports a substance must collect all available and relevant information for hazard identification and assessment. In many cases, the information gathered consists of test data. However, other types of information such as QSAR and Read-Across may also be accepted, especially when used in a Weight-of-Evidence (WoE) approach (see below). This means that registrants use combined evidence from multiple sources to assess a substance property. In certain circumstances, generating standard data required by REACH may not be necessary (e.g., no exposure to humans and the environment throughout the life cycle of the chemical) or technically not possible. For such cases, REACH provides the option not to provide (i.e., waive) such information.

The registrant is obliged to incorporate all relevant available information in the registration dossier, using IUCLID, a software provided by the European Chemical Agency. To that end the existing physico-chemical, toxicological, and eco-toxicological information are gathered.

Sharing of information on substances among the registrants is strongly encouraged by REACH to reduce testing on vertebrate animals. Information must be shared

with other registrants in a substance information exchange forum (SIEF). The task of a SIEF also includes to agree on a classification.

REACH came into force in 2007. So-called phase-in substances (“existing substances”) benefited from a 10-year transition period with extended registration deadlines. Deadlines set for registration were tonnage- and hazard-driven. Substances with the highest production volumes, classified as CMR (carcinogenic, mutagenic, or toxic to reproduction) or toxic to the environment, needed to be registered first. The registration deadline for the lowest tonnage band of phase-in substances ended in 2018 (see Fig. 1).

For all substances registered after the 2018 deadline for non-phase-in substances, a so-called “inquiry” has to be sent to ECHA to make sure that the substance intended for a new registration was not filed in parallel by another actor. ECHA must approve the inquiry confirming that to their knowledge no duplicate registration efforts are undertaken for the described chemical. Without this confirmation testing on vertebrates in order to meet the information requirements is prohibited.

In case of data gaps, the registrants must generate new data for all substances to be registered or provide justification on why the data is not needed. For example, certain tests can be waived based on physico-chemical properties or on exposure.

Also, information on exposure, use, and risk management measures must be collected.

For the tonnage up to 100 t/year, the information requirements are laid down in annexes VII and VIII (see Table 1).

If relevant information for more endpoints is available, this needs to be submitted as well, regardless of whether information on this given endpoint is required at this tonnage level or not.

**Fig. 1** Timeline for the registration of phase-in substances

**Table 1** Information requirements for substances below 100 t/year

Annex no	Endpoint
VII	Melting/freezing point
VII	Boiling point
VII	Relative density
VII	Vapor pressure
VII	Surface tension
VII	Water solubility
VII	Partition coefficient n-octanol/water
VII	Flash point
VII	Flammability
VII	Explosive properties
VII	Self-ignition temperature
VII	Oxidizing properties
VII	Granulometry
VII	In vitro skin corrosion
VII	In vitro skin irritation
VIII	In vivo skin irritation/corrosion <sup>a</sup>
VII	In vitro eye irritation
VIII	In vivo eye damage/irritation <sup>a</sup>
VII	Skin sensitization <sup>b</sup>
VII	In vitro gene mutation in bacteria
VIII	In vitro cytogenicity study in mammalian cells or in vitro micronucleus study
VIII	In vitro gene mutation in mammalian cells
VII	Acute toxicity: Oral
VIII	Acute toxicity inhalation
VIII	Acute toxicity: Dermal
VIII	Short-term repeated dose toxicity (28 day)
VIII	Screening for reproductive/developmental toxicity
VII	Short-term toxicity on invertebrates (Daphnia, acute)
VII	Growth inhibition study aquatic plants (algae)
VIII	Short-term toxicity on fish (fish, acute)
VIII	Activated sludge respiration inhibition test
VII	Ready biodegradability study
VIII	Hydrolysis as a function of pH
VIII	Adsorption/desorption screening

VII – requirements of annex VII – 1 to <10t/y

VIII – requirements of annex VIII – 10 – < 100 t/y

<sup>a</sup>In vivo study shall only be considered if in vitro study methods are not applicable or results obtained are not adequate for classification and risk assessment

<sup>b</sup>Initially performed in vitro/in chemicco – in vivo testing if in vitro tests methods are not applicable or results obtained are not adequate for classification and risk assessment

Compared to the requirements for the tonnage bands up to 100 t, the test program for *higher* tonnage levels needs to be tailored in a substance specific manner.

Substance characteristics and information already gathered will influence the data requirements for the next stage (i.e., under annex IX and X). The following additional toxicological information may be required under the regime of annex IX and X:

- Subchronic toxicity study (90-day)
- Prenatal developmental toxicity study
- Extended One-Generation Reproductive Toxicity Study (EOGRT)
- Carcinogenicity study
- In the field of ecotoxicity and environmental fate, further investigations may be needed on effects on aquatic organisms after long term exposure (invertebrates and fish)
- Toxicity on terrestrial organisms
- Long-term or reproductive toxicity to birds
- Bioaccumulation
- Degradation

At this tonnage level the registrant must file a test proposal upfront. The proposal needs to be endorsed before the registrant can launch any test (see also Table 5).

In order to generate data on intrinsic properties of substances for a registration under REACH, the test method regulation 440/2008/EC must be consulted (European Union 2008–2017). It contains a compendium of methods for the determination of physico-chemical properties, of toxicity and other health effects, and of ecotoxicity. The regulation is regularly updated and accounts for progress that is being made in the OECD program for the development of test methods (OECD 2005). Due to different processing speeds in incorporating new methods into the regulation, the OECD and EU compendium do not always match each other. In some cases, the OECD was ahead such as in tests for eye damage (OECD 437 and 438). In other cases, the EU compendium was ahead, such as a test for skin irritation (Test method no B46).

REACH considered the tremendous progress in the last 10 years in the development and application of *in vitro* methods. In the case of investigating local skin and eye effects, hazard classification is often possible in the absence of *in vivo* tests. For example, until 2009 animal-free assays existed only for the identification of skin corrosion; however, this changed with the acceptance of a test method using reconstructed human epidermis for the investigation of skin irritation (ECHA 2017a). Unless the substance does *not* fall under the applicability domain of the test, the full scale of hazard categories can be addressed now without the use of animal tests, be it skin corrosion, skin irritation, or no classification (see also flow chart – Table 3).

However, up to now no *in vitro* test for eye irritation is available. Therefore, excluding this hazard may necessitate *in vivo* testing if other approaches (e.g., WoE) are insufficient or inconclusive (ECHA 2018a).

Strong prescriptions for record keeping and quality assurance procedures are a prerequisite for acceptance of data submissions to ECHA. Tests to identify intrinsic

adverse properties for human health in general must follow the principles of Good Laboratory Practices (GLP).

In an ideal world the test of first choice would be a definitive test. This type of test provides enough stand-alone information on dose response and adverse effects to make a final decision with regard to hazard assessment. However, in many cases, data from screening tests go first in a tiered testing strategy and definitive tests come only at a later stage. In special cases additional investigations are needed which do not follow a standard approach but are tailor-made for the hazard assessment of a specific substance. Those adjunct tests help to interpret the results of other tests and provide information useful for the hazard and risk assessment process (OECD 2005).

Physico-chemical data are often used for initial considerations of a specific hazard potential (see ► [Chap. 8, “Characterization of Physicochemical Parameters in Toxicology”](#)). Knowledge on selected properties (e.g., water solubility, acidity, alkalinity, hydrophilicity/lipophilicity, volatility) can foster an understanding whether a substance is bioavailable and to which extent it may be metabolized or be locally toxic.

Such data can also be used to support a read across strategy. For example, grouping of nanomaterials based on physico-chemical and toxicokinetic data should allow to fill data gaps for relevant hazard endpoints by reading across to another nanomaterial or the respective bulk material.

---

## Quality Check of Gathered Information

All information must be assessed for its reliability, relevance, and adequacy.

Reliability is the inherent quality of the information as related to preferably standardized methodology and the way experimental procedure and results are described to give evidence of the clarity and plausibility of the findings. In general, the Klimisch code system allows ranking of the information for further review (see [Table 2](#)). The system consists of four categories (Klimisch et al. 1997):

1. Reliable without restrictions
2. Reliable with restrictions
3. Not reliable
4. Not assignable

In general, only Klimisch category 1 and 2 data are suitable for the hazard assessment of an endpoint. However, for the sake of completeness and transparency studies with a Klimisch code 3 or 4 should be included in the registration dossier.

“Relevance” is the extent to which data and tests are appropriate for a particular hazard assessment. Adequacy is the usefulness of the data for hazard and risk assessment purposes and combines reliability and relevance.

Highest relevance for hazard and risk assessment are reliable human data. However, in cases other than pharmaceuticals, human data generally are scarce.

**Table 2** Klimisch codes/category of reliability**Reliability 1 (reliable without restriction)**

● Guideline study (OECD, etc.) ● Comparable to guideline study ● Test procedure according to national standards (DIN, etc.)

**Reliability 2 (reliable with restrictions)** ● Acceptable, well-documented publication/study report which meets basic scientific principles ● Basic data given; comparable to guidelines/standards ● Comparable to guideline study with acceptable restrictions

**Reliability 3 (not reliable)** more detailed free text

● Method not validated ● Documentation insufficient for assessment ● Does not meet important criteria of today standard methods ● Relevant methodological deficiencies ● Unsuitable test system

**Reliability 4 (not assignable)** short free text ● Only short abstract available ● Only secondary literature (review, tables, books, etc.)

A major pitfall for many human case reports is the lack of robust exposure data. Therefore, a dose-response analysis is rarely possible.

Experimental data, comparable in quality to those generated in controlled pharmaceutical clinical trials, are hardly available. Due to ethical concerns, testing on humans for hazard identification is not allowed. Controlled experimental studies may be used only as confirmatory tests for the assumption on safety made previously based on non-human data.

Poison control centers (PCC) may provide valuable data on the toxic potential of a product and its ingredients. At this point in time, discussion is ongoing how to make better use of the information collected at the PCC (Hahn and Feistkorn 2019).

---

## Hazard Identification and Assessment

For the purpose of hazard assessment, the rules of the CLP regulation apply. These rules are described comprehensively and in detail in the chapter on classification and labeling of this booklet.

In this respect, the WoE approach is a guiding principle of REACH and CLP and is explained in detail in CLP regulation annex I:

*“A weight of evidence determination means that all available information bearing on the determination of hazard is considered together, such as the results of suitable in vitro tests, relevant animal data, information from the application of the category approach (grouping, read-across), (Q)SAR results, human experience such as occupational data and data from accident databases, epidemiological and clinical studies and well documented case reports and observations. The quality and consistency of the data shall be given appropriate weight. Information on substances or mixtures related to the substance or mixture being classified shall be considered as appropriate, as well as site of action and mechanism or mode of action study results. Both positive and negative results shall be assembled together in a single weight of evidence determination.”*

**Table 3** Example for a weight-of-evidence approach

Step	Parameter	Finding	Action
1a:	Existing human or animal skin corrosion/irritation data	Skin corrosive	Classify as skin corrosive
1b:		Skin irritant	Classify as skin irritant
1c:		Not skin corrosive or skin irritant	Not classified
	No/ negative/ insufficient/inconclusive data		
2	Other, existing skin data in animals	Yes; other existing data showing that substance may cause skin corrosion or skin irritation	May be deemed to be skin corrosive or skin irritant
	No/negative/insufficient/inconclusive data		
3	Existing ex vivo/in vitro corrosivity data	Positive: Skin corrosive	Classify as skin corrosive
	No/negative/ insufficient/inconclusive data		
	Existing ex vivo/in vitro irritation data	Positive: Skin irritant	Classify as skin irritant
	No/insufficient/inconclusive data		
4	pH-based assessment (with consideration of acid/alkaline reserve of the chemical)	$\text{pH} \leq 2$ or $\geq 11.5$ with high acid/alkaline reserve or no data for acid / alkaline reserve	Classify as skin corrosive
	Not pH extreme, no pH data or extreme pH with data showing low/no acid/alkaline reserve		
5	Validated structure activity relationship (SAR) methods	Skin corrosive	Deemed to be skin corrosive
		Skin irritant	Deemed to be skin irritant
	No/insufficient/inconclusive data

		Skin irritant	Deemed to be skin irritant
7	Not classified		

Additional provisions are laid down in REACH annex XI, which provides options for meeting the information requirements in annex VII–X by other means than testing.

In a weight of evidence approach, different pieces of available information are weighted. This may be necessary when several reliable studies are available with conflicting results. Moreover, evidence from less relevant information is weighted for the hazard assessment. WoE is endpoint-specific and in general needs expert judgment.

Among the endpoints for which the WoE approach is frequently used is the hazard identification of local skin and eye effects which is demonstrated in the flow chart (Table 3). The flow chart follows the hierarchy of relevance with human

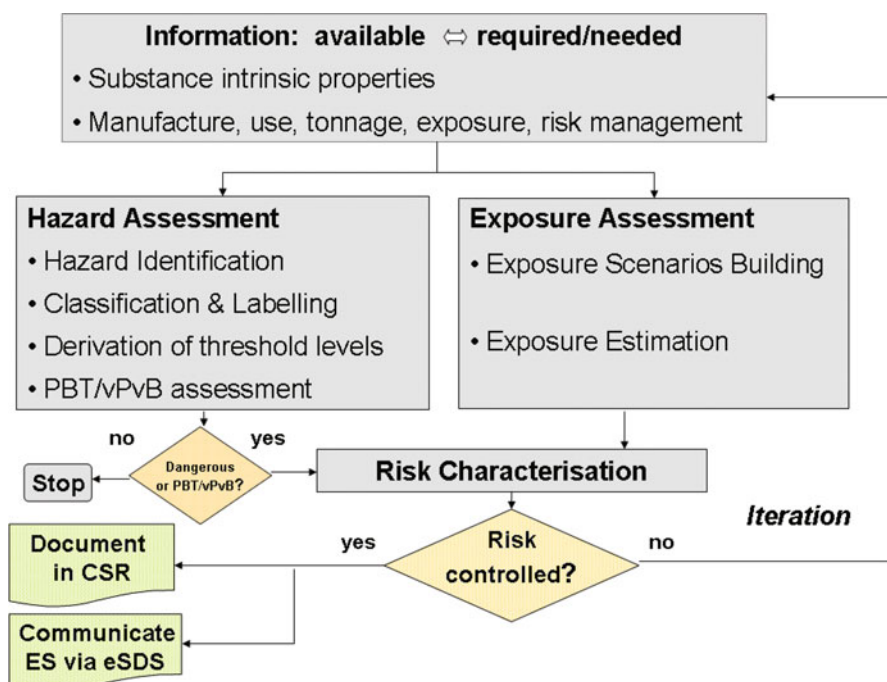

experience as the starting point and going down the road to in vivo data, in vitro data, pH, and alkaline/acidic buffer reserve, and QSAR predictions (ECHA 2017b).

The WoE approach grants flexibility and may reduce the costs and avoid animal tests. A major pitfall of the approach is that it is associated with lower legal certainty as compared to conducting a test.

## Chemical Safety Assessment (CSA)

If a substance to be registered requires classification as dangerous or turns out to be persistent, bioaccumulative or toxic (PBT), or very persistent and very bio-accumulative (vPvB), the risk must be characterized in a chemical safety assessment. The exposure assessment and the risk characterization must be targeted at the specific hazard that had been identified, be it either for human health, physicochemical, environmental, or PBT or vPvB.

The chemical safety assessment is required for all substances subject to registration under REACH in quantities of 10 t or more per year per registrant. Its aim is to ensure that all risks are identified and under control (see Fig. 2) by relating exposure to threshold levels for hazards.

**Fig. 2** Flow scheme for the chemical safety assessment

Exposure assessment is a tiered approach for which three levels are available. Entry into the process is possible at any of the three tiers. This *basic exposure assessment* can be used for all target groups (i.e., workers, general population [consumers, humans via the environment]). The tool commonly used for the basic assessment is the ECETOC targeted risk assessment (ECETOC 2004; ECETOC 2009). With relatively limited entry data results can be quickly obtained.

The next higher assessment tier can be for example *sector-specific generic exposure scenarios*. They are based on sets of exposure scenarios agreed along the supply chain between manufacturers and importers on one hand and downstream users (DUs) on the other hand. Risk management measures must be considered in order to ensure a use is safe to human health and the environment. Exposure scenarios are the communication tool to the user describing how to use a substance in a safe way. They are filed in the CSR together with other information and communicated to DUs via an annex to the safety data sheet (SDS), resulting in an extended safety data sheet (eSDS).

Whenever needed, *tier 3 specific assessments* may be conducted by modeling cases of specific applications as an outcome of joint efforts between supplier and downstream user. Exposure assessment may then be based on actual measurements from downstream use.

(For further background see the chapter on exposure assessment in this booklet – Chap. ► 30, “Exposure Scenarios in Toxicology”).

The last phase of the chemical safety assessment is the risk characterization. Exposure levels must be compared to threshold doses or concentrations for which no adverse effects are expected. They are denoted as “derived-no-effect-levels (DNELs).” In cases where no thresholds can be derived, for example, for genotoxic carcinogens, a “DMEL” (derived minimum effect level) can be assigned. DMELs are defined as levels with a minimum risk that can be tolerated. The discussion below will focus on the DNEL concept, because this is the more commonly used.

DNEL setting must account for several aspects. All conditions of manufacturing or use must be addressed. Different factors must be applied depending on the target (workers, general population). Specific target organ toxicity data after acute and repeated exposure needs to be evaluated with special regard to the character of effects (systemic versus local).

The first step in the derivation of a DNEL is the decision on the initial point-of-departure (POD) value. Most frequently, the lowest reliable, relevant, and adequate no observed adverse effect level (NOAEL) from the registration data set is used as the POD. At this dose or concentration, no adverse treatment-related findings are observed. The NOAEL can be considered as the starting point for the risk assessment. The initial dose descriptor may require modification to address specific needs of the risk characterization. Assessment factors (AF, commonly referred by other regulatory jurisdictions as “modifying” or “uncertainty” factors) are then applied to the POD. Such factors address interspecies and intraspecies uncertainty and variability, exposure duration differences, dose-response considerations, and the overall quality of the dataset. The various AFs are multiplied, and the resulting product is

		ECETOC	ECHA TGD
Interspecies	rat–human	4	4
	,remaining differences‘		2.5
Intraspecies	Worker	3	5
	General population	5	10
Exposure Duration	28days → 90days	3	3
	90days → 2 years	2	2
	28days → 2 years	6	6
Route-to-route	Oral → inhalation		2

**Fig. 3** Assessment factors for DNEL setting

used to divide the POD to derive a DNEL. The DNEL implies that humans should not be exposed to doses or concentrations above this level. Exposures below the DNEL are considered as “adequately controlled.”

The ECHA technical guidance provides standard default assessment factors for DNEL setting. Several reviews showed that the ECHA factors are significantly more conservative than any other currently existing health benchmarks. Consequently, the DNELs derived, especially for the worker population are far lower than existing occupational exposure levels (OELs) utilized in Europe like the MAK and SCOEL values (Kreider and Spencer Williams 2010). Figure 3 provides a comparison of assessment factors as used, for example, by ECETOC and as described by the ECHA guidance (ECETOC 2010).

Risks are regarded as adequately controlled under REACH when the exposure levels to the substance are below the DNELs. This renders a “risk calculation ratio” (RCR). If risks are not under control, an iterative process starts. The chemical safety assessment must be refined, either by obtaining more data on the properties of the substance or by refining the exposure estimations to achieve more realistic estimates or implementing risk management measures.

(For further background see the following chapters: ▶ 6, “Toxicological Risk Assessment,” ▶ 22, “Dose-Response Analysis: Identification of Threshold Levels for Chemicals,” ▶ 23, “Extrapolation Procedures for Carcinogenic and Non-carcinogenic Compounds,” ▶ 65, “Assessment of Limit Values in Regulatory Toxicology,” ▶ 66, “Limit Value Setting in Different Regulatory Areas of Toxicology”).

As a result of the risk characterization, the registrant defines the appropriate risk management measures to adequately control the risks. The measures are communicated down the supply chain by extended safety data sheets (eSDS). If for a specific use of a substance the risks are not under control, the supplier designates and communicates a use which he does not support. To this end Chapter 1.2 of the safety data sheet (“use advised against”) is the right place for communication.

Exposure scenarios facilitate communication along the supply chain.

**Table 4** Use descriptor system under REACH

Descriptor types		(Examples)
LCS	6 life cycle stages	IS: Use at industrial sites
SU	23 sectors of use	SU 11: Manufacture of rubber products
PROC	31 process categories	PROC 15: Use as a laboratory reagent
PC	43 product categories	PC17: Hydraulic fluids
AC	39 article categories	AC3–2: Electrical batteries and accumulators
ERC	25 environmental release categories	ERC6c: Production of plastics

Exposure scenarios are a set of conditions [usually based on a Process Category (PROC code) for workers, Product Category (PC Code) or Article Category (AC) for consumers or Environmental Release Category (ERC) for the environment] that describe how a substance can be safely used throughout its life cycle (see Table 4). Such scenarios include the necessary operational conditions (OCs) and risk management measures (RMMs). For each exposure scenario, the exposure levels of humans and the environment need to be determined. The exposure scenarios will cover all supported uses and life stages of the substance (ECHA 2011–2019).

If a downstream user notes that his own uses are not covered in the safety data sheet of his supplier, he can either contact his supplier in order to get the own uses covered or prepare his own CSA. To that end he may make use of the available information in the safety data sheet of the supplier.

The chemical safety assessment is documented in the Chemical Safety Report (CSR). A chemical safety report must always be current.

---

## Evaluation

Registration dossiers are initially subjected to a technical completeness check which must be distinguished from the phase of dossier evaluation. A completeness check is conducted for each registration dossier before a registration number is allocated whereas the subsequent dossier evaluation (“compliance check”) to assess the completeness and adequacy of the information provided is done on a spot-check basis by ECHA. Additionally, a substance evaluation is being performed for specific substances of potential high concern, being listed in the Community Rolling Action Plan (CoRAP). The criteria for substance selection combine both hazard and exposure aspects in a risk-based approach. Hazard related selection criteria comprise for example endocrine disruption, CMR, and sensitizing properties (see Table 5).

The responsibility for this evaluation is with the different member states which scrutinize whether a substance constitutes a risk to human health or the environment. In contrast to the compliance check, information requested from registrants during a substance evaluation typically goes beyond the standard requirements of REACH as they are needed to clarify a specific concern. Based on the outcome of the substance

**Table 5** Evaluation processes under REACH

Item	By whom?
Technical completeness check	ECHA (automatically with manual verifications by ECHA staff)
Dossier evaluation (ECHA) – Compliance check	ECHA
Substance evaluation (CoRAP)	Competent authorities of the member states
Evaluation of test proposals (annex IX und X)	ECHA

evaluation, a follow-up regulatory action such as a need for harmonized classification and labeling or the need to start authorization or restriction processes might be identified by the respective competent authority.

## Authorization and Restriction

Authorization and Restriction are the risk management instruments of the competent authorities of the member states and the EU commission under REACH.

The REACH regulation intends to filter out substances of very high concern (SVHC) by controlling their use. Temporary authorizations are granted under certain conditions of uses while working towards their substitution. High concern is raised by substances that are CMRs, PBTs, or vPvBs. Apart from these SVHCs which are explicitly mentioned in the regulation, article 57 contains an opening clause that enables competent authorities to carry out individual case-by-case examinations for further substances. In cases of “scientific evidence of probable serious effects to human health or the environment which give rise to an equivalent level of concern,” these substances may also be proposed for authorization. Candidate substances for this procedure are endocrine disruptors.

Authorizations of uses for the placing on the market are granted by the Commission if the risks arising from their use are adequately controlled, in principle when derivation of limit values is possible. In those cases where a substance causes an unacceptable risk to human health or to the environment, its substitution must be considered. The considerations account for suitable alternatives, if available, that are economically and technically feasible. In cases where no adequate control can be ensured (e.g., non-threshold substances), a socio-economic analysis (SEA) must be prepared, demonstrating that the benefit of further use of the substance outweighs societal risk.

*Authorized* substances are generally banned except for some specific uses, which have been authorized by the EU Commission after application. Companies must apply for exemptions and provide a justification for a continuous use.

In contrast, the *restriction* of substances does not represent a total ban but the prohibition of certain uses. Restriction can be understood as a measure from authorities to manage situations where specific risks are not adequately controlled.

## Learnings

Up till now approximately 98,500 dossiers have been submitted for about 22,800 substances by 15,300 companies. This equals total registration costs of up to 3 billion Euro (Haider 2019).

The processes of substance evaluation and risk management are ongoing. As of December 2019, 376 substances have been included in the CoRAP list. The evaluation of 117 substances has been completed. 201 substances have been included in the SVHC list and the authorization list already comprises 43 substances.

So far, 73 restrictions for 70 different substances have been adopted under REACH.

After 10 years of REACH, the Commission did a review of the achievements and concluded that “the REACH regulation functions well, delivers results and addresses citizens” concerns about chemical safety. However, the report states that further improvements are needed to make the legislation more efficient – especially for the evaluation, restriction and authorization processes. The report sets out actions for ECHA, the Member States, Commission, and industry (ECHA 2018b).

A recent study on REACH compliance by the German Federal Institute for Risk Assessment (Bundesinstitut für Risikobewertung – BfR 2018) emphasized the need for improvement. The BfR study indicated that at least one third of the registrations reviewed in the project are considered as non-compliant because they use insufficient alternative data or data waiving to cover higher tier endpoints. It is not surprising that the outcome of the BfR conclusion triggered controversial discussions between industry and authorities. As the regulation allows animal testing only as the last resort, many registrants used derogations/data waivers to avoid testing. Uncertainty seems evident in two aspects: *safety* uncertainty because important data may be missing that impacts the risk characterization and *legal* uncertainty given the “complaint of non-compliance” by the authority to registrants that used derogations/data waivers for animal welfare and cost saving reasons.

A major issue when REACH was introduced was the need for animal testing to obtain data on the hazard potential of chemicals. The ECB estimated the number of animals required for the phase-in substances at 40 million animals (European Commission 2006).

This scary number led to several provisions in the regulation to reduce animal use, mainly by opening options for alternatives in testing and evaluation. Indeed, ECHA rapidly took responsibility to embrace newly developed alternative methods as soon as they were available and accordingly amended the requirements of the annexes VII through X. Both in vitro tests for local irritation and corrosion on skin and eye effects were included in the standard data set. They (partly) replaced the in vivo methods. The same applies to skin sensitization, for which now a set of five in vitro tests is available and must be used as the starting point by the registrant. These approaches save the life of 6 rabbits (irritation) or 16 mice (sensitization). However, tests with high animal use (repeated dose testing, reproductive and developmental toxicity, carcinogenicity) currently lack accepted test alternatives. One exception to be mentioned here is the replacement of the two-generation reproductive toxicity

study by the EOGRT (“Extended one generation reproductive toxicity study”), which significantly reduces the number of animals used per test: 1400 instead of 2600.

Before the adoption of REACH alternative *assessment* strategies were regarded as a salvage pathway (European Union 2006b). Especially, the weight of evidence approach including read-across, QSAR modeling, and exposure-based waiving (TTC-concept) were ideas to reduce the number of tests with high animal consumption. However, experience from the first 10 years shows that waivers are increasingly challenged by the evaluating authorities.

(Further background can be found in the following chapters: ► 14, “Computer-Based Prediction Models in Regulatory Toxicology,” ► 12, “Toxicity Testing In Vitro: Regulatory Aspects”).

Statistics on the number of animals used so far due to the REACH requirements are not available.

With the trend not to accept waivers, it is questionable whether the target to reduce animal use as defined in the 2006 JRC statement will be reached.

---

## Outlook

The European Commission intends to amend the regulation to increase dossier compliance. The future target for ECHA will be to evaluate 20% (instead of 5%) of all registration dossiers in each tonnage band which equals to about 30% of all registered substances. Whilst ECHA is focusing on dossier evaluation, registrants are requested to steadily update their registration dossiers with new information.

One of the major focus areas of substance evaluations scheduled for the next years are endocrine disruptors (EDs) which are eligible as being identified as SVHC based on equivalent level of concern as for PBT and CMR substances.

While the evaluation of ED properties in the REACH dossiers is currently based on available study data, for example, higher tier reproductive toxicity studies, the European Commission proposed to update the regulation to include specific testing requirements for ED including the need for a formal ED assessment in the dossier. However, no conclusion on these proposals has been reached yet.

Other topics currently discussed for potential including in the regulation are registration requirements for polymers, which are currently exempted from the regulation.

There is no doubt that REACH is having global implications. Many regulatory jurisdictions outside of Europe have been adopting new regulations that model after REACH. As part of the process of harmonization with European law, in 2017 Turkey published a chemical regulation that is 95% identical with the European REACH regulation. It requires all substances imported or manufactured in/into Turkey to be registered by 2023. In contrast to EU REACH, there are very strict requirements around the chemical safety assessment (CSR). Any chemical safety assessments must be done by a certified expert, trained by an accredited institution. The requirements of certification are clearly defined in the regulation. Like Turkey, Korea

published a REACH-like regulation with a final registration deadline for substances above 1 t in 2030. While the main requirements are similar to the EU REACH, some specifics are different. For example, Korea requires the registration of polymers, which are currently exempted from the EU REACH.

REACH is an unprecedented chemical legislation, which continuously increases the safety information on chemical substances. Communication along the supply chain is intense. Numerous new threshold values have been and continue to be generated. More substances than in the past are under discussion at the same time due to newly identified hazard properties. Evaluation leads to broad-scale legislative actions, be it new hazard classifications with corresponding impact to downstream legislation or REACH-related, authorizations, and restrictions.

REACH is a highly complex regulation which requires and will continue to require huge endeavors from all impacted stakeholders.

## Abstract

In general, test data for mixtures are available only in rare cases. For a hazard assessment, a common surrogate method is to delineate their hazard potential from data of individual ingredients. Another approach exists to extrapolate from mixtures with test data to nontested mixtures. Such bridging principles have been in use in certain sector-specific applications already in the past. With the adoption of the new globally harmonized system for classification and labeling of chemicals (GHS), bridging principles gained a broad regulatory acceptance for the hazard assessment of mixtures. In order to make use of the principles, strong formal requirements must be fulfilled. This chapter describes the various applicable principles, such as the principle of “dilution,” “concentration,” “interpolation,” and “batching” of “substantially similar mixtures.”

Another way for the assessment of a mixture is the weight of evidence approach leading to an expert judgment. It is less formal, but it suffers from legal certainty and may be challenged more frequently by third parties.

## Introduction

Test data on mixtures are scarce. This is due to the fact that the number of mixtures on the market by far exceeds the number of single substances: the world of chemistry is mainly a world of mixtures. To make best use of limited resources and to limit animal tests to a minimum, mixtures are basically assessed on their toxicological hazard by other means than direct testing.

EU Regulation (EC) No 1272/2008 on the classification, labeling, and packaging of substances and mixtures (“CLP Regulation”) incorporates the concept of using reference mixtures by suggesting the following options:

- Additivity principle
- Evaluation of the degree of modification of a nontested mixture as compared to the reference mixture (concept of “minor modification”)
- Assessment of mixtures based on existing toxicological data on similar mixtures (i.e., bridging principles)
- Weight of evidence and expert judgment

---

## The Additivity Principle

A commonly used approach is modular: Toxicity is evaluated based on the toxicological properties of the individual components and their mass content in the mixture. This approach follows general conventions which are laid down under the globally harmonized system. In the EU, they were adopted under the Regulation on Classification, Labelling and Packaging (CLP). They are known as “additivity principles.” For more details, consult the CLP regulation and also additional guidance in this booklet, see ► [Chap. 68, “Health Hazard Classification and Labelling”](#).

In those rare cases where test data on mixtures are available, rules exist to extrapolate from a mixture for which the hazard must be assessed to a tested mixture.

Extrapolation needs a comprehensive technical justification. At a practical level, a reference mixture is defined as a mixture of known composition which has been tested for a toxicological or ecotoxicological endpoint of interest (e.g., skin or eye irritation/corrosion). Both the reference mixture and the untested mixture must be well characterized to allow a classification decision. Chemical characterization includes data on relevant physicochemical properties, such as the pH of the mixture and its buffer reserve (alkalinity/acidity) in the case of pH extreme formulations (see also ► [Chap. 8, “Characterization of Physicochemical Parameters in Toxicology”](#)). Well-documented data on the toxicological properties on the mixtures and their ingredients must be comprehensive and reliability-checked (see also ► [Chap. 76, “REACH and CLP: Its Role in Regulatory Toxicology”](#)).

---

## The Concept of “Minor Modifications”

A separate and complete toxicity assessment of a modified mixture does not need to be carried out if the modification is only minor in comparison to a classified reference mixture for which toxicity data are available. In this context, “minor” means that the modification lies within the permitted variations for the initial concentrations of the hazardous constituents, as shown in Table 1.

**Table 1** Permitted variations for consideration as a minor modification

Initial concentration Range of the constituent	Permitted variation in initial concentration of the constituent
<2.5%	±30%
2.5% < C < 10%	±20%
10% < C < 25%	±10%
25% < C < 100%	±5%

If the variations in the modified mixture exceed the limits, they no longer can be considered “minor.” Then, the mixture should be evaluated with concepts other than the “minor-modification principle.”

## Bridging Principles

In the absence of adequate toxicity information for a mixture *as such*, it should be considered whether available toxicity data from *similar* mixtures can be used. The underlying concept encompasses the comparison (i.e., “bridging”) of the available technical information. The comparison endpoint is specific. In other words, a bridging may, e.g., be possible for local skin effects, but not necessarily also for systemic repeated dose toxicity.

The following “bridging principles” are part of the Globally Harmonized System (GHS – United Nations 2005)/European Classification, Labeling and Packaging Regulation (CLP – European Union 2008):

- *Concentration* of highly hazardous mixtures – Where a mixture is already classified in the highest hazard category, then it can be assumed that a more concentrated mixture will also be in the highest hazard category.
- *Dilution* – The test mixture is diluted with a substance (diluent) that has the same or a lower hazard category than the least hazardous ingredient in the original mixture. In this case it can be assumed that the respective hazard of the new mixture is equivalent to that of the original tested mixture.
- *Interpolation* within one toxicity category – defines how much the concentration of a hazardous mixture may vary without changing the classification. Usually two reference mixtures are needed which are broadly similar and in the same hazard category for a given endpoint. Typically, a third mixture has the same hazardous constituents in concentrations that are between those of the two reference mixtures and can be classified the same as the reference mixtures. It is noted that this approach may allow greater variation for individual constituents than those permitted in the “minor” “modification method” highlighted in Table 1.
- *Substantially similar mixtures* – this applies if constituents with the same hazard category and the same potency are exchanged in a mixture. In this case, the hazard category of the mixture does not change. Potency may be expressed by specific concentration limits: If two ingredients are in the same hazard category, e.g.,

category 2 – “severe eye irritation,” but the specific concentration limits are, e.g., 5% and 20%, then they do *not* have the same potency. In this case, the principle of “substantially similar mixtures” cannot be applied.

- *Batching* – If a batch of a mixture is produced under a controlled process, then it is assumed that the hazards of each new batch are equivalent to those of previous batches. This method cannot be used where there is significant variation between batches which may affect hazard classification.

Long before the adoption of GHS and CLP, such bridging principles had been tried and tested in certain chemical sectors like the detergents industry (AISE 1993). They gained broad, but not unanimous acceptance in the regulatory community. With CLP, a strong basis and higher legal certainty as compared to the past were achieved across the overall European Union and beyond.

Experience over decades showed that “Interpolation within one toxicity category” and “substantially similar mixtures” are the bridging principles mostly used in the day-to-day classification business.

Further details on the use of bridging principles are given in the CLP Regulation and in the Guidance on the application of Regulation (EC) No 1272/2008 (ECHA 2017).

---

## Weight of Evidence (WOE) Approach and Expert Judgment

Generally, the criteria for using the bridging principles for the classification of mixtures are strict. Often, they are not applicable for formal reasons. Therefore, the use of expert judgment to decide on the classification or nonclassification of a mixture can be helpful.

Expert judgment requires knowledge of the chemistry and toxicological profile of the product categories in question. Also, expertise is required to weigh the relevance of different types of test systems. The latter is particularly important when the classification of the reference mixture is based on heterogeneous data sets including data from scientifically valid but not fully validated methodologies or in cases where conflicting information is available.

Classification of a mixture based on WOE requires the consideration of all available information bearing on the determination of a given health endpoint. This includes results of suitable *in vitro* tests, relevant animal data, chemical category information, quantitative structure activity relationship (QSAR) results, and human experience taken from occupational, epidemiological, clinical studies, and well-documented case reports. The quality and consistency of the information must be given appropriate consideration. Positive and negative results should be collected in a single WOE determination (see ► [Chap. 76, “REACH and CLP: Its Role in Regulatory Toxicology”](#)).

The priority given to different pieces of information is generally determined on a case-by-case basis. Some guidance is provided by the CLP Regulation to address conflicting findings (European Union 2008). From this guidance, basic qualitative rules can be established for the classification and labeling of mixtures:

1. When several studies with conflicting results are available for one reference mixture, the quality and reliability of the studies, as well as their relevance for classification and labeling, must be taken into account. Toxicity data derived from *in vitro* and *in vivo* studies are generally viewed as acceptable if they receive a reliability score of 1 or 2 according to the Klimisch criteria (Klimisch et al. 1997). When the reliability of studies is comparable, studies considered the most relevant for the particular hazard are given more weight in the assessment. In general, the following relevance hierarchy applies:  
human studies > animal studies > *in vitro* studies > QSAR studies  
However, deviation from this hierarchy may occur on a case-by-case basis when study specifics are considered. Hence, the final decision, which studies are most relevant, is subject to expert judgment.
2. In case, the study results of two or more reference mixtures are in conflict, the degree of similarity of the reference mixture to the mixture to be assessed, in addition to the factors mentioned above, will need consideration. The data from the reference mixture that is judged to be the closest to the comparison mixture under assessment should be given the greatest weight.
3. In cases of no appreciable differences in study reliability or ranking, the study giving rise to the highest concern should be taken as the key study for the classification of the comparison mixture.

---

## Outlook

Over the last two decades *in vitro* methods were adopted especially for eye and skin. They provide new tools to overcome the initial imperative not to test mixtures: Animal welfare considerations do not play a role when applying *in vitro* methods.

Not surprisingly, the new *in vitro* methods are increasingly used also for the testing of mixtures. Today, e.g., for the investigation of skin effects a full battery is available to enable a decision whether a mixture is either corrosive, irritant, or does not require hazard classification. However, caution is needed because experience with the new methods is limited. The applicability of the new methods for the plethora of substances still needs to be proven, given the fact that the validation trials included only a limited number of substances and mixtures.

Toxicologists must keep in mind the frequently limited data base which leads to the adoption of *in vitro* tests. No doubt, they offer new opportunities. However, toxicologists need to continue to collect and analyze the test results and compare them with gold-standard data (human or *in vivo*) to increase confidence that the methods are applied appropriately in every case.

## Abstract

Poisons centers (PC) support medical management of poisoning cases in all parts of the health system. Most often, PC are involved in emergency cases, providing a rapid clinical risk assessment (RCRA). RCRA includes identification of products the patient is exposed to, retrieval of their chemical formulas, compilation of specific information on the toxicity of the ingredients, and evaluation of the patient's individual exposure and condition. The result of the RCRA forms the basis for advices on medical management of the poisoning case. To perform

RCRA adequately, it is crucial that PC receive information on the composition and toxicological properties of products placed on the market. To ensure this, submission of information on hazardous mixtures and cosmetic products by companies to PC is a legal obligation in all EU Member States. Harmonized notification formats and procedures and two modern European database systems, i.e., the European Chemicals Agency (ECHA) Poison Centre Notification (PCN) Submission Portal (PCNP) and Cosmetic Products Notification Portal (CPNP), help to increase dataset quality and to reduce notification workload for industry.

## Introduction

Poisons centers provide information on poisons and give medical advice in cases of accidents with substances, including toxins and synthetic chemicals. For this purpose, they need all the available information on the often complex ingredients of chemical products and cosmetic products.

The European Commission has harmonized information requirements for mixtures classified as hazardous for human health or physical effects becoming mandatory in 2021 or 2024. Importers and downstream users shall submit this mixture information to Member States, to be used by their poison centers for emergency health response.

EU Cosmetics legislation requires that cosmetic products to be marketed in the EU must be registered in the Cosmetic Products Notification Portal before being placed on the market since 2013. This portal is making this information available to poison centers for the purposes of medical treatment and for enforcement authorities for market surveillance.

---

## Poisons Centers Have an Important Role in Clinical and Regulatory Toxicology

Today, about 80 poisons centers (poison control centers, poison information centers, PC) play an important role in toxicological risk assessment and management of human (and animal) poisonings in Europe, especially in emergency medicine. Worldwide, about 200 PC are registered in a directory of the World Health Organization. PC either are independent public institutions or are affiliated with a (university) hospital or an authority.

In PC, toxicologically trained medical doctors and other experts (specialists in poison information (SPIs), e.g., pharmacists or nurses) provide information to general practitioners, medical doctors at the hospital, or other professional healthcare

personnel on poisoning risks, clinical symptoms, and medical treatment of patients exposed to a toxic agent. As an intoxication progresses and/or if a patient is admitted to a hospital, often several calls are needed to complete the toxicological risk assessment, medical diagnosis, advice on the individual poisoning management plan, and case recording.

In most countries, PC also give advice directly to the exposed patient or to family members, especially if children are exposed. An “all-clear” can be given in the majority of these cases and thus saves thousands of unnecessary presentations to the emergency medical system every day (European Commission Services 2020).

PC are often contacted by local, national, and European authorities and by industry to report on their experiences with specific poisonings. To answer these questions – and to analyze cases for quality assessment of the service and for medical studies – PC register all exposure cases in local or national case databases. PC case databases are recurrently analyzed to describe poisoning frequencies, detect new poisoning risks, and identify poisoning trends, e.g., novel poisoning risks arising from new agents and products in an early stage (*toxicovigilance*).

---

## **Notification of Product Information for Poisons Centers Facilitates Rapid Clinical Risk Assessment**

The most important part of the PC service is to perform or to support clinical risk assessment. Together with findings of the physical examination of the patient and in ambiguous cases the results of toxicological lab investigations, the risk assessment constitutes the basis for correct medical diagnosis and subsequent medical decisions on patient treatment and monitoring.

To facilitate toxicological risk assessment after exposure to a potentially hazardous commercial product, access to toxicity-related product information, especially detailed information on the product formula, is needed. Two European Union (EU) regulations are directed to harmonization and centralization of product notification in EU Member States.

## **Harmonized Notification of Hazardous Products According to CLP Regulation (EC) No. 1272/2008, Article 45 and Annex VIII**

Article 45 of the Regulation on classification, labelling, and packaging of substances and mixtures (EU) No. 1272/2008 (CLP Regulation) states that poisons centers shall have at their disposal all product information needed to carry out “the tasks for which they are responsible,” i.e., mainly for clinical risk assessment in emergency cases (European Parliament and Council 2008 Regulation (EC) No 1272/2008).

For this purpose, all EU Member States had to appoint a body or bodies responsible for receiving this information including “the chemical composition of mixtures placed on the market and classified as hazardous on the basis of their health or physical effects.” The appointed body, i.e., a governmental authority in most Member States or a PC, continuously collects product information notified by duty-

holding companies, i.e., “importers and downstream users.” Product data have to be kept confidential and must not be used for any purpose except (1) medical management of poisoning cases or (2) statistical data analysis to facilitate poisoning prevention if requested by the Member State (de Groot et al. 2017).

However, Article 45 does not describe in detail what information is required and how it should be notified. This shortcoming was recognized at a late stage in the development of the CLP Regulation, leading to introduction of Paragraph 4 to Article 45: following this paragraph, the European Commission Services carried out a review to see whether European harmonization of product notification is feasible. The review process included consultations with relevant stakeholders such as the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT), industry associations, and national authorities from 2009 to 2011. After a positive outcome, the European Commission Services, together with all stakeholders, developed Annex VIII to the CLP Regulation, released as Regulation (EU) No 2017/543. Annex VIII defines the procedures and information requirements for harmonized electronic product notification in all EU Member States. These requirements applies in 2021 for mixtures for consumer and professional use and for mixtures with industrial use in 2024. Advised by the Regulation, the European Chemicals Agency (ECHA) has developed the technical Poison Centres Notification (PCN) format for submission of the required information.

The main features of the Annex VIII/PCN format are:

1. In contrast to the requirements for Safety Data Sheets, also non-classified ingredients shall be notified if present above a threshold concentration.
2. Concentration of ingredients in a mixture can be notified using flexible ranges with well-defined width.
3. A Unique Formula Identifier (UFI), a 16-digit alphanumeric code, that has to be printed on or affixed to the product label, is assigned to each mixture composition dataset.
4. The format contains an intended use product category for each product; a European Product Category System (EU-PCS) was developed for this purpose.
5. The PCN format is described by Extensible Markup Language (XML) scheme.

The PCN format is a subset of IUCLID, a format developed and maintained by OECD in close collaboration with the ECHA, used for the registration of substances according to the REACH Regulation. For further facilitation of product data submission, the “ECHA PCN Submission Portal” (PCNP) was established in 2019. It allows industry to upload notification dossiers or to prepare and submit notification dossiers online. In addition, the portal performs a technical validation of the submissions and distributes the datasets to those Member States’ appointed bodies addressed by the submitter. The ECHA Submission Portal is accessible via ECHA’s “Poison Centres Website” (European Chemicals Agency (ECHA) 2020).

As late development and based on a European Commission’s decision, ECHA has developed and is maintaining a searchable database containing all Poison Centre

Notifications submitted for each Member State, the so-called “Poison Centre Notification (PCN) Database.”

## The Cosmetic Products Notification Portal

According to Article 13 of the Cosmetics Regulation (EC) No. 1223/2009, there is an obligation for all manufacturers and importers of cosmetic products to notify product information to a central European database, the “Cosmetic Products Notification Portal (CPNP)” (European Parliament and Council 2009 Regulation (EC) No 1223/2009). The CPNP is located at the European Commission Services in Brussels. Poisons Centres of all EU Member States have access to the complete CPNP dataset; competent national authorities have access to a data subset needed for market surveillance. PC can either access the CPNP online or download datasets for import into local PC product databases. Local product data download enables reliable and easy linkage between poisoning case documentation and product formula in the PC databases to facilitate reporting (toxicovigilance, see above) (European Commission Services 2002a (CPNP) – Cosmetics – Consumer Affairs).

Notification to the CPNP is performed online through a secured website. One out of three different formats can be chosen:

1. Frame formulations (FF) for products containing only ingredients of low toxicological concern under most exposure conditions. FF are indicating maximum concentrations for ingredients. The set of frame formulations was defined and is maintained by a working group of the European Commission, Poisons Centres, and cosmetic industry.
2. FF plus indication of exact concentrations for ingredients with moderate or high toxicity.
3. Notification of full formula with exact concentration for all ingredients.

Besides the formula, further data have to be submitted, e.g., exact and complete product name(s) in all relevant languages, pH value, and image of the packaging. There are strict rules for when an update of product information is required (European Commission Services 2002b (CPNP) – User Manual).

successful and continue until today. But nevertheless, it was not possible to forestall their use completely as shown recently by the events in Syria and most probably the attack on Kim Jong Nam. This chapter gives a short introduction in the field. It also characterizes some important agents and outlines, what is necessary to be prepared against a possible attack.

---

## Introduction and History

Chemical warfare agents are chemicals, which have a very high toxicity and may therefore be misused as weapons to cause death or disease among the target population. For historical reasons, the term “chemical warfare” agent includes synthetic chemicals (toxicants) but usually does not include the toxins, which are poisons produced by living organisms. Toxin agents are often taken as a subgroup of biological agents (see below). However, for the toxicological risk assessment, there is no basic difference between toxicants and toxins. The disabling effect of such weapons on target persons is horrific. It is in the nature of such agents that they will without differentiation affect the exposed population.

It is probably a result of the widespread use of chemical weapons during World War I that international efforts were made, to restrict and ban such agents. In 1925, the use of asphyxiating, poisonous, or other gases and of bacteriological methods of warfare was prohibited and included in the Geneva Protocol. Mandatory regulations regarding the possession and development of warfare agents followed in 1968 (Chemical Weapons Convention) and 1972 (Biological Weapons Convention). On 29 April 1997 the Chemical Warfare convention entered into force, and 193 (data from today, one more nation is a member). Despite these regulations, several offenses occurred. The exile Bulgarian Markov died after an attack with ricin toxin in London in 1978. About 10 years later, members of the Japanese Aum Shinrikyo cult tried to poison attendants of a royal wedding party spraying medium supernatant from cultures of neurotoxin-producing *Clostridium botulinum* strains. According to the American “Working Group on Civilian Biodefense,” 19,000 l of botulinum neurotoxin were produced during the 1990s in Iraq. Officially, there are no existent biological warfare programs nowadays. However, their presence cannot be completely denied as there are no legal control mechanisms. In 1995, the sarin subway attack was of terrorist origin. Such an attack is able to scare a whole nation and has high impact on politics and decision-making. In 2013, ricin toxin was used in a bioterror attack in the United States when three series of letters containing the substance were sent to officials and even the President. Although nobody was injured, the news attracted public attention and intensive media coverage worldwide. Chemical warfare agents are likely to be used in terrorist attacks as they are relatively easy to produce and designed to have a high lethality.

The use of poison in military conflicts is very old. One of the first attempts to use toxic substances in military operations was during the Cirraean war [595–585 BC].

The city of Kirrah was attacked by the Amphictyonic League of Delphi. A secret water supply of the city was poisoned with *Helleborus* roots. Helleborin caused severe diarrhea and weakened the defenders of the city. This is believed to be the first report of chemical warfare. Later in history, more toxic substances have been stockpiled and used as chemical weapons.

For example, historical documents claim the Assyrians to consciously poison their enemies by the application of *Claviceps purpurea*'s ergot in the sixth century BC. Later in time, one of Hannibal's warfare strategies aimed at throwing poisonous snakes on Pergamenes' ships.

Chemical warfare agents are still stockpiled and available for military use. After the last chemical war between Iran and Iraq 30 years ago, there was a long lag-period, in which there was no proof for the use of chemical or biological weapons in war. However, the situation changed dramatically, when in August 2013, news on a possible use of chemical weapons in a populated area in Syria made the headlines. Meanwhile, the use of sarin and sulfur mustard during the Syria crises was reported by the OPCW as having been verified and responsible for more than 1000 victims.

---

## Chemical Weapons

### Definitions

Article II of the Chemical Weapons Convention (CWC) defines a *toxic chemical* as "any chemical which through its chemical action on life processes can cause death, temporary incapacitation or permanent harm to humans or animals." *Toxic chemicals* and/or devices (munitions) to disperse toxic chemicals are regarded as *chemical weapons*. Toxic chemicals, synthesized for military purposes, used in this context, are also called chemical weapon agents (CWAs). *Old chemical weapons* are produced before 1925.

CWAs are commonly classified as blood, blister, nerve, psychological, and pulmonary agents. This classification is commonly used but scientifically not correct, e.g., blood agents do not solely react with blood constituents. Blister agents may cause (more severe) systemic poisoning.

The CWC Annex of Chemicals distinguishes so-called Schedule 1–3 chemicals, which are regarded as CWAs.

Schedule 1 substances are toxic chemicals which have been used as chemical weapons or may be used for manufacturing chemical weapons (Table 1). Their civil use is limited. Some of the Schedule 1 chemicals have limited use in medicine or research. Saxitoxin and ricin are also Schedule 1 substances.

Toxic chemicals with possible use as chemical weapons or in their manufacturing process and which have legal use as well are listed in Schedule 2 (small-scale applications) and Schedule 3 (large-scale applications).

**Table 1** Examples of chemical warfare agents listed in Schedule 1 and their physicochemical properties

Substance [NATO code]	Chemical name	CAS	MW	Boiling point [°C]	Freezing point [°C]	Vapor pressure [mmHg at 20 °C]	Vapor density [air = 1.0]	Solubility in water [g/100 g H <sub>2</sub> O, 20 °C]
Schedule 1								
Sarin [GB]	Isopropyl methylphosphonofluoridate	107-44-8	140.1	158	-56	2.1	4.9	Miscible
Soman [GD]	Pinacolyl methylphosphonofluoridate	96-64-0	182.2	167-200	-42	0.4	6.3	2.1

## Characteristics of Chemical Weapon Agents (CWAs)

### Nerve Agents

Organophosphorus (OP) compounds are widely used pesticides in agriculture. More than 160,000 deaths after OP poisoning occur worldwide. The main causes are of suicidal nature or accidents. A subgroup of OP compounds has highly toxic properties and was stockpiled as chemical weapons. OP nerve agents are divided into two groups: G agents and V agents. G agents contain a fluorine or cyanine as leaving group, whereas V agents contain a sulfur substituent leaving group.

### Clinical Picture

OP poisoning shows typically the signs and symptoms of cholinergic crisis. Respiration is the most critical affected system. Severe poisoning causes respiratory depression, bronchosecretion, bronchospasm, and paralysis of respiratory muscles. Additional effects are miosis, increased secretions from glands, increased peristaltic activity, vomiting, general muscle weakness and twitching, hypothermia, bradycardia and hypotension, and convulsions followed by unconsciousness.

### Toxicodynamic

Acetylcholinesterase (AChE) is one of the fastest-acting enzymes of the human body, which hydrolyzes the cholinergic transmitter acetylcholine (ACh), thereby inactivating its action on muscarinic or nicotinic receptors. Membrane-bound AChE is located at cholinergic synapses and neuromuscular junctions. Soluble AChE is present in the cerebrospinal fluid and in cholinergic nerve terminals. Nerve agents phosphorylate AChE at the active enzyme site, thereby inhibiting activity. As a consequence, ACh accumulates and overstimulates cholinergic receptors, leading to a cholinergic crisis. Antidotal therapy is directed either to competitively displace acetylcholine from the receptor (atropine) or to remove causally the nerve agent from its binding site (reactivation). To the later end, “reactivators” so-called oximes (e.g., obidoxime, pralidoxime) were introduced in causal therapy. This therapeutic strategy appears suitable in case of poisoning with several nerve agents (Sarin, VX). Unfortunately, however, AChE inhibited by several nerve agents can hardly be reactivated, e.g., tabun. Moreover, bound nerve agents undergo an “aging” process, where an alkyl or alkoxy group leaves the nerve agent AChE complex. The velocity of aging is dependent on the nerve agent and is extremely rapid in case of soman (aging half time about 2 min in humans). The “aged” complexes can no longer be reactivated. As a consequence, AChE reactivators as well as atropine should be given within minutes after exposure. Nevertheless, symptomatic treatment, e.g., artificial ventilation, may be necessary.

### Biomonitoring, Bioanalytic, and Verification

To confirm clinical diagnosis based on typical signs and symptoms of cholinergic crisis, determination of red blood cell, AChE activity appears appropriate. This parameter can be determined even under field conditions or bedside within few minutes by the ChE-check mobile that is commercially available as certified as

medical products in Europe or in the United States by the Testmate<sup>®</sup>. Under several circumstances, however, ongoing treatment may be necessary, especially when active poison remains longer in the body than early administered antidotes. In such cases, aside from atropine, oxime treatment may be necessary for a longer period. To enable optimized patient-oriented application of oximes as long as needed, a laboratory test system, the so-called cholinesterase status, was established and is commercially available since early 2013. Apart from these clinically most relevant parameters, the analysis of intact nerve agent, its metabolites as well as protein and albumin adducts in body fluids are possible in special laboratories. However, for such analytical tasks, advanced techniques are necessary that are available only in a few laboratories.

### **Long-Term Effects**

After exposure of organophosphate insecticides, an organophosphate-induced delayed neuropathy (OPIN) has been described. This clinical picture has not been observed in survivors of nerve agent poisoning. No reports about mutagenic, cancerogenic, or teratogenic effects after sarin, tabun, or VX poisoning have been published.

### **Vesicants**

Sulfur mustard (bis(2-chloroethyl)sulfide, HD) was first synthesized in 1822 by Despretz. In World War I, it has been extensively used as chemical weapon and was called the “king of war gases.” During World War II, nitrogen analogues such as ethylbis(2-chloroethyl)amine (HN-1), bis(2-chloroethyl)methylamine (mechlorethamine, HN-2), and tris(2-chloroethyl)amine (trichlormethine, HN-3) were synthesized in the United States. All these agents share their ability to induce skin blistering and were classified as “vesicants.” Sulfur mustard is by far the most produced and stockpiled vesicant until today.

### **Clinical Picture (Short and Long Term)**

Skin contact with sulfur mustard liquid or gas will produce blisters after a symptomless interval of several hours. Gaseous exposure affects more moist and hairy regions of the body as the genito-anal region, the chest, and axillae. The eyes are very susceptible. Even low vapor exposure results in ocular injury with severe blepharospasm. Inhalation of sulfur mustard vapor damages mainly the upper part of the respiratory tract. The trachea and bronchial epithelia become necrotic and detach from the wall (pseudomembranes). Besides this local effects, absorption of sulfur mustard results in systemic poisoning. Reproductive and developmental toxicity, gastrointestinal effects (vomiting, diarrhea), hematological effects (pancytopenia), and immunosuppression have been reported.

### **Toxicodynamic**

Sulfur mustard is a lipophilic, alkylating substance with two reactive moieties. Sulfur mustard can easily penetrate the skin or other body surfaces and reacts with a huge variety of molecules. It can alkylate macromolecules and cross-link them.

The most important reaction is with the DNA. Sulfur mustard reacts predominantly with guanine at the N<sub>7</sub> position, which accounted for 61% of total DNA alkylation. Less likely are cross-links, 17% of alkylations involve two guanines (G-alkyl-G). However, cross-linked DNA strands are difficult to repair and cell division may result in DNA strand breaks, which are lethal lesions of the cell. Apoptotic cell death occurs with a delay of several hours.

This explains the late onset of clinical symptoms in organs characterized by high cell proliferation (e.g., skin). Despite a century of research and deeper insight in the pathophysiology of sulfur mustard poisoning, no causal treatment has been identified so far.

### Late Effects

Sulfur mustard poisoning results in a variety of late effects. The most common late effects were found in the respiratory tract (42.5%), eyes (39%), and skin (24.5%).

The most disabling late effects after sulfur mustard inhalation are respiratory disorders, e.g., bronchiolitis obliterans, chronic obstructive pulmonary disease, asthmatoïd bronchitis, and bronchial stenosis.

Late effects at the eyes are chronic keratoconjunctivitis. Only a few of exposed soldiers (0.5%) complain of a delayed type of ulcerative keratitis, which occurs several years after exposure and results in opacification of the cornea.

Balali-Mood et al. (2005) published a study on soldiers heavily exposed to sulfur mustard. The most important dermatological late effects are hyperpigmentation (55%), hypopigmentation (25%), erythematous papular rash (42.5%), dry skin (40%), multiple cherry angiomas (37.5%), and skin atrophy (27.5%).

As a DNA-damaging agent, it has been linked to several forms of cancer observed in workers or soldiers. Lung cancer (e.g., adenocarcinoma) has been reported in workers of sulfur mustard production facilities. Skin cancer (e.g., basalioma) may occur at exposed sites.

---

## Biological Weapons

### Definition

Biological weapons may be used for strategic or tactical reasons to intimidate, incapacitate, or kill an opponent, single individuals, or entire groups. The highest risk of a deliberate release of a biothreat agent currently arises from bioterrorism. Numerous species of highly infectious bacteria or viruses and various biological toxins have been misused as biological warfare agents in the past or are associated with an inherent risk to be misused due to their specific properties. Moreover, some species of fungi and parasites are listed as potential biothreat agents by some authors. Listing and current ranking of biothreat agents can be accessed at the websites of the American CDC, in the Chemical Weapons Convention, in the textbook of military medicine, or in the NATO handbook on the medical aspects of NBC defensive operations (AMedP-6(B)).

Among the biological warfare agents, biological toxins in contrast to live bacteria and viruses represent a group of noninfectious substances. Only toxins that can be utilized independently of their producer organisms are considered as autonomous biothreat agents and must be differentiated from toxins that are produced by the microorganisms during the course of infection and act as pathogenicity factors, such as the toxins of *Bacillus anthracis*. Biothreat toxins may cause Incapacitation, severe intoxication, or even death in exposed humans or animals. Early in history, various poisonous substances used to be employed not only for man's own survival but also to attack enemies. For the toxicologist, the risk assessment of toxin-derived "biological warfare agents" is principally the same as that of chemical warfare agents.

### Characteristics of Biological Toxins

Toxins represent a subset of biothreat agents, which are also called mid-spectrum agents. They are noninfectious and do not reproduce in the host. The clinical manifestations of toxin-related diseases usually appear after a shorter latency period as compared to infectious agents. Naturally occurring biological toxins are synthesized by plants (curare, ricin), fungi (aflatoxins), amphibians (dart frog's batrachotoxin), bacteria (botulinum neurotoxin), or algae (paralytic shellfish poison) and are mostly part of the self-protection strategies of the producing organisms. The structures of biological toxins range from complexly assembled structures to simple bioregulator molecules: Complex AB toxins are produced by bacteria or plants. They consist of a binding (B) and an active (A) domain and interfere with internal cell functions. The binding subunit (B) binds to a cell surface receptor and enables the transport of the cytotoxic A-subunit into the cell. The sizes of AB toxins range from 25 kD to 200 kD (Table 2). Other toxins are non-peptide substances and rather bioregulator molecules. Their onset of action is immediate in contrast to AB toxins, which take effect with a latency period of hours, sometimes days. Their molar mass is smaller, ranging from 300 g/mol to 3000 g/mol (Table 2). They are also markedly stable under various environmental conditions, versus heat and pH alterations. They can even be synthesized *in vitro* (STX), which is not possible for the proteinaceous toxins. The trichothecene mycotoxins belong to the non-peptide substances and, moreover, are contact poisons. They gained notoriety as the "yellow rain" agent during the 1970s and 1980s in Cambodia and Laos, Southeast Asia, which is – for lack of unambiguous evidence – not without controversy.

Toxicological effects of biological toxins were studied mostly after alimentary uptake. However, more severe physiological consequences may result from exposure through a non-enteric route. Intentional exposure to toxins in aerosol and droplet clouds and after subcutaneous injection has occurred. Yet only few and inconsistent data is available with regard to the associated health effects. A variety of nonspecific clinical symptoms and multiorgan effects may develop depending on the way of exposure, ranging from acute emesis and diarrhea, nervous disorders,

## **Risk Assessment Aspects**

Due to their relative ease of production and immense toxicity, some biological toxins are considered as potential biological warfare agents. The Centers for Disease Control (CDC, Atlanta, United States) provide the most widely used priority categorization of bioterrorism agents according to the risk to national security associated with them. Features determining the categorization are the ease of transmission/dissemination, the mortality rates, and the public health impact. The botulinum neurotoxins are classified as category A (highest priority). Ricin, staphylococcal enterotoxins, further clostridial toxins, and cholera toxin are classified as category B (second priority) agents. As listed in Table 2, biological toxins are also considered in the NATO handbook on the medical aspects of NBC defensive operations (AMedP-6 (B)) and most officially in the Chemical Weapons Convention.

In a military scenario, ricin and the botulinum neurotoxins are – besides the causative agents of anthrax or pneumonic plague – also considered as high-risk agents for bioterroristic or warfare activities. Risk-ranking respects the dimension of damage and the probability of an intentional event associated with the respective substance in a given scenario.

Low-dose pharmaceutical drugs containing botulinum neurotoxin (Botox) are commercially produced for the medical treatment of various neurological syndromes (Dysport<sup>®</sup>, Ipsen Biopharmaceuticals; Myobloc<sup>®</sup> Solstice Neurosciences; Botox<sup>®</sup>, Allergan). Moreover, in recent years, the cosmetics industry has established a fairly new market for botulinum neurotoxin due to its effect of wrinkle reduction. Every year, around 75 billion dollars are reaped with such products, which has given rise to large-scale non-licensed production of Botox drugs that are distributed via the internet. Illegal Botox production plants have settled in China, India, and the successor states of the former Soviet Union and might become a potential toxin source for bioterrorists. Ricin was researched for its ability to kill tumor cells during cancer treatment. However, pharmaceutical products have never emerged from such scientific approaches.

---

## **Risk Management**

### **Biological Weapons Convention (BWC)**

The BWC is an international agreement on the prohibition of the development, production, and stockpiling of bacteriological (biological) and toxin weapons and on their destruction. It was implemented in 1975 as a first multilateral disarmament agreement based upon the 1925 Geneva Protocol. It lacks the listing and ranking of

possible agents. So far, the BWC has 179 member states and 6 signatories. Eleven states have neither signed nor ratified the BWC. A major shortcoming of the BWC is its lack of a verification regime, which makes it difficult to prosecute noncompliance.

## **Chemical Weapons Convention (CWC)**

### **Organization for the Prohibition of Chemical Weapons (OPCW)**

Since 1997, the OPCW, located in The Hague, Netherlands, has been authorized to execute the controls and sanctions regarding the CWC as the official implementing body. Today, the organization comprises 193 member states and is directly responsible to the United Nations committee. OPCW received the Nobel Peace Prize in the year 2013.

To fulfill its tasks, the OPCW is comprised of several organs: the Technical Secretariat regulates administration, controls verification of international CWC implementation, and coordinates routine inspections. In return, decisions are made by the Executive Council and the Conference of the States Parties. They resolve questions of policy and matters arising between the States Parties on technical issues or on interpretations of the Convention.

Two of the biological toxins are listed in Annex B, Schedule 1, Numbers 7 (saxitoxin) and 8 (ricin).

## **National Regulations: Installation of Preparedness Standards**

### **Laboratory Safety**

As regulated in the CWC, the production, acquisition, and handling of quantities of more than 100 grams of a listed agent per year require permission. For the time being, only a few biological toxins are available in small amounts in the free market for research, analytical, or therapeutic issues.

Regarding safety at work on biological toxins in Germany, a national Committee on Biological Agents establishes or adapts the rules, which are officially released by the Federal Ministry of Labour and Social Affairs as Technical Rules for Biological Agents (TRBA). The most basic documents are the following TRBAs: “Protective Measures for Specific and Non-specific Activities involving Biological Agents in Laboratories” (TRBA 100) and “Basic Measures to be taken for Activities involving Biological Agents” (TRBA 500). Accordingly, handling of biological toxins is allowed in laboratories at containment level 1 (toxins) or a higher containment level corresponding to the risk group of an associated organism (e.g., level 2 for *Clostridium botulinum* strains). According to the international Globally Harmonized System of Classification and Labeling of Chemicals (GHS), tagging of vials containing biological toxins is required by use of a pictogram and a signal word (i.e., “Danger” or “Hazard”). Additionally, an individual material safety data sheet is required for each substance or mixture that mandatorily lists all hazard and precautionary statements.

**Table 3** AEGL values (mg/m<sup>3</sup>) for selected chemical warfare agents (Watson et al. 2006)

		Sarin (GB)	Tabun (GA)	Soman (GD)	Cyclosarin (GF)	VX

### Risk Management

Besides international regulations to reduce the stockpiles of chemical warfare agents, national regulations are necessary to reduce health risks for the general population and emergency personnel. As the risk for terrorist attacks with chemical warfare agents or similar substances rises, toxicity estimates and exposure guidelines have been recently updated to ensure a more realistic national preparedness. In the United States, Acute Exposure Guideline Levels (AEGLs) have been developed and published (Watson et al. 2006). AEGLs were calculated for vapor exposure (10 min–8 h). AEGL-1 has been defined as a threshold where first mild symptoms are noticed, e.g., miosis for nerve agents. On the other hand, AEGL-3 vapor concentrations may induce severe life-threatening health effects. The published data (Table 3) can be used for planning and risk management to counteract terrorist attacks with chemical warfare agents.

### Laboratory Standardization Approaches

Since 2012, an expert laboratory network has been constituted for the Establishment of Quality Assurance for the Detection of Biological Toxins of Potential Bioterrorism Risk (EQuATox), which since 2016 is continued in the Horizon 2020 funded network European program for the establishment of validated procedures for the detection and identification of biological toxins (EuroBioTox). Its goal is to build up a network of European laboratories that use equal standards for the detection and identification of biotoxins. The network is about to develop and validate improved analytical tools, reagents, reference materials, and standard operating procedures based on realistic incident scenarios. After comprehensive proficiency testings, best practice procedures will be determined and disseminated across Europe.

## Pharmacy

The availability and development of antidotes against chemical warfare agents is a continuous challenge. For several chemical warfare agents, e.g., mustard, no specific antidote exists in spite of decades of research. In recent years, new technologies were developed, allowing a deeper insight into the mechanism of toxicity, and new approaches are under investigation possibly enabling improved wound healing. In other cases, e.g., nerve agents, new autoinjectors containing an oxime, atropine, and benzodiazepam are under development. As commercial interest in antidote development generally is very low, national financial support is crucial to sustain research efforts and to allow development of new devices, e.g., autoinjectors or new promising approaches to improve therapy.

During World War II, toxoid vaccines were investigated by the United States to protect researchers working on the production of biological warfare agents. Since then, further vaccines against biological toxins have been developed, among them the pentavalent PBT vaccine (CDC) against five serotypes of botulinum neurotoxin, the RiVax™ Ricin Toxin Vaccine (Soligenix), and a candidate vaccine against staphylococcal enterotoxin B (USAMRIID).

A very limited number of heterologous antitoxin products are available for the treatment of botulism (e.g., trivalent Botulismus-Antitoxin Behring, Novartis, heptavalent BAT® Emergent BioSolutions Inc. (FDA approved)). Besides the few specific treatment options, therapy relies on supportive measures and in most cases requires intensive care facilities.

A network of specific poison control centers is available throughout European countries. They are associated with local hospitals and store antitoxins and provide expertise regarding the treatment of intoxications.

## Decontamination

Decontamination of body parts after exposure to chemical warfare agents or biological toxins is accomplished by cleaning with soap and water. Pharmaceutical products such as Reactive Skin Decontamination Lotion (RSDL) may be used for decontamination of skin surfaces contaminated with chemical warfare agents or biological toxins with skin absorption (trichothecene group) (Table 2). Wounds and lesions may be flushed with physiological solutions. For the decontamination of equipment, protein-denaturing dilutions of sodium or calcium hypochlorite may be used.

## Abstract

Since the year 2000, nanotechnology has been an emerging factor in science, economy, and also daily life. Although nano size was well known in the past in chemistry (e.g., colloids, catalysts), due to the huge number of engineered synthetic nanomaterials and their wide range of technical applications, a new broad economic field has come up. Regulatory bodies developed strategies to include nanomaterials into the existing legislation of chemicals, biocides, and food additives. This process was facilitated by the fact that principally not the chemistry changed from micro- to nanoscale but mainly physico-chemical properties (specific surface, solubility, agglomeration status, etc.). Thus, toxicological effects were not expected to be principally different; however, the evaluation had to be expanded from target organ effects (e.g., lungs, skin) to potential systemic effects. Due to the tiny size and an increased dissolution of nanoparticles, the toxicokinetics became a predominant additional endpoint. This summary is based on the technical guidelines, decisions, and laws issued by the main regulatory

## Introduction

The nanotechnology industry has expanded enormously since the 1990s as scientists, engineers, and technologists have developed useful applications of nanomaterials in manufacturing, transportation, communications, energy production, waste treatment, consumer products, and medicine. The rapidly increasing number of engineered nanomaterials (ENM) raised the question how potential risks could be minimized and managed to allow a safe commercialization. There is a common understanding that existing legal frameworks sufficiently protect public health and the environment and could be used by policymakers to regulate ENMs, provided that nano-specific adaptations would be introduced.

Nanomaterials are solid, liquid, or gaseous substances typically between 1 and 100 nm in diameter or length. A single nanoparticle shows a “viral” size in between subatomic particles (protons, electrons) and the smallest microscopic ones seen through a conventional light microscope (e.g., red blood cells). By origin, they have natural or engineered sources. Nanoparticles are often highly reactive because of their large surface area-to-volume ratio and chemical reactions occur on surfaces (e.g., use as catalysts).

Many nanoscaled metal oxides are important high-volume chemicals, for example, titanium dioxide and zinc oxide nanoparticles (used as pigment dusts and sunscreens). Besides industrial and consumer applications nanomaterials are used in the medical field: for example, silver nanoparticles have antimicrobial properties and nanoscaled “carriers” can be used to administer pharmaceuticals selectively at body localizations with higher concentrations than achievable by intravenous administration. According to an estimate, the global market for products containing ENMs will be more than 3 billion € by 2020.

---

## Regulation of Nanomaterials

### Initial Considerations

#### Assessing the Risks of ENMs

ENMs may pose some risks to human health and the environment that are not well understood at this time. Exposure to ENMs can occur in many ways. The most direct forms of exposure can happen when ENMs are used in medicines, cosmetics, foods, or other consumer products. Exposure can also occur, however, when manufacturing, distributing, selling, disposing of, or recycling products containing ENMs. Nanomaterial waste products, which can be released to the environment at various stages of manufacture, use, and disposal, are another source of exposure to ENMs.

The toxicokinetic behavior of ENMs differs from their microscaled counterparts. Because of their tiny size, ENMs can enter the bloodstream, translocate through the body, accumulate in organs or tissues, cross the blood-brain barrier, and even penetrate into the cell nucleus.

### **How Should ENMs Be Regulated?**

There is existing a controversial discussion:

Proponents of new regulations argue that ENMs are so different from existing substances and pose such far-reaching and poorly understood risks to public health and the environment that new forms of government oversight, such as regulations that address ENMs as a class, are needed. Opponents of new regulations argue that existing legal frameworks have been successfully applied to emerging technologies in the past (such as gene therapy and genetically modified organisms), so there is no need for new regulations tailored to ENMs. Opponents also point out that the heterogeneous nature of ENMs makes it difficult if not impossible to develop regulations for ENMs as a class.

Since the 1980s, the precautionary principle has played an important role in policy debates concerning climate change, chemical regulation, food safety, and other public health and environmental issues. A precaution is reasonable if it appropriately balances competing moral and social values, such as protecting public health and the environment, on the one hand, and promoting industry, agriculture, and the economy, on the other.

Policymakers should use existing laws to (1) regulate ENMs and the best available evidence to set regulation levels without creating new laws or an overarching system to regulate ENMs and (2) support additional research on the risks of ENMs (Resnik 2019).

Presently, there is no specific international regulation, no internationally agreed upon protocols or legal definitions for production, handling or labeling, testing toxicity, and evaluating the environmental impact of nanoparticles (NP). Medical standards related to ethics, environmental safety, and medical governance have been modified to cover the introduction of engineered nanomaterials (NM) into the biomedical field. Currently, the USA and the European Union (EU) have strong regulatory bodies and guideline legislation to control the potential risks of NMs. The European Commission has developed several pieces of EU legislation and technical guidance, with specific references to ENMs. This legislation has been employed inside EU countries to ensure conformity across legislative areas and to guarantee that an ENM in one sector will also be treated as such when it is used in another sector (Jeevanandam et al. 2018).

According to Jeevanandam et al. the toxicity of NMs depends on various factors:

- Dose and exposure time effect;
- Agglomeration and concentration effect. Increasing the NP concentration promotes agglomeration (microsized NP agglomerates);
- Particle size effect;

- Particle shape effect, for example, graphenes or MWCNTs;
- Surface area effect: the specific surface of a given particle mass increases with decreasing particle diameters;
- Crystal structure effect, for example, the two crystalline polymorphs of TiO<sub>2</sub> (rutile and anatase) show different toxicity;
- Surface functionalization effect.

### **Exposure Paths**

The most relevant exposure path of powdrous nanomaterials at workplaces is the inhalation route during the production process because a majority of nanomaterials are dry powders and can easily build aerosols. Alternative exposure paths such as oral or dermal exposure are of lower importance and, however, can reach relevance for consumers (e.g., cosmetics, sunscreens, silver on surfaces of beverage cans). In fact, nanoscaled particles are capable of entering the body through skin pores, debilitated tissues, injection, and olfactory, respiratory, and intestinal tracts. Their entry may lead to various diversified adverse biological effects (Yah et al. 2011).

## **Chemicals: Present Regulatory Status of Nanomaterials**

### **Regulatory Status at OECD**

Together with the Test Guidelines Programme (TGP) of the Organisation for Economic Co-operation and Development (OECD), the OECD Working Party on Manufactured Nanomaterials (WPMN) has explored the need for adaptation of some of the existing OECD Test Guidelines (TGs) and Guidance Documents (GDs) as well as developing new TGs and GDs to specifically address NM issues. An overview of progress is provided in the TGP and WPMN, and information on supporting initiatives, regarding the development of TGs for nanomaterials addressing physical chemical properties, effects on biotic systems, environmental fate and behavior, and health effects. Three TGs were adopted, dealing specifically with additional questions concerning the proper testing of manufactured nanomaterials: a new TG318 “Dispersion Stability of Nanomaterials in Simulated Environmental Media,” and adaptation of TG412 and TG413 on “Subacute Inhalation Toxicity: 28-Day Study/90-Day Study.” The associated GD39 on “Inhalation Toxicity Testing” has also been revised. The TGP currently develops four new TGs and four GDs. One new TG and six GDs are developed in the WPMN. Six new proposals were submitted to the TGP in 2018. Furthermore, as TGs are accompanied by OECD harmonized templates (OHTs) for data collection, an outline of recently developed OHTs particularly relevant for NMs was also included (Rasmussen et al. 2019).

### **EU Definition of Nanomaterials**

As a basis for a harmonized regulatory approach, the European Commission has developed a recommendation for a definition of the term “nanomaterial” for regulatory purposes:

“A natural, incidental or manufactured material containing particles, in an unbound state or as an aggregate or as an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimensions is in the size range 1 nm - 100 nm.

In specific cases and where warranted by concerns for the environment, health, safety or competitiveness the number size distribution threshold of 50% may be replaced by a threshold between 1 and 50%.

By derogation from the above, fullerenes, graphene flakes and single wall carbon nanotubes with one or more external dimensions below 1 nm should be considered as nanomaterials.” (EU Commission 2011).

Currently it is still a challenge to identify nanomaterials, in particular when integrated in products, that is, to measure particle size and size distribution. The identification is relevant for finding out whether the nano-specific provisions apply. Furthermore, since several regulations require hazard testing of nanomaterials, for example, before authorizing them for the use in consumer products, there is the need to confirm that available test methods and guidance are suitable for nanomaterials and, where relevant, to develop nano-specific tests. Moreover, to facilitate the testing of a potentially huge variety of different nanomaterials, a sound approach to group them is necessary. More specific data on nanomaterials are required to address regulatory needs, to account for the specificities of nanomaterials, and to assess their safety (Rauscher et al. 2017).

### **Regulatory Framework of European Union**

The European Chemicals Agency (ECHA) is in charge of registration of chemicals. The EU's regulatory framework generally covers nanomaterials. Companies producing or importing nanoscaled chemicals in volumes more than 1 ton per annum need to register their nanomaterials. The Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) regulation addresses all chemicals including nanomaterials.

Legislation on specific products (cosmetic products, novel foods, biocidal products, medical devices) addresses nanomaterials, including requirements for information on nanomaterials (labeling) and assessment of the safety of these materials.

As grounds for a regulatory approach, the European Commission has created a suggested definition of nanotechnology. Currently, it is still a challenge for regulators to recognize and describe nanomaterials, significantly when they have been incorporated into products. The identification is essential for finding out if the nano-specific rules apply. Moreover, since many policies mandate hazard evaluation of nanomaterials before authorizing them for use, regulators must confirm that available test procedures and guidance are compatible with nanomaterials and, if not, develop nano-specific tests (Smith 2018).

ECHA introduced nano-specific clarifications and new provisions in the REACH annexes coming into act by January 1, 2020:

- Requirement to identify and characterise nanoforms (size, shape, surface chemistry of particles of the nanoforms).
- *'Particle' means a minute piece of matter with defined physical boundaries; 'agglomerate' means a collection of weakly bound particles and 'aggregate' means a particle comprising of strongly bound or fused particles.*
- *A 'set of similar nanoforms' can be handled jointly for hazard assessment, exposure assessment, and risk assessment because of low variation within property boundaries. (ECHA 2018).*

### **Regulatory Framework of the USA**

In the USA, the regulation of nanotechnology largely falls under the auspices of the Food and Drug Administration (FDA) due to safety issues surrounding its use in medicine and personal consumer products.

While the FDA has voiced its support for the use of nanotechnology in innovative new products under its purview, the agency has also said it seeks to establish clear regulatory guideline grounded in existing practices and the available science.

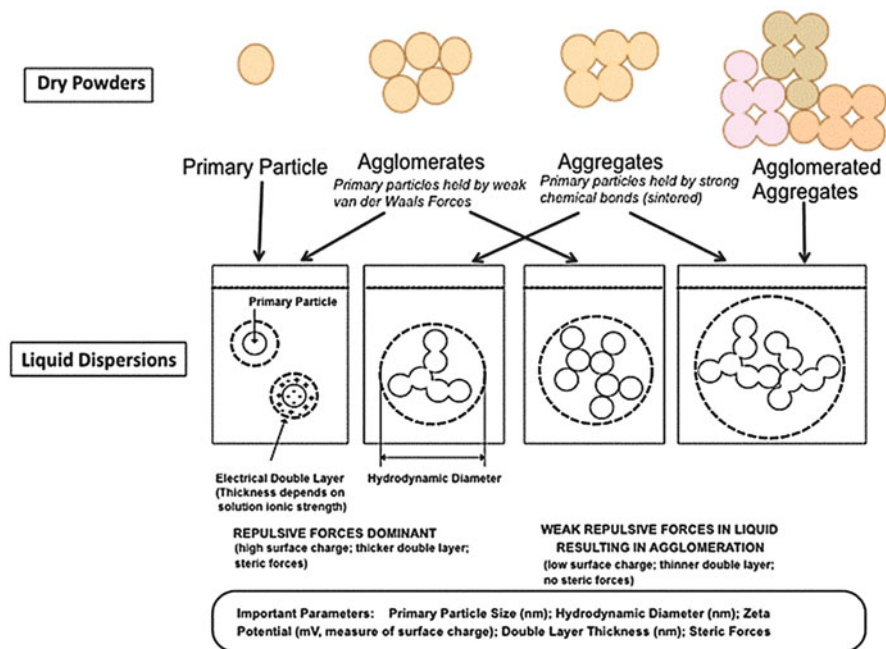

When evaluating food additives, the FDA looks to find little to no risk from the intended use of nanotechnology products. Medications, by contrast, are examined not just based on their risk profile but also their expected benefit. These varying legal standards show how different contexts could result in multiple regulatory outcomes, even if two products have the same degree of risk (Smith 2018).

The following FDA statements were presented in a fact sheet:

- FDA does not make a categorical judgment that nanotechnology is inherently safe or harmful but uses an adaptive and flexible approach.
- Particular approaches for each product area will vary according to the statutory authorities.
- FDA's nanotechnology regulatory science research portfolio focuses on understanding interactions of nanomaterials with biological systems; and on the adequacy of testing approaches for assessing safety, effectiveness, and quality of products containing nanomaterials.
- FDA's regulatory policy approach is consistent with relevant overarching U.S. government policy principles supporting innovation. (FDA 2018).

Due to these different processes of manufacturing, different forms occur termed as primary particle, agglomerates, and aggregates (Fig. 1). The respective definition for nanomaterials is as follows:

- "particle is a minute piece of matter with defined physical boundaries";
- "agglomerate means a collection of weakly bound particles or aggregates where the resulting external surface area are similar to the sum of the surface areas of the individual components";

**Fig. 1** Different forms of nanoparticles – schematic. (Adapted from Oberdörster 2010)

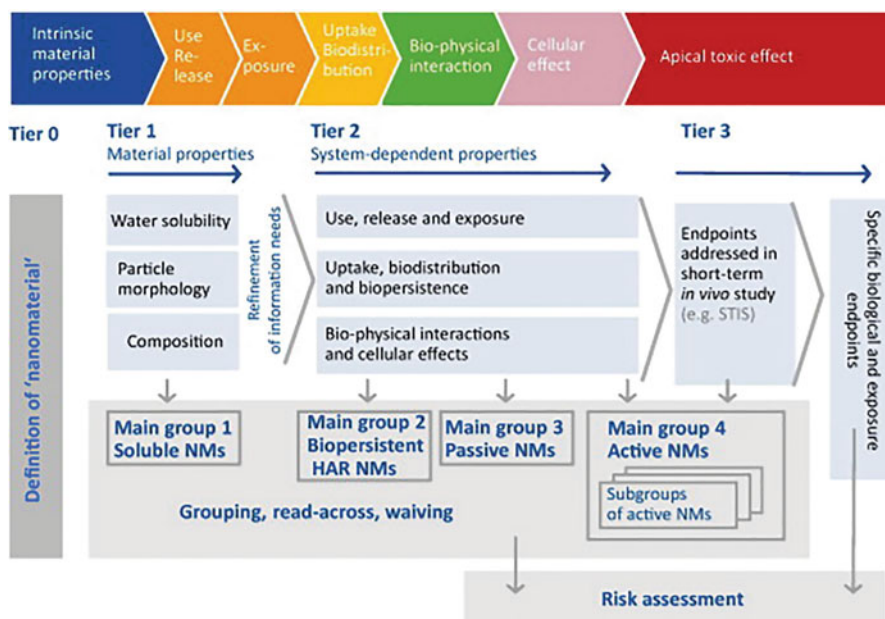

- “aggregate denotes a particle comprising strongly bound or fused particles” and the external surface can be smaller than the sum of the surface areas of the individual particles (Oberdörster 2010).

### Approaches for Grouping and Categorizing Nanomaterials

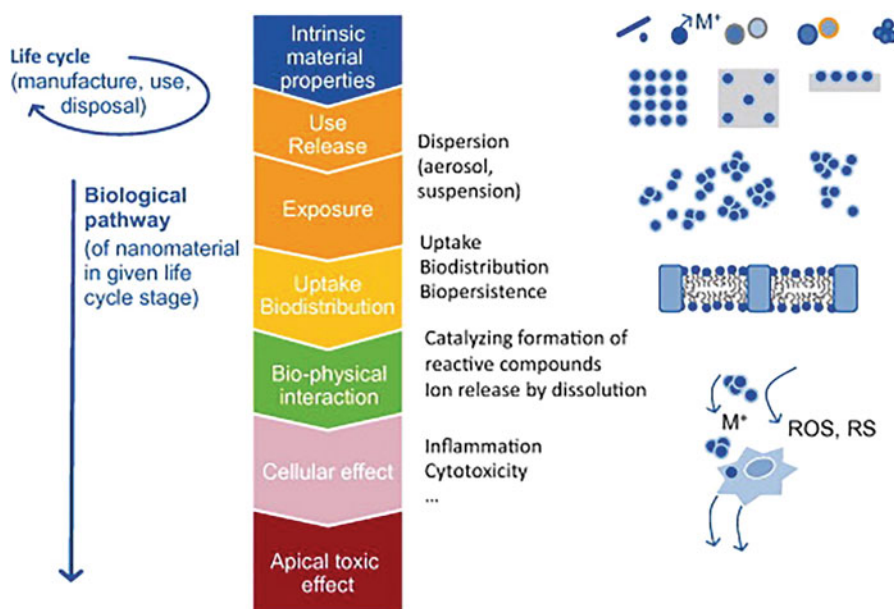

A “Decision-making framework for the grouping and testing of nanomaterials (DF4nanoGrouping)” was proposed by the European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) “Nano Task Force.” It consists of three tiers to assign nanomaterials to four main groups, to perform sub-grouping within the main groups and to determine and refine specific information needs (Fig. 2). The DF4nanoGrouping covers all relevant aspects of a nanomaterial’s life cycle and biological pathways, that is, intrinsic material and system-dependent properties, biopersistence, uptake and biodistribution, cellular and apical toxic effects (Fig. 3). The four main groups encompass

1. Soluble nanomaterials;
2. Biopersistent high aspect ratio nanomaterials;
3. Passive nanomaterials;
4. Active nanomaterials.

The DF4nanoGrouping aims to group nanomaterials by their specific mode of action that results in an apical toxic effect. This is eventually directed by a nanomaterial’s

**Fig. 2** The decision-making framework for the grouping and testing of nanomaterials. (Adapted from Arts et al. 2015)

**Fig. 3** Life cycle and biological pathway of nanomaterials. (Adapted from Landsiedel et al. 2010)  
 $M^+$ : metal ion; ROS: reactive oxygen species; RS: reactive species

intrinsic properties. The DF4nanoGrouping uses the “functionality” of nanomaterials for grouping rather than relying on intrinsic material properties alone. Such functionalities include system-dependent material properties (such as dissolution rate in biologically relevant media), bio-physical interactions, *in vitro* effects, and release/exposure (Arts et al. 2015).

---

## Nanomedicine: Regulatory Status

Pharmaceutical manufacturing of nanomaterials involves two different approaches: top down (breakdown of a bulk material) and bottom up (starts with atomic or molecular species, then increasing in size).

The application of nanotechnology for medical purposes has been termed “nanomedicine” and is defined as the use of nanomaterials for nanodiagnosis, controlled drug delivery (nanotherapy), and regenerative medicine.

For regulatory purposes in Europe, the biological nanomedicines are under the framework set by European Medicines Agency (EMA). The industry frequently asks for scientific advice and a case-by-case is analyzed by the EMA.

Sometimes, the biological framework is the base for the **regulation** of the Non-Biological Complex Drugs (NBCDs) because they have some features in common: the structure cannot be fully characterized and the *in vivo* activity is dependent on the manufacturing process and, consequently, the comparability needs to establish throughout the life cycle, as happens to the biological nanomedicines.

For some NBCDs groups like liposomes, glatiramoids, and iron carbohydrate complexes, there are draft regulatory approaches, which help the regulatory bodies to create a final framework for the different NBCDs families (Schellekens et al. 2014). EMA issued principles addressing general issues regarding the complexity of the nanosystems and providing basic information for the pharmaceutical development, non-clinical and early clinical studies of block-copolymer micelle, “liposome-like,” and nanoparticle iron (NPI), medicinal products created to affect pharmacokinetic, stability, and distribution of incorporated or conjugated active substances *in vivo*.

For regulatory purposes in the USA, the FDA oversees safety and efficacy of a broad spectrum of medical products (i.e., drugs, biologics, and devices) under the auspices of federal legislation and agency regulations and policy. Complex nanoscale products challenge this regulatory framework and illuminate its shortcomings for combination products. Fundamentally, definitions and supplemental FDA policies distinguish among three product areas based on whether the product has

- a chemical mode of action (drug),  
a drug is any chemically synthesized product intended for use in the “diagnosis, cure, mitigation, treatment, or prevention of disease”;  
new drugs are those “not generally recognized” by qualified experts “as safe and effective for use under the conditions prescribed”;

- a biological product is a product that is “a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, protein . . . or analogous product . . . applicable to the prevention, treatment, or cure of a disease or condition of human beings.”
- a mechanical mode of action (device); a medical device is a product that is not a drug, meaning that it does not act through chemical action and is not dependent upon metabolism to achieve its primary intended purpose.
- a biological source.

The FDA published two guidance documents on nanotechnology in the context of medical products. One outlines considerations for industry when determining whether a product involves an application of nanotechnology, which indicates the need for sponsors to communicate nanotechnology status to the FDA as part of the product review process.

The other discusses a nanotechnology risk-based framework, specific requirements for conduct of non-clinical and clinical trials, manufacturing quality and controls, and special environmental considerations for drug and biologic products containing nanomaterials.

## **Cosmetics: Regulatory Status of Nanomaterials in Europe**

Cosmetics are regulated as a specific class (EU Cosmetics Regulation – [EC No 1223/2009](#)) including nanomaterials. Nanomaterials are defined as “insoluble or biopersistent and intentionally manufactured material with one or more external dimensions, or an internal structure, on the scale from 1 to 100 nm.” Cosmetic products containing nanomaterials must be notified to the Commission via the online Cosmetic Products Notification Portal at least six months prior to being placed on the market, including specific data relevant for risk assessment purposes (e.g., substance identification, physico-chemical properties, toxicological profile, and reasonably foreseeable exposure conditions). The Commission is using the Scientific Committee on Consumer Safety (SCCS) to perform a proper risk assessment of nanomaterials under concern. Cosmetics containing a nanomaterial require a “nano” label in the list of ingredients (SafeNano [2020](#)).

## **Food/Food Packaging: Regulatory Status of Nanomaterials in Europe**

Some nanomaterials can be detected in food products. These nanomaterials either occur as a by-product of the food additives’ manufacturing process or they originate from natural sources. In contrast, nanomaterials are already used in food contact materials.

Materials that may contain **nanoparticles** and are used in food products can be divided into two groups: (1) inorganic compounds such as silicon dioxide, titanium dioxide, or silver and (2) organic compounds based on proteins, fats, or sugars.

**Table 1** Synthetic nanomaterials used as food additives

Compound	E number	Usage
TiO <sub>2</sub>	E 171	- whiten sweets, mozzarella, ice cream, or cake glaze
SiO <sub>2</sub>	E 551	- drip aid for sauces, seasonings, or cappuccino powder - carrier for dyes or flavors - prevent turbidity of beverages
Silver	E 174	- Coloring of product surfaces (e.g., sugar, confectionery and bakery products)
Iron oxide	E 172	- color change
Gold	E 175	- coating of confectionery and chocolate or in liqueur

The most prominent representatives of this group are silicon dioxide (E 551), titanium dioxide (E 171), and silver (E 174); see Table 1. These approved food additives are not produced as nanomaterials and usually fulfill their purpose as significantly larger particles. During production, however, it cannot be prevented that a certain proportion of nano-sized particles are formed which can be considered as nanomaterials. The usage of such food additives is restricted to certain food products/groups and the maximal amount to be added is subject to official daily intake rates, for example, only 10 g/kg (corresponds to 10 per thousand) silicon dioxide in cheese are allowed.

Most commonly used food additives, which may contain certain percentage of nanomaterials © DaNa team.

## Exemplary Cases of Nanoparticles Dominant in Commercialization

Classes of metals/metal oxides and carbonaceous materials are the most prominent players on the market. In the following, some substance-specific **regulations** are presented. Metals/metal oxides exhibit their toxicity by means of the particle surface and, in addition, by dissolved metal ions. The degree of solubility of this material class in body fluids determines considerably the toxicological impact. Colloidal or nanosilver is used in biocidal products for disinfection and microbial inhibition on surfaces (fungi, viruses, algae, bacteria).

### Titanium Dioxide (TiO<sub>2</sub>)

TiO<sub>2</sub> is one of the high-volume chemicals that is commercialized in numerous nanoscaled variants. It exists in two important crystalline structures, rutile and anatase; often these forms are mixed and, in addition, made more hydrophilic or hydrophobic by coating the surface with functional groups. TiO<sub>2</sub> is regulated in various sectors, for example, as chemicals, as cosmetics, and as food additives.

*Use as chemical (REACH classification):* TiO<sub>2</sub> is an example showing the ongoing re-evaluation processes at ECHA; considered for decades as a non-carcinogen, new draft assessments are currently underway: in May 2016, the French Agency for Food, Environmental and Occupational Health & Safety (ANSES) submitted a proposal to ECHA for the classification of TiO<sub>2</sub> as a presumed

carcinogen (category 1B) by inhalation. After evaluating the proposal, ECHA's Committee for Risk Assessment (RAC) decided in September 2017 that there was insufficient evidence to classify  $\text{TiO}_2$  in category 1B. Instead, the RAC was of the opinion that the evidence could only support a lower classification of  $\text{TiO}_2$  as a suspected carcinogen (category 2) by inhalation only (TDMA 2020; ECHA 2017).

*Cosmetic usage:* Titanium dioxide is currently approved as a colorant and as a UV-filter in cosmetic products, including in the form of nanomaterial. Titanium dioxide (nano) is listed in entry 27a of Annex VI to Regulation (EC) No 1223/2009. It is allowed at a maximum concentration of 25% in ready for use preparation, except in applications that may lead to exposure of the end user's lungs by inhalation and subject to the characteristics listed in the entry (European Commission 2009).

*Usage as food additive:*  $\text{TiO}_2$  is approved for use in food as the coloring additive E171, under the EU's General Food Law regulation. The safety of E171 is evaluated by the European Food Safety Authority (EFSA), which established in 2016 that data on E171 showed no health concerns for consumers.

In 2018, French authorities began a substance evaluation of  $\text{TiO}_2$ . Since then, the *Titanium Dioxide* Manufacturers Association (TDMA) has been working closely with the French ANSES and the ECHA to provide information and expertise responding to concerns and questions raised during this process.

On June 29, 2018, the EFSA reaffirmed the safety of E171, following a request for a scientific opinion from the European Commission (TDMA; EFSA 2019).

## Silver

Silver nanoparticles release silver ions, which act as a biocidal substance. The biocidal activity of silver primarily was identified as an oligodynamic effect, that is, only very small portions of the active substance are needed for significant antimicrobial activity. Silver nanoparticles are incorporated, for example, into polymers to avoid microbial growth on their surface. The principal mode of action is described in Fig. 4. This mode of action (MoA) makes it difficult for regulators to judge the risk effects related to silver

**Fig. 4** Nanosilver effect on surfaces (depot effect). (Adapted from Schneider (2017))

nanoparticles. If materials are treated with silver to avoid the growth of germs (bacteria, fungi, yeast, virus, etc.) this application is inside the scope of the Biocidal Products Regulation BPR; 528/2012 EU (Schneider 2017).

### **Single-Walled (SWCNT) and Multi-Walled Carbon Nanotubes (MWCNT)**

The global market of carbon nanotubes (thinner than 20 nm) is estimated to be around 200–250 tonnes (€30–40 million, mostly multi-walled carbon nanotubes) in 2009. The largest use is as a product imparting electrical conductivity to plastic materials, for example, in disk drive components or automotive plastic fuel lines and fenders (electrostatic coatings). Other uses include polymer additives, paints and coatings, fuel cells, electrodes, electrolytes and membranes in batteries, especially in miniature lithium batteries (BAuA 2018).

There are basically two shapes of CNT with different morphology: one variant with a tangled, low-density agglomerate form (SWCNT, MWCNT) and another one with a rigid, long-fiber (asbestos-like) morphology (MWCNT). The wall number and diameter determines the morphological outcome of MWCNT and a value between 20 nm and 45 nm makes the difference between the two morphological groups. All SWCNT and MWCNT with low wall number show the tangled form. MWCNT with higher wall number show asbestos-like fiber geometry and can correspondingly exert fiber-specific toxicity.

Experimental MWCNT samples (synthesized at lab scale) with diameters more than 50 nm (rigid type) were investigated in a chronic study in rats after intraperitoneal injection and showed a strong potential for the induction of mesotheliomas (Rittinghausen et al. 2014).

The International Agency for Research on Cancer (IARC) classified a certain group of multi-walled carbon nanotubes (MWCNTs) known as MWCNT-7 as “possibly carcinogenic to humans” (Group 2B) based on rodent studies that showed that MWCNT-7 caused peritoneal mesotheliomas in male and female rats after injection of CNTs into the peritoneum (intraperitoneal injection) and the scrotum (intrascrotal injection) and that inhalation promoted bronchioloalveolar adenoma and carcinoma in male mice. IARC found limited evidence for the two other types of MWCNTs with dimensions similar to MWCNT-7 and inadequate evidence for single-walled carbon nanotubes (SWCNTs) (IARC 2017).

### **Graphenes**

Graphenes are two-dimensional allotropes composed of a single layer of carbon atoms, hexagonally arranged. Their experimental preparation succeeded in 2005 and the commercialization has started; however, regulation for this new material class is lagging behind.

## Abstract

Recreational drugs constitute a continuing problem worldwide that has recently been aggravated by the emergence of a growing number of new psychoactive designer drugs. The drugs of abuse problem is associated with risks of intoxications and is a menace to public health and safety. New designer drugs that emerge on the black market tend to be considered legal (also known as “legal highs”) when labeled “not for human use” (e.g., “bath salts”) and are not in the list of internationally controlled substances. The analogue-principle in its various forms aims at shutting down this open gate of abuse.

This chapter reviews the types of psychoactive designer drugs, their biochemical mechanisms of action, the difficulties of unequivocal identification of novel drugs and their metabolites, basic principles of regulation, and aspects of the analogue principle.

## Keywords

Analogue principle · Analytical toxicology · Designer drug · Opiate · Psychoactive drug · Toxicology · EMCDDA · UNODC · DEA

## Introduction

The term designer drug came up in the mid-1980s in connection with abuse of the then new, very potent synthetic opioid fentanyl and some of its derivatives (Henderson 1988). The problem of ever new designer drugs has since increased and led to a cat and mouse game (Elliott 2011): Whenever a novel designer drug is identified and placed under control of the controlling agencies, new chemical analogues tend to appear on the illicit market for which no routine analytical method exists to detect and identify them and no science-based knowledge about their way of action and their pharmacological and toxicological effects. Such a cycle constitutes a big problem for policy and health authorities aside from the clinical and forensic toxicology experts.

## Designer Drugs and Drug Design

### Types of Designer Drugs

Designer drugs are found and misused or abused in various application areas, such as: (a) athlete doping (Cowan and Abbate 2020) which for instance involve novel beta-mimetics, synthetic anabolic steroids, absorbable peptide-analogues of growth hormone releasing hormone (GHRH), (b) performance supports such as phosphodiesterase type 5 inhibitors (PGE5i), (c) “fat burners” like the mitochondrial uncoupling agent dinitrophenol, (d) immediately acting poppers, and (e) the large

group of psychoactive drugs (Pourmand et al. 2018; Weinstein et al. 2017). Designer drugs often evolve as analogues of substances with known chemical structure and/or pharmacological activity. Such drugs are brought to the market, often via the “surface web” (internet) or darknet. They may or may not possess the pharmacological activity expected by the consumer. They are usually missing any quality control or safety testing such as routine preclinical- and clinical studies that are conducted during genuine drug development to evaluate effectiveness and toxicity. This situation is clearly of high concern for public health. It is increasingly challenging the law-enforcing institutions (Krasowski and Brown 2017), clinical and forensic toxicologists (Abbott and Smith 2015), and analytical chemists (Elliott 2011).

## Drug Design

“Drug design” is a technical term that describes any targeted work of medicinal chemists in research and pharmaceutical development in synthesizing new pharmacologically active molecules. The concept of “drug design” came up in the last century, when structure-activity relationships became evident in connection with advances in the field of neurotransmitters and neurotransmission (Belleau 1970). Natural plant-derived pharmaceutical compounds and endogenous mediators were chemically modified in the search for pharmacologically active substances that would be superior to the then available therapeutic drugs with regard to efficiency, pharmacokinetics or safety profile. In such attempts, entirely new substance scaffolds were detected and developed, such as the synthetic opioids or the emerging designer benzodiazepines. Some substances were developed and marketed as prescription drugs, others introduced as research tools that helped to elucidate biochemical pathways or mechanisms of toxic action. Drug design today still works in a similar way, and includes modern methods, such as structure-activity relationship, QSAR models and synthesis-enforcing high throughput procedures.

---

## Narcotic and Psychoactive Drug Classes

Ancient cultures have developed and used psychoactive drugs from local sources, such as plants or mushrooms. As a consequence of globalization, many previously culture-specific agents have spread all over the world. Some of them are now of medical importance as pharmaceuticals or precursors (e.g., morphine, cocaine, ephedrine).

## Terms and Names

The meaning of the term “narcotic” partly differs among countries and jurisdiction, ranging between sleep-inducing, anesthesia-inducing, or stupefying substance that

may dull the senses, and opioid-like agents or any strongly addictive controlled substance. The term psychoactive or psychotropic is wider, encompassing any effect on neuronal brain function that alters the mind.

## Types and Classes

Narcotics and psychoactive drugs of abuse can be classified in three groups, according to medically relevant psychic effect, chemical class, or biochemical mode of action, as shown in the three panels of Fig. 1. The left panel shows major medically defined groups and the associated characteristic psychic effects. The middle column lists some major chemical groups and substances. The brackets between the left and the middle panel provide a rough orientation for the typical assignment of chemical classes to pharmacological effects. The panel on the right specifies important receptor types that are targeted by neuroactive designer drugs.

The official lists released by drug-controlling agencies are governed primarily by chemical names according to the nomenclature of the International Union of Pure and Applied Chemistry (IUPAC, <https://iupac.org>), which describes the position of each atom and chemical group in the three-dimensional molecular structure. As an

### Psychoactive Recreational Drugs Medical-, Chemical- and Biological Classes (Examples)

Medical (Pharmacological) Classes	Chemical Classes	Biochemical Classes Interaction with:	
Narcotics opioid-like, mind-dulling	Opiates, Opioids Benzodiazepines Barbiturates Propofol Gamma-hydroxybutyric acid Ethanol Cannabinoids Cocaine-analogues Volatile agents (poppers) Phenylethylamines -Cathinones -Amphetamines -Mescaline Piperazines Tryptamines Ketamines	NT-Receptor Opioid-R GABA-R Cannabinoid-R Adrenergic-R Dopamin-R Serotonin (5HT)-R Glutamate-R Histamine-R Acetylcholine-R NT-Reuptake (inhibition) NT-Release (induction) NT = Neurotransmitter, R = Receptor	
Sedatives/Hypnotics relaxing, sleep-inducing			Effect: Agonist or Antagonist Transport coupling: Direct or G-protein
Empathogens making feel socially close			
Stimulants energizing, activating			
Euphoria-inducing making feel good			
Hallucinogens dissociative (split-ego) psychedelic (visions) deliriant (confusion)			

**Fig. 1 Psychoactive Recreational Drugs.** The three panels demonstrate how drugs can be classified according to medical, chemical and biochemical features. Narcotics and sedatives/hypnotics together form the majority of depressants. The brackets between the left and middle panel provide a simplified and incomplete assignment of chemical class to medical class; there exist overlaps and exceptions, e.g., mescaline (hallucinogen), belonging to the chemical group of phenylethylamines, that would typically be expected to be stimulants or empathogens

example, carfentanil, a potent synthetic opioid, is now included in the list of scheduled substances with the IUPAC name “methyl 1-(2-phenylethyl)-4-[phenyl (propanoyl)amino]piperidine-4-carboxylate.” Other chemical names for this substance can be found in several reference sources (e.g., in PubChem “methyl 1-(2-phenylethyl)-4-(*N*-propanoylanilino)piperidine-4-carboxylate”), which are also valid synonyms for naming carfentanil according to IUPAC naming rules. Despite the possible occurrence of several synonyms, IUPAC names are very important as a tool for chemical experts to unambiguously report and communicate the chemical structure of a substance. On the other hand, they are of little use for most people and for the non-chemists in particular. The latter tend to use International Nonproprietary Names (INN) for drugs (e.g., “carfentanil”) or in some cases names that are composed of initials (often from the institution that synthesized, detected and/or recorded the substance), followed by a substance number. In addition, many designer drugs also have street names, sometimes even several other names after vendors or users habits. For each new designer substance, there may be a large number of names or terms to define it, which creates a further layer of burden to their already complex scenario.

Psychoactive drugs act upon the central nervous system (CNS), resulting in transient changes of consciousness, attention, perception, emotion, or mood. As recreational drugs, they are often taken purposefully to induce such changes. Many psychoactive drugs exhibit some (side-) effects on the peripheral neuronal system, thus affecting blood pressure, intestinal motility, or other functions.

A rapid uptake flux into the brain may be important for experiencing the full effect and having an immediate kick or “high.” Intravenous injection, nasal administration (“snorting”), uptake via the oral mucosa or inhalation (smoking or “vaping”) are among the most common routes for rapid uptake into the blood stream, while ingestion of a pill would lead to a protracted absorption and in some cases (partial) inactivation by means of first pass hepatic metabolism (biotransformation).

## Parent Substances and Derivatives

A basic idea of psychoactive drug design concept is to use the scaffold of a known pharmacologically active drug and introduce chemical modifications. Increasing lipophilicity of these groups may improve permeability through the blood-brain barrier (BBB) and thus enhance the specificity of a drug to the central nervous system (CNS), compared to its effects on the peripheral neuronal system. The length of a lipophilic side chain, introduction of heterocycles, or introduction of halogen atoms belong to the more common modes of searching for derivatives that specifically act in the CNS, for instance, due to their increased BBB-permeability, or given the more favorable target receptor interactions. The synthesized product will then get purified, and in a pharmacological context, the most active chiral (if any) form may be isolated, however, racemic mixtures are found on black- and street markets due to the generally cheaper and easier synthetic routes for racemic substances. The

interaction with the biological target, very often a membrane-receptor that is associated with a membrane-transporter, may be stronger, weaker, inverse, or entirely absent, compared to the parent substance. A wide spectrum of effects is for example seen with the various noradrenalin-related drugs, some exhibiting preferentially CNS-effects (methamphetamine, cathinones), others preferentially acting as peripheral adrenalin mimetics or peripheral beta-receptor blocking agents.

It is not uncommon that minor chemical modifications lead to a substance that partly or fully interacts with other than the expected target in the CNS (“off-site” effects). An example is mescaline, which is primarily a hallucinogen (serotoniner-gic), in contrast to many other phenylethylamines that are CNS stimulants (norad-renergic and/or dopaminergic).

Finally, effect, strength, and toxicity profile of a psychoactive drug may be co-determined by minor but potent synthetic impurities.

## Novel Psychoactive Substances

Novel (or New) psychoactive substances (NPS) are a broad and heterogenous group of substances of abuse that are presently not (yet) controlled by international conventions and pose a public health threat (Abbate et al. 2018; UNODC 2019; Fattore and Weinstein 2019).

Some NPS have formerly been developed as research drugs, e.g., as diagnostic tools to study in vitro neurobiological pathways. Others were synthesized in academic institutes or pharmaceutical industries, but later not marketed, e.g., due to insufficient therapeutic activity or safety concerns. A third group constitutes a category of entirely new substances, more recently synthesized on the basis of known scaffold molecules, which get slightly modified by including additional chemical residues. Some NPS are well-known recreational drugs, for which pharmacological, forensic, and toxicological literature exists; however, for many other substances, there exists no scientific literature or information, which poses high concerns for the public safety.

Synthetic cannabinoids and synthetic cathinones are the largest groups of NPS that were seized and/or reported for the first time to regulatory bodies in the past decades; however, many other derivatives of other chemical groups and subclasses also exist. Figure 2 shows chemical structures of nine selected NPS and the chemical class to which they can be assigned. The derivatives of morphine (opiates) have a long history that started with heroin more than 100 years ago. Later, the fully synthetic compound fentanyl and some of its derivatives were identified, as well as the non-fentanyl synthetic opioids.

Figure 3 shows in the upper row the parent substances that are used in different medical treatments (country-dependent, e.g., morphine for pain reduction or control, fentanyl for anesthesia and pain reduction, methadone as substitution therapy); the lower row shows structures of analogues (heroin, carfentanyl, U-47700) that are abused as recreational drugs.

## Psychoactive Designer Drugs (Examples)

**Fig. 2 Psychoactive Designer Drugs (Examples).** The figure shows chemical structures of substances belonging to different psychoactive designer drug groups. Substance names are in red, names of the groups to which they belong are in black

Carfentanil has a very high potency. It is approved as veterinary pharmaceutical to tranquilize large animals, but not approved for human use. Carfentanil has recently been responsible for many fatalities due to overdoses despite the low dose that may have been used (Wilcoxon et al. 2018; Delcher et al. 2020). Some derivatives such as the opiate naloxone inhibit the opioid receptor. Naloxone is medically used as fast-acting antidote to reverse an opioid intoxication or opioid-induced respiratory depression.

## Actions at the Neuronal Synapse

### The Normal Neurotransmission Process

Psychoactive drugs have in common that they interfere with signal-transmission from the terminal of one neuron to a connected neuron. In the various brain areas, neurons fulfill specific functions, interconnected with the other areas. The information transfer and communication between neurons is via narrow gaps, the synapses, where arrival of an action potential in a presynaptic neuron leads to neurotransmitter release into the synaptic space. The various types of

neurotransmitter substances include small amino acid-derived molecules (e.g., noradrenalin), peptides (e.g., endorphins), lipid-derived substances (endocannabinoids), acetylcholine, and others. Binding to the respective membrane receptor on the postsynaptic neuron opens an ion channel, either directly (ionotropic) or via G-protein-mediated signaling (metabotropic) and thus elicits an action potential. Most neurotransmissions are directed from the presynaptic to the postsynaptic membrane. But there are exceptions. Thus, the endogenous cannabinoid system works in the opposite direction, endocannabinoids being released at the postsynaptic side, binding to a cannabinoid-receptor on the presynaptic membrane and then inhibiting or modulating the release of the principal neurotransmitter of this synapse.

Knowledge about the involved neurotransmitters, receptors and signal transduction pathways can be gained experimentally by a combination of *in vitro* tests with cultured neurons and isolated receptors, plus *in vivo* studies in lab animals using brain imaging methods, measurement of electric activities, or analysis of neurotransmitter patterns in various areas of the brain.

### **Interaction with Neurotransmitter Receptors**

Neurotransmitter receptors on neuronal terminals tend to be quite specific for binding “their” (endogenous) neurotransmitter, though there are exceptions, such as the trace amine-associated receptors (TAARs) that accept several different neurotransmitters. Psychoactive drugs typically bind as ligands to neurotransmitter receptors and thus mimic or sometimes antagonize neurotransmitter-effects. An example are opiates/opioids. The endogenous ligands of opiate receptors are the endorphins, which are peptides. Surprisingly, the structurally unrelated substance morphine and analogues such as codeine or heroin also bind these receptors. Moreover, other classes of structurally unrelated fully synthetic substances like fentanyl and its derivatives as well as non-fentanyl opioids also bind to opioid receptors (Fig. 3).

Most neurotransmitter receptors exist in multiple subtypes, as exemplified with receptors for endorphin ( $\kappa$ -,  $\mu$ -,  $\delta$ -, and more), serotonin (5-HT-1 to 5-HT-7), adrenalin ( $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ ), dopamine ( $D_1$  and  $D_2$  families and their subtypes), endocannabinoids ( $CB_1$ ,  $CB_2$ ), or the TAAR families. Receptor subtypes tend to differ with regard to their distribution on neurons or brain areas. Some subtypes mediate identical, others different or even opposite effects, some are subject to up- or downregulation by neuronal feedback mechanisms. The differential location within the network of brain neurons and the specific biochemical interactions of recreational drugs with the receptor subtypes will determine the total psychoactive effect.

### **Interaction with Neurotransmitter Transport**

Some psychoactive substances act indirectly by inhibiting the reuptake transporter that shuts off a neurotransmission signal by shuffling the neurotransmitter from the

## Opiates and Opioids

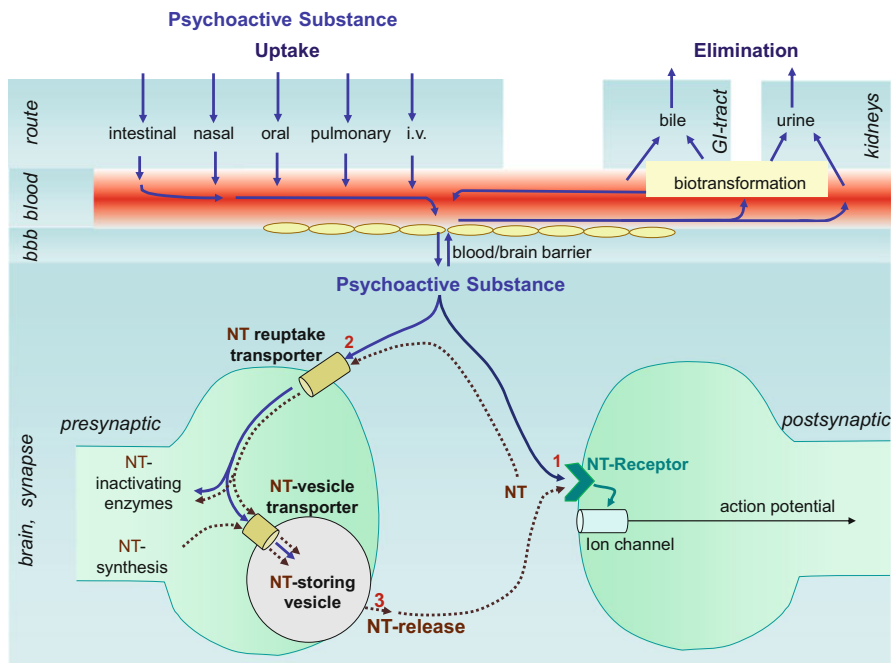

**Fig. 3 Opiates and Opioids.** The upper row shows chemical structures of three different classes of parent molecules that interact with the opioid-receptor. Opiates include herbal morphine or thebaine and semi-synthetic analogues derived thereof, like heroin. Opioids are synthetic compounds. Shown are fentanil-analges and non-fentanil structures. The structures in the lower row are examples for respective analogues. Carfentanil is an extremely potent drug, U-47700 is a non-fentanil novel opioid, both found in the drug scene

synaptic space back into the presynaptic neuron. This inhibition leads to increased and prolonged presence of the neurotransmitter in the synaptic space and thus to a prolonged and increased signal. Another indirect mechanisms of action is seen with psychoactive drugs that are taken up into synaptic vesicles, causing displacement of the neurotransmitter into the synaptic space and thus activation of the postsynaptic neuron, even in the absence of a signal.

### Interaction with Neurotransmitter Degradation

Other types of psychoactive drugs interfere with synthesis or degradation of neurotransmitter molecules. Examples include monoaminoxidase (MAO) inhibitors, a group of therapeutic drugs used to treat depression disorders.

Many psychoactive substances interact with more than one receptor type and affect several neurotransmitter pathways, thus producing the substance specific changes of brain function. The TAAR pathways (Freyberg and Saavedra 2020) are often involved (Fig. 4).

**Fig. 4** Schematic drawing showing psychoactive substance (PS) disposition, and interaction with neurotransmitters (NT) in synapses (examples). PS may be taken up into the body via different routes. Once in the blood, a high lipophilicity tends to favor uptake across the blood-brain barrier (BBB) into the brain. Directly acting PS bind as agonist to the neurotransmitter NT-receptor (1), usually on the postsynaptic membrane, inducing via opening of ion channels an action potential. PS may also act indirectly either by inhibiting reuptake of the NT into the neuron (2), or displacing NT from NT-storing vesicles, thus inducing NT-release (3). Interactions with local NT synthesis or breakdown may also be involved. Main routes of PS elimination are via the liver and bile into the gastrointestinal tract (GI tract) or via the kidneys into urine, either unchanged or following biotransformation

## Metabolism and Elimination

The metabolic inactivation of many endogenous neurotransmitters occurs rapidly by enzymes in or around the synapse. Some psychoactive drugs interfere with this breakdown.

The psychoactive drug molecules are usually subject to biotransformation primarily in the liver. This produces less active or inactive metabolites, which are then eliminated via bile or kidneys. But caution is required, since some metabolites may still be pharmacologically active. Examples are morphine-conjugates or certain phase I metabolites of synthetic cannabinoids.

In the analysis of psychoactive drugs in human body fluids of intoxicated persons or postmortem, it is of utmost importance to search not only for the parent substance but also to detect metabolites. Depending on the biological fluid used for the analytical investigation, metabolites may be present at concentrations exceeding those of the

parent drug. The full analytical pattern of parent drug plus metabolites provides a more complete picture to the clinical and forensic toxicologist with regard to the total amount of consumed drug or the time that elapsed since the most recent drug intake.

## **Toxicology and Clinical Toxicology**

### **Acute Intoxication**

Acute drug intoxications and fatalities are common when abusing (particularly the unregulated) psychoactive substances. One of the reasons is that drug consumption may cause a transient euphoria, and when the intensity of the effect subsides, the consumer takes further drug doses, until a toxic or fatal level is unexpectedly reached. This is often aggravated by the simultaneous intake of several different types of drug, some stimulating, some sedating (“polydrug” use), or when the agent has a higher potency, than expected by the consumer.

Thus, intake of propofol in connection with agents such as cathinones or amphetamines that affect intermediate metabolism may cause severe imbalances of energy metabolism. Fentanyl and its derivatives, notably the very potent carfentanyl today causes many intoxications (Wilcoxon et al. 2018; Delcher et al. 2020), with respiratory arrest, often leading to death. Amphetamines activate the cardiovascular system and produce hypertension often leading to cardiovascular emergencies.

When confronted with an intoxicated patient, the clinical toxicologist will initiate a general supportive therapy and general biochemical and drug-analyses if possible. Once the consumed substance is identified, this may help to use specific therapy such as an antidote or antibody.

A big problem arises from designer drugs, for which no toxicological profile, no forensic literature, and no specific therapeutic regimen exists. Given the low dose needed to cause intoxication for some novel potent derivative substances, often times the analytical toxicology of these substances is highly complex and requires sensitive and specific analytical instrumentations. Often times these are not available in clinical settings. Furthermore, in the absence of a patient anamnesis, a complete analytical investigation to identify the substances responsible for the intoxication, requires time-consuming analytical investigations carried out by highly trained personnel. The clinicians have thus to rely on common observed patterns of toxicity for the rapid clinical management of the intoxication. This again is difficult in the case of a new designer drug or polydrug use due to complex clinical manifestations.

### **Dose-Response Relationships**

With increasing doses, the CNS-effects of psychoactive drugs tend to shift, as exemplified by the well-known sequence of ethanol-effects. These evolve with rising doses from initial sedation towards excitation, aggressiveness, coma, delirium, and sometimes death. The sequence may vary at the inter-individual level and depends on factors such as preceding stress, co-medication, age. In drug tolerance, the desired pharmacological response will require increased dosing, cause physical dependency, and increase the risk of acute toxicological emergencies.

## Chronic Toxicity and Dependency

Prolonged abuse of amphetamine-like substances may cause severe paranoid psychosis. Cannabinoids have a deleterious effect on the still developing brain of teenagers, some hallucinogens produce long-lasting flash-back experiences. Drug consumption during pregnancy is a common risk for the developing fetus and the normal development of neuronal networks in their brain. Babies with prenatal exposure to methamphetamine were reported to suffer from various deficit. This aspect of designer drug consumption will have long-lasting consequences for families and society and is alarming for public health institutions.

The variants of brain deteriorating effects are known for traditional recreational drugs, but the risks are unknown for novel designer drugs. Moreover, even impurities may exhibit potent neurotoxic effects; an example is the substance MPTP (“1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine”) that occurred as a contaminant of the synthetic opioid-mimetic MPPP (“1-methyl-4-phenyl-4-propionoxypiperidine”). MPTP sadly induces Parkinson’s-disease, after it is converted in the brain by monoamine oxidase to the neurotoxic agent MPP<sup>+</sup>. MPTP has since been used as a tool to study the pathogenesis of Parkinson disease (Langston 2017).

---

## Central Role of Analytics

Drug identification is a pillar in drug control. Seized samples, often powders, are brought to the specialized analytical lab. The material is checked with regard to visual appearance, color, smell, and consistency, analyzed with available immunochemical tests, and when required subject to detailed chemical analysis. When neither literature nor catalogues of analytical chemistry help to identify the analytical signals, a detailed procedure employing a full spectrum of methods, such as hyphenated chromatography-mass spectrometry and NMR may lead to the absolute structure elucidation and identification.

The pre-analytical procedures and sample clean-up are often simpler in urine than in blood. Urine has, however, the disadvantage that it tends to contain metabolites of the drug, rather than the original drug. To circumvent this problem, conjugate-metabolites can be subjected to chemical or enzymatic hydrolysis to release the scaffold for analytical detection. Nevertheless, the released substance is not identical to the consumed drug, when it has undergone hepatic phase-I biotransformation. Analysis in blood samples provides the problem of multiple background substances (matrix components) from which the analyte has to be separated. If separation from background noise is successful, the chance for detecting the original drug may be greater than in urine samples, provided that not too much time has elapsed since drug intake.

Another analytical challenge is associated with the analyte itself. Many recreational drugs and designer drugs occur in enantiomeric forms, all having the same basic structure, of which only one chiral form may exhibit the psychoactive effect.

Smuggled drugs (e.g., as “black cocaine”) have sometimes been mixed with agents to render difficult their detection in conventional assays or by sniffing dogs. These agents can get removed with specific methods by the dealer to make the drug “clean”

again. Similarly, when novel designer drugs are laced with prescription therapeutics, standard test methods may cause misleading results. Often a very detailed analytical procedure is required for an identification (Lobo Vicente et al. 2016). Communication and exchange between the analytical centers is important (Guillou et al. 2018).

---

## Aspects of Regulation, Control and Health Protection

Drug regulation and the delineation of pharmaceutical drugs against recreational drugs have a long history. A milestone of regulation was around 1920, when many countries regulated the problems associated with opiates and the then new opiate-derivative heroin in “dangerous drug acts.” Amendments were later made according to upcoming new types of drugs and international conventions followed.

It is inherently difficult to find a widely accepted regulation between full liberalization and full prohibition of recreational drugs, and the attitudes and rules are not entirely static, as demonstrated by the transient alcohol prohibition in the USA in the 1920s, the part-liberalization of cannabis starting in various countries around the year 2015, or the withdrawal in some countries of formerly available pharmacologically used agents such as the stimulating substance prolintane from markets. Scientific interest and drug development need a liberal regulation, when they are pushed too much towards prohibition, this may negatively affect a societies’ scientific expertise and at the same time even enhance the danger of clandestine synthesis somewhere in the world.

## National and International Efforts

In 1961, a number of international conventions were replaced by an updated, combining UN-convention “Single convention on narcotic drugs” that regulated mainly opioids, cocaine, and cannabis. In 1971 followed the “Convention on psychotropic substances,” that included many other agents, such as hallucinogens. In 1988 followed the United Nations convention against illicit traffic in narcotic drugs and psychotropic substances, with respective lists. Relevant chemical precursor substances are also placed under control such as naphthoylindole, a precursor of designer cannabinoids or thebaine, a precursor for opiates (CND 2020).

Though the principles of regulation are adopted in national laws to the United Nations conventions, national laws tend to include country-specific aspects. At international level, agencies such as DEA in the USA, EMCDDA in Europa, and UNODC of the United Nations are well organized, cooperating institutions. The principles of the 1971 convention are basically still valid. Health aspects play a significant role including avoidance of addiction, public health protection, and the availability of important medicines (Fig. 5).

While many traditional recreational drugs of abuse are still in use and constitute an on-going dilemma, the ever-increasing number of new designer drugs poses additional new problems for the controlling agencies and health protection institutions. Illicit designer drug producers have access to the official lists of

### Psychotropic Substances UN-Classification Types (1971)

Schedule	Risk of Abuse	Threat to Public Health	Therapeutic Value	Level of Control
I	Very high	Very serious	Absent - little	Very strict
II	Risk	Serious	Low - moderate	Less strict
III	Risk	Serious	Moderate - high	Less strict
IV	Risk	Minor	High	Less strict

**Fig. 5 United Nation Classification system (simplified table).** Depicted are the schedules for psychotropic substances, and the respective criteria

NPS. With the help of published synthesis methods, they can reproduce substances or synthesize new derivatives that are not yet listed as controlled substances. For the controlling agencies, it tends to be a long way from unequivocal substance identification until the final international consensus is found to place the substance in the list of controlled substances. Nevertheless, this eventually happens. Examples are the substances mephedrone, BZP (1-benzylpiperazine) and MDPV (3,4-methylenedioxypropylvalerone), the synthetic cannabinoids JWH-018 and AM-2201, that moved from the status of NPS to scheduled international control in 2015. More recently, several other synthetic cannabinoids (AB-CHMINACA, ADB-CHMINACA, 5F-MDMB-PINACA, CUMYL-4CN-BINACA) and fentanyl analogues including furanylfentanyl, acrylylfentanyl, 4-FIBF (4-fluoroisobutyrylfentanyl), THF-F (tetrahydrofuranylfentanyl), carfentanil, cyclopropylfentanyl, methoxyacetylfentanyl were then added to the list of substances of the Convention on Psychotropic Substances and to that of the Single Convention on Narcotic Drugs respectively.

## The Analogue Principle

### Types and Advantages

Regulation often applies the analogy principle to make NPS illegal in the absence of precise knowledge about their character, even before they come to the market. International, national, and state agencies use different wording, not least because a too simple definition of “analogue” may inadvertently include natural substances present in coffee and chocolate or alcohol, and any wording tends to still have gaps. In accordance with the classes in Fig. 1, the analogy principle is usually applied in any of three ways: by type of pharmacological class, chemical

class, and biochemical mechanism of action. A newly seized substance, for example, may be identified in the forensic analysis as a phenylethylamine derivative, but it is initially not known, what kind of psychoactive effect it bears. Therefore, it is hoped that receptor binding studies provide information about the mode of biochemical interaction with major neurotransmitter systems such as adrenergic, serotonergic, dopaminergic, etc. But even when specific receptor-binding studies give positive results, it is possible, that no signal transduction via, e.g., G-proteins to open a metabotropic pathway occurs. This detail must be studied in additional experiments. In conclusion, it may become very difficult to provide a final proof for analogy. In practice, the problem may be even more difficult to solve, when the seized material contained more than one phenylethylamine-analogues. This is a challenge for clinical and forensic toxicology, and notably for chemical analytics.

The multidimensionality of the analogue problem is reflected by the very detailed wording used in regulations, such as the 2019 Florida statutes (Florida 2019) first paragraph of the section on synthetic cannabinoids:

190. Synthetic Cannabinoids.—Unless specifically excepted or unless listed in another schedule or contained within a pharmaceutical product approved by the United States Food and Drug Administration, any material, compound, mixture, or preparation that contains any quantity of a synthetic cannabinoid found to be in any of the following chemical class descriptions, or homologues, nitrogen-heterocyclic analogs, isomers (including optical, positional, or geometric), esters, ethers, salts, and salts of homologues, nitrogen-heterocyclic analogs, isomers, esters, or ethers, whenever the existence of such homologues, nitrogen-heterocyclic analogs, isomers, esters, ethers, salts, and salts of isomers, esters, or ethers is possible within the specific chemical class or designation. Since nomenclature of these synthetically produced cannabinoids is not internationally standardized and may continually evolve, these structures or the compounds of these structures shall be included under this subparagraph, regardless of their specific numerical designation of atomic positions covered, if it can be determined through a recognized method of scientific testing or analysis that the substance contains properties that fit within one or more of the following categories:...

## Measures for Health Protection and Control

The international community and most countries have developed many different activities and concepts that are suited to help drug addicted people, control, and avoid drug use. Here are some examples:

- Support for individuals with acute drug toxicity, e.g., Euro-DEN (Wood et al. 2016)
- Seizure-Activities
- Control of precursor substances
- Prediction of designer drugs (Carlsson et al. 2016, 2018)
- Shutdown of internet/darknet platforms
- Early warning systems, national, international

- Analysis in wastewater samples to monitor the broad population consumption
- Drug checking campaigns in party settings (voluntary, non-voluntary)
- Support for drug analyzing toxicology-centers (Guillou 2017)
- Support for clinical toxicology centers, specialized on intoxication treatments
- Abuse-resistant prescription drugs (Coleman et al. 2005), e.g., inapt for injection or nasal application
- Injection devices free of charge
- Methadone (or similar) substitution programs

Taken all together, the addictive drug field and the many new psychoactive drugs are serious challenge for societies and regulations and presently quite difficult to manage.

## Abstract

Nicotine is highly addictive, interacts with particulates and infection in respiratory disease and promotes cancer in the lung and other organs. Cardiovascular morbidity and mortality were related to fine and ultrafine particles, free radicals, reactive oxygen species, nicotine and other toxins inhaled by smoking, second hand smoking, use of water pipe, heated tobacco, and to vaping e-cigarettes. Steepest increase of risk is observed in the low dose range, explaining the considerable increase of chronic disease by regular passive exposure and its acute hazards for risk groups like persons with ischemic heart disease or asthma. All forms of tobacco are harmful, and there is no safe level of exposure. Oral nicotine does not expose bystanders, but in users of smokeless tobacco cardiovascular disease, oral cancer and pancreatic cancer may increase and like exposure to tobacco smoke in pregnancy it raised rates of stillbirth and low birth weight. Sudden infant death is associated with prenatal and postnatal exposure of the child and also long-lasting effects of parental smoking were observed on

respiratory health of children and on the development of their brains. Regulation of all nicotine products should be based on the World Health Organization (WHO) Framework Convention on Tobacco Control. Long-term goal is to raise a nicotine-free generation and to stop selling nicotine products on the free market.

### Keywords

Tobacco · E-cigarette · Passive smoking · Nicotine · Health · Disease · Cancer

## Introduction

Tobacco kills up to half of its users, more than seven million people worldwide each year as a result of active smoking, and another 1.2 million as a result of involuntary breathing of second-hand smoke (SHS). Compared to earlier reviews (WHO 2008, Fig. 1), annual victims are on the increase and tobacco is projected to kill one billion people this century unless countries take strong action now to prevent it (WHO 2020b).

Tobacco smoke is a complex, dynamic and reactive mixture of hazardous gases and particles, containing thousands of chemicals, including toxic carbon monoxide and highly addictive nicotine. Nicotine promotes cancer growth (Ginzel et al. 2007), initiated by products of pyrolysis (N-nitrosamines, polycyclic aromatic hydrocarbons - PAHs, aromatic amines, volatile hydrocarbons, other organics, heavy metals, and metal compounds). In sidestream smoke (released between puffs from the end of a burning cigarette, cigar, or pipe), particles are smaller and products of pyrolysis higher than in mainstream smoke.

Passive smoking includes inhalation of sidestream smoke and smoke exhaled by smokers. In addition also third-hand smoke deposited on and released from surfaces

**Fig. 1** Eight leading causes of death (2005) and proportions attributable to tobacco smoking © WHO. Reproduced from *WHO REPORT on the global TOBACCO epidemic, 2008* (WHO 2008)

(floor, walls, furniture, house dust) is an involuntary exposure of particular importance for children. Most frequently used are tobacco cigarettes (combustion products), but electronic cigarettes (ecigs) and heated tobacco products (HTPs) are on the increase and many adolescents start their smoking career with these novel products or with water pipe (shisha). Some enter nicotine addiction by oral tobacco like snus<sup>R</sup> or oral nicotine like skruf<sup>R</sup>. All these products are not controlled like nicotine products from pharmacies and all are advertised for continuous use and not for limited treatment. Less products of pyrolysis are emitted by HTPs and ecigs, nevertheless nicotine exposure is hazardous, especially in combination with irritant, toxic, and carcinogenic compounds on the large surface of small particles inhaled by “vapers.” Oral and dermal applications of nicotine products do not expose the lungs of users and bystanders with aerosols, but like ecigs oral products can serve as a gateway into nicotine addiction, and some increase of cardiovascular and metabolic disease and cancer (oral cavity, esophagus, pancreas) has been observed after long-term use of oral tobacco. Daily maternal use in pregnancy was associated with increased risk of preterm delivery, stillbirth, neonatal apnea, and higher systolic blood pressure in childhood and altered autonomic cardiac control.

---

## Vascular Effects of Tobacco Products and Nicotine

Most frequent causes of death related to tobacco smoking are from cardiovascular and cerebrovascular disease (CVD). Even SHS triggers acute changes of endothelial function, blood coagulability, heart rhythm, and promotes the development of arteriosclerosis (Neuberger 2019). Main driver of vascular effects seem to be fine and ultrafine particles and toxic compounds.

Both outdoor particle pollution from motor traffic and indoor particle pollution from tobacco smoke trigger endothelial dysfunction, platelet activation, and thrombogenesis (Neuberger 2008). In patients with coronary artery disease, active or passive smoking produces acute myocardial ischemia by adversely affecting the balance of demand for myocardial oxygen and nutrients with myocardial blood supply.

Carbon monoxide (CO) – a major constituent of cigarette smoke – binds avidly to hemoglobin, reducing the amount of hemoglobin available to transport oxygen and impeding release of oxygen by hemoglobin to tissues. CO-reduced exercise tolerance in patients with angina pectoris or intermittent claudication (Neuberger 1979).

Cigarette smoke delivers a high level of oxidizing chemicals to smokers, including oxides of nitrogen and many free radicals and reactive oxygen species (ROS) from both the gas and tar phases of cigarette smoke (Church and Pryor 1985). Exposure to oxidant chemicals in smoke was associated with depletion of endogenous levels of antioxidants like vitamin C (Lykkesfeldt et al. 2000), increased levels of lipid peroxidation products, oxidation of low-density lipoprotein (LDL), inflammation, endothelial dysfunction, and platelet activation (Burke and FitzGerald 2003).

Acrolein, a reactive aldehyde present at high levels in cigarette smoke, forms protein adducts, implicated in loss of protection by high density lipoprotein (HDL)

and in atherogenesis (U.S. CDC 2010). Acrolein also oxidizes antioxidant proteins, which can result in dysfunction and death of endothelial cells, contributing to atherosclerosis. In addition, acrolein inhibits antithrombin activity and could contribute to smoking-induced coronary vasospasm.

Nicotine has a central role in CVD from tobacco use and from SHS. It is a sympathomimetic drug that increases heart rate and cardiac contractility, transiently increasing blood pressure and constricting coronary arteries, which is most risky in persons with preexisting hypertension. Nicotine also contributes to endothelial dysfunction, insulin resistance, and lipid abnormalities. Both tobacco use and SHS are risk factors for diabetes and aggravate insulin resistance in persons with diabetes. The mechanism appears to involve the effects of oxidizing chemicals in the smoke and the sympathomimetic effects of nicotine. Combined effects of smoking and ambient air pollution on CVD are more than additive (Fig. 2): From the hazard ratios for CVD deaths the dominant influence of smoking can be seen, but also additional increases from ambient air pollution with PM2.5, which are higher in current smokers than in never-smokers.

Combined toxins distributed on the large surface of (ultra)fine smoke particles trigger pulmonary reflexes and inflammation, reach the alveoli, some of them cross the alveolar-capillary membrane, elicit acute endothelial dysfunction with inactivation of nitric oxide (mediating vasodilatation), impair the viability of endothelial cells and reduce the number and functional activity of circulating endothelial

**Fig. 2** Cardiovascular mortality: Hazard ratios for active smoking and for ambient air pollution with fine particles – PM2.5 (Turner et al. 2017). ©Elsevier, with kind permission

progenitor cells. Platelets of non-smokers appear to be susceptible to quick pro-aggregatory changes with every SHS exposure. Apart from vasoconstriction and thrombus formation from sticky platelets, increased fibrinogen and other factors of blood coagulation, further impairment of the myocardial oxygen balance is promoted by nicotine-induced adrenergic stimulation and particle-induced autonomic dysfunction with heart rhythm disturbances and worsening of left ventricular diastolic function. Experiments in healthy men showed that a 30-min exposure to SHS (e.g., the time of a meal in a smoking room) was sufficient to reduce coronary flow velocity reserve (Otsuka et al. 2001) and sustained vascular injury characterized by mobilization of dysfunctional endothelial progenitor cells with blocked nitric oxide production and activation of platelets in blood. Chronic vascular effects of SHS start with endothelial dysfunction in children, arterial stiffness, and the development of a thickening of the intima-media and other signs of early atherosclerosis. Combined effects of tobacco smoke with ambient air pollution with urban aerosols have been detected and complex interactions with nutrition are likely, especially in connection with diabetes. SHS is a risk factor for metabolic syndrome, glucose intolerance, insulin resistance, and the development of type 2 diabetes mellitus. A meta-analysis by Wei et al. 2015 on seven prospective studies investigating the risk for developing type 2 diabetes from SHS found a RR of 1.33 (95% CI 1.20–1.46) and after adjustments for publication bias 1.27 (95%CI 1.16–1.40). After manifestation of diabetes vascular complications are increased by further exposure to tobacco smoke.

Accelerated atherosclerosis from tobacco smoke may result in ischemic heart disease, increased risk of acute myocardial infarction, and sudden cardiac death, stroke, peripheral artery disease with gangrene of extremities, aortic aneurysm, atrial fibrillation, pulmonary embolism, and other sequelae (Banks et al. 2019). The largest smoking-related disease burdens in adults are from CVD, with highest RR at young ages, but continuous increase of risk with pack-years, age, and years of smoking. Over the years also regular passive smokers build up a considerable risk for ischemic heart disease. Classifying male non-smokers in the lowest quarter of serum cotinine (0–0.7 ng/ml) as “light passive smokers” and non-smokers within the upper three quarters of cotinine concentrations (0.8–14 ng/ml) as “heavy passive smokers,” Whincup et al. (2004) observed that the risk for major coronary heart disease increased by years of follow-up significantly steeper in heavy passive smokers, comparable to the increase in light active smokers, consuming 1–9 cigarettes per day.

In a European cohort on circulatory mortality a hazard ratio of 1.25 (95%CI 1.04–1.50) was calculated for passive smoking (verified in a subsample by plasma cotinine) per each additional daily hour of exposure (Gallo et al. 2010). A meta-analysis found for SHS a relative risk of 1.35 (95% CI: 1.22–1.50) for stroke and 1.27 (95% CI: 1.10–1.48) for ischemic heart disease, with higher risks in women (Fischer and Kraemer 2015). Many studies underestimated relative risks for CVD, because they compared active smokers with non-smokers, of which many were exposed to SHS. If choosing non-smokers without exposure to SHS as the proper control group (Bonita et al. 1999), the odds ratio of stroke from active smoking increased from 4.14 (95% CI 3.04–5.63) to 6.33 (95% CI 4.50–8.91). Flores et al. (2016) found that the premature mortality hazards of recalled and unconscious

exposure to SHS are comparable and predicted by serum cotinine at beginning of observation. There was a significant increase in years of life lost, adjusted for confounders, across cotinine categories, similar in non-smokers reporting SHS and in non-smokers reporting no SHS exposure.

Dose-response relationships are not linear, but a much steeper increase of cardiovascular risk is observed in the low-dose range, covering SHS and occasional active smoking. SHS increases the risk of coronary heart disease by about 30%. In occasional smokers consuming an average of less than one cigarette per day a hazard ratio of 1.71 (95% CI 1.33–2.21) was found for CVD (Inoue-Choi et al. 2017) and the consumption of 1–4 cigarettes per day raised relative risk of dying from ischemic heart disease to 2.74 (95% CI 2.07–3.61) in men and 2.94 (95% CI 1.75–4.95) in women (Bjartveit and Tverdal 2005). Disproportionately, high risk at low levels of exposure suggest that there is no safe lower limit of SHS exposure for risk groups. Even if reduction of active smoking is sustained, the reduction of daily cigarettes smoked reduces the risk only marginally compared to complete cessation.

Most at risk for acute effects of SHS are patients with preexisting coronary or cerebrovascular diseases, which in turn are promoted by chronic exposure to SHS. Since Sargent et al. (2004) reported reduced incidence of admissions for myocardial infarction after a public smoking ban, numerous studies confirmed that enforcement of smoke-free laws rapidly reduces admissions for acute coronary syndrome and other cardiac and cerebrovascular diseases (Neuberger 2008). Smoke-free legislation is associated with a lower risk of hospitalization and death from CVD, significantly lower rates of hospital admissions or deaths from coronary events (relative risk, 0.85; 95%CI 0.82–0.88), other heart disease (relative risk, 0.61; 95%CI 0.44–0.85), and cerebrovascular accidents (relative risk, 0.84; 95%CI 0.75–0.94). More comprehensive laws were associated with larger changes in risk. Indoor smoking bans reduced myocardial infarction by 10–20%, in the first year mainly associated with the elimination of passive smoking and followed by sustainable decreases of coronary syndrome, myocardial infarction, stroke, and incident diabetes also in ex-smokers (Tan and Glantz 2012; Akter et al. 2015).

Shisha (water pipe, hookah, narghile) produces similar risks for users and bystanders as tobacco cigarettes, but concentrations of carbon monoxide in charcoal-heated shisha and of heavy metals are higher. Depending on intensity and duration of exposure, acute CO intoxications were reported and in long-term similar CVDs can develop as in cigarette smoking (Waziry et al. 2017). Animal experiments showed hypercoagulability, inflammation, as well as systemic and cardiac oxidative stress (Nemmar et al. 2017). Also the smoking of other pipes and cigars, whether active or passive, carries significant risk of smoking-related CVD (Shaper et al. 2003).

Because less products of pyrolysis are formed by heating than by burning tobacco, HTPs are marketed as less dangerous than conventional cigarettes; however, biomarkers of potential cardiovascular harm did not support this claim (Glantz 2018). HTPs impair vascular endothelial function measured by arterial flow-mediated dilatation in rats to the same extent as by cigarette smoke (Nabavizadeh et al. 2018). An important advantage of all electronic devices over conventional cigarettes

is that SHS or second-hand aerosol is only produced when the user exhales and not continuously like in conventional smoking between puffs. The doses calculated for second-hand uptake of particles, toxins, and carcinogens from electronic devices are usually much lower than from traditional tobacco products, below  $1.6 \times 10^8$  particles/kg bodyweight, but dosimetry estimates were 50–110% higher for HTPs than for ecigs (Protano et al. 2017). The carrier function of aerosols from electronic devices might be similar, but the clearance of liquid particles is certainly faster than of solid, carbonaceous particles released by conventional cigarettes. On the other hand, some electronic devices release even more ultrafine aerosols carrying tobacco-specific nitrosamines and heavy metals and also volatile organic compounds are released, which are harmful for users and bystanders. In addition hemodynamic changes and adverse effects of nicotine on blood lipids, as well as the induction of insulin resistance contribute to cardiovascular risk of HTPs and ecigs (Zhang et al. 2018; Protano et al. 2020).

Electronic cigarettes (ecigs) have been called “a wolf in sheep’s clothing,” because they may serve as a gateway drug for youth, prolong nicotine addiction, and the ritual in smokers who would otherwise be willing to quit. So they keep up the handling and use of cigarettes in public and the denormalization of cigarettes is undermined (Neuberger 2015). Even bystanders absorb considerable amounts of nicotine (Ballbè et al. 2014) and inhale particles, which are smaller than in SHS (Schripp et al. 2013). Aerosols exhaled during vaping are less persistent than SHS, nevertheless they are carriers for toxins, which they adsorb on their large surface and transport them to persons in the same room and even to neighboring rooms (Khachatoorian et al. 2018), and into the depth of the lung, where clearance is less efficient and where ultrafine particles can reach the bloodstream. Most dangerous is the contamination of small rooms like passenger cars (Schober et al. 2019). WHO (2020a) clearly stated that ecigs (electronic nicotine delivery systems – ENDS and electronic non-nicotine delivery systems – ENNDS) and other vaping products are dangerous for both users and bystanders exposed to the aerosol. Cohort studies on long-term effects are still missing, but similar cardiovascular risks seem to exist as from tobacco products and HTPs, indicated by a sustained hyperadrenergic effect (triggering arrhythmias and other harmful cardiac reactions), oxidative stress and activation of inflammatory pathways (leading to atherosclerosis, plaque progression and instability, and myocardial ischemia), endothelial dysfunction (leading to impaired nitric oxide release and oxygen supply to tissues), arterial stiffness (caused by nicotine and predicting CVD), and pathological thrombus formation from platelet activation (Middlekauff 2020). The chronic use of ENDS produced platelet aggregation to a similar degree as in chronic users of tobacco products (Nocella et al. 2018). Most worrying are first cross-sectional studies showing associations of ecigs use with myocardial infarction (Alzahrani et al. 2019). Many users of ecigs return to tobacco cigarettes or become dual users and dual use was associated with higher odds of CVD than smoking tobacco only (Osei et al. 2019). Cohort studies on long term risks of use and second hand inhalation of ecigs and HTPs are still lacking, but from the indicators mentioned above it has to be assumed that also passive vaping increases CVD. Because of risks for CVD, respiratory disease, cancer, and addiction

(see below), HTPs and ecigs cannot be recommended as a help for smoking cessation, even though health risks of smoking and SHS are even higher. Some ecigs are labelled “without nicotine,” despite of releasing considerable amounts. Adjustable voltage, nicotine salts, and additives were developed to increase nicotine uptake and to mimic the rapid transfer of nicotine to blood and brain like in smoking. For smoking cessation, dermal and oral nicotine products from pharmacies are safer for nicotine replacement and do not contaminate the breathing air of bystanders. Their nicotine content is controlled and can be reduced gradually during cessation. In young and light smokers, preference should be given to cessation aid without any nicotine. Also for pregnant women any form of nicotine is harmful for mother and child (Ginzel et al. 2007). Higher systolic blood pressure in childhood and altered autonomic cardiac control were associated with nicotine consumed by the mother in pregnancy, whether by inhalation or by oral products (Watanabe and Parikh 2019). Stop of oral tobacco (snus) use after a myocardial infarction nearly halved mortality risk, similar to the benefit associated with smoking cessation (Arefalk et al. 2014).

---

## Respiratory Effects of Tobacco Products and Nicotine

Tobacco smoking is the leading preventable cause of death and disability, with important contributions of respiratory diseases (Fig. 1). The earlier smoking is stopped, the better are respiratory outcomes. To end accelerated decline of lung function compared to non-smokers, smokers need complete smoking cessation. Similar to CVD, reduction of daily consumption to below 5 cigarettes is insufficient to stop respiratory function decline (Fig. 3).

In industrialized countries smoking prevalence decreased, nevertheless some studies attributed up to two-thirds of deaths in current smokers to tobacco and an even higher number of diseases, which are not registered as main cause of death (Banks et al. 2019). In respiratory diseases, asthma and chronic obstructive pulmonary disease (COPD) from smoking are most important for disability, early retirement, and invalidity. In 2015, COPD caused 2.6% of global disability adjusted life years (DALYs) and asthma 1.1% of global DALYs, with smoking, air pollution, and SHS as the main risk factors (Soriano et al. 2017). Smokers had a fourfold increase in risk of developing COPD (Bellou et al. 2019), and there are combined effects of active and passive smoking with other environmental and occupational air pollution.

Other important interactions of tobacco smoke in respiratory diseases occur with infections, especially in childhood. Smokers are touching their face and mouth more often and they can also transfer bacteria causing meningitis or viruses causing respiratory disease by kissing a child. Combined effects of smoking and tuberculosis are a world-wide problem (Fig. 1), especially in the developing world. Smoking and SHS impair mucociliary clearance and lung function. By reducing defense of the respiratory system, weakening and damaging it, tobacco smoke enables viruses and bacteria to invade. Some infectious diseases become more serious or even lethal, e.g., pneumonias in children from SHS or bronchiolitis from respiratory syncytial virus. Higher mortality was also reported in smokers from influenza and corona virus

**Fig. 3** Decline of Forced Expiratory Volume in first second (FEV1) by age and smoking (Oelsner et al. 2020). ©Elsevier with kind permission

infection (Middle East Respiratory Syndrome and COVID-19), especially in smokers with COPD (Alqahtani et al. 2020).

Also HTPs and ecigs aerosols contain numerous respiratory irritants and toxicants, triggering increased airway hyperreactivity, distal airspace enlargement, mucin production, as well as cytokine and protease expression. Just 15 min of exposure to ecig aerosol induced transient lung inflammation and impaired gas exchange in healthy volunteers. Defense by ciliary function, neutrophils, and alveolar macrophages is impaired and cross-sectional studies found an increase of asthma and of bronchitis symptoms, even in adolescents who had never used tobacco. Long-term observations are still missing, but experiments with animals and with human tissues showed similar structural lung changes from ecigs as in the development of COPD from tobacco, protease release from alveolar macrophages and blood neutrophils, and nicotine dependent elastase release (Gotts et al. 2019). Respiratory toxicity of ecigs is determined by a large number of aromas, nicotine, and the carriers propylene glycol, vegetable glycerin, and other solvents forming aerosols with small particle diameter. Heavy metals (Ni, Cr, etc.) contribute to respiratory risks of ecigs (Fowles et al. 2020). Some ingredients, additives or their decomposition products might cause special respiratory diseases, e.g., diacetyl, which caused bronchiolitis and “popcorn lung” in occupational exposures. In 2019 in the USA, 2558 persons were hospitalized and 60 patients died from acute vaping disease, called “e-cigarette, or vaping, product use–associated lung injury” (EVALI), characterized by gastrointestinal and severe respiratory symptoms with bilateral pneumonia and Acute Respiratory Distress Syndrome (Werner et al. 2020). Days

to weeks after consumption of ecigs also, young people without previous lung disease and without detectable infection developed respiratory failure with pulmonary edema, hypoxemia, diffuse alveolar & endothelial damage, protein-rich inflammatory fluid in alveolar space, and need for mechanical ventilation. The heterogeneity of clinical appearance might resemble the high variety of uncontrolled additives used in ecigs. Most (but not all) cases of EVALI had used ecigs with cannabis or tetrahydrocannabinol (THC). These mixtures contained vitamin E acetate, used as a thickening agent in THC products, which was also found in bronchoalveolar lavage of patients. At temperatures reached in vaping devices the exceptionally toxic ethenone ( $C_2H_2O$ ) and other ketenes may be formed by pyrolysis of vitamin E acetate (Wu and O'Shea 2020), possibly amplified by metal catalysts. Since the outbreak of SARS-CoV-2 epidemic new cases of EVALI are easily misdiagnosed as COVID-19 (Armatas et al. 2020).

---

## Cancer from Tobacco Products and Nicotine

Tobacco smoke contains dozens of carcinogens, including class 1 carcinogens like benzo[a]pyrene, N'-nitrosornicotine (NNN), nicotine-derived nitrosamine ketone (NNK), 2-toluidine, 2-naphthylamine, 4-aminobiphenyl, benzene, 1,3-butadiene, ethylene oxide, vinyl chloride, and metals like As, Be, Cd, Cr(VI), and  $^{210}Po$ . Also other products of tobacco pyrolysis contribute to cancer risks in many organs, e.g., benz[a]anthracene, dibenz[a,h]anthracene, formaldehyde, N-nitrosodimethylamine, N-nitrosodiethylamine, 2-amino-3-methylimidazo[4,5-f]quinoline (IQ), acrylamide, glycidol. From these genotoxic compounds or their metabolites cancer can develop in lungs, bronchi, trachea, larynx, mouth, throat, esophagus, stomach, colon, rectum, liver, pancreas, kidney, renal pelvis, bladder, uterine cervix, or blood (acute myeloid leukemia). Combined effects of tobacco smoke with alcohol are of importance in cancer of the upper digestive tract, larynx, colon, liver, pancreas, and female breast, and with chronic infection, e.g., with human papilloma virus (HPV) in cervical cancer and with hepatitis B or C in hepatocellular carcinoma. Increased risk of tobacco smoking was also found for mucinous ovarian cancer, chronic myeloid leukemia, and for breast cancer after exposure (active or passive) during the time when the female breast develops. Frequent and intensive SHS is a verified risk for cancer of the lung and of other locations (breast, pancreas, bladder, etc.), subject to similar combined effects as active smoking.

Smoking of pipes and cigars was found associated with cancer of lung, larynx, oral cavity, hypopharynx, esophagus, pancreas, stomach, and urinary bladder. Waterpipe does not filter carcinogens and the nicotine load of one pipe corresponds to the inhalation of approximately 10 cigarettes. Additional carcinogens enter the smoke of shisha from the burning of coal. Some PAHs, benzene, and heavy metals like Cd, Cr<sup>VI</sup>, Ni, Co, As are higher in shisha smoke than in cigarette smoke and put users and persons sharing the same room at risk for cancer. In users metabolites of tobacco-specific nitrosamines were detected in urine and in regular shisha users

studies found an increase of cancers of the head and neck, esophagus, and lung (Mamtani et al. 2016).

Cigarette smoking is the number one cancer risk, largely due to lung cancer (Shaper et al. 2003). Cigarette smokers are 15–30 times more likely to get lung cancer or die from lung cancer than people who do not smoke. Even smoking a few cigarettes a day or smoking occasionally increases the risk of lung cancer (Bjartveit and Tverdal 2005). Lung cancer increases with packyears and decreases after smoking cessation much more slowly than the cardiovascular risk. Smoking attributable lung cancer amounts to 70–90%. Other causes are particulate air pollution, other environmental exposures indoors (residential radon, SHS), and occupational exposures. Some combined effects of smoking are overadditive (radon, amphibole asbestos), so that attributable cancer risks sum up to more than 100% and high decreases of lung cancer risk can be achieved by elimination of only one risk factor.

As a defense against microbes, macrophages react to small particles with the induction of nitric oxide and reactive oxygen intermediates. Like in diesel soot the carcinogenicity of tobacco smoke seems to be less dependent on the mass of carcinogens than on the surface of small particles by which traces of genotoxic substances are transported into the lung. The particle size of SHS is smaller and on its large surface products of pyrolysis are transported, which are formed in higher concentrations in sidestream smoke between puffs than in mainstream smoke. Important for cancer development is also nicotine, which is not only genotoxic on human epithelia of the upper aerodigestive tract (Sassen et al. 2005), mediated through oxidative stress (Bavarva et al. 2004), but is also an important epigenetic risk, promoting cancer cell proliferation by several mechanisms, inhibiting apoptosis and thereby increasing cancer cell survival, stimulating angiogenesis, and thereby vascularization of the growing tumor, and promoting cancer migration (Fig. 4). Possible promotion of a smoking induced cancer by nicotine is one of the reasons, why nicotine replacement therapy after smoking cessation should be limited in time (Ginzel et al. 2007). The potent lung carcinogens NNK and NNN can form during blending of tobacco, but also in the smoker by endogenous nitrosation. Smoking itself increases nitrogen oxides and other nitrosating agents in saliva, stomach, urine, etc. For endogenous nitrosation of nicotine to NNN and NNK, the amount of ingested nitrite and nitrate is less important than chronic infection and diseases with chronic inflammation, which cause continuous increase of NO and peroxynitrite, capable of forming nitrosamines from nicotine and aminoketone (Parzefall et al. 2005).

Cancer risks of HTPs and e-cigarettes are lower than from tobacco products, but not negligible. Certainly the mass of carcinogens in aerosols of HTPs and ecigs is much smaller than in tobacco smoke, but traces of genotoxic agents might be sufficient to induce cancer if distributed on the large surface of very small particles in these aerosols and combined with potent promoters like nicotine (see above). Propylene glycol, glycerol, and flavors in ecigs produce free radicals and reactive oxygen species (Bitzer et al. 2017). Depending on voltage and temperature propylene glycol produces formaldehyde and its hemiacetal in the aerosol (Jensen et al. 2015). Ni, Cr, and other heavy metals were found to be transferred from the heating coils to the e-liquids (Fowles et al. 2020) and some of these carcinogenic metals

**Fig. 4** Lung cancer promotion by nicotine, signaling pathways downstream of nAChRs promoting drug resistance and antiapoptosis (for abbreviations see Cheng et al. 2020). Creative Commons License. Cheng et al. 2020

(from cartridge, fluid, etc.) were higher in e-cigarette aerosols than in SHS (Zhao et al. 2020). N-nitrosamines like NNN and their metabolites were found in saliva and urine of vapers (Bustamante et al. 2018). Also some of the sugars and aromas added to attract children can decompose to carcinogens. Bavarva et al. (2004) found nicotine induced mutations in human breast cells and other epithelial cells across 1,585 genes, of which 49% were associated with cancer, with genes of the mucin family among the top mutated genes. 26% of genes linked to cancer development are deregulated both in buccal mucosa of vapers and of smokers, partly different genes, which are implicated in cancer of lung, esophagus, bladder, ovary, and leukemia (Tommasi et al. 2019). Martin et al. (2016) found decreased expression of immune-related genes in the nasal mucosa of vapers, 53 genes like in smokers (some more suppressed), and 305 genes in vapers only. Damaged DNA and impaired DNA repair from exposure to e-cigarette aerosol was found in mice (lung, heart, bladder) and in human lung cells and bladder cells (Lee et al. 2018).

Oral uses of smokeless tobacco have the advantage that there is no inhalation risk for users and bystanders, but carcinogens like tobacco-specific nitrosamines are a cancer risk for betel quid chewers and for users of oral tobacco. Overall, there is sufficient evidence that smokeless tobacco causes oral cancer and pancreatic cancer in animal studies and in humans (Cogliano et al. 2004), possibly also esophageal cancer. Levels of cotinine and metabolites of tobacco-specific nitrosamines in urine

were found higher in smokeless tobacco users than in smokers (Hecht et al. 2007). Most risky is the combination of oral tobacco with tobacco smoking.

All nicotine products promote carcinogenesis and may interfere with cancer therapy. By example human pharyngeal cancer cells became resistant to Cisplatin by exposure to ecigs aerosol (Manyanga et al. 2019). Figure 4 shows some of the pathways by which nicotine, the primary addictive constituent of cigarettes, contributes to cancer progression through activation of nicotinic acetylcholine receptors (nAChRs), which are membrane ligand-gated ion channels. Activation of nicotine/nAChR signaling is associated with lung cancer risk and drug resistance (Cheng et al. 2020).

---

### **Other Important Diseases Promoted by Tobacco and Nicotine Products**

Numerous other diseases leading to disability were associated with smoking tobacco and with exposure to SHS. For newly developed nicotine products, there is still a lack of epidemiological data on their effects on chronic diseases, but from animal experiments and bioindicators in humans, there is sufficient evidence for metabolic effects of tobacco smoke and of nicotine. HTPs showed no difference in most biomarkers of potential harm from conventional cigarettes (Glantz 2018), possible hepatotoxicity and a potential for unexpected organ toxicity not previously associated with cigarettes (Chun et al. 2018).

Smoking is linked to the development of rheumatoid arthritis and their severity and exacerbation. Animal experiments proved that nicotine causes specific alterations in the disease-related cellular and humoral immune responses and exacerbate inflammatory arthritis (Lee et al. 2017). Smoking has also been identified as a major risk factor for osteoporosis, resulting bone fractures and impaired healing. Nicotine affects estrogen and calcium metabolism, osteocyte development and bone lamellar structure, inhibits catalase and glutathione reductase activity, contributing to an accumulation of ROS by cigarette smoke exposure, and induces apoptosis in human osteoblasts (Marinucci et al. 2018).

Smoking or heavy exposure to SHS increase the risk of blindness, macular degeneration, and a number of other eye diseases (dry eye, cataracts, uveitis, diabetic retinopathy, glaucoma with optic nerve damage). For some of these diseases, impairment of microcirculation by nicotine plays an important role, which can be triggered also in healthy subjects by oral nicotine (Cinar et al. 2019).

---

### **Effects of Tobacco Products and Nicotine on Fetus and Child**

Maternal smoking during pregnancy is associated with numerous adverse offspring outcomes (Horak et al. 2012). Complications of gravity, birth, and reduced birth weight are mainly seen if pregnant smokers continue to smoke into the last trimester,

but the problem of tobacco smoke exposure starts with conception since active smoking reduces the sperm count, male and female fertility. Impairments of fetal life cannot only be measured by higher rates of abortion and stillbirths, but also by increased fetal heart rate, limb movements, and fetal activity associated with later infants' attention and self-regulation (Stroud et al. 2019). Neonatal morbidity and mortality and malformations (orofacial clefts) are increased, and birthweight is decreased by an average of 200 g. The leading cause of death in the first year is sudden infant death syndrome (SIDS), which doubles when the mother smokes one cigarette per day and increases ninefold if she smokes more than 20 cigarettes per day. Also long-term neurobehavioral deficits develop more frequently, in particular attention deficit hyperactivity disorder, but also addictive behavior, and disruptive behaviors/conduct disorder. Also lung development of children is impaired by maternal smoking during pregnancy and afterwards by parental smoking (Pattenden et al. 2006) and the risk for infectious and allergic respiratory disease and asthma increases. A meta-analysis on parental smoking and the risk of congenital heart defects concluded, that maternal active smoking was significantly associated with risk of atrial septal defect and right ventricular outflow tract obstruction and that also maternal passive smoking as well as paternal smoking increased the risk of congenital heart defects in offspring (Zhao et al. 2019). Many effects of prenatal exposure to tobacco smoke have been attributed to nicotine (Ginzel et al. 2007), with adverse perinatal outcomes associated to placental syndromes and direct toxic effects on arteries supplying the fetus and his heart. Prenatal exposure to constituents of tobacco smoke can also have long lasting effects on children like metabolic disease and visceral adiposity, but only few epidemiological studies were able to disentangle them from effects of postnatal exposure. Transgenerational effects of smoking in pregnancy seem to be related to altered DNA methylation patterns in cell nucleus and mitochondria, which are gender-specific and tissue dependent. Epigenetic impacts of in utero exposure to maternal smoke, e-cigarette aerosol, and maternal SHS on fetal respiratory development may persist across subsequent generations, regardless of the smoking habits of the second generation, so that asthma in grandchildren was associated with the smoking habit of the grandmother in pregnancy (Zakarya et al. 2019).

Also passive smoking of the mother puts the fetus at risk of growth retardation and shortening of gestational age. Individual risks for mother and child from mothers' passive smoking are substantially lower than from her active smoking. But since the number of exposed pregnancies are higher, the number of attributable cases is in the same order of magnitude as for active smoking in pregnancy. Postnatal exposure of children to parental smoking was estimated to cause approximately 10% of children's respiratory and middle ear diseases (Moshhammer et al. 2007).

SHS leaves accumulating contaminants on surfaces like carpets, wallpapers, upholstery, blankets or soft toys and these remnants called "Third Hand Smoke (THS, Cold Smoke)" endanger in particular children by oral, dermal, and inhalation uptake from house dust, etc. (Neuberger 2018). Even parents omitting contamination of indoor air nevertheless bring toxins and carcinogens to indoor

spaces and to their children by clothes, hair, skin, and breath, but the highest contamination is found on surfaces of rooms used for smoking. From these surfaces toxins are released back into the air and by aging and chemical transformations more toxic pollutants are formed, e.g., residual nicotine from tobacco smoke adsorbed to indoor surfaces reacts with ambient nitrous acid to form carcinogenic nitrosamines. Animal experiments demonstrated numerous effects of THS: hyperactivity, persistent changes in the immune and hematopoietic system, lung cancer, liver damage, increased thrombogenesis, and metabolic effects, including elevated triglycerides, increased LDL, decreased HDL, and insulin resistance through oxidative stress. Estimates of harm from THS are all by inference, since direct evidence of human health problems arising from THS is still missing (Neuberger 2019).

Tobacco cigarettes carry the highest risk for parents and child, but any use of nicotine in pregnancy should be discouraged, because for many of the fetal hazards described above (SIDS, brain development, lung development, etc.) nicotine plays an essential role (Ginzel et al. 2007). Rodent and primate studies found that the effects of maternal SHS exposure on developmental outcomes are comparable to effects seen with isolated nicotine, including effects on number of neurons, neuronal and synaptic damage, and cognitive dysfunction. The motivation to stop smoking during pregnancy should be supported, but nicotine replacement was unsuccessful and has adverse effects on fetal development. Even more dangerous are ecigs without proper control of nicotine dose and problematic additives. Maternal smokeless tobacco use increased rates of stillbirth, low birth weight, and altered the male/female live birth ratio (Ratsch and Bogossian 2014).

Nicotine exposure during adolescence altered development of cerebral cortex and hippocampus and was associated with deficits in working memory, attention, and auditory processing, as well as increased impulsivity and anxiety (England et al. 2017). First nicotine exposure of children is usually by SHS, which could lead to later active smoking not only by imitation of parent's behavior and easy access of cigarettes, but also by providing a molecular basis for later nicotine addiction and possibly other addictions (Kandel and Kandel 2014).

---

## Addiction

Nicotine is a highly addictive drug, by smoking rapidly absorbed into the blood and delivered quickly to the brain, so that nicotine levels peak within 10 s of inhalation, releasing the neurotransmitter dopamine in the brain and activating reward pathways which regulate reinforcement and feelings of pleasure. This happens with every puff in cigarette smoking, but the smoker adapts by increasing nAChRs and as a result needs to increase the number of cigarettes and the depth and duration of inhalation in order to sustain slight, brief euphoria. Even after this euphoria had disappeared completely over the years, the smoker still longs for the next cigarette, which quickly relieves withdrawal symptoms like irritability, craving, depression, anxiety, cognitive and attention deficits, sleep disturbances, and increased appetite. These

withdrawal symptoms may begin within a few hours after the last cigarette, quickly driving people back to tobacco use, which has also been learned meanwhile to be used as a coping strategy for stress and – like in classical conditioning – prompts associations with all kinds of environmental stimuli and things we desire.

Given the rapid rise of nicotine and associated psychoactive effects, smoking of combustible cigarettes allows the smoker to titrate the level of nicotine and related effects during smoking. This makes smoking the most reinforcing and dependence-producing form of nicotine administration. Nicotine products absorbed more slowly are less addictive, but the tobacco industry attempts to achieve a quick rise in brain nicotine concentrations also by other products, e.g., nicotine salts with organic acids like benzoic acid, which make ecigs taste milder, so that users can inhale deeply and reach nicotine levels in blood and brain within 5 min, which are comparable to combustion products. This way ecigs can become a gateway drug into nicotine addiction for young non-smokers, and for smokers ecigs make it more difficult to leave nicotine addiction, frequently resulting in dual use of ecigs and tobacco cigarettes. Replaceable podstyle nicotine cartridges have also become popular ecigs among youth because of efficient nicotine delivery, appealing flavors, sleek designs, ease of concealment, and social media marketing (Lee et al. 2020).

In smokeless tobacco products nicotine is absorbed through mucous membranes in the mouth and reaches peak blood and brain levels more slowly than from inhalation, why they are less addictive. Nevertheless also smokeless tobacco products proved to cause addiction and are most dangerous if combined with tobacco cigarettes. Products for skin application are absorbed much slower, are much less addictive, and should therefore be preferred, if nicotine replacement is needed at all. Only for heavy smokers, fast absorbed nicotine products like a gum are necessary, usually in combination with a nicotine patch, but for a limited time only. Help in smoking cessation is possible without nicotine (varenicline, bupropion, cytisine, etc.) and all pharmaceutical help must be accompanied by professional counseling, because motivation is the most important part in the treatment of smokers.

Though nicotine exerts a priming effect on illegal drug use through global acetylation in the striatum, creating an environment primed for the induction of gene expression (Kandel and Kandel 2014), only a small part of nicotine addicts turn to illegal drugs; however, most persons addicted to marijuana (cannabis), cocaine and similar drugs are also addicted to nicotine and the majority started with nicotine in their career of addictions. These addicts also continue to use nicotine, which may enhance the physiological effects of other drugs.

From animal research, a number of additives in combustible cigarettes and ecigs are known to increase the reinforcing properties of nicotine, e.g., acetaldehyde created by the burning of sugars (added as sweeteners for children) or monoamine oxidase inhibitors (Hogg 2016). Cooling of the smoke like in shisha or adding of aromas like menthol makes deep inhalation easier, resulting in higher nicotine concentration in blood and brain and speeding the transition from occasional to regular smokers.

## Guidelines and Regulation on Tobacco Products and Nicotine

The most important guidelines are connected to the WHO Framework Convention of Tobacco Control (FCTC), an evidence-based global treaty signed and ratified by 181 nations and the European Union. This convention was adopted during the 56th World Health Assembly in 2003, entered into force in 2005 and is supplemented by details at regular meetings of the meanwhile 182 parties. A key element is article 5.3, which states that there is a fundamental and irreconcilable conflict between the tobacco industry's commercial interests and public health policy interests. FCTC is raising awareness of international instruments that governments should use to protect tobacco control policies from tobacco industry interference. Politicians and officials need to limit interactions, communications, and contacts with the tobacco industry to those necessary for effective regulation and to make them transparent for civil society. This is an essential prerequisite for reduction of the demand for tobacco (Art. 6, 7), for protection from SHS (Art. 8), for regulation of constituents and emissions of tobacco products (Art. 9) and their packaging and labelling (Art. 11), as attempted in the EU Tobacco Products Directive (TPD) 2014/40/EU. The TPD was a progress for public health limiting the sale and merchandizing of tobacco and related products in the EU, but was weakened because FCTC Art. 5.3 had not been implemented before in member states. Also a comprehensive ban of all tobacco advertising, promotion, and sponsorship (Art. 14) is still missing in many countries and very limited budgets are available for promotion of non-smoking by media campaigns and educational programs (Art. 13), compared to the huge amounts of money the international tobacco industry is investing in direct and indirect tobacco advertising. FCTC also recommends a number of measures to reduce the supply of tobacco, e.g., elimination of all forms of illicit trade in tobacco products (Art. 15). An own protocol on illicit trade tracking, tracing, etc. entered into force in 2018, was ratified by 61 nations meanwhile and details are updated regularly. Youth protection from commercial interests of the tobacco industry and retailers (Art. 16) is still insufficient in many countries and several surveys showed that the age control by tobacconists is insufficient and the electronic age control by vending machines is unreliable (Berger and Neuberger 2020). Unacceptable are also the serious risks posed by tobacco growing to human health and to the environment (Art. 17). Child labor in tobacco growing is aggravated by nicotine poisoning, because during harvesting nicotine of the wet, green leaves gets absorbed through the skin of the children. Common agricultural practices in tobacco farming, especially in low- and middle-income countries, lead to deforestation and soil degradation, agrochemical pollution, destruction of ground water resources, sedimentation of rivers, reservoirs, and irrigation systems, which in turn lead to ecological disruptions that cause a loss of ecosystem services, including land resources, biodiversity, and food sources, all of which negatively impact human health (WHO 2017). All phases of cigarette production, from leaf cultivation through cigarette manufacture to transportation, contribute to environmental hazards and greenhouse gas emission responsible for global climate change. Cigarette butts are toxic waste, endangering playing children, polluting water and air, and finally ending as microplastics in the ocean. E-cigarettes

and their batteries are a new and growing environmental threat, which would need regulation.

Besides FCTC and policy options convened at the “conferences of the parties,” there have been a number of other important guidelines from WHO and the World Bank. In 2008, WHO released the strategy MPOWER: Monitor tobacco use and prevention policies, Protect people from tobacco smoke, Offer help to quit tobacco use, Warn about the dangers of tobacco, Enforce bans on tobacco advertising, promotion and sponsorship, Raise taxes on tobacco. The success of the adoption and implementation of MPOWER on national level was analyzed in later WHO reports, in particular on decreasing smoking prevalence and consumption and estimated smoking-attributable deaths (Ngo et al. 2017). As early as 1999, the World Bank published that tobacco tax should be increased to 80% of retail price and that increase of tax and price, which is the most powerful tool to reduce smoking, should be supplemented by comprehensive advertising bans, smoke-free public places and work places, support of smoking cessation and intensive information on health effects including prominent warning labels (The World Bank 1999). Also later reports of the World Bank came to very similar conclusions.

In Europe, the Tobacco Control Scale of the European Cancer Leagues made use of recommendations by WHO and World Bank, granting a maximum score of 30 for a high average price of cigarettes (adjusted for purchasing power), a maximum score of 22 for smoke-free legislation and enforcement in work places, other public places and private cars, of 13 for comprehensive bans on direct and indirect advertising and promotion of tobacco products and cigarettes, of 10 each for spending on public information campaigns, for large pictorial health warnings with plain packaging, and for smoking cessation support. To reach a total maximum score of 100 also ratification of the Illicit Trade Protocol and compliance with its track and trace system (score 3) and enforced measures to restrict tobacco industry interference (score 2) were necessary (Joossens et al. 2020). Table 1 shows best ranks for United Kingdom, France, and Ireland, followed by Scandinavian countries. It has to be acknowledged, however, that tobacco control is more advanced in several countries outside of Europe, e.g., Australia, where tobacco prices are much higher, nicotine containing fluids are banned for ecigs, and smoking prevalence is much lower than in UK, especially in children. Australia introduced plain packaging in 2012 already.

In Europe, poor tobacco control and lowest progress was seen in Germany, still allowing tobacco advertising on billboards and in cinemas, and smoking is allowed in the hospitality industry in 11 of 14 federal states; in Switzerland hosting the headquarters of the international tobacco companies, probably the cause for the weak tobacco advertising legislation and why this country has not ratified the FCTC; and in Luxembourg, which has very low taxes on tobacco products, in order to attract cross-border shopping from neighboring countries. Prices of cigarettes adjusted for purchasing power are also too low in Central and Eastern Europe (Neuberger 2019a).

Progress in tobacco control was slower in Europe than in Australia or North America and average smoking prevalence is considerably higher. International comparisons of tobacco control legislations including country laws regulating ecigs and HTPs are provided, e.g., by the Johns Hopkins Bloomberg School of

Public Health at <https://globaltobaccocontrol.org>. This site helps to keep up with rapid changes in laws and policies from across 98 countries. This policy bank has been verified by public health professionals in the respective country and is

separated into domains so that users can compare various national policies for minimum age, sale, marketing, packaging, product regulation, reporting, clean air, and taxation. Similar comparisons within Europe are made by the European Network for Smoking and Tobacco Prevention at <http://ensp.network/>. Binding regulations as given in the TPD can be found at [https://ec.europa.eu/health/sites/health/files/tobacco/docs/dir\\_201440\\_en.pdf](https://ec.europa.eu/health/sites/health/files/tobacco/docs/dir_201440_en.pdf) and a commentary on its revision at <https://tobaccotactics.org/wiki/eu-tobacco-products-directive-revision/>.

Even more diverse than the regulation of ecigs and HTPs is the legislation on other nicotine products. Oral tobacco has been banned in the EU except for Sweden, but oral nicotine has not been regulated yet. The problem with nicotine is that it is easily imported and that it can be mixed with just about anything. The historical mistake to sell tobacco products on the free market should not be repeated with other nicotine products. A positive example is Australia, which banned import of vape liquids with nicotine. For buying nicotine you need a prescription. In most countries, however, nicotine products are not subject to pharmaceutical law, but are sold without proper control of dose, additives, etc. and even provided in vending machines, which are not “child-safe” (Berger and Neuberger 2020), disregarding their high addictive potential.

The European Cancer Leagues in 2020 recommended 10 priorities to be fulfilled by all EU member states: to spend a minimum of €2 per capita per year on tobacco control, to implement at least the six World Bank priority measures in line with FCTC (Art. 4, comprehensive tobacco control policy), to address tobacco industry interference in public health policy making (Art. 5.3), to implement significant tax increases for cigarettes, hand rolled tobacco, etc. and a comprehensive smoke free legislation (Art. 8), including private cars carrying minors, to introduce standardized/plain packaging for all tobacco products, to ban the display of tobacco products at the point of sale, to accelerate implementation of tobacco cessation support (Art. 14), to ratify the FCTC Protocol to eliminate illicit trade and adopt tracking & tracing standards, and to invest in research to monitor and measure the effect of tobacco control policies (Art. 20).

The EU allows member states to go beyond the TPD (e.g., by requiring plain packaging) and also Art. 2.1 FCTC states “In order to better protect human health, Parties are encouraged to implement measures beyond those required by this Convention and its protocols, and nothing in these instruments shall prevent a Party from imposing stricter requirements that are consistent with their provisions and are in accordance with international law.” Progress in tobacco control in some countries have led to plans of ending the tobacco epidemic completely, often called the “endgame.” Usually the envisaged goal is to reduce smoking prevalence to below 5% in the population. Up to now only Bhutan banned tobacco sales and production, however, an increasing number of governments formulated long-term goals. In Finland a strategy was proposed to become not only smoke-free, but nicotine-free. Denmark’s goal in 2016 was: “none of the children born today smoking in 2030.” Australia, New Zealand, Sweden, Iceland, Norway, Ireland and multiple other nations might reach this goal in the next decade. Endgame strategies have to build on existing tobacco control measures that have proved effective. In countries where

tobacco industry and retailers still influence policy, the phasing out of cigarettes sales will take longer, but should be possible by applying the principles of consumer protection and human rights in a fair and equitable way to halt the sale of a deadly product (Smith and Malone 2019).

## Abstract

Caries, periodontal diseases, and dental traumata belong worldwide to the most widespread diseases leading to tooth decay and missing teeth. Dental materials are playing a central role in treating these pathologies. Legal regulations concerning the safety of these materials were initiated in the 1970s of the last century (USA), and dental materials were classified as medical devices. This regulation was principally adopted by the EU in 1993 (Medical Device Directive, MDD) and revised in 2017 (Medical Device Regulation, MDR). International standards for assessing the safety have been developed for medical devices (ISO 10993 series) and also specifically for dental materials (ISO 7405). The latter respects the specific anatomical and physiological conditions in the oral cavity. Clinical risk assessment according to ISO 14971 determines the lacking information for a new material and defines the test strategy. Special attention was recently directed to nanomaterials, and the MDR has introduced a special classification rule for materials releasing nanoparticles. Dental materials need to be finalized intraorally, and thus dust is generated by grinding and polishing, but also by removing defective restorations. Worst-case calculations, however, revealed negligible exposure. Titanium (Ti) and zirconium (Zr) are preferentially used for endosseous dental implants, and the properties of Ti implants may be improved by coating them with nanostructured Ti-containing particles or Ti nanoparticles. However, it was claimed that periimplantitis can arise by exposure to TiO<sub>2</sub> particles, even in the absence of bacteria. Low release of Ti nanoparticles was found from dental Ti implants into the human mandibular bone, and therefore they might have no toxicologically clinical effects. Zr release from zirconia implants in animal mandibular bone was much lower compared to the Ti release from Ti implants. No histological abnormalities were found in animal tissues around zirconia implants.

In vivo tests for CMR and systemic toxic effects may be waived, if results from in vitro cytotoxicity/mutagenicity tests and chemical analyses of different material eluates in comparison with market products give no indication for such an effect. The TTC (Threshold of Toxicological Concern) according to ISO TS 21726 can be applied. Recently, EU regulations are directed to evaluate environmental aspects for dental materials, which may play an increasing role in the future.

## Introduction

Diseases of the orofacial area include besides oral cancer and malformations mainly caries, periodontal diseases, and oro-dental traumata. Dental caries affects 2.5 billion adults (untreated caries) and 560 million children worldwide per year and is thus the most widespread non-communicable disease (Listl et al. 2015). According to the WHO, worldwide 15–20 percent of people aged 35–44 suffer from periodontal disease, an inflammation and infection of the gums. Its more serious form, periodontitis, if left untreated, often leads to an increased percentage of tooth loss. Globally, approximately 30 percent of people between ages 65 and 74 have no natural teeth remaining (Kassebaum et al. 2017; World Health Organization 2020). Oro-dental trauma is due to a number of issues, including unsafe schools and playgrounds, accidents, and violence, and between 16 and 40 percent of children aged 6–12 years old are affected by dental trauma (World Health Organization 2020).

The therapy of these pathologic conditions is heavily based on the use of dental materials, e.g., for restorations/fillings, crowns, and prostheses as well as of auxiliary tools like impression materials. To date regulatory safety regulations for these materials are meant to protect the patient, the dental personnel, and the environment. A special aspect for dental materials is the fact that many of them are delivered from industry in an unfinished state and that they are only finalized by the dentists; e.g., a resin paste is cured by using light curing units or by mixing with a separate catalyst paste, and then the cured material is adjusted intraorally by grinding and polishing.

The aims of this chapter are:

- To describe the development of regulatory safety regulations for dental materials.
- To address the specific regulations for dental materials.
- To discuss aspects typical for dental materials.

---

## Development of Safety Regulations

### History

Until the 1950s of the last century, in only few publications, the safety of dental materials was experimentally investigated: one of the first was the study from Fasoli about dental pulp reactions of dog teeth in response to the application of a filling material as early as 1924 (Fasoli 1924). In the 1950s and 1960s of the last century, the number of such animal-based studies increased, and the histological techniques as well as the evaluation procedures within involved experiments were improved (Schmalz 2002). Also at that time, cell culture techniques were first used to test the biological properties (here, cytotoxicity) of dental materials, which later developed into a major pillar of regulators biocompatibility evaluation of dental materials (Schmalz 2002). However, until the 1960s of the last century, no systematic approach on safety testing or safety assessment had been followed, and this field

was basically unregulated. Only by the beginning of the 1970s, the need for biological testing of dental materials was more and more advocated for, and the idea of standardization of such tests was born (Schmalz 2002).

## Legal Framework

The first country to establish a legal framework regulating the safety of dental materials was the USA. In 1976 the “Medical Device Amendments” had passed the US Congress. While in the text of this regulation, the term “medical device” was used but not defined, later on in the Medical Device Directive (MDD), (European Union 1993) a medical device was characterized as any instrument, apparatus, appliance, material, or other article, which did not achieve its principal intended action in or on the human body by pharmacological, immunological, or metabolic means (for the full text of the current definition, see Medical Device Regulation (MDR) (European Union 2017a). Therefore, dental materials are classified as medical devices. Interestingly, the experiences from toxicity testing of dental materials in the USA had been one pillar for establishing this legislation (Schmalz 2002).

Within the European Union, the Medical Device Directive was adopted by the European Parliament in 1993 and became effective in 1998 (European Union 1993). As in the USA, also in Europe dental materials were classified as medical devices. This directive was constitutively revised and amended in 2017 and adopted as the Medical Device Regulation (MDR) in 2017 (European Union 2017a). One of the drivers for the tighter regulations of the MDR compared to the MDD was the breast implant scandal, where breast implants had been produced and sold by the company Poly Implant Prothèse (PIP), using illegally industrial-grade silicone since 2001. The MDR should become effective in spring 2020, but due to the coronavirus crisis in 2020, this had been postponed for 1 year (European Union 2020). Whereas the Medical Device Directive of 1993 had to be translated into national legislation of each EU country – leading to slight differences between EU member countries – the Medical Device Regulation of 2017 has become as such national law of all EU member countries. The abovementioned legal regulations define the general regulatory requirements for the safety and performance of medical devices including dental materials before being marketed. In the EU the manufacturer must show compliance (“Conformity”) with the general safety and performance requirements laid down in the MDD or the MDR, and he is responsible for the safety of the medical device brought to the market by him. Depending on the risk class (see below), a third party (“Notified Body”) is also involved for control.

Four risk classes have been defined within the MDD (European Union 1993) and the MDR, I, IIa, IIb, and III, taking into account the intended purpose of the devices and their inherent risks. From the dental material field, examples for the different classes are class I, paper points; class IIa, filling/restorative materials; and class IIb, materials for dental implants. Dental materials, which contain pharmaceutically active ingredients, are assigned to class III.

The assignment of new materials to the different risk classes is guided by a set of rules delineated in detail in the MDD/MDR. The conformity assessment procedure for class I devices should be carried out, as a general rule, under the sole responsibility of manufacturers in view of the low level of vulnerability associated with such devices. For class IIa, class IIb, and class III devices, an appropriate level of involvement of a third party (“Notified Body”) is obligatory.

For class I dental materials, the manufacturer (whose quality management system is certified according to ISO 13485 Medical Devices) declares conformity with the relevant regulation (MDD or MDR) and keeps the technical documentation, which is only used in case of clinically overt adverse effect observed after clinical use. An exception is class I medical devices, which are placed on the market in sterile condition, have a measuring function, or are reusable surgical instruments; for these medical devices, these special properties require additionally the involvement of a notified body. For class II dental materials, the manufacturer completes the technical documentation and declares himself conformity with the relevant regulations, if he has installed a quality management system. The relevant technical documentations are subject to a regular audit by a notified body. For class III generally more stringent regulations apply. For instance, for class III devices, manufacturers should summarize the main safety and performance aspects of the device and the outcome of the clinical evaluation in a document that should be publicly available (MDR). Furthermore, the manufacturer shall lodge with the notified body an application for assessment of the technical documentation relating to the device which it plans to place on the market. For more details see Annex IX MDR (European Union 2017a). In the MDR a number of new classification rules were introduced; rule 19 especially addresses so-called nanomaterials and assigns them to the different risk classes, which for dental materials is of special relevance (see below).

Besides the abovementioned legal regulations, which directly refer to aspects of regulatory toxicology, a number of other legal regulations have been passed within the EU affecting more indirectly this area. One example is the EU CLP regulation, which has been developed for labelling and packaging of substances and mixtures (European Union 2008). While not legally binding, the symbols of the CLP regulation are also used for labelling of the medical devices like dental materials. Chemicals used for the production of dental materials have to comply with REACH (Registration, Evaluation, Authorisation and Restriction of Chemicals), which is a regulation of the European Union, adopted to improve the protection of human health and the environment from the risks that can be posed by chemicals (European Union 2006). However, under REACH, there is no obligation to register substances in amounts below 1 ton/year.

Outside of Europe similar legal regulations have been developed in the recent years. As was mentioned above, the Medical Device Amendments in the USA regulated the safety of dental materials, and the Food and Drug Administration (FDA) was made responsible for the process of classification and market approval. In contrast to the MDD/MDR, the FDA classifies according to three classes: class I, low risk, general controls [generally exempt from 510 (k)]; class II, moderate risk,

general controls and special controls [510 (k) generally required]; and class III, high risk, general controls and Premarket Approval (PMA) required and must demonstrate safety and effectiveness without relying on a predicate device. For dental materials, the most common pathway is the 510 (k) procedure (according to class II). Here, the substantial equivalence (SE) of a new product compared to a market product (predicate device) must be demonstrated. This substantial equivalence means that the new device being compared to a predicate device has:

- The same intended use as the predicate device.
- The same technological characteristics as the predicate device.
- Different technological characteristics, but does not raise new types of safety and effectiveness questions and is at least as safe and effective as the predicate device (Anusavice and Schmalz 2012; United States Food and Drug Administration 2014).

## Development of Standardized Testing Procedures

The actual test methods and specific safety requirements to be fulfilled by each new dental material in order to demonstrate conformity with the general requirements of the MDD or MDR are not regulated by these legislations. However, the manufacturer can demonstrate the conformity with the abovementioned general legal requirements by testing their materials according to national/international standards or other technical specifications. Special reference within the EU legislation is made to “harmonized standards” (see below).

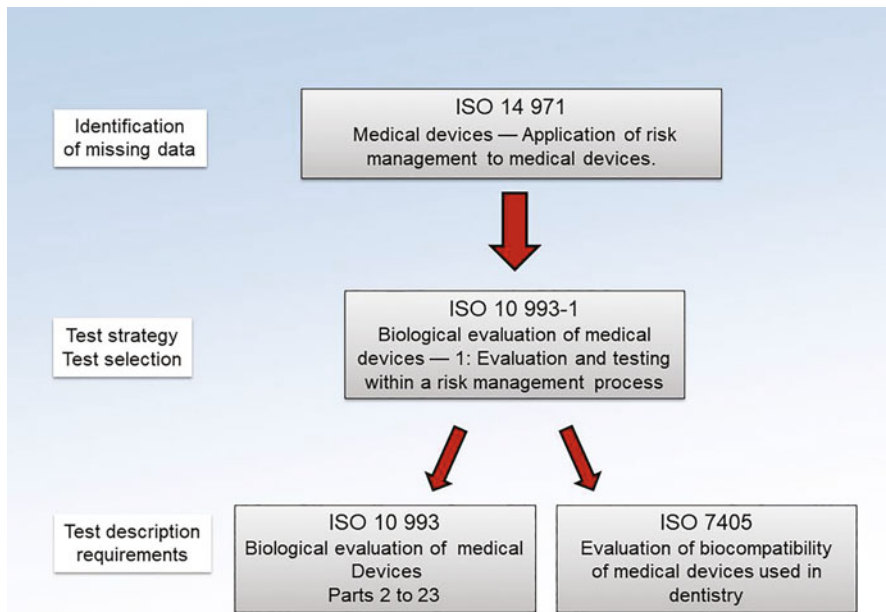

In 1972, the American Dental Association published recommendations on standard practices for biological evaluation of dental materials, which was then further developed and published in 1979 as ANSI/ADA document No. 41 (ANSI/ADA 1979). In Germany in the 1980s of the last century, the DIN 13930 was developed being mainly in line with the ANSI/ADA document No. 41 (Schmalz 2002). On an international level, the World Dental Federation (FDI) published in 1980 the FDI’s “Recommended standard practices for biological evaluation of dental materials” (World Dental Federation 1980). This document was then further elaborated by the International Organization for Standardization (ISO) Technical Committee 106 (Dentistry) and published in 1997 as ISO 7405. The second edition was published in 2008 and the third in 2018 as “Dentistry—Evaluation of biocompatibility of medical devices used in dentistry” (ISO 7405 2018).

In the 1990s, the ISO Technical Committee 194 was founded, being in charge of developing standard testing procedures for the safety of medical devices. Since then a series of standards and technical specifications under the heading ISO 10993 was published by this committee (Table 1). Finally, “ISO 14971 – Medical devices—Application of risk management to medical devices” was published (ISO 14971 2019) describing the general procedures for performing a clinical risk assessment, which is required by the MMD/MDR. The clinical risk assessment according to ISO 14971 identifies missing necessary information on the safety of a new material. The general guidelines for selecting the specific test procedures to obtain this information

**Table 1** ISO 10993 series of standards

Number: ISO 10993 part	Year	Title
1	2018	Evaluation and testing within a risk management process
2	2006, confirmed 2015	Animal welfare requirements
3	2014	Tests for genotoxicity, carcinogenicity, and reproductive toxicity

**Fig. 1** The relation between the different standards used in the biocompatibility assessment according to the MDD or the MDR

are then described in ISO 10993-1 (ISO 10993-1 2018). The actual test descriptions are delineated in the following parts of ISO 10993 (Table 1) and in ISO 7405. The relation between the standards 14971, the ISO 10993 series, and the ISO 7405 is shown in Fig. 1. Within ISO 7405 three groups of tests are described:

- Group 1: cytotoxicity tests including the dentin barrier test (see below); reference is also made to ISO 10993-5 (tests for in vitro cytotoxicity).
- Group 2: systemic toxicity, skin irritation and intracutaneous reactivity, delayed skin sensitization, genotoxicity, and implantation tests; here no procedures are described in ISO 7405, but reference is made to the relevant ISO 10993 standards.
- Group 3: dentally specific usage tests (see below).

In dentistry, international standards developed by ISO are automatically accepted by CEN (European Committee for Standardization) as European standards (EN standards) as part of the so-called Vienna Agreement (CEN CENELEC ISO 1991). Within the MDD and the MDR, especially compliance with so-called harmonized European (EN) standards as defined in Regulation (EU) No 1025/2012 (European Union 2012) should be a means for manufacturers to demonstrate conformity with the general safety and performance requirements (“presumption of conformity”). Such EN standards have passed an acceptance

procedure by the EU commission. For the MDD, a number of ISO dental standards for dental materials have been harmonized within the cumulative standard EN1641:2009 – Dentistry – Medical devices for dentistry, Materials (EN1641:2009 2009) containing also a reference to ISO 7405. Also ISO 10993 standards have been harmonized. Therefore, standards set up by international organization and by corresponding standards bodies have gained considerable importance. Within the new MDR, all standards harmonized so far within the frame of the MDD will become invalid. A new system of harmonized standards is assumed to be established by 2024. However, harmonized or not, standards are recognized as the state of the art for property testing (not only) the safety of dental materials.

Besides ISO standards, the OECD (Organisation for Economic Co-operation and Development) has issued so-called OECD guidelines for testing of chemicals assessing the potential effects of chemicals on human health and the environment. They are accepted internationally as standard methods for safety testing; they are continuously expanded and revised (<https://www.oecd.org/env/ehs/testing/oecdguidelinesforthetestingofchemicals.htm>). Some of these tests are also incorporated into abovementioned ISO standards and adjusted for testing medical devices.

---

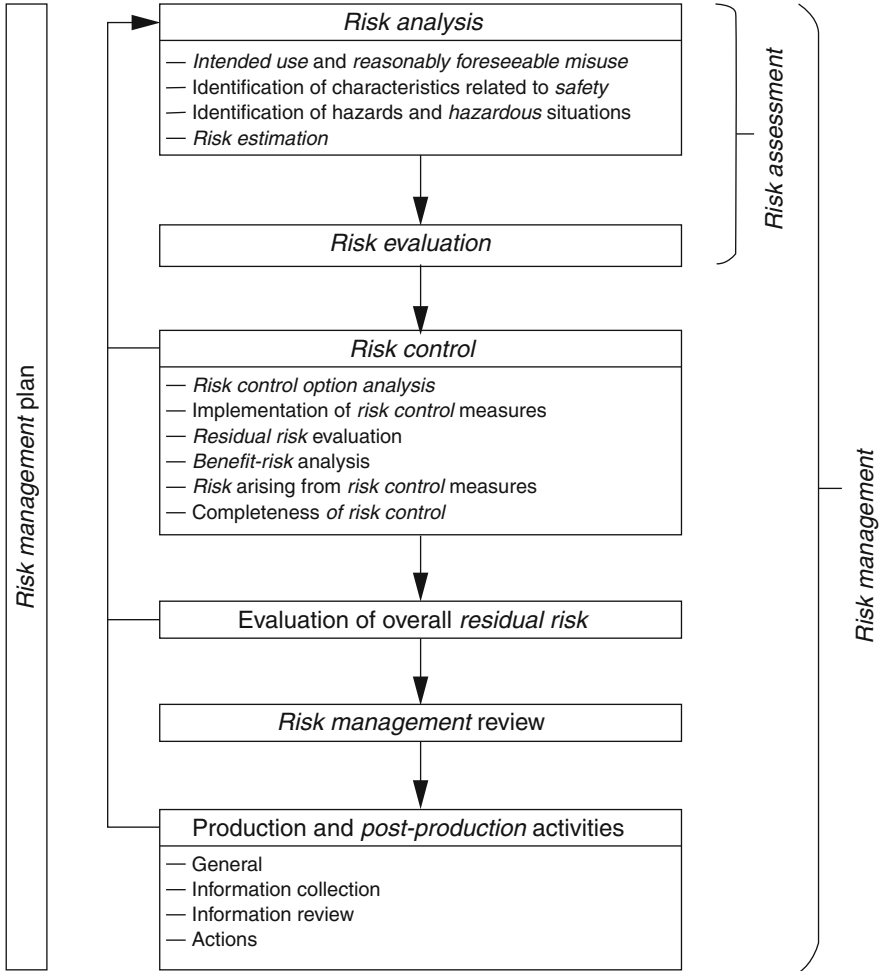

## Clinical Risk Assessment

The evaluation of the biocompatibility of (new) dental materials according to current regulatory toxicology concepts starts with a clinical risk assessment (Fig. 1). The procedure is described in detail in ISO 14971 (ISO 14971 2019). The process described in this document intends to assist manufacturers of medical devices to identify the hazards associated with the medical device, to estimate and evaluate the associated risks, to control these risks, and to monitor the effectiveness of the controls. This comprises:

- Risk analysis;
- Risk evaluation;
- Risk control;
- Production and post-production activities (Fig. 2).

Within the process of risk analysis and risk evaluation, it must be determined, if and which data are missing. Also dental materials have to be assigned to the relevant risk classes according to the classification rules, e.g., from the MDD or the MDR. Test selection and actual tests can be performed using ISO standards, for the EU also harmonized standards (see above). Then the final technical documentation with all necessary data is compiled as required by the MDD or MDR.

This whole system of a tiered regulatory approach defining responsibilities, testing strategies, test protocols, and control mechanisms according to the involved

**Fig. 2** Risk management scheme according to ISO 14971

risks has proven to be in most cases effective for dental materials since 1998. In the early phase of MDD implementation, new market products caused problem during clinical use (Braun et al. 2001). However, later on no major complications have become evident.

### Unspecific Versus (Dentally) Specific Tests

In the abovementioned standards ISO 7405 and ISO 10993 series, so-called unspecific tests are described; additionally in ISO 7405 also dentally specific tests for safety evaluation are depicted. Unspecific tests are those, in their technical setup,

do not take the specific anatomical and physiological conditions in the oral cavity into account, whereas specific tests (“usage tests”) do.

Unspecific tests are related to endpoints like cytotoxicity, genotoxicity/mutagenicity, or systemic toxicity. Tests are those described in the ISO 10993 series (Table 1) and – in part – in the ISO 7405, and they in some cases refer to relevant OECD guidelines (e.g., genotoxicity/mutagenicity tests, test for systemic toxicity after oral application). Many of these tests are *in vitro* tests or those using small laboratory animals, for instance, the subcutaneous implantation test in rats (ISO 10993-6) (ISO 10993-6 2016 2016). Extensive experience is available using unspecific tests for safety evaluation of dental materials (Schmalz et al. 2016; Schmalz and Galler 2017). Such tests are also an important part for demonstrating conformity with the general safety requirements of the MDD/MDR. While mechanistic approaches (Schweikl et al. 2006; Krifka et al. 2013) of dental materials have generally played no or only a minor role in regulatory toxicology, recently a test evaluating the anti-oxidative response of cells after exposure to (dental) materials has been suggested for being included as annex into ISO 7405 (antioxidant response element (ARE)) reporter assay.

Extrapolation of results derived from unspecific toxicity tests to the patient situation proved to be difficult in certain situations (Schuster et al. 2001; Schmalz et al. 2016). For instance, the restorative/filling material zinc oxide and eugenol, which is highly cytotoxic in standard cell culture tests, does histologically not show any damage on the dental pulp when applied in cavities of human teeth or those from experimental animals. The reason for this discrepancy is apparently that the specific anatomical and physiological situations of the tooth are not reflected in standard cytotoxicity test. The dentin between the cavity floor and the dental pulp seems to play a major role (Schmalz and Galler 2017) (Fig. 3).

The dentally specific tests, also named “usage” tests, are mainly animal-based tests and include according to ISO 7405 the:

- Pulp/dentin and pulp capping usage tests.
- Endodontic usage test.
- Endosseous dental implant usage test.

In general, dental materials are applied in these usage tests in a similar way as they are placed in patients; e.g., for testing dental restorative/filling materials, cavities are drilled in teeth of experimental animals like subhuman primates, dogs, or rats and then filled with the test materials and appropriate controls. Pulp reactions are evaluated histologically after up to 3 months *in situ*. A special test method is the “dentin barrier test”, which is a cell culture-based method but simulates the anatomical situation in the tooth by interposing a dentin disk between the test material and the target cells (“simulation test”; see below) (Fig. 4) (Schuster et al. 2001; Schmalz and Galler 2017). All usage tests involve test animals like subhuman primates, dogs, or rats. These tests are costly and time-consuming and encounter ethical problems.

**Fig. 3** Dentin between the restorative/filling material and the dental pulp may decrease the chemical damage upon the dental pulp (Schmalz and Arenholt-Bindslev 2009)

**Fig. 4** Dentin barrier test, simulating the anatomical situation in the tooth by interposing a dentin disk between the test material and the target tissue (Schmalz and Arenholt-Bindslev 2009)

## Specific Problems in Dentistry

### Dental Pulp Damage

As has been delineated above, the dental pulp is an important target organ for the safety testing of dental (here, restorative/filling) materials. The chemically induced dental pulp damage due to the applied material results in inflammation and finally loss of pulp vitality (pulp necrosis). The standard test for evaluating a possible pulp damage according to ISO 7405 is the pulp/dentin usage test (see above). However, such a test involves the use of large test animals, which encompasses ethical and financial problems. Furthermore, the time frame for such a test including histologic evaluation is usually more than 1 year for one test series. Moreover, for such tests healthy teeth from test animals are used; in the clinical situation, however, teeth, which need restorations, have usually experienced caries or trauma, which both may lead to an already existing pulp inflammation. This then may add up to the chemically induced damage due to the restorative material. It is virtually not possible to reproducibly simulate such a cumulative effect in an experimental situation like in the pulp/dentin usage test. Therefore, a pulp inflammation as a consequence of material application in such tests is of clinical relevance; if no such pulp inflammation can be observed, this though is no guarantee that there will be no pulp damage in patients as a consequence of additive effects of a pre-existing inflammation and of the restorative material.

Therefore, the indication for this test must be considered very carefully. Today such a test is mainly recommended for dental restorative/filling materials with a complete new chemistry. For instance, some years ago, a complete new chemistry for restorative materials was introduced in order to reduce the material shrinkage during polymerization (Schweikl et al. 2002; Schmalz and Galler 2017). In contrast to the commonly applied acrylates, special epoxy compounds were used. In this case, the pulp-dentin test was justified. Other examples are materials which claim tissue regenerative properties, which presently cannot be evaluated in *in vitro* experimental setups. In most other cases, however, the pulp-dentin test can be waived, and data from cell culture tests according to ISO 7405 or ISO 10993-5 may be used instead. In comparing the cytotoxicity data of the new material with a market product (reference material), the expected reaction of the dental pulp can be estimated, if the chemical analyses of eluates are available. This is especially possible with materials with similar compositions as market products and if the mechanism for cytotoxicity is similar between test and reference material like a redox imbalance (Schweikl et al. 2006; Krifka et al. 2013).

An alternative to the pulp-dentin usage test is the abovementioned dentin barrier test (Fig. 4). Here, a dentin disk is placed between the test materials and the target cells, and thus the modifying influence of dentin acting as a partial diffusion and adsorption barrier is simulated. Furthermore, a three-dimensional cell culture has been developed based on immortalized dental pulp cells. This test has been adopted into the ISO 7405. For some dental materials, like those with a low pH (e.g., self-etching dental adhesives) or very hydrophobic materials (e.g., zinc oxide and

eugenol), which in classical cell culture test like those in ISO 10993 part 5 are cytotoxic, no cell reaction was seen in this dentin barrier test. This is in accordance with results after application of these materials in human teeth and those from experimental animals (Galler et al. 2005). For such tests the use of a standard positive (toxic) reference materials is necessary. Such a materials has been developed and has been included into the ISO 7405; it has produced reproducible in vitro toxic results in different laboratories (Schmalz et al. 2011)

## Sensitization

Allergic reactions after exposure to dental materials have been observed in about 2% of dental personnel (Munksgaard et al. 1996). The frequency of such reactions in patients is less than 0.3% (Hensten-Pettersen 1992; Hensten-Pettersen 1998; European Commission 2015a), but the risk of sensitization has to be taken care of during the preclinical risk assessment. Mainly type IV reactions have been observed in patients, more seldom type I reactions (Schmalz and Arenholz-Bindslev 2009). The guinea-pig maximization test has largely been used for preclinical testing the sensitization potential of dental materials for type IV reactions (Schmalz and Arenholz-Bindslev 2009). This test is also adopted into ISO 10993-10 (ISO 10993-10 2016). Similar tests described for this purpose within ISO 10993-10 are the closed patch test (Buehler test), also performed in guinea pigs, and the murine local lymph node assay (LLNA). ISO 10993-10 is presently under revision with the aim to formulate two separate standards, one for sensitization (revision of ISO 10993-10, new title, tests for skin sensitization) and one for irritation (planned ISO 10993-23, test for irritation).

A technical problem of these tests is that the test substances should not be skin irritating. For some dental materials, this is a problem, because they may have a pH of 1 or even less (e.g., self-etching dental adhesives). Therefore, these materials/substances cannot be tested as such. Eluates can be used instead, and in preliminary tests it should be shown that the test substances are not skin irritating; otherwise they must be diluted.

Another problem is related to the fact that the abovementioned sensitization tests according to ISO 10993-10 evaluate skin sensitization. However, dental materials may have only skin contact with the user (dental personnel), but patients are generally having contact with their oral mucosa. Oral mucosa and skin differ in some aspects, e.g., the skin is keratinized, whereas the oral mucosa is mainly not. Thus the barrier effect may be different. Furthermore, materials in contact with the oral mucosa are also in contact with saliva, and this may dilute substances eluted from the test material. And finally, dendritic cells (DCs) are antigen-presenting cells that capture, process, and present antigens to lymphocytes to initiate and regulate the adaptive immune response (Reinartz et al. 2016; Song et al. 2018). They are present in the oral mucosa (especially Langerhans cells) and play a major role as both activators and silencers of allergic immune responses within the immunological network of mucosal surfaces (Novak et al. 2010). However, the composition of the

**Fig. 5** Test results from the guinea maximization test (Schmalz and Arenholt-Bindslev 2009)

DC populations in different locations (e.g., dermis vs. mucosa) is different (Novak et al. 2010). Therefore, the relevance of skin testing for verifying the allergenic nature of the inflammatory response after oral application is under discussion. Contact allergy tests using the oral mucosa as target have been performed (epimucosal test) (Okamura et al. 2003). However, this test method proved to be less sensitive, and therefore today still the epidermal tests are recommended.

Recently, *in vitro* tests for preclinical evaluation of the different steps of sensitization have been developed and referred to in the annex to a working document ISO-DIS 10993–10 with reference to OECD 442C, OECD 442D, and OECD TG 442E. Experiences with such tests exist with pure substances; however little or no experience exists with testing medical devices or extracts from medical devices. Therefore, for the time being and for showing the conformity with the MDD/MDR, still animal-based methods are used, for dental materials preferably the guinea maximization test (Fig. 5).

## Oral Mucosa

The oral mucosa is another target organ for dental materials. In patients, adverse reactions of the oral mucosa mainly comprise whitish strongly localized reactions limited to the contact area with the dental materials (local lichenoid reaction) (Fig. 6). The etiology of such reactions is yet unclear, but in more than 50% of such cases, a type IV allergy toward the contacting material could be shown (Schmalz and Arenholt-Bindslev 2009). Other factors may be localized repeated trauma of the oral mucosa due to rough material surfaces or sharp edges.

**Fig. 6** Lichenoid reaction of the oral mucosa toward amalgam; patch test positive to mercury (Schmalz and Widbiller 2018)

For testing the effect on dental materials upon the oral mucosa, the hamster pouch test has been published (Harsanyi et al. 1991). A major problem with this test, however, was to keep the material in place for an appropriate amount of time (several weeks). Fixing the materials with sutures was not very effective, and the sutures themselves induced inflammatory reactions which superimposed those from the test material. Using a collar around the neck of the test animal was shown to be more effective (Harsanyi et al. 1991). However, such tests have not been adopted into toxicity testing standards for medical devices/dental materials, and experiences with tests like the hamster pouch test evaluating the mucosal reactions of dental materials are very limited. As a surrogate test, cell cultures are used according to ISO 7405 or ISO 10993-5, where the reaction of the test material is compared to market materials (reference material) with no clinical history of mucosa irritations.

## Nanoparticles

### Nanomaterials and Medical Devices

Nanoparticles having a size of 1 to 100 nm in at least one dimension are widely used in many products of daily life mainly to improve the performance, e.g., of materials or of drugs, but also of cosmetics, food stuff, and dietary supplements (Schmalz et al. 2017; Schmalz et al. 2018). Concerning regulatory toxicology, nanoparticles have recently gained increased public and scientific interest, and national and international agencies are dealing with safety aspects, e.g., WHO, ISO, EU Commission, or the FDA (Schmalz et al. 2017; Schmalz et al. 2018). In this context mainly the term “nanomaterial” is used.

According to the definition from the EU (2011), the term “nanomaterial” means a natural, incidental, or manufactured material containing particles, in an unbound state or

as an aggregate or as an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimensions is in the size range 1 nm–100 nm. In specific cases and where warranted by concerns for the environment, health, safety, or competitiveness, the number size distribution threshold of 50% may be replaced by a threshold between 1 and 50% (Schmalz et al. 2017; Schmalz et al. 2018). This definition of the EU is a recommendation and – according to the new EU Medical Device Regulation – a dynamic definition, which means that it can be changed, if new scientific information justifies it. However, so far, the above definition applies.

Rule 19 of the MDR deals especially with the risk classification of nanomaterials and defines:

- Class III if they present a high or medium potential for internal exposure;
- Class IIb if they present a low potential for internal exposure;
- Class IIa if they present a negligible potential for internal exposure (European Union 2017a).

### Nanoparticles in Dental Materials

Nanoparticles play an important role in dental materials. They are intentionally added to dental materials, e.g., to resin-based composites, to improve technical properties like polishability and surface gloss. Typically, pyrogenic silica ( $\text{SiO}_2$ ) is added, but also mixed oxides, such  $\text{ZrO}_2\text{-SiO}_2$ . Furthermore, nanoparticles are also unintentionally added. A large number of dental materials contain filler particles (mainly around several micrometers in size) in order to improve, e.g., mechanical properties, like in restorative materials, impression materials, or dental cements used for luting crowns. During the grinding process to generate such fillers, inevitably nanoparticles will result as by-products, even if the main size of the filler powder is intended to be in the micrometer area. The mass of this nanoparticle fraction is small, but the number of particles is comparatively high due to their small size. Therefore, it was estimated that more than 3500 dental materials fall under the EU definition of a nanomaterial (Schmalz et al. 2017; Schmalz et al. 2018).

As was mentioned above, dental materials in many cases are delivered in an unset state and are finalized (e.g., cured) by the dentist in the mouth of the patient. Then, the materials must be adjusted intraorally by grinding and polishing. During this process nanoparticles are released, even if the material itself does not contain nanoparticles (Bogdan et al. 2014). The same is true, if the material must be removed in the course of restoration replacement.

Nanoparticles are also intentionally placed on titanium implant surfaces. Such nanoparticles are strongly bound to the surface of the implant. The term “fixed” nanoparticles has also been used in the literature in this context. Nanoparticles on these surfaces are used for coating a medical device to prevent infection (e.g., silver nanoparticles) or to improve biocompatibility (e.g., apatite or Ti particles) (Schmalz et al. 2017; Schmalz et al. 2018).

This all demonstrates the importance of nanoparticles and of rule 19 of the MDR within the field of regulatory toxicology of dental materials. Finally, another consequence of this rule is that certain dental materials are now (MDR) assigned to a

higher-risk class than before under the MDD; for instance, dental impression materials, which were under the MDD in class I, are now under the MDR in class IIa. This all demonstrates the importance of a clinically relevant exposure assessment.

## Nanoparticle Exposure from Dental Materials

According to rule 19 MDR, the internal exposure has to be evaluated. Although the term “internal exposure” has not been defined yet, the exposure in general has recently been estimated for the dental environment (Schmalz et al. 2017; Schmalz et al. 2018). Occupational exposure in the dental laboratory occurs due to the release of nanoparticles during handling of different materials like gypsum products and during grinding and polishing resinous materials, metals, or ceramics. Only if legal regulations for occupational safety are not followed, this may cause lung diseases (Schmalz et al. 2017; Schmalz et al. 2018). Occupational exposure in the dental office (dentist, dental auxiliaries) is of special relevance, because generally, dental personnel is considered to be a high-risk group for adverse effects of dental materials, due to their frequent and high exposure to dental materials. For premixed materials (pastes), an estimate of the nanoparticle exposure has revealed that virtually no nanoparticles are released from the nanomaterials. For materials, where a powder and a liquid are mixed, nanodust may develop during mixing, which may be inhaled. However, most powder/liquid materials are today delivered in capsules. Therefore, also for such materials, the exposure was estimated to be low to negligible (Schmalz et al. 2017; Schmalz et al. 2018).

Intraoral grinding and polishing of the set materials are often necessary, in order to adjust the applied material to the oral conditions like the adjustment to the opposing teeth (occlusion). Exposure has been estimated exemplarily for resin-based composites (Schmalz et al. 2017; Schmalz et al. 2018). Worst-case calculations were performed on a mass basis using data from Germany concerning the number of restorations annually placed and the number of dentists. The placement of ten restorations per day and a removal of 1 mm from the surface have been assumed. It was calculated that as a worst case grinding/polishing generates between 18 and 20  $\mu\text{g}$  nanoparticles per day (Schmalz et al. 2017; Schmalz et al. 2018). This can be compared to the proposal of the German Agency for Occupational Safety (Bundesinstitut für Arbeitsschutz und Arbeitsmedizin) indicating a maximum acceptable nanodust concentration over a working day of 8 h and a concentration of 110–190  $\mu\text{g}/\text{m}^3$  which corresponds to a daily exposure of 1100–1900  $\mu\text{g}$  per day (Schmalz et al. 2017; Schmalz et al. 2018).

Exposure of patients to nanoparticles may occur during the application of the unset materials; but as was delineated for dental personnel, virtually no nanoparticles are released from unset resin-based composites (Schmalz et al. 2017; Schmalz et al. 2018). When set materials are adjusted intraorally, dust is produced, which is inhaled by patients. A similar worst-case scenario was formulated as for the exposure of dental personnel (see above) and the placement of five restorations/fillings per year

and the removal of 1 mm from the surface were assumed. An exposure of about 25 ng per day was calculated. For the wear of dental restorative materials during mastication, 50  $\mu\text{m}$  and 100  $\mu\text{m}$  surface loss per year was assumed based on the relevant literature. This resulted in a maximum mass loss of 133–266  $\mu\text{g}$  per day, with only a minor part ( $\ll 0.1\%$ ) being nanoparticles. This can be compared to the normal daily exposure under unpolluted conditions, which was reported to be 400 mg nanoparticles per day (Terzano et al. 2010; Schmalz et al. 2017; Schmalz et al. 2018).

### **Titan (Ti) and Zirconium (Zr) Nanoparticles from Dental Implants**

Titan (Ti) is one of the most biocompatible metallic materials because of its ability to form a stable and insoluble protective oxide layer ( $\text{TiO}_2$ ) on its surface (Castilho et al. 2006; Elias et al. 2008). Ti and Zr are preferentially used for endosseous dental implants (Elias et al. 2008). It has been found that the properties of Ti implants can be improved by coating with nanostructured Ti-containing particles or Ti nanoparticles (Ti-NPs (NP = nanoparticles, the size is smaller than 100 nm)) (Valiev et al. 2008).

Even though Ti- and Zr-based implants are considered to be biocompatible, Ti-induced side effects such as hypersensitivity and allergic reactions have been reported/claimed (Lalor et al. 1991; Egusa et al. 2008; Sicilia et al. 2008). It has also been found that Ti-based materials may cause immuno-inflammatory reactions (Voggenreiter et al. 2003). These side effects might have been caused by the interaction between tissues and implants (Yang and Merritt 1994; Hansen 2008). Previous in vitro and in vivo studies showed that Ti ions and Zr can be released from Ti-/Zr-based implants, for example, by corrosion or wear (Woodman et al. 1984; Bianco et al. 1997; Jacobs et al. 1999; Browne and Gregson 2000; Okazaki and Gotoh 2005; He et al. 2020). The release of Ni ions from NiTi alloy also has been reported (Setcos et al. 2006).

A recent in vitro study (He et al. 2015) demonstrated a size-dependent cytotoxicity and DNA damage of Ti particles in periodontal ligament (PDL)-human telomerase reverse transcriptase (hTERT) cells. The  $\text{EC}_{50}$  values (representative for cytotoxicity) of investigated particles were 2.8 mg/mL (Ti-NPs  $<100$  nm), 41.8 mg/mL (NiTi-MPs (MP = macroparticles, the size is bigger than 100 nm)  $<44$   $\mu\text{m}$ ), and  $> 999$  mg/mL (Ti-MPs  $<44$   $\mu\text{m}$ ). Genotoxicity was described for Ti particles in the following range (Ti-NPs highest toxicity): Ti-MPs  $<$  NiTi-MPs  $<$  Ti-NPs (He et al. 2015). The highest cellular uptake efficiency was observed with Ti-NPs, followed by Ti-MPs and NiTi-MPs. Only Ti-NPs were found in the nucleus. Compared to Ti-MPs and NiTi-MPs, Ti-NPs induced higher cellular uptake efficiency and higher toxic potential in PDL-hTERT cells (He et al. 2015; He et al. 2020). Phagocytosis of Ti particles ( $<5$   $\mu\text{m}$ ) could induce cytotoxicity in rat calvarial osteoblasts and MG63 human osteosarcoma cells (Pioletti et al. 1999; Lohmann et al. 2000). Genotoxic effects of Ti particles ( $<5$   $\mu\text{m}$ ) have also been detected, which induced apoptosis in mesenchymal stem cells (Wang et al. 2002; Wang et al. 2003). It was found that the particles size can influence the toxicity of metal particles (Karlsson et al. 2009; Hackenberg et al. 2011). The ability of different particles

entering cells may also affect the toxicity (Karlsson et al. 2009; Oh et al. 2010; Hackenberg et al. 2011), and it is reported that particle size can impact the cellular uptake efficiency and pathway (Lee et al. 1993; Jiang et al. 2008; Zhu et al. 2013). Pettersson et al. (2017) found that Ti particles (and dental pathogenic germs) can activate the inflammasome-cascade reactions in macrophages and can increase the formation of cytokines. They concluded that periimplantitis can arise by titan oxide particles even in the absence of bacteria (Pettersson et al. 2017).

Previous studies reported that particles  $<1 \mu\text{m}$  could be taken up by non-phagocytic eukaryotic cells via endocytosis (Rejman et al. 2004) and particles with diameters exceeding  $0.75 \mu\text{m}$  can be taken up by macrophages, neutrophils, and monocytes via phagocytosis or through macropinocytosis ( $>1 \mu\text{m}$ ) by all cell types (Conner and Schmid 2003). Therefore, transportation of Ti particles with size of  $0.5\text{--}5 \mu\text{m}$  into cells was observed in the human bone marrow tissues (He et al. 2016). Bone marrow fibrosis, avital bone tissues, and multinucleated cells were seen near dental implants (He et al. 2016). Bone marrow fibrosis might be induced by marrow injury and inflammation (Travlos 2006). These effects were reported to be associated with surgical trauma during insertion of implants (Piattelli et al. 1998). Multinucleated giant cells could be elicited by wear particles in periimplant tissues in human specimens, and these cells might contain phagocytized wear particles (Anazawa et al. 2004). Zr released from dental zirconia implants did not lead to abnormalities in animal bone marrow tissues (He et al. 2020).

Increased concentrations of metals (e.g., Ti, Cr, Co, and Al) derived from orthopedic implants in body fluids might induce acute or chronic toxicological effects (Hallab et al. 2001). The long-term effects of Ti and Zr derived from dental implants are still not fully understood, but associated hypersensitivity and allergic reactions in patients have been reported only for Ti in very few patients (Lalor et al. 1991; Sicilia et al. 2008). In a clinical study, the presence of titanium allergy was evaluated by the anamnesis and examination of patients, together with the selective use of cutaneous and epicutaneous testing, in patients treated with or intending to receive dental Ti/zirconia implants. In this study, 0.6% of 1500 patients were found to exhibit Ti allergic reactions (Sicilia et al. 2008). However, this has not yet been confirmed by other studies. Additionally, it has been found that detached metal debris from implants might cause marrow fibrosis, necrosis, and granulomatosis (Dannenmaier et al. 1985; Amstutz et al. 1992; Case et al. 1994). For the worst-case situation for patients with Ti implants, the following calculation can be made: the highest Ti content detected in human mandibular bone was  $37,700 \mu\text{g}/\text{kg}$  bone (He et al. 2016). It is assumed that if all Ti in the bone is nano-Ti and 1 kg bone is 1 L fluid, a nano-Ti concentration can be calculated of  $37 \mu\text{g}/\text{mL}$ . The EC50 value for nano-Ti in human cells is  $2800 \mu\text{g}/\text{mL}$  (He et al. 2015). Therefore, it is assumed that Ti nanoparticles released from dental implants might have no toxicologically clinical effects. Zr release from zirconia implants in animal mandibular bone was much lower compared to the Ti release from Ti implants in human mandibular bone. No histological abnormalities were found in animal tissues with zirconia implants (He et al. 2020). From a clinical point of view, bacterial infection is still regarded to play a major role in eliciting/initiating a periimplantitis for both Ti and zirconia implants.

### Protective Measures

Personnel protection, such as wearing a face mask against small particles, could be considered for protection against nanoparticles. Surgical masks with pore size of  $> 5 \mu\text{m}$  provided in a study quite some protection (64% for the respirable fraction of  $< 4 \mu\text{m}$ ), taking into consideration that the normal dust exposure (i.e. without face mask) for dental personnel is low to negligible. However, as expected, FFP3 masks have a higher efficiency (72% for the respirable fraction of  $< 4 \mu\text{m}$ ), but they are cost intensive, complicate dental treatment (Breul et al. 2020) and not all persons can use them. FFP masks are certified according to EN 149:2001 + A1:2009 in class FFP2 and FFP3 and correspond to the indications of the World Health Organization (WHO) infection prevention and control guidance and according to the European Regulation (EU) 2016/425 (personal protective equipment) (World Health Organization 2019).

---

### CMR and Systemic Toxicity

The term CMR refers to substances, which are carcinogenic, mutagenic, or toxic to reproduction. According to the new MDR, annex I, medical devices shall only contain CMR substances of category 1A (based on evidence from humans) or 1B (based on evidence from animal studies) in a concentration above 0.1% weight by weight (w/w), where especially justified and labeled. The classifications 1A and 1B follow the CLP regulation.

### Carcinogenicity of Dental Materials

Certain substances, which are ingredients of dental materials, have shown under specific experimental condition carcinogenic properties, like nickel, beryllium, or cobalt (Wataha 2000; Geurtsen 2002; Schmalz and Garhammer 2002; Schmalz and Arenholz-Bindslev 2009). According to the International Agency for Research on Cancer (IARC), there is sufficient evidence in humans for the carcinogenicity of mixtures that include nickel compounds and nickel metal (International Agency for Research on Cancer 2018) and is assigned to group 1 (carcinogenic to humans), although for certain nickel compounds like nickel chloride, there is limited evidence in experimental animals. There is sufficient evidence in humans for the carcinogenicity of beryllium and beryllium compounds. Beryllium and beryllium compounds cause cancer of the lung. Beryllium and beryllium compounds are carcinogenic to humans (group 1) (International Agency for Research on Cancer 2018). According to the classification of the EU CLP regulation (European Union 2008), cobalt has recently been classified into category 1B (presumed to have carcinogenic potential for humans), and this classification was largely based on animal evidence.

However, in a recently issued literature compilation, the US FDA stated in 2019 for metal implants (including cobalt-chromium alloys) used in (orthopedic) surgery

that in summary, while isolated reports exist of cancers associated with metal implants, data from multiple large registries has failed to support any increased risk of malignancy with metal implants (United States Food and Drug Administration 2019). For dental materials there is no evidence from the dental literature that indicates that dental alloys are carcinogenic (Wataha 2000; Geurtsen 2002; Schmalz and Garhammer 2002; Schmalz and Arenholz-Bindslev 2009).

For certain acrylic monomers like TEGDMA or HEMA, which are used in certain resin-based restorative/filling materials and in dental adhesives, it has consistently been shown that they were mutagenic in different *in vitro* genotoxicity/mutagenicity tests. This was probably due to an induced redox imbalance (Schweickl et al. 2006; Krifka et al. 2013) or due to genotoxic/cancerogenic epoxy intermediates (Reichl et al. 2002). Again there is no evidence for carcinogenicity of dental resinous materials. And to the best knowledge of these authors, there have no reports in the literature been published demonstrating an association of oral cancer and applied dental materials in general. So, there is a discrepancy between mainly *in vitro* based data for genotoxicity/mutagenicity of dental material ingredients or eluates and the lack of clinical evidence for material-induced tumor formation.

As carcinogenicity tests using animal models are time-consuming and costly, carcinogenicity of dental materials is preclinically evaluated by *in vitro* genotoxicity/mutagenicity tests (see below) together with quantitative data from elution tests (amount of eluted substances) based on the TTC (Threshold of Toxicological Concern) concept according to ISO/TS 21726:2019.

## Genotoxicity/Mutagenicity of Dental Materials

As mentioned above, genotoxicity/mutagenicity tests are mainly used as surrogate tests in the course of evaluating a possible carcinogenicity, and they should be considered during the clinical risk assessment. Genotoxicity tests are using mammalian or non-mammalian cells, bacteria, yeasts, fungi, or whole animals to determine whether gene mutations, changes in chromosome structure, or other DNA or gene changes are caused by the test samples (ISO 10993-3 2014). While genotoxic effects may be limited to a special cell generation, mutagenicity is referred to the fact that the genetic damage is transferred to the next cell generation.

Dental materials have elicited genotoxic effects, e.g., some root canal sealers (Schweickl et al. 1995; Ersev et al. 1999) in the bacterial reverse mutation assay (Ames test). Resin-based composite materials and the monomer components were genotoxic in the *in vitro* micro-nucleus test or the comet assay (Heil et al. 1996; Kleinsasser et al. 2004; Schweickl et al. 2006). However, this effect was mainly shown for the unset or very freshly mixed materials and for constituent monomers. Genotoxicity/mutagenicity tests, which generally are to be performed in the course of premarket evaluation of dental materials, are described in ISO 10993 part 3 (ISO 10993-3 2014) also with reference to relevant OECD tests. Modification of OECD tests for evaluating medical devices is described in ISO/TR 10993-33 (2015).

According to ISO/TR 10993-33:2015 (2015), the following in vitro tests are recommended:

- Test for gene mutations in bacteria. Bacterial reverse mutation assay, OECD 471 technically modified for medical devices to allow, for example, testing with extracts from devices.
- And either:
  - An in vitro test with evaluation of chromosomal damage in mammalian cells. Chromosome aberration test, OECD 473 technically modified for medical devices.
  - An in vitro mouse lymphoma thymidine kinase assay, OECD 490 technically modified for medical devices including detection of small (slow-growing) and large colonies.
  - An in vitro mammalian cell micronucleus test for chromosomal damage and aneugenicity, OECD 487 technically modified for medical devices.

In vivo tests were included in the initial test battery of ISO 10993-3 in order to provide intact mammalian metabolism, and they have also been used to clarify results from in vitro tests. Currently, in vivo tests are not recommended generally for medical device assessment, but are reserved for rare circumstances (ISO/TR 10993-33:2015 2015). For dental materials, usually eluates are prepared, e.g., according to ISO 10993-12 (ISO 10993-12 2012), and the highest non-toxic/slightly toxic concentration is used for genotoxicity testing. If the results of the two in vitro tests are negative, further genotoxicity testing in animals is unnecessary (ISO 10993-3 2014).

## Reproductive Toxicity of Dental Materials

Reproductive toxicity tests cover the areas of reproduction, fertility, and embryo-fetus development (ISO 10993-3 2014). These biological endpoints are also to be considered during clinical risk assessment. So far, no such effects have ever been reported for patients after exposure to dental materials. Tests for reproductive toxicity are described in ISO 10993-3. Reproductive and developmental toxicity testing is not required where an acceptable toxicological risk assessment of the medical device takes into account the fact that the risk of reproductive and developmental toxicity has been adequately mitigated (ISO 10993-3 2014). As for dental materials, such effects have not been clinically observed, these tests are generally waived. Again, data from standard cell culture tests and from the chemical analyses of material eluates can be used instead.

## Systemic Toxicity of Dental Materials

For dental materials, systemic toxicity has mainly been a topic of concern for dental amalgam. In a 2015 report of the European Commission (SCENIHR), the more

recent literature on this topic has been compiled, and the conclusion was that the available data do not preclude the use of dental amalgam for the general population (European Commission 2015a). As a consequence of the Minamata Convention (see below), the EU has in 2017 enacted a regulation, by which dental amalgam should not be used in deciduous teeth, in pregnant and lactating women, and in children up to the age of 15 (European Union 2017b) except deemed necessary for medical reasons.

More recently, the effect of endocrine disruptors such as bisphenol A (BPA) has attracted increased interest, and BPA has been claimed to be responsible for many diseases like diabetes, obesity, or infertility (Talsness et al. 2009). In parallel to CMR substances, also endocrine disruptors have especially been mentioned in the new MDR, annex I, and again a concentration above 0.1% weight by weight (w/w) is only allowed, if specifically justified, and special labeling is required. Also dental restorative materials have been discussed in the context of BPA. Widely used resin composites contain resin bases like bis-GMA and similar compounds or (seldom) bis-DMA, and orthodontic bracket may be fabricated from polycarbonate resins. Although such dental materials do not deliberately contain BPA, it is a precursor of the abovementioned resins and thus is used in the production process (European Commission 2015b; Schmalz and Galler 2017). Residues of BPA are still present in the produced monomers in low quantities. It was shown that bis-GMA does not hydrolyze under physiologic conditions to BPA and bis-DMA does (Schmalz et al. 1999), but the abovementioned BPA residues are released (Sevkusic et al. 2014). However, concentrations of released BPA – even from bis-DMA-containing market products – are very low and beyond the derived temporary oral TDI of 4 µg/kg b.w./day (American Dental Association Council on Scientific Affairs 2014; European Food Safety Authority 2015; European Commission 2015b).

Tests for dental materials addressing acute, subacute, and chronic systemic toxicity are to be considered according to ISO 10993-1, depending on the exposure period of the medical device. Tests are described in ISO 10993-11, Biological evaluation of medical devices – Part 11: Tests for systemic toxicity (ISO 10993-11:2017 2017), which addresses the evaluation of unspecific systemic toxicity, not specific target organ or organ system toxicity. For dental materials oral application is the most reasonable route of administration.

Literature data from testing unspecific systemic toxicity as mentioned above indicate that dental materials do generally not elicit any acute systemic toxic reactions (Schmalz and Arenhof-Bindslev 2009). Such tests require the use of animals, and thus it has to be critically evaluated, if such tests are indicated for new dental materials. As recommended in ISO 10993-11 (ISO 10993-11:2017 2017), such tests for acute systemic toxicity may be waived, if cytotoxicity data are in the same range as for market products and if the chemical analysis of the eluates does not provide an indication for possible acute systemic toxic reactions. Basically the same is true for subacute, subchronic, and chronic systemic toxicity. Here the TTC concept can be applied, based on the total amount of extractable substances (see above).

---

## Environment

Recently, the influence of dental materials on the environment has become a topic of interest, and thus scientific commission of the European Commission (SCHER) has issued an opinion of the impact of dental materials upon the environment (European Commission 2014) (It was concluded that under conditions that amalgam separators are installed in the dental practices and the use of amalgam is low, no risk for the environment and secondarily for human health can be expected. This is the case for instance in Germany. The environmental risk for other restorative materials was assumed to be low, but there were no data for a sound risk assessment available. Such considerations are especially relevant when such materials are removed and discharged via the wastewater into the environment. The environmental impact of amalgam being discharged into the sewage water was also addressed in the Minamata Convention (United Nations Environmental Programme 2013), by which the use of mercury should worldwide be reduced due to environmental reasons. The consecutive EU regulation on mercury (European Union 2017b) has been mentioned above as well as to the restriction of amalgam use. Further to this, the discharge of amalgam waste into the environment has been regulated, and reference has been made to ISO 11143 for amalgam separators, which have to guarantee an efficiency (>95%) of amalgam particle removal (ISO 11143:2008 2008). Data for the environmental impact of other dental materials are missing, especially for resin-based composite materials. Here, the above mentioned release of substances from discharged resin particles after restoration removal may be of interest due to a possible accumulation of such substances in the environment. A recent in vitro study (Cokic et al. 2017) reported that relatively high concentrations of unpolymerized methacrylate monomers and of BPA were liberated from composite resin dust, which has been prepared by grinding a composite resin block. This demonstrates that further research is needed in this area.

---

## Conclusions

Biocompatibility of dental materials is today tightly regulated by legal frameworks virtually all over the world, which are all based on the same principles, although they differ in details. The manufacturers are responsible for the safety and the performance of their products. They have to provide evidence (technical documentation) according to a scheme of different risk classes, and a third party is mainly involved in the medium- and high-risk classes (II and III) for control. Based on a risk assessment, missing data are identified, and relevant tests are mainly performed according to ISO standards. The changes introduced by the MDR in 2017 are in part due to problems which had been encountered with breast implants produced and sold by the company Poly Implant Prothèse (PIP), using illegally industrial-grade silicone since 2001. No experiences with the MDR are existing so far.

## Abstract

The ubiquitous contamination of the environment with plastic debris and the possible associated risks to ecosystems and, ultimately, human health has recently attracted a great deal of public and scientific attention. Among the plastic materials found in aquatic environments, microplastic particles have attracted particular attention since harmful effects on various organisms have been discussed, especially related to their ingestion. However, possible risks associated with microplastics cannot be generalized, as microplastics comprise a very heterogeneous group of particles that differ in their physicochemical properties. At present, there is a considerable lack of knowledge on the effects of microplastics at the molecular, cellular, tissue-specific, and organismic levels and the

## Introduction

### Modern Plastics: A Success Story Turned into an Environmental Problem

Plastics have become essential components of our everyday life and have made a wealth of technical and medical innovations possible (Andrady and Neal 2009). Plastic products are light yet stable and corrosion-resistant and have excellent insulating properties, to name only a few of their advantages. Due to the versatile material properties and the low production costs compared to other materials, plastics can be found in a variety of products. For instance, plastic packaging reduces food waste by extending shelf life. Plastics play a central role in the lightweight construction of vehicles, ensuring that they consume less fuel and reduce greenhouse gas emissions such as carbon dioxide (CO<sub>2</sub>). In freight transportation over long distances, fewer greenhouse gases are emitted with the use of plastic products compared to alternative heavier materials like glass. Plastics are also used in the insulation of houses to reduce energy consumption, and they play a crucial role in the construction sector as pipes and cables, cladding, seals, adhesives, and gaskets. Plastic is essential in medicine, for instance, to ensure the sterility of medical products, and without plastic, neither computers nor smartphones would make our lives easier. Although there are a huge variety of plastics, the majority of plastics processed are limited to only a few types: polyethylene, polypropylene, polyvinyl chloride, polyurethane, polyethylene terephthalate, and polystyrene.

Since the 1950s, plastics' global production has risen from 1.5 million tons to 359 million tons in 2018, with production rates forecast to continue to rise sharply, doubling in 20 years (Plastics – the Facts 2019). China has the largest share of world production with 25%, followed by the European Union with 20% and North America with 19%. Among the main applications for plastics (~40%) are short-lived disposable products in the packaging industry. Correspondingly, the amount of plastic waste produced has also risen rapidly over the years. The proportion of plastics going into the recycling process was estimated to be only 31% in Europe in 2016. The remainder of plastic waste continues to be dumped in landfills across

Europe or sent for other forms of exploitation, such as incineration (Plastics – the Facts 2017). However, it can be assumed that in developing countries in particular, which often lack a proper collection system, the proportion of recycled plastic is far lower than in Europe.

Unfortunately, a significant proportion of plastic waste is released into the environment through careless and improper disposal (Browne et al. 2011; Dubaish and Liebezeit 2013). Especially this improper disposal of plastic waste inevitably leads to a long-term environmental problem. That is why plastic has changed from being a cheap problem-solver to an environmental problem itself.

The World Economic Forum has calculated, for example, that every year, approximately 32% of plastic packaging material alone is improperly disposed of in the environment (World Economic Forum 2016). The main problem of plastics in the environment arises from the high resistance and durability of the material. Due to the slow degradation dynamics, it is assumed that many plastics are persistent in the environment for hundreds of years, depending on the polymer type (Barnes et al. 2009). Therefore, it can be assumed that most of the plastic that has been released into the environment since the beginning of mass production is still to be found there and represents far more than just an aesthetic problem.

Once released into the environment, plastic disintegrates over time into ever-smaller particles due to weathering processes. Fragmentation occurs due to various environmental influences such as solar radiation and chemical and biological degradation. As a result, the material becomes cracked and brittle and continues to break up due to mechanical effects such as wave movements. The resulting particles are referred to as microplastics (Fig. 1).

**Fig. 1** Microplastics: Different kinds of microplastics found on the shoreline of Lanzarote. (© Christian Laforsch, University of Bayreuth)

## Microplastics: A Young Field of Research

The term “microplastics” refers to fragments, fibers, films, foams, and spherical particles of plastics smaller than 5 mm. Accordingly, this definition covers a wide range of materials that, due to their specific chemical and physical properties, are likely to exhibit different behaviors and effects in the environment. Till now, there is no consensus on the definition of the actual size range of microplastic particles. The upper size limit of 5 mm is widely accepted, whereas the lower size limit is still under debate. The suggestions of the lower size limit range from 100  $\mu\text{m}$  down to 100 nm, depending on the scientific field. For instance, for analytical studies of microplastics in the environment, the definition of the lower size limit often refers to the technological detection limitations, whereas for toxicological studies, lower size limits are proposed, as these may promote its bioavailability under laboratory conditions (Wright et al. 2013b; Frias and Nash 2019). Furthermore, there is no consensus on the definition of nanoplastics because it depends on the lower size limit of microplastics. However, an overall accepted distinction is made between “primary microplastics” and “secondary microplastics.” “Primary microplastic” is manufactured industrially as a component of, for example, cosmetics, cleaning products, or abrasives and is discharged into the environment mainly via the wastewater (sewage treatment plants, rainwater, and combined sewerage systems). “Secondary microplastic” results from mechanical, chemical, and/or biological degradation from large waste fragments (macroplastics) or an abrasion from various plastic products (e.g., agriculture, construction industry, traffic, clothing) and can enter the environment in large quantities via various input paths. One example is tire abrasion from motor vehicles, consisting mainly of polyisoprene in the form of tiny particles. It is now considered certain that microplastics occur worldwide in all habitats, in some cases in considerable quantities.

Although the occurrence of microplastic in marine systems was reported as early as 1972 (Carpenter and Smith 1972), it took over 30 years until it became a hot topic with the publication of Thompson et al. (Thompson 2004) “Lost at Sea: Where Is All the Plastic?”. Since then, microplastic has been detected in marine ecosystems worldwide and classified as a potential threat to biota, economy, and society (Fig. 2). Although 50–80% of the waste found in the sea is produced and disposed of on land until recently, research has focused mainly on the supposed main sink of plastic waste, the ocean, where significant amounts of plastic waste are floating on the surface (Eriksen et al. 2014). Extrapolations indicate that between 1.1 and 12.7 million tons of plastic waste are discharged into the oceans via rivers worldwide each year (Jambeck et al. 2015; Lebreton et al. 2017). Despite a large number of publications on the marine system’s microplastic contamination, there is still a lack of decisive information, for example, on the spatial distribution of microplastic in the oceans. Nevertheless, microplastics are reported to occur from tropical to pristine polar areas and from beaches to deep-sea sediments.

Freshwater ecosystems such as rivers and lakes have more recently received attention, and plastic particles have been found in areas used by tourists and even in remote mountain lakes (Imhof et al. 2013; Dris et al. 2015). Considering that the

**Fig. 2** Beach on Lanzarote. Visible contamination with large microplastic fragments. (© Christian Laforsch, University of Bayreuth)

majority of plastic waste is generated and emitted on land, it is not astonishing that plastic particles have only recently been found in the atmosphere and terrestrial ecosystems, especially in urban and agricultural soils (Fig. 3) (Dris et al. 2016; Piehl et al. 2018; Weithmann et al. 2018).

Studies show that limnetic and terrestrial systems can serve, as well as marine systems, as sinks of plastic waste. No clear correlation could be established between the occurrence of microplastic in the environment and population density and

**Fig. 3** Plastic on agricultural soils. All larger fragments can disintegrate into microplastics over time. (With kind permission from © Stefan Leible (University of Bayreuth))

proximity of industrial plants, which underlines both the complexity of the issue and the need to understand the mechanisms of the environmental behavior of microplastic. An estimate of the abundance of microplastic on agricultural land suggests that the pollution in Europe and North America alone is higher than the total amount of microplastics in the oceans (Nizzetto et al. 2016). Recent estimates suggest that there is almost 40 times more macro- and microplastics on land than in the ocean (Kawecki and Nowack 2019). The latter underlines the fact that plastic contamination of the environment not only affects the world's oceans but is of global relevance as a terrestrial pollutant.

It is predicted that, as a result of global population growth, increasing urbanization, and rising consumption in developing and emerging countries, the production and consumption of plastics will continue to grow strongly on a global scale and that the problem of the entry of microplastic into the environment will, therefore, become increasingly important. The resulting publicly discussed need for action is enormous, from which an urgent need for research can be derived to close the considerable gaps in knowledge that are becoming increasingly apparent despite or because of the topicality of the issue.

According to current estimates, “secondary microplastic” represents the main component of environmental contamination by microplastics. However, the extent of the contamination of the environment cannot yet be fully determined. Microplastics in the environment, unlike soluble pollutants, are neither temporally nor spatially homogeneously distributed, and therefore most studies on microplastic contamination are snapshots in time. In addition, microplastic analysis methods are only just being developed, as it is far from trivial to isolate and analyze microplastic particles smaller than the diameter of a human hair from complex

environmental samples. Particles in the nanometer size range have not yet been detected in the environment. Further, data on contamination of the environment with microplastics are often not comparable with each other, as no uniform methodology for the detection of microplastics has yet been established, and different methods are used for sample processing and analysis.

## Microplastics: Analysis of Environmental Concentrations

Representative sampling is among the most critical step in the analysis of microplastics. Non-representative sampling leads to unreliable data, regardless of how reliable the subsequent sample processing and analysis is. Each sampling design must be adapted to the specific research question.

To chemically identify and quantify each plastic particle occurring in environmental samples, potential microplastic must be extracted from the sample volume. Usually, an environmental sample contains more natural particles in the form of plant, animal, and mineral constituents than microplastic. Water samples usually contain only a few mineral particles and a high proportion of organic material. For non-homogeneous solid samples such as soils, microplastic isolation is even more challenging. The difficulty in the purification of the samples is to avoid method-related damage or fragmentation of the microplastic particles as far as possible. The simplest method for microplastic isolation is sieving and manual sorting using a stereomicroscope. This method is not only limited to sizes  $>500\ \mu\text{m}$  but is also very susceptible to misidentifications and observer bias, so a subsequent reliable polymer identification is essential.

Suggested methods for removing the mineral fraction include electrostatic separation, oil extraction, froth flotation, magnetic extraction, vertical density gradient separation, and density separation. Usually, saturated salt solutions of sodium chloride, zinc(II) chloride, or sodium polytungstate are used. A density of 1.6–1.8 g/mL is suitable for all environmentally relevant plastics. Various methods have been developed based on the principle of density separation for sample preparation, such as the Munich Plastic Sediment Separator (MPSS) (Imhof et al. 2012).

For the removal of the organic fraction, the use of strong acids and bases has proven to be unsuitable, as some polymer types can be strongly damaged or even completely dissolved. Small microplastics and fibers are particularly affected. The treatment with various technical enzymes combined with mild oxidizing agents such as hydrogen peroxide has proved to be a gentle method of extracting microplastic from environmental samples (Löder et al. 2017).

The pretreated samples are then applied to filters for the chemical analysis. Raman spectroscopy and Fourier transform infrared (FTIR) spectroscopy are the most commonly used state-of-the-art analytical methods in microplastic research. Both vibrational spectroscopy techniques enable the precise identification of polymer types and their abundance, shape, and size. Software-based automatic detection of microplastics has been developed (Fig. 4) (Hufnagl et al. 2019). However, next to

**Fig. 4** Software-based automatic detection of microplastics using focal plane array (FPA)-FTIR (Huftnagl et al. 2019). Right-hand side: optical image of a filter after sample processing. The blue-labeled particle is identified as polyethylene (PE). Left-hand side: respective fingerprint spectra of the polyethylene particle. (© Martin G. J. Löder and Christian Laforsch, University of Bayreuth)

the restricted size limit of the respective methods (10  $\mu\text{m}$  for FTIR, 300 nm for Raman), the spectra of environmentally aged plastics cannot always be clearly identified because biofilms on the particle surfaces can interfere with the spectroscopic methods.

If the shape and size of microplastic, which is indispensable if the toxicity on organisms is considered, are not in the focus of the study, microplastic can further be analyzed using pyrolysis gas chromatography mass spectrometry (Pyr GC-MS) or thermal extraction desorption gas chromatography mass spectrometry (TED GC-MS). With these methods, the polymer components, as well as the contained additives, can be examined under defined thermal conditions. However, these methods are restricted in the sample volume, which can be used (Fries et al. 2013; Dümichen et al. 2017).

In general, during sampling, sample processing, and analysis of microplastics, it should be noted that the risk of contamination of environmental samples is very high, as synthetic polymers are ubiquitous. Therefore, precautions must be taken at each processing step: blank samples should be used at each step, and plastic material should be avoided and replaced by alternative materials such as metal or glass wherever possible.

Woodal et al. (2015) comprehensively describe the application of a forensic-scientific approach to minimize sample contamination. A comprehensive discussion on the advantages and disadvantages of further and all described methods are listed in Möller et al. (2020).

## Microplastics: Environmental Risks

The ubiquitous contamination of the environment with microplastics and the possible associated risks to ecosystems and ultimately to human health has recently attracted a great deal of public and scientific attention. Potential biological risks of plastic particles in the environment arise from the small size of the particles through which it can easily enter the food chain, mistaken as food or by inhalation. Microplastic particles can further degrade into even smaller particles, which have been termed “nanoplastics.” Nanoplastics, with their smaller sizes, may have a higher bioavailability than microplastics and may even pose a higher environmental risk. Contamination of the environment with plastic particles, therefore, represents a global challenge and is (G7 Summit2015) classified as a “top emerging global issue” due to the as yet unassessed hazard potential and ubiquitous occurrence (GESAMP 2015).

The ingestion of plastic particles, together with natural food, has already been investigated in various organisms from aquatic and terrestrial habitats. The resulting effects on organisms and human health are still under discussion. It has to be noted that possible risks associated with plastic particles cannot be generalized since micro-/nanoplastics comprise a very heterogeneous group of particles that vary in polymer composition, additive content, size, shape, aging state, and, consequently, their physicochemical properties.

Hence, microplastic is only a collective term for small particles ( $< 5$  mm) of various types of plastics with a wide range of chemical and physical properties as well as different surface conditions (e.g., functional groups, zeta potential). Non-polymerized monomers, as well as adsorbed organic material and coating with biomolecules and inorganic substances, contribute to the further complexity of the particles. Overly broad generalization over the potential biological effects predicted for microplastic is hence of limited value.

A central bottleneck in the assessment of the environmental relevance of microplastic is the lack of comprehensive data on biological mechanisms of action of microplastics as a function of the chemical and physical properties of the various plastics degraded in the environment. A comparison of microplastic with naturally occurring particulate materials, which can also be ingested with food, is indispensable. Considerable knowledge deficits currently exist at the molecular, cellular, tissue-specific, and organismic levels and the resulting ecological consequences.

Next to direct effects on organisms, which are discussed in the following paragraphs, plastic debris could also exert indirect effects in the environment leading to ecological consequences. Plastic debris could, for instance, act as a substrate and transport vector for alien species (Rech et al. 2016). Further, Trotter et al. (2019) found the interspecific communication between predator and its prey being interfered by the sole occurrence of plastic in the aquatic environment. The authors assume that the allelochemicals used for communication may adsorb to the surface of the plastic particles. The resulting misperception of the chemical cues may lead to a false adjustment of the prey's defensive strategies and may, therefore, affect population dynamics in higher orders of the food web.

To date, most studies about the effects of microplastic pollution mainly focused on the direct effects resulting from exposure. In particular, physical effects like injuries due to entanglement can cause severe inflammation of the affected tissue. Other possible consequences are drowning due to reduced mobility.

Moreover, if plastic particles are mistaken with natural food, the stomach capacity can be reduced, or the stomach passage blocked, which can lead to a false sense of fullness and, in turn, to a slow death from starvation.

### **Ingestion: The Main Entrance Route of Microplastics into Organisms**

The degradation of plastic particles into smaller and smaller fragments increasingly affects organisms at lower trophic levels. Microplastics can float on the surface of water bodies, disperse in the water column, or accumulate in the sediment, making them accessible to a wide array of organisms in different habitats. Hence, the ingestion of plastic particles together with natural food has already been investigated in a variety of organisms, ranging from low trophic levels like zooplankton and mussels right up to higher trophic levels like vertebrates, from aquatic and terrestrial habitats. Several laboratory experiments, mainly conducted with aquatic organisms (including ciliates, cnidarians, rotifers, annelids, copepods, cladocerans, amphipods, mysids, euphausiids, barnacles, mussels, tunicates, and fishes), confirmed microplastic ingestion and uptake across the gill (e.g., Duis and Coors 2016). Some studies have already been carried out with terrestrial organisms, and ingestion was confirmed, for example, in detritivore soil invertebrates (Zhu et al. 2019). The ingestion of microplastic particles is additionally enhanced for microplastic being environmentally aged (Hodgson et al. 2018; Vroom et al. 2017). Moreover, some studies suggest that the presence of a microbial biofilm makes the microplastics more palatable for those organisms (Helmberger et al. 2019).

Upon ingestions, laboratory experiments suggest the excretion of microplastic particles within hours or days (Duis and Coors 2016), although the knowledge about microplastics retention time and excretion is still scarce. Some studies carried out with the Mediterranean mussels (*Mytilus galloprovincialis*) had conflicting results. Kinjo et al. (2019) reported that 99% of the ingested microplastics were excreted within 2 days after exposure. This study pointed out that very small microplastics were excreted faster than the larger ones. Those were detected in the feces up to 40 days after the exposure. Opposite results were obtained by Fernández and Albentosa (2019), as their work suggested that larger particles are excreted faster from the intestinal tract than the smaller ones. These contrary results are likely due to the different size range used in the two independent studies.

An investigation carried out on fathead minnows (*Pimephales promelas*) described excretion occurring within hours of exposure and dependent on the microplastics' size, with again the larger particles being excreted faster (Hoang and Felix-Kim 2020). The excreted microplastics were left available for reconsumption and were detected within the gut at all monitoring points. The excreted microplastics were coated with intestinal liquids, resulting in their aggregation and precipitation to the bottom of the exposure beakers. This suggests that the excretion process may contribute to the vertical movement of microplastics from the

**Fig. 5** Ingestion of fluorescent microplastic fibers (orange color) by an aquatic worm. The distinctly visible fiber is outside the worm (*Lumbricus variegatus*). All other fluorescent particles are ingested and inside the gut. (© Christian Laforsch, University of Bayreuth)

water column to the waterbed, making them potentially more bioavailable for benthic organisms (Fig. 5).

Nevertheless, it has been shown that microplastics often remain in the digestive tract longer than natural particulate material, such as clay minerals (Wright et al. 2013a, b). Thus, organisms are confronted with this foreign substance for a longer time. With the enhanced retention period of microplastic particles within the gastrointestinal tract, the probability of bioaccumulation and biomagnification within the food web is much higher.

### **Trophic Transfer**

Active selection of microplastic particles might occur when animals mistake plastic for food (Nelms et al. 2018). Further, microplastics are often in the size range of

particles that are eaten by indiscriminate filter feeders. Especially those microplastic particles with a neutral or a positive surface charge can further adhere to phytoplankton and can, therefore, be found on the surface of suspended seaweed, rendering also herbivorous organisms prone to microplastic ingestion. As microplastics are persistent contaminants and often retain longer in the digestive tract than naturally occurring particles, all these mechanisms can lead to bioaccumulation in organisms from different functional feeding groups. To date, more than 690 species were found to be contaminated with microplastics (Toussaint et al. 2019; Wang et al. 2019). When such contaminated prey is consumed by a predator, the latter also ingest microplastics unintentionally. Thus, even organisms that do not have a food preference in the size range of microplastics can still ingest these particles indirectly via their food. This process leads to trophic transfer of microplastics along the food web, which may result in biomagnification. As a result, even in areas contaminated with relatively low concentrations of microplastics, the continuous ingestion of microplastic-containing organisms by predators may result in high concentrations in keystone predators (Au et al. 2017).

Trophic transfer has already been demonstrated on a laboratory scale, for instance, using low-density polyethylene microspheres on a model food chain relevant to North American estuaries (Athey et al. 2020). Further, Farrell and Nelson (2013) studied the transfer from the blue mussel (*Mytilus edulis*) to the shore crab (*Carcinus maenas*), since both are prevalent species in marine environments. Their analyses confirmed that the ingestion of contaminated blue mussels determined the concentration of microplastics in the crab, which was persistent even after 21 days post-exposure. Although different laboratory studies have assessed trophic transfer in low trophic level organisms, data on trophic transfer in the wild are still scarce. However, microplastics have been found in many wild fishes' gastrointestinal tracts, making the transfer to predators likely. Nelms et al. (2018) studied a correlation between the presence of microplastic particles in the gastrointestinal tract of Atlantic mackerels (*Scomber scombrus*) and the guts of their predators, the gray seals (*Halichoerus grypus*), suggesting that trophic transfer occurs in natural environments as well.

Since it has been shown that seafood is often contaminated with microplastics, the consumption of the latter may lead to a trophic transfer up to humans, which may also have implications on human health (Smith et al. 2018).

### **Ingested Microplastic Particles: Possible Effects in the Gastrointestinal Tract**

The effects of microplastics at an organismal level can be separated in physical and chemical effects (Campanale et al. 2020). According to the authors, physical effects are related, for instance, to the particle size, shape, and concentration of microplastics, and chemical effects are related to chemicals that are associated with microplastics.

### **Effects Caused by Additives**

Microplastics should not be considered as chemically inert particles. Due to the plethora of additives used during their production or intended to exert specific

characteristics, the physicochemical properties of the microplastic particles may lead to chemical effects at an organismal level. Plastic additives, which enable the various material properties of plastic or incompletely converted starting materials (monomers, oligomers), can leach out in the environment or upon ingestion in the gastrointestinal tract of organisms. Among chemical additives added to the polymers in the versatile production process are plasticizers, colorants, fillers, or flame retardants, just to name a few. The plasticizer to polymer ratio strongly depends on the material's desired property but can amount up to 50%, for example, in PVC.

Carcinogenic and hormonal effects on organisms have already been proven for some of these additives. Well-known examples are bisphenol A and phthalates (Prata et al. 2020). However, the release of additives in the digestive tract of organisms is controversially discussed in the scientific community and is considered low, since a biodynamic model (Koelmans et al. 2014) has shown a negligible release of additives in the digestive tract. Nevertheless, it has been shown that rigid PVC particles (PVC without phthalate) did not affect the growth rate and the number of offspring in *Daphnia magna*, whereas flexible PVC (the phthalate DiNP was added) did show adverse effects (Schrank et al. 2019). Other types of additives are trace metals. Trace metals are used as flame retardants, stabilizers, or biocides, which have been shown to induce effects on human health. For instance, trace metals potentially induce allergic reactions; have endocrine reactivity, which enhances the probability of hormone-induced cancer; and show genotoxic effects, the formation of reactive oxygen species, and other cytotoxic effects (Campanale et al. 2020).

### Effects Caused by Adsorbed Pollutants

Besides being used as additives, trace metals and other environmental pollutants like pesticides are widely discussed to adsorb from the surrounding environment to the surface of microplastic particles. In this context, once again, the physicochemical properties of the specific microplastic particle, such as hydrophobicity or surface roughness, play a critical role in the adsorption of pollutants. Once organisms ingest microplastic particles, either with additives within their polymer matrices or adsorbed pollutants from the environment, they can suffer from adverse effects. Nevertheless, the ecological relevance of this vector effect is still under discussion. The transfer of adsorbed pollutants to organisms and the resulting possible effects of these substances are considered negligible, since there is currently a consensus, resulting from laboratory and modeling studies, that the quantities of substances absorbed by this route are small compared to those absorbed directly from the water (Bakir et al. 2014; Koelmans et al. 2016).

### Effects on the Gut Microbiome

Although the mere passage of plastic particles through the digestive tract may have no direct effect on organisms, it may alter the gut microbiome instead. A recent study in mice shows that the intestinal microbiome is altered by the intake of polystyrene microplastic, resulting in a disturbance of fat metabolism (Lu et al. 2018). Similar results on the murine model system have also been found by Li et al. (2020).

Microplastic exposure resulted in a significant increase in bacterial abundance and diversity in mice fed with high microplastic concentrations. Further, microplastic exposure induced intestinal dysbacteriosis and inflammation. Even in fishes, microplastic exposure leads to alterations in the gut microbiome's composition, though the mechanism is still unknown (Triebkorn et al. 2019). Furthermore, a dysbiosis (disturbance of the intestinal microbiome) after the intake of polystyrene microplastic particles in zebrafish was found (Jin et al. 2018). Whether other organisms were also affected at this level and what role the type of plastic with the corresponding physical and chemical properties plays in this is entirely unexplored. Since gut microbiomes affected by microplastics may have different effects on the immune function, further studies are required to better understand this topic and its potential threat to animal and human health (Li et al. 2020).

### Microplastics: Tissue Translocation

One potential risk that has been intensively discussed but not yet sufficiently investigated and understood is the translocation of microplastic particles from the digestive tract and respiratory system into cells and tissue. It has been shown that microplastics not only pass through the intestinal tract but are also absorbed on and encapsulated within the tissue, which can lead to inflammatory responses, as shown in mussels (von Moos et al. 2012). Further microplastics were found to be translocated from the digestive tract into the mussels' circulatory system (Browne et al. 2008). In the shore crab (*C. maenas*), microplastics were detected in the hemolymph, hepatopancreas, ovaries, and gills, indicating that some particles can cross the gut epithelium (Duis and Coors 2016). The translocation of microplastics in different body compartments is not just described in invertebrates but recently also in vertebrates including zebrafish, where hyperspectral imaging was used to identify nanopolymer particles translocated from the intestine into the liver (Galloway et al. 2017a, b). Additionally, the translocation of microplastic is not exclusively found under laboratory conditions but also occurs in natural environments in fish (Barboza et al. 2020).

As mammalian model systems to study tissue translocation, mainly mice and rats or murine cell lines are used. Feeding experiments showed the translocation of micro- and nanoplastics from the gut to excretory organs like the liver and kidney (Yong et al. 2020). Particulate substances in the size range of microplastic particles, as found in environmental samples, can, therefore, potentially also be translocated into the tissue of humans, which underlines the environmental relevance of this issue.

To date, neither the corresponding interactions between the cells of the intestinal tract and the microplastic particles have been understood, nor has it been investigated whether microplastics are internalized by cells directly or which internalization mechanisms are potentially involved.

It is known that particles in the micrometer size range can, in principle, be internalized by epithelial cells and identified as potential pathogens by cells of the

**Fig. 6** Cellular internalization of a spherical microplastic particle. Fluorescently labelled J774A.1 murine macrophage cells exposed to 3  $\mu\text{m}$  polystyrene microplastic particles. The cytoskeleton of the cell surrounds the microplastic particle. immune system, e.g., macrophages (Fig. 6). Particles are further internalized by cells via, e.g., phagocytosis when coated with antibodies (Desjardins and Griffiths 2003).

There are mainly two possible pathways of how micro- and nanoplastic particles may translocate into tissues. Either the particles are transported paracellularly, which means in between cells through, e.g., tight junctions, or transcellularly, which means the endocytosis of particulate matter into cells directly (Wright and Kelly 2017). Endocytosis mechanisms depend on several factors. Besides receptor-mediated internalization mechanisms, which require ligand-proteins and suitable receptors, the size of the particles is an essential factor (Doherty and McMahon 2009). Smaller particles are suggested to become internalized passively, whereas larger particles in the lower micrometer size range are discussed to become internalized by cells in an energy-dependent active manner (Shang et al. 2014; Wright and Kelly 2017). However, even the particle's surface properties are responsible for tissue translocation, and therefore, the environmental coating of the particle may play a crucial role in cellular internalization (Galloway et al. 2017a, b).

### The Coating of Microplastic Particles: Biofilm, Coronas, and Pathogens

Once micro- or nanoparticles enter aquatic environments, a biofilm can develop on the particles' surface. In the marine environment, the development of a biofilm has been shown on various polymer types (Oberbeckmann et al. 2015). The development of a biofilm can generally be described to occur in five successive steps. In the first step, microorganisms reversibly attach to the surface. Within the second step, microorganisms excrete extracellular polymeric substances (EPS), enabling them to stick to the surface better and, in the third step, start to proliferate within the EPS matrix. By forming 2D and 3D colonies, the biofilm grows within the fourth step. A biofilm is a highly dynamic system, as, within the fifth step, microorganisms are also able to detach from the surfaces (Renner and Weibel 2011). Next to the adhesion of microorganisms within the first step, another important factor is the adhesion of biomolecules on the particle surfaces. It has been suggested that the adhesion of biomolecules on surfaces appears within seconds (Loeb and Neihof 1975). The initial biomolecule coating is not a stable system, as biomolecules with higher binding affinities may substitute biomolecules with lower binding affinities. Over time a so-called (more or less) stable hard corona develops on the surface of the particle. On top of this hard corona, an additional corona develops, which is highly dynamic with its surrounding environment. This dynamic corona is called the soft corona and is in high exchange with its surrounding environment (Monopoli et al. 2012). The process of the development of a protein corona, especially on the surface of nanoparticles, has intensively been studied in medical research, e.g., for drug delivery using target nanoparticles.

A rather new research field is the coating with biomolecules from complex environments like marine or limnetic ecosystems. The coating with environmental biomolecules is said to be an ecocorona, referred to the similar term "protein corona." An ecocorona can consist of different kinds of biomolecules, like proteins, lipids, or carbohydrates, just to name a few (Galloway et al. 2017a). On a cellular level, it has been shown that particles coated with protein coronas interact differently with cells (Monopoli et al. 2012; Francia et al. 2019). On an organismal level, it has already been shown that the coating with an ecocorona mediates the impact of polystyrene nanoparticles to *D. magna*. Additionally, *D. magna* was less sufficient in removing particles with an ecocorona from their digestive tract compared to particles without an ecocorona. This highlights the importance of including micro- and nanoplastic particles coated with an ecocorona in future experimental attempts, as these may show severe effects that may not occur by using pristine microplastic particles (Nasser et al. 2019).

Another critical aspect that has been widely discussed in the context of environmental impact is the adherence of pathogens on the surface of plastic particles or within the biofilm matrix (Zettler et al. 2013). However, it is not clear whether or not there is a difference in pathogen load on microplastics compared to occurring natural particles coated with a biofilm (Rummel et al. 2017). This again highlights that

besides the use of pristine microplastics and plastic particles coated with an ecocorona, natural particles must also be included as a reference for the risk assessment of microplastics.

### **Effects on Cellular, Tissue, and Physiological Level**

Once ingested, it has been shown in laboratory studies that microplastics can exert adverse histopathological effects in fish, i.e., causing damage to villi structures in the gastrointestinal tract and on the gill membranes. Further, the longer the residence time of microplastic within the organisms is, the more damage occurs to the immune system and blood parameters. In addition, alterations of metabolic profiles indicating disturbed lipid and energy metabolism were reported (Triebkorn et al. 2019). Furthermore, it has been reported that maternal exposure to polystyrene in mice led to metabolic disorders in the offspring (Luo et al. 2019). Beyond laboratory feeding experiments, Barboza et al. (2020) analyzed the microplastic ingestion and accumulation in wild fish. For fish containing microplastics in their brains, gills, and dorsal muscles, they found a significantly higher lipid peroxidation level and increased brain acetylcholinesterase enzyme activity. Some studies have also shown effects at the molecular level using different terrestrial and aquatic organisms by applying an “omics” approach (e.g., Limonta et al. 2019). Here, the authors report on alterations in the expression of immune system genes, indicating that microplastics are identified as stressors.

First attempts have been made to investigate possible negative effects on human cell lines. Similarly, when investigating effects at an organismal level, contradictory results were found. In general, the most often reported effects in human cell lines are the generation of reactive oxygen species and the increase in inflammatory responses (Yong et al. 2020), whereas, in some studies, no effects were found. This inconsistency may originate from various factors. Different cell lines may interact differently with the used particles. The sizes of the particles, as well as the concentrations used, were profoundly different and could, therefore, lead to different results. Another critical aspect in cytotoxicity studies is the choice of particles. The use of surfactants for colloidal stable particle solutions may alter the surface of the used particles. Additionally, surface-functionalized particles may behave entirely different compared to non-functionalized particles.

### **Microplastics: Effects on Morphology, Behavior, Population, and Life History**

The ingestion and possible accumulation of micro- and nanoplastics within body compartments has been suggested to pose a risk to organisms. Depending on the sampling site, environmental concentrations can vary accordingly from few to several thousand particles/L; hence, experimental designs have to consider this. Micro- and nanoplastic particles can alter the behavior, morphology, or life history of an organism at concentrations relevant to environmental exposures. For instance, the exposure of zebrafish (*Danio rerio*) to plastic particles (100 and 1000  $\mu\text{g/L}$ , 50% polystyrene +50% high-density polyethylene) resulted in

alterations of their circadian timekeeping mechanism, resulting in an increased activity during the dark and the loss of the regular diurnal pattern of activity (Limonta et al. 2019). Alterations in the phototactic behavior were shown for *D. magna*, along with increased swimming activity and reproduction after the exposure to three different polystyrene microplastic concentrations (0.125, 1.25, and 12.5  $\mu\text{g}/\text{mL}$ ) (De Felice et al. 2019). The authors suggested that increased swimming activity might be explained as an avoidance behavior or an attempt to eliminate the microplastic particles.

Energy depletion caused by a large number of microplastics in the digestive tract results in reduced food intake, and it can additionally lead to a significantly reduced survival rate, increased development time, and reduced fecundity, as it has been shown for copepods (*Tigriopus japonicus*) and lugworms (*Arenicola marina*) (Duis and Coors 2016). In *Daphnia magna*, microplastic exposure resulted in a reduction in the population growth rate and so in an impairment in the cladoceran's fitness, probably due to a decrease in food intake in the presence of microplastic particles (Martins and Guilhermino 2018).

Impairment in fertility and larval growth was also examined in sea urchins (*Paracentrotus lividus*). In detail, a lower fertilization rate was observed in eggs exposed to plastic particles along with larvae abnormalities and a decreased developmental time (Martínez-Gómez et al. 2017). Other studies reported similar results on plutei larvae (Messinetti et al. 2017). Adverse effects on fertility and larval development were assessed in oysters (*Crassostrea gigas*) as well. In particular, both the sperms and oocytes' numbers decreased and were deteriorated in quality compared to the control organisms. Further, the larval developmental was significantly slower (Sussarellu et al. 2016). The mentioned effects of micro- and nanoplastic exposure to organisms are not only shown for aquatic organisms. Effects from microplastic exposure have already been shown for terrestrial invertebrates, like nematodes, oligochaeta, collembola, or isopods. Studies on nematodes (*Caenorhabditis elegans*) have revealed that smaller microplastic particles impaired the survival rate, the average lifespan, and body growth. Collembolans were found to be more sensitive to microplastic exposure, showing a significant inhibition in growth and reproduction (Zhu et al. 2019).

Considering morphological alterations due to microplastic exposure, the current results are less consistent. Some suggestions have been made that the exposure to microplastic particles may also alter the morphological parameters of daphnids. For instance, it has been shown that *D. magna* shows a larger body size than the control treatment when exposed to microplastics (De Felice et al. 2019). For similar concentrations used, Eltemsah and Bøhn (2019), on the other hand, show now alterations in the body length of daphnids.

This highlights that the causes of the effects on the organisms investigated are not yet understood, primarily since exposure to the same type of plastic has led to adverse effects in some studies, but in others, no effects on the organisms investigated could be observed. Some authors suggest that the alterations on a cellular level may subsequently lead to morphological, behavioral, or life history changes. For

instance, Limonta et al. (2019) discussed that the behavioral alterations observed in zebrafish might originate from very small microplastic particles crossing the blood-brain barrier.

## Microplastics in Plants: A Fairly New Research Field

A fairly new topic on micro- and nanoplastic research is the contamination of plants (Fig. 7). In general, due to the application of sewage sludge from wastewater treatment plants, which has been shown to contain a massive amount of microplastic particles and fibers (Corradini et al. 2019), or due to the application of organic fertilizers (Weithmann et al. 2018), agricultural fields can be contaminated with plastics (Piehl et al. 2018). The possible effects of micro- and nanoplastic pollution on plants can be divided into indirect and direct effects. For terrestrial plants, indirect effects may come from altered soil structure. Depending on the physicochemical parameters as well as the size and shape of the micro- and nanoplastic particles, the soil bulk density, structure, and water holding capacity may be altered (Rillig et al. 2019). This may have effects on the root growth or microbial community composition, which in turn may affect nutrient acquisition. The aquatic plant *Lemna minor* was found not to be altered

**Fig. 7** Plastic and plant growth. A plastic bottle degrades on an agricultural field. (© Simona Mondellini, University of Bayreuth)

in its leaf growth rate and amount of photosynthetic pigments but negatively affected in its root growth. The authors suggest the microplastic particles being adsorbed onto the surface of the roots and mechanically blocking the root growth (Kalčíková et al. 2017). A direct effect of microplastic and nanoplastic contamination is the uptake of the particles into plant tissues. This has been suggested to be unlikely for microplastics but generally accepted for particles in the nano-size range. Recently, it has been shown that functionalized nanoplastic particles adhere to the root surface of *Arabidopsis thaliana* and reduce the root growth correlating with particle concentrations. Furthermore, the nanoparticles may even translocate into the root epidermis cells and the catheter of the xylem (Sun et al. 2020). Although the authors used functionalized particles which are unlikely to occur in nature, these findings indicate that the translocation and further accumulation of nanoplastics in plants are generally possible. Due to methodical and technical limitations in identifying nanoplastics in environmental matrices, the environmental pollution of nanoplastics is currently unknown. Nevertheless, the fact that plants used for food production may accumulate plastics within their tissues may elicit environmental and human health risks.

---

## Microplastics Risk to Humans?

The exposure of humans to plastic particles has extensively been discussed and investigated in the last years. The ubiquitous occurrence of plastics in the environment and consumer products makes human exposure to microplastics inevitable. The most reasonable pathway is discussed to be via ingestion. Microplastic contamination of food and beverages has already been shown. For instance, microplastic particles were found in salt, sugar, processed food, and beverages like beer and drinking water and seafood (Wright and Kelly 2017). Once in the digestive system, there are several adverse effects discussed. Microplastics can potentially be adsorbed by M-cells in the intestine, penetrating the intestinal mucus (Prata et al. 2020). Moreover, the ingestion of microplastics and transfer of endocrine-disrupting chemical additives potentially could be associated with a range of chronic metabolic effects, including infertility, obesity, and cancer (Sharma and Chatterjee 2017).

A further as yet unexamined risk is the intake of microplastic particles via the air we breathe, as it has been shown that up to 16 microplastic particles can be present per m<sup>3</sup> of air (Vianello et al. 2019). Microplastic fibers are shown to be possibly inhaled, likely most of them undergo mucociliary clearance, but in some cases, they can persist in the lung causing obstructions and inflammation, especially in individuals with compromised clearance mechanisms. Persistence in the lungs seems to be connected to the particles' dimension. The longer fibers are the more persistent and the more likely to create obstructions or to penetrate deep in the lung. Furthermore, microplastics can determine granulomatous lesions in the lung tissues and respiratory irritation, a phenomenon mainly observed in the textile industry workers after chronic exposure (Gasperi et al. 2018).

Although the addition of plastics to cosmetics was banned in several countries (Conkle et al. 2017), the uptake via derma is generally discussed to be a possible pathway to enter human bodies, especially for nanoplastics. Nevertheless, the exposure to the associated additives such as bisphenol A or phthalates is discussed to be more alarming (Prata et al. 2020). The extent to which harmful additives such as phthalates are transferred into the human body via microplastics or directly through water, food, or contact with consumer items remains unknown, but it is known that virtually everyone has plastic-associated chemicals in their bodies (CDC 2020).

---

## Synopsis

Overall, the mechanisms underlying the direct and indirect effects of plastics on organisms, as shown so far, are not yet understood. In general, macroplastics cause more obvious ecological effects, whereas the effects of microplastics are not so easy to elucidate. The nature of the effect probably depends mainly on the particles' physicochemical properties, the particle shape, the corresponding degradation stages, and environmental coating and concentration. Yet, the majority of the studies on biological effects were carried out with unrealistically high concentrations of microplastics, whereby the sheer quantity of foreign substances could have caused the observed effects and not the plastic particle per se.

The discrepancy that in some studies, although the same type of plastic was used, effects were found at different biological levels, but not in other studies, is due to the complexity of the issue.

As a result, there are still considerable gaps in knowledge regarding the biological effects of microplastics under realistic conditions. There is a dearth of studies that have been carried out concerning the physicochemical properties of microplastic particles and in comparison to naturally occurring particulate material since ecotoxicological studies have mostly used virgin ground plastics whose physical and chemical properties have not been characterized. Hence, more environmentally relevant studies are needed to assess the risk of microplastics for environmental and human health.

## Abstract

This chapter provides an overview about requirements of textiles regarding different regulation aspects. These legal requirements, among others, must be considered by, e.g., manufacturers and distributors, if textiles or clothing is to be placed on the market. At first, the regulation of harmful substances and chemicals on textiles is described. Since there are separate specifications for antimicrobials

on textiles, this aspect is included, and the regulation of antimicrobial textiles is listed in particular. Furthermore, there is a brief description of regulation of personal protective equipment and medical textiles. As the legal guidelines for textile regulation are country-specific, the requirements are listed for both the European Union and the United States.

**Keywords**

Textile regulations · Harmful/toxic substances · Antimicrobial textiles · Personal protective equipment · Medical textiles

---

**Introduction**

Depending on the intended use, whether in the private or professional sector, customers demand high standards on clothing or protective textiles. In order to meet their specific requirements, the textile fibers used are subject to high-quality process engineering and various finishing processes to give the fabrics high-quality properties (Iheaturu et al. 2019: 23). Those properties are, for example, easy care finishing, water repellency, or flame retardancy (Choudhury 2017: 5).

As a result of these processing steps, residues of harmful substances may possibly remain on the textiles (Muthu 2020: 45–46). Since the textiles are usually worn directly on the skin or very close to the body, it is essential that the textiles do not pose any risk to the wearer.

Another important property of textiles, especially in the professional sector, is the provision of one or more protective functions. These include, for example, protection against microorganisms by antimicrobial textiles; protection of the wearer against hazards such as poor visibility, weather influences, or electrical charge by personal protective equipment (PPE), as well as the protection of patients and medical staff against infections by medical textiles.

To ensure that certain quality and safety standards are maintained by manufacturers and distributors, textiles are subject to country-specific regulations for certain aspects. This should ensure a constant high quality of the textiles, a comparability on the market, and above all a maximum security for the customer.

---

**Regulation of Harmful Substances on Textiles**

Due to impurities from the manufacturing process or addition of certain finishing substances, textiles can be contaminated with harmful chemicals. These can be, for example, organohalogen compounds (AOX), colorants, heavy metals, or formaldehyde (Muthu 2020: 45–46). In order to bring textiles on the market that are harmless to human or environmental health, the textiles must be regulated with regard to harmful chemical residues for which there are country-specific legal requirements.

## Regulation of Harmful Substances on Textiles for European Market

According to European law, chemical substances have to be registered by the Regulation (EC) 1907/2006 REACH (Registration, Evaluation, Authorization and Restriction of Chemicals) at the European Chemicals Agency (ECHA) (Regulation (EC) 1907/2006 [2006](#)). REACH was designed to improve the protection of human health and the environment from the risks posed by chemicals while increasing the competitiveness of the EU chemical industry (European Chemicals Agency [ECHA] [2020a](#)).

At regular intervals, ECHA publishes a Restricted Substances List (RSL) with substances of very high concern (SVHC) that are either completely banned or restricted by limit values. The criteria that identify substances as SVHC are defined in Article 57 of REACH (Regulation (EC) 1907/2006 [2006](#)). These are substances with, for example, carcinogenic, mutagenic, or reprotoxic properties of category 1A or 1B or substances that are persistent, bioaccumulative, and toxic.

REACH obliges all actors in the entire supply chain of the textile and clothing industry to inform ECHA and their customers if the produced goods contain SVHC in a quantity of more than 0.1 mass percent (Haas et al. [2016](#): 23). Products that do not comply with the limit value regulations may no longer be placed on the market after January 11, 2020. According to Article 7(6) the notification obligation is waived if the substances have been registered for a corresponding use. Additionally, the regulation does not apply to textiles that fall within the scope of the Regulation (EU) 2016/425 on personal protective equipment (Regulation (EU) 2016/425 [2016](#)) and the Regulation (EU) 2017/745 on medical devices (Regulation (EU) 2017/745 [2017](#)).

## Regulation of Harmful Substances on Textiles for US Market

According to US law, regulatory actions for specific chemicals (except food, drugs, cosmetics, and pesticides) fall under the Toxic Substances Control Act (TSCA) (15 U.S.C. §2601 *et seq.* [1976](#)). The Environmental Protection Agency (EPA) has regulatory authority under TSCA (Environmental Protection Agency [2020e](#)). This means that EPA evaluates potential risks for human health and the environment from new and existing chemicals and restricts the use of the chemicals if the risk is too high. The process for ensuring the safety of chemicals includes prioritization, risk evaluation, and risk management (Environmental Protection Agency [2020f](#)). Based on information and data provided from chemical suppliers and manufacturers, EPA publishes an inventory list of the existing chemicals with possible restrictions for manufacturing or use in products (Environmental Protection Agency [2020g](#)). Only textiles that comply with the list may be placed on the market.

Additionally, there should be mentioned briefly that in 2008, the Consumer Product Safety Improvement Act (CPSIA) came into force (15 USC §2051 *et seq.* [2008](#)). This law makes demands on consumer goods (for children up to the age of 12) imported into the United States or produced in the United States and has a particular impact on a large number of products, e.g., apparel (Benson and Reczek [2016](#)).

---

## Standard 100 by Oeko-Tex

Different organizations or brands, e.g., the American Apparel & Footwear Association (AAFA), regularly publish their own RSLs in addition to the legally prescribed RSLs (American Apparel and Footwear Association 2020). In 1992, the Oeko-Tex<sup>®</sup> Service GmbH published the first RSL, even before legal requirements regarding the chemical content of textiles were available (Oeko-Tex 2020a). This RSL is updated at least annually and published in the document “Standard 100 by Oeko-Tex<sup>®</sup>” (Oeko-Tex 2020b). The aim of this globally accepted standard was the indication, by means of the label “Confidence in Textiles/Textiles Vertrauen,” to the consumer that textile products are harmless to health. Textile products can only be certified according to Standard 100 by Oeko-Tex<sup>®</sup> if all components meet the required criteria, e.g., not only the fabric but also the sewing threads, prints, buttons, etc. The certificate is valid for 1 year and can be renewed afterward.

The standard considers (i) legally prohibited substances, e.g., by REACH, such as carcinogenic azo dyes; (ii) legally prescribed limit values, e.g., by CPSIA, for chemicals such as formaldehyde, plasticizers, heavy metals, and pentachlorophenol; (iii) substances that are hazardous to health but not prohibited by law, such as pesticides, allergenic dyes, and organotin compounds; and (iv) color fastness, skin-friendly pH value.

The advantage of a globally standardized and recognized certification is that a verified harmlessness of the textile is visible at first sight. This can be used, for example, by conformity assessment bodies for certification of personal protective equipment (PPE). If the products are not tested in the EU but have a valid Standard 100 by Oeko-Tex<sup>®</sup> certificate, the conformity assessment body can rely on that the requirements according to chemical content on the product are fulfilled (see section “Regulation of Personal Protective Equipment (PPE)”).

---

## Regulation of Antimicrobial Textiles

Textiles that are treated or finished with antimicrobials are considered separately for regulation, as the substances used are classified as biocides/pesticides. Again, there are different regulations for the EU and the United States that have to be satisfied regarding the applied antimicrobial substance but also the textile product itself.

## Registration of Antimicrobial Textiles for European Market

When textiles are finished with antimicrobial substances in the EU, these antimicrobial substances have to be registered according to European law by the regulation REACH (Regulation (EC) 1907/2006 2006), whereas registration of antimicrobial textiles is subject to the Biocidal Products Regulation (BPR) ((EU) 528/2012 2012 and (EU) 334/2014 2014).

## Registration of Chemicals by REACH

Since the European regulation REACH entered into force in 2007, substances with at least 1 ton per year manufacturing or usage quantity in Europe have to be registered at ECHA (Bundesinstitut für Risikobewertung [BfR] 2020a). Without registration chemicals may not be placed on the market or may not be further processed (Umweltbundesamt 2020). With some exceptions, which are subject to different legislations, REACH applies to all substances (chemicals) manufactured or used in the EU and also to substances in mixtures or articles (e.g., colors or clothing) (Bundesinstitut für Risikobewertung [BfR] 2020a).

To comply with the regulation, companies must identify and manage the risks associated with the substances they manufacture or place on the EU market. They must demonstrate to ECHA how the substance can be used safely, communicate the risk management measures to users, and cooperate with other companies that register the same substance (Fisk 2014). Additionally, downstream users have to provide information on the exact use of the processed substances (e.g., in antimicrobial textiles) for manufacturers or importers so that they can consider the use in their technical dossier and, if necessary, in their exposure scenarios and recommend appropriate risk reduction measures (Fisk 2014). ECHA's authorities and scientific committees assess after submission of the registration documents whether the risks of substances can be controlled. The authorities can also prohibit hazardous substances if their risks cannot be controlled (European Chemicals Agency [ECHA] 2020a).

In addition to regulations for chemical substances that are further processed in the EU, there are also regulations for the production, market provision, and marketing of antimicrobial products.

## Registration of Antimicrobial Textiles According to the BPR

The Biocidal Product Regulation (EU) 528/2012 (Regulation (EU) 528/2012 2012 and Regulation (EU) 334/2014 2014) regulates the sale, supply, and use of biocidal products, except medical devices, in the EU which are defined as compounds or compositions that contain active substances that engage harmful organisms chemically or biologically.

The objective of the regulation is to harmonize the provision of biocidal products on the market and their use within the EU while ensuring a high protection level of human, animal, and environmental health (Bundesanstalt für Arbeitsschutz und Arbeitsmedizin 2020a).

The authorization of biocidal products is carried out in two steps. First, the biocidal active substance has to be approved (EU active substance test), and the biocidal active substance is included in an EU list (EU-wide positive list; published by ECHA) of approved active substances (European Chemicals Agency [ECHA] 2020b). Afterward, biocidal products containing the active substance can be approved in an authorization procedure. For this, each EU member state has a competent authority that examines the submitted information by the companies regarding efficacy, toxicology, residue, and environmental fate of the biocidal product. If the authorities have no concerns, the biocidal product will be authorized for the requested application (Bundesinstitut für Risikobewertung [BfR] 2020b).

Depending on their intended application, antimicrobial textiles do not always need to be authorized because the BPR also differentiates between treated goods and biocidal products (Bundesanstalt für Arbeitsschutz und Arbeitsmedizin 2020b). Treated goods include textiles that are finished with antimicrobial agents for their own protection against microorganisms, for example, to increase their lifetime (e.g., geotextiles or outdoor textiles). Regarding authorization, treated goods do not need to be approved. But the active substances contained must be approved for the relevant product type and intended use and have to fulfill the conditions or restrictions specified in the approval (Regulation (EU) 528/2012 2012 and (EU) Regulation (EU) 334/2014 2014). Antimicrobial textiles that claim to kill or reduce microorganisms are biocidal products and need to be authorized by the BPR.

The registration of an antimicrobial textile has a maximum duration of 10 years, but after this time an extension of the registration is possible. There is also a requirement for special labelling for information of customers or distributing companies regarding biocidal substances in antimicrobial textiles. Concerning advertisement, it is not allowed to trivialize the biocidal activity of the antimicrobial textile.

## Registration of Antimicrobial Textiles for US Market

In the United States, the federal law that directs the registration, distribution, sale, and use of pesticides is the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) (7 USC). (Environmental Protection Agency 2020a). The Environmental Protection Agency (EPA) has regulatory authority under FIFRA for pesticides which means that before a pesticide may be sold, distributed, or used in the United States, it must be registered by the EPA (Sanders 2003). If products are to be sold in different US states, they must be registered in each state in which these products are distributed. Pesticides produced by foreign manufacturers and imported for sale or distribution in the United States must comply with all requirements. This includes registering the pesticide product before starting production (Environmental Protection Agency 2020b).

FIFRA defines an antimicrobial pesticide on the one hand as any substance or mixture of substances that is intended to disinfect, sanitize, reduce, or mitigate growth of microorganisms (fungus, virus, bacteria, or other microorganisms which are not located in or on humans/animals). On the other hand, antimicrobial pesticides are supposed to protect surfaces or substances from contamination, fouling, or deterioration caused by microorganisms (Environmental Protection Agency 2020c).

Since the enactment in 1947, the main objective of FIFRA is to ensure that pesticides do not pose an unreasonable risk to human health or the environment when they are used as intended (Environmental Protection Agency 2020a). Registration requires the submission of various technical and scientific data to demonstrate that the product is safe. Depending on the intended use of the antimicrobial product or textile, there have to be, for example, proposals for product labelling, additional

toxicity tests, skin safety tests, or antimicrobial efficacy tests to enable EPA to evaluate the product for registration.

Regarding antimicrobial textiles, a distinction is made between public health and non-public health antimicrobial textiles (Environmental Protection Agency 2020d). Public health textiles claim to be effective in controlling microorganisms infectious to humans (Environmental Protection Agency 2020d). Such products need registration and efficacy test data. A sufficient effectiveness is demonstrated when the amount of test microorganisms on the textile is reduced by 99.9% in comparison to a control textile. Public health antimicrobial pesticide textiles are labeled with terms like “fights germs” or “provides antibacterial protection.”

Non-public health textiles claim to control microorganisms of economic or aesthetic significance where the presence of the microorganism would not normally lead to infection or disease in humans (Environmental Protection Agency 2020d). For registration of non-public health textiles, no efficacy data are required, but they still have to be kept on file in case of data requests. The purpose of the textile has to be labeled on the product like, e.g., “control of odor-causing bacteria” or “control of bacteria which cause spoilage, deterioration or fouling.”

Treated articles (specific criteria in 40 CFR 152.25 (a)) contain a pesticide only to protect the product itself and do not need registration. They make no claims about the treatment, or they claim only that it is treated to resist microbial growth (Environmental Protection Agency 2020d).

---

## Regulation of Personal Protective Equipment (PPE)

Personal protective equipment (PPE) is any equipment intended to be used or worn by employees to protect themselves against a hazard to their safety and health. There are different types of PPE, for example, head protection, eye protection, hearing protection, respiratory protection, hand and arm protection, protective clothing, leg and foot protection, or protection against falls.

In Europe, the regulation of medical textiles is not covered in all cases by PPE Regulation but also by the Medical Device Regulation or both. For this reason, medical textiles are dealt with in a separate chapter (see section “[Regulation of Medical Textiles](#)”).

## Regulation of PPE for European Market

PPE for the European market must meet the requirements of the Regulation (EU) 2016/425 (Regulation (EU) 2016/425 2016) before a product is to be placed on the market. This requires that manufacturers and distributors must prove in the context of a conformity assessment procedure that the PPE actually meets the requirements for each product (European Commission 2020). Depending on the risk to which the wearer is exposed, products are divided into three different categories. The classification of PPE into categories is based on Annex I of the PPE Regulation (Regulation

(EU) 2016/425 2016). Depending on the category of the product, there is variation in the conformity assessment procedure:

- Category I (low risk): no EU-type examination is required, the EU declaration of conformity is under manufacturer's own responsibility, and an internal production control is required (Annex IV (module A)).
- Category II (every risk that is not listed under category I or category III): the conformity assessment body issues an EU-type examination certificate based on a product model as well as an EU declaration of conformity (Annex V (module B)). A regular internal production control of the manufacturer is required (Annex VI (module C)).
- Category III (high risk; PPE designed to protect against fatal risks or serious irreversible damage to health): the conformity assessment body issues an EU-type examination as well as an EU declaration of conformity (Annex V (module B)). A regular control of the product according to Annex VII, module C2, or Annex VIII, module D, is required.

Additionally, PPE must meet the so-called essential health and safety requirements. These requirements are specified in Annex II of the Regulation (EU) 2016/425. Examples for these requirements are compliance with design principles, convenience, harmlessness with regard to chemicals, presence of instructions, and information like a technical documentation (specified in Annex III). Depending on the protective function of the product, e.g., against weather, electrical charge, etc., additional requirements for the different types of PPE or for special risks have to be fulfilled. These special requirements are summarized in different standards, e.g., for high visibility (DIN EN ISO 20471 2017), electrostatic properties (DIN EN 1149-5 2018), or protection against heat and flames (DIN EN ISO 11612 2015). If the PPE product meets all requirements, this will be identified with a CE marking.

## Regulation of PPE for US Market

In the United States, a PPE product for a certain industry (e.g., general industry, construction, agriculture) must meet the requirements of the Occupational Safety and Health Act (29 CFR part 1910 subpart I; part 1926 subpart E 1970) which is regulated by the Occupational Safety and Health Administration (OSHA). OSHA sets and enforces standards and additionally provides training, outreach, education, and assistance for PPE. Furthermore, depending on the security level, the product is classified, and performance tests have to be carried out at a nationally recognized testing laboratory.

Separate standards have also been defined for diverse application areas. These include PPE for the fire service (National Fire Protection Association NFPA Standard) or the US army (Army Regulation AR 385-10 2017). Since the description of the individual standards is too complex for this chapter, they will not be discussed further.

## Regulation of Medical Textiles

Medical textiles are designed to protect the patient as well as medical personnel against, e.g., injuries caused by laser beams or the transmission of infectious agents. A distinction is made, for example, between radiation protection clothing, mouth-nose protection, and surgical clothing.

### Regulation of Medical Textiles for European Market

In contrast to the United States, in Europe the classification of a textile as a medical device or as PPE depends on the intended purpose of the product. If the product is intended to protect a patient, the product is a medical device. If the product is supposed to protect the user against one or more risks to his health or safety, the product must be classified as PPE. A simultaneous classification as a medical device and PPE is possible if a product serves both purposes. In this case the requirements of the Medical Device Regulation (EU) 2017/745 and the PPE Regulation (EU) 2016/425 [2016](#) have to be fulfilled.

In order to obtain a marketing authorization for medical devices in Europe, proof must be provided that essential performance and safety requirements meet the Medical Device Regulation (EU) 2017/745 (Regulation ( mEU) 2017/745 [2017](#)). The conformity assessment procedure of medical devices which is carried out of a conformity assessment body is class dependent (class I, class II a, class II b, or class III) and in some points similar to the procedure for PPE, e.g., provision of a technical documentation, testing, and quality assurance. The fact that the basic requirements for a medical device are fulfilled is also documented by the CE marking.

### Regulation of Medical Textiles for US Market

In the United States, the OSHA requires medical personnel to wear PPE for their protection against infections (Kilinc [2016](#)). Depending on the intended use, this PPE may be certified as a medical device (FDA [2020a](#)). Medical devices are regulated by the Food and Drug Administration (FDA) in order to meet the Federal Food, Drug, and Cosmetic Act (FD&C Act)(21 USC ch. 9). FDA's Center for Devices and Radiological Health (CDRH) is responsible for regulating firms who manufacture, repackage, re-label, and/or import medical devices sold in the United States. Depending on the intended use of the medical device, the products are classified (FDA [2020a](#)):

- Class I (low risk): either no premarket approval or a 510(k) process (21 CFR Part 807 Subpart E) is required; general controls have to be conducted.
- Class II (moderate risk): a 510(k) process or a premarket approval process (PMA) (21 CFR Part 814) is required for approval; general or special controls have to be conducted.

- Class III (high risk): devices have to be approved by the PMA process; general controls or special controls have to be conducted.

For example, due to its barrier performance (ANSI/AAMI PB70:2012) against liquid and microorganisms, a medical gown is subdivided into three types of gowns (FDA 2020b) with different classification as medical device: non-surgical gowns (class I), surgical gowns (class II), and surgical isolation gowns (class III) (21 CFR 878.4040).

Besides a premarket approval, there is a need for, e.g., performance tests, special labelling of the product, and proof and compliance of quality system regulations or medical device reporting (FDA 2020b).

---

## Conclusion

This chapter shows that a regulation of textiles is very comprehensive and can vary widely depending on the intended use of the textile. In Europe as well as in the United States, strict and complex regulations are established, and compliance with them is monitored. However, these regulations are essential to ensure that certain quality and safety standards of the products are maintained and that users can rely on the highest possible level of safety and protection.

## Abstract

While most greenhouse gases are not toxic and no pollutants, their increasing concentration in the atmosphere is enhancing the greenhouse effect and causing climate change. Climate change however is a massive threat to all global life-sustaining systems, and it will among other highly damaging consequences probably also create significant health problems. This chapter first explains the natural science basics of the greenhouse effect and its link to the global commercial energy system. Second, it outlines the challenges connected to changing the global energy systems and what changes would be needed to prevent dangerous global warming. Third, the global governance system is presented which has been established at the United Nations since 1992 to address climate change. Finally, the chapter discusses what societal changes would be necessary and enable the “great transition” to a just and sustainable global society, how the current Coronavirus pandemic could be a start to such a transition, and how the recently announced European Green Deal might be a prototype policy on this way.

## Introduction

The so-called greenhouse gases have no adverse health effects at the concentrations that prevail in the atmosphere. The two most important, water vapor and carbon dioxide, are natural components in the atmosphere. However, due to the massive burning of fossil energy carriers, such as coal, oil, and natural gas, the human economy is increasing the atmospheric content of carbon dioxide and other greenhouse gases in the atmosphere. For carbon dioxide, the concentration has increased by almost 50% above the levels that prevailed before the beginning of the Industrial Revolution in the mid-nineteenth century. Thereby, the beneficial balance of the greenhouse effect is altered, and global mean temperatures are bound to increase with very significant consequences for virtually all life on Earth.

Although the effect was detected and already described by Swedish scientist Svante Arrhenius in the late nineteenth century, it took the global community almost a century before starting to act. In 1992 at the Earth Summit in Rio de Janeiro, the

UN Framework Convention on Climate Change (UNFCCC) laid the foundations for a global governance system to tackle climate change. However, as basically all economic activities are linked to the use of energy from fossil fuels, reducing their use is a huge challenge which affects all areas of daily life. In spite of their political aims, so far the global community has not been able to stop the still growing trend of greenhouse gas emissions. Therefore, significant action becomes ever more urgent if catastrophic consequences from climate change are to be prevented.

Today the world is at crossroads regarding climate change. Virtually in these days, the world is reaching the point after which it will be impossible to prevent global temperatures to rise beyond the level of dangerous interference with the climate system. At the same time, due to the global Coronavirus crisis, the world has for the first time in years seen falling greenhouse gas emissions in 2020. If nations around the globe are able to use the current crisis and the immense expenditures that are being undertaken to buffer its consequences on the global economy as a catalyst to change the trajectories of the energy system toward a more sustainable route, the world may currently see its probably last chance to escape some of the worst potential consequences of climate change. If, however, a “back-to-normal fossil energy use” will dominate the coming months and years, the world will probably not be able to bend the curve fast enough later. This will mean that the world will set itself inevitably on a highly dangerous climate trajectory.

In the following, first the basics of the greenhouse effect and its link to the global commercial energy system are explained. The second section sketches the challenge of changing global energy systems and what changes would be needed to prevent dangerous global warming. The global governance system established since 1992 is then described in the third section. Finally, the fourth section discusses what societal changes would be necessary and enable the “great transition” to a just and sustainable global society, how the current crisis could be a start to such a transition, and how the recently announced European Green Deal might be a prototype policy on this way.

What this chapter does not cover is the vast field of adaptation of human societies and natural ecosystems to the impacts of climate change that can no longer be avoided.

---

## **Global Warming and the Greenhouse Effect**

The fact that the Earth is habitable depends on its unique atmosphere which provides air to breathe, water, and mild temperatures. The moderate temperatures on the surface of the globe are mainly resulting from the fact that the atmosphere traps large parts of the sunlight reaching the planet and converts it to heat, which is then distributed all over the planet’s surface via mass movements of air and water.

This trapping function can be compared to a greenhouse, which also traps sunlight to keep its inside warmer than its surroundings. Its basic physics is explained briefly in sections “[Brief Explanation of the Greenhouse Effect](#)” and

“[Overview of Greenhouse Gases and Their Global Warming Potential](#).” Unfortunately, the amount of gases in our atmosphere (the atmospheric concentration of greenhouse gases) that create this beneficial greenhouse effect is rising. This leads to a higher radiative forcing, i.e., higher amounts of solar radiation are trapped and the greenhouse – our habitat on the Earth’s surface – is warming. Section “[Global Warming Caused by the Greenhouse Effect](#)” briefly sketches global mean temperature fluctuations since the last Ice Age and what change is expected for the coming decades. Section “[Climate Damages and Tipping Points: Why Is It Necessary to Limit Global Warming?](#)” then explains why the rapid changes in global mean surface temperatures that we are witnessing today and expecting for the decades to come are so dangerous for nature and humankind.

## Brief Explanation of the Greenhouse Effect

For understanding climate change, it is important to distinguish between the terms “climate” and “weather.” The term “weather” refers to the short-term condition in terms of temperature, precipitation, wind, etc. at a specific location at a specific time. The term “climate,” on the other hand, refers to the long-term average of the weather over a certain period of time. Normally, these variables are averaged over a period of 30 years. Climate change therefore means a change in the long-term average or the variability of the variables (IPCC 2018a). For decades, in particular, the average global air temperature has been rising steadily despite annual fluctuations. It is currently around 1 °C above the average before the start of industrialization (IPCC 2018c).

### **Box: The Intergovernmental Panel on Climate Change (IPCC)**

While the basic mechanisms of the greenhouse effect and climate change had been described correctly already in the nineteenth century, it was only in the 1980s that there was an increasing realization that climate change was indeed occurring and was going to cause severe impacts. As one reaction, in November 1988, the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) established the Intergovernmental Panel on Climate Change (IPCC). Nowadays, nearly all countries of the world are members of the IPCC (IPCC Website 2020).

Its task is to investigate the risks and consequences of climate change and to present strategies and measures for avoiding dangerous climate change and for adapting to it. The IPCC does not conduct any research of its own but compiles the results of existing research in so-called Assessment Reports and Special Reports. Its latest (fifth) Assessment Report was published in 2013/2014, but scientists are currently working on the sixth Assessment Report due in 2021 or 2022.

(continued)

Each Assessment Report consists of three volumes, each of which is prepared by a specific working group. Working group 1 addresses the scientific basis of climate change, i.e., the details behind the facts outlined in section “[Global Warming and the Greenhouse Effect](#).” Working group 2 addresses the vulnerability of socioeconomic and natural systems to climate change and its impacts as well as ways in which people can adapt to global warming, topics not covered in this chapter. Working group 3 discusses political and technological measures to mitigate climate change, i.e., aspects touched upon here in section “[Current and Future Emissions of Greenhouse Gases](#).”

The Assessment Reports undergo a multi-stage peer review in three consecutive rounds, including reviews by governments and outside experts. In addition, independent review editors make sure that the revisions take due account of all the comments. Each report contains a summary for policy-makers. These summaries are discussed and adopted line by line by governments in a plenary session of the IPCC. At the end of the procedure, the IPCC plenary approves the entire report, including the summary for policy-makers (IPCC 2013a). By this procedure, governments officially recognize the validity of the scientific statements made in the IPCC reports.

Most of the material presented in this chapter draws on several reports by the IPCC.

Climate change can therefore not be “proved” or “disproved” by a particularly hot or cold season or year. Only the long-term trend is meaningful. The change in the global average temperature should also not be measured by fluctuations in daily temperature. Seemingly small changes in average temperature quickly have considerable consequences. The difference in global average temperature between today and the last glacial maximum at around 20,000 BC, when vast ice sheets covered much of North America, Northern Europe, and Asia, is only 5 °C (Otto-Bliesner et al. 2006). Even the warming of about 1 °C that has occurred so far already has clear consequences for food and water supplies (see further below).

Central to climate change is the so-called greenhouse effect. In a greenhouse, sunlight passes through the glass roof and walls largely unhindered and heats the greenhouse. The heat cannot escape through the roof and walls. A similar effect occurs in the atmosphere due to the so-called greenhouse gases (GHG). From the sun, high-energy short-wave radiation falls to the Earth and penetrates the atmosphere to the Earth’s surface largely unhindered. As the Earth’s surface is absorbing the short-wave radiation, it warms up and emits the heat in the form of long-wave radiation. This radiation is to a large extent absorbed by the GHGs in the atmosphere and then radiated again in all directions (see Fig. 1). The GHGs thus retain a part of the heat energy on the Earth’s surface that would otherwise be radiated into space. It is the natural greenhouse effect that made life on Earth possible in its present form in

**Fig. 1** Estimate of the Earth's annual and global mean energy balance. Over the long term, the amount of incoming solar radiation absorbed by the Earth and atmosphere is balanced by the Earth and atmosphere releasing the same amount of outgoing long-wave radiation. About half of the incoming solar radiation is absorbed by the Earth's surface. This energy is transferred to the atmosphere by warming the air in contact with the surface (thermals), by evapotranspiration, and by long-wave radiation that is absorbed by clouds and greenhouse gases. The atmosphere in turn radiates long-wave energy back to Earth as well as out to space. (Source: Le Treut et al. 2007, FAQ 1.1, Figure 1, with kind permission of IPCC Secretariat, Web Information and Publications)

the first place: it causes the Earth's surface to warm by 33 °C, raising the average global temperature to about 14 °C. Without the natural greenhouse effect, it would be about -18 °C (IPCC 2007).

## Overview of Greenhouse Gases and Their Global Warming Potential

Various GHGs occur naturally, including water vapor (H<sub>2</sub>O), carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>), nitrous oxide (N<sub>2</sub>O), and ozone (O<sub>3</sub>) (IPCC 2018a). Through various industrial and agricultural activities, humans are increasing the concentration of greenhouse gases in the atmosphere. CO<sub>2</sub> is the main contributor to the anthropogenic greenhouse effect. It is released by the combustion of fossil fuels – lignite and hard coal, crude oil, and natural gas – and the progressive clearing of forests. Since the beginning of industrialization, humanity has increased the atmospheric CO<sub>2</sub> concentration from 280 ppm (parts per million, i.e., parts of carbon dioxide per million parts of the atmosphere) to about 410 ppm. This value exceeds by far the natural range of atmospheric CO<sub>2</sub> concentration of the last 800,000 years, which could be determined by ice drilling (Lindsey 2020).

Other GHGs emitted by humanity are (IPCC 2007):

- Methane (CH<sub>4</sub>), which is emitted during the production and transport of coal, natural gas, and oil. Livestock rearing, rice cultivation, and other agricultural practices also cause methane emissions, as well as the decay of organic waste in solid waste landfills.
- Nitrous oxide (N<sub>2</sub>O), which is emitted by certain agricultural and industrial activities, combustion of fossil fuels and solid waste, as well as during treatment of wastewater.
- Fluorinated gases do not occur naturally and are entirely human-made: Hydrofluorocarbons, perfluorocarbons, sulfur hexafluoride, and nitrogen trifluoride are synthetic gases that are emitted from various industrial processes.

All these gases have differing impacts on the climate system, depending on their behavior in the atmosphere and their atmospheric lifetime. GHGs are compared according to their global warming potential (GWP), which is a measure how much heat a GHG captures in the atmosphere during a specific timeframe. CO<sub>2</sub> is defined as the baseline with a GWP of one over all time periods.

Table 1 shows the GWP of the main categories of anthropogenic GHGs.

One of the reasons why it is so difficult to solve the climate problem is that almost all economic activities emit greenhouse gases. The generation of electricity and heat accounts for the largest share of these emissions, accounting for a quarter. Agriculture and forestry are only just behind with 24%. Emissions from these sectors are mainly due to the clearing of forests in southern countries and high emissions from livestock farming and rice cultivation. Other high emissions come from industry with 21% and transport with 14% (IPCC 2013b).

**Table 1** Atmospheric lifetime and GWP relative to CO<sub>2</sub> at different time horizons for various greenhouse gases

Gas name	Lifetime (years)	Global warming potential (GWP) for a given time horizon without feedbacks	
		20 years	100 years
Carbon dioxide (CO <sub>2</sub> )	N.a. <sup>a</sup>	1	1
Methane (CH <sub>4</sub> )	12	84	28
Nitrous oxide (N <sub>2</sub> O)	121	264	265
HFC-134a (hydrofluorocarbon)	13.4	3710	1300
CFC-11 (chlorofluorocarbon)	45.0	6900	4660
Sulfur hexafluoride (SF <sub>6</sub> )	3200	17,500	23,500
Nitrogen trifluoride (NF <sub>3</sub> )	500	12,800	16,100

Source: Own compilation based on IPCC 2013b

<sup>a</sup>For CO<sub>2</sub>, it is difficult to give a single estimate of its lifetime, as a part of it is rather quickly absorbed, e.g., by oceans, but other parts remain in the atmosphere for a very long time (<https://www.yaleclimateconnections.org/2010/12/common-climate-misconceptions-atmospheric-carbon-dioxide/>)

## Global Warming Caused by the Greenhouse Effect

### History

The relation between the atmospheric concentration of greenhouse gases, the radiative forcing (i.e., the increased retention of long-wave heat radiation within the atmosphere), and global mean surface temperatures has been well established by science (see section “[Overview of Greenhouse Gases and Their Global Warming Potential](#)”). This has been shown by physical modelling as well as observations of past global trends. While the physical basics, i.e., the fact that greenhouse gases trap heat radiation, are well known, it is difficult to measure the effects on the mean temperature of such a big and complex system as the Earth as a whole. Latest research therefore has mainly concentrated on better understanding how the Earth’s mean surface temperature has changed in different places over land and over sea and in different layers of the atmosphere and over time, as well as how the energy stores provided by the oceans, the glaciers, and big ice sheets have changed. This has been done by “diverse measurement groups in multiple countries using different technologies, investigating various climate-relevant types of data, uncertainties and processes” (IPCC 2007, p. 129).

Figure 2 shows that global average CO<sub>2</sub> concentrations have been slightly increasing over the last 10,000 years since the last ice age as proven by ice core measurements. However, since the twentieth century, their levels have been increasing at a speed that has been unprecedented over the 10,000 years before (Holocene epoch). Global mean temperatures have shown a largely similar trend with a strong increase since the beginning of the industrial revolution around 1850 (see Fig. 3). Today, average temperatures have reached levels around 1 °C above preindustrial levels and are rising with seemingly increasing speed. The figure shows that by now global mean surface temperatures have left the range of temperatures seen in the

**Fig. 2** Atmospheric concentrations and corresponding radiative forcing of carbon dioxide over the last 10,000 years. Measurements are shown from ice cores (symbols with different colors for different studies) and atmospheric samples (red lines). The corresponding radiative forcings are shown on the right-hand axis of the large panel. (Source: IPCC 2007, Figure SPM.1 with kind permission of IPCC Secretariat, Web Information and Publications)

**Fig. 3** Evolution of global mean surface temperatures (GMST) over the period of instrumental observations. Gray shaded line shows monthly global mean surface temperatures from different datasets, expressed as departures from 1850 to 1900, with varying gray line thickness indicating inter-dataset range. All observational datasets shown represent GMST as a weighted average of near surface air temperature over land and sea surface temperature over oceans. Human-induced (yellow) and total (human- and naturally forced, orange) contributions to these GMST changes are shown calculated following Otto et al. (2015) and Hausteine et al. (2017). Fractional uncertainty in the level of human-induced warming in 2017 is set equal to  $\pm 20\%$  based on multiple lines of evidence. Thin blue lines show the modelled global mean surface air temperature (dashed) and blended surface air and sea surface temperature accounting for observational coverage (solid) from the CMIP5 historical ensemble average extended with RCP8.5 forcing (Cowtan et al. 2015; Richardson et al. 2018). The pink shading indicates a range for temperature fluctuations over the Holocene (Marcott et al. 2013). Light green plume shows the AR5 prediction for average GMST over 2016–2035 (Kirtman et al. 2013). (Source: Allen et al. 2018, Figure 1.2 with kind permission of IPCC Secretariat, Web Information and Publications)

Holocene (i.e., since the Ice Age) and are well on track to reach 1.5 °C warming soon.

## Future

How global mean surface temperatures will develop in the coming years depends on three main factors. The first factor are the greenhouse gases that have already been emitted. A significant share of the main anthropogenic greenhouse gas  $\text{CO}_2$  remains in the atmosphere for thousands of years. Therefore, it will contribute to warming for a very long time. Other greenhouse gases such as  $\text{CH}_4$ , however, stay in the atmosphere for shorter periods, so the effects of past emissions will fade sooner. The second factor increasing warming are the future emissions of greenhouse gases, as they further add to the already increased warming potential. The third factor are feedback effects by the Earth system. These are so-called “flywheel-effects” and “tipping points” that are to be expected due to temperature rises already seen. For

example, the oceans have stored a significant share of additional warming over the last decades, as they warm up very slowly. Now this might change and they may not store that much of the additional warming any more, and they will prevent temperatures from declining for long. Other effects are the melting ice shields and declining snow covers in high latitudes. With less white ice and snow on the Earth’s surface, more solar radiation is absorbed by the now darker surfaces of land and sea which again accelerates warming.

Figure 4 shows how future global mean surface temperatures could develop under a set of assumptions on future GHG emissions. Due to many uncertainties in knowledge and particularly feedbacks by the Earth system, these projections have wide ranges of uncertainty as depicted for the case of no future GHG and aerosol emissions. The figure shows (in yellow) that for the hypothetical case that the world would basically stop emitting anything now, temperatures would probably still rise

**Fig. 4** Warming commitment from past emissions of greenhouse gases and aerosols. Global mean surface temperature change for scenarios with different combinations of greenhouse gas and aerosol precursor emissions reduced to zero in 2020. Variables were calculated using a simple climate-carbon cycle model (Millar et al. 2017) with a simple representation of atmospheric chemistry (Smith et al. 2018). The bars on the right-hand side indicate the median warming in 2100 and 5–95% uncertainty ranges (also indicated by the plume around the yellow line), taking into account one estimate of uncertainty in climate response, effective radiative forcing and carbon cycle sensitivity, and constraining simple model parameters with response ranges from AR5 combined with historical climate observations (Smith et al. 2018). Temperatures continue to increase slightly after elimination of CO<sub>2</sub> emissions (blue line) in response to constant non-CO<sub>2</sub> forcing. The dashed blue line extrapolates one estimate of the current rate of warming, while dotted blue lines show a case where CO<sub>2</sub> emissions are reduced linearly to zero assuming constant non-CO<sub>2</sub> forcing. The time to stabilize temperatures at 1.5 °C is approximately double the time remaining to reach 1.5 °C at the current warming rate. (Source: Allen et al. 2018, Figure 1.5, with kind permission of IPCC Secretariat, Web Information and Publications)

during the 2020s but decline after 2030 and reach a level of about 0.8 °C above preindustrial levels by the end of the century (right axis). There would, however, be a small chance that temperatures by 2100 would still be higher than today. The dotted blue line shows what would happen if CO<sub>2</sub> emissions were reduced to zero globally over the next 50 years. In that case, global temperatures would almost stabilize with a 50% chance at 1.5 °C above preindustrial levels. Further reductions in other GHG emissions could further reduce temperature levels but only slightly. However, GHG mitigation typically goes hand in hand with reduction of air pollutants which reduces atmospheric contents of, e.g., sulfur dioxide. This is very good for health and environment, but current levels of these aerosols (or simply spoken air pollution) have a cooling effect on the global atmosphere as they reflect some of the incoming solar radiation back to space. However, this effect will probably decline as emissions are reduced.

These rather simple modelling exercises demonstrate what it would take to stabilize global warming to something around 1.5 °C above preindustrial levels, as agreed by international climate policy (see following sections): CO<sub>2</sub> emissions need to be phased out over the next 50 years, and other GHG emissions also need to be reduced quickly, if the chance of reaching the target shall be above 50%.

## **Climate Damages and Tipping Points: Why Is It Necessary to Limit Global Warming?**

Climate change is already having noticeable and overall negative effects on global crop yields and the availability of drinking water. This development will intensify in the future. Due to rising temperatures, many types of food will produce lower yields in the areas where they were previously grown; some will no longer be able to be grown there at all. In addition, climate change will lead to a shift in precipitation patterns: in many regions where there is already little precipitation today, even less will fall in the future. As a result, the yields of rain-irrigated agriculture will fall sharply in some regions. The changing precipitation patterns will also significantly affect the availability of drinking water. Numerous rivers that are central to the drinking water supply are currently supplied with water from melting snow and ice in the summer, especially in the dry season. As the glaciers melt, these natural water reservoirs will decline or disappear, and water supply of the rivers will increasingly fluctuate with much higher chances of draught in the dry seasons. In addition, rising sea levels in coastal areas and on smaller islands lead to salinization of groundwater and soil. Sea-level rise also threatens the very existence of many small island states, many of which are only barely higher than the current sea level (IPCC 2014a).

Furthermore, there is a high likelihood of sudden, nonlinear, and irreversible changes if certain “tipping points” are crossed. While the precise levels of climate change that would trigger a tipping point are uncertain, if one was triggered, the impacts would be highly negative. Potential tipping points that have been identified by climate science include (Lenton et al. 2008, 2019):

- The Atlantic Meridional Overturning Circulation, which brings warm water from the Gulf of Mexico to Europe and transports cool water southward, could be shut down by the influx of freshwater from the Polar ice melt.
- The Greenland ice sheet and the West Antarctic ice sheet could disintegrate, each of which would raise sea levels by several meters.
- The Amazon rainforest as well as boreal forests in Northern latitudes could die back as a result of weather changes, increasing forest fires and insect disturbances, which would release the carbon currently stored in the forest biomass into the atmosphere.
- The permafrost in Northern latitudes could melt, which would lead to the release of methane hydrates (i.e., strong greenhouse gas emissions of CH<sub>4</sub>) currently locked into the permafrost.
- Coral reefs, which are crucial ecosystems and support fishing and tourism in many countries, may die off irreversibly.
- The Indian monsoon could shift, endangering food supplies in the world's most populated region.

Overall, climate changes will be far more pronounced in the tropical and subtropical climate zones – where the majority of the so-called developing countries are located – than in the temperate climate zones, which is predominantly home to industrialized countries. It is therefore precisely those people who have contributed least to the effects of global warming who will suffer most. Moreover, many of the people living in these regions lack the physical, social, economic, and technological resources to adapt to the forthcoming climate changes. People and population groups who are disadvantaged by society on the basis of their gender, age, illness, or membership of a minority and who are already suffering from hunger and poverty are therefore particularly vulnerable. These are above all the rural population, especially small farming families, landless farmers and day laborers, and nomads (IPCC 2014a).

For a long time, climate policy had operated under the assumption that such impacts would be manageable if global warming was stabilized below 2 °C. However, new scientific findings over the last decade have increasingly led to the realization that severe impacts must be expected already at 2 °C and that some tipping points may already be crossed at this level of warming. In 2018, a special report by the Intergovernmental Panel on Climate Change (IPCC) concluded that the differential of risk is indeed substantial. For example, if warming was stabilized at 1.5 °C, a part of the global coral reefs might be saved, while probably nearly all coral reefs will die off if warming is stabilized only at 2 °C (IPCC 2018c).

---

## Current and Future Emissions of Greenhouse Gases

The discussion above makes it clear how dangerous the emission of greenhouse gases is. It is therefore extremely relevant to reflect on future trajectories of greenhouse gas emissions, which are strongly linked to the core economic activities

ranging from housing, transport, industrial activities, and waste treatment to agriculture and land use. The following section gives some details about the main activities causing the emission of greenhouse gases and their relative shares. It also shows how these emissions would develop if the current level of action to reduce GHG emissions remained unchanged and how they would need to develop if the world was to achieve its targets on mitigating dangerous climate change. Section “[What Would It Take to Stay Within the Limits of the Climate System?](#)” provides more detail on what it would mean to reduce emissions so far that the 1.5 °C target would be achievable. Finally, section “[The Economics of GHG Emissions and Their Mitigation](#)” discusses what it would cost to change the trajectory of the global energy system and which sectors would be losers or winners.

## Scenarios of Future GHG Emissions

Anthropogenic emissions of CO<sub>2</sub> and other greenhouse gases are mainly stemming from our energy use and energy systems plus from agriculture as well as burning and destruction of forests and moors. With growing population and wealth, energy needs as well as GHG emissions have steadily grown over the last decades – with only small interruptions due to the financial crisis from 2008 to 2010 or the oil price crises of the 1970s – and are expected to rapidly increase in the future if no countermeasures are taken.

As these are the underlying systems and energetic drivers of our whole economy, or as it is often put our “industrial metabolism” as a society, changes are difficult and will be felt everywhere. In other terms, the energy use of our homes, as well as of the factories producing the goods we consume and of shops, hospitals, and other service sector installations emits CO<sub>2</sub> and other GHGs. Cars, trucks, trains, ships, and airplanes add to this. Agricultural and particularly agro-industrial production are further important emitters of greenhouse gases with the production of beef being particularly relevant (see for the 2010 absolute emissions of these sectors the dashed lines in Fig. 5 below). This list alone shows that avoiding GHG emissions needs many changes in many places which affect all parts of our daily lives as well as all parts of our economies – not to speak of the underlying effects for income, power, and wealth.

As already mentioned, the global energy system is rapidly developing with increasing wealth in the industrialized countries of the Global North, as well as increasing numbers of people in the emerging nations being able to afford industrialized energy and consumption patterns.

Together with significant changes in the energy supply structure such as higher shares of renewable energies, this all will lead to significant changes in the energy system.

As the provision of energy to modern societies needs heavy investment in long living infrastructures such as electricity grids, power plants, wind farms, coal mines, oil and gas fields, pipelines, and terminals, many stakeholders such as oil giants (Shell, BP), governments (US Department of Energy), international agencies (IEA,

IRENA), or NGOs (Greenpeace) as well as academic literature provide studies on the future of the energy system, often looking as far ahead as the middle of the century.

An increasing number of these energy scenario studies or energy outlooks has been concerned with analyzing and describing how future energy systems could be shaped in order to drastically reduce greenhouse gas emissions from the use of fossil fuels and sometimes also to achieve other sustainability targets.

Figure 5 condenses the results of a large number of such scenario studies for six major groups of GHG emitters: CO<sub>2</sub> emissions from transport, buildings, industry, electricity generation, as well as agriculture, forestry, and land use and all other GHG emissions from all sectors. Aggregated results are given for 2010 as a base year and the scenario years 2030, 2050, and 2100. The figure shows that the so-called baseline scenarios project strongly increasing emission growths for all segments apart from agriculture, forestry, and land use, where baselines expect slight decreases. The

**Fig. 5** Direct CO<sub>2</sub> emissions by major sectors, and non-CO<sub>2</sub> emissions, for baseline and mitigation scenarios. Carbon dioxide (CO<sub>2</sub>) emissions by sector and total non-CO<sub>2</sub> greenhouse gases (Kyoto gases) across sectors in baseline (faded bars) and mitigation scenarios (solid color bars) that reach about 450 (430–480) ppm CO<sub>2</sub>-eq concentrations in 2100 (likely to limit warming to 2 °C above preindustrial levels). Mitigation in the end-use sectors leads also to indirect emission reductions in the upstream energy supply sector. Direct emissions of the end-use sectors thus do not include the emission reduction potential at the supply side due to, for example, reduced electricity demand. The numbers at the bottom of the graphs refer to the number of scenarios included in the range (upper row, baseline scenarios; lower row, mitigation scenarios), which differs across sectors and time due to different sectoral resolution and time horizon of models. Emission ranges for mitigation scenarios include the full portfolio of mitigation options; many models cannot reach 450 ppm CO<sub>2</sub>-eq concentration by 2100 in the absence of carbon dioxide capture and storage (CCS). Negative emissions in the electricity sector are due to the application of bioenergy with carbon dioxide capture and storage (BECCS). “Net” agriculture, forestry, and other land-use (AFOLU) emissions consider afforestation, reforestation, as well as deforestation activities. (Source: IPCC 2014b, Figure SPM.14 with kind permission of IPCC Secretariat, Web Information and Publications)

baseline scenarios are often called “business-as-usual” scenarios, although one might question if such developments would really occur as usual business until 2100, given the strong growth in GHG emissions and thus effects on climate change that these baselines imply. The collection of baselines by the IPCC shows an unmitigated growth of emissions until 2100 with a median increase of roughly two thirds between 2010 and 2100. Such growth in energy use and GHG emissions would lead to global mean temperature increases of around 4 °C or even more by the end of the century with significant related consequences for global ecosystems and human development. Countries all over the world have already committed themselves to reduce their GHG emissions significantly over the coming years (see section “Global Regulation of Greenhouse Gas Emissions”) in order to move from baseline to emission trajectories in line with the global climate targets.

Figure 5 covers such climate mitigation scenarios, i.e., scenarios that achieve maximum global atmospheric concentrations of greenhouse gases between 430 and 480 parts per million (ppm). With such concentrations, most climate models expect global mean surface warming rates of 1.5–2 °C. The figure shows that the mitigation scenarios describe completely different trajectories than the baseline scenarios. Instead of strong growth trends in emissions, they display strongly declining emissions in all sectors with the deviations starting significantly before 2030 (or in other words, now). The difference is most pronounced for the currently largest emitter, the electricity sector. Instead of more than doubling between 2010 and 2100, emissions in the sector decline to zero by 2050 and are negative by 2100. But also in industry, transports, and buildings, emissions are reduced to levels close to zero in the median of all scenarios. Only emissions of non-CO<sub>2</sub> greenhouse gases remain quite stable, and these gases represent the largest emitter of GHGs already by 2030 and are responsible for the vast majority of emissions by 2100.

These differences in the emission segments mainly depend on the different technological options to reduce energy demand and GHG emissions. Table 2 gives an overview per emission sector for the year 2050. Deviating from Fig. 5, non-CO<sub>2</sub> GHGs are accounted for in the sector in which they occur (and not displayed as a separate segment). It can be seen that two factors are dominating GHG emissions: the final energy demand and the share of low carbon fuels in the sector. With declining energy demand and higher shares of low carbon fuels (or typically renewable energies), greenhouse gas emissions from the sectors can be reduced while they still provide (typically increasing) energy services to societies. The sectors, however, show significantly differing mitigation pathways. The final energy demand for electricity grows strongly in the baselines as well as the mitigation scenarios, but the share of low carbon fuels is up to almost 100% in the mitigation scenarios, while the baselines show even a small decline vs. 2010. These values reflect the characteristic of the electricity system as not being a final energy consumer. Instead, increasing amounts of low-carbon electricity will be used in transport, industry, and buildings providing these sectors indirectly with low carbon fuels. In transport and buildings, the mitigation scenarios see high increases in energy efficiency which compensate for a growth in energy service demand so that final

**Table 2** Sectoral CO<sub>2</sub> emissions, related energy system changes, and examples for sectoral mitigation measures

Sectoral CO <sub>2</sub> emissions and related energy system changes			Examples for sectoral mitigation measures				
Sector	CO <sub>2</sub> emission (GtCO <sub>2</sub> , 2050)	Low-carbon fuel share (% ,2050)	Final energy demand (EJ, 2050)	Key low-carbon energy options	Key energy saving options	Other options	
<b>Energy supply*</b>				Renewables (wind, solar, bioenergy, geothermal, hydro, etc.), nuclear, CCS, BECCS, fossil fuel switching	Energy efficiency improvements of energy supply technologies, improved transmission and distribution, CHP and cogeneration	Fugitive CH <sub>4</sub> emissions control	
<b>Transport</b>				Fuel switching to low-carbon fuels (e.g., hydrogen/electricity from low-carbon sources), biofuels	Efficiency improvements (engines, vehicle design, appliances, lighter materials), modal shift (e.g., from LDVs to public transport or from aviation to HDVs to rail), eco-driving, improved freight logistics, journey avoidance, higher occupancy rates	Transport (infrastructure) planning, urban planning	
<b>Building</b>				Building integrated RES, fuel switching to low-carbon fuels (e.g., electricity from low-carbon sources, biofuels)	Device efficiency (heating/cooling systems, water heating, cooking, lighting, appliances), systemic efficiency (integrated design, low/zero energy buildings, district heating/cooling, CHP, smart meters/grids), behavioural and lifestyle changes (e.g., appliance use, thermostat setting, dwelling size)	Urban planning, building lifetime, durability of building components and appliances, low energy/GHG intensive construction and materials	
<b>Industry</b>				Process emissions reductions, use of waste and CCS in industry, fuel switching among fossil fuels and switch to low-carbon energy (e.g., electricity) or biomass	Energy efficiency and BAT (e.g., furnace/boilers, steam systems, electric motors and control systems), (waste) heat exchanges, recycling, reduction of demand for goods, more intensive use of goods (e.g., improve durability or car sharing)	HFC replacement and leak repair, material efficiency (e.g., process innovation, re-using old materials, product design, etc.)	
<b>AFOLU</b>				<p><b>Emissions reduction measures:</b> Methane (e.g., livestock management), nitrous oxide (e.g., fertilizer use), conservation of existing carbon pools (sustainable forest management, reduced deforestation and forest degradation, fire prevention, agroforestry), reduction in emissions intensity</p>	<p><b>Sequestration options:</b> Increasing existing carbon pools (e.g., afforestation, reforestation, integrated systems, carbon sequestration in soils)</p>	<p><b>Substitution options:</b> Use of biological products instead of fossil/GHG intensive products (e.g., bioenergy, insulation products)</p>	<p><b>Demand-side measures:</b> Reduction of loss and waste of food, changes in human diets, use of long-lived wood products</p>

Contribution of Working Groups I, II and III to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change [Core Writing Team, R.K. Pachauri and L.A. Meyer (eds.)]. IPCC, Geneva, Switzerland

energy use in these sectors remains roughly stable. In industry however, final energy demand grows only slightly slower in the mitigation scenarios as compared to the baseline scenarios. In a median, low-carbon energy shares achieve over 50% of

GHG emission reductions in buildings and industry and slightly less in transport. What it would take globally to achieve the mitigation scenarios will be described in more detail below.

## **What Would It Take to Stay Within the Limits of the Climate System?**

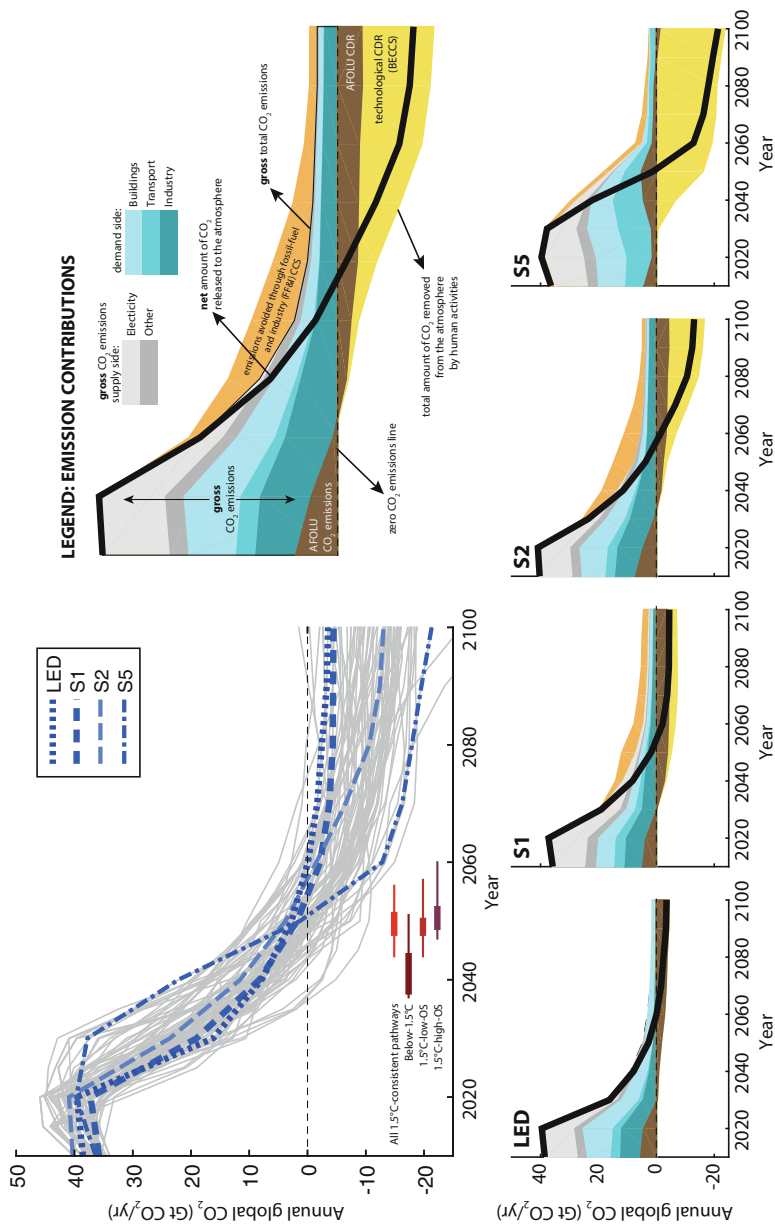

As discussed in previously, the international community had debated an upper limit of 2 °C warming above preindustrial levels as being the maximum that diverse ecosystems and life-supporting functions of the planet could cope with and at which there would be a fair chance that most tipping points of the climate system would not be reached. Newer scientific results have shown, however, that to really avoid catastrophic changes, the threshold should rather be set at 1.5 °C. Politically, a number of small island states also pushed strongly to reduce the targeted upper limit of global warming, as it became evident that most of them would vanish by the end of the century due to sea level rise if temperatures increased by 2 °C. Therefore, the international community tasked the IPCC to develop a report that shows what would be needed to keep global temperature rise below 1.5 °C.

As the world has failed to reduce GHG emissions so far (Höhne et al. 2020), it is now very ambitious (Fig. 4 above), which makes it clear that global mean surface temperatures might reach this threshold in this decade already.

Figure 6 again shows a collection of mitigation scenarios from recent literature. The scenarios given are all compatible with the 1.5 °C target. The comparison of the scenarios shows the sooner and the faster emissions decline now, the easier the targets can be achieved in the long run. The low energy demand (LED) scenarios (SR15, p110) show an immediate and sharp decline of energy demand and emissions from 2020 on and achieve global zero CO<sub>2</sub> emissions by about 2050. As not all sectors can reduce that fast, some negative emissions (e.g., via bioenergy use with capturing and storing of the carbon) are assumed to compensate for the remaining GHG emissions.

The other scenario types are variations of this pattern but assume different energy system pathways. Emissions decline later or even still rise for a small number of years. In these scenarios, temperatures will “overshoot” the 1.5 °C threshold for some decades and decline later in the century, back to 1.5 °C. In addition, already from 2040 onward, very significant amounts of negative emissions would be necessary to compensate for the remaining emissions and much more for the emission overshoot accumulated between 2020 and 2050. It is, however, highly contested if negative emissions of such an immense volume would even be technologically feasible, let alone what their costs would be.

All scenarios show that in order to achieve the 1.5 °C target, the world needs to stop increasing emissions almost now and has to reduce them at very high and unprecedented annual rates for the coming decades. The reason for this is simple. As the amount of cumulative emissions that is compatible with the 1.5 °C limit, the “global climate budget,” is limited, the mathematics are very clear: if emissions still rise instead of going down, this requires much faster action later. Governments around the globe were not able to stop emission growths over the last almost three

**Fig. 6** Evolution and breakdown of global anthropogenic CO<sub>2</sub> emissions until 2100. The top-left panel shows global net CO<sub>2</sub> emissions in below 1.5 °C, 1.5 °C low overshoot (OS), and 1.5 °C high OS pathways, with four illustrative 1.5 °C-consistent pathway archetypes highlighted. Ranges at the bottom of the top-left panel show the 10th–90th percentile range (thin line) and interquartile range (thick line) of the time that global CO<sub>2</sub> emissions reach net zero per pathway

decades. Therefore, the available emission budget has already been almost fully used and every year with current or even higher emissions will consume a disproportionate share of the remaining budget. This means that reductions in the years to come have to be even more pronounced.

Figure 7 shows the result of these facts. Achieving the 1.5 °C target therefore means that the strategies depicted to reduce emissions have to start very early and have to be significantly accelerated as compared to the 2 °C scenarios. Figure 8 in the next subsection is even more telling as it shows the related global investments in the energy system.

## The Economics of GHG Emissions and Their Mitigation

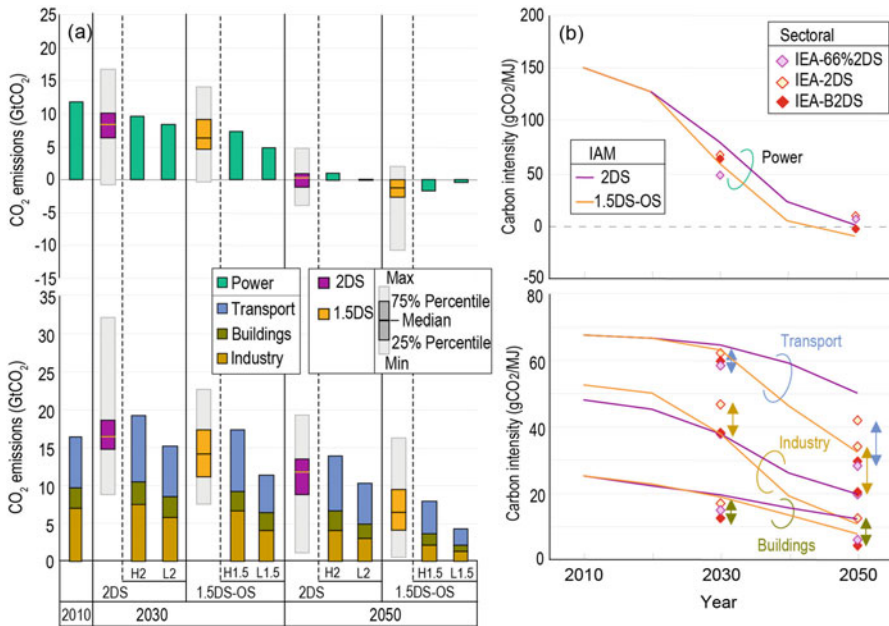

The climate mitigation scenarios discussed above assume significantly different investment trajectories as seen in the past or expected in a “business-as-usual” future. This is in itself a challenge, not only because of the volume of investments which is moderately above historic values, but mainly because investments in some sectors such as fossil generation see a massive decline, while investments in others such as renewable energies or energy efficiency need to be ramped up massively.

Figure 8 explores details on the investments necessary to convert energy systems around the globe. It compares historical with future (2016–2050) annual investments in different segments of the global energy system for different scenarios. These are baseline scenarios (see above), NDC scenarios which describe what would happen if governments around the globe implemented their emission reduction pledges under the Paris Agreement (see section “[Regulation After 2020 Under the Paris Climate Agreement](#)”), 2 °C scenarios, and 1.5 °C scenarios. The first result from the figure is that all the changes in the energy system indicated above would not result in significantly larger volumes of investment in the global energy system. Investment totals as modelled increase from 2300 billion US \$ per year in the baselines, which is roughly comparable or up to 10% higher than historic investment volumes, to slightly above 3000 billion US \$ per year in the 1.5 °C scenarios. This would be an increase in investment of less than a third vs. baselines, but given the highly uncertain ranges, it is also possible that the difference would be significantly smaller.

Next to moderately ramping up global investments to make the energy systems climate compatible, there are huge changes necessary regarding which investments are made. Investments into the so far largest segment of emissions, fossil fuel extraction and conversion, are cut by half in the 2 °C and by two thirds in the

**Fig. 6** (continued) class and for all pathway classes combined. The top-right panel provides a schematic legend explaining all CO<sub>2</sub> emission contributions to global CO<sub>2</sub> emissions. The bottom row shows how various CO<sub>2</sub> contributions are deployed and used in the four illustrative pathway archetypes (LED, S1, S2, S5). Note that the S5 scenario reports the building and industry sector emissions jointly. Green-blue areas hence show emissions from the transport sector and the joint building and industry demand sector, respectively. (Source: Rogelj et al. 2018, Figure 2.5 with kind permission of IPCC Secretariat, Web Information and Publications)

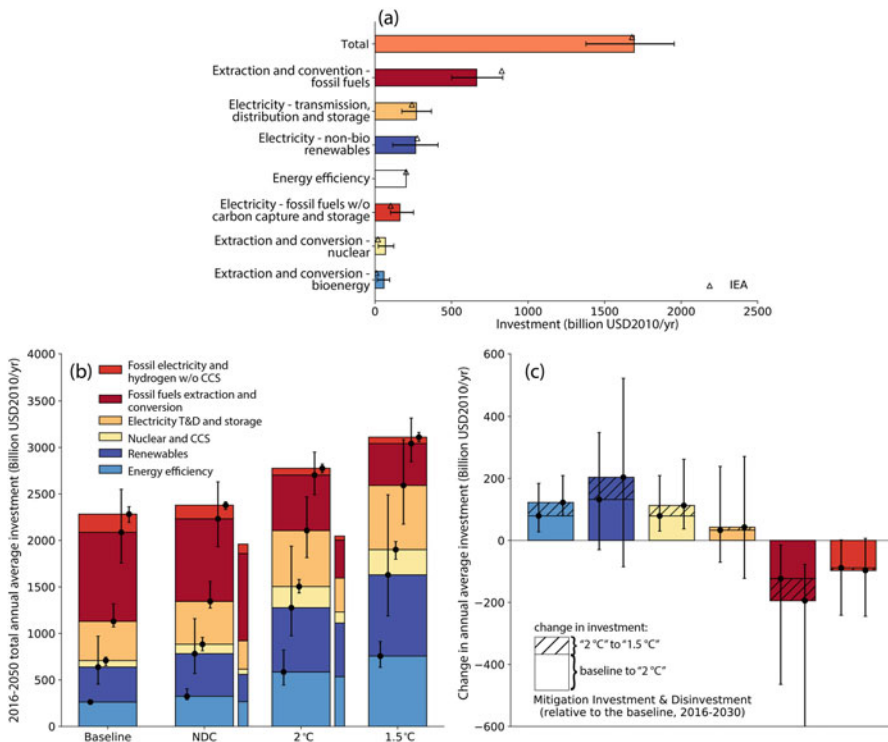

**Fig. 7** Comparison of (a) direct CO<sub>2</sub> emissions and (b) carbon intensity of the power and energy end-use sectors (industry, buildings, and transport sectors) between Integrated Assessment Models (IAMs) and sectoral studies by IEA and IRENA. Diamond markers in panel (b) show data for IEA-ETP scenarios (2DS and B2DS) and IEA/IRENA scenario (66% 2DS). Note: for the data from IAM studies, there is rather large variation of projections for each indicator. (Source: Rogelj et al. 2018, Figure 2.20 with kind permission of IPCC Secretariat, Web Information and Publications)

1.5 °C scenarios. Investments in the fossil electricity generation without carbon capture and storage (CCS) will have to be almost completely stopped soon, even for the 2 °C scenarios. Instead investments in renewable energies, energy efficiency, and other low-carbon generation options have to be at least doubled between the baselines and the 1.5 °C scenarios, and investments into the electricity system also need to be significantly increased.

Having in mind that these changes need to occur almost immediately, the dimensions of the challenge become clearer. The massive decline in fossil investment creates of course massive challenges for regions and companies now living from fossil fuel extraction and conversion. These range from traditional coal regions in many countries all over the world, via the big oil and also gas-producing countries, whose economies often are dependent on the revenues of their fossil resources. Also international maritime trade with around 50% of the tonnage being fossil fuels, port, and logistic businesses as well as refineries are all affected. Builders and developers of fossil power plants will lose a large share of related businesses. On the other hand, ramping up global renewable energy, energy efficiency, and other low carbon as well

**Fig. 8** Historical and projected global energy investments. **(a)** Historical investment estimates across six global models from (McCollum et al. 2018) (bars = model means, whiskers full model range) compared to historical estimates from the IEA (International Energy Agency (IEA) 2016) (triangles). **(b)** Average annual investments over the 2016–2050 period in the “baselines” (i.e., pathways without new climate policies beyond those in place today), scenarios which implement the NDCs (“NDC,” including conditional NDCs), scenarios consistent with the lower 2 °C pathway class (‘2 °C’), and scenarios in line with the 1.5 °C low overshoot pathway class (“1.5 °C”). Whiskers show the range of models; wide bars show the multimodel means; narrow bars represent analogous values from individual IEA scenarios (OECD/IEA and IRENA 2017). **(c)** Average annual mitigation investments and disinvestments for the 2016–2030 periods relative to the baseline. The solid bars show the values for “2 °C” pathways, while the hatched areas show the additional investments for the pathways labelled with “1.5 °C.” Whiskers show the full range around the multimodel means. T&D stands for transmission and distribution, and CCS stands for carbon capture and storage. Global cumulative carbon dioxide emissions, from fossil fuels and industrial processes (FF&I) but excluding land use, over the 2016–2100 timeframe range from 880 to 1074 GtCO<sub>2</sub> (multimodel mean: 952 GtCO<sub>2</sub>) in the “2 °C” pathway and from 206 to 525 GtCO<sub>2</sub> (mean: 390 GtCO<sub>2</sub>) in the “1.5 °C” pathway. (Source: Rogelj et al. 2018, Figure 2.27 with kind permission of IPCC Secretariat, Web Information and Publications)

as electricity system investment also poses massive challenges to governments and investors. Current markets still fail largely in creating appropriate conditions to make these investments viable, which means that a large (but declining) share of the investments needed rely strongly on public support.

Particularly the loosing regions and sectors, who are typically well-established players for whom the fossil assets are an important part of their (economic) power, will most probably not easily buy in to such scenarios. The discussions around coal phase out in many countries provide telling examples but are only the tip of the iceberg if it comes to implementing 1.5 °C scenarios. On the other hand, it is extremely difficult to double economic activities in clean energy investment virtually overnight. New forms of political cooperation might be needed to achieve ramp-up rates and cost decreases strong enough to achieve the target.

The economic consequences of climate change, however, are much wider than the changes in energy system investments depicted above. Climate change will also cause significant economic damages due to losses in agricultural yields, higher costs in water supply, and damages due to climate-related weather events such as stronger storms, floods, etc. (see section “[Climate Damages and Tipping Points: Why Is It Necessary to Limit Global Warming?](#)”). While in the past there had been a discussion if warming-related benefits could compensate for these losses on a global level, nowadays the analyses seem to agree that climate damages will significantly outpace benefits, if these occur at all.

---

## Global Regulation of Greenhouse Gas Emissions

Although the greenhouse effect and the role energy use plays were known since the end of the nineteenth century, it took until the 1990s to establish a political response globally. In 1992, the UN established the Framework Convention on Climate Change (UNFCCC) as the global level legal framework for regulating greenhouse gas emissions and the fight against climate change. Under this framework, an intensive global climate diplomacy has emerged since then. Since 1990, climate policy has seen three phases of regulation of greenhouse gas emissions as well as climate mitigation and adaptation. Each of these phases is described in one of the following subsections. Finally, the section is concluded by a subsection on the Sustainable Development Goals which complement the climate regulation with regard to other fields of global sustainability.

### The UN Framework Convention on Climate Change (UNFCCC)

In 1990, the UN General Assembly decided to start negotiations on an international treaty on climate change. After 2 years of negotiations, the result – the United Nations Framework Convention on Climate Change (UNFCCC) – was adopted in the framework of the United Nations Conference on Environment and Development (UNCED), the so-called Earth Summit, in Rio de Janeiro in 1992. The UNFCCC entered into force on 21 March 1994, 90 days after it had been ratified by 50 states. To date, 197 states – nearly all countries in the world – are Parties to the UNFCCC (UNFCCC Website [2020b](#)).

The UNFCCC is the constitution of international climate policy, establishing its main goals, principles, and institutions. Article 2 establishes its central objective: to prevent dangerous anthropogenic interference with the climate system “within a timeframe that is sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner.” However, the Convention did not define which level of climate change was considered to be “dangerous.” This question was resolved only nearly 20 years later with the adoption of the 2 °C limit (see subsequent sections).

One of the key principles of the Convention is that industrialized and developing countries have common but differentiated responsibilities and that industrialized countries are supposed to take the lead in combating climate change (Article 3.1). This principle is intended to take into account the fact that industrialized countries have already emitted high amounts of GHGs since the beginning of industrialization and are still responsible for high per capita emissions and high absolute emissions today. The Convention therefore divides the countries of the world into Annex I Parties on the one hand and non-Annex I Parties on the other. Annex I of the Convention lists the traditional industrialized countries and the former Eastern bloc countries with economies in transition. Annex I Parties are required to implement policies and measures on the mitigation of climate change by limiting GHG emissions and protecting and enhancing GHG sinks and reservoirs, with the aim to return their CO<sub>2</sub> emissions to 1990 levels (Article 4.2). In addition, they committed to supporting developing countries financially, technologically, and with capacity building (Article 4.3). On the other side, the Convention explicitly conditions the extent to which developing countries implement their commitments on the extent to which developed countries provide financial and technological support (Article 4.7).

Furthermore, to provide transparency on implementation and progress made, all Parties committed to regularly providing national inventories of GHG emissions and removals by sinks as well as a description of steps taken to implement the Convention (Article 12). Content requirements and timetables for these “national communications” were differentiated for Annex I and non-Annex I Parties, developed out in detail in subsequent years, and repeatedly tightened. The progressive tightening of the transparency requirements culminated in the “Enhanced Transparency Framework” established by the Paris Agreement in 2015 (see below).

Article 7 of the UNFCCC establishes annual meetings. The task of the Conference of the Parties to the Convention (COP) is to review the implementation of the Convention and related legal instruments and to take decisions necessary to ensure the implementation of the Convention. Articles 9 and 10 establish two subsidiary bodies to the COP: the Subsidiary Body for Scientific and Technological Advice and the Subsidiary Body for Implementation. While the COP usually meets annually, the subsidiary bodies usually meet two times per year. Furthermore, Article 8 of the Convention establishes a permanent Secretariat to support its implementation.

## Regulation from 1995 to 2012 Under the Kyoto Protocol to the UNFCCC

While the UNFCCC established the framework for international climate policy, it does not contain any specific commitments to act against climate change. The intention was that more specific commitments should be established by subsequent legal instruments. Accordingly, the first COP (COP1), which met in Berlin in 1995, 1 year after the Convention had entered into force, adopted the so-called Berlin Mandate to negotiate a protocol to the Convention (Oberthür and Ott 1999).

The negotiations initiated in Berlin were concluded with the adoption of the Kyoto Protocol at COP3 in Kyoto, Japan, in 1997. The negotiations had been hampered by a fundamental North-South conflict. The main controversy had been around countries' respective responsibilities for climate change and which commitments they should undertake correspondingly. While the developing countries wanted to discuss binding commitments only for the industrialized countries in accordance with the Berlin Mandate, the USA in particular emphasized that the new treaty could and should also address binding emission targets for developing countries (Oberthür and Ott 1999).

In the final outcome, only the Parties listed in Annex I to the Convention undertake to reduce their collective GHG emissions by at least 5 percent compared to 1990 levels between 2008 and 2012 (first commitment period of the KP) (Article 3.1). This commitment refers to a "basket" of six GHGs and groups of GHGs listed in Annex A of the Protocol:

- Carbon dioxide (CO<sub>2</sub>).
- Methane (CH<sub>4</sub>).
- Nitrous oxide (N<sub>2</sub>O).
- Hydrogenated fluorocarbons (HFCs).
- Perfluorinated fluorocarbons (PFC).
- Sulfur hexafluoride (SF<sub>6</sub>).

The aggregate reduction commitment of 5% refers to the GWP of these gases over a 100-year period (see above).

Each Annex B Party has its own emission target, called quantified emission limitation and reduction commitment listed in Annex B to the KP. Annex B comprises all industrialized countries listed in Annex I to the Convention, minus Belorussia and Turkey. The European Union (at that time still the European Community) has a special role; it acts in concert and has a collective target listed in Annex B.

In addition to the commitment to emission targets, the other main feature of the KP is the introduction of emission trading mechanisms to help Parties to meet their commitments, the so-called flexible mechanisms. These include:

- Emission trading among Parties, i.e., the purchase and sale of emissions units, which is regulated in Article 17 of the Protocol.

- “Joint Implementation (JI),” the implementation of climate protection projects among Annex B Parties, which is regulated in Article 6
- The “Clean Development Mechanism (CDM),” implementation of climate protection projects in developing countries, which is regulated in Article 12.

Four more years of negotiations were required to flesh out the implementation details for the KP. These negotiations were finally concluded at COP7 in Marrakech in 2001 with the adoption of the “Marrakech Accords.” However, in the meantime, the USA had formally withdrawn from the Protocol. This posed a problem for the entry into force of the KP, which required ratification by at least 55 countries that together accounted for at least 55 percent of Annex I CO<sub>2</sub> emissions in the base year (1990). The USA alone accounted for more than one third of this value, in their absence the entry into force required ratification by most other Annex B countries, in particular Russia (Walsh 2004). Nonetheless, the threshold was crossed on 4 November 2004, and the Protocol entered into force on 16 February 2005, 90 days later (UNFCCC Website 2020a).

In 2012, the KP lost another Annex B Party. Instead of reducing its emissions, Canada’s emissions had increased substantially. In order to avoid the penalties envisaged in the KP, Canada therefore withdrew its participation (The Guardian & Agencies 2011).

The remaining Annex B Parties complied with their emission targets. However, it has to be noted that compliance was greatly helped by (a) the severe economic contraction in the former Eastern bloc countries in the 1990s and (b) the financial crisis that started in 2008 and severely reduced economic output around the world (Shishlov et al. 2016).

## **Regulation Till 2020 Under the Cancún Agreements**

Following the entry into force of the Protocol, the annual climate conferences were no longer only the Conference of the Parties to the Framework Convention on Climate Change (COP), but also the “Conference of the Parties serving as Meeting of the Parties to the Kyoto Protocol” (CMP). The first COP/CMP met in Montreal in 2005. In addition to taking further decisions on the implementation of the UNFCCC and KP, the conference also started new rounds of talks on binding commitments for “post-2012,” i.e., the period after the first commitment period of the Kyoto Protocol (Wittneben et al. 2006).

However, industrialized countries were not willing to envisage a second Kyoto period without enhanced action from developing countries. In addition to the Kyoto negotiations, the Montreal conference therefore also started a second negotiating stream to enhance action under the Convention. While developing countries were at first opposed to engaging more strongly in GHG reductions, COP13 in Bali in December 2007 marked a breakthrough. In the “Bali Action Plan (BAP)” adopted at COP13, developing countries agreed to undertake “nationally appropriate mitigation actions (NAMAs)” in the context of

sustainable development, contingent on enhanced financial, technological, and capacity building support from industrialized countries. Another section of the BAP covered adoption of emission targets for developed countries, with the intention to include the USA in the new arrangements, which continued to abstain from the Kyoto Protocol (Watanabe et al. 2008).

The new arrangements were supposed to be adopted at COP15 in Copenhagen in 2009. However, COP15 failed to deliver on the expectations. Marked by logistical failures and political confusion in the final days of the conference, negotiations among a limited number of Parties behind closed doors produced a “Copenhagen Accord.” In the Accord, countries for the first time agreed on the long-term target to limit global temperature increase to at most 2 °C above preindustrial levels. The Accord also contained provisions for the registration of emission targets of developed countries, NAMAs of developing countries, and enhanced support from developed to developing countries. In particular, industrialized countries pledged to increase the provision of climate finance to USD 100 billion annually by 2020 (UNFCCC 2010).

However, the Accord was not accepted by the plenary of the COP as many countries complained about its lack of ambition and the closed process which had produced the Accord (Sterk et al. 2010).

Subsequent negotiations were able to pick up the pieces. COP16 in Cancún, Mexico, yielded the “Cancún Agreements (CA),” a lengthy COP decision that set a new framework for enhanced climate action until 2020. It confirmed and further fleshed out the elements that had been contained in the Copenhagen Accord, in particular the 2 °C limit, provisions for emission targets of developed countries, and NAMAs of developing countries. In addition, the CA provided for the establishment of a Green Climate Fund (GCF) and of a Technology Mechanism to enhance support for developing countries. The CA also strengthened the requirements for how often and in how much detail Parties need to report on their GHG emissions and climate actions they are taking (UNFCCC 2011).

However, the CA are only a COP decision, not a treaty, and hence have relatively limited legal standing. In addition, the future of the Kyoto Protocol was still open. In the course of the negotiations up to Cancún, most industrialized countries had adopted a position of wanting a new comprehensive agreement covering all countries, instead of continuing on two tracks, with the KP covering industrialized countries and another agreement covering the rest of the world. COP17 in Durban, South Africa, in 2017 therefore started another round of negotiations. The EU agreed to go ahead with a second commitment period under the KP in order to satisfy the demands of developing countries. In return, all countries agreed to start negotiations on a new comprehensive agreement covering all countries from 2020 onward (Sterk et al. 2011).

COP18 in Doha, Qatar, adopted the “Doha Amendment” which contains the details for the second Kyoto Period. However, several of the countries that had undertaken commitments in the first commitment period did not offer new commitments for the second one, in particular Japan and Russia (Sterk et al. 2012).

## Regulation After 2020 Under the Paris Climate Agreement

After 25 years of international climate negotiations, in 2015, COP21 in Paris finally adopted a universal agreement requiring climate action from all countries. The necessary ratifications came together at nearly unprecedented speed; the Agreement entered into force already on 4 November 2016 (UNFCCC Website 2020b).

The Agreement has three long-term objectives. First, the Agreement strengthens the long-term temperature limit. Whereas the Cancún Agreements had set down the objective to stabilize temperature increase below 2 °C, the Paris Agreement aims at “well below” 2 °C and to make “best efforts” to stay below 1.5 °C (Article 2.1(a)). This strengthening of the temperature limit was due to the insistence of small island states and least developed countries, which are particularly vulnerable to the impacts of climate change.

The Paris Agreement also stipulates what achieving the temperature limit will need to mean in terms of emission pathways: according to Article 4.1, global emissions are to peak as soon as possible; and a balance between emissions of GHGs from sources and GHG removal by sinks is to be achieved in the second half of the century.

The second long-term objective of the Agreement is to increase the ability to adapt to the adverse impacts of climate change and foster climate resilience and low greenhouse gas emissions development (Article 2.1(b)). The third objective is to make all financial flows consistent with low greenhouse gas emissions and climate-resilient development (Article 2.1(c)).

However, the adoption of this universal agreement came at a price: the Paris Agreement does not contain legally binding commitments for the individual countries, as is the case in the Kyoto Protocol. Instead, there is only a procedural obligation for countries to submit and maintain a “nationally determined contribution (NDC)” (see also section “[What Would It Take to Stay Within the Limits of the Climate System?](#)”). There are no international requirements on the format and content of the NDCs. The agreement only suggests that developed countries should undertake to define economy-wide absolute emission reduction targets as in the Kyoto Protocol, whereas developing countries “are encouraged to move over time towards economy-wide emission reduction or limitation targets” (Article 4.3). NDCs are supposed to reflect Parties “highest possible ambition,” but there is no guidance as to what this is supposed to mean. There also is no requirement for Parties to actually achieve their NDCs, only a requirement to pursue domestic measures toward this end (Article 4.2).

As result of this lack of formal requirements, the traditional industrialized countries have all submitted Kyoto-style absolute emission targets, whereas developing countries feature a variety of relative emission targets indexed to GDP or framed in a comparison to a business as usual scenario. Many countries with low capacity have notified no emission targets whatsoever. Instead, their NDCs contain lists of specific policies and measures they intend to undertake. Furthermore, the target dates of the NDCs vary. Some have 2025 as target date; the majority has 2030; some have even longer timeframes (WRI 2020).

Furthermore, the ambition of nearly all NDCs is much weaker than what would be necessary to achieve the temperature limits of the Paris Agreement. Instead of limiting temperature increase well below 2 °C or even 1.5 °C, the current NDCs would lead to warming of between 3 °C and 4 °C if not strengthened further. Moreover, in many countries, the policies implemented so far will not even deliver the reductions pledged in the NDCs (Roelfsema et al. 2020; UNEP 2019, p. 2019).

To counteract these weaknesses, the Paris Agreement contains a so-called ambition cycle. Parties are required to revise their NDCs or submit new NDCs every 5 years, for the first time in 2020, then 2025, etc. Furthermore, Parties will collectively evaluate their progress toward the objectives of the Paris Agreement, also every 5 years (Article 14). The results of these “Global Stocktakes (GST)” are to inform the revision of existing and elaboration of new NDCs. The first GST will take place in 2022/2023. The Paris Agreement thereby establishes a continuous series of political reflection and subsequent NDC revision. This mechanism is supposed to contribute to a continuous “ratcheting up” of ambition, to ultimately bring the NDCs in line with the achievement of the long-term objectives.

Another element that is supposed to compensate for the lack of legally binding commitments is the “enhanced transparency framework for action and support” under Article 13. The aim of the framework for *transparency of action* is “to provide a clear understanding” of climate action and to track progress, while the aim of the framework for *transparency of support* is “to provide clarity on support provided and received” and to provide an overview of aggregate financial support. In addition, the transparency framework is supposed to inform the Global Stocktake.

The PA removes the binary distinction between developed and developing countries that was established by the Convention and provides that all Parties shall account for their contributions (Article 4.13). To nonetheless account for the different circumstances of Parties, the transparency framework “shall provide flexibility (...) to those developing country Parties that need it in the light of their capacities” (Article 13.2).

In detail, Article 13 requires Parties to regularly provide national greenhouse gas inventories that need to be prepared using IPCC good practice guidance, as well as information necessary to track progress made in implementing and achieving NDCs. All Parties are required to submit this information at least every 2 years, with the exception of small island developing states and least developed countries (UNFCCC 2016, p. 90). Furthermore, Article 13 requires developed country Parties to report on financial, technology, and capacity building support provided by them to developing countries. All this information reported by Parties will undergo a technical expert review. The review is supposed to identify areas of improvement and to review the consistency of the information provided with the reporting requirements. Moreover, Parties will discuss each other’s performance as part of a “facilitative, multilateral consideration of progress.”

On climate finance, the COP decision adopting the PA reconfirms developed countries’ commitment of mobilizing USD 100 billion in 2020 and beyond. In addition, Parties agreed that a new collective financing target will be adopted by 2025 (UNFCCC 2016, p. 53).

The 2018 climate conference in Katowice adopted detailed implementation regulations for most aspects of the PA. The Katowice conference also conducted a precursor to the Global Stocktake, named “Talanoa Dialogue.” The outcome of the Talanoa Dialogue confirmed that the level of ambition of currently submitted NDCs is insufficient, but countries were not able to agree on a strong call to action (Obergassel et al. 2019).

As of the time of writing this text in the spring of 2020, it remains to be seen whether the PA’s “ratchet” mechanism will work as intended. Parties are supposed to submit new or updated NDCs by 2020. The strengthening of NDCs is becoming ever more urgent. Climate change is caused by the accumulation of GHGs in the atmosphere over time. Despite 25 years of climate diplomacy, global GHG emissions are still growing. The longer it takes to halt and reverse this trend, the steeper the subsequent reduction will need to be. According to the IPCC special report on the 1.5 °C limit (see section “[What Would It Take to Stay Within the Limits of the Climate System?](#)”), balancing emissions from sources and removals by sinks in the second half of the century, as aimed for in the Paris Agreement, is actually no longer sufficient to keep the 1.5 °C limit within reach. Maintaining a good chance of achieving the 1.5 °C limit would require to essentially halve global CO<sub>2</sub> emissions by 2030 and reduce them to net zero by 2050 (IPCC 2018c).

Unfortunately, the USA repeated the performance they had given in relation to the Kyoto Protocol – walking away from a treaty the content of which they had determined to a large extent. In November 2016, about a year after the adoption of the Agreement in Paris, Donald Trump was elected as new US president. He had campaigned on ending national climate policy and withdrawing from the Paris Agreement and publicly announced the US withdrawal on 1 June 2017 (The White House 2017). Under President Obama, the USA had been a key driver of the adoption of the PA. It remains to be seen what progress the rest of the world will be able to make without the USA.

## **The Link to the UN Sustainable Development Goals (SDG)**

2015 was a watershed for international sustainability governance. The international community adopted not only the Paris Agreement but also Agenda 2030 (United Nations 2015). The Agenda was developed in a participatory process involving governments, civil society, business, academia, the UN, and also individuals and was adopted by the UN General Assembly on 25 September 2015. It builds on the outcomes of the UN Conference on Sustainable Development (Rio + 20) in 2012 and the Millennium Development Goals (MDGs) and their targets, which refer to the year 2015. The Sustainable Development Goals (SDGs) reflect the global challenges to sustainable development and define goals to be achieved by 2030 (Fig. 9). In contrast to their predecessors, the Millennium Development Goals (MDGs), the SDGs refer not only to developing countries but to all countries of the world. They are to be understood as an overall system of global development goals. The SDGs are interdependent and inseparable.

**Fig. 9** The UN Sustainable Development Goals, source and Copyright © United Nations, adapted by Wuppertal Institut, “The content of this publication has not been approved by the United Nations and does not reflect the views of the United Nations or its officials or Member States.” <https://www.un.org/sustainabledevelopment/sustainable-development-goals/>

Nevertheless, they can be logically grouped into four categories. The SDGs are concretized by 169 sub-objectives and indicators, which enable an assessment of the achievement of objectives.

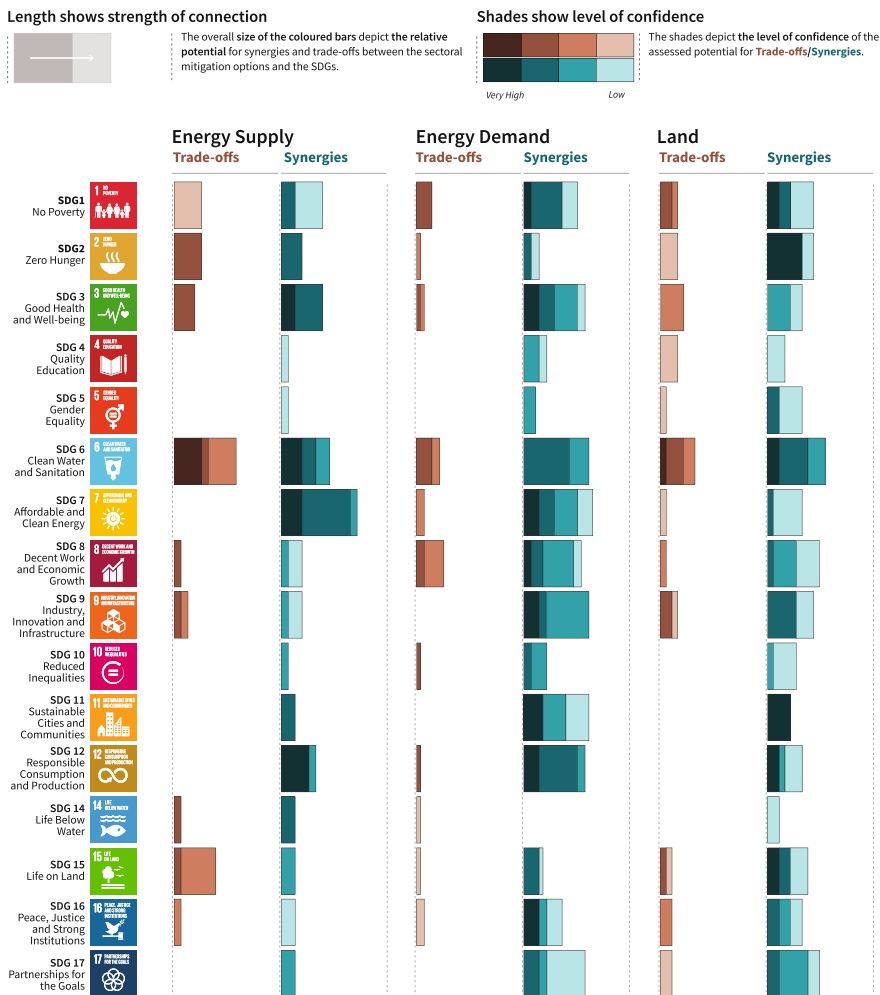

Both, the Agenda 2030 and the Paris Agreement stress the need for integration. In its preamble, the PA emphasizes “the intrinsic relationship that climate change actions, responses and impacts have with equitable access to sustainable development and eradication of poverty.” Also, under the Agreement’s Article 2, its objectives are to be achieved “in the context of sustainable development and efforts to eradicate poverty.” The Agenda 2030, for its part, includes climate action as one of the Sustainable Development Goals (SDGs) to be achieved by 2030 and stresses the interlinkages between and the integrated nature of all SDGs.

Actions to fulfill one SDG may impact others in some way – often positively but also negatively. For example, transport relates to no less than 12 targets of 9 SDGs directly or indirectly (SLoCaT 2015). The largest share of transport emissions comes from motorized road transport. Minimizing road use, e.g., through optimized infrastructure and planning processes, shifting toward less-polluting travel modes (e.g., rail freight, public transport, bicycles, or walking) as well as improving fuel and vehicle efficiency yields many benefits that go beyond mere GHG abatement. For example, less vehicle use means less local air pollution and thus better public health. Active forms of transport such as walking and cycling have positive health effects as well.

The IPCC in its special report on the implementation of the 1.5 °C target comprehensively identifies potential synergies and trade-offs between climate protection measures and the SDGs in relation to sectoral portfolios of measures on energy demand, energy supply, and land use and their probability. Figure 10 shows that although there are risks of conflicting objectives, the potential for synergies is much greater. Both the

### Indicative linkages between mitigation options and sustainable development using SDGs (The linkages do not show costs and benefits)

Mitigation options deployed in each sector can be associated with potential positive effects (synergies) or negative effects (trade-offs) with the Sustainable Development Goals (SDGs). The degree to which this potential is realized will depend on the selected portfolio of mitigation options, mitigation policy design, and local circumstances and context. Particularly in the energy-demand sector, the potential for synergies is larger than for trade-offs. The bars group individually assessed options by level of confidence and take into account the relative strength of the assessed mitigation-SDG connections.

**Fig. 10** Potential synergies and trade-offs between the sectoral portfolio of climate change mitigation options and the Sustainable Development Goals (SDGs). The SDGs serve as an analytical framework for the assessment of the different sustainable development dimensions, which extend beyond the time frame of the 2030 SDG targets. The assessment is based on literature on mitigation options that are considered relevant for 1.5 °C. The assessed strength of the SDG

mix of policy instruments used and the concrete design of the instruments and the strategy behind them as well as local circumstances determine the extent to which synergies can be realized and conflicts of objectives reduced and avoided.

The WHO Special Report “Climate Change and Health” emphasizes the links between health and climate change, pointing out that climate change and health risks often have the same causes, in particular air pollution resulting from the use of fossil fuels in the transport and energy sectors. If it is not possible to limit climate change, a deterioration of the health level in all regions of the world is to be expected, especially in urban regions. As a result of consistent climate protection measures to meet the goals of the Paris Agreement by 2050, more than one million lives could be saved annually by reducing air pollution alone. The same analysis shows that the value of health gains alone would be about twice as high as the costs of climate protection policies (WHO 2018).

---

## The Great Transition to a Climate-Neutral Global Society

Sections “[What Would It Take to Stay Within the Limits of the Climate System?](#)” and “[The Economics of GHG Emissions and Their Mitigation](#)” show what a significant challenge achieving the target of a maximum global warming of 1.5 °C above preindustrial levels will be for all states and all parts of society globally. This target would mean that the world becomes almost completely climate-neutral as early as the middle of the century. Such a change would be as significant as the Industrial Revolution of the nineteenth century but much faster and with a clear directionality needed. How such significant changes may be perceived is discussed in the next section, followed by a discussion of the importance of the current situation with the Coronavirus crisis creating one of the largest economic downturns witnessed in the last centuries. We end with a brief description of the “European Green Deal,” one of or even the first ambitious policy program that aims at really implementing the great transition toward climate neutrality, and by this it could – and should – be an example for many nations around the globe to take ambitious and integrated measures to align their economic and social developments with the needs of mitigating the global climate crisis.

## The Concept of a Great Transition

The previous sections showed that the regulation and mitigation of greenhouse gases is a relatively young field of policy which has emerged only since 1990. The past

**Fig. 10** (continued) interactions is based on the qualitative and quantitative assessment of individual mitigation options. (Source: IPCC 2018, Figure SPM.4 with kind permission of IPCC Secretariat, Web Information and Publications)

30 years, however, saw the field rapidly emerging on all political levels, and now it is one of if not the primary field of cross-cutting policy globally. Yet the challenges lying ahead if the global community wants to avoid catastrophic climate change are even bigger and would need unprecedented efforts globally and on all political, economic, and societal levels (IPCC 2018b). The huge changes necessary which affect basically all fields of economy and society have been compared in size, consequence, and radicality to be equivalent to the Neolithic Revolution, i.e., the emergence of agricultural society, and the Industrial Revolution, i.e., the conversion to an industrial society. The challenge to achieve a climate neutral society has been therefore called a “Great Transformation” (Hamann et al. 2014, p. 1 ff.). What is unique compared to previous transformations is that the Great Transformation has to be organized in order to be fast enough to cope with the challenges the climate system imposes on human society. Historical transitions in contrast emerged as gradual and evolutionary changes.

Nevertheless, the German Advisory Council on Global Change WBGU refers to the work by Karl Polanyi who showed that the uncontrolled market forces and innovation processes of the industrial revolution were only then accepted and controlled when they were embedded in new social and political norms such as democracy and the welfare state. The learning is that the Great Transition toward a climate-neutral and sustainable society also needs a new social contract. The basic feature of such a “new global social contract for a low-carbon and sustainable global economic system” is the joint responsibility of individuals, civil societies, states, the global community, economy, and science.

According to the WBGU, this new social contract is needed to create three types of cultures which are needed to cope with the three central challenges of the future:

- Ecological responsibility: Culture of attentiveness
- Democratic responsibility: Culture of participation
- Future responsibility: Culture of obligation toward future generations

## **The Coronavirus Crisis Recovery as Critical Also for Handling the Climate Crisis**

Parallel to writing this chapter about the Coronavirus, the world has seen the emergence of a global pandemic not witnessed in equal size for over a century. Both the potential death toll of the pandemic, particularly in the poorer parts of the world, and the already unfolding consequences of the complete stop of most of the social life and a huge share of all economic activities around the globe will have significant consequences on the road mankind will take in the coming years.

On short notice, the lockdown of most activities is significantly reducing greenhouse gas emissions and pollution all around the globe and has led to the first absolute drop in global GHG emissions for several decades. Given a longer-term perspective, currently many are seeing the states as well as the global

community at a clear crossroads. Preserving the economy during the lockdown and restarting it afterward will need immense government support, and governments around the globe, or at least in the more affluent parts of it, have announced expenditures of dimensions never seen before. The crisis recovery measures now might be the main factor deciding which direction the global economy will take over the coming years and possibly decades. Either policy-makers will be willing and able to use these immense public expenditures to invest into climate neutral and sustainable energy and production systems and societies, or these funds will largely be used to simply restore or reset economy and society to the status quo ante the crisis.

The first option is highly challenging as all decisions and investment are being made under high time pressure. It is necessary that governments and market actors find ways to invest into “future” proof technologies and systems for recovery. This means that globally quick investments of massive scale need to be directed toward energy efficiency, climate-neutral industrial processes, circular economy, renewable energy generation, clean energy infrastructures, public transport, and more resilient and climate friendly cities (see section “[The Economics of GHG Emissions and Their Mitigation](#)”). An investment boom of such unprecedented size could be able to create a strong directionality in the further development of societies and, by this, speed up many processes and lock in societal and economic trajectories into a direction toward climate neutrality. While many of these investments could be ramped up quickly, lacking institutional capacities, old cultures, and paradigms, lack of technology readiness or resistance against new infrastructures might impose significant barriers and slow down such investment into sustainable and climate neutral societies.

Particularly the perceived urgency to act fast to limit the economic effects of the crisis, together with the power of incumbent interests, may be a strong driver to merely invest along the lines of existing investment patterns, thereby restoring and conserving old fossil-based structures in the economy and society. In this case, the future trajectory would be locked into a “baseline” route for quite a number of years and possibly decades to come, as a business-as-usual recovery would result in a large stock of new high-emission technology and infrastructure assets. Moreover, as the massive recovery expenditures will sharply increase public debt, societies would lack the funds to quickly replace these new high-emission assets with low-emission ones.

## **The European Green Deal as an Integrated Regulatory Approach**

In fall 2019, the new European Commission started its term with the grand plan of a “European Green Deal” and the aim to make Europe the first climate-neutral continent. This Green Deal – clearly inspired by Roosevelt’s New Deal that had helped the USA to recover from the Great Depression of the 1930s – has the ambition to be a comprehensive program for Europe’s future. By directly linking policies for economic development and innovation to policies for a sustainable and

climate neutral economy as well as to policies for a fair and just transition, it clearly combines the three dimensions of sustainable development, i.e., ecology, economy, and social sustainability. What is new about this grand plan is that it aims at really integrating those targets. This follows the learning, driven by climate change and other environment-related crises, that economic and social development can no longer be seen as antipodes to ecologic sustainability but all three have to be achieved jointly and that also the economic future of Europe depends to large extent on its success to become frontrunner of a climate neutral and circular economy. Climate change together with digitalization is perceived as the major global megatrend and thus as the core driver for innovation.

To implement the European Green Deal, the European Commission has defined a set of policy areas that together create a comprehensive and integrated package of the following eight policy areas to be tackled in a coordinated manner ([https://ec.europa.eu/info/strategy/priorities-2019-2024/european-green-deal\\_en](https://ec.europa.eu/info/strategy/priorities-2019-2024/european-green-deal_en)):

- Clean energy/opportunities for alternative, cleaner sources of energy
- Sustainable industry/ways to ensure more sustainable, more environmentally respectful production cycles
- Building and renovating/the need for a cleaner construction sector
- Sustainable mobility/promoting more sustainable means of transport
- Biodiversity/measures to protect our fragile ecosystem
- From farm to fork/ways to ensure more sustainable food systems
- Eliminating pollution/measures to cut pollution rapidly and efficiently
- Climate action/making the EU climate neutral by 2050

Given the immense and urgent challenges to avoid catastrophic climate change and to make societies more sustainable as depicted in the previous chapters, such integrated and ambitious approaches are urgently needed in order to underpin ambitious climate targets as aimed at in the global process of raising the ambition. Therefore, the European Green Deal can be seen as a model also for other states to organize their policies toward ambitious climate goals. If climate mitigation is increasingly seen by the global community as a core source for innovation and economic well-being, there will be chances that states, societies, and companies will be able to deliver on the needed strategies to keep global temperature change below the critical levels of 1.5 °C.

## Abstract

Plant protection products (PPPs) have to be authorized prior to their placing on the market. PPPs may only contain active substances (or safeners and synergists) that have been previously approved. The approval process for active substances involves the evaluation of an extensive toxicological data set and results in the setting of reference doses and hazard-based classification for human health effects. Exclusion criteria preclude the approval of active substances that are carcinogenic, mutagenic, and toxic to reproduction, or that have endocrine-disrupting properties.

PPPs can be only authorized if they are efficacious and safe for human health and the environment. The human health risk assessment for PPPs is based on reference doses that represent safe exposure levels for active substances for operators and consumers. The reference doses are derived from no-effect levels observed in a battery of toxicological tests ranging from acute to chronic studies.

**Introduction**

Agrochemicals are strictly regulated with regard to their potential human health effects. This is necessary because human exposure potentially occurs on many levels. Applicators may be exposed during use of plant protection products (PPPs), but especially the potential exposure of the public at large to residues of agrochemicals and their transformation products requires regulatory attention. Such residues may be present in food, air, or drinking water. For this reason, PPPs and their active ingredients have to be approved and/or authorized prior to their placing on the market and use. The present chapter focuses on the regulatory toxicology aspects and requirements for agrochemicals.

The term “agrochemical” comprises any component of a PPP, e.g., active substances (ASs), synergists, safeners, solvents, solid carriers, or emulsifiers. This chapter deals mainly with the active substances, safeners, and synergists because they receive most of the toxicological attention stipulated by regulatory requirements. The non-active components, also called co-formulants, while not neglected, play a lesser role for the toxicological assessment of PPPs.

The present chapter mainly reflects the regulatory situation in the European Union, but the principles of agrochemical regulation are similar in many regions of the world.

---

**Regulation of Agrochemicals**

In most world regions, PPP registration follows a two-stage process. In the first stage, all active substances (and also all synergists and safeners, if relevant) in the PPP have to be approved. As soon as all active substances in a PPP are approved, the PPP itself needs to be authorized. The majority of toxicological data is generated for the approval of the active substance.

**Data Requirements for Active Substances**

The current data requirements for active substances are shown in Table 1.

The testing into **irritating and corrosive properties** should follow a tiered approach with the aim of avoiding in-vivo testing, especially when the AS is a strong irritant or corrosive. An in-vitro test for skin corrosivity should be conducted

**Table 1** Toxicological data requirements for active substances in the European Union (Commission Regulation (EU) No 283/2013 of 1 March 2013)

Endpoint	Requirement
<b>Absorption, distribution, metabolism, and excretion (ADME)</b>	
ADME in rats, oral route	Required, single high dose, single low dose, and repeated low dose
Comparative in vitro metabolism study	Required, liver microsomes, human and any relevant species from pivotal studies
<b>Acute toxicity</b>	
Acute oral toxicity	Required
Acute dermal toxicity	Required
Acute inhalation toxicity	Required if vapor pressure $> 1 \times 10^{-2}$ Pa at 20 °C the AS is a powder containing $> 1\%$ (w/w) particles $< 50 \mu\text{m}$ the AS is included in PPPs that are powders or are applied by spraying
Primary eye irritation	Required, in vitro
Primary dermal irritation	Required, in vitro
Skin sensitization	Required, local lymph node assay (LLNA) preferred
Phototoxicity	Required if extinction coefficient is $\geq 10$ L/mol/cm in the 290–700 nm range
<b>Short-term toxicity</b>	
Oral 28-day study	If available
Oral 90-day study	Required, rat and dog
<b>Genotoxicity</b>	
Bacterial assay for gene mutation	Required
Clastogenicity in mammalian cells, structural and numerical aberrations	Required Preferred: in vitro micronucleus assay
Bacterial assay for gene mutation	Required unless already positive from <i>hprt</i> or mouse lymphoma assay
In vivo studies in somatic cells	Required, in vivo micronucleus test
In vivo studies in germ cells	Normally not required
<b>Long-term toxicity and carcinogenicity</b>	
Long-term oral toxicity and carcinogenicity study (2 years) in the rat	Required, preferably combined
Carcinogenicity study in the mouse	Required
<b>Reproductive toxicity</b>	
Generational studies	Required. Two-generation study or extended one-generation study in rats
Developmental toxicity studies	Required, rat and rabbit
<b>Neurotoxicity</b>	
Neurotoxicity studies in rodents	Required for structural analogues to known neurotoxicants or if specific indications for neurotoxicity have been observed in other toxicity studies

(continued)

**Table 1** (continued)

Endpoint	Requirement
Delayed polyneuropathy studies	These studies shall be performed for active substances of similar or related structures to those capable of inducing delayed polyneuropathy such as organophosphorus compounds
<b>Other toxicological studies</b>	
Toxicity studies of metabolites	Metabolites that are detected in plants or animal products, soil, or groundwater are tested to establish their relative hazard compared to the active substance if they are not major metabolites in the main test species (mostly the rat)
Supplementary studies on the active substance	These studies are mostly performed to elucidate the mechanism of action behind critical effects observed in the standard tests. Frequently, the human relevance of tumors observed in rodents is the subject of these studies

first, if this study is positive, the AS can be classified accordingly and no further testing for eye effects, dermal toxicity, or skin sensitization needs to be conducted.

Regarding **genotoxicity**, positive findings in any in-vitro test need to be followed up by a suitable in-vivo test. A positive clastogenicity assay has to be verified by an in-vivo micronucleus assay. However, this test is part of the basic data set. The situation is more complicated in case of a positive gene mutation test in bacteria or mammalian cells. This would require an in-vivo gene mutation assay as follow-up investigation. A transgenic rodent somatic and germ cell gene mutation assay are among the recommended tests to satisfy this data requirement. This regulatory use of this assay is still relatively new, and experience with this assay is not widespread, both among industry and regulators.

In addition to these basic data requirements, studies into **endocrine disrupting properties** may be triggered, depending on the quality of the database and on possible concerns raised by findings in the available data.

## Data Requirements for Plant Protection Products

The current EU data requirements for PPPs are shown in Table 2. Vertebrate studies shall not be conducted if the toxicity for each endpoint can be reliably predicted using the calculation methods laid down in the CLP Regulation 1272/2008.

## Human Health Risk Assessment

The human health risk assessment for agrochemicals follows the principle of comparing measured or estimated exposures to regulatory reference doses.

**Table 2** Toxicological data requirements for plant protection products in the European Union (Commission Regulation (EU) No 284/2013 of 1 March 2013)

Endpoint	Requirement
Acute oral toxicity	Required
Acute dermal toxicity	Required
Acute inhalation toxicity	Required if the PPP (a) Is a gas or liquefied gas (b) Is a smoke-generating plant protection product or fumigant (c) Is used with fogging/misting equipment (d) Is a vapor-releasing plant protection product (e) Is supplied in an aerosol dispenser (f) Is in a form of a powder or granules containing >1% (w/w) particles <50 $\mu\text{m}$ (g) Is to be applied from aircraft in cases where inhalation exposure is relevant (h) Contains an active substance with a vapor pressure $> 1 \times 10^{-2}$ Pa and is to be used in enclosed spaces such as warehouses or glasshouses (i) Is to be applied by spraying
Primary eye irritation	Required, in vitro
Primary dermal irritation	Required, in vitro
Skin sensitization	Required, LLNA preferred

## Exposure Assessment

### Dietary Exposure

Plant protection plays an essential role in production of agricultural crops. Assessment of exposure of consumers to pesticide residues in their diet or drinking water is therefore an important aspect in the regulatory process. Residues of the active substance(s) and their potential metabolites in food matrices of plant or animal origin are measured. Using these residue levels as input, acute and chronic exposures via diet can be estimated via food basket models such as PRIMo (EFSA 2019).

Pesticide residues in drinking water must not exceed the legal limit of 0.1  $\mu\text{g/L}$  set by the EU Drinking Water Directive 98/83/EC. Residue levels in drinking water can be estimated using designated modeling algorithms, simulated application onto soil (lysimeter studies), or in rare cases, by actual sampling.

### Non-Dietary Exposure

Exposure to ASs in PPPs is estimated for operators, workers, bystanders, and residents. Operators are individuals who apply PPPs by spraying, spreading of granules, seed treatment, etc. Operators may be exposed to undiluted PPP while mixing and loading application equipment and also to diluted spray broth during application. Workers are potentially exposed to residues of the PPP when re-entering treated cultures, e.g., for harvesting, manual weed control, or other operations.

Bystanders and residents are members of the general public who may stand, walk, or live in the vicinity of treated cultures. Bystanders can be exposed via inhalation or dermal contact with drifting spray mist. Residents, including children, could encounter residual PPP on their own lawn.

Exposure models are available for estimating exposures of the described sub-populations with a variety of application conditions. In the EU, the Agricultural Operator Exposure Model (AOEM) is currently the recommended exposure model that covers the most common application techniques and exposure situations (EFSA 2014).

Exposure models yield conservative estimates by their very nature. In cases where the modeled exposure estimates exceed the reference doses, actual exposure measurements can be undertaken. In such exposure studies, operators wearing dosimeters apply the PPP in question under field conditions. Similarly, dosimetry on mannequins simulating bystanders can be performed to refine the exposure estimation.

Non-dietary risk assessment is based on systemic reference doses (see following section “[Hazard Assessment](#)”). It is therefore necessary to account for the absorption of the AS via various routes of exposure. In most cases, only measured dermal and oral absorption data will be available, while 100% absorption will be assumed for the inhalation route. The extent of oral absorption is estimated based on the ADME studies with the AS itself. In contrast, dermal absorption studies are performed with the formulated PPP (as concentrate and in-use dilution) to account for matrix and dilution effects. In the absence of suitable dermal absorption data, default values can be used, depending on the physical state of the PPP, whether it is water- or solvent-based and on whether the concentrated or diluted form of the PPP is assessed. The rules for evaluation of dermal absorption data and the application of default values are laid down in a specific guidance document by EFSA (EFSA 2017).

## **Hazard Assessment**

The risk assessment is based on reference doses that are typically set using No-Observed-Adverse-Effect Levels (NOAELs) as points of departure. NOAELs are adjusted by division by an assessment factor that accounts for inter-species differences between experimental animals and humans as well as intraspecies variability among exposed populations. Acute, subchronic, and chronic NOAELs are considered, depending on the duration of the exposure scenario for the exposed population.

The acceptable operator exposure level (AOEL) is the relevant reference dose for all modes of nondietary exposure. Since PPP applications are mostly restricted to certain seasonal growth stages, AOELs are often derived from NOAELs of sub-chronic toxicity studies. For active substances with substantial acute toxicity, an acute AOEL (AAOEL) is also necessary. In current regulatory practice, the (A) AOEL is corrected for systemic bioavailability if the measured oral absorption is lower than 80%.

For dietary risk assessment, the acceptable daily intake (ADI) is the relevant reference dose covering chronic intake of the pesticide residues via food and

drinking water. The ADI is typically derived from the lowest long-term NOAEL. For active substances with appreciable acute toxicity, the acute reference dose (ARfD) is also derived. Since there are currently no designated test protocols for establishing acute NOAELs, the ARfD is often based on short-term studies such as acute neurotoxicity or developmental toxicity studies. Unlike the (A)AOEL, ADI and ARfD are not corrected for oral bioavailability.

If a PPP contains several ASs, a combined risk assessment for human health is required. In a first tier, dose additivity will be assumed, i.e., several ASs will affect the same target in an additive fashion. If the combined coverage of the respective reference dose exceeds 100%, a refined assessment will be necessary. This refinement requires an analysis of each of the effects caused by each single AS. If, for instance, several ASs in the PPP affect the liver at a certain dose, a reference dose (e.g., an AOEL) for the target organ “liver” will have to be considered. If the combination of organ-specific AOEL coverage still exceeds 100%, a further refinement might look at different liver cell types that are affected (e.g., bile duct epithelium versus parenchymal cells) or a detailed mode-of-action analysis could support the independent, nonadditive action of two or more ASs. It is obvious that the situation can get very complicated if this risk assessment is extended to residues and their metabolites in food, and regulatory guidance for such an assessment is not yet available on EU level.

In addition to the quantitative risk assessment relative to these reference doses, there are hazard-based exclusion criteria that will exclude the AS from being approved, unless human exposure to the AS or its residues is negligible. This may apply to PPPs used in closed systems. The exclusion criteria comprise ASs that are classified as carcinogenic, mutagenic, or toxic to reproduction (Category 1A or 1B; CMR) or that are considered to have endocrine-disrupting (ED) properties. ASs that are persistent, bioaccumulative, and toxic to the environment (PBT) are also excluded from approval.

Thus, ED properties will normally lead to non-approval of the AS. Only quite recently, a first guidance document for assessment of ED properties has been published (ECHA and EFSA 2018). This assessment focuses on ED properties mediated via estrogenic, androgenic, thyroid hormone, or steroidogenic (EATS) pathways.

The OECD-testing guidelines in their current versions include hormone measurements (OECD TGs 408, 414) or assessment of sexual maturation in newborn animals (OECD TG 416). If an AS has been tested according to the latest versions of the test guidelines, the absence of ED-mediated adverse effect allows the conclusion that the AS is not an ED substance with relevance for human health.

However, this is currently an unlikely scenario as most active substances on the market have been tested according to earlier guideline versions that lack the ED-relevant parameters. Thus, a weight-of-evidence assessment of the available data needs to be conducted. It is likely that at least in-vitro screening assays into effects on estrogen- or androgen-receptor activation and steroidogenesis need to be performed for most existing ASs.

In addition to ED effects with human relevance, an assessment of the ED potential with regard to the environment is also conducted, but this is outside the scope of this chapter.

## **Authorization of Plant Protection Products**

In the EU, “authorisation of a plant protection product” means an administrative act by which the competent authority of an EU Member State authorizes the placing on the market of a PPP in its territory.

A PPP can only be authorized if all the ASs (and any synergists and safeners) it contains have been approved.

The PPP is subjected to a human health risk assessment as described above, based on the reference doses set for all ASs in the product under the use conditions proposed by the applicant. The toxicological data set for the PPP mainly serves classification and labeling and ensures that appropriate protective measures are taken when handling the PPP.

Assessment of efficacy and environmental safety are also essential cornerstones for the successful authorization of a PPP.

## **Approval of Active Substances**

In the EU, an AS is evaluated by a member state competent authority, acting as so-called “rapporteur Member State” (RMS) on behalf of the EU member states. A co-RMS is assigned to assist with the evaluation.

The producer of the AS submits to the RMS an application and a dossier containing the information stipulated by Regulation 1107/1009. The RMS should prepare a Draft Assessment Report (DAR) within 12 months after the dossier has been found to be complete. This 12-month period can be interrupted by so-called “stop-the-clock” procedures when the RMS requires the submission of additional information that is found necessary in the course of the evaluation process.

The DAR is then commented on by other MS, and the European Food Safety Authority (EFSA) will organize a peer review of the DAR. EFSA will draw a conclusion on the evaluation and recommend the approval or nonapproval of the AS and any conditions for the approval. Approval will typically be granted if at least one safe use for the AS could be demonstrated. This use is assessed based on information on a representative product which is assessed for its safety to humans and the environment. In addition, the hazard-based exclusion criteria (CMR, ED) must not be met.

The approval act is completed by an Approval Regulation issued by the EU Commission. The first approval of an active substance will be for a maximum period of 10 years. The renewal of an approval can be granted for a maximum of 15 years. To allow a seamless transition between approval periods, the renewal application must be submitted no later than 3 years before the expiry of the approval.

## The Glyphosate Controversy

The approval procedure and criteria for active substances are laid down in Annex II to Regulation 1107/2009. The procedure is the evaluation of scientific data by member states and EFSA experts.

However, the example of the glyphosate approval renewal shows that political pressure can supersede the recommendations of the scientific experts. The German competent authority as rapporteur proposed a renewed approval for 15 years in the renewal assessment report dated 18 December 2013. In 2015, the International Agency for Research on Cancer (IARC) published a monograph in which glyphosate was classified as “probably carcinogenic to humans” (Group 2A; IARC 2015). This prompted the EU Commission to mandate a reassessment by EFSA of the carcinogenicity data for glyphosate. The reassessment confirmed the initial finding that glyphosate is not carcinogenic. The subsequent substance evaluation by the European Chemicals Agency (ECHA) also confirmed that glyphosate is not carcinogenic (ECHA 2017). The difference between EU and IARC assessments can at least partly be explained by the fact that IARC did not take the numerous regulatory studies in which no carcinogenic activity was observed into account (see Greim et al. 2015 for review). IARC claimed that the full study reports were not available for assessment. Instead, epidemiological studies in which exposure to glyphosate-containing formulations was identified as risk factor for tumor diagnoses were weighted high in the IARC assessment, even if none of the critical studies were scientifically robust (Acquavella et al. 2016).

However, the IARC evaluation had already sparked initiatives by non-governmental organizations toward an EU-wide ban of glyphosate, and a European Citizens’ Initiative garnered enough signatures so that the EU Commission had to consider the proposal for a ban. Member states could not agree on either approval or non-approval, and the decision was postponed. Finally, a renewed approval for 5 years was agreed on by member states. Thus, the initial 15-year approval proposal was turned into a 5-year renewal, even though all concerned scientific bodies in the EU agreed that glyphosate was non-carcinogenic.

The example of glyphosate approval in the EU goes to show that the political decisions can overrule scientific judgment.

## Co-Formulants

Co-formulants are non-active ingredients of a PPP that do not qualify as safeners or synergists. Co-formulants comprise, e.g., solvents, thickeners, surfactants, emulsifiers, or pigments. The use of co-formulants is restricted by Annex III to Regulation 1107/1009 which is essentially a negative list. Substances listed on Annex III are not accepted for inclusion in a PPP.

Co-formulants essentially underlie the same exclusion criteria as ASs. With regard to human health effects, co-formulants must not be classified as carcinogenic, mutagenic, or toxic to reproduction (Category 1A or 1B) or have ED properties.

An import example of a now-banned co-formulant is the polyethoxylated (POE) tallow amines (CAS No. 61791-26-2) which were frequently used in glyphosate-based herbicides. Even though the polyethoxylated tallow amines did not fulfil any of the exclusion criteria (e.g., CMR, ED, and PBT), EFSA concluded that “compared to glyphosate, a higher toxicity of the POE-tallow amine was observed on all endpoints investigated.” Additional concerns were highlighted as regarding the potential of POE-tallow amine to negatively affect human health, and POE tallow amines were excluded from use in PPPs containing glyphosate. The ban was extended to all PPPs by the EU Commission, and POE tallow amines were added to Annex III of Regulation (EC) No 1107/2009.

There is no data requirements for co-formulants under Regulation (EC) No 1107/2009. It suffices to submit safety data sheets for co-formulants along with the PPP authorization dossier. However, co-formulants must be registered for their use in PPPs under the REACH Regulation 1907/2006. The use pattern of agrochemicals differs from the professional or industrial use of other chemicals, e.g., the application mostly occurs in the open field, resulting in intentional release into the environment. The standard tools for human and environmental exposure assessment that are regularly employed for industrial uses are not suitable for agricultural applications. To facilitate the risk assessment for co-formulants under REACH, the European Crop Protection Association (ECPA) has developed the “REACH-IN” initiative. REACH-IN provides risk assessment tools fit for agrochemical applications that also meet the requirements of REACH (Dobe et al. 2016; Mostert et al. 2019). The co-formulant uses should preferably be registered by the manufacturer or importer of the coformulant. However, niche uses as in PPPs may be easily overlooked by manufacturers of bulk chemicals. In this case, the agrochemical use may also be registered by the PPP manufacturer in a downstream-user chemical-safety report.

## Abstract

Small molecule therapeutics are chemically defined compounds. Their large-scale production and the molecular structure are highly defined. In contrast, biopharmaceuticals are large and very complex molecules and described by its primary, secondary, tertiary, and quaternary structure. To make it more complex, biopharmaceuticals are recombinantly produced in cells by transfecting the cells

with the genetic code of the protein. In the early days, different cell types are used for protein production, but today Chinese hamster ovary cells (CHO cells) are the cells used for biopharmaceutical production. In this chapter, all the important aspects for biopharmaceutical production like cell line development, cell clone selection, upstream development (USP), and downstream development (DSP) will be discussed.

**Introduction**

The global therapeutic protein market was valued at about \$93.14 billion in 2018 and is expected to grow to \$172.87 billion at a compound annual growth rate (CAGR) of 16.7% through 2022 (Therapeutic Proteins Global Market Report 2020). In order to benefit from this growing market, it is imperative that those involved in the chemistry, manufacturing, and control (CMC) aspects of biopharmaceutical products provide “first time right” product development information in the quality module of the common technical document (CTD) to health authorities. By doing so, sponsors can expect to obtain approval to conduct clinical trials and ultimately to obtain marketing authorization for their drug candidates in the most expeditious time possible. Not knowing the expectations of the health authorities who review the CMC information in regulatory filings can cause delays in the approval process and therefore delays in obtaining marketing approval for the sponsor’s drug and associated loss of revenues. In the following paragraphs of this chapter, the author will review and discuss “CMC points to consider” from a regulatory perspective when developing a protein-based therapeutic. These points to consider are not as much from any one health authority’s “points to consider” or “code of regulations” but are a culmination of experiences from the author’s 35+ years in drug development and contributions to regulatory filings and responses submitted to health authorities. While health authorities may be consistent generally on the majority of drug development requirements and topics, it is highly likely that at least one health authority may have a different standard or perspective on a given topic in a global filing. The author also does not claim that this list as “all inclusive.” The information discussed is some of the more critical aspects and requirements for biotechnology and biopharmaceutical companies to consider when developing the filing strategy for an investigatory new drug (IND) application or Investigational Medicinal Product Dossier (IMPD). The authors recommend that the readers review the guidance documents listed for more information. In the following chapter, the author defines the term “new molecular entity” or “NME” as a generic term applied to a new therapeutic molecule that enters formal drug development at the preclinical toxicology stage.

## Foundations of Drug Development: TPP, Quality TPP, CQAs, and Control Strategy

In order to stress the importance of developing a drug candidate in a pragmatic manner, FDA published a draft guidance document on the concept of target product profile (TPP) and its role guiding the overall drug development strategy for a clinical drug candidate (Guidance for Industry and Review Staff 2007; Part 1 2008; [Target product](#)). The TPP is a format to summarize the drug development program of a new molecular entity (NME) as described in terms of the drug’s intended label at commercialization. The TPP describes, at a high level, the goals of the drug development program and documents the studies that are required to support the label in a manner that allows for future interactions with the FDA. Key sections of the TPP from a CMC perspective which become the quality TPP (QTPP) are as follows:

- Dosage and administration
- Dosage forms and strengths
- How supplied/storage and handling

To drill deeper into the requirements of the TPP, the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) issued Q8 which describes in greater detail the concept of the quality TPP (QTPP). The QTPP provides an understanding of what will ensure the quality, safety, and efficacy of a specific product for the patient. In the ICH quality guideline [ICH Q8\(R2\)](#), guidance is provided on the goals for pharmaceutical development in the overall drug development strategy or QTPP. Sponsors should define the quality target product profile (QTPP) of an NME and include attributes such as the route of administration, dosage form, bioavailability, strength, and stability. Quality attributes of an NME are those that directly impact quality, safety, and efficacy. In addition, ICH Q8 provides guidance on identifying potential critical quality attributes (CQA) and then defining a control strategy for those attributes to ensure that a product is consistently manufactured to meet those attributes. The QTPP therefore describes the design criteria for the product and should form the basis for the development of CQAs, critical process parameters (CPP), critical attributes (CMA), and the overarching control strategy.

ICH Q8 defines CQAs as a physical, chemical, biological, or microbiological property or characteristic that should be within an appropriate limit, range, or distribution to ensure the desired product quality. These are attributes of the molecule that the sponsor needs to control to ensure that a product is safe and efficacious. Some of the CQAs will originate from health authority expectations and others from the molecule’s mechanism of action. For example, an antibody which binds to a target cancer cell and then elicits an ADCC response to kill the target cancer cell would have both antigen binding and Fc effector function activity as CQAs. In addition, it is known that the fucosylation levels of an antibody designed to elicit an ADCC response are also critical to achieve the desired effect (i.e., low fucose levels

correlate to higher ADCC activity). As such, fucose levels would also be a CQA for such an antibody. In addition to those CQAs that are related to the MoA, CQAs related to purity (% monomer), strength (protein concentration), quality (sterility, endotoxin content), identity, and potency (bioactivity) are also expected CQAs for a therapeutic protein. A final subset of CQAs fulfilling health authority expectations such as color, turbidity, pH, and appearance also need to be identified as CQAs and controlled by the sponsor.

“Control” of a CQA can be achieved by (1) controlling the raw materials needed to manufacture the product, (2) in process and final product testing, or (3) controlling critical manufacturing process parameters (CPPs). A CPP is a process parameter whose variability has an impact on a CQA and therefore needs to be monitored or controlled to ensure that the process produces the desired quality product. Examples of CPPs include the production bioreactor temperature and pH set point and allowable range and the duration that cells are grown (production day). Although not mentioned in ICH Q8, the concept of control strategy is also applied in the biopharmaceutical industry to the quality of raw materials used to manufacture the product. It would therefore also be critical to define the critical material attribute (CMA) of all raw materials used in the manufacturing process to ensure that a safe and efficacious product is consistently manufactured. A CMA is a physical, chemical, biological, or microbiological property or characteristic of an input material that should be within an appropriate limit, range, or distribution to ensure the desired quality of the output material. Sponsors therefore also need to define the CMAs as part of their control strategy.

In summary, health authorities expect sponsors to define the QTPP, control strategy, and associated CQAs, CPPs, and CMAs in great detail in a market application. In order to gain approval, the sponsor will need to provide assurances (i.e., drug development data) in the marketing application to demonstrate they have gained sufficient knowledge about the raw materials used in manufacturing and about the processes used to manufacture the desired commercial that consistently meets the defined specification. In essence, the specifications define the acceptance criteria for the product CQAs that are filed in the marketing application.

For more information on the concept of QTPP, control strategy, CQAs, CPPs, and CMAs, the author recommends that the reader review “A-Mab: A Case Study in Bioprocess Development” (A-Mab, 2009).

---

## **Quality Levels for Development and Manufacture of GLP, Phase 1/Phase 2, and Phase 3/Commercial Supplies**

The health authority community develops and issues regulations and guidances to protect humans enrolled in clinical trials and in the commercial marketplace. These documents do not apply when specifying the quality requirements needed to manufacture GLP toxicology supplies. The regulations do specify that such supplies do not need to be manufactured under the same (i.e., GMP) conditions

necessary to produce drugs for clinical evaluation; however, supplies used in GLP preclinical safety studies do need to be representative of those to be subsequently used in clinical trials. Regulations do require that the testing of GLP supplies be performed using qualified methods under the auspices of an overarching quality system (i.e., quality assurance oversight). The reason for this is that the GLP and GMP regulations that focus on testing serve two different purposes. GLPs are designed to protect scientific data integrity and to provide health authorities with a clear and auditable record of open-ended research studies. In contrast, GMPs are intended to demonstrate to the health authorities whether or not individual batches of a regulated product are manufactured according to predefined manufacturing criteria. Given the time constraints and sense of urgency that many drug developers work under, it is best practice to use the same qualified methods to test the first in human (FIH) enabling GLP supplies and P1 supplies. The reason for this is the data generated on both test articles can be used to support comparability of GLP supplies to P1 supplies as this exercise is necessary if the sponsor manufactures GLP supplies and P1 supplies under different conditions such as scale or facility location. Additionally, since the products are tested by the same methods, the sponsor will also be able to use the stability data on the GLP toxicology batch to set the expiration date for P1 supplies which are typically manufactured at a later time.

---

## Analytical Development

Analytical methods should be validated for their intended use in early development. A method validation study needs to be performed under an approved protocol for each method used for in-process and release/stability testing. The protocol needs to specify the procedure with acceptance criteria for each method with respect to the method's specificity, accuracy, repeatability, precision, linearity, range, and limit of detection/quantitation. In early development, a validation study performed by one or two analysts on a single instrument may be sufficient. The sponsor typically describes each method used for in-process, characterization, release, and stability testing in Section 3.2.S.2.4 and 3.2.P.5.2 of the quality module in a CTA (clinical trial application) in an early development regulatory filing. The sponsor also provides a summary of the acceptance criteria and results from each method validation study for health authority review.

When a CMC program transitions to P3 late development, analytical methods need to meet the expectations for commercial methods as these methods will be used to test P3, validation, and commercial batches. P3/commercial methods need to be fully validated. A full validation will typically include multiple analysts using multiple instruments in both the analytical development lab and the commercial testing site. The sponsor will describe the commercial analytical methods and method validation results in much greater detail in the same sections as an early development filing in their commercial marketing application.

## Forced Degradation Studies

Formulation scientists do their best to deliver a stable drug product formulation into the clinic. They perform screening studies to determine the optimal pH at which to minimize product degradation. In addition, they may add antioxidants (methionine, EDTA), stabilizers (sucrose, sorbitol), and surfactants as excipients to minimize/prevent the product from degrading over time in the final formulation buffer. Despite their best efforts, the product may inevitably degrade due to adverse environmental conditions such as temperature excursions and excessive light exposure during storage, excessive shaking during shipping, and time in solution. As such, biopharmaceutical companies should determine as soon as feasible what the potential degradation pathways and resulting products of their therapeutic protein are that will be under clinical evaluation. Sponsors should first perform a preliminary assessment by examining the amino acid structure of the NME to identify concerning “hot spots.” Hot spots include amino acid sequences susceptible to clipping (e.g., ASP/PRO sequences), deamidation (such as ASN or ASP), or oxidation (MET or TRP). Without this data, the sponsor will not have sufficient insight to identify/determine which analytical methods need to be developed and implemented to assess changes in the critical quality attributes of the molecule at release and on stability. Degradation products can lead to increased toxicity/immunogenicity and/or in a reduction in the potency of the molecule or half-life. Therefore, health authorities expect sponsors to file the results from forced degradation studies in the regulatory filings and expect the sponsor to employ a sufficient number of analytical methods to detect changes in those degradant levels over time. Clipping whether it be by proteases or peptide bond hydrolysis under acidic conditions at susceptible amino acid sequences leads to fragmentation which can be monitored using analytical methods based on molecule weight such as size exclusion HPLC or capillary electrophoresis methods run under reduced conditions. Deamidation and oxidation species can be detected and tracked using charge-based methods such as capillary electrophoresis (cIEF) or ion exchange chromatography (IE-HPLC). Molecular changes can also be identified and quantified using peptide mapping techniques, but such methods are difficult to implement on a routine basis in a QC lab environment. Glycosylation is one of the most common posttranslational modifications (PTMs) of biopharmaceutical drugs and may have a pivotal role in their safety and efficacy by modulating a wide range of drug properties, including immunogenicity, in vivo circulatory half-life, and effector functions (13). Glycosylation levels typically do not change over time unless there are enzymes present in the product. The author has not seen this phenomenon during his tenure in drug development.

## Stability

One of the biggest challenges facing development scientists is providing a stable drug product formulation in the appropriate presentation for initial clinical studies. Typically, the dose range for the P1 study is not known and may not be finalized until

after health authority feedback. As such, the required design space for a P1 formulation strength may need to span several log units. This is especially true on oncology programs where the starting dose could be as low as nanograms per kilogram body weight due to safety concerns with the mode of interaction (e.g., CD3 redirectors). The highest dose in the dose escalation scheme may reach mg/kg levels. For a single drug product formulation/presentation, to span the dosing requirements for the entire 5-log-unit range is challenging to say the least. The uncertainty posed by an unknown dose range to bracket translates into the development risk that a suboptimal concentration for active in the drug product is selected. If this occurs, it could negatively impact the stability of the drug product becoming a significant risk that the clinical study could be interrupted.

It is of the utmost importance that the formulation scientists base their formulation decision on a well-planned stability program to generate sufficient stability data with the lead formulation in the selected container closure system. Once the sponsor identifies the proper formulation and methods to assess the stability of the drug substance and product, it is time to develop a stability strategy. ICH guidelines are the most appropriate to follow. Based on the risk that the product will not be stable over the intended shelf life, the sponsor needs to demonstrate that they have enough knowledge about the stability of the drug product in the selected formulation in the regulatory filing to gain approval to start clinical trials. A typical strategy would be for the formulation scientist to first generate development data on several formulations. Many companies now use high-throughput screening in microtiter plates to evaluate multiple formulations in a short period of time. Once an acceptable lead candidate is identified, the formulator typically prepares a lead lot representative of the P1 clinical material. The resulting drug substance is filled as a lead lot in the P1 container closure system under comparable conditions at least 6–9 mo. prior to a regulatory filing. The clinical lot is subsequently filled 4–6 mo. prior to the filing. It is worth noting that the clinical drug product will lose at least 6 mo. shelf life prior to the administration of the first dose. By following this strategy, the sponsor will be able to file with 3–6 mo. data on the lead lot and 1–3 mo. data on the clinical lot.

The lead and first clinical lots are placed in a stability program under real-time, accelerated, and stressed conditions. Storage temperatures and testing time points for the stability program should be based on the International Conference on Harmonisation (ICH) guidelines (ICH Guideline Q1A Stability Testing of New Drug Substances and Products; ICH Guideline Q5C: Quality of Biotechnological Products, Stability Testing of Biotechnological/Biological Products). Table 1 is an illustration of a stability plan for a typical therapeutic protein drug product stored under refrigerated conditions.

By generating stability data in excess of the recommended storage temperature of 5 °C in a standard stability study, sponsors will be able to support temperature excursions that may occur when the product is stored in the warehouse, when the product is in transit to the clinical site, or when the product is stored at the clinical site. With acceptable accelerated and stressed stability data, the sponsor will be able to extrapolate the shelf life of the product from the real-time value. In other words, with acceptable 3 mo. stability data at all three temperatures (real time, accelerated,

a: Release data is T = 0

A = 5 °C, B = 25 °C, C = 40 °C

and stressed), the sponsor will be able to claim 6 mo. shelf life on the clinical supplies.

If the sponsor intends to change formulations during later stages of development, then there is limited information that can be gained studying additional batches of P1 clinical drug substance or drug product on stability. Under these circumstances, drug developers can save resources by not formally testing drug substance or drug product batches after the first clinical batch. The developer may choose to place subsequent batches in the appropriate stability chambers (i.e., place “on station”) and then pull and freeze samples at – 80 °C at the designated time points. If there are inconsistencies in the stability data from the lead or first clinical lot, the drug developer can thaw the samples that were placed “on station” to generate additional stability data in order to make decisions about the stability of the molecule in the designated formulation.

In addition to the health authority expectation that the storage temperature and shelf life for drug substance and drug product be defined and supported, health authorities (especially in Europe) expect intermediate hold times to be justified by supportive data even in a P1 filing. Sponsors should generate stability data for all process step intermediates in their process development studies. When generating intermediate hold time data, a worst-case approach should be considered. For example, if the product is permitted to be stored at room temperature for 24 h, the sponsor should generate data at the highest temperature defined as room temperature (typically 15–25 °C so study at 25 °C) for a period of time in excess of >24 h. This will provide additional margin in case the manufacturing plant experiences a delay or a temperature excursion due to any downtime with the facility HVAC heating/cooling system.

## Comparability

Health authorities consider the process used to manufacture a protein-based therapeutic product starting from clone selection to the final filled drug product as the investigational product. Any change to the cell line or the process to manufacture the biologic-based therapeutic could impact the structure of the molecule and hence the safety and/or efficacy of the molecule. Process changes include cell line changes, purification step changes, conjugation reaction step changes, manufacturing site/scale changes, and drug product presentation changes (e.g., liquid vial to lyophilized vial), to name a few. The more changes made to the “process,” the more extensive the comparability exercise is required to demonstrate that the molecule pre- and post-change is highly similar/comparable. The key question to address from a regulatory perspective is: “Have any of the process changes caused the critical quality attributes of the molecule to be altered, and if so, what is the impact of those changes on product safety/immunogenicity and/or efficacy?” Changes that impact attributes such as aggregate or fragment levels can enhance the immunogenicity of the molecule and hence negatively impact the safety profile of the molecule. This would call into question the nonclinical and/or clinical study data previously generated with the pre-change product. As such, health authorities may insist that a safety study be conducted on the post-change molecule to ensure that there is no change on the safety profile of the drug. Changes to glycosylation patterns can cause changes with the FcRn binding characteristics and therefore impact the pK<sub>1/2</sub>/half-life/C<sub>max</sub> of the molecule (Zhang et al., 2016). If so, health authorities may require a pK study with the post-change molecule to ensure similar exposure levels pre- and post-change. The most impactful comparability requirement could be enforced if a process change(s) impact critical quality attributes associated with the activity of the molecule such as ability to bind to the target and elicit the necessary biological response. It is well known that fucose levels impact an IgG1’s effector function activity. Low fucose levels are associated with higher effector function activity (such as antibody-dependent cell cytotoxicity or ADCC) as compared to higher fucose levels. Any change to cell line or media can impact glycosylation and therefore can impact biological activity. If these changes are significant, health authorities may require a study to assess the impact on efficacy if not also safety. Sponsors should consult with health authorities in advance on this topic. It is generally not “value added” to discuss comparability plans without having side-by-side pre- and post-change attribute testing data to propose a plan to address what the impact of any changes in attributes could mean on safety and efficacy.

### Early Development Comparability Strategy

Realistically, there is minimal development time allotted to biopharmaceutical developers to define the process and formulation for GLP toxicology supplies. Sponsors want to find out as soon as possible with the minimal level of investment if an NME will progress into clinical development and then to the commercial market. GLP supplies are typically manufactured in a non-GMP facility at a smaller scale than P1 clinical supplies. They may also be manufactured with a

crudely developed purification process and formulated in a suboptimal excipient matrix. As such, any change in process, formulation, site, or scale will trigger a comparability exercise. If the change is relatively minor (a change in a column process step, change from a frozen liquid vial presentation to a refrigerated liquid or lyophilized vial presentation, change in manufacturing site, etc.), “CMC” comparability is generally sufficient. CMC comparability involves a detailed comparison of product quality attributes leveraging both release tests and characterization tests. Characterization tests must include those tests that can discriminate for changes in biological (Fc effector receptor binding or function, FcRn binding, target antigen binding, etc.), biochemical (carbohydrate analysis, amino acid sequence/modifications, etc.), and biophysical (sedimentation rate by ultracentrifugation, melting point, etc.) attribute differences. These tests should also be performed on stressed and stability samples to ensure that the molecule degrades at a similar rate yielding similar degradation products pre- and post-change(s). If changes, no matter how small, cause changes to critical quality attributes of the molecule, then *in vivo* comparability will be required to advance the asset into the next phase of clinical development.

### **Late Development Comparability Strategy**

The goal of most biopharmaceutical companies is to have the commercial process implemented in the commercial manufacturing plant at commercial scale prior to manufacturing P2b pivotal or P3 clinical supplies. It is imperative that the clinical supplies used to generate the pivotal clinical study data be statistically representative (i.e., the “same”) as commercial supplies for health authorities to approve a commercial license application. Product quality data generated on pivotal supplies is used to set specifications, and that data needs to be correlated to the clinical safety and efficacy data generated from the pivotal study. Given the large investment required to move into and support/conduct pivotal studies, biopharmaceutical companies will make most process changes required to ensure that the final process is robust and commercially viable from a cost of goods and capacity perspective, that the formulation is robust/stable, and that the presentation is focused on appeasing the patient prior to entering P3. Changes considered during P3 or prior to commercial launch should be highly scrutinized. Prior to P2b/P3, the sponsor may make cell line and media changes to boost titer and productivity, process changes to improve yield and throughput, and presentation changes (vial to prefilled syringe) to boost convenience and therefore market acceptance. Material representative of the P3 process and product should be manufactured as soon as possible so the data can be evaluated and compared to pre-change product data. Once changes are known, an acceptable comparability strategy as discussed previously can be reviewed with the health authorities. Health authorities may accept the proposal to approve process and formulation changes based on CMC comparability, or they may request that the changes/product attribute differences are significant enough to warrant that a clinical comparability study be conducted. If so, the sponsor will need to generate clinical data (pK, safety/immunogenicity, and/or efficacy) to support the differences seen in the post-change molecule.

## Product Characterization: Elucidation of Structure and Impurities

The health authorities expect the sponsor to know their molecule and the impurities associated with their molecule so they can make an assessment about the safety of the molecule and the potential for toxicity associated with any impurities of the molecule. For the desired product and product-related substances, the sponsor should provide detailed information on the biochemical, biophysical, and biological properties of the molecule. The sponsor should demonstrate how the structure of the molecule determines the biological activity of the native protein. Biopharmaceutical companies employ a number of analytical tools to determine the primary, secondary, tertiary, and quaternary structure of the molecule in the hopes of linking the structure to the functionality/biological activity of the molecule. Examples of the analytical tools employed to determine the structure of a biotherapeutic are listed in Table 2.

Once the structure of the molecule is defined, the sponsor characterizes the biological activity of the molecule linked to the defined structure. Examples of the analytical tools employed to determine the functionality/biological activity of a therapeutic protein are listed in Table 3.

In addition to characterizing the product of interest, the sponsor must also identify and characterize product-related and process-related impurities associated with their molecule, typically those exceeding 1% relative abundance. Product-related impurities include aggregates and fragments of the native molecule and posttranslational modifications such as glycation, oxidation, deamidation, C-terminal lysine cleavage, pyroglutamate, etc. Process-related impurities include any chemicals used in the manufacture that could be carried through the process and present themselves in the final product such as protein A ligand, antifoam, or reduction agents. Impurities associated with the biological process such as host cell protein or DNA are also quantified and reported.

The sponsor is expected to provide the raw data (chromatograms, thermograms, mass spectrums, curves, etc.) associated with those analyses used to elucidate the

structure and characterize the product and associated product-related impurities in Section 3.2.S.3.1 of their regulatory filing.

## Manufacturing Material Inputs

### Master and Working Cell Banks

Master and working cell banks used to manufacture a biotherapeutic protein should be considered as the GMP starting material and therefore need to be manufactured under GMP with the origin of the host cell line and resulting clones fully traceable. The sponsor should describe in detail the origin of the production host cell line in 3.2.S.3.2.3 of the quality module. If the sponsor intends to use the host cell line for multiple NMEs, the sponsor should create a master and working cell bank prior to transfection and have the cell bank tested with the appropriate methods including safety.

Now that the host cell line has been properly documented to ensure traceability and quality, the sponsor would need to describe how the expression construct was created. A diagram depicting the expression plasmid with each gene called out needs to be illustrated in the dossier. The sponsor will then generate a number of clones containing the expression construct/plasmid and will need to select a single clone from that pool that will produce the molecule of interest at the desired level of quality and productivity. Multiple clones are screened for titer, stability, product quality, etc., at small scale. Possible lead candidates are selected and grown in small-scale reactors. The selection process continues until a single clone is chosen. The sponsor will then create a master and working cell bank and then extensively test those banks to ensure that they are free of bacterial, mycotic, and mycoplasma contaminants, as well as adventitious and endogenous viruses originating from the host cell line or

**Table 4** Generic master and working cell bank testing plan

Tests	Testing plan	
	MCB	WCB
Viability	+	+
Purity (e.g., sterility, myco)	+	+
Retroviruses and other endogenous viruses (e.g., infectivity such as S+L-Focus Assay, reverse transcriptase)	+	–
Non-endogenous or adventitious viruses	+	+/-
Identity	+	+

+ = Test required

– = Test not required

+/- = Depends on test, not required if MCB was tested and not likely to change when creating WCB, e.g., QPCR for bovine viruses

any component used to make the cell bank. In order to determine what tests should be performed on the master cell, the sponsor needs to determine what the likely/potential sources of endogenous and adventitious agents are in the cell banking process. Potential sources include the host cell line and materials used to create or grow the cell line (e.g., fetal bovine serum), personnel involved creating the cell line/banks, and the environment the cell line/banks were created/manufactured. Once the sources are identified, a testing plan is developed as shown in Table 4.

The author recommends that the developer familiarize themselves with the cell bank testing requirements delineated in ICH Q5a and ICH Q5d for additional information on testing strategies.

The transfection process and the process to create the production cell line from research cell bank to master and/or working cell bank also need to be provided. The test results for the master and working production cell line also need to be provided to health authorities for their review in Sect 3.2.S.3.2.3. If animal-derived products such as fetal bovine serum were used in the cloning process or production cell line creation process, the sponsor must describe the sourcing of the material and any test results on the material and provide a Certificate of Suitability in that section as well.

## Raw Materials

Health authorities expect the sponsor to control the quality of the raw materials used to manufacture their biopharmaceutical product. The controls implemented need to be described in the Control of Materials section of the dossier. For compendial raw materials, the sponsor will need to test those materials using the compendial methods and acceptance criteria of the countries where the product will be studied (i.e., in clinical trials) or markets launched/sold. If the product is intended for global studies or commercial marketing approval, then the sponsor would need to employ test methods and acceptance criteria that simultaneously meet USP/NF, EP, and JP standards. If the sponsor intends to conduct studies and launch in China, then ChP

standards must also be met. If the sponsor desires to market their product globally, it is best for the sponsor to meet all compendial requirements as early as possible but no later than at P3. If the sponsor reaches late development and finds out that one of the raw materials does not meet the standards for a region that they intend to commercialize in, it can pose a dilemma. The sponsor would either need to switch to a material that complies to the requirements for all markets which would require a supporting comparability program or the sponsor may choose not to commercialize in that region. The recently published ChP purity requirements for polysorbate are quite stringent, more so than other compendia. As a result, many companies are having to switch to alternative sources of polysorbate that differ from those used to manufacture their product. These companies now need to conduct comparability studies with their product formulated in polysorbate 80 sourced differently than what they have been manufacturing and clinical experience with if they wish to enter or remain on the market in China. If the product performs differently in the new polysorbate 80, the sponsor may not be able to conduct clinical studies in or market their product in China.

Not all raw materials used to manufacture a biopharmaceutical product are compendial. Cell culture media and chromatography resins fall into this category. For the non-compendial raw materials, health authorities expect the sponsor to establish and provide product specifications, certificates of analyses, and other information on the qualitative composition and controls of those materials. If those raw materials are considered proprietary by the manufacturer, the manufacturer will most likely not share the necessary product information with the sponsor. In those instances where the manufacturer has filed a Drug Master File, a letter of authorization (LOA) from the supplier should be provided in the dossier which authorizes the health authorities to view the supplied information on the composition of the material.

It is well known within the biopharmaceutical industry that all raw materials and components used in the manufacturing process be derived, whenever possible, from nonanimal sources. This requirement applies to media components (human recombinant insulin and transferrin vs. animal derived) and excipients (vegetable-derived vs. animal-derived polysorbate). What may not be as well known is that even reagents used in the subcloning process to create the manufacturing cell line are viewed as a “raw material” by health authorities. As such, the material needs to be certified as being animal-free.

In order to prove to the health authorities that the sponsor is in control of the raw materials used to manufacture their products, it is recommended that the following steps be proceduralized and implemented. The sponsor should develop a master certificate for every raw material established that can be provided to the health authorities upon request. Each master certificate should contain the following minimum documentation:

- Product specification and certificate of analysis for each batch received.
- For excipients, a GMP certificate and formal risk assessment as required per EMA directive 2015/C 95/02.

- Certificate to confirm the absence of human or animal components.
- BSE/TSE certificate and/or certificate of suitability (if appropriate).
- Melamine statement (if appropriate).
- For media and feeds, a completed questionnaire containing the qualitative composition of critical components should be requested from the manufacturer.

Taking these steps when the sponsor first develops their supplier and raw material qualification effort will save the sponsor time and effort on the back end during regulatory filing reviews or during quality audits.

---

## Specifications

Health authorities expect the NME under consideration to be tested at key intermediate steps and at the final product stage and compared to a predefined acceptance criteria with limits or specifications. Tests performed depend on the critical quality attributes of the product and the defined control strategy for that attribute as described earlier in this chapter. The test employed for each attribute as well as the acceptance criteria are justified in 3.2.S.4.5, Justification of Specification of the dossier. Such testing is to be performed when the product is first manufactured (release or  $T = 0$  testing) and at predefined times that the product is stored at predefined temperatures. Key intermediate steps are steps in the process where the product may be stored for extended periods at a predefined (and supported) temperature and time prior to further processing. The drug substance (i.e., formulated or preformulated bulk) stage is a typical intermediate storage step leveraged by companies prior to the drug product filing stage. As such, the drug substance is tested according to the specification. The final drug product be it formulated bulk in a vial or prefilled syringe is also tested at release and on stability. The release results are described in the certificate of analysis (CoA) which is shared with health authorities in the regulatory filing.

Health authorities have been moving away from accepting acceptance criteria with “report results” and now expect all release tests to have acceptance criteria with numerical limits defined. For most therapeutic proteins, a specification for monomer of  $\geq 95\%$  is typically expected. With a monomer specification of  $\geq 95\%$ , impurity levels for higher molecular weight species or aggregate levels and low molecular weight species such as fragment would therefore need no more than 5% in total. Higher impurity levels than 5% would need to be justified by the sponsor and qualified as acceptable in the toxicity study.

In the commercial filing, health authorities expect the commercial specification to be based on a statistical analysis of the batches made and used in the clinic. As such, the sponsor needs to manufacture as many pivotal process batches as possible and include those batches (especially aged batches) in the pivotal trial. If possible, the sponsor should try to manufacture products with as much “variability” as possible so they can gain clinical experience with those batches and seek a commercial specification as broad as possible in the marketing application.

**Table 5** Generic drug substance specification for an early development biopharmaceutical

Attribute	Test method	Acceptance criteria	
		Release	Stability
General characteristics	For example, pH, osmolality	Range A–B	Range A–B
Identity		Identity confirmed	N/A
Quantity	Protein concentration	C +/- 10%	C +/- 10%

<sup>a</sup>K/M where K = 5 USP-EU/kg of body weight for any parenteral route of administration other than intrathecal and M = the maximum recommended bolus dose of drug per kg of body weight (Endotoxin Limits for Parenteral Drug Products 2017)

The specification for drug substance is described in S.4.1 and for drug product in Sect. P.5.1 Specifications. The specification is broken down into release specification (the acceptance criteria to release product at T = 0) and stability specification (the acceptance criteria which need to be met over the shelf life filed). A generic drug substance specification for an early development biopharmaceutical is provided in Table 5.

The reader is encouraged to familiarize themselves with ICH Q 6a (ICH Topic Q 6A Specifications) for more information on how to determine the necessary analytical methods required to establish specifications for their drug substance and drug product.

## Compatibility

The sponsor not only needs to control the quality of the product from the creation of the production clone through the manufacture and storage of the labeled drug product steps, they also need to document control during the preparation and

administration of the drug product to the patient. The sponsor not only needs to define the procedure to store, prepare, and administer the drug, they also need to test those steps to ensure the quality of the product is still assured. In order to do so, the sponsor will conduct simulation studies mimicking the same drug product storage, preparation, and administration steps through the completion of the dosing process at the clinical sites, hospital/clinic, or patient’s home. In these studies, the sponsor will define the acceptable time limits (e.g., 8 h) to prepare and administer the drug under the permitted environmental conditions (e.g., room temperature, protected from or under light). Depending on the diluent and the country, if the preparation and administration time is expected to exceed 4 or 8 h, the sponsor will need to conduct microbial challenge studies to ensure that the risk of contamination is properly mitigated by the preparation and administration procedure. The sponsor will define exactly how to prepare the drug if dilution is required and what the acceptable diluent(s) is/are. The sponsor also needs to define the acceptable material of construction (e.g., polypropylene, polyvinyl chloride, etc.) and the diluent if used (e.g., saline) for the ancillary supplies such as IV bags, administration sets, and syringes that are needed to prepare and administer the drug. Results from simulation testing need to affirm that the product attributes monitored in the study are not altered by the handling, preparation, and administration process and that the intended dose (quantitatively) is safely administered to the patient. A summary of the compatibility testing strategy and the results from the simulation study are provided to the health authority reviewer in Sect 3.2.P.2.6: Compatibility of the dossier.

---

## **Viral Clearance**

Many biopharmaceutical products are produced by mammalian cell culture-based processes. The mammalian cell lines leveraged include Chinese hamster ovary and SP20 cells. Even though CHO cells have never been found to harbor infectious rubella virus-like particles, RVLP (although they always show type A and sometimes type C RVLP when tested and have always been found to be noninfectious in 40 years of testing by numerous labs), for purposes of risk assessment and viral clearance, CHO particles are assumed to be infectious. As such, these “potentially” infectious particles need to be accounted for and removed from the process to a “safe” level. Most biopharmaceutical companies follow the following strategy to demonstrate adequate levels of viral clearance by process steps that are after the production bioreactor step to achieve a theoretically acceptable level of virus particles per dose.

First, the number of potential infectious particles is assessed by performing analyses on the end-of-production cells from the production bioreactor stage. End-of-production cells are analyzed by TEM (transmission electron microscopy) and the number of particles quantified and the number of infectious particles per mg of desired (crude) product quantified. An example of how to calculate this has been extracted from ICH Q5a (R1) and provided below to illustrate the concept.

### Assumptions

Measured or estimated concentration of virus in cell culture harvest =  $10^6$ /ml

Calculated virus clearance factor =  $>10^{15}$

Volume of culture harvest needed to make a dose of product = 1 l ( $10^3$ ml)

### Calculation

[Estimated particles/dose ( $10^6$  virus units/ml)  $\times$  ( $10^3$  ml/dose)] /clearance factor ( $>10^{15}$ ) =  $>10^{-6}$  particles/dose. Therefore, less than one particle per million doses would be expected.

Virus clearance studies are designed based on a model virus selected based on either their appropriateness to the production cell line or a worst-case virus. XMuLV (xenotropic murine leukemia virus-related virus) is typically chosen as a model virus for CHO cell-based manufacturing processes. MMV (mouse minute virus) is typically chosen as the worst-case model virus because (Therapeutic Proteins Global Market Report 2020) it has high chemical resistance and therefore is used to challenge chemical inactivation steps, and (Guidance for Industry and Review Staff 2007) because of its very small size, it can be used to challenge sizing based on removal steps such as the viral filtration step. Once the model viruses are chosen, viral clearance studies are then conducted under reduced scale conditions as it is impractical to execute such studies at the production scale. Virus-spiked feed streams are prepared for selected purification steps and the process step executed at reduced scale. Samples are collected for testing at various process steps (e.g., load, flow through, wash, and elution steps of a bind and elute chromatography step). The amount of virus spiked (vol. in x titer in) is compared to the amount of virus in the product containing pool (vol. out x titer out) yielding a log reduction value ( $[\text{vol. in x titer in}] / [\text{vol. out x titer out}]$ ) for the process step evaluated. For a simplistic example, if the amount of virus spiked was  $10^6$  and the amount of virus in the product containing pool was  $10^2$ , then a 4-log viral clearance value can be claimed for that specific step. The virus quantitation assay is run with the proper positive and negative controls to confirm that the virus titer obtained on the spiked samples or in the process samples is accurate and that the product in or buffer components in the solutions analyzed do not interfere with the viral quantitation assay.

Viral clearance studies are performed on specific steps of the purification process designed to remove or inactivate virus. For antibody products, the protein A chromatography step is a good step to study. First, the mode of interaction is affinity based so that virus particles (which lack affinity to the protein A ligand) will pass through with the flow through and wash. Second, the eluate is in a low pH buffer which acts as a viricidal agent. Genentech performed a meta-analysis on its own viral clearance database of protein A chromatography validation studies from 22 mAbs and 30 processes over the past 15 years; it was observed that clearance of X-MuLV measured by QPCR ranged from 2 to 4  $\log_{10}$  (Zhang et al. 2014). When the protein A affinity step is paired with a low pH hold/inactivation step after the eluate step, developers can expect additional clearance values (Chinniah et al. 2016).

Guideline ICH Q5 A (R1) provides detailed information on viral clearance strategies and methodologies and should be consulted by developers before designing a viral clearance study. It should be noted that health authorities expect such studies be performed in duplicate and that the lower clearance value for each step be used to calculate the overall viral clearance capability of the process.

---

## Conclusions

In the preceding paragraphs, the authors selected and discussed a small subset of CMC development activities that health authorities focus on when reviewing INDs and IMPDs. As a sponsor continues to develop their molecule, the expectations of the health authorities increase as does the amount of information expected in a regulatory filing. Much of that information is usually shared in Sect 3.2.S.2.6 and 3.2.P.2.3 Manufacturing Process Development overview. Information such as the sponsor’s experience with the development of each process stage, integrated control strategy, criticality assessment, analytical method history, compilation of all comparability exercises over the life of the molecule, etc., is provided in this section. Given the importance of each topic discussed, it is understandable why these sections contain many hundreds of pages in a marketing application and, for that reason, why the author did not discuss the requirements in any detail. It also bears reinforcing that the expectations of health authorities continue to increase with each filing that is submitted. As such, it is very important that the sponsor have the expertise based on either past filing experience or a detailed understanding of the regulations about the data required in a health authority submission. CMC development and CMC regulatory personnel should map out a content plan for each section of the quality module for each phase of development before performing the development work. Doing so after the work is completed will be too late necessitating the need to generate additional data to fill gaps identified when compiling the regulatory dossier. It takes many years to get a drug into the clinic and then to the market. Adding additional months to the development timeline after a filing is submitted and not accepted will not be viewed favorably. CMC professionals in the biopharmaceutical industry need to spend as much time designing quality into the protocols and reports that are used as source documents for the quality module of a CTA as they do writing the modules themselves. Only by doing so can one expect first time right/approval on their submission.

## Abstract

Traffic exhaust emissions are a major driver of premature diseases and deaths. A reduction of traffic exhaust emissions can be supported by a continuous climate-friendly transportation policy. The *European Green Deal* includes such policy measures, for example, the investment in green technologies and cleaner forms of public and private transport. In this chapter, we focus on the adverse health effects of air pollutants caused by traffic exhaust emissions. In particular, low- to middle-income countries but also industrialized regions are affected by traffic-related air pollution. The World Health Organization (WHO) estimated about 4.2 million premature deaths worldwide caused by air pollution. In particular, nitrogen dioxide and particulate matter (PM<sub>10</sub> and PM<sub>2.5</sub>) are major components of traffic exhaust and can lead to severe health conditions. While nitrogen dioxide has mainly local (respiratory) effects, particulate matter leads to an increase of total and cause-specific mortality. However, European limit values and WHO

guideline values show a huge disparity with limit values for  $PM_{2.5}$ . The European limit values are twice as high as the WHO recommendation. Various stakeholders involved in limit value definitions might be a reason for that disparity. Different technical and non-technical measures are introduced to achieve the European climate goal of 2050 – a climate-neutral European Union. Technical measures include particulate filters for light and heavy vehicles and the support of electromobility. Non-technical measures include smart traffic systems, low-emission zones, free public transportation services, and supporting the use of car-sharing services and bicycles.

**Introduction**

The transport sector is the third biggest polluter/perpetrator of greenhouse gas emissions in Germany with almost 20% of all generated pollutants (Bundesministerium für Umwelt Naturschutz und nukleare Sicherheit 2019). Although the federal government supports climate-friendly transportation policies and a significant increase in electric cars on the streets can be seen, only about 63.000 electric cars were officially registered in 2019, compared to 3.600.000 cars powered by combustion technology (Statista 2020; Kraftfahrtbundesamt 2020). A decreasing effect of traffic exhaust emissions can be clearly observed during the current coronavirus pandemic. The coronavirus pandemic leads to a significant reduction in the use of the transport sector resulting in impressive pictures of clean air and blue skies in the world's biggest "smog cities," such as Los Angeles, Jakarta, or New Delhi. As the world still takes a short pause from the significant pollution caused by various economic sectors, a certain sense of optimism for economic recovery is already gaining traction. The federal government of Germany initiated an economic stimulus package to drive consumption behavior. One part of that package includes the sales discount of electric cars. Though unionists and the automotive industry argue and fight that cars with combustion technologies were not included in the stimulus package, the federal government is setting an important marker for the necessity of turning toward a climate-friendly policy. But the discussion about environmental impact of traffic exhaust emissions caused by vehicles with combustion technology is not enough. Traffic exhaust emissions are a major driver of premature diseases and deaths. Though there is clear evidence of an increased mortality associated with traffic exhaust emissions, the impact of its individual components is still part of ongoing research activities. In this chapter, we want to address the different components of traffic exhaust emissions and explain the specific impact on human health. We will discuss what is evident and what is still under debate. Furthermore, we will explain the differences in traffic exhaust regulations, such as the definitions and differences of the terms guidance and limit values

with regard to specific traffic exhaust components. At the end of this chapter, we want to introduce the European legal mechanisms and measures to reduce these emissions.

---

## Air Pollutants

The emission of air pollutants decreased significantly since the 1990s in Germany. Only for ammonia, mostly emitted by the agriculture sector, constant emission values were detected over the last decades. The reduction of pollutant emissions could be observed in all 28 EU member countries including non EU member countries Iceland, Lichtenstein, Norway, Switzerland, and Turkey. However, EU-wide analyses showed an increase of emissions in certain sectors, such as in the shipping (in particular nitrogen dioxide) and in the aviation sector.

For traffic exhaust emissions, carbon dioxide emissions remain on a high level, though efficiency on combustion technologies has been widely implemented. In 2018, the transport sector was responsible for the emission of 162 million tons of carbon dioxide equivalents, compared to 163 million tons of carbon dioxide equivalents in 1990. The self-declared climate goal of the federal government of Germany is to achieve a reduction of carbon dioxide emissions about 40% – by 2030. A reduction of carbon dioxide by implementing sustainable and climate-friendly policy strategies is one of the main recommendations of the Leopoldina National Academy of Science. In particular traffic exhaust leads to health implications beyond the burden with hazardous pollutants (Leopoldina Akademie der Wissenschaften 2019). Besides carbon dioxide, traffic exhaust emissions contain several other components, with particulate matter and nitrogen dioxides as its most prominent representatives.

Particulate matter (PM<sub>10</sub>, PM<sub>2.5</sub>, ultrafine particles (UFP)) describes the mixture of solid particles and liquid droplets in the air. Particulate matters are emitted ubiquitously. The natural sources of particulate matter are volcanic eruptions, for example. Industrial sources for PM are the transport sector and the agriculture sector among others. PM can be divided into three different groups, depending on the particle size. PM<sub>10</sub> has a diameter less than 10 µm, PM<sub>2.5</sub> has a diameter less than 2.5 µm, and ultrafine particles (UFP) have a diameter less than 0.1 µm. The particle diameter has a significant influence on the distribution in the human body. For example, PM<sub>10</sub> remains mainly in the upper respiratory tract, while PM<sub>2.5</sub> can penetrate the lower respiratory tract (alveoli). UFP are able to pass the air-blood barrier and can induce systemic health effects. PM can be further divided into primary and secondary particulate matter. Primary particulate matter is emitted directly into the atmosphere. Secondary particulate matter is formed by photochemical reactions of different molecules in the atmosphere. The health impacts of PM depend on the particle size and surface which is the crucial factor for the penetration depth in the body and the composition of the PM. Secondary PM can take up hazardous components, such as heavy metals or organic pollutants with carcinogenic

potential. If these components have a particle size less than 0.1  $\mu\text{m}$ , they can pass the air-blood barrier and distribute in different organ systems.

Black carbon (BC) is a component of particulate matter and is formed by the incomplete combustion of fossil fuels. Black carbon is co-emitted with other particles and gases. Main sources for black carbon emissions are open burnings, traffic, and heavy industry. Black carbon has a significant environmental impact by driving global warming. Regarding health impacts, BC can be assigned to the PM group with its specific health effects, depending on the particle size.

Nitrogen monoxide or dioxide ( $\text{NO}/\text{NO}_2$ ) belongs to the group of gases called nitrogen oxides ( $\text{NO}_x$ ) and is mostly emitted by burning fossil fuels. Regarding the impact on human health and environment,  $\text{NO}_2$  is of great concern. Vehicles using diesel are the main sources for  $\text{NO}_2$  in road traffic. Aside from the transportation sector, power plants are a main issuer of  $\text{NO}_2$  emissions. Discussions about driving restrictions usually focus on  $\text{NO}_2$  emissions, although health impacts are mostly restricted to the respiratory system. The environmental impact of  $\text{NO}_2$  and other  $\text{NO}_x$  is the formation of acid rain with its dramatic implications on sensitive ecosystems, such as forests.

Ozone ( $\text{O}_3$ ) is an odorless gas and a so-called “secondary” pollutant. It is formed from gases, such as nitrogen oxides or volatile organic compounds in the presence of solar light. Since nitrogen dioxides are the basis for the formation of ozone, nitrogen oxide-emitting sources are the cause for high ground-level ozone concentrations. High ozone concentrations are dependent on the season, since high levels of solar radiation and high temperatures during summer lead to its formation. Ozone can lead to an irritation of the airways. In particular in persons with underlying respiratory conditions, high levels of ozone can lead to severe clinical symptoms.

Sulfur dioxide ( $\text{SO}_2$ ) is a toxic gas with a typical acrid smell. Although sulfur dioxide can originate from natural sources, about 99% of the sulfur dioxide in the air comes from industrial processes, such as industrial heating installations and power plants. Sulfur dioxide is mostly responsible for acid rain with its environmental implications for water, soil, and forests. The human health impact of  $\text{SO}_2$  is, similar to ozone, the irritation of the respiratory system.

---

## Health Effects

Ambient air pollution is a health risk, and traffic exhaust emissions are a major contributor to ambient air pollution. The World Health Organization (WHO) states that reducing air pollution can lead to a decrease in the prevalence of cardiovascular diseases, such as stroke or coronary heart disease, acute and chronic respiratory diseases, as well as lung cancer (World Health Organization 2018). In 2016, more than 90% of the world’s population was living in places, where the recommended WHO guideline values for air pollutants were not met. In particular, low- to middle-income countries are affected by air pollution causing about 4.2 million deaths worldwide, the WHO estimated. While air pollution caused by traffic exhaust emissions contains several different components, we want to focus on the two

substances that play a major role in assessing and estimating health consequences – nitrogen dioxide (NO<sub>2</sub>) and particulate matter (PM<sub>10</sub> and PM<sub>2.5</sub>). For the evaluation of the health effects, toxicological as well as epidemiological data have to be taken into account.

---

## Nitrogen Dioxide (NO<sub>2</sub>)

For nitrogen dioxide, several animal and human exposure studies examined the impact of this particular pollutant on health. In *animal studies*, rats have been exposed to NO<sub>2</sub> via inhalation which led to the definition of a workplace limit value of 950 µg/m<sup>3</sup>. Several other inhalation studies in animals showed toxic changes at concentrations of more than 3000 µg/m<sup>3</sup>. *In vitro studies* showed cytotoxic effects on bronchial epithelial cells at concentrations more than 7520 µg/m<sup>3</sup>. NO<sub>2</sub> can damage proteins and lipids in vitro, newer studies showed (Beratungskommission der Gesellschaft für Toxikologie 2019).

In *human exposure studies*, study participants were short-time exposed to NO<sub>2</sub> under controlled conditions. NO<sub>2</sub> levels exceeding 1900 µg/m<sup>3</sup> led to an impairment of the respiratory function. Persons with respiratory preconditions showed already an impairment of the respiratory function at NO<sub>2</sub> levels of 560 µg/m<sup>3</sup> (Beratungskommission der Gesellschaft für Toxikologie 2019).

Regarding short-term and long-term exposure to NO<sub>2</sub>, several *epidemiological studies* examined and evaluated potential health effects (Beelen et al. 2014; Brown A.C. Health Effects of Particulates and Black Carbon 2013; Goodman et al. 2009; Agency EE 2019; US Environmental Protection Agency 2016; Folinsbee 1992; Heinrich et al. 2013; Hoek et al. 2013; Gehring et al. 2015). Short-time exposure to NO<sub>2</sub> can lead to respiratory effects, such as the worsening of symptoms, in particular in persons with respiratory preconditions. The worsening of respiratory symptoms can lead to higher hospital admission rates. Regarding long-term effects of NO<sub>2</sub>, the EEA (European Environment Agency) and the WHO evaluated the effects differently in comparison to the US-EPA (United States Environmental Protection Agency). For the EEA, long-term exposure to NO<sub>2</sub> may increase the mortality (Agency EE 2019). However, adjustment on other pollutants has not been carried out. The US-EPA only describes a *suggestive evidence* between NO<sub>2</sub> exposure and total mortality. Same applies to other effects outside the respiratory system, such as cardiovascular effects, diabetes, birth outcomes, and cancer (US Environmental Protection Agency 2016). The US-EPA states that nitrogen dioxide is unlikely to enter the bloodstream and cause systemic effects outside the respiratory system. Furthermore, the potential influence of other traffic-related pollutants has not been taken into account. In the analyses of traffic exhaust emissions, a clear correlation between NO<sub>2</sub> and black carbon (BC) as well as other UFP could be observed (Wichmann 2018). In epidemiological studies, a differentiation between those components has not been carried out (US Environmental Protection Agency 2016). Therefore, it is difficult to differentiate between the NO<sub>2</sub> effect and the effect of the other components. The elevated mortality in some studies

**Table 1** Short-term and long-term effects of nitrogen dioxide and particulate matter

Pollutant	Short-term exposure	Long-term exposure
<b>Nitrogen dioxide (NO<sub>2</sub>)</b>	<ul style="list-style-type: none"> <li>• Respiratory effects, such as the worsening of symptoms in particular for persons with respiratory preconditions</li> <li>• Higher hospital admission rates</li> <li>• (Increase of mortality)<sup>a</sup></li> </ul>	<ul style="list-style-type: none"> <li>• Respiratory effects, such as development of asthma, exacerbation of respiratory symptoms</li> <li>• (Increase of mortality)<sup>a</sup></li> </ul>
<b>Particulate matter (PM<sub>2.5</sub>)</b>	<ul style="list-style-type: none"> <li>• Effects on the respiratory and cardiovascular system</li> <li>• Increase of mortality</li> </ul>	<ul style="list-style-type: none"> <li>• Increase of total, cardiovascular, and respiratory mortality</li> </ul>

<sup>a</sup>EEA, WHO only

could therefore be assigned to the exposure to UFP or other compounds and not NO<sub>2</sub>. However, NO<sub>2</sub> is a surrogate marker for traffic exhaust emissions, and a reduction in the NO<sub>2</sub> air concentrations should be definitely a policy goal. Short-term and long-term effects of NO<sub>2</sub> are summarized in Table 1.

## Particulate Matter

While EEA, WHO, and US-EPA came to varying conclusions regarding NO<sub>2</sub> long-term exposure, the evaluation of the impact of particulate matter is more unified. Short-term exposure to particulate matter affects the respiratory and cardiovascular system and leads to an increase of mortality, as well (Agency EE 2019; Wichmann 2018; US Environmental Protection Agency 2019). The short-term effects are supported by positive associations for the cause-specific mortality. Cause-specific mortality includes cardiovascular and respiratory mortality. Fatal cardiovascular events that increase the mortality are ischemic events and heart failure. Fatal respiratory events include the exacerbation of COPD or asthma. The long-term effects include an increase of cardiovascular, respiratory, and total mortality (Table 1) (Leopoldina Akademie der Wissenschaften 2019; Heinrich et al. 2013; Hoek et al. 2013; Wichmann 2018; US Environmental Protection Agency 2019; Kaifie et al. 2019; European Environmental Agency 2019; Chen et al. 2008). The increase of mortality is classified as *causal* by the US-EPA (US Environmental Protection Agency 2019). The associations between long-term exposure to PM<sub>2.5</sub> and mortality remained significant, even after controlling for ecological and individual covariates, such as socioeconomic status and smoking habits. Similar to the short-term exposure, the total mortality is supported by positive associations for cardiovascular (i.e., coronary heart diseases, stroke), respiratory (i.e., COPD), and lung cancer mortality (US Environmental Protection Agency 2019). A decrease in PM<sub>2.5</sub> exposure leads to an increase in life expectancy, studies showed (US Environmental Protection Agency 2019).

Further relationships between PM<sub>2.5</sub> exposure and the development of certain diseases have been evaluated by the US-EPA, as well. Regarding long-term exposure

to PM<sub>2.5</sub> and nervous system effects, the US-EPA described a *likely to be causal* relationship. Toxicological studies in animals showed nervous system effects, such as neuroinflammation, neurodegeneration, cognitive effects, and effects on neurodevelopment (US Environmental Protection Agency 2019). The toxicological data were supported by epidemiological studies that detected changes in brain morphology, cognitive decrements, and dementia after long-term exposure to PM<sub>2.5</sub>. In addition, there is limited epidemiological evidence that long-term exposure to PM<sub>2.5</sub> is associated with autism spectrum disorders (US Environmental Protection Agency 2019).

The relationship between long-term exposure to PM<sub>2.5</sub> and cancer is classified as *suggestive of a causal relationship*. PM<sub>2.5</sub> is leading to genotoxic and epigenetic effects and has carcinogenic potential. Genotoxic effects include DNA damage, epigenetic alterations can lead to hypo- and hypermethylation of DNA, and cytogenetic effects and alterations in gene expressions can promote cancer pathogenesis. Further PM<sub>2.5</sub> effects are the induction of oxidative stress and electrophilicity. Regarding lung cancer, US-EPA classified this relationship as *likely to be causal*. In particular, the positive associations between PM<sub>2.5</sub> exposure and lung cancer in never smokers underlined that assessment (US Environmental Protection Agency 2019).

The German Respiratory Society supports further pathogenic effects that can be related to general exposure to air pollutants. Those effects include the development of diabetes mellitus and effects on pregnancy and fetus. In particular vulnerable groups, such as pregnant women, children, or elderly, are under particular risk by air pollution (Schulz et al. 2018).

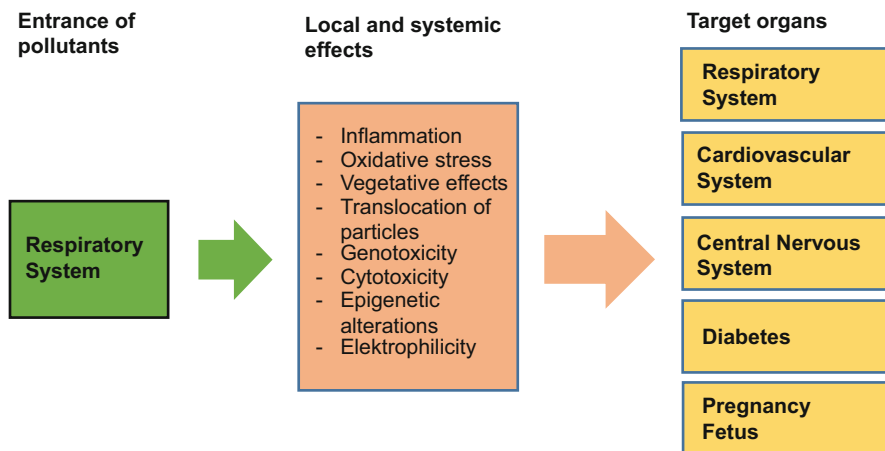

The development of diabetes mellitus may be caused by the continuous activation of systemic inflammation that leads to inflammatory effects in the liver, muscle, central nervous system, and fat tissue. Eventually, these inflammatory processes can lead to disorders in the carbohydrate metabolism (Schulz et al. 2018).

For pregnancy and the fetal development, potential effects are disturbances in placenta growth and function, as well as alterations in the maternal circulation. Potential effects on the mother may be hypertension, pre-eclampsia, and disorders of placental growth and function. A reduced fetal weight, premature births, and stillbirths are potential fetal effects. For infants, a reduced respiratory function as well as allergic diseases and disorders is described (Schulz et al. 2018). All potential effects of air pollution are summarized in Fig. 1.

---

## Guidance Values Versus Limit Values

Though the health impact of air pollutants is highly relevant, political implication does not necessarily reflect these findings. The differences in guidance values and limit values underline this statement. The WHO guidance values mark the limit for certain pollutants, in which exceedance can lead to health effects. The guidance values are generated under consideration of toxicological as well as epidemiological studies. Health experts reviewed all studies and determined the concentration which

**Fig. 1** Summary of potential air pollution effects. (Based on information of Schulz et al. 2018)

**Table 2** Limit and guidance values of PM<sub>2.5</sub>, PM<sub>10</sub>, and NO<sub>2</sub>. (Based on informations of European Commission 2019)

Pollutant	EU limit values	WHO guidance values	Averaging period
<b>PM<sub>2.5</sub></b>	–	25 µg/m <sup>3</sup>	24 h
	25 µg/m <sup>3</sup>	10 µg/m <sup>3</sup>	1 year
<b>PM<sub>10</sub></b>	50 µg/m <sup>3</sup>	50 µg/m <sup>3</sup>	24 h
	40 µg/m <sup>3</sup>	20 µg/m <sup>3</sup>	1 year
<b>NO<sub>2</sub></b>	200 µg/m <sup>3</sup>	200 mg/m <sup>3</sup>	1 h
	40 µg/m <sup>3</sup>	40 µg/m <sup>3</sup>	1 year

should not be exceeded in order to avoid adverse health effects. The country-specific limit values also include a political dimension and can be defined as a consent between different stakeholders. The main disparity between these values is the consequences followed by an exceedance of these values. While an exceedance of limit values has legal consequences, guidance values are only recommendations. An exceedance of guidance values has no consequences for the particular country. The following table (Table 2) summarizes the guidance values of the WHO as well as the limit values of the European Union.

While limit and guidance values for nitrogen dioxide are similar, there is a huge disparity for particulate matter. The WHO recommends not to exceed an annual concentration of 20 µg/m<sup>3</sup> for PM<sub>10</sub>, while the EU limit value is twice as high with 40 µg/m<sup>3</sup>. For PM<sub>2.5</sub>, the EU limit value is even 2.5 times higher than the recommended guidance value of the World Health Organization. In particular, particulate matter with a small diameter, such as PM<sub>2.5</sub>, can penetrate the air-blood barrier and enter the circulatory system. Therefore, this huge disparity is difficult to understand, under consideration of the systemic health effects of particulate matter

with an increase of total and cause-specific mortality (cardiovascular and respiratory mortality). The German Respiratory Society states that with the current limit values, health effects on the population can be expected. This is of particular interest for the previously described vulnerable groups, such as pregnant women, children, and elderly.

For nitrogen dioxide, the accordance of limit and guidance values is a progress. Though nitrogen dioxide is most likely not increasing mortality rates after long-term exposure, the short-term adverse health effects are significant, such as respiratory exacerbations and an increase in hospital admissions. In the USA, the limit value for nitrogen dioxide is set at  $100 \mu\text{g}/\text{m}^3$  for long-term exposure. This reflects the evidence of the US-EPA that observes local effects for  $\text{NO}_2$ , such as an exacerbation of symptoms in patients with respiratory preconditions or the development of asthma. However,  $\text{NO}_2$  is also a surrogate marker for other traffic exhaust emissions, such as ultrafine particles or black carbon. Epidemiological studies were not able to differentiate between the particular health impacts of the single components so far. Therefore, a low limit value for nitrogen dioxide should be sought. In contrast to nitrogen dioxide, the limit value for particulate matter ( $\text{PM}_{2.5}$ ) in the USA is set to  $12 \mu\text{g}/\text{m}^3$ , less than half compared to the EU limit value and in closer accordance to the WHO guideline values.

The guidance values of the WHO were determined by scientific evidence under consideration of all available experimental and epidemiological data. The question is why are the EU limit values for particulate matter so much higher than the guidance values of the WHO though the adverse health effects of particulate matter are evident? The reasons for that can be found in a communication letter from the European Commission (EC). The EC states: “For particulate matter, compliance with EU limit values was due as of 1 January 2005. Concentrations of particulate matter continue to exceed these values in large parts of Europe – with exceedances reported in 19 out of 28 Member States. Based on the latest available data, 19% of the urban population in the EU have been exposed to particulate matter levels above the EU daily limit value and about half was exposed to concentrations exceeding the stricter recommendations by the World Health Organization” (European Commission 2018). That statement clearly indicates that several EU member states were not able to comply with the specific EU limit values for particulate matter. An exceedance of limit values has legal consequences. The European Court of Justice is already prosecuting several EU members due to the exceedance of air pollution limit values. A tightening of limit values, as suggested by the WHO, would lead to further violations of the EU Directive for clean air by the EU member states. The decision, to keep the limit values at that level, can be clearly stated as political intention in order to avoid an endless number of legal proceedings against EU member states. However, it is the duty of the EU administration to keep their citizens healthy. Therefore, it is urgently required to stepwise approximate the EU limit to the WHO guidance value of  $10 \mu\text{g}/\text{m}^3$  for  $\text{PM}_{2.5}$ .

The EU has several mechanisms to promote a climate-friendly policy in order to reduce air pollution via traffic exhaust emissions. The legal mechanisms of the EU are further described in the next paragraph.

## Legal Mechanisms

Ursula von der Leyen, president of the European Commission, stated in July 2019 that she wanted Europe to be the first climate-neutral continent in the world to make the EU completely carbon neutral by 2050. In December, she presented the *European Green Deal* to the EU leaders in order to initiate a green transition. To achieve a climate-neutral EU by 2050, a European climate law was proposed to turn the commitment into legal obligation. The required actions to achieve this goal include:

- Investing in green technologies
- Cleaner forms of public and private transport
- Support energy efficiency of buildings
- Decarbonizing the energy sector

To achieve these goals, international cooperations on a global basis are necessary. However, several other legal mechanisms have been implemented by the EU, so far. In May 2008, the Directive 2008/50/EC on ambient air quality and cleaner air for Europe has been introduced (European Parliament 2008). The main goal of this directive was to reduce pollution to minimize adverse health effects and to pay attention to vulnerable populations and the environment as a whole. Mechanisms to reduce the air pollution included the combat of emissions on local, national, and community level. The critical pollutants were defined and included sulfur dioxide, nitrogen dioxide, and oxides of nitrogen, particulate matter (PM<sub>10</sub> and PM<sub>2.5</sub>), lead, benzene, and carbon monoxide. All EU member states were obligated to assess ambient air quality with regard to these pollutants.

In 2013, a Clean Air Program for Europe has been set up that efforts rested on three pillars. The first pillar included ambient air quality standards that were to be attained by all member states. The second pillar focused on national emission reduction targets, in particular for substances, such as sulfur oxides, nitrogen oxides, ammonia, volatile organic compounds, and particulate matter. The third pillar comprised emission standards for key sources of pollution, such as vehicle emissions and industrial processes. For vehicle emissions, the Regulation (EC) No 443/2009 setting CO<sub>2</sub> emission standards for new passenger cars and Regulation (EC) No 510/2011 setting CO<sub>2</sub> emission standards for new light commercial vehicles, and Regulations on CO<sub>2</sub> emission standards for new cars and light duty vehicles have been introduced.

Reflecting the important contribution of traffic-related air pollution, local and regional clean air plans have been implemented. These included setting of limit values for traffic-related pollutants and limits on total emission as well as setting emission standards, such as Euro emission standards 1–6 or by setting requirements for fuel quality. After the vehicle emission scandal in 2015, driving emission rules were put in place to ensure air pollutant emission standards were properly implemented, in particular for nitrogen oxides and particulate matter.

Other mechanisms in order to reduce traffic exhaust emissions include technical measures, behavior change and demand management, and infrastructure investment (European Commission 2018). In 2017, the European Commission introduced two Mobility Packages. The first Mobility Package included rules on road pricing and extending the European focus on buses, vans, and passenger cars. The second Mobility Package included measures for a cleaner public transport or the shifting to low- and zero-emission vehicles through new carbon dioxide standards for cars and vans. Another important aspect is infrastructure guidelines for alternative fuels that included charging opportunities for electric cars. A third Mobility Package focused on carbon dioxide emission standards for heavy vehicles as well as the establishment of a Europe-based battery manufacturing industry. Those batteries are intended to be included into low- and zero-emission vehicles. The EC is furthermore supporting local administrations in addressing aspects of vehicle access restrictions to foster consistency and information on regulation. Sustainable Urban Mobility Plans were already included in the Directive 2008/50/EC.

---

## Technical Measures

The vehicle emission scandal uncovered the manipulations of the automotive industry using illegal technical measures to maintain exhaust emissions below the limit values, in particular nitrogen dioxide and carbon dioxide. A vehicle using an illegal switch-off design is frequently emitting a higher amount of pollutants; therefore, a software solution was the initial measure to reduce NO<sub>2</sub> and CO<sub>2</sub> emissions.

Besides the use of software solutions, further technical measures are necessary in order to reduce traffic exhaust emissions. Here, the installation of catalytic converters and diesel particulate filters represents two possible mechanisms. Particulate filters with closed systems can reduce the emission of particulate matter around 90%. To support this technical measure, a law concerning retrofitting diesel cars has been passed in 2007. Owners of diesel cars were financially supported if they install diesel particulate filters in their cars. In addition, financial incentives have been implemented to support the use of low-emission heavy vehicles. Heavy vehicles with low traffic exhaust emissions pay less road pricing rates. For Germany, the government financially supports the purchase of low-emission trucks.

A cleaner public transport using technical measures comprises a further important measure to reduce air pollution by the transport sector. The installation of particulate filters in busses and the transition to electromobility have been implemented in several locations. In San Francisco, the San Francisco Municipal Railway maintains the worldwide second largest trolleybus system. Governmental financial support in purchasing and maintaining electric private or public transport vehicles is a useful measure to reduce traffic exhaust emissions in the urban setting.

## Non-technical Measure

Several non-technical measures have been implemented to reduce traffic exhaust, so far. The main burden from air pollutant emissions can be found in cities; increasing urbanization will reinforce that problem. Therefore, sustainable strategies to improve the air quality in cities are urgently needed.

In Germany, environmental or low-emission zones have been created for big cities with air pollution problems. Altogether, there are 58 environmental zones, in particular in metropolitan areas, such as North Rhine-Westphalia and Baden-Württemberg. Only cars with a green sticker that indicates a low-emission vehicle can travel freely in these environmental zones. A green sticker covers a category of vehicles with the lowest particulate and harmful emissions level. The other three of altogether four categories are indicated by the colors yellow and red and no sticker. Vehicles without a catalytic converter and old diesel cars are not allowed to enter the low-emission zones. Low-emission zones have not only been established in Germany but in whole Europe covering more than 300 environmental zones in 13 different countries.

Besides low-emission zones, speed restrictions are a further measure to reduce air pollution by traffic exhaust emissions. Speed restrictions lead to a reduction of particulate matter and nitrogen dioxide emissions. As the Leopoldina National Academy of Science stated, traffic exhaust leads to health implications beyond the burden with hazardous pollutants (Leopoldina Akademie der Wissenschaften 2019). Those health implications include adverse effects through noise as well as (deadly) road accidents, which can all be reduced by speed restrictions.

Smart traffic systems to reduce air pollution may be another non-technical measure. One option is the construction of peripheral roads in order to reduce the high traffic load in certain urban areas. A smart traffic light system might be able to decrease the particulate matter emissions by reducing repeated braking and accelerating which leads to high emissions with air pollutants. Financial incentives to use autonomous driving constitute a further useful measure.

Governmental financial support to use public transport services has been implemented already in several European countries. In Latvia, the public transport services can be used for free for several years. Monheim in North Rhine-Westphalia introduced free public transport services in 2020 since only 10% of the population used busses, so far. In Pfaffenhofen in Bavaria, free public transport services lead to a doubling of passengers using busses. However, more detailed analysis revealed that free public transport services are frequently used by passengers who previously walked or used their bicycle. So far, only a minority switched from car to bus. Free public transport services are therefore only able to a limited extend to get car drivers off the street. Car-sharing services could therefore be a more low-threshold measure to reduce urban air pollution. Car drivers can stay with their habitual use of cars, but sharing services lead to a reduction of total car density on the street. The improvement and expansion of bicycle tracks are a further measure to achieve such a goal. As weather conditions and geographical features may play a significant role in the regular use of bicycles, further studies need to evaluate the success of such a

measure. However, there are several possibilities to reduce in particular the urban traffic load. The political momentum and initiative are essential for a climate-friendly traffic policy, in particular in an automotive country, such as Germany.

## Abstract

Driven either from self-expressing, religious, or cosmetic motivations, tattooing has been a long-lasting practice for centuries and will probably remain being for the years to come. Permanent body decorations are not anymore allied with sailors, prisoners, or soldiers only but rather penetrated into the mainstream of modern society. Given the rising popularity, research interest has been directed to assess possible health effects caused by the injection of substances into the human dermis. The regulatory side has in parallel put efforts for identifying the most appropriate measures for protecting public health. Here, we provide a recent literature update on tattoo toxicology. Further, the milestones leading to the first European-wide regulation of substances in tattoo inks and permanent makeup are presented.

## Introduction

Tattoos and permanent makeup (PMU) have become very popular during the last decades. The tattooed population comprises people of different ages and cultures estimated up to 12% in the EU and 33% in the USA, with slightly higher percentages in the younger ages of 18–29 years (Bäumler 2016; Breuner et al. 2017; JRC 2016; Renzoni et al. 2018). Tattoo inks contain a large number of ingredients, including pigments, binders, solvents, and additives (Giulbudagian et al. 2020). A major concern in the context of pigments used for tattooing is the fact that they are mostly manufactured for other than tattooing applications, e.g., the automotive, construction, or cosmetics industries (Laux et al. 2016). Even if their usage in numerous products may be considered safe, their intradermal application has never been tested (Foerster et al. 2020). Hazardous substances are still detected recurrently in tattoo inks (Foerster et al. 2020; Laux et al. 2016; Schreiver et al. 2015). Their hazard classification mostly refers to the topical, oral, or respiratory uptake, but not to intradermal exposure, which however may cause a different kind of toxicity. This is also an obstacle in terms of tattoo ink risk assessment. Strategies for the identified substances rely on the evaluation of chemical hazards identified by oral, topical, or inhalation administration. These data cannot easily be extrapolated to subcutaneous use.

Despite this alarming situation, it has to be noted that most people remain without severe complications (JRC 2016). This especially applies to systemic effects. While local reactions can rather easily be assigned to the site of the tattoo, postponed or chronic effects appearing on remote organs are challenging for attribution. As substances in the inks are subject to metabolism upon their injection, the identification of the exact molecular fragments responsible for the observed reaction is inevitable for assessing their risks. These facts together with the widespread use have encouraged scientific as well as regulatory efforts to identify possible health effects and to develop a risk assessment strategy of the tattoo inks.

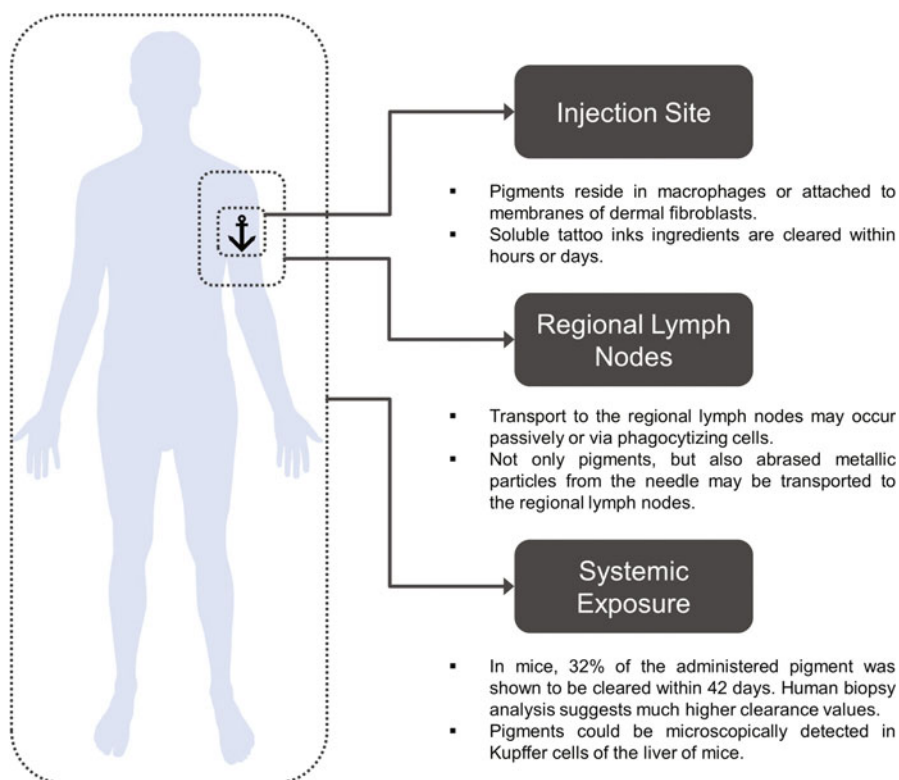

This chapter describes the state of knowledge on adverse effects following tattooing and introduces approaches on the risk assessment of tattoo inks.

---

## Health Risks of Tattoos: Clinical Evidences

Health risks as a consequence of tattooing are diverse and can be attributed to different causes, modes of actions, as well as different sites of the human body. Triggers of possible adverse effects may be the tattooing process as such, the ingredients of the tattoo ink, as well as decomposition products following metabolism of the pristine substances within the body. Adverse effects can occur immediately after tattooing but also weeks or years later. Associated therewith, effects may appear on the tattooed site, the surrounding region, or other organs after systemic distribution of the respective compounds (Fig. 1). Nonetheless, evidences for the latest are mostly limited to observations in animals.

Immediately after the tattooing process, acute aseptic inflammation may occur comprising swelling and erythema, together with transient bleeding and lymphadenopathy

**Fig. 1** Depiction of a tattoo and its local, regional, and systemic features

(Kluger 2010). The healing process lasts about 1–4 weeks. The crusted lesion may provoke pain, itching, blistering, and burning sensation. The sensation of severity of these symptoms is individual. In a German internet survey conducted in year 2010, people described the severity between negligible and very intense (Klugl et al. 2010). Apart from these non-infectious indications, infectious risks provoked by bacteria and viruses have been described. Bacterial infections concern about 1–5% of the tattooed people. To be mentioned here is the occurrence of *Staphylococcus* spp. (e.g., *Staphylococcus aureus*), *Streptococcus* spp. (e.g., *Streptococcus pyogenes*), mycobacteria (nontuberculous and tuberculous), and pseudomonads (JRC 2016; Laux et al. 2016; Rodriguez-Blanco et al. 2011). Causes for infections are diverse, potentially arising from the tattoo artist, non-sterile instrumentation or inks, as well as infections during the wound healing process (JRC 2016). According to Baumgartner and Gautsch (2011) and Høgsberg et al. (2012), up to 20% of sampled inks were found to be contaminated, even when they have been labelled as sterile. Of particular concern, they mentioned the environmental pathogen *Mycobacterium chelonae* (Hogsberg et al. 2013; Kennedy et al. 2012; Rodriguez-Blanco et al. 2011). Clearly more seldom are infections due to fungi or viruses after

professional tattooing. Only in exceptional cases, severe effects such as pyogenic infection with abscess formation, cellulitis, or gangrene may occur and can develop into systemic and life-threatening infection, like sepsis or endocarditis (Laux et al. 2016).

---

## Components

Tattoo inks are being composed of pigments, binders, solvents, and additives. It is estimated that they comprise up to 100 different chemicals (Foerster et al. 2020). The diversity of ingredients together with the occurrence of possible impurities like primary aromatic amines (PAAs), nitrosamines, or various polycyclic aromatic hydrocarbons (PAHs) impedes the search for effects and their causes. The formulations used for tattooing might further contain phenols, formaldehyde, or phthalates. While the development of acute inflammatory reactions, as described before, is frequently a consequence of the tattooing process itself, adverse reactions arising from different ingredients cannot be excluded. For instance, skin reactions were slightly more frequent when colored rather than when black ink was tattooed. This may be attributed to the decomposition of organic pigments (Klugl et al. 2010). Serup et al. (2015) further reported soft tissue lymphatic edema simultaneously occurring with a pigmentation of the surrounding skin and sometimes of regional lymph nodes. He further considered papular or nodular thickening and elevation in specific tattoo areas as a result of pigment overload.

The vast majority of complications that can be traced back to the tattoo ink are related to hypersensitivity, primarily linked to colored inks, rather than to black pigments. As was carried out in a study of patients who had been tested positive for allergic tattoo reactions (Serup and Carlsen 2014), the primary allergen identified was nickel ( $n = 16$  out of 90 probands). This element represents a contaminant not intentionally added to tattoo inks. Allergic reactions to nickel were followed in frequency by four positive results for pigments and two for dyes normally used in textiles. The red color was reported often with relation to allergic skin reactions. Patients with positive reactions did not respond to patch tests of the respective pigment; the source of allergic reaction was seen in the formation inside the skin, probably through metabolism, haptization, or both. As was analyzed in a further study of Serup et al. on 104 dermatome biopsies, P.R. 22, P.R. 170, and P.R. 210 were determined as the predominating pigments behind chronic allergic reactions in red tattoos (Serup et al. 2020). The authors concluded that the reactions can be traced back to a pigment degradation product. They further found elevated levels of different metals like Fe, Cr, or Ni; however, their contribution to allergic reactions in red tattoos could not be proven.

A new finding requiring attention was recently revealed by Schreiver et al. (2019). They found that the needle may release nano- and micrometer-sized nickel (Ni) and chromium (Cr) particles during the tattooing procedure, which is promoted if the ink contains abrasive materials like titanium dioxide. These particles were

found in the skin as well as in the local lymph nodes. These findings are important concerning the assessment of Ni-driven allergies arising from tattoos.

The cleavage of pigments in general is an important issue of concern. Generally, aromatic chromophores may underlie photodecomposition. Some of these decomposition products are suspected or known human carcinogens. Examples comprise pigment yellow 74, decomposing to various primary amines or orange 13, decomposing to substances such as 3,3'-dichloro-4-aminobiphenyl or 3,3'-dichlorobenzidine (Cui et al. 2004). Together with the aforementioned substances like PAAs or PAHs, including benzo[*a*]pyrene, which may occur in colorants, a number of substances of known carcinogenic potential come in contact with human blood and lymph tissue upon tattooing. In this context, it is comprehensible to investigate if tattooing increases the risk of developing cancer. Even though this research is in the beginning and epidemiological studies are rare, a closer examination of the biodistribution of substances may give first insights.

As tattoo inks come into direct contact with blood and lymph fluids, they must be considered as 100% systemically bioavailable (Giulbudagian et al. 2020). Especially for the soluble ingredients such as preservatives, conditioners, or solubilizing additives, participation in metabolic processes is supposed. The solubilizing additives may present up to 70% of the ink and become systemically bioavailable right after the tattooing process (Sapota et al. 2003). It cannot be excluded that this short-term exposure, temporarily reaching very high amounts, could increase the risk to develop cancer on long term (Foerster et al. 2020).

As for pigments, some scientists believe that the low solubility renders them to be biologically inactive (Engel et al. 2006). This argument is underlined by the persistence of the tattoo coloring at the site of administration. However, it cannot be excluded that even a slow metabolism is relevant. Further, insoluble pigments could be detected in regional lymph nodes (Gopee et al. 2005) of SKH-1 mice and human biopsies. Using the same mouse model, the transport and decomposition of P.R. 22 was investigated by Engel et al. (2010). They showed that 32% of the pigment was cleared from the site of injection. After exposure to simulated solar radiation the cleared amount increased to >60%. While some of the fading may be allocated to wound healing (Foerster et al. 2020), the results indicate a degradation of the pigment followed by clearance of the metabolites. An even higher clearance rate of about 87–99% directly after tattooing was estimated by Lehner et al. (2011) from human skin biopsies. Even if this value might be overestimated, there is clear evidence that the lymphatic system plays a major role in the transport/migration of pigments. In support of this theory, Lehner et al. (2014) detected PAHs, most probably associated to carbon black ink, simultaneously in skin samples (0.6 µg/cm<sup>2</sup>) and in lymph nodes (11.8 µg/g).

In a study of Sepehri et al. (2017) on the systemic distribution of tattoo pigments, several organs of mice tattooed with black and red inks were analyzed. While in most of the organs pigments were absent, some could be identified in lymph nodes and in Kupffer cells of the liver, suggesting pigment distribution via the bloodstream. In this study, pigments could not be detected in any other organs. However, according to Gopee et al. (2007) and Tang et al. (2009), evidence of the deposition in other

organs such as the liver, spleen, kidney, and hepatic lymph nodes following intradermal and subcutaneous injection of particles is given.

So far, the causal link between tattooing and tumor formation could neither be established nor excluded, which is most likely explained by their long latency and their multifactorial character (JRC 2016). According to Kluger (2010) who reviewed studies of the last 40 years, the small number of 50 tumors on tattoos appears negligible compared to the millions of tattooed individuals and the millions of skin cancers per year (Serup et al. 2015). The number making the association between the two events is rather coincidental. Epidemiological studies may deliver valuable data for understanding effects on the systemic level. Numerous case studies have reported on tumors co-localized with the tattoos (Kluger et al. 2017; Kluger and Koljonen 2012). Although tattoo products may contain carcinogenic substances, no clear evidence has been provided for a causal relationship between cancer and tattoos. A recent study examined the prevalence of basal cell carcinoma in a population with cosmetic tattoos, also known as permanent makeup (PMU) (Barton et al. 2020). The total cohort size was 1745 persons in an age range of 25–50 years. In particular, it was investigated whether early basal cell carcinoma was related to the location and color of the tattoo. The adjusted odd ratio of basal cell carcinoma co-located with a tattoo was 1.8 compared to other parts of the body. The authors concluded that the development of an early basal cell carcinoma is particularly common among yellow and green tattoos. However, due to the lack of baseline characteristics of the study, the causal effect of tattoos on early basal cell carcinoma remains questionable (Kluger and Dub 2020). In particular, the anatomical site of the carcinoma was not defined as being developed on the tattoo itself. Moreover, the calculation was based on people who wore a tattoo and were diagnosed with basal cell carcinoma, leaving out the non-tattooed population. Since the area of the skin covered or the tattooing agents used were not considered in the study, no dose-response affiliation could be derived.

---

## Risk Assessment

Common toxicological and regulatory tools, which rely on the evaluation of chemical hazard administered by oral or cutaneous pathways, supply only limited information for the assessments of risks associated with tattoos. In addition to tattooing, the injection of substances into the human dermis is also being used for the application of PMU by procedures termed as micro-blading or micro-shading. Common pigments used in PMU are different compositions of iron oxides in shadows of yellow, red, brown, or black. Although differing somewhat from tattooing in terms of the pigments used or the amount and depth of application, these have to be treated equally for the purpose of risk assessment and regulation. Moreover, the common to all pigments used for tattooing or PMU applications is their very low solubility in water as well as in many organic solvents. Hence, the distinction in terminology of pigments (particles) and their water-soluble analogs referred as dyes is crucial. Nevertheless, dyes may be converted into non-soluble pigments by precipitating them with various metals, referred as lakes.

**Table 1** Selected requirements for the safety assessment of tattoo and PMU inks as assessed by the German Federal Institute for Risk Assessment (BfR) and the European Directorate for the Quality of Medicines & Health Care (EDQM) (BfR 2012; EDQM 2017)

Physicochemical characterization	Toxicological endpoint assessment
1. Chemical identity	1. Skin irritation
2. Physical form	2. Irritation to mucous membranes
3. Molecular weight	3. Phototoxicity Photo-sensitization
4. Characterization and purity of the substance	4. Sensitization
5. Characterization and quantification of impurities	5. Mutagenicity/genotoxicity
6. Solubility	6. Carcinogenicity
7. Partition coefficient (Log Po/w)	7. Reproductive toxicity
8. Further chemical and physical specifications	8. Acute toxicity
9. Homogeneity and stability	9. Repeated dose toxicity
10. Function and application	

A major challenge in evaluating potential health risks posed by tattoo inks is the assessment of exposure toward a certain chemical. Degradation products as a consequence of sun exposure or enzymatic activity may result in continuous release of chemicals into the blood circulation. Although considered inert, pigments present in the inks have a broad particle size distribution, falling also in the nanometer range (Schreiber et al. 2017). Hence, these aspects must be considered when assessing protective measures.

According to the General Product Safety Directive (GPSD) (Directive 2001/95/EC), tattoo ink manufacturers and distributors are responsible for their safety. As guidance for the safety evaluation procedure, numerous protocols have been compiled (BfR 2012; EDQM 2017). Yet, the main challenge in the application of standardized methods such as the OECD (Organisation for Economic Co-operation and Development) guidelines is the compatibility of these methods with insoluble substances such as pigments used in tattoo inks. The required endpoints as well as the specifications are summarized in Table 1. These can be divided into physicochemical characterization and toxicological evaluation.

A comprehensive physicochemical characterization of tattoo inks is inevitable for the evaluation of their safety. Beyond the chemical identity of the intentionally added pigments and auxiliary substances, impurities as well as degradation products shall be thoroughly identified and quantified. Nonetheless, results might differ depending on the sample preparation procedure. For example, the extraction of impurities from the pigments may vary in efficacy or trigger their degradation.

A battery of toxicological analysis adopted for the intradermal application route should be carefully considered for the ability of achieving conclusive results. Obstacles for the implementation of the tests guidelines are expected to appear in the following aspects:

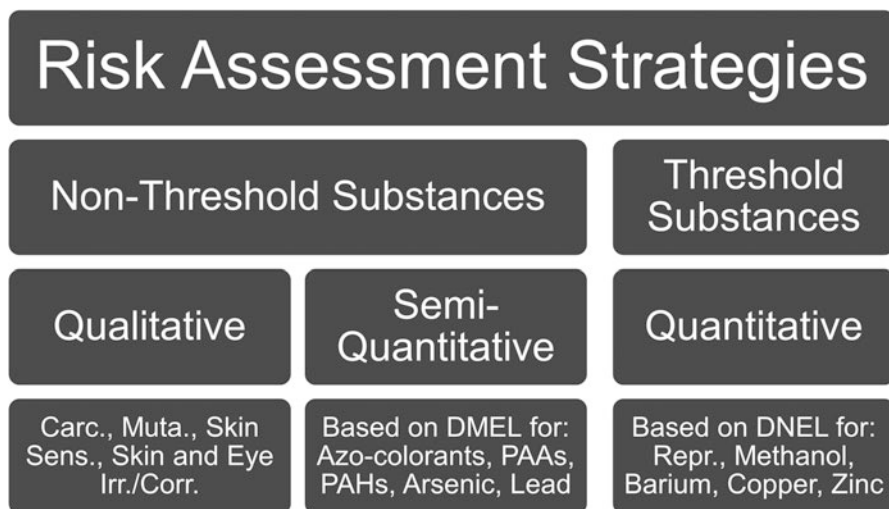

1. Given the complexity of the ink mixture, the experimental design should describe whether a single substance or the entire mixture is being analytically addressed.

2. When performing *in vitro* assays, colorimetric measurements might not be suitable due to the broad light absorption spectra of the pigments used.
3. The applied dose of the test material may be compromised due to the sedimentation of the insoluble pigment particles.
4. The adjustment of the recommended guidelines is needed to assess possible toxic effects upon UV irradiation for simulating solar exposure or the removal of the tattoo with a laser. The phototoxicity may result in reduced viability of cells, causing subsequent photo-sensitization or genotoxicity. However, at present no methods exist which supply reliable information on the phototoxicity of tattoo inks.
5. For certain endpoints, *in vivo* testing might be unavoidable. For instance, the sensitizing or irritation nature of substances may be expressed or enhanced when combined with the trauma induced during the tattooing procedure. Moreover, *in vivo* tests may be triggered due to positive *in vitro* assays. The toxicological evaluation in living animals becomes even more required when assessing the systemic distribution of the substances, their accumulation in organs, as well as excretion kinetics. Although attempts have been made to envisage the biodistribution of pigments in mice, substantial and representative information is missing. In particular, for the extrapolation ability, mini pigs represent a much more suitable model relatively similar to human anatomy and physiology (Bode et al. 2010; Sullivan et al. 2001). Nevertheless, the OECD Test Guidelines are to date not validated for the intradermal application route.

Given the application route and the complex tattoo ink composition, the regulatory approach to ban the use of chemicals with known hazardous properties seems comprehensible. Based on a dossier compiled by the European Chemicals Agency (ECHA), the European Commission (EC) has published the first Union-wide restriction of substances used in tattoo inks and PMU (ECHA 2019). Briefly, according to the Regulation No. 1272/2008 of the European Parliament and of the Council, substances with harmonized classifications of hazard classes for carcinogenicity, mutagenicity, or toxicity to reproduction category 1A, 1B or 2; skin sensitization category 1, 1A, or 1B; skin corrosion category 1, 1A, 1B, or 1C or skin irritation category 2; or serious eye damage category 1 or eye irritation category 2 are subject to this restriction. Furthermore, substances restricted for use in cosmetic products according to the Regulation No. 1223/2009 shall not be used in tattoo and PMU inks. The rationale of this link to the cosmetic regulation is that substances, which were assessed as being unsafe when applied on top of the skin, shall not be injected into the skin. Further groups of restricted chemicals comprise heavy metals and certain pigments bearing an “azo” bond, which may result in cleavage and the release of carcinogenic PAAs.

The restricted substances shall not be present in tattoo inks and PMU above a certain concentration limit. Such concentration limits were established considering the minimization of health risks as well as the technically achievable detection limits of the substances. The utilized approaches for the assessment of risks posed by ingredients of tattoo inks and PMU are depicted in Fig. 2. Substances

**Fig. 2** Schematic representation of risk assessment strategies for the different groups of compounds

with no threshold hazard were evaluated in a qualitative manner. The qualitative assessment of risks is based on the fact that no concentrations could be determined at which the hazardous potency would be eliminated. In other words, for substances potentially causing carcinogenicity, mutagenicity, skin sensitization, and skin and eye irritation/corrosion, no dose-response correlations could be established due to missing data in general and missing assessments for the intradermal application route in particular.

For another group of non-threshold substances, concentration limits were set by applying the derived minimum effect level (DMEL). This approach may be used when adequate animal data is available to resolve a low concern of lifetime cancer risk (ECHA 2012). In this manner, substances present in tattoo inks, which pose a concern to human health, were treated. These include colorants of “azo” nature which may decompose by hydrolysis, enzymatic degradation or by UV irradiation into PAAs. Despite the low solubility of azo colorants, the systemic availability of dissolved molecules cannot be excluded. Moreover, PAAs may be present in azo colorants as impurities from the production stage. Hence, a representative DMEL value for *o*-anisidine was used to set a concentration limit for PAAs of concern using the endpoint carcinogenicity. For other substances of concern present in tattoo inks, e.g., impurities such as PAHs or heavy metals, DMELs for the most critical effect were used to set concentration limits.

Finally, a quantitative evaluation of risks could be performed for a group of substances by deriving their corresponding Derived No-Effect Level (DNEL). In this manner, reprotoxic substances, methanol, as well as certain heavy metals such as barium, copper, and zinc could be assessed. For example, a representative DNEL based on reprotoxic effects was derived for dibutyl phthalate, which was previously

detected in tattoo inks. In addition to assessment factors due to inter- and intraspecies differences, a factor due to possible cumulative effects was applied, resulting in a DNEL of 0.0007 mg/kg bw/day. The DNEL for barium compounds used as a common additive in tattoo inks could be established after applying correction factors for their intradermal injection. This value was derived for soluble compounds, assuming 100% absorption for oral studied where only 7% of the compound was absorbed after a single dose. In contrast, due to a very low solubility of barium sulfate, no release of ions is expected.

The concentration limits were derived subsequently to risk characterization. As an exemplary procedure for a quantitative assessment, the deviation of a concentration limit for reprotoxic substances of category 1A/B is described below. For the estimation of the exposure, mean parameters for the tattoo size, 300 cm<sup>2</sup>, and the amount of injected ink, 14.36 mg ink/cm<sup>2</sup>, for an average body weight (bw) of 60 kg were calculated to be 72 mg/kg bw/day (Engel et al. 2008; Laux et al. 2016; Prior 2015). The probability of occurrence of adverse effects for the defined exposure is expressed by the risk characterization ratio (RCR), which is the division product of the exposure estimate and the derived DNEL. Finally, the concentration limit for a certain substance in the ink is calculated by the reciprocal RCR for the substance of concern.

$$\text{Concentration limit} = \frac{\text{DNEL substance}}{\text{Amount of ink injected}}$$

Hence, based on the derived DNEL for dibutyl phthalate (0.0007 mg<sub>substance</sub>/kg bw/day) and the calculated mean amount of tattoo ink injected (72 mg<sub>ink</sub>/kg bw/day), the concentration limit was rounded to be 10 mg<sub>substance</sub> / kg<sub>ink</sub>, which are 10 ppm or 0.001%.

It is important to mention that the parameters used for the exposure assessment depict a rather worst-case scenario in terms of the tattoo size, the repetitive exposure, as well as the bioavailability of the pigments and the released impurities. For instance, soluble substances were treated in a similar manner as non-soluble ones while assuming a complete release of impurities imbedded within the pigment particles. Yet, given the uncertainties, these parameters were considered as an appropriate estimation for reduction of health risks. Such uncertainties include the very limited knowledge on the toxicokinetics of substances injected into the skin in terms of chemical persistence or particle degradation into smaller fragments. The uncertainties become even greater when assessing the risks which may arise by nanoparticles (NPs). Numerous analyses of tattoo inks and tattooed skin have demonstrated the presence of particles in the nanometer size range (Høgsberg et al. 2011; Schreiber et al. 2017). However, differing from toxicological mechanisms described for distinct chemicals, NPs may trigger formation of reactive oxygen species, facilitate photochemical reactions, or cause immunoreactions as a result of particle overload. Parameters such as shape, size or crystallinity vary strongly for pigment particles and challenge the assessment of their toxic potential. For these reasons, the considerations of the worst-case scenario seem to comprise a rational measure for risk minimization.

---

## Conclusion

Assuming a continuous increase in the tattooed population worldwide for the next decades, it seems that the first and foremost task of consumer protection authorities remains the clarification of risks associated with the tattooing procedure. Despite many uncertainties, much progress has been achieved so far. These findings served an important milestone for regulatory measures in the EU. Moreover, they allowed the clarification of possible adverse effects which might help individuals deciding for or against receiving a tattoo. Avoiding known allergens and keeping basic hygienic rules shall certainly decrease the likelihood of developing adverse reactions.

## Abstract

Food additives are substances used for technological purposes, such as preservation, sweetening, or coloring, during the production of food. The requirements for the risk assessment of food additives are described in guidance documents of the Joint FAO/WHO Expert Committee on Food Additives (JECFA) and the European Food Safety Authority (EFSA). According to the EFSA guidance, a tiered approach which balances toxicity data requirements against the risk is applicable for the risk assessment of food additives. The approach was established to evaluate the following core areas: toxicokinetics, genotoxicity, toxicity (encompassing subchronic toxicity, chronic toxicity, and carcinogenicity), and reproductive and developmental toxicity. Additional studies on other toxicological endpoints may be required on a case-by-case basis. The approach

consists of three tiers. It provides guidance to applicants in designing their toxicity testing strategy in which the decision on the requirement for further testing can be based on the results of certain initial studies. While maintaining the high level of consumer safety, the application of this tiered approach could result in a smaller number of animal tests or more refined animal studies, compared to the requirements applied before, and thus benefit animal welfare. This chapter provides the legal background and delineates the principles and requirements for the risk assessment of food additives based on the guidance documents for food additive evaluations established by JECFA and EFSA.

**Introduction**

The use of chemical substances in order to maintain the quality of food has been a common procedure for a very long time. Accordingly, questions about the safety of these substances were addressed already many years ago. In 1955, the Food and Agriculture Organization (FAO) and the World Health Organization (WHO) of the United Nations established the Joint FAO/WHO Expert Committee on Food Additives (JECFA). In its first report, JECFA provided general principles for the use of food additives and pointed out that “critically designed animal tests of the physiological, pharmacological and biochemical behavior of a proposed additive can provide a reasonable basis for evaluating the safety of use of a food additive at a specified level of intake” (WHO 1957). Procedures for the testing of food additives were published by JECFA in 1958 and 1987 (WHO 1958, 1987). Currently, JECFA performs risk assessment of food additives based on principles and methods for the risk assessment of chemicals in food that were published in 2009 (WHO and FAO 2009). Since then, FAO and WHO have started several projects to update (sub) chapters (<https://www.who.int/publications-detail/principles-and-methods-for-the-risk-assessment-of-chemicals-in-food> (accessed on 26 May 2020)).

At the European level, the Scientific Committee for Food (SCF) was established by the Commission of the European Communities in 1974. The SCF evaluated food additives and advised the European Commission. In the course of re-organization of scientific committees, the SCF was re-named in 1997 into Scientific Committee on Food (SCF). The SCF was active until the European Food Safety Authority (EFSA) was established in 2003. Since then food additives have been evaluated by the respective EFSA Panels (Panel on Food Additives, Flavourings, Processing Aids and Materials in Contact with Food (AFC Panel) until 2008, Panel on Food Additives and Nutrient Sources Added to Food (ANS Panel) from 2008 to 2018, and Panel on Food Additives and Flavourings (FAF Panel) since 2018).

Any substances added intentionally to food including flavoring substances and processing aids might be considered as food additives; however, according to

European legislation, the term *food additive* is restricted to those substances which are used for technological purposes only. According to Article 3 of Regulation (EC) No. 1333/2008, a food additive “shall mean any substance not normally consumed as a food in itself and not normally used as a characteristic ingredient of food, whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport or storage of such food results, or may be reasonably expected to result, in it or its by-products becoming directly or indirectly a component of such foods.” According to Article 6 of Regulation (EC) No. 1333/2008, a permission for the use of food additives can only be given for a substance provided that “(a) it does not, on the basis of the scientific evidence available, pose a safety concern to the health of the consumer at the level of use proposed; (b) there is a reasonable technological need that cannot be achieved by other economically and technologically practicable means; and (c) its use does not mislead the consumer.” Accordingly, the safety of food additives is to be assessed by the EFSA prior consideration by the European Commission for market authorization. Applicants seeking such an authorization are required to provide all relevant data.

At a global level, based on risk assessments performed by JECFA, food additive standards were established by the Codex Committee on Food Additives (CCFA) of the Codex Alimentarius Commission (CAC) in the framework of the *Joint FAO/WHO food standards program*. In this respect, the CCFA established a General Standard for Food Additives (GSFA) with provisions for the use of food additives in certain food categories (<http://www.fao.org/fao-who-codexalimentarius/codex-texts/dbs/gsfa/en/> (accessed on 26 May 2020)). The GSFA is not legally binding in the European Union. It may, however, be relevant for trade issues between the European Union and third countries if such cases were to be negotiated at the World Trade Organization (WTO).

---

## Data Required for the Risk Assessment

The data required by JECFA for risk assessment of food additives are described in calls for data for each JECFA meeting (<https://www.who.int/foodsafety/call-data/en/> (accessed on 26 May 2020)). These requirements are based on principles and methods for the risk assessment of chemicals in food (WHO and FAO 2009) and include chemical and technical considerations, biochemical aspects, toxicological studies, and observations in humans as well as data for exposure estimations. Specific guidance on the evaluation of and data requirements for food additives are also available from FAO (<http://www.fao.org/food/food-safety-quality/scientific-advice/jecfa/guidelines0/en/> (accessed on 26 May 2020)) and WHO (<http://www.who.int/foodsafety/chem/jecfa/guidelines/en/index.html> (accessed on 26 May 2020)). According to these guidance documents, information from five main categories of toxicity studies on food additives should be routinely included: acute toxicity, short-term studies of toxicity, long-term

studies of toxicity and carcinogenicity, genotoxicity, and reproductive and developmental toxicity. Based on results obtained in these routine studies, there may be a need to perform special studies in order to investigate particular target organs, tissues, or endpoints.

The data required by EFSA for the risk assessment of food additives are described in a guidance document adopted by the ANS Panel in 2012 (EFSA 2012a). This guidance replaced the guidance established in 2001 by the European Commission's former SCF (2001) on which EFSA's AFC and ANS Panels based their risk assessments previously. According to the guidance from 2012, a tiered approach which balances toxicity data requirements against the risk is applicable for the risk assessment of food additives. The approach was established to evaluate the following core areas: toxicokinetics, genotoxicity, toxicity (encompassing subchronic toxicity, chronic toxicity, and carcinogenicity), and reproductive and developmental toxicity. Additional studies on other toxicological endpoints may be required on a case-by-case basis. The approach consists of three tiers. It provides guidance to applicants in designing their toxicity testing strategy in which the decision on the requirement for further testing can be based on the results of certain initial studies. While maintaining the high level of consumer safety, the application of this tiered approach could result in a smaller number of animal tests or more refined animal studies, compared to the requirements applied before, and thus benefit animal welfare.

According to EFSA's guidance for submission of food additive applications, a minimum set of data is required for all food additives at Tier 1. It covers data on absorption (i.e., systemic availability), genotoxicity *in vitro*, and subchronic toxicity. Depending on the results, further toxicity studies are required at Tier 2 and Tier 3. Tier 2 studies will be required in order to generate more extensive data for substances which are absorbed or demonstrate toxicity or genotoxicity in Tier 1 tests. If higher tier testing is required based on results in one of the core areas, such testing would only be required in this core area but not in the others, e.g., where results from the subchronic toxicity study require further Tier 2 studies but Tier 1 *in vitro* genotoxicity is clearly negative, there would be no need for Tier 2 follow-up of genotoxicity. Tier 3 testing should be performed on a case-by-case basis. Results at higher tiers will in principle supersede results observed at lower tiers.

## Chemical Aspects and Manufacturing

Chemical data, including data on identity, chemical composition, purity, and stability of the food additives, are pivotal for reliable risk assessments. Requirements are described in Chap. 3 of the FAO and WHO guidance *Principles and Methods for the Risk Assessment of Chemicals in Food* (WHO and FAO 2009) and in the EFSA guidance *for submission for food additive evaluations* (EFSA 2012a). An example for the importance of adequate specification is titanium dioxide for which

the EFSA ANS Panel recommended in its scientific opinion on the re-evaluation of this food additive that the EU specifications for titanium dioxide (E 171) should include a characterization of particle size distribution using appropriate statistical descriptors (e.g., range, median, quartiles) as well as the percentage (in number and by mass) of particles in the nanoscale (with at least one dimension <100 nm) present in titanium dioxide (E 171) used as a food additive (EFSA 2016). The EFSA FAF Panel which is meanwhile responsible for the evaluation of food additives suggested an amendment for the current specification of titanium dioxide and recommended that, based on the proposed change in the specifications, revisiting the toxicological database on titanium dioxide (E 171) as a food additive should consequently be conducted in line with the data requirements specified in the EFSA guidance on nanotechnology (EFSA 2018, 2019a).

Information on the manufacturing of a food additive could provide useful indication for potential presence of impurities or unintended by-products that may require further consideration.

## Toxicokinetics

The aim of investigations on systemic availability is to establish whether the substance or its breakdown products are absorbed from the gastrointestinal tract. In this respect the physico-chemical properties (e.g., molecular weight, hydro- and lipophilicity) of the substance should be considered as well as models for bioavailability from *in vitro* and *in vivo* studies. Demonstration of negligible absorption, either through experimental studies or based on theoretical considerations, may be considered as a scientific justification for not undertaking higher tiered toxicological studies provided that the results of the genotoxicity tests are clearly negative and no toxicity in the subchronic toxicity study is observed at Tier 1. Absorption data available for structurally related substances may contribute useful information. However, the required sensitivity to determine negligible absorption levels will generally necessitate *in vivo* studies using labelled compounds. If the absorption cannot be considered negligible at Tier 1, further data on absorption, distribution, metabolism, and excretion (ADME) including identification and quantification of metabolites are required at Tier 2. Basic single-dose toxicokinetic parameters, e.g., area under the curve of plasma concentration of the compound against time after oral administration, maximum concentration, time to reach maximum concentration, elimination half-life, and bioavailability, should be determined based on *in vivo* studies according to the Organisation for Economic Co-operation and Development (OECD) Technical Guidance (TG) No. 417. A range of dose levels should be applied in order to examine the linearity of kinetic parameters and possible saturation. The trigger for Tier 3 studies would be limited or slow excretion or any other mechanism resulting in bioaccumulation. In such a case, studies with repeated doses in experimental animals or human kinetic data from volunteer studies may be required.

## Genotoxicity

The *in vitro* investigations on genotoxicity at Tier 1 should cover gene mutations and structural and numerical chromosomal alterations as recommended by the EFSA Scientific Committee (EFSA 2011a). In line with this recommendation, a bacterial reverse mutation assay (OECD TG 471) and an *in vitro* mammalian cell micronucleus test (OECD TG 487) are required for all food additives. Any inconclusive, equivocal, or positive results observed with *in vitro* tests at Tier 1 should be further investigated. According to EFSA's guidance document on genotoxicity testing strategies (EFSA 2011a), inconclusive and equivocal test results may be clarified by further *in vitro* testing, but *in vivo* studies might also become necessary. A positive result in a Tier 1 study requires follow-up at Tier 2 in order to investigate whether the hazard is expressed *in vivo*. Suitable tests for a follow-up of results from Tier 1 studies are an *in vivo* micronucleus test (OECD TG 474), a transgenic rodent somatic and germ cell gene mutation assay (OECD TG 488), and an *in vivo* comet assay (OECD TG 489). Detailed advice on strategies for genotoxicity testing is given in an opinion of the EFSA Scientific Committee (EFSA 2011a). In the case of negative *in vivo* genotoxicity tests, it is crucial to demonstrate, based on cytotoxicity or kinetic data or other lines of evidence, that the target tissue was exposed. EFSA's Scientific Committee provided advice on the adequacy to demonstrate target tissue exposure in *in vivo* studies, particularly in the mammalian erythrocyte micronucleus test (EFSA 2017a). In case the food additive is a mixture of substances, the statement of EFSA's Scientific Committee on the genotoxicity testing of chemical mixtures (EFSA 2019b) should be consulted. The Scientific Committee was also asked to provide guidance on the most appropriate *in vivo* tests to follow up on positive *in vitro* results for aneugenicity and on the approach applicable for risk assessment of substances that exhibit aneugenicity but do not induce gene mutations or clastogenicity. A draft guidance on aneugenicity assessment was published for public consultation in March 2020 (<http://www.efsa.europa.eu/en/consultations/call/public-consultation-draft-scientific-committee-guidance-assessment> (accessed on 26 May 2020); after public consultation (deadline 31 May 2020), EFSA's websites may be consulted for the final version).

Genotoxicity *in vivo* is to be considered as an adverse effect *per se*, even in cases where cancer bioassays are negative, since genotoxicity is also implicated in diseases other than cancer and one of the aims for genotoxicity testing is to identify substances which could cause heritable damage in humans (EFSA 2011a). There is no Tier 3 for genotoxicity testing. If a substance is positive at Tier 2, it is usually assumed that it is a somatic cell genotoxin and will be potentially carcinogenic and also mutagenic in germ cells. Such substances are not considered acceptable as food additives. Hence careful consideration should be given to animal welfare before conducting any further *in vivo* studies (EFSA 2012a). It should, however, be noted that the assessment of genotoxicity is generally based on all available data and that the quality and reliability of data are taken into consideration (EFSA 2011a). Accordingly, it is important to differentiate between indication and clear evidence for genotoxicity *in vivo*. An indication for *in vivo* genotoxicity would require further clarification.

## Subchronic and Chronic Toxicity and Carcinogenicity

A subchronic toxicity study should be performed for a period of at least 90 days in rodents (OECD TG 408) at Tier 1. The design of this study should be modified to include the assessment of some additional parameters described in the more recent guideline on repeated-dose 28-day oral toxicity studies in rodents (OECD TG 407). Toxicity observed in the subchronic toxicity study would trigger investigation of chronic toxicity at Tier 2. A chronic toxicity study may reveal effects which were not observed in subchronic studies, or it may confirm effects at the same or even lower doses than those applied in the subchronic study. Chronic toxicity and carcinogenicity are to be investigated at Tier 2 either separately (OECD TG 452 and 451) or in a combined study (OECD TG 453). The EFSA ANS Panel noted in its guidance document that there was a considerable debate in the area of risk assessment of pharmaceuticals about the value of the two rodent species approach for the evaluation of carcinogenicity and that this debate has led to the suggestion that there may be no need to continue investigating carcinogenicity routinely in two species (EFSA 2012a). The Panel supported this position and recommended, deviating from former requirements, to perform the studies with a single species only, generally the rat. However, under certain circumstances, e.g., indications for species-specific effects, a study in a second species may become necessary. At Tier 3, studies on the mode of action may be performed if required.

## Reproductive and Developmental Toxicity

The subchronic toxicity study performed at Tier 1 provides only limited information on reproductive toxicity and no information on developmental toxicity. It provides information on potential effects on the reproductive organs and, if assessed, the estrous cycle, but it does not cover fertility and the whole reproductive cycle. However, the decision on whether studies on reproductive and developmental toxicity are required could be based on the outcome of the subchronic toxicity study provided that the absorption of the substance is negligible. Studies on reproductive and developmental toxicity will generally be required for substances which are systemically available. In addition, any indication for effects on reproductive organs or parameters in the subchronic toxicity study will trigger testing for reproductive and developmental toxicity at Tier 2. This comprises a prenatal developmental toxicity study (OECD TG 414) in rabbits and an extended one-generation reproduction toxicity study (EOGRTS) (OECD TG 443). According to the OECD Guideline 443, the EOGRTS covers parameters on reproductive endpoints, pre- and postnatal developmental endpoints, and specific endpoints on developmental neurotoxicity, immunotoxicity, and endocrine disruption. The EOGRTS protocol includes the assessment of parameters which can be used for the decision on whether assessment of a second generation is required. The risk assessment may be based on the results of these studies; however, the effects observed might trigger additional studies at Tier 3, e.g., on endocrine effects, developmental neurotoxicity (OECD TG 426), and mode of action (EFSA 2012a).

## Other Studies

In addition to the core areas for evaluation, other studies may be required for the risk assessment of food additives, e.g., studies on immunotoxicity, hypersensitivity, and food intolerance. Likewise, human studies, e.g., ADME studies and tolerance studies, could provide useful information (EFSA 2012a). However, the quality and reliability of tolerance studies are mainly dependent on the study design. The prevalence of intolerances against food additives which are already on the market could reliably only be determined with placebo-controlled double-blind oral challenge tests, a condition which is met only by a few studies (Simon 2003; Wilson and Bahna 2005; Skypala et al. 2015).

Several symptoms have been attributed to food additive exposure, but the cause-and-effect relationship has not been well demonstrated in all (Wilson and Bahna 2005; Turner and Kemp 2012; Bahna and Burkhardt 2018). Allergenicity may result from the consumption of food additives which are proteins or peptides, e.g., lysozyme (E 1105) and invertase (E 1103), while pseudoallergenicity could be due to other (non-protein) food additives. The EFSA ANS Panel noted in its guidance document (EFSA 2012a) that there are no validated studies in laboratory animals which would allow assessment of the potential of a substance to cause allergic reactions in susceptible individuals following oral exposure. The panel recommended to consult the EFSA guidance on the allergenicity of genetically modified organisms (EFSA 2010) if the additive is a potential allergen, e.g., a protein or a peptide, or contains residues of proteins or other known allergenic molecules (EFSA 2012a). However, the panel pointed out that defining a threshold or a no observed adverse effect level (NOAEL) is difficult and that, accordingly, an adverse effect would be taken into account on a case-by-case basis (EFSA 2012a).

For new food additives, an indication for immunotoxicity may be obtained from the studies performed at Tier 1 and Tier 2. The subchronic toxicity study in rats (OECD TG 408) performed at Tier 1 involves investigation of a number of parameters that may be indicative of an immunotoxic or immunomodulatory effect, e.g., changes in spleen and thymus weights relative to body weight in the absence of overt toxicity, histopathological changes in these and other organs of the immune system, as well as changes in total serum protein, albumin/globulin ratio, and the hematological profile of the animals. Such effects may be confirmed or, alternatively, observed for the first time in Tier 2 studies, notably the EOGRTS (OECD TG 443), but also in chronic toxicity/carcinogenicity studies conducted according to OECD TGs 452, 451, or 453. In the EOGRTS, a cohort of animals is specifically dedicated to assess the potential impact of exposure on the developing immune system. If the results from these studies provide indication for immunotoxicity, additional studies may be performed at Tier 3 in order to investigate the underlying mechanisms of the effects seen and to assess their relevance for the risk assessment (EFSA 2012a). The EFSA ANS Panel noted in its guidance document that there are no OECD guidelines for such extended specialized studies and recommended to consult a WHO guidance for

immunotoxicity risk assessment for chemicals (WHO 2012). The respective sections on immunotoxicity and food allergy and other food hypersensitivities of the *Principles and Methods for the Risk Assessment of Chemicals in Food* (WHO and FAO 2009) may also be consulted.

---

## Derivation of an Acceptable Daily Intake

A main purpose of the risk assessment of food additives is the derivation of an Acceptable Daily Intake (ADI) as a health-based guidance value. An ADI is the estimated maximum amount to which individuals may be exposed daily over their lifetimes without appreciable health risk. Based on the most sensitive endpoint from a range of toxicological hazards and their dose-response relationships, a No Observed Adverse Effect Level (NOAEL) or, preferably, a benchmark dose lower confidence limit (BMDL) is established and used as point of departure for deriving an ADI (EFSA 2012a, 2017b). This point of departure is divided by an uncertainty factor which covers uncertainties due to the extrapolation of data from animal studies to the human situation as well as individual variabilities. Generally, a factor of 100 is applied as a default value. A smaller factor could be applied if human data are available, e.g., toxicokinetic data, which allow for comparison of internal doses in experimental animals and humans. A factor larger than 100 would be applicable if additional uncertainties were to be covered. The ADI is expressed in mg per kg body weight and is established for compounds for which a threshold mechanism of toxicity can be demonstrated. The ADI is applicable to the general population except infants below 16 weeks (WHO 1978; SCF 1998; EFSA 2017c). The EFSA Scientific Committee provided guidance on the risk assessment of substances present in food intended for infants below 16 weeks of age (EFSA 2017c).

The EFSA ANS Panel (EFSA 2014) presented a conceptual framework for the risk assessment of certain food additives

- which are of low intrinsic toxicity, e.g., substances with Acceptable Daily Intake (ADI) “not specified” (no numerical ADI),
- which are authorized in food categories according to *quantum satis* (QS) (Regulation (EC) No 1333/20084) which precludes a reliable exposure estimate,
- which, while they are not of low intrinsic toxicity, are of low toxicological concern as used in food, e.g., sodium hydroxide.

According to this conceptual framework, the outcome of the risk assessment, taking into account all available information, depends on the availability of reliable information on both exposure and toxicity and on whether or not the food additive and/or its breakdown products/metabolites are identical to a compound which is a normal constituent in the body (an endogenous compound) and/or is a regular component of the diet.

## Exposure Assessment

For exposure assessment of food additives, a tiered approach is recommended by FAO and WHO (WHO and FAO 2009) and is used by JECFA for the evaluation of food additives. The initial steps rely on conservative screening methods such as the budget method or models based on poundage data.

EFSA developed a Food Additives Intake Model (FAIM) template to support the calculation of exposure estimates to food additives. An updated FAIM version is available at <https://www.efsa.europa.eu/en/applications/foodingredients/tools> (accessed on 26 May 2020). This FAIM template is a screening tool for estimating long-term exposure to food additives. It can be used as a first step in the dietary exposure assessment by applicants, risk assessors, and risk managers. It is based on summary food consumption statistics (in grams per kg body weight) from the EFSA Comprehensive European Food Consumption Database tailored to food additive categories. Based on FAIM, the mean and high-level exposure to food additives can be estimated for different population groups throughout several European countries and age groups. According to the “Guidance for submission for food additive evaluations” (EFSA 2012a), two scenarios can be applied, taking into account:

- The maximum permitted levels (MPLs) of use, as set in the current EU legislation.
- The levels of use as reported for existing food additives, if available, or as proposed, in the case of new applications.

The model also provides information on the food groups contributing to the total mean exposure. The FAIM template can be used for the estimation of exposure to a new food additive or exposure resulting from new uses of an already authorized food additive.

More refined methods should be applied when screening methods cannot rule out a safety concern, e.g., when the exposure estimated based on FAIM exceeds the ADI. Data from the EFSA Comprehensive European Food Consumption Database (Comprehensive Database) (EFSA 2011b) can be used for refined exposure assessment. A guidance for the use of the Comprehensive Database is available at <http://www.efsa.europa.eu/en/food-consumption/comprehensive-database> (accessed on 26 May 2020). This database is used by EFSA to estimate exposure for the six following population groups: infants (from 12 weeks of age), toddlers, children, adolescents, adults, and the elderly. Dietary exposure is in the majority of cases estimated based on consumption data for all foods and all subjects involved in the dietary surveys, but estimates for “consumers only” are also calculated under specific circumstances and brand loyalty is considered by EFSA if appropriate (Gürtler and Arcella 2020).

In addition to food consumption data, the concentration of the additive in food as consumed is an important aspect for the exposure assessment. Depending on the purpose of the exposure assessment (pre-regulation or post-regulation), food additive concentration data can originate from:

- Legislated maximum permitted levels (MPLs)
- Usage levels reported by manufacturers
- Monitoring and surveillance programs
- Total Diet Study (TDS).

More details on refined exposure assessments for food additives, including recommendations of international expert committees, uncertainties and challenges related to the exposure estimation for food additives, and the monitoring of food additive intake, are described elsewhere (Gürtler and Arcella 2020).

---

## Risk Management Based on Risk Assessments

Based on a numerical ADI and an exposure assessment, conditions of use, e.g., maximum level for certain food categories, can be derived for food additives by risk managers. The current conditions of use applicable in the European Union are defined in Regulation (EC) No 1333/2008 and its amendments. For some food additives, there are no numerical ADIs. For substances of very low toxicity which, on the basis of the available data on toxicity and intake, do not represent a hazard to health, e.g., citric acid and citrates (E 330–E 333), the outcome of the evaluation by JECFA or SCF was “ADI not specified.” Such substances may be used at “*quantum satis*” level. According to Regulation (EC) No. 1333/2008, “‘*quantum satis*’ shall mean that no maximum numerical level is specified and substances shall be used in accordance with good manufacturing practice, at a level not higher than is necessary to achieve the intended purpose and provided the consumer is not misled.”

At a global level, the Codex Alimentarius Commission with its Codex Committee on Food Additives (CCFA) is responsible for risk management measures for food additives based on risk assessments carried out by JECFA. CCFA established a General Standard for Food Additives (GSFA) (<http://www.fao.org/fao-who-codexalimentarius/codex-texts/dbs/gsfa/en/> (accessed on 26 May 2020)) with provisions for the use of food additives in certain food categories.

An occasional exceedance of the ADI might be tolerated provided that (i) there is still a tolerable margin of safety between the NOAEL and the exposure, (ii) the effect on which the ADI was derived is not observed after acute exposure, and (iii) the exceedance does not occur frequently so that the long-term exposure is not significantly affected (Gürtler 2010). However, the provisions of use should ensure that the ADI is generally not exceeded. Therefore, exposure assessments need to take into account not only the reported uses but also the provisions of use, e.g., the maximum levels for certain food categories.

For compounds for which no safe level of exposure can be anticipated, for example, genotoxic carcinogens, an ADI would not be established. Such substances would not be acceptable as food additives. For the assessment of the risk resulting from levels of unavoidable contaminants or residuals in the additive which are genotoxic and carcinogenic, the EFSA FAF Panel generally uses the margin of exposure (MOE) approach described in an EFSA Scientific Committee opinion

(EFSA 2005, 2012b). The Threshold of Toxicological Concern (TTC) approach would be considered for the evaluation of unavoidable genotoxic residuals, for which carcinogenicity data are not available. In such cases exposures for high-level consumers at the proposed maximum use levels would be expected to be below the TTC for potential DNA-reactive mutagens and/or carcinogens of 0.15 µg/person/day (EFSA 2012c, 2019c). The TTC approach could also be applied to low-exposure substances such as impurities, metabolites, and degradation products of deliberately added substances for which genotoxicity data may be unavailable (EFSA 2012a).

In 2010, a re-evaluation program was established in the European Union for all existing food additives. According to Regulation (EU) No. 257/2010, food additives which were permitted before 20 January 2009 shall be subject to a new risk assessment carried out by EFSA. In order to prioritize the evaluation of more than 300 food additives, priority criteria such as time since the last evaluation by SCF or EFSA and the availability of new scientific evidence and exposure were applied (<http://www.efsa.europa.eu/en/topics/topic/food-additive-re-evaluations> (accessed on 26 May 2020)). The highest priority was assigned to certain food colors for which the evaluations were to be completed until the end of 2010, while the lowest priority was applied to sweeteners, except aspartame, which should be evaluated until the end of 2020.

---

## Perspective

There are several challenges related to the exposure estimation for food additives and the monitoring of food additive intake, including challenges related to classification of food into food categories and challenges related to analytical methods (Gürtler and Arcella 2020). The links between food consumption information on the one hand and food additive concentration data on the other are mostly not compatible with each other due to inconsistent food classification systems. Food categories, as defined in legislation, e.g., Regulation (EC) No 1333/2008, for which in many cases food additive concentration data are available, are not fully identical with the food categories for which food consumption data are available. It is therefore a challenge to reduce the resulting uncertainties, e.g., by harmonization of such classification systems. Another challenge is related to the monitoring of the use of food additives. Validated analytical methods are needed to fulfill the monitoring requirements according to Regulation (EC) No 1333/2008. However, whereas there is a European reference laboratory for feed additives, no reference laboratory exists for food additives. Thus, it is still a challenge to harmonize the analytical methods that are required for the monitoring of food additives.

The current EFSA guidance document for food additive evaluations (EFSA 2012a) provides a flexible approach which acknowledges the use of integrated testing strategies and alternative methods in order to complement the data required in this guidance. In some cases, e.g., for the evaluation of aspartame, physiologically based pharmacokinetic modelling was applied, and it may be expected that such

modelling will become more relevant for the evaluation of additives in future. “In silico—/(quantitative) structure activity relationships (QSAR)” methods may contribute to evaluate impurities and metabolites and may also be used for screening purposes before embarking on any Tier 1 testing. Special studies may be used to investigate the mode of action in the tiered approach as recommended by EFSA (2012a). Investigation of adverse outcome pathways (AOPs) might provide useful information that may support risk assessments for food additives in future. In an analysis performed by Kramer et al. (2019), the adverse effects and related points of departure based on which an ADI was derived by EFSA, SCF, or JECFA were compiled for all food additives permitted in the European Union. According to this study, a point of departure for adverse effects was identified by EFSA/SCF/JECFA only for 31% of the 326 food additives considered. Adverse effects were mainly observed in the liver, kidney, cardiovascular system, lymphatic system, central nervous system, and reproductive system. Several AOPs related to these endpoints were identified by Kramer et al. (2019) in an OECD compilation of AOPs (<https://aopkb.oecd.org/> (accessed on 26 May 2020)). However, the level of development and documentation was different for these AOPs, and there is still a lack of AOPs for several adverse effects such as gastrointestinal tract irritation and a number of non-specific, late-onset, and/or local effects, including body weight changes (Kramer et al. 2019; Vinken et al. 2020). Kramer et al. (2019) pointed out that AOPs cannot be used as stand-alone tools. In combination with other relevant data, AOPs might, however, be used as supporting information for risk assessments for food additives in future. According to Vinken et al. (2020), a wider role for AOPs in future risk assessment may probably best focus on providing support for read-across; however, a number of challenges need to be tackled.

## Abstract

In view of a persisting trend to use botanicals and botanical preparations especially in food supplements but also in replacing synthetic additives or flavorings in food, aspects of the safety evaluations of plants and plant-derived components in food are discussed. In addition risk assessment regarding unintentional intake of botanical ingredients via contamination of food with whole plants, plant parts, or their components is addressed. Examples are presented taking the complexity in composition of botanicals and their matrix effects into account. Requirements and principles of present guidelines for the safety evaluation of botanicals and their components for food use, including a presumption of safety approach based on existing knowledge, are outlined. The essentials of relevant regulatory frameworks are summarized, and an outlook on possible future developments is given.

## Botanicals in Food: An Introduction

*Plant*-derived food forms an intrinsic part of traditional diets all over the world. Furthermore, diets rich of vegetables and fruits are associated with health benefits. As part of a continuing trend to a preference for natural, “organic,” *herbal*, and plant-based products, especially *food supplements* (synonym: *dietary supplements*) based on *botanicals*<sup>1</sup> and their preparations,<sup>2</sup> became widely available on the European and North American market. This was accompanied by the tendency to replace synthetic food additives or flavorings in food products by those of botanical origin. Novel foods or genetically modified foods represent another source of intentional dietary intake of botanicals and are not dealt with here (see ► [Chap. 93, “Risk Assessment of Genetically Modified Food and Feed”](#)). Unintentional exposure of consumers to botanicals and their components is occurring via *contamination* of food with whole plants, plant parts, or their ingredients, e.g., as a consequence of inadequate harvesting or cleaning methods, adulteration or due to carry over from animal feed through meat or animal products, or via mistaking edible and nonedible plants (Speijers et al. 2010; Koleva et al. 2012; Dusemund et al. 2017a). The use and occurrence of plants and their components in feed are not a subject of this chapter.

The use of a large variety of botanicals in food supplements and related products includes that of certain medicinal plants. In particular plants used for therapeutical purposes may contain a diversity of biologically active substances such as alkaloids; cardiac glycosides; mono-, di-, tri-, and sesquiterpenes; and anthraquinones for which the induction of desired or adverse effects depends on dosage. As known from many lawsuits, the borderline between plant-based food supplements (not subjected to an authorization procedure in the European Union (EU)) and plant-based medicinal products (subjected to an authorization procedure in the EU) is often difficult to define. In relevant literature the need of an EU-wide harmonized approach based on appropriate systematical safety evaluations of botanicals and botanical preparations used in food supplements is described to assure that intake doses of biological active plant components in these products are within safe limits (EFSA 2009a, b; Silano et al. 2011; EFSA 2014).

---

## Specifics in the Risk Assessment of Botanicals: Some Examples

Independent from the role of the botanical, being either added for sensory, technological, or health purposes to a food product or occurring as a natural typical component or an impurity in food, risk assessments of botanicals and their preparations differ from that of clearly defined single substances as a component of food. Thus, it has to be considered that botanicals generally consist of a *complex mixture of phytochemicals*. Regarding the active principle of interest for technological or health reasons, the purity is often rather low, and the remaining substances are not characterized sufficiently. A botanical preparation of a specific species may be represented by different extracts varying in composition, due to the use of different source materials (e.g., different botanical subspecies, different geographical origin and

conditions of growth and harvesting, different parts of a plant) and different extraction methods and solvents. In case of selective extractions, enrichments of natural ingredients of concern or contaminants such as heavy metals or pesticides may occur. Pharmacological and toxicological effects of botanical products are usually associated with their contents of secondary plant metabolites which can vary among plants belonging to the same species or variety as a consequence of multiple biotic and abiotic factors.

## Identity and Specifications

The contents of secondary plant metabolites and the botanical origin have to be taken into account by defining the *identity and specifications* of botanical preparations which of course is also basically important to exclude adulteration and misidentification of plants. Furthermore it has to be ascertained in the risk assessment that specifications of the products of trade and those investigated in the toxicity testing are the same or allow read-across.

These reasonings may be illustrated by an example. For the natural botanical food color lutein (E 161b), belonging to the category of food additives, the content of total carotenoids/saponified carotenoids as coloring matter may be as low as 5% when extracted from grass, nettle, lucerne, or spinach but amounts to  $\geq 60\%$  when *Tagetes erecta* flowers are used as a source. While the EFSA (European Food Safety Authority) Panel on Food Additives and Nutrient Sources Added to Food (ANS) in the process of reevaluation of food additives could establish an ADI of 1 mg/kg body weight (bw)/day for the more concentrated extracts (total carotenoids  $\geq 60\%$ ) from *Tagetes erecta* flowers, it decided that the database available is too limited to conclude that the ADI also applies to lutein preparations of lower purity or from other sources (EFSA 2010, 2011a).

## Interactions of Secondary Plant Components

Furthermore, in a botanical biologically active substances usually occur accompanied by chemically related compounds formed, e.g., as precursors or by-products of biosynthesis pathways. Due to similar structures, a variety of components of a botanical or botanical preparation may have the same structural alerts for specific toxicity endpoints, may react as agonists or antagonists regarding receptor-mediated reactions, or may compete for binding sites in metabolizing enzymes responsible for activation, deactivation, or elimination. In consequence *interactions with accompanying ingredients* which may weaken or enhance the toxic effects of a known substance of concern have to be considered in the risk assessment of plant materials (*matrix effects*). Thus, in general, basing the risk assessment of botanicals, botanical preparations, or botanical contaminants on the exposure and toxicity data of only one active ingredient and ignoring the accompanying ones may be inappropriate. It also becomes evident that breeding methods, influencing biosynthesis pathways, may

change the pattern in which bioactive substances occur in a botanical and thus affect its toxicity profile. If botanical preparations of different plants are used in combinations, which is frequently observed, the possibilities of interactions increase.

Possible interactions including synergistic effects have been addressed, e.g., in the risk assessments of botanical contaminants in food and feed recently performed by national authorities and EFSA (e.g., Dusemund et al. 2017b). Evaluating the contamination of poppy seeds, derived from *Papaver somniferum*, by opium alkaloids, in addition to the presence of morphine that of codeine as a precursor in the biosynthesis of morphine, has been considered, both alkaloids acting as agonists binding to the  $\mu$ -opioid receptors (BfR 2005; EFSA 2011b). An altered pattern of alkaloids was, e.g., observed in Australian poppy seeds originating from poppy cultivars developed by genetic regulation of certain enzymatic biosynthesis processes to give a high yield of thebaine and oripavine, two other intermediates in the biosynthesis of morphine, which are used as precursors in drug synthesis (EFSA 2011b). In the risk assessment of ergot alkaloids occurring in the sclerotia of *Claviceps purpurea*, which are contaminating grain, reference is made to a sum of ergot alkaloids including, i.a., ergometrine, ergotamine, ergosine, ergocristine, ergocryptine, and ergocornine. They have in common the tetracyclic ergoline ring system which is associated with their activity as ligands for adrenergic, serotonergic, and dopaminergic receptors (EFSA 2012a). Additive toxic effects have also been taken into account in the risk assessments of pyrrolizidine alkaloids, which have been performed for the contamination of salad with parts of *Senecio vulgaris* (BfR 2007), and for the occurrence of pyrrolizidine alkaloids in honey (BfR 2011a; EFSA 2011c), herbal teas, and other food commodities including food supplements (BfR 2013, 2016; EFSA 2017a). A cumulative assessment approach is recommended for all 1,2-unsaturated pyrrolizidine alkaloids, the double bond being a prerequisite for metabolic activation to genotoxic carcinogens (COT 2008; BfR 2016, EFSA 2017a). A group approach has also been chosen in the risk assessment of quinolizidine alkaloids, such as sparteine, lupanine, and lupinine, exhibiting anticholinergic activity and occurring in food prepared from seeds of bitter lupines (certain varieties of, e.g., *Lupinus albus*, *L. angustifolius*, *L. luteus*) without adequate debittering process (BfR 2017). Interactions may as well play a role regarding the toxicokinetic and toxicodynamic effects of polyphenols contained in green tea extracts derived from the leaves of *Camellia sinensis* which are inter alia used in food supplements. It has been hypothesized that the principal ingredient (–)-epigallocatechin-3-*O*-gallate (EGCG), taken as part of a green tea extract, shows slower elimination than when used as an isolated compound due to competition for binding sites in metabolizing enzymes with other accompanying polyphenols in the extract (EFSA 2009a).

## Experiences from Human Exposure

The risk evaluation of botanicals which have been traditionally used for years as food or *herbal* medicine is often based on the *experiences and data from human exposure*, covering potentially epidemiological and clinical studies, reports of

adverse health effects, and case reports of intoxications, while data of validated toxicological studies in experimental animals are often sparse.

Furthermore, botanical ingredients that commonly occur at low levels in botanical components of the diet may be extracted and reintroduced in concentrated form in certain specific food supplements or related health products resulting *in comparatively high exposure levels* (EFSA 2004). There are some examples where partly even serious adverse effects have been assigned to this type of products. Thus, capsules containing high-dosed dried green tea extracts taken for weight-loss purposes have been associated with severe liver toxicity, while these adverse effects are not reported for traditional consumption of green tea infusions (EFSA 2009a; Speijers et al. 2010). Certain case reports on adverse cardiovascular effects are suspected of being associated with intake of food supplements advertised for weight loss or improvement of physical fitness containing high doses of (–)-synephrine as part of bitter orange (*Citrus aurantium* ssp. *aurantium*) extracts partly in combination with caffeine. No adverse effects are known from (–)-synephrine exposure via traditional foods such as orange juice or bitter orange marmalades (NTP/NIEHS 2004; EFSA 2009a; Health Canada 2011; BfR 2012a, Bakhyia et al. 2017).

---

## Guidance for Safety Evaluation: An Approach by EFSA

In view of the described specific aspects in the safety evaluation of plant-based food supplements and their expanding market volume and increasing variety with numerous claims, EFSA saw a need for a better characterization of the botanicals in use and for a harmonization of their risk assessments (EFSA 2004). To identify the data needed to assess the safety of botanicals and to suggest a science-based approach for the safety assessment, EFSA developed the “*Guidance on safety assessment of botanicals and botanical preparations intended for use as ingredients in food supplements*” (EFSA 2009b). The guidance is intended to assist risk assessors and food manufacturers considering the safety of a given botanical. Even though the guidance is focussed on the use of botanicals in food supplements, EFSA emphasizes that the principles of the approach chosen are applicable also to other uses of botanicals and botanical preparations in the food and feed areas. This guidance does not refer to the use of botanicals or botanical preparations for use as a novel food or botanicals representing genetically modified food, since for both categories special guidances do exist (see ► Chap. 93, “*Risk Assessment of Genetically Modified Food and Feed*”).

The information considered as necessary for a botanical or botanical preparation is *technical*, *exposure*, and *toxicological* data. The *technical* data comprise details on (i) the identity and nature of the source material, (ii) the manufacturing process of the botanical (preparation), (iii) its chemical composition, (iv) its specifications, (v) its stability in food (supplements), (vi) the proposed uses and use levels, and (vii) the information on existing assessments. Regarding *exposure* data information is required on (i) the anticipated exposure via the food supplement; (ii) the cumulative exposure via different categories of food, including food supplements, and medicinal

products; (iii) the modality of use; and (iv) the information on historical use of different categories of food, including food supplements, and medicinal products. Regarding the *toxicological* data, studies on toxicity and toxicokinetics including metabolism of botanicals and botanical preparations should be conducted using internationally agreed protocols.

A two-level tiered approach for the safety evaluation of the botanical (preparation) is proposed depending on the available knowledge. It consists primarily on *level A* of a risk assessment in which, based on all available data, a decision is derived if there is (i) a safety concern, (ii) no safety concern, or (iii) a need for additional data. In the latter case, the requirement for further testing is specified on a subsequent level (*level B*).

On *level A* the decision “no safety concern” may be based on the principle of a “presumption of safety.” The guidance describes that a *presumption of safety* could be applied when available data would allow to conclude that exposure to known levels of the botanical (preparation) has occurred in large population groups for many years without reported adverse effects and that thus no additional data are judged necessary for the safety evaluation. Requirements for a “presumption of safety” are that not only use levels but also chemotypes of the botanicals and the chemical composition of the botanical preparations should be in line with historically used ones and intakes due to the intended levels of use are within the range of intake levels derived from the European Member States’ average diets. The approach relies mainly on the objective of not significantly increasing exposures beyond the levels linked to the safe history of use.

If specific compounds of concern can be well defined on *level A*, the evaluations can focus on them. For a botanical (preparation) with a potential to contain toxic, addictive, psychotropic, or other substances that may be of concern, “presumption of safety” can be applied only if there is convincing evidence that these undesirable substances are either absent or significantly reduced or inactivated during processing. In these cases a “presumption of safety” of the botanical (preparation) is only justified when the overall exposure to the substances of concern is not too high compared to existing health-based guidance values such as the acceptable/tolerable daily intake (ADI/TDI). Consideration of exposure to the substance of concern in relation to the Threshold of Toxicological Concern (TTC) values may also be helpful. When the botanical (preparation) contains substances that are both genotoxic and carcinogenic, the “Margin of Exposure” (MOE) approach (EFSA 2005) could be applied. Furthermore, the EFSA guidance (EFSA 2009b) addresses the possibility that the kinetic and toxicodynamic of a naturally occurring substance could be modified by the matrix in which it is present which may result in reduced or increased toxicity. Advice is also given regarding read-across between two different preparations of a botanical or between different botanicals for which equivalence of composition data and consumption patterns regarding the substances of concern is a precondition.

On *level B* decision is taken which additional studies are needed for those botanicals or botanical preparations for which a “presumption of safety” was not justified on *level A* because, e.g., the anticipated intake is significantly higher than

the estimated historical intake level or the historical intake level cannot be assessed. According to the EFSA guidance (EFSA 2009b), the study requirements on *level B* can be deduced from the “Guidance on submissions for food additive evaluations by the Scientific Committee on Food (SCF 2001).”<sup>3</sup> The spectrum of toxicological data asked for comprises primarily studies on toxicokinetics including metabolism, genotoxicity, and subchronic toxicity. Depending on the outcome of these studies and other specific relevant information, further studies, e.g., on reproductive toxicity, developmental toxicity, neurotoxicity, immunotoxicity, and chronic toxicity/carcinogenicity, may be required. The specifications and identity criteria for the botanical preparation(s) used for the toxicity studies and their relationship to the final product to be used in the food supplement should be described in detail.

The adequacy of the two-level tiered approach described in the guidance document was tested with a selected number of examples including botanicals known to contain acute or subchronic toxic substances or potentially genotoxic carcinogens and botanicals with an established history of food use. The results of this study were published in a report illustrating how to apply the guidance document (EFSA 2009a). In 2014, EFSA considered the suitability of a “Qualified Presumption of Safety (QPS) approach,” initially developed for the assessment of microorganisms, as a practical method for assessing botanicals and botanical preparations for which an adequate body of knowledge exists. However, in view of the high variability especially in chemical composition, only limited possibilities were seen to establish a QPS status at high taxonomic levels for botanicals. Still, the use of a developed structured assessment scheme was recommended as an extension of the 2009 EFSA guidance for the safety assessment of botanicals and botanical preparations intended to be used in food supplements (EFSA 2014).

As a further tool for risk evaluation of botanicals, EFSA listed more than 1,200 plant genus, species, and varieties in a “Compendium of botanicals reported to contain naturally occurring substances of possible concern for human health when used in food and food supplements” (EFSA 2012b; Silano et al. 2011). Its purpose is to draw the attention of manufacturers and food safety authorities to possible safety issues when these botanicals are used in food. There is no final judgment as to whether botanicals listed in the Compendium are safe or not safe for food use.

The “Guidance for submission for food additive evaluations” (EFSA 2012c) by the EFSA Panel on Food Additives and Nutrient Sources Added to Food (ANS) is relevant for the safety evaluation of botanical preparations used as food additives. It reflects widely the principles of the “Guidance on safety assessment of botanicals and botanical preparations intended for use as ingredients in food supplements” presented above. In the safety evaluation of food additives of botanical origin for use in infant formula, such as certain thickening agents (e.g., guar gum, locust bean gum, xanthan gum), an additional EFSA guidance considering the specific vulnerability of infants below 16 weeks of age has to be taken into account (EFSA 2017b).

The existing guidance for the use of botanical preparations as flavorings is dealt with in ► [Chap. 91, “Risk Assessment of Food Additives.”](#)

## Legal Background

The use and the occurrence of plants in food are heterogeneous and therefore subject to different national and international regulatory frameworks, which in general are based on the outcome of the scientific risk assessments of competent national or international authorities, such as the Joint FAO/WHO Expert Committee on Food Additives (JECFA) or the EFSA.

The Codex Alimentarius Commission, established by FAO and WHO in 1963, provides a global framework. It develops harmonized international food standards, guidelines, and codes of practice to protect the health of the consumers which are also relevant for botanical components in food. For food additives of botanical origin, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) publishes specifications and safety evaluations including health-based guidance values (e.g., curcumin (E 100): JECFA 2004, 2006). On the basis of these monographs, the Codex Committee on Food Additives may endorse permitted maximum levels for individual food additives. Another Codex panel, the Codex Committee on Contaminants in Foods, establishes or endorses permitted maximum levels or guideline levels for contaminants including naturally occurring toxicants in food and feed. For grains and pulses, the Codex Alimentarius standards state, e.g., that they shall be free from the following toxic or noxious seeds in amounts which may represent a hazard to human health: *Crotalaria* (*Crotalaria* spp.), corn cockle (*Agrostemma githago* L.), castor bean (*Ricinus communis* L.), and jimson weed (*Datura* spp.) (CODEX STAN 153-1985; CODEX STAN 171-1989; CODEX STAN 172-1989; CODEX STAN 199-1995; CODEX STAN 201-1995).

In Europe the use of botanicals and botanical preparations in food is regulated by national and EU legislations, where mainly the latter will be addressed in the following.

Overall botanicals and botanical preparations found in food fall under the basic regulations of the General Food Law (Regulation (EC) No. 178/2002/EC), in which Article 14 protects against unsafe food and which attributes responsibility for the safety of the products on the market to the food business operators.

It is known that conventional plant-derived food, e.g., certain fruits, vegetables, herbs, and spices, may contain a variety of naturally occurring substances of concern, such as  $\alpha$ -solanine, furocoumarins, cyanogenic glycosides, capsaicin, coumarin, estragole, and thujone (e.g., Dusemund et al. 2017b). With a normal diversified diet, the intake of these substances generally only amounts to low levels not known to cause any health damage in humans. However, for preventive action, national authorities are informing the public by communicating nutritional recommendations to avoid potential risks of high or excessive individual consumption of a certain foodstuff, e.g., to consume cassia cinnamon, containing relatively high levels of the hepatotoxic coumarin only in moderate amounts (BfR 2012b), or advising against excessive intake of extremely hot chili sauces with high concentrations of capsaicin, which may cause irritation of mucous membranes, nausea, vomiting, and hypertension (BfR 2011b). Specific regulations exist for some of the abovementioned naturally occurring food ingredients, but they refer only to

flavoring purposes (Regulation (EC) No. 1334/2008). They aim at avoiding an increase of exposure not allowing to add the isolated substances to food (e.g., capsaicin, coumarin, estragole, thujone) and restricting their concentration in compound food containing flavorings or flavoring food ingredients (coumarin, estragole, thujone). Further details on the regulations of flavorings in general are given in ► [Chap. 91, “Risk Assessment of Food Additives.”](#)

Regarding plant-based food additives, present uncertainties regarding the differentiation between natural food colors, being food additives (e.g., beetroot red (E 162), an extract of beetroots), and coloring foods (e.g., concentrated cherry juice), considered to be normal characteristic natural food ingredients, are noteworthy. In contrast to the latter, food additive colors undergo an approval procedure (Regulation (EC) No. 1331/2008), need labeling as an additive (Directive 2000/13/EC), and have to meet the purity criteria set out in Commission Regulation (EU) No. 231/2012. A criterion to determine whether or not a food color is an additive is that of “selective extraction of the pigments” which is per definition associated with the manufacturing of a food color considered as an additive (Annex I of Regulation (EC) No. 1333/2008). Further details on regulations of food additives in general are outlined in ► [Chap. 91, “Risk Assessment of Food Additives.”](#)

Regulations for novel foods and genetically modified foods of botanical origin are not presented here but in ► [Chap. 93, “Risk Assessment of Genetically Modified Food and Feed.”](#)

With respect to food supplements, the use of botanicals and botanical preparations has not yet been harmonized within the EU but is regulated in the Member States by differing national rules. Partly, (positive) lists of safe botanicals and/or (negative) lists of botanicals which are banned or restricted for food use have been established. In some EU Member States, plant-based food supplements are subject to a notification procedure before being introduced to the market (Bast et al. 2002). The EU Directive 2002/46/EC gives general provisions for food supplements and specifically addresses modalities for use of vitamins and minerals listed in the annexes to this directive. It also allows the use of “other substances with a nutritional or physiological effect,” for which no further definition or regulation is given. However, it is generally understood that this term could include botanicals and botanical extracts besides substances such as amino acids, enzymes, pre- and probiotics, and essential fatty acids (Silano et al. 2011). Furthermore, there is an announcement in the eighth recital of this directive that specific rules concerning these other substances as ingredients of food supplements should be laid down at a later stage, provided that adequate and appropriate scientific data become available.

If a harmful effect on health is suspected for a botanical or botanical preparation, a procedure based on Article 8 of the food fortification legislation (Regulation (EC) 1925/2006) may be initiated by the European Commission which may result in a placement of the botanical (preparation) in Annex III of this regulation. On the basis of a risk assessment by EFSA, it can be banned (Annex III, Part A), restricted in use (Annex III, Part B), or in case of uncertainties reevaluated on the basis of additional safety data (Annex III, Part C). So far, following demands of EU Member States, only ephedra herb and its preparations originating from *Ephedra* species

(Annex III, Part A) and yohimbe bark and its preparations originating from yohimbe (*Pausinystalia yohimbe* (K. Schum) Pierre ex Beille) (Annex III, Part C) have been regulated by this means on the basis of existing EFSA opinions (EFSA 2013a, b).

Nutrition and health claims regarding botanical food supplements are regulated by Regulation (EC) 1924/2006. This regulation does not foresee an assessment of the safety of the product carrying the claim.

As far as botanical contaminants are concerned, Article 2 of the Council Regulation (EEC) No. 315/93 stipulates that, where necessary, maximum tolerances for specific contaminants shall be established in order to protect public health. Thus, Commission Regulation (EC) No. 1881/2006 lays down maximum levels for certain contaminants in foodstuffs, but regarding natural toxicants at present, it only includes various mycotoxins. Regarding natural toxicants, besides various mycotoxins including ergot alkaloids, only tropane alkaloids and erucic acid are addressed, EFSA risk assessments being available for both contaminants (EFSA 2013c, 2016).

In the USA the use of botanicals in food supplements (dietary supplements) is regulated under the Dietary Supplement Health and Education Act of 1994 (DSHEA), which places the burden on the Food and Drug Administration (FDA) to prove that a dietary supplement presents a significant or unreasonable risk of illness or injury under the labeled conditions of use. Under certain conditions a notification process is required for new dietary ingredients that were not marketed before October 15, 1994. The law requires the collection of all adverse event reports by manufacturers, distributors, and retailers of dietary supplements and the reporting of serious adverse event reports to the FDA. Due to case reports on adverse effects, FDA published a final rule on February 11, 2004, declaring dietary supplements that contain ephedrine alkaloids adulterated on the basis that these products present an unreasonable risk of illness or injury (FDA 2010).

---

## Future Perspectives

Since plant-based preparations are widely present in different categories of food commodities with expanding market volume and increasing exposures of consumers, the need for a better chemical and toxicological characterization and a harmonized systematic approach of scientific risk assessment of botanicals and botanical preparations is growing.

The establishment of the EFSA guidance document for the safety assessment of botanicals and botanical preparations supplemented in 2014 (EFSA 2009b, 2014) was a first step to achieve similar standards in safety evaluations performed by the national competent authorities of Member States. The next step would be to determine systematically which botanicals should be evaluated with priority considering significant levels of substances of concern, reports on adverse effects, increases of intake rates, and negative lists of Member States (EFSA 2009b).

While the EU legislation is covering the use of botanical additives and flavorings, a general EU-wide approach is lacking for plant-based food supplements. Especially

for botanicals or botanical preparations used in products, where the borderline between food supplements (not subjected to an authorization procedure in the EU) and medicinal products (subjected to an authorization procedure in the EU) is difficult to define, continuing measures are desirable to guarantee that intakes of toxicologically relevant botanical components are within safe limits. Thus, in addition to ephedra herb and its preparations originating from *Ephedra* species (Annex III, Part A) and yohimbe bark and its preparations originating from yohimbe (*Pausinystalia yohimbe* (K. Schum) Pierre ex Beille) (Annex III, Part C), further botanicals and botanical preparations may be listed in the future in Part A, B, or C of Annex III of Regulation (EC) 1925/2006 in accordance with its Article 8. In addition activities are expected with respect to the definition of coloring foodstuffs. A catalogue of clear criteria will presumably soon be established on how to distinguish coloring foods, which are not requiring a safety evaluation and an approval, from additive food colors which need an authorization. With respect to consumer safety, unambiguous definitions of coloring foods and their uses are considered to be necessary to ensure that their application does not lead to toxicologically unacceptable higher exposures with coloring components, accompanying substances, and impurities of these sources than would result from their normal dietary intake. Legal definitions and specific provisions regarding the use of coloring foods might be necessary.

Furthermore, other EFSA risk assessments of botanical contaminants, namely, of opium alkaloids in poppy seeds and of pyrrolizidine alkaloids in food and feed (EFSA 2011b, 2017b), may result in legal consequences. A decision by the European Commission may be taken if in these cases there is a need for legal measures in the frame of Council Regulation (EEC) No. 315/93 laying down community procedures for contaminants in food to protect public health. Other measures may also be taken, such as the development of codes of practice. This has been especially recommended in a discussion paper by the Codex Committee on Contaminants in Foods to prevent and reduce pyrrolizidine alkaloid contamination of food products (FAO/WHO 2011).

## Endnotes

1. This term refers to plants, including algae, fungi, and lichens, and parts of plants as a whole or cut.
2. This term refers to preparations obtained by all kind of processing, e.g., pressing, extraction, fractionation, concentration, drying, and/or fermentation.

3. This guidance was replaced in 2012 by the “Guidance for submission for food additive evaluations by the EFSA Panel on Food Additives and Nutrient Sources Added to Food (ANS)” (EFSA 2012c).

## Abstract

In the European Union (EU), genetically modified (GM) food and feed are subject to strict legal requirements. Thus, food and feed products derived from genetically modified organisms (GMO) may only be placed on the market if they have previously undergone a safety assessment. According to the concept of “substantial equivalence,” the safety assessment is centered on the comparison of the GM food and feed with non-GM food and feed that have a so-called history of safe use. The current approach usually comprises a molecular characterization of the genetic modification, agronomic and phenotypic analyses, as well as comparative analyses of nutritional, anti-nutritional, and toxic or allergenic constituents. Depending on identified changes in the composition, further investigations may be necessary to prove that a GMO-derived product is as safe as the non-GM comparator. Irrespective of this, feeding studies in rodents are usually required to account for the possibility of unforeseeable health effects. In the following, the general principles of the human health risk assessment as part of the market

**Introduction**

The first commercialized genetically modified crop was the so-called Flavr Savr™ tomato entering the US market in 1994. By introducing an additional antisense copy of the gene expressing the enzyme polygalacturonase into the genome of tomatoes, the ripening process was supposed to be slowing down preventing the softening of tomatoes and consequently the susceptibility for damage. The US Food and Drug Administration (FDA) evaluated all information related to safety submitted by the applicant, the company Calgene, and concluded that the tomato “is as safe as tomatoes bred by conventional means.” This statement was based on the risk assessment principle established a bit earlier by a working group of the Organisation for Economic Co-operation and Development (OECD) dealing with safety in biotechnology (OECD 1993). The OECD concept of “substantial equivalence” takes the idea that existing food products with a so-called history of safe use can serve as the starting point for comparison of the safety assessment and the nutritional values of a food product that has been modified using biotechnological methods. Consequently, in case a genetically modified food product is found to be substantially equivalent to an existing product, no safety concerns other than for the existing product are expected. On the contrary, in case the new product is considered not to be substantially equivalent to its appropriate non-genetically modified (GM) comparator, it does not necessarily indicate that it is unsafe. It just indicates to the assessors different characteristics that need to be evaluated in a more targeted manner to conclude on the safety of the respective product (OECD 1993).

Globally, in at least 26 countries, more than 190 million hectares of genetically modified organisms (GMO), mainly soybeans, maize, cotton, and rapeseed, were cultivated in 2018. Beside these big “four” also potatoes, papaya, sugar beets, squash, and eggplant are approved and on the market in various countries. In terms of GM food and feed, more than 70 countries do have legislation in place regulating risk assessment and authorization of products derived from GMO (ISAAA 2018).

Until now, there are no commercially available genetically modified farm animals approved and commercially grown around the world with the exception of the AquAdvantage Atlantic salmon bearing a growth hormone-regulating gene from

the Pacific Chinook salmon, together with a promoter from the ocean pout in its genome. Although approval for human consumption has been granted by the Canadian and US authorities already in 2015, it still not reached US consumers due to court cases not finally solved yet. However, many new genetically modified animal traits are under development and foreseen for commercialization. Since the use of GMO animals is still considered to be marginal in comparison to the vast amounts of biotech crops approved and cultivated around the world, this chapter is mainly focusing on GM plants.

---

## Legislation Framing the Use of GMO in the European Union

According to European legislation the term “genetically modified organism (GMO)” means an organism, with the exception of human beings, in which the genetic material has been altered in a way that does not occur naturally by mating and/or natural recombination. However this includes organisms obtained through certain techniques of genetic modification such as mutagenesis and cell fusion (including protoplast fusion) of plant cells of organisms which can exchange genetic material through “traditional breeding methods” (European Union 2003). In practice, it means that genetic elements from different sources are combined and introduced into the genome of a host organism resulting in a specific GM event since the location of the event in the genome of the GMO could not be predicted before the “New Breeding Techniques (NBT)” have been developed.

Since 1990 GMO are regulated for the deliberate release into the environment in the European Union (EU) (European Communities 1990a). In parallel also legislation came into force regarding the contained use of genetically modified microorganisms (European Communities 1990b). The latter one is out of the scope of this book chapter; nonetheless, it is worth mentioning that a comprehensive legislation has been established considering the whole cascade starting from research on GMO in the laboratory up to the commercialization of GMO on the EU market.

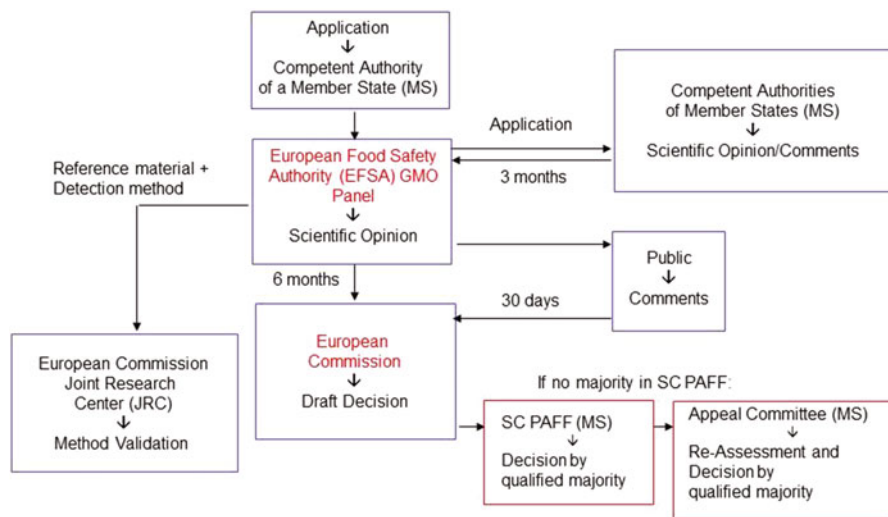

Nowadays, the deliberate release of GMO into the environment is regulated by Directive 2001/18/EC and includes, besides the risk assessment described in detail below, also a comprehensive environmental impact assessment (European Union 2001). Since GMO which are deliberately released into the environment are potentially unable to get back into a contained use, particular attention to the environmental impact is needed. The main questions to be answered are the potential for surviving in the environment and the possibility to cross with native species in the EU. In the EU, only a single GMO, an insect-resistant GM maize line called ‘MON810,’ is currently approved for cultivation. However, its cultivation for commercial purposes is currently only done in the north of Spain.

In 2015, after long debate about reservation against GMO cultivation in the public in different EU member states, the new Directive (EU) 2015/412 has been adopted allowing EU countries to restrict or prohibit GMO cultivation on their territory by “invoking compelling grounds such as environmental or agricultural policy objectives, town and country-planning, land use, coexistence, socio-economic impacts, or

public policy.” Seventeen member states and two autonomous regions took the opportunity to declare their territory or parts of their territory to be excluded from commercial cultivation of GM plants. However, it is not clear yet, if the goal to motivate member states granting the authorization of new GMO will be achieved. In the future, it remains to be seen if new European Commission (EC) proposals based on European Food Safety Authority (EFSA) favorable risk assessment opinions for the authorization of GMO will be positively voted by member states in the respective expert committee (Eriksson et al. 2019).

In 2003, with the adoption of Regulation (EC) No 1829/2003, specific legislation on genetically modified food and feed was implemented covering risk assessment and labeling of products thereof (European Union 2003). Further specifications have been introduced with Regulation (EU) No 503/2013 providing detailed information on the molecular characterization; the agronomic/phenotypic and compositional analyses; the toxicological, allergenic and nutritional characterization; and finally the environmental consideration of the genetically modified food or feed (European Commission 2013). Applicants need to follow these requirements and submit a complete dossier to the centralized risk assessment process led by the EFSA located in Parma, Italy (Fig. 1). According to the EU law, a cross between two authorized GMO is resulting in a new so-called stacked GM event that needs a separate application including a new risk assessment. Consequently, the whole EU legal framework regarding GMO is considered to be process-based in contrast to a product-based approach as it is implemented by countries outside the EU such as Argentina, Canada, and the USA.

As a prerequisite before entering the EU market, “genetically modified food and feed must not (a) have adverse effects on human and animal health or the

**Fig. 1** Authorization procedure for GM food and feed. The final decision upon the authorization is made by the Standing Committee on Plants, Animals, Food and Feed (SC PAFF)

environment; (b) mislead the consumer; (c) differ from the food which it is intended to replace to such an extent that its normal consumption would be nutritionally disadvantageous for the consumer” (European Union 2003).

Consequently, applicants need to provide all studies necessary to support the safety of a GM food and feed intended for marketing in the EU. Such dossier can be submitted to a competent authority of any EU member state which is subsequently passing on the application to the EC for its consideration. The EC is requesting EFSA to carry out the risk assessment within a time frame of six months. However, the time needed to finalize the risk assessment is often much longer, on average about two years. This is due to the fact that for almost all applications, the EFSA is requesting clarifications on the dossier submitted or is requesting the applicant to provide new or additional studies needed to carry out a proper risk assessment. While the applicant is preparing the answers to EFSA questions, the clock for the application is stopped and will be restarted when EFSA receives the answer from the applicant. Using the EFSA opinion as a basis, the EC is preparing a draft proposal either for granting an authorization in case of a positive opinion or refusing the authorization in case the EFSA opinion is negative. The final decision is made in a member states expert committee comprising representatives from all member states. If no concluding decision is agreed upon (adopted or not), the EC is asking the so-called Appeal Committee, which also consists of representatives from all member states, to discuss again the draft decision. In most cases, member states were not able to vote either for or against the adoption of an EC draft decision. In these cases, the EC is adopting the draft decision, and the GM food and feed will have the right to enter the EU market. Up to the end of 2019, food and feed derived from 73 different GM plants are approved for the EU market. Those GM food and feed have to be labelled as “genetically modified” with the purpose to inform consumers about the respective ingredient. Since the implementation of legislation regarding GMO, new and more efficient methodologies for the specific modification of genomes have been developed. These methodologies are summarized under the term *New Breeding Techniques* (NBT). The most prominent example is called *Clustered regularly interspaced short palindromic repeats* (CRISPR) and CRISPR-associated (Cas) systems. Besides the introduction of foreign deoxyribonucleic acid (DNA) similar to what can be achieved by classic techniques of genetic modification, using different NBTs, it is possible to introduce a site-directed mutation resulting in an organism without foreign DNA but with a modification in an individual gene or in a regulatory DNA sequence. Many examples of such modified plants and animal species are described in the scientific literature.

In 2014, the European Court of Justice (ECJ) was asked by the French Council of State, if mutagenesis as it can be achieved using NBT leads to GMO and if such organisms fall under the regulations laid down by Directive 18/2001/EC. In July 2018, the ECJ came to the conclusion that organisms obtained by mutagenesis using techniques that alter the genetic material in a way that does not occur naturally are considered to be GMO. The only exemptions from this rule are “organisms obtained by means of techniques/methods of mutagenesis which have conventionally been used in a number of applications and have a long safety record” (ECJ 2018). The

ECJ further specifies in its argumentations that those techniques developed and applied before the respective Directive 2001/18/EC came into force are the application of chemical or physical mutagenic agents that have a long history of safe use (ECJ 2018). For further details on this issue, please refer to Broll et al. (2019). It needs to be mentioned that from a scientific point of view, it is impossible to distinguish whether a single mutation is derived from the application of a NBT, was conventionally introduced using chemical or physical mutagenic agents, or results from a spontaneous mutation as it happens naturally in genomes as part of evolution. However, the regulation requires the labeling of GM food and feed after it is authorized in order to provide to the consumer an informed choice (European Union 2003). Therefore, it is necessary to provide along with the application an unambiguous identification possibility to control correct labeling. “Classical” GMO containing new foreign DNA fragments can be detected applying routine diagnostic tools such as polymerase chain reaction (PCR) established in many laboratories around the EU.

---

## Assessment Procedure for Food and Feed from GM Plants

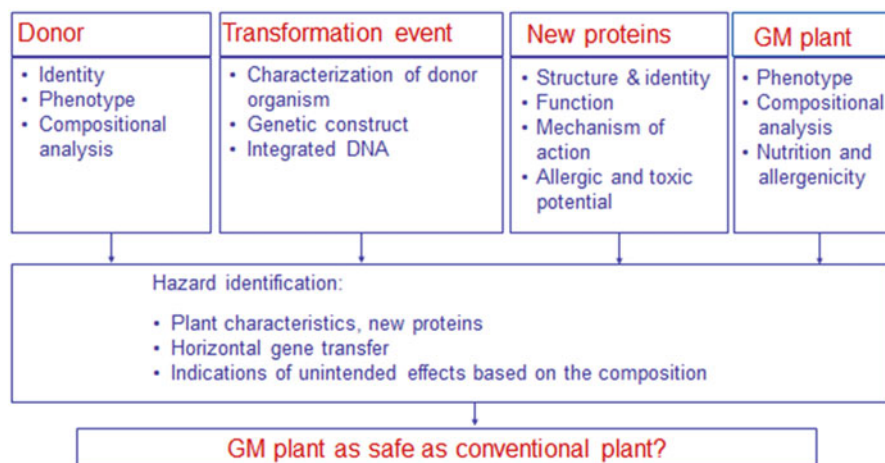

The safety assessment of a food product relative to an appropriate non-GM comparator considers at least three aspects: (i) intended and unintended effects; (ii) the identification of new hazards; and (iii) the identification of changes, which are relevant to human health including key nutrients. While the term “intended effects” covers basically the genetic modification introduced into the plant genome and the intended modifications in plant biochemistry resulting from that modification, unintended effects might happen due to genetic rearrangements during the process of genetic modification and subsequently result in metabolic perturbations.

As mentioned above, “substantial equivalence” is basically describing the characteristics of a GM plant compared to a conventional product. However, nowadays, it is considered more appropriate to use “comparative analysis” or “comparative approach” because these terms refer to the whole risk assessment process rather than focusing explicitly on the final outcome. The risk analysis comprises the agronomic and phenotypic characteristics, composition, toxicity, allergenicity, and nutritional values of the GM plant in comparison to a non-GM comparator genetically as close as possible. An overview over the assessment procedure for GM food and feed is given in Fig. 2.

## Hazard Identification and Characterization

### Molecular Characterization

An initial molecular characterization of all genetic modification events in GM plants is indispensable, regarding the identification of intentionally as well as unintentionally generated biologically relevant changes, especially those that might raise safety concerns. This includes – among other things – information on

**Fig. 2** Assessment procedure for GM food and feed

the introduced gene, the donor, data on consumption history of the newly expressed protein(s) by humans and animals, as well as information on potential similarities with proteins, which may induce/mediate adverse effects.

Consequently, for the assessment of the molecular characteristics of the GM plant in question, the nature and source of the genetic modification needs to be analyzed. In particular the organisms (donors) from which the genetic elements derived need to be characterized regarding their allergenic potential and toxicity. Therefore the applicant is requested to run specific bioinformatic analyses of the DNA fragments/genes and new proteins transferred to the genetically modified organism using databases including DNA sequences of potential allergens and toxins.

Using up-to-date databases, the resulting amino acid (AA) sequence, obtained from the DNA sequence of the insert and the regions spanning its junction sites, have to be analyzed regarding homologies to sequences of known allergens and toxins via adequate *in silico* methods (bioinformatics).

Besides characterization of the toxicological and potential allergenic potential, it is also important to analyze the potential for horizontal gene transfer from the GM plant either to humans, animals, or microorganisms. In cases intact DNA fragments are transferred horizontally, the risk remains that organism uptaking the foreign DNA, e.g., a gene responsible for an herbicide tolerance.

For the molecular characterization, a detailed description of the development of the GM plant needs to be provided by the applicant. This includes the description of the vector(s) used for the transformation process with all the individual elements and their function(s) (“mode of action”) in the organism(s) they are derived from and how they have been introduced into the genetic construct. The applicants are requested also to provide the whole DNA sequence of the actual insert into the host genome including the sequence of the integration site. Bioinformatic analyses have to be carried out at the DNA as well as AA sequence level. DNA-based *in silico*

approaches are used to identify possible genetic rearrangement of the inserted construct or at the genomic site of insertion. Furthermore, the DNA sequence is used to check for the absence of disruption of endogenous genes, as well as for the presence of putative novel open reading frames, which might have been formed as a consequence of the insertion of the foreign genetic material.

AA sequences from the GM plant are compared to sequences already described as potentially allergenic or toxic in well-known up-to-date databases. Relevant similarities will need to further detailed investigations, which might also include additional laboratory work or animal feeding studies in case a valid hypothesis for a concern can be formulated. In case the new GM plant expresses foreign proteins due to the genetic modification, analytical investigation of the respective proteins in the plant material is mandatory. Determination of certain ribonucleic acids and/or intermediary metabolites may be relevant if the genetic modification is intended to lead to the silencing of a certain gene or if the modulation of metabolic pathways in the GM plant is intended. Information regarding the stability of the new traits over at least five generations is also needed.

In case single events were crossed to obtain so-called stacked events, the risk assessment is focused on the potential interaction between the individual genes or gene products of the respective single events to identify any synergistic, antagonistic, or additive effect. Therefore, the structure of the inserts in the stacked event is compared to the structure in the single events. Moreover, comparative data on gene expression are required and will provide important information if any newly inserted gene is up- or downregulated due to potential interactions.

### **Comparative Analyses**

Thorough comparative analyses of the composition of genetically modified plants are conducted, as well as of their phenotypic and agronomic characteristics, which aim to identify differences between the GM plant and derived food and feed and its most appropriate non-GM comparator. In the best case, the parental line used for the genetic modification can be used as the non-GM comparator. For the comparative analysis, the application of two separate tests is needed: The test of difference is used to clarify, if the GM plant, besides the intended modification, is statistically significant different from its non-GM comparator. The test of equivalence is used to identify if the properties of the GM plant are considered within the range of natural variation, as is determined based on a set on non-GM reference varieties which do have a so-called history of safe use. For herbicide-tolerant GM plants, it is necessary to additionally examine whether treatment with the intended herbicide(s) affects the plant's characteristics.

Applicants should conduct at least eight field trials within the receiving environment in which the GM plants will be grown for commercial purposes. At each site, the GM plant either treated with the intended herbicide or with conventional herbicides only will be planted along with the non-GM comparator and additional non-GM plants suitable for the respective regions.

Regulation (EU) no 503/2013 provides further detailed guidance on the selection of comparators, field trials design, and the appropriate statistical methods in the

comparative analyses. Those parameters that are identified to show statistically significant differences between the GM plant and its non-GM comparator and lack of equivalence with non-GM plants taking into account natural variation need to be analyzed further in the safety assessment (see sections on “[Toxicological Assessment](#),” “[Assessment of Allergenicity](#),” and “[Nutritional Assessment](#)”).

For the identification of variations in the phenotype and agronomic characteristics, a comparison of parameters including yield, plant morphology, flowering time, plant height, growing degree days to maturity, kernel weight (maize or rape seed), duration of pollen viability, response to plant pathogens and insect pests, and sensitivity to abiotic stress are compared between the GM plant and its conventional counterpart taking into account also the natural variation determined by the additional non-GM plants growing in the same field trial. Regarding the analysis of the composition, an ‘OECD Working Group for the Safety of Novel Foods and Feeds’ has been established and is continuously elaborating so-called Consensus Documents on compositional considerations for new varieties of crops identifying key components that might be used for the analysis. Ranges of variation are also provided. The parameters comprise key components such as micronutrients (vitamins and minerals), macronutrients (fat, protein, carbohydrates), natural toxins, antinutrients, as well as allergens and other plant metabolites typical for the plant species. For oil-rich plants, a fatty acid profile needs to be determined, as well as an AA profile for plants used as an important source of protein. In case the introduced trait results in a modification of a metabolic pathway, the analysis of metabolites of the metabolic pathway(s) affected has to be carried out. The comparative analyses are only able to detect differences in known characteristics or parameters as described above. New non-targeted profiling techniques (the so-called “Omics” techniques such as genomics, transcriptomics, proteomics, and metabolomics) need to be further examined before their use in comparative analyses (EFSA 2011a). In particular, the reliability and comparability as part of a thorough validation process need additional efforts in order to generate results that can be reproduced independently.

### **Toxicological Assessment**

Targeted genetic manipulation of plants leads to changes in the composition of generated GM plants and consequently also of derived food and feed. Since this could potentially affect human and animal health, the toxicological impact of the genetic modification has to be evaluated. In this context, it is mandatory to consider all – intentionally as well as unintentionally – generated biologically relevant changes in GM plants. This includes the presence of new constituents, such as proteins, metabolic products or regulatory ribonucleic acids, as well as alterations of endogenous constituent levels beyond normal variation.

### **Newly Expressed Proteins**

Proteins are commonly present in most food and feed. They are of high nutritional relevance and only few of them induce adverse effects after oral uptake. Nevertheless, for GM plants and derived food and feed, an evaluation of the potential toxicity

and allergenicity of newly expressed proteins has to be done (European Commission 2013). In this context, the AA sequence, molecular weight, post-translational modifications (e.g., glycosylation), and biological function of the protein should be characterized. If the protein is enzymatically active, the substrate specificity and possible reaction products should also be considered. To investigate possible sequence similarities with known toxins or allergens, bioinformatic analyses using up-to-date databases should be performed. Depending on the results, further analyses may be needed to complete the risk assessment. Additionally, the evaluation should consider protein stability a) under conditions relevant for processing and storage of food and feed derived from the GM plant and b) against digestive enzymes, such as pepsin as well as potential interactions between the newly expressed proteins and other plant constituents (European Commission 2013).

Whether further toxicological studies are needed or not is determined by a) available information on a history of safe consumption and b) the results of the aforementioned evaluation. No additional toxicological analyses are necessary if a proper use and safe consumption as food and feed of the plant as well as of the newly expressed proteins is duly documented. However, if the available toxicological information is insufficient or raises safety concerns, specific toxicity testing of newly expressed proteins is needed (European Commission 2013). In this context, a repeated dose 28-day oral toxicity study using rodents should be conducted according to the OECD Guideline 407 (OECD 2008). Depending on the results of that study, further targeted analyses may be required. Moreover, if there is a possibility for synergistic or antagonistic interactions between two or more newly expressed proteins that may affect safety, additional studies with combined administration of these proteins should be performed. Due to the limited availability of plant-produced test material, the specific toxicity of newly expressed proteins is often assessed using a substitute material generated via microbial expression systems. In this context, it is necessary to provide adequate evidence for structural and functional equivalence of the microbial substitute compared the protein expressed in GM plants, including the AA sequence, molecular weight, post-translational modifications, immunological reactivity, and, if applicable, the enzymatic activity.

### **New Constituents Other than Proteins**

As mentioned before, genetic modifications, such as insertion of a specific DNA sequence in GM plants, can lead to the generation of new constituents other than proteins, such as metabolic products or regulatory ribonucleic acids. In this context, the generation of GM plants that are resistant to specific pathogens due to the synthesis of specific secondary metabolites is also an important scope. For all identified new constituents, a safety assessment has to be done, including an evaluation of their toxic potency, which may also require toxicological analyses. The specific testing strategy should be selected according to the EFSA guidance for food additive evaluations (EFSA 2012a), as described in ► Chap. 91, “Risk Assessment of Food Additives” Toxicological testing is not necessary if there is a documented history of safe use and consumption as food and feed of the respective constituent.

### **Altered Levels of Endogenous Constituents**

Genetic modification may affect levels of endogenous constituents beyond normal variation, such as modification of fatty acid patterns in seeds of maize or rape used for vegetable oil production. However, besides intended modifications, unintentionally generated changes of biological relevance may be associated with the genetic modification, which also need further evaluation. The safety of any altered content of food and feed constituents, such as macro- and micronutrients, natural toxins, or other plant metabolites, has to be adequately evaluated. Therefore a risk assessment is required, based the knowledge of the physiological function, the potential toxicity, and the anticipated changes in intake levels of the respective constituent. Depending on the results, further toxicological testing may be required to complete the risk assessment.

### **Assessment of Whole Food and/or Feed Derived from GM Plants**

According to Regulation (EU) No 503/2013, testing of the whole food and/or feed derived from GM plants is mandatory. This is also the case if the preceding molecular, compositional, or phenotypic evaluations lead to indications for potential occurrence of unintended effects. For GM plants containing stacked events, an assessment of whole food and/or feed is also required if the abovementioned evaluations indicate possible interactions between the events stacked within the plant. The assessment of whole food and/or feed usually includes a modified subchronic 90-day feeding study in rodents based on the principles of OECD guideline 408 (EFSA 2008; OECD 2018). This type of study is considered to offer sufficient specificity and sensitivity to characterize toxicologically relevant differences as well as nutritional deficiencies which may be induced by genetic modification, including intentionally as well as unintentionally generated effects (EFSA 2008). In 2011, EFSA published a document providing guidance regarding design, performance, and evaluation of such studies (EFSA 2011b). Among other things, this guidance document provides advice regarding the preparation of appropriate test diets, dose selection, animal housing and determination of sample size, statistical analysis, as well as the interpretation of study data. Depending on the results of the subchronic study, additional toxicological studies may be required, such as studies on reproductive effects or chronic toxicity. Further information regarding the possible occurrence of unintended effects may be obtained from additional studies with young rapidly growing animal species, such as broiler chickens as an animal model for non-ruminants (EFSA 2011a).

Over the past decade, the necessity and design of feeding trials in the context of GMO risk assessment has been subject of a lively discussion. The debate was further stimulated by the publication of a controversial study on potential chronic effects of a herbicide-tolerant GM maize, which was retracted after its initial publication and subsequently republished elsewhere (Séralini et al. 2014). In this context, the scientific value of animal feeding trials and the potential health risks of GM maize were intensively studied in three research projects (GRACE, G-TwYST, GMO90+) (Zeljenková et al. 2014, 2016; Coumoul et al. 2019; Steinberg et al. 2019). The general conclusions of these activities were that a) neither subchronic (90 days) nor

long-term feeding trials (0.5–2 years) revealed any health risks of the GM maize tested and b) the additional scientific value of feeding trials is very limited in the absence of a targeted hypothesis. However, after reviewing the respective information requirements in relation to the findings of the GRACE project and other scientific knowledge available by that time, as foreseen by Commission Implementing Regulation (EU) No 503/2013, the European Commission concluded to maintain the requirement for the mandatory submission of a 90-day feeding study (European Commission 2017).

### **Assessment of Allergenicity**

Food allergies, mainly associated with immunoglobulin E (IgE)-mediated processes, are often induced by proteins contained in these foods. Therefore, the allergic potential of all proteins newly expressed in GM plants has to be evaluated applying the weight-of-evidence approach (EFSA 2010a; Codex Alimentarius 2009). In order to minimize uncertainty regarding the allergenicity assessment for those newly expressed proteins, different aspects have to be considered to gain a cumulative body of evidence for its allergic potential.

First of all, it should be analyzed whether the source of the introduced protein-coding gene exhibits an allergenic potential. In order to identify potential IgE cross-reactivity, analyses regarding structural similarities and/or homologies of the AA sequence of the newly expressed protein(s) compared to known allergens have to be done. If there is a sequence identity of  $\geq 35\%$  in a frame of at least 80 AA, further examinations are mandatory. In this regard, additional *in vitro* tests determining the binding capacity of the protein of interest to specific IgEs present in serum of allergic patients (specific serum screening) are required, if structural and/or sequence homologies were indicated. The same applies in the case that the source of the introduced protein-encoding gene is considered allergenic (even if there is no sequence homology to known allergens). In this context, individual sera from well-characterized allergic subjects as well as adequate immunochemical methods (e.g., enzyme-linked immunosorbent assay (ELISA) or electrophoresis followed by immunoblotting) should be utilized.

Besides the abovementioned processes, potential triggering effects of the newly expressed protein(s) on non-IgE-mediated gluten-sensitive enteropathy (also called celiac disease – CD) should be evaluated if the protein-encoding gene was derived from cereal crops, such as wheat, rye, oat, or barley. However, other non-IgE-mediated enteropathies cannot be considered yet because their pathological mechanisms are insufficiently understood (EFSA 2017). In principle, the assessment of the ability of newly expressed proteins to trigger CD follows the same strategy as the allergenicity assessment. It starts with searching of the available information regarding the source of the protein and on human exposure to the protein. If the available knowledge on the protein is insufficient to support its safety, additional considerations and *in silico* approaches should be applied (e.g., sequence comparisons with known CD peptides and motif searches). Furthermore, additional *in vitro* tests can be performed (e.g., human leukocyte antigen locus DQ (HLA-DQ)- peptide binding assays or testing with T-cell clones derived from CD patients).

Since stability to enzymatic proteolytic digestion is regarded as a characteristic of allergenic proteins, the pepsin resistance test carried out under standardized conditions is still considered as relevant additional information (even though there is no absolute correlation). However, a refined *in vitro* digestion test is yet under experimental validation and will replace the simple pepsin resistance test in the near future. This elaborated test includes additional conditions more representative of the gastric environment (e.g., regarding the pepsin level and pH), together with an intestinal digestion phase (EFSA 2017). Cell-based *in vitro* assays as well as *in vivo* tests utilizing animal models may also provide further relevant data. However, those tests have not yet been validated for use in the assessment of allergenicity.

Another possible unintended effect of a genetic modification may arise from insertion of the protein-coding gene in recipients, which are known to be allergenic, such as soybeans (*Glycine max*). It cannot be excluded that this could lead to elevated levels of naturally occurring endogenous allergens, consequently increasing the allergenicity of the whole food. Therefore, it is mandatory to compare the levels of relevant naturally occurring endogenous allergens of the GM plant with those of the non-GM comparator. In this context, proteomics or immunochemical analyses (e.g., ELISA utilizing sera from allergic subjects) are considered as appropriate analytical methods. According to Regulation (EU) 503/2013, the levels of allergens should be analyzed in the same way as any other complex compounds in the comparative assessment procedure. If the level of a specific allergen in a GM plant is significantly higher than the corresponding level in the appropriate non-GM comparator(s) and is not within the estimated range of natural variation, the biological relevance in relation to human health should be assessed in the light of its anticipated intake in the European population (EFSA 2017).

In order to confirm the absence of an elevated allergenic risk after market launch, post-market monitoring (PMM) may be required on a case-by-case basis. However, so far, no specific concern was formulated by EFSA in any scientific opinions on GM plants (EFSA GMO Opinions up to March 2020) requiring a follow-up by PMM.

## Nutritional Assessment

Different aspects regarding the composition of the food have to be considered in the nutritional assessment. This includes the levels of nutrients and antinutrients as well as the bioavailability and biological efficacy of nutrients. Additionally, the anticipated dietary intake of the food as well as resulting nutritional impact has to be taken into account. If the comparative compositional analysis (see section on “[Comparative Analyses](#)”) revealed no biologically relevant differences between the GM plant and the non-GM comparator, except for the introduced trait(s), the exposure assessment focuses on the newly expressed proteins and no further studies regarding nutritional equivalence are needed. In this case the dietary exposure estimations should cover average and high consumers across all the different age classes and special population groups and identify and consider particular consumer groups with expected higher exposure (EFSA 2019). Consumption data and guidance for the exposure assessment are provided by EFSA with the Comprehensive European Food

Consumption database covering the national food consumption surveys from 21 EU member states (EFSA 2015).

If compositional characteristics are different, an evaluation of their nutritional biological relevance is required. Sometimes, it may be sufficient to base the nutritional assessment on an estimation of the expected intake level changes regarding the relevant nutrient(s), which may result from replacement of the respective traditional food product. This can be done taking into account current dietary recommendations and nutritional reference values. In other cases, specifically designed animal studies may be needed to evaluate the biological relevance, e.g., when altered bioavailability raises nutritional concerns. The first GM plant with an intended change in nutrient levels assessed by EFSA was a soybean variety exhibiting a modified fatty acid profile in seeds. An increased content of oleic acid (C18:1) as well as reduced levels of linoleic acid (C18:2),  $\alpha$ -linolenic acid (C18:3), and palmitic acid (C16:0) were the main differences compared to commercial non-GM varieties. The nutritional assessment for this GM plant compared to non-GM varieties focused on soybean oil, the main product for human consumption, and was based on consumption data from the UK. In this context, differences regarding the intake of relevant fatty acids were determined considering different scenarios. Among others, this included a scenario for total replacement of conventional soybean oil by oil derived from the GM variety, which reflects a theoretical extreme case, possibly leading to an overestimation of the actual intake. As anticipated, the replacement would lead to an increased oleic acid intake and to a decreased intake of palmitic acid, which is in line with current dietary recommendations (EFSA 2010b). Moreover, no nutritional concerns were identified regarding the expected decreased intake of  $\alpha$ -linolenic acid and linoleic acid (EFSA 2012b).

## Exposure Assessment

In addition to hazard-related information, the risk assessment according to Regulation (EU) No 503/2013 requires a thorough assessment of the anticipated extent of use and intake of the genetically modified food and feed. As already detailed in the context of the nutritional assessment, the exposure assessment should be based on the expected use pattern of the GM plant, and the expected intake should be estimated from representative consumption data for products obtained from the respective conventional crops (European Commission 2013). Moreover, the expected intake of new constituents (e.g., proteins) and endogenous constituents with altered levels of the GM plant should be estimated, taking into account the influences of processing, storage, and expected treatment of the food and feed (European Commission 2013).

## Risk Characterization

Regulation (EU) No 503/2013 requires a comprehensive risk characterization which considers all available information from hazard identification, hazard characterization, and exposure assessment. Among other things, the risk characterization aims to

ensure that (a) the GM food has no adverse effects on human health, (b) replacement of conventional food by GM food is not nutritionally disadvantageous for the consumer, (c) the GM food does not mislead the consumer, and (d) the GM feed does not indirectly harm or mislead the consumer by altering the animal products (European Commission 2013). In this context, the probability and severity of adverse health effects and the magnitude of uncertainties in the risk assessment should also be taken into account.

## Abstract

The ongoing globalization, together with a continuing development of new technologies, has led to the emergence of novel foods seeking to enter the markets. These include exotic food from distant countries, biotechnologically gained products, edible microorganisms, or components containing new types of molecules or nanosized food components.

Safety regulations have been developed by many countries with the major aim to allow only safe novel food on the market.

In order to clearly exclude any known risks that may be associated with various nutrients and their ingredients or residues, and to avoid unknown risks that may potentially accompany novel technologies, the regulations became increasingly differentiated and complex.

Department “Food Safety”, German Federal Institute for Risk Assessment (BfR), Berlin, Germany  
e-mail: [julika.lietzow@bfr.bund.de](mailto:julika.lietzow@bfr.bund.de); [claudia.luckert@bfr.bund.de](mailto:claudia.luckert@bfr.bund.de); [bernd.schaefer@bfr.bund.de](mailto:bernd.schaefer@bfr.bund.de)

The present contribution briefly introduces regulations in different jurisdictions around the world, and analyzes the new European Novel Food Regulation (EU) 2015/2283 in greater detail.

It elucidates the historic evolution of the European regulation by comparing with the previous Regulation (EC) No 258/97 and presents central new aspects aiming of the new regulation to enhance the efficiency of the authorization process and reduce unnecessary trade barriers, while ensuring food safety. Along with the authorization process, the chapter elaborates the risk assessment process and, amongst others, the requirements concerning the assessment of compositional, toxicological, and allergological safety. Beyond this, the simplified notification procedure for traditional foods from third countries with a safe history of use is presented, including the respective requirements for the safety assessment.

## Introduction

In general, food law does not impose any authorization or licensing requirements for the production, import, or marketing of food which is commonly consumed by the resident population. With respect to particular food, which are “new foods” on the market, great differences between the regulatory systems across the countries worldwide exist.

For example, “new foods” on the market in the **USA** are not specifically defined and do not require a premarket approval by governmental authorities. Basically, food business operators who want to bring “new foods” on the US market have a legal obligation to ensure that the foods they offer to consumers are safe under the conditions of use and in compliance with applicable legal requirements. In this so-called GRAS (generally recognized as safe) self-affirmation, the food business operator has the ability to self-affirm the safety of the Novel Food. If a food or ingredient is not very customary, its GRAS status can be affirmed by an independent panel of recognized experts. The pivotal studies used in the risk assessment must be generally available, e.g., through publication in the scientific literature. If the expert panel concludes the product is GRAS, the manufacturer may or may not consult the US Food and Drug Administration (FDA). Besides GRAS self-affirmation, the food business operator can voluntarily notify the FDA of a conclusion that a substance is GRAS under the conditions of its intended use. In contrast, if a substance is used as food additive it needs approval by the FDA before retailing (details on FDA webpage (FDA (U.S. Food and Drug Administration) [2020](#))).

Novel foods in **Japan** are likewise not specifically defined. No premarket assessment and authorization is required for “new” food ingredients that are used as food, but compliance with the Food Sanitation Act has to be warranted. If the “new” food ingredient is a “new” food additive, a premarket assessment and authorization by the Ministry of Health, Labour, and Welfare (MHLW) is required (details on MHLW webpage (MHLW (Ministry of Health, Labour and Welfare) 2020)).

Comparable to the European Union, novel foods and novel food ingredients in **Australia and New Zealand** are specifically defined and regulated under the Food Standards Code (Standard 1.5.1). Novel foods are nontraditional foods that require premarket safety assessment by the statutory authority Food Standards Australia New Zealand (FSANZ) in order to determine their safety before they are offered to consumers. If the Novel Food passes this assessment, it is listed in the Standard and can be sold as food or used as food ingredient in Australia and New Zealand, as long as it complies with any specified conditions (details on FSANZ webpage (FSANZ (Food Standards Australia New Zealand) 2020)).

Novel foods in **Canada** are regulated under Division 28 of the Food and Drug Regulations (FDR) setting out the definition of a novel food, including foods derived from genetically modified organisms (GMOs) as well as premarket notification requirements. In the approval process the food business operator who wants to sell or advertise a novel food has to notify Health Canada, in particular the Food Directorate, and submit information regarding the product in question so that an assessment can be made by Health Canada with respect to the product’s safety prior to sale (details on webpage of Government of Canada (2020)).

In the **European Union**, it is basically in the responsibility of the food business operator to ensure that food is safe when placed on the market and the requirements of food law based on Regulation (EC) No 178/2002 (2002) are met. With respect to particular food, for instance food additives, foods from genetically modified organisms (GMO), or new types of food, food ingredients or ways of producing food, specific regulations arose from the circumstances implementing premarket approval systems in the European Union. Contrary to food defined by Regulation (EC) No 178/2002, these particular foods are not considered as a priori safe. Therefore, authorization accompanied by assessment of the safety risk arising from consumption of those foods is regarded as mandatory to achieve a high level of protection of human health and of consumers.

Hence, the regulation of novel foods and novel food ingredients evolved among others in response to applications of new technologies in the food sector (e.g., use of genetic modification in food) or exotic foods which may be traditional with a long history of use outside the EU as well as the continuous search for new sources of nutrients. On 15 May 1997, Regulation (EC) No 258/97 (1997), known as Novel Food Regulation, came into force to harmonize national procedures and to introduce a statutory approval system for Novel Foods across the European Union. The stated objective of the regulation was to ensure food safety and protection of human health related to new products or ingredients

intended for human consumption on the European market. To enable integration of recent developments in Union law and technological progress and to simplify the current authorization procedures, the Union's rules on Novel Foods initially established by Regulation (EC) No 258/97 of the European Parliament and of the Council and by Commission Regulation (EC) No 1852/2001 (2001) were replaced by the new Novel Food Regulation (EU) 2015/2283 (2015).

---

## Regulation of Novel Foods in the European Union

### Previous History: Situation Before 1 January 2018

Before 1 January 2018, novel foods were recently governed by the Regulation (EC) No 258/97 establishing a mandatory, decentralized premarket authorization system. The definition of Novel Food was based on two cumulative criteria that had to be fulfilled. The first defining criterion was that the food or ingredient was not used for human consumption to a significant degree within the European Union before the introduction of the legislation on 15 May 1997. The second defining criterion implied that the food had to fall within one of the defined food categories explicitly mentioned in Article 1 of Regulation (EC) No 258/97 (latest consolidated version from 07.08.2009).

Prior to placing a food or food ingredient falling under this regulation on the Community market an application in accordance with Commission Recommendation 97/618/EC (1997) concerning the scientific information and the safety assessment report was required. The risk assessment process involved an initial assessment by a Member State and if no objections were raised and no additional assessment was required, the novel food could be placed onto the market. In case of reasoned objections by another Member State or the European Commission to the initial assessment, the EC's Scientific Committee on Food (SCF)<sup>1</sup> or the European Food Safety Authority (EFSA) was consulted.

Based on the positive or negative opinion of this expert panel, an authorization decision had to be taken by the European Commission assisted by the Standing Committee on the Food Chain and Animal Health (SCFCAH) (previously known as the Standing Committee for Foodstuffs) consisting of Member States' representatives. According to experience, duration of the authorization process could take several years (e.g., decision on Chia seeds – 6 years (Commission Decision 2009/827/EC 2009); decision on Baobab dried fruit pulp – 2 years (Commission Decision 2008/575/EC 2008); and Decision on synthetic Zeaxanthin – 9 years (Commission Implementing Decision 2013/49/EU 2013)).

If novel foods or novel food ingredients were considered to be “substantially equivalent” to an existing food or food ingredient already available on the European market with regard to their composition, nutritional value, metabolism, intended use, and the level of undesirable substances, only a notification to the European Commission was required.

## **The New Novel Food Regulation (EU) 2015/2283: What Is Actually New?**

Following Article 14 of the Regulation (EC) No 258/97, a revision was initiated after evaluation of the regulation which discussed issues that had emerged due to the practical implementation. Stakeholder consultations on a European Commission discussion document and a subsequent evaluation emphasized the need for an update and revision of the former provisions for Novel Food (EC (European Commission) 2008). To take into account the scientific and technological developments since 1997, it was necessary to specify and update the existing Novel Food categories, enhance the efficiency of the authorization process, and reduce unnecessary trade barriers, while ensuring food safety.

A final draft agreed upon by the EU institutions resulted in the preparation of the new Novel Food Regulation (EU) 2015/2283, which entered into force on 1 January 2018. The new Regulation centralized the authorization procedure at EU level with deadlines imposed on certain stages and the immediate involvement of EFSA in the risk assessment process. The applicant-based authorization was replaced by a generic authorization to avoid duplication of work and an Union list comprising all authorized novel foods was established. Furthermore, the definition and categories of Novel Foods were revised and a procedure for the determination of a Novel Food status was implemented. To simplify the authorization of traditional foods safely used in third countries a faster and structured notification process was introduced. For the sake of clarity and to facilitate understanding, all legislation and guidance documents concerning the new Novel Food Regulation (EU) 2015/2283 are listed in Table 1.

### **Revision of the Novel Food Categories**

The Article 3 (2a) of the Regulation (EU) 2015/2283 contains the fundamental definition of Novel Food meaning “[...] any food that was not used for human consumption to a significant degree within the Union before 15 May 1997, irrespective of the dates of accession of Member States to the Union, and that falls under at least one of the following categories.” The 15 May 1997 refers to the date of entry into force of the former Novel Food Regulation and was established in the new Novel Food Regulation to ensure continuity between both Regulations. The novel food categories covered by Regulation (EU) 2015/2283 comprise now ten categories of which four already existing categories have been revised, clarified, and updated, and whereas six further categories have been newly added (Table 2).

As under Regulation (EC) No 258/97, food enzymes (falling within the scope of Regulation (EC) No 1332/2008 (2008)), food additives (falling within the scope of Regulation (EC) No 1333/2008 (2008)), food flavorings (falling within the scope of Regulation (EC) No 1334/2008 (2008)), and extraction solvents used or intended to be used in the production of foodstuffs or food ingredients are excluded. However, some foods may be considered as novel foods if employed for a different intended use or manufactured in a different way. One example is Lycopene which is used

**Table 1** Overview over legislation and guidance documents related to the Novel Food Regulation (EU) 2015/2283

Regulation (EU) 2015/2283	Regulation (EC) No 258/97 (2009)*
i Food with a new or intentionally modified molecular structure, where that <b>structure was not used as, or in, a food</b> within the Union before 15 May 1997	Foods and food ingredients with a new or intentionally <b>modified primary molecular structure</b>
ii Food <b>consisting of, isolated from or produced</b> from microorganisms, fungi or algae	Foods and food ingredients <b>consisting of or isolated from microorganisms, fungi or algae</b>
iii <b>Food consisting of, isolated from or produced from material of mineral origin</b>	
iv Food <b>consisting of, isolated from or produced from plants or their parts, except when the food has a history of safe food use within the Union</b> and is consisting of, isolated from or produced from a plant or a variety of the same species obtained by: <ul style="list-style-type: none"> <li>— traditional propagating practices which have been used for food production within the Union before 15 May 1997; or</li> <li>— non-traditional propagating practices which have not been used for food production within the Union before 15 May 1997, where those practices do not give rise to significant changes in the composition or structure of the food affecting its nutritional value, metabolism or level of undesirable substances</li> </ul>	Foods and food ingredients <b>consisting of or isolated from plants and food ingredients isolated from animals</b> , except for foods and food ingredients obtained by traditional propagating or breeding practices and having a history of safe food use
v Food <b>consisting of, isolated from or produced from animals or their parts</b> , except for animals obtained by traditional breeding practices which have been used for food production within the Union before 15 May 1997 and the food from those animals has a history of safe food use within the Union	
vi <b>Food consisting of, isolated from or produced from cell culture or tissue culture</b> derived from animals, plants, micro-organisms, fungi or algae	
vii Food <b>resulting from a production process not used for food production within the Union</b> before 15 May 1997, which gives rise to significant changes in the composition or structure of a food, affecting its nutritional value, metabolism or level of undesirable substances	Foods and food ingredients to which has been applied a <b>production process not currently used</b> , where that process gives rise to significant changes in the composition or structure of the foods or food ingredients which affect their nutritional value, metabolism or level of undesirable substances.
viii Food consisting of <b>engineered nanomaterials</b> as defined in point (f) of this paragraph	
ix <b>Vitamins, minerals and other substances</b> used in accordance with Directive 2002/46/EC, Regulation (EC) No 1925/2006 or Regulation (EU) No 609/2013, where: <ul style="list-style-type: none"> <li>— a <b>production process not used for food production</b> within the Union before 15 May 1997 has been applied as referred to in point (a) (vii) of this paragraph; or</li> <li>— they <b>contain or consist of engineered nanomaterials</b> as defined in point (f) of this paragraph</li> </ul>	
x Food used exclusively in food supplements within the Union before 15 May 1997, where it is <b>intended to be used in foods other than food supplements</b> as defined in point (a) of Article 2 of Directive 2002/46/EC	

for technical purposes as food additive (E160d) and falls within the scope of Regulation (EC) No 1333/2008, whereas any other food uses of this product have to be authorized pursuant to the Novel Food Regulation (e.g., purified lycopene from tomatoes [*Lycopersicon esculantum* L.]).

It is worth noting that two more categories (foods and food ingredients containing or consisting of genetically modified organisms within the meaning of Directive 90/220/EEC; foods and food ingredients produced from, but not containing, genetically modified organisms) existed in the original version of Regulation (EC) No 258/97 (version 14.2.97) but were deleted due to an amendment by Regulation (EC) No 1829/2003 of the European Parliament and of the Council of 22 September 2003 on genetically modified food and feed. Thus food products containing, consisting, or produced from genetically modified organisms (GMOs) do not anymore fall within the scope of the Novel Food Regulation but are regulated under the separate, specific Regulation (EU) No 1829/2003 (2003) on genetically modified food and feed since 2003.

Furthermore, foods consisting of/isolated from/produced from plants or their parts are now listed separately from food consisting of/isolated from/produced from animals or their parts. While Regulation (EC) No 258/97 comprised a legal uncertainty for whole insects as the applicable food category was defined as “food ingredients isolated from animals,” the situation regarding the authorization of insect-based products, whole insects, parts of insects, or food ingredients isolated from insects as Novel Foods, if no history of consumption is approved, is now clarified. Consequently, a number of applications under the new Novel Food Regulation are now dedicated to insects, e.g., the house cricket (*Acheta domesticus*), the larvae of the lesser mealworm (*Alphitobius diaperinus*), the larvae of the black soldier fly (*Hermetia illucens*), the male pupae of the honey bee (*Apis mellifera*), the tropical house cricket (*Gryllodes sigillatus*), the migratory locust (*Locusta migratoria*), or the larvae of the mealworm beetle (*Tenebrio molitor*).

Considering the expansion of nanotechnologies used in the food industry, food containing or consisting of engineered nanomaterials was also included as Novel Food along with a definition of engineered nanomaterial as “intentionally produced material that has one or more dimensions of the order of 100 nm or less or that is composed of discrete functional parts.”

### **Determination of Novel Food Status**

Article 4 of the Novel Food Regulation (EU) 2015/2283 lays down basic principles on the procedure for the determination of the novel food status and requires food business operators to verify whether the food which they intend to place on the Union market falls within the scope of that Regulation or not.

Accordingly, the Novel Food catalog may serve as an indicative source of information on the history of use of the product. This nonexhaustive list maintained by the European Commission is based on information provided by the Member States and gives an orientation on whether a product of animal and plant origin or other substances will need an authorization under the Novel Food Regulation. Nevertheless, the food business operator should take into account specific national

regulations that may restrict the use of the product as food (e.g., considered as medicine), even in the case products have a history of use for human consumption in some Member States.

In case of uncertainties regarding the Novel Food status, the food business operator can consult the Member State, where the food is first intended to be marketed. This recipient Member State then determines, based on necessary information provided by the food business operator, whether or not a food was used for human consumption to a significant degree within the Union before 15 May 1997. In order to determine the Novel Food status the recipient Member state may also consult other Member States and the European Commission. Within 4 months after verifying the validity of the consultation request the recipient Member State concludes on the Novel Food status of the food and the outcome is made publicly available by the European Commission on the Commission's website.

More detailed guidance on the consultation process can be found in Commission Implementing Regulation (EU) 2018/456 (2018). In addition to determining the Novel Food status according to Article 4 of Regulation (EU) 2015/2283, Article 5 authorizes the European Commission to decide, on its own initiative or upon a request by a Member State, on the novel food status of a particular food.

A key element in the determination of a novel food status is the history of human consumption to a significant degree within the Union before 15 May 1997. To address the sometimes difficult question of "human consumption to a significant degree" an information and guidance document is available on the European Commission's webpage (EC (European Commission) 2020) laying down specific criteria that should be considered. In addition, the Novel Food Regulation (EU) 2015/2283 clarifies that the history of consumption of a food as food supplement before 15 May 1997 is not relevant for the evaluation of whether a food was used for human consumption to a significant degree within the Union before 15 May 1997. However, foods that were exclusively used as food supplements before 15 May 1997 are not considered to be novel if they are intended to be used as or in food supplements after this date.

More than 30 consultation requests under Article 4 have already been decided until now (March 2020), including among others an application for consultation to determine the Novel Food status of berries of *Aristotelia chilensis* (Maqui berries). Here, it was decided by the German Federal Office for Consumer Protection and Food Safety that Maqui berries are considered to be not novel for use as or in food supplements due to an authorization of Maqui berries as or in food supplements in Italy. Apart from that, Maqui berries have a history of being used for the coloring of wine in the EU. However, this was not approved to constitute a "consumption to a significant degree." As there were no evidences for the use of Maqui berries for nutritional purposes, it was decided that they have to be considered as Novel Food when used for food uses other than food supplements.

### **Traditional Foods from Third Countries**

A further substantial specification was introduced by defining specific rules for novel foods with a history of safe food use in a third country. In order to be acknowledged as a "traditional food from a third country" the safety of the food

has to be confirmed with compositional data along with a history of safe consumption by a significant number of people in at least one-third country for at least 25 years. Furthermore, the food has to be derived from primary production as defined in Regulation (EC) No 178/2002. For example, a juice derived from an exotic fruit not consumed in the European Union before 15 May 1997, but having been part of a regular diet in a third country, would be considered as a “traditional food.” If this is the case, a faster and simplified notification procedure is set out.

However, this applies only to novel foods belonging to the categories “micro-organisms, fungi, or algae,” “animals or their parts,” “plants or their parts,” and “cell or tissue cultures derived from animals, plants, microorganisms, fungi, or algae” (for detailed description see food categories ii, iv, v, and vi in Table 2). The Articles 14 to 20 of the Regulation (EU) 2015/2283 lay down the specific rules and requirements for this category of Novel Foods (see section “[Notification and Application for Authorization of Traditional Foods from Third Countries](#)”).

Up to now (March 2020), nine notifications of traditional foods from countries outside the EU have been submitted. All of these notifications concern foods derived from plants. Three of the notified foods have already been authorized as traditional foods from third countries: berries of *Lonicera caerulea* L. (Commission Implementing Regulation (EU) 2018/1991 [1991](#)), decorticated grains of *Digitaria exilis* (Commission Implementing Regulation (EU) 2018/2016 [2018](#)), and syrup from *Sorghum bicolor* (L.) Moench (Commission Implementing Regulation (EU) 2018/2017 [2018](#)). Additionally, two notifications concerning the same traditional food, namely fruit pulp from the cocoa plant *Theobroma cacao* L. (Commission Implementing Regulation (EU) 2020/206 [2020](#)), have recently been authorized as well. Regarding the traditional foods leaf powder from *Moringa stenopetala* (EFSA (European Food Safety Authority) [2019a](#)) and powder or juice concentrate of berries of *Aristotelia chilensis* (Maqui berries) (EFSA (European Food Safety Authority) [2019b](#)), EFSA has raised safety objections to the placing on the market within the EU. In contrast, no safety objections were submitted by EFSA concerning an infusion from coffee leaves (*Coffea arabica* L. and/or *Coffea canephora* Pierre ex A. Froehner) as a traditional food from a third country (EFSA (European Food Safety Authority) [2020](#)). For roasted sacha inchi seeds the notification process is still ongoing and the safety assessment by the EFSA is not yet published.

### **Union List of Generic Authorized Novel Foods**

Once a food is authorized as a novel food, or a traditional food from a third country is successfully notified, it is included in the Union list of Novel Foods authorized to be placed on the market within the Union. According to Article 7 of the Novel Food Regulation (EU) 2015/2283, the European Commission only authorizes and includes a novel food in the Union list if it is in accordance with the following conditions:

- (a) The food does not, on the basis of the scientific evidence available, pose a safety risk to human health.
- (b) The food's intended use does not mislead the consumer, especially when the food is intended to replace another food and there is a significant change in the nutritional value.
- (c) Where the food is intended to replace another food, it does not differ from that food in such a way that its normal consumption would be nutritionally disadvantageous for the consumer.

The Union list contains the name of the authorized novel food, the specification, the specified conditions of use regarding food category and maximum levels, additional specific labeling requirements, and other requirements like post-market monitoring requirements which may be imposed by the European Commission for food safety reasons.

In addition to the authorized Novel Foods under Regulation (EU) 2015/2283, the Union list also contains all Novel Foods authorized and notified under the former Novel Food Regulation (EC) No 258/97. These novel foods were included in the Union list established through Implementing Regulation (EU) 2017/2470 (2017). On 23 July 2018, the Union list was corrected by replacing the Annex to Implementing Regulation (EU) 2017/2470 with the Annex to Implementing Regulation (EU) 2018/1023 (2018) due to the inclusion of newly authorized novel foods and the correction of a number of errors and omissions regarding existing entries of already authorized novel foods.

Once a novel food is included in the Union list, the authorization is generic meaning any food business operator can directly market their products following the conditions and specifications set out in Implementing Regulation (EU) 2018/1023. If that is not the case, food business operators may request a so-called extension of a Novel Food authorization, and therefore have to submit a new application to the European Commission for adding, removing, or changing the conditions, specifications, or requirements set out in the Union list.

The Union list will be updated regularly by the European Commission when a novel food is added or removed from the list, or when the conditions of commercialization have changed.

The concept of generic authorizations replaces the previously valid principle of the former Regulation (EC) No 258/97 that foods being substantially equivalent to existing foods were not subject to authorization. To protect the applicant's investment and to promote research, development, and innovation within the agri-food sector, applicants that submit newly developed scientific evidence and proprietary data can request data protection for 5 years. Subsequent applicants cannot benefit from the application during this period unless they obtain authorization for the novel food without reference to the protected data or with the agreement of the initial applicant. Where data protection is granted, the Union list specifies it, and indicates that during the period of data protection the novel food is authorized for placing on the market within the Union only by the initial applicant.

## Transitional Measures

Foods which were lawfully placed on the market prior to 1 January 2018 and did not fall within the scope of the former Regulation (EC) No 258/97, but are subject to the new Novel Food Regulation (EU) 2015/2283, are covered by transitional provisions laid down in Article 35 of this Regulation. Provided that an application for authorization of a Novel Food or a notification of a traditional food from a third country has been submitted by 1 January 2019, these foods can continue to be placed on the market until an outcome of the authorization procedure has been decided. In addition, the transitional measures also regulate that applications for placing a novel food on the market under the former Novel Food Regulation (EC) No 258/97 not finally decided by 1 January 2018 are treated as applications under the new Regulation (EU) 2015/2283.

---

## Authorization Procedure in the EU

Food business operators, who intend to introduce a “new food” into the EU market, have to determine in advance whether their food is subject to the Novel Food Regulation (EU) 2015/2283. This means they have to check if the food falls under the definition of Novel Food and into one of the specified novel food categories as presented in section “[Revision of the Novel Food Categories.](#)” The novel food catalog (section “[Determination of Novel Food Status](#)”) may serve as an orientation in addressing the question of whether a food has to be regarded as a novel food or not. Food business operators may also submit a formal request to a Member State according to Article 4 to clarify the status of the food. If the “new food” is indeed regarded as a novel food, it will need an authorization under Regulation (EU) 2015/2283, either as an authorization of a novel food or as a notification of a traditional food from a third country.

## Authorization Procedure for Novel Foods

To ensure an EU-wide harmonized authorization and safety assessment of novel foods the new Novel Food Regulation introduced a centralized authorization procedure managed by the European Commission. The different steps of the authorization procedure are laid down in chapter III of Regulation (EU) 2015/2283 in Articles 10 to 13.

Before placing a novel food on the market within the European Union for the first time, the applicant, as defined in Article 3 (2a) of Regulation (EU) 2015/2283, has to directly submit an application for authorization to the European Commission in line with the requirements of Article 10 of the Regulation using the “e-submission”-system (Fig. 1). The application dossier should be in accordance with Commission Implementing Regulation (EU) 2017/2469 (2017) which lays down specific rules for the implementation regarding the administrative and scientific requirements for applications as well as the transitional measures.

**Fig. 1** Authorization procedure according to Novel Food Regulation (EU) 2015/2282. \* Verification of validity + possible consultation with EFSA; \*\* Time period may be extended when EFSA requests additional information from the applicant; \*\*\* Standing Committee on Plants, Animals, Food and Feed

Having received the application, the European Commission verifies the validity of the application dossier. If the European Commission requests the opinion of the European Food Safety Authority (EFSA) it forwards the valid application without delay and within 1 month of verifying the validity of the application to EFSA which carries out a scientific assessment of the safety of the proposed novel food within 9 months from the date of receipt of the valid application. If EFSA requests additional information from the applicant, the 9-month period may be extended. After EFSA has forwarded its opinion to the European Commission, to the Member States and, where applicable, to the applicant, the Commission submits a draft implementing act for the authorization of the novel food and updating of the Union list to the Standing Committee on Plants, Animals, Food and Feed (PAFF Committee), composed of

representatives of the Member States, within 7 months from the date of the publication of the EFSA opinion. In case the European Commission has not requested an opinion from EFSA, the 7-month period starts from the date on which a valid application is received by the Commission. Once the implementing act receives a positive response from the PAFF Committee and is adopted and published by the European Commission, the authorized novel food can be placed on the market within the European Union and the Union list is updated (see section “[Union List of Generic Authorized Novel Foods](#)”).

### **Risk Assessment Process**

The risk assessment of novel foods aims to ensure that the requested Novel Food does not pose a safety risk to human health. In order to enable a comprehensive risk assessment of the novel food in question, the applicant should, according to Article 10 of the Novel Food Regulation (EU) 2015/2283, provide information on the name and description of the novel food, the production processes, the composition of the novel food, scientific evidence demonstrating that the novel food does not pose a safety risk to human health, the analysis methods (where appropriate), and a proposal for the conditions of intended use as well as a proposal for specific labeling requirements which do not mislead the consumer.

Upon request by the European Commission, the EFSA assesses the safety of the novel food under the proposed conditions of use. EFSA carries out its scientific risk assessment based on the dossier provided by the applicant and considers the following aspects (see EFSA guidance document 2016 (EFSA NDA Panel (European Food Safety Authority Panel on Dietetic Products, Nutrition and Allergies) [2016a](#))):

1. Whether the novel food concerned is as safe as food from a comparable food category already existing on the market within the Union.
2. Whether the composition of the novel food and the conditions of its use do not pose a safety risk to human health in the Union.
3. A novel food, which is intended to replace another food, does not differ from that food in such a way that its normal consumption would be nutritionally disadvantageous for the consumer.

EFSA has developed two guidance documents (EFSA NDA Panel (European Food Safety Authority Panel on Dietetic Products, Nutrition and Allergies) [2016a](#); EFSA (European Food Safety Authority) [2018a](#)) which provide scientific information and data needed for the safety assessment of novel foods and present a common format for the organization of the requested data. The guidance documents are intended to support applicants in the preparation of comprehensive applications and to facilitate an effective and consistent evaluation by EFSA in order to ensure a harmonized scientific assessment of novel foods. Apart from administrative data the application should contain technical and scientific data specific to the novel food which are of relevance for the risk assessment and provided in more detail in the following sections.

### **Introduction and Identity of the Novel Food**

The novel food should be briefly introduced by describing the source, the principle of the production process, typical compositional features as well as the purpose and the intended use. For novel foods referring to chemical substances, polymers, or food consisting of, isolated from, or produced from material of mineral origin information on the identity of the novel food should comprise the chemical name, CAS number, or other identification numbers, synonyms, trade names and abbreviations, molecular and structural formulae, stereochemistry, molecular weight as well as particle size, shape, crystal form, and distribution. For novel foods consisting of, isolated from, or produced from microorganisms, fungi, algae, plants/plant parts, animals/animal parts, or cell/tissue culture derived from animals/plants/fungi/algae, the identity should be substantiated by providing the scientific name, synonyms, common names, verification of the identity of plants, algae, and fungi according to internationally recognized databases and methodology, organ and tissue or parts used of the source organism, geographical origin, and laboratory or culture collection used as source. The characterization and identification of food consisting of engineered nanomaterials calls for a broader range of parameters. The required information regarding engineered nanomaterials are elaborated in detail in the EFSA guidance on risk assessment of the application of nanoscience and nanotechnologies in the food and feed chain (EFSA SC (European Food Safety Authority Scientific Committee) 2018).

### **Production Process**

To ensure that no safety concerns arise from the production process of the novel food, a comprehensive description of all information relevant to the production and processing of the novel food needs to be provided. This includes the detailed description of the processes involved in the production of the novel food. Information regarding the handling of sources, post-harvest handling of unprocessed foods, raw materials, and/or chemical substances used, processes employed to convert the raw materials into the product, specification of reaction conditions, purification methods, and identification of potential by-products, impurities, and contaminants should be provided. Furthermore, a description of operational limits and key parameters of the production process, measures concerning production control as well as quality and safety assurance, production flow charts indicating quality and safety control checks, and standardization criteria should be included.

One category of novel foods in the Novel Food Regulation (EU) 2015/2283 explicitly concerns the novelty of the employed production processes and refers to food resulting from a production process not used for food production within the Union before 15 May 1997. As the Regulation, in this regard, confines the term novel to production processes that do not significantly change the composition or structure of a food and do not affect the nutritional value, the metabolism or the level of undesirable substances, it is essential that all novel aspects of the production process as well as its effects on the bioavailability, nutritional value and safety of the Novel Food in question are characterized in detail by the applicant.

### **Compositional Data**

The composition of the novel food should be demonstrated by qualitative and quantitative data and should include information on physicochemical, biochemical, and microbiological characteristics. The data should contain the identification and quantification of substances of toxicological concern, impurities, by-products, residues, and contaminants. The analytical methods used should be validated and the provided data should include a description of the methods, the limit of detection and quantification as well as information on the accreditation of laboratories. To represent a certain range of variability, at least five representative and independently produced batches of the novel food should be analyzed. If the Novel Food refers to a single compound or fully chemically characterized mixtures thereof, compositional data should contain information on the identity and relative ratios of all components, the mass balance, identity tests used for the analyses, physicochemical properties as well as minimum purity. In contrast, complex mixtures or whole foods cannot be fully chemically characterized. Here, the qualitative and quantitative analysis should focus on the main constituents, proximate analyses, nutritionally relevant components, substances posing a possible concern to human health, and naturally or chemically derived components typically characteristic for the novel food. Analytical data on the composition of the novel food should be compared with data from literature.

Safety concerns may also arise from the storage and transport of the Novel Food. Therefore, the physicochemical, biochemical, and microbiological stability have to be tested and evaluated preferably on at least five representative and independently produced batches of the novel food.

### **Specification**

The specification shall ensure that the product intended to be placed on the EU market complies with the analyzed and evaluated Novel Food. It should appropriately characterize the novel food by setting physicochemical, biochemical, and microbiological key parameters including the contents of nutritionally or biologically active compounds, contents of major groups of food constituents, purity, limits for impurities, and degradation products as well as maximum levels for chemical and microbiological contaminants.

### **History of the Novel Food and/or of Its Source**

Information on the experience gained with a Novel Food regarding the previous exposure and use of a novel food outside the EU is of high relevance for the risk assessment. This includes data on the use of the Novel Food outside the EU as well as for nonfood purposes. Relevant aspects to assess the history of use are the extent of use, the characterization of the population groups which have consumed the Novel Food, the role of the novel food in the diet of these population groups, specific information regarding the handling and preparation of the food as well as precautions regarding its preparation and use. Furthermore, information on human studies about relevant safety aspects of the novel food in question resulting from a thorough and comprehensive literature review should be provided by the applicant. In general,

data concerning the history of use of a novel food should not be limited to the novel food itself but, in addition, should also include information on the composition, production, and experience from use of other products derived from the same source (e.g., a certain plant) as the novel food.

### **Proposed Use and Use Levels and Anticipated Intake**

An essential part of risk characterization is the exposure assessment. To estimate the intake of the novel food in question, information on the use levels of the novel food and data on the food consumption are needed. The use and use levels are proposed by the applicant. This requires to specify the target population, the form of uses, the food categories in which the Novel Food is intended to be used, the proposed maximum use levels, and concentrations in the final product intended to be consumed and the proposed daily intakes. It also needs to be clarified whether the novel food is meant to replace another food. Food consumption data should be retrieved from representative databases like the EFSA Comprehensive European Food Consumption Database (EFSA (European Food Safety Authority) 2011a) or national dietary surveys. Based on these information the anticipated mean and high daily intakes are estimated taking into account different population groups, combined consumption of all the food categories the Novel Food is proposed to be used in, and different consumption scenarios. Additionally, it might occur that a novel food also has other dietary sources like being a natural constituent in food. In this case, the combined exposure from the novel food and the background diet must be taken into consideration and the extent of the additional intake of the novel food in relation to the overall intake should be assessed. Even nondietary sources like cosmetics or pharmaceuticals might be relevant and considered in the overall exposure assessment. As the compositional analysis of the novel food might also reveal undesirable compounds present in the novel food, the intake assessment must also comprise such constituents. Based on the exposure assessment and all available data concerning the safety of the novel food, relevant precautions and restrictions regarding the use of the novel food should be specified.

### **Absorption, Distribution, Metabolism, and Excretion (ADME)**

A comprehensive assessment of all relevant toxicological and nutritional aspects of the Novel Food also requires toxicokinetic information. Data on absorption, distribution, metabolism, and excretion should be preferably provided for all toxicologically and nutritionally relevant constituents of the Novel Food according to the principles outlined in the EFSA guidance for the evaluation of food additives (EFSA ANS PANEL (European Food Safety Authority Panel on Food Additives and Nutrient Sources added to Food) 2012). These principles describe a tiered approach to toxicokinetic testing. Tier 1 assesses whether the Novel Food or its breakdown products are absorbed. If it can be demonstrated that the absorption is negligible, omitting higher tiered toxicological studies may be scientifically justified. Tier 2 requires *in vivo* assessment of absorption, distribution, metabolism, and excretion as well as basic single dose toxicokinetic parameters after systemic exposure to a single dose. If indications for bioaccumulation like limited or slow excretion are observed,

tier 3 toxicokinetic testing is necessary to define toxicokinetic parameters following repeated administration. Requirements regarding ADME studies for Novel Foods consisting of engineered nanomaterials are specified in the EFSA guidance on risk assessment of the application of nanoscience and nanotechnologies in the food and feed chain (EFSA SC (European Food Safety Authority Scientific Committee) 2018).

### **Nutritional Information**

According to Article 7 of the Novel Food Regulation (EU) 2015/2283, a novel food that is intended to replace another food does not differ from that food in such a way that its normal consumption would be nutritionally disadvantageous for the consumer. The applicant has to demonstrate that the consumption of the novel food in question does not lead to nutritional disadvantages under the proposed conditions of use. To assess the novel food's impact on nutrient intake, comprehensive information about the nutritional composition regarding macro- and micronutrients and the bioavailability of the novel food are required. This also includes information regarding the presence of antinutritional constituents and any possible effects and interactions with nutrients. Furthermore, the proposed use levels and estimated exposure for nutritional and antinutritional factors should be considered and assessed in relation to available dietary intakes, tolerable upper intake levels, and relevant health-based guidance values. If the target population includes sensitive subpopulations with particular physiological or metabolic characteristics (e.g., infants, young children, pregnant, or lactating women), these population groups should be specifically considered in the nutritional evaluation.

### **Toxicological Information**

As the safety of the novel food is assessed, the toxicological information should be derived from toxicological studies analysing the novel food in the form as it is intended to be placed on the market. Information on compounds having a structure similar to the Novel Food are suitable to assist in the safety assessment of the novel food in question. In general, the toxicological testing should follow international guidelines and principles of good laboratory practice. Similar to the evaluation of ADME data, toxicological testing should be carried out according to EFSA's tiered toxicity testing approach described for food additives (EFSA ANS PANEL (European Food Safety Authority Panel on Food Additives and Nutrient Sources added to Food) 2012). It addresses genotoxicity, subchronic toxicity, chronic toxicity, and carcinogenicity as well as reproductive and developmental toxicity.

Assessing the genotoxic and mutagenic potential in a chemical risk assessment aims for the identification of substances capable of causing heritable damage in humans, the prediction of potential genotoxic carcinogens when no carcinogenicity data are available, and elucidation of the specific mechanism of actions of chemical carcinogens. Following a stepwise approach a series of *in vitro* assays (bacterial reverse mutation assay (OECD (Organisation for Economic Co-Operation and Development) 1997), *in vitro* mammalian cell micronucleus test (OECD (Organisation for Economic Co-Operation and Development) 2016a)) are initially

recommended to evaluate the induction of gene mutation and chromosomal aberrations (clastogenicity/aneuploidy). In the case of positive results, further approaches are recommended including substitution and completion of *in vitro* assays with other appropriate *in vitro* and *in vivo* assays (e.g., *in vivo* micronucleus test (OECD (Organisation for Economic Co-Operation and Development) 2016b), *in vivo* Comet assay (OECD (Organisation for Economic Co-Operation and Development) 2016c), and transgenic rodent assay (OECD (Organisation for Economic Co-Operation and Development) 2013)). The evaluation of test results and the selection of follow-up assays should always consider all available relevant data of the substance including chemical reactivity, bioavailability, metabolism, toxicokinetics, target organ specificity, and endpoints. For novel foods representing complex mixtures or whole foods which naturally encompass a multitude of different compounds, it is recommended to focus on toxicologically relevant constituents of the Novel Food.

In addition to genotoxicity, the safety assessment of a Novel Food requires the evaluation of subchronic toxicity. Subchronic toxicity studies aim to provide information on the affected target organs and tissues, the type, extent, and severity of any effects as well as on dose-response relationships including the determination of reference points/points of departure like the relevant benchmark dose lower confidence limit (BMDL) or the no observed adverse effect level (NOAEL). Furthermore, they should assist in estimating appropriate dose levels for chronic toxicity studies and provide information regarding the need for additional in-depth investigation of particular effects and endpoints, e.g., neurotoxic effects, immunological effects, reproductive organ effects, or endocrine-mediated effects. Subchronic toxicity data should be derived from a repeated dose 90-day oral toxicity study in rodents (OECD (Organisation for Economic Co-Operation and Development) 2018a) modified to include additional parameters to assess endocrine activity as described for repeated dose 28-day oral toxicity studies in rodents (OECD (Organisation for Economic Co-Operation and Development) 2008). In absence of systemic availability, analyses should focus on pathological and physiological effects in the gastrointestinal tract.

Critical findings resulting from preceding genotoxicity tests and subchronic toxicity studies may raise the need for conducting a chronic toxicity (OECD (Organisation for Economic Co-Operation and Development) 2018b) and a carcinogenicity study (OECD (Organisation for Economic Co-Operation and Development) 2018c). Both studies are preferably performed in rats for a duration of 12 months (chronic toxicity) or 24 months (carcinogenicity). Alternatively to conducting two separate studies, it is also possible to perform a more time and cost-effective combined chronic toxicity/carcinogenicity study (OECD (Organisation for Economic Co-Operation and Development) 2018d).

Reproductive toxicity studies aim to reveal effects on male and female fertility, on the female's ability to carry pregnancy to term and on maternal lactation and care of the young. Regarding effects on the offspring, they provide information on the prenatal and postnatal survival, growth, functional and behavioral development, and reproductive capacity. Additionally, the studies enable the histological identification of important target organs for toxicity in parents and offspring. Prenatal

developmental toxicity studies provide information on lethal, teratogenic, or other toxic effects on the embryo and fetus. The need for reproductive and developmental toxicity studies has to be evaluated based on available toxicokinetic and toxicity information. In the case of proven or suspected systemic availability of a substance or if the repeated dose 90-day oral toxicity study indicates any effects on reproductive organs or parameters, reproductive and developmental toxicity testing is required. Recommended testing studies are a prenatal developmental toxicity study in the rabbit (OECD (Organisation for Economic Co-Operation and Development) 2018e) and an extended one-generation reproduction toxicity study in the rat (OECD (Organisation for Economic Co-Operation and Development) 2018f).

Furthermore, relevant information regarding the safety of a novel food can be derived from available human studies. Such studies may assist in evaluating potential adverse effects and in demonstrating the safety of the novel food under the proposed conditions of use.

There is an increasing interest in the consumption of insects as novel foods. The production and consumption of insects as food and feed may be associated with specific microbiological, chemical, and environmental hazards. These insect-related risks have been comprehensively identified and evaluated by EFSA and should be carefully considered in the safety assessment of insects as novel food (EFSA SC (European Food Safety Authority Scientific Committee) 2015).

Novel Foods may also be composed of, isolated from, or produced from microorganisms. Thus, ensuring that the novel food in question does not pose a risk to human health requires a microbiological safety assessment. This includes taxonomic classification at the species level and strain characterization at the genomic sequence level for the detection of potential virulence-related genes, antibiotic resistances, and their potential horizontal transfer. Additional potentially adverse genotypic and phenotypic characteristics and features should be evaluated as well. If a microorganism has a history of safe use and is assigned to a group of microorganism with a qualified presumption of safety (QPS) status, the requirements for the safety evaluation are reduced to complying with the criteria and qualifications specified in the QPS list (EFSA (European Food Safety Authority) 2008) and the risk assessment of antimicrobial resistance (EFSA FEEDAP Panel (European Food Safety Authority Panel on Additives and Products or Substances used in Animal Feed) 2012). A QPS status is granted for taxonomic groups posing no safety risk or where safety concerns can be defined and excluded.

Regarding the toxicological safety assessment of novel foods consisting of engineered nanomaterials, the specific data requirements and principles are outlined in the EFSA guidance on risk assessment of the application of nanoscience and nanotechnologies in the food and feed chain (EFSA SC (European Food Safety Authority Scientific Committee) 2018).

### **Allergenicity**

To ensure the safety of a novel food, the allergenic potential of the novel food needs to be evaluated. As most food allergens are protein-based, all novel foods containing proteins are assumed to potentially elicit allergic reactions. To assess the allergenic

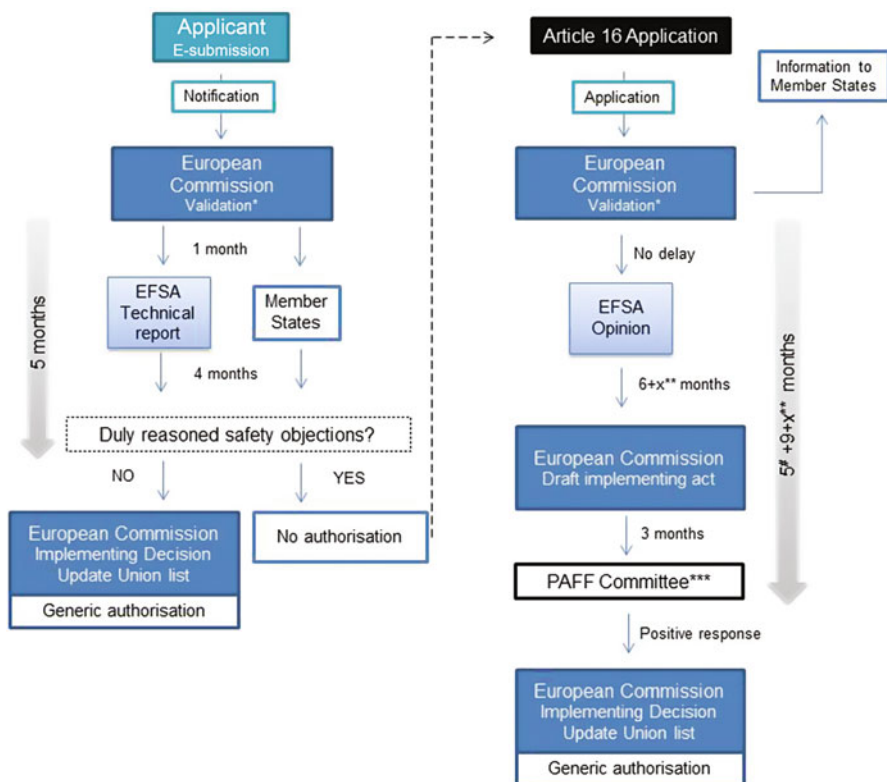

potential information regarding sensitization, studies on allergenicity and case reports concerning allergic reactions are needed. Investigation of allergenicity may include data on structural aspects of the proteins or peptides, detection of cross-reactive IgE antibodies, skin prick testing, or double-blind placebo-controlled oral food challenges. Evidence for potential allergenic reactions of a novel food requires risk management measures like restriction and labeling of the novel food to protect potentially affected consumers.

### **Notification and Application for Authorization of Traditional Foods from Third Countries**

The new Novel Food Regulation (EU) 2015/2283 introduces a faster and more appropriate notification procedure for traditional foods from non-EU countries with a demonstrated safe history of use of at least 25 years. The specific requirements applying to traditional foods from third countries are set out in Article 14 to 20.

Before placing the food on the market within the European Union as traditional food, the applicant has to directly submit an online notification for authorization to the European Commission (Fig. 2) which has to be in accordance with the requirements in Article 14 of the Regulation (EU) 2015/2283 and Commission Implementing Regulation (EU) 2017/2468 (2017) setting out administrative and scientific requirements for applications for authorizations of traditional foods from third countries. Within 1 month after verifying the validity of the notification, the European Commission forwards the notification to the Member States and EFSA. If EFSA and Member States do not raise duly reasoned safety concerns regarding the placing on the market within the Union of the traditional food within a period of 4 months, the traditional food is authorized by the European Commission and the Union list is updated. However, in case of duly reasoned safety objections submitted by EFSA or Member States, the European Commission neither authorizes the traditional food concerned nor updates the Union list. Instead, the applicant may submit an application for the authorization of traditional foods from third countries to the European Commission following the requirements of Article 16 of Regulation (EU) 2015/2283. Here, in addition to the information already requested for the notification procedure for traditional foods from third countries according to Article 14, the applicant is also required to provide specific data related to the duly reasoned safety objections raised by EFSA or Member States.

The application for the authorization of traditional foods from third countries is forwarded without delay to EFSA and made available to the Member States by the European Commission. EFSA is requested by the European Commission to review the application and assess the safety of the traditional food from a third country within 6 months. The 6-month period may be extended if EFSA requests additional information from the applicant. After receiving EFSA's opinion on the application within 3 months the European Commission submits to the PAFF Committee a draft implementing act authorizing the placing on the market within the Union of the traditional food from a third country. When the authorization is granted, the Union

**Fig. 2** Notification procedure and application for authorization of traditional foods from third countries according to Novel Food Regulation (EU) 2015/2282. \* Verification of validity + possible consultation with EFSA; \*\* Time period may be extended when EFSA requests additional information from the applicant; \*\*\* Standing Committee on Plants, Animals, Food and Feed; # Time period due to notification procedure

list will be updated. Overall, the time frame for the EFSA opinion and the European Commission decision are somewhat shorter for an application for the authorization of a traditional food from a third country compared to the regular authorization procedure of Novel Foods, though the process is still complex and time-consuming for the applicant.

### Safety Assessment Procedure for Traditional Foods from Third Countries

Before a traditional food from a third country pursuant to Regulation (EU) 2015/2283 and Commission Implementing Regulation (EU) 2017/2468 (2017) can be placed on the market within the EU, it must be subjected to a premarket safety assessment based on a history of safe food use. Notifications according to Article 14 of Regulation (EU) 2015/2283 should contain sufficient information and scientific

documentation for the European Commission to verify the validity and enable Member States and EFSA to evaluate the history of safe use of the traditional food in at least one country outside of the EU for a period of at least 25 years. These information should include the name, description, and composition of the traditional food, the country/countries of origin, documented data demonstrating the history of safe food use in a third country as well as a proposal for the conditions of intended use and for specific labeling requirements not misleading the consumer.

In order to support applicants in providing the entire type and quality of information relevant to conclude whether there are reasoned safety objections, EFSA provided a scientific and technical guidance document for the preparation and presentation of the notification dossier (EFSA NDA Panel (European Food Safety Authority Panel on Dietetic Products, Nutrition and Allergies) 2016b). As indicated in this guidance document, it is the duty of the applicant to provide all the available and reliable data that are pertinent to the safety of the traditional food.

Consistent with application dossiers of novel foods according to Article 10 of Regulation (EU) 2015/2283, the notification dossier needs to contain information on the identity of the traditional food and reliable data on the respective production process, the composition and specifications of the traditional food as described in sections “[Introduction and Identity of the Novel Food](#),” “[Production Process](#),” “[Compositional Data](#),” and “[Specification](#).” In addition, the applicant has to demonstrate the experience of continued use of the traditional food and has to propose conditions of use for the EU market. In contrast to the evaluation of novel foods, the applicant is not specifically requested to provide specific information or perform specific studies on toxicokinetic, toxicological, nutritional, and allergenic properties of the traditional food (see Table 3). However, if such data are available they should be provided to ensure a comprehensive risk assessment of the traditional food covering all relevant safety aspects.

### **Data from the Experience of Continued Food Use in the Third Country**

A central point in the safety assessment of a traditional food is the experience of continued use of the traditional food for at least 25 years in the third country. Data should cover a description of the extent of use including data on production (e.g., place, volume per year) and geographical areas along with information on intake levels and intake estimates. For example, in the case of notifying the placing on the market of berries of *Lonicera caerulea* L. (Haskap berries) as a traditional food from a third country, the applicant provided amongst others references to document the annually average consumption per person over the past 30 years in Hokkaido (Japan) (EFSA (European Food Safety Authority) 2018b).

In addressing the continued food use, information on the specific population group(s) of consumers (e.g., general population or subpopulations defined by specific criteria like age and ethnic background) along with the group size should be provided by the applicant. The role of the traditional food in the diet should also be documented including consumption pattern and frequency (e.g., consumed in the form of beverages or as food ingredient in processed foods). It may be conducive to supply data on how the intake of the traditional food contributes to the total intake of

**Table 3** Data requirements of the application/notification dossier for risk assessment of novel foods and traditional foods from third countries (EFSA NDA Panel (European Food Safety Authority Panel on Dietetic Products, Nutrition and Allergies) 2016a, b)

Application for authorization of novel foods	Notification for authorization of traditional foods from third countries

Specifications	Specifications
History of use of the novel food and/or of its source	Data from experience of continued use
Proposed uses and use levels and anticipated intake	Proposed conditions of use for the EU market
Absorption, distribution, metabolism, and excretion	
Nutritional information	
Toxicological information	
Allergenicity	

macro- and micronutrients of the population. Additionally, the traditional manufacture, preparation, preservation, packaging, or storage should be described.

Precautions regarding preparation and handling of the food as well as restrictions of use (e.g., for specific subpopulations like children) should be provided along with any kind of treatments or methods leading to the reduction of toxicological relevant and antinutritional substances or improving the digestibility of the food. Furthermore, any available human data related to the safety of the traditional food should be reported including clinical trials, observational studies, and information from case and surveillance reports. Additionally, data on specific and typical components of the traditional food or on similar foods from related sources as well as other important data (e.g., animal toxicity studies and nonfood use in medicine) should be addressed to support a conclusion on the history of safe use of the notified traditional food.

### Proposed Conditions of Use for the EU Market

In order to place on the market within the EU a traditional food from a third country, the notification should clearly and specifically define the target population intended to consume the traditional food. It is particularly important to provide specific information about the proposed uses and use levels to evaluate whether the traditional food may pose a risk for human consumption. This includes the form of uses and clearly defined food categories (preferentially by following the EFSA food classification system (EFSA (European Food Safety Authority) 2011b)). It needs to be clarified whether the traditional food is supposed to replace another food and that the consumption of the traditional food is not nutritionally disadvantageous for the consumer. The proposed maximum use levels and concentrations in the final

product as well as the proposed daily intake levels for different subgroups classified by age and gender should, if applicable, also be indicated.

Regarding restrictions of use of the traditional food the (sub)groups of the population which should avoid the consumption should be defined and any other restrictions and precautions related to the handling, preparation, and consumption should be described along with any effects of potential overconsumption on population or subgroups of population.

**Abstract**

The recent rise of science in the microbiome field has brought to light new opportunities of health technologies development. Microbiome-derived products are very diverse and encompass several product categories such as foods as well as medicinal products. While some guidance and recommendations are being drawn for very specific microbiome applications, there is no consolidated regulatory framework applicable to all microbiome products. Any specific requirements should be carefully considered on a case-by-case basis in order to demonstrate the safety and efficacy of these new high potential healthcare solutions.

Specific challenges due to the nature of microbiome health products must be addressed for toxicology assessment and clinical translation. Colonization and proliferation processes for live microorganisms need to be controlled. Some solutions are already available for microbiome products development, such as dedicated nonclinical models, and emerging tools such as *in silico* modeling may potentially prove useful. This chapter aims to draw the regulatory landscape for microbiome-derived products prior to debating various nonclinical tests systems to evaluate their toxicology.

**Introduction**

The emergence of the microbiome field is leading toward new considerations in the areas of human health, well-being, and potentially even host personality traits (Johnson 2020), as well as the development of health technologies, especially for therapeutic purposes. As close as the relationship between microorganisms and their host may be, microbiota, as a “not-self” entity, cannot be considered the same way as human tissues.

The wide spectrum of therapeutic indications that may be the result of microbiome disorders is the consequence of the vast environment that microorganisms can inhabit in humans. More than 100 trillion microbes reside within tissues or biological fluids of different microbiota including but not limited to the gut, oral, skin, or vaginal microbiota. There is a lack of hindsight on these organisms’ specificities and how to take them into account for therapeutic development. It is a common misconception that the commensal nature of the indigenous microorganisms guarantees their safety for the host. *Escherichia coli* (*E. coli*) is for instance an early colonizer of the intestinal tract, and it persists throughout the entire individual’s life. However, certain *E. coli* strains are also among the most known bacterial pathogens.

Although microbiome-focused science is quite new, the odds are that a healthy microbiota-host relationship lies more in the balance of the overall microbiota composition rather than in the presence of specific strains and species. Thus, most microbial species and strains are not intrinsically beneficial or detrimental to the host's health. To make the most out of the very promising microbiome science for the development of alternative therapeutic solutions, accurate toxicology assessment is fundamental and constitutes a critical step toward clinical translation. Microbiome toxicology presents specific challenges which require the development of dedicated nonclinical models. Such investigations are as of now supported by the rise of the “omics” technologies (e.g., metagenomics, metataxomics, and metabonomics) (OECD 2017; Segal et al. 2019).

There is a paradigm shift as products known for decades and used in foods as technological aids are now investigated for their potential health benefits. They may be considered as foods with particular nutritional or health-related properties, or as medicinal products, defined by their mode of action, their therapeutic effect, and a dose defining their efficacy threshold.

In the fast-moving microbiome field, a key to success is to be aware of the extent and limitations of the current scientific knowledge in order to adopt and develop adequate solutions that will help ensure this emerging technology is explored and used in the most controlled possible way for the common good.

---

## Regulatory Landscape for Microbiome Products

### Lay Terminology and Regulatory Status

In the lay language, microbiome-health products are commonly designated as “prebiotics” and “probiotics.” These terms have been used for decades with the first uses dating back to 1965 (Lilly and Stillwell 1965). In the past decade, the term “postbiotics” was coined to designate a new type of microbiome-related products.

There is to date no absolute consensus on these terms' definitions. Multiple interpretations have been proposed in the literature over the years. In addition, the microbiome field has grown considerably, and the development of new applications may render obsolete some of these definitions. Prebiotics and probiotics have often been considered as food components or foods themselves (Pineiro et al. 2008; Gibson and Roberfroid 1995; Patel and Denning 2013; El-Ashram et al. 2019). However, such wording may conflict with applications in the therapeutic field: the European Regulation indicates that “Foods” should not designate Medicinal products (EMA 2002b). Some definitions also suggest that these products are limited to gastrointestinal applications (Gibson and Roberfroid 1995; El-Ashram et al. 2019; Guarner and Schaafsma 1998; Parker 1974; LeBegue et al. 2020), while the benefits of prebiotics and probiotics on other tissues such as skin (Kaur and Rath 2019), brain (Heyck and Ibarra 2019), or vagina (Al-Ghazzewi and Tester 2016) are gaining more and more interest. It has also been suggested that prebiotics, probiotics, or

postbiotics could be limited to bacteria-related benefits (Gibson and Roberfroid 1995; Patel and Denning 2013; El-Ashram et al. 2019; Havenaar and Huis In't Veld 1992). Yet, the microbiome field is extending to other microorganisms such as yeasts (Massacci et al. 2019), fungi (Pareek et al. 2019; Huss and Raman 2020), or viruses (Pareek et al. 2019; Huss and Raman 2020).

For the purpose of this chapter, the following definitions will be considered for prebiotic, probiotic, and postbiotic:

- Prebiotic: Nonviable substance which, when administered in adequate amount, selectively promotes the growth, development, and/or activity of beneficial microorganisms hosted by the individual taking the product.
- Probiotics: Living microorganism(s), when administered in adequate amount, confer (a) health benefit(s) to the host (Food and Agriculture Organization of the United Nations (FAO) and World Health Organization (WHO) 2002, 2006).
- Postbiotics: Nonviable substance produced by or derived from microorganisms, which, when administered in adequate amount, confer (a) health benefit(s) to the individual taking the product.

None of the “prebiotic,” “probiotic,” or “postbiotic” terms has ever been coined by the formal European or American regulatory lexicons. The FDA clarified in 2018 that probiotics are not defined as a regulatory product category (FDA 2018). In addition, there are no correspondences between these wordings and regulatory statuses. “Prebiotics,” “probiotics,” and “postbiotics” may encompass many official categories of products, both in the food or the therapeutic field.

In the food field, microbiome-related components are likely to be considered as “New” (US) or “Novel” (EU): where innovative ingredients have little history of use, and safety for human consumption may need to be demonstrated in order to obtain regulatory approval of use. Besides, statements of specific health benefits on food products are subject to scientific review and regulatory approval. “Prebiotic,” “probiotic,” and “postbiotic” are implicit references to general, nonspecific benefits of the nutrient or food for overall good health or health-related well-being; however, they still have to be accompanied by a specific authorized health claim in the EU (EMA 2006). Health claims may be present on general foods; however, they are particularly prone to be used on food supplements as those are intrinsically expected to provide a nutritional or physiological effect to their consumer (EMA 2002a).

When indicated for therapeutic use, microbiome products may fall within the medicinal product status. Probiotics and postbiotics are also likely to be regarded as biological products in both the EU and the USA as they are typically issued from microorganisms and of biological nature themselves. Probiotics are the only microbiome products susceptible to fall within the Live Biotherapeutic Products (LBP) scope in the USA. Where the cell constituent of the microbiome product (e.g., bacteria, yeasts) has been substantially manipulated or engineered, requirements for Advanced Therapy Medicinal Products (ATMPs) may be applicable in the EU (EMA 2007; see also ► Chap. 96, “Toxicological Aspects in the Regulation of Gene Therapy Medicinal Products”).

Fecal Microbiota Transplants (FMT) illustrate the variety of regulatory statuses potentially applicable to microbiome health products. While the approach is rather close to a graft, human stool is usually not considered to be a constituent part of the human body itself, which may conflict with existing Regulations applicable to cells and tissues, defined in the EU and the USA as human materials (EMA 2004; FDA 2019a). Where administered to treat *Clostridium difficile* infection, FMT meets the definition of a biological product as per the FDA definition (FDA 2016a). The status of FMT is not harmonized in the EU community, and no specific framework has been designated in most Member States (MS). The European Commission has advised that FMT does not meet the definitions of “tissues and cells”; however, they are considered substances of human origin (European Commission Directorate General for Health and Food Safety – Competent Authorities on Substances of Human Origin Expert Group (CASoHO E01718) 2019). Some MS regulate FMT under Tissues and Cells standards (2), others as Medicinal Products (non-ATMPs) (5) or as Foods (1) (European Commission – Commission Staff Working Document 2019).

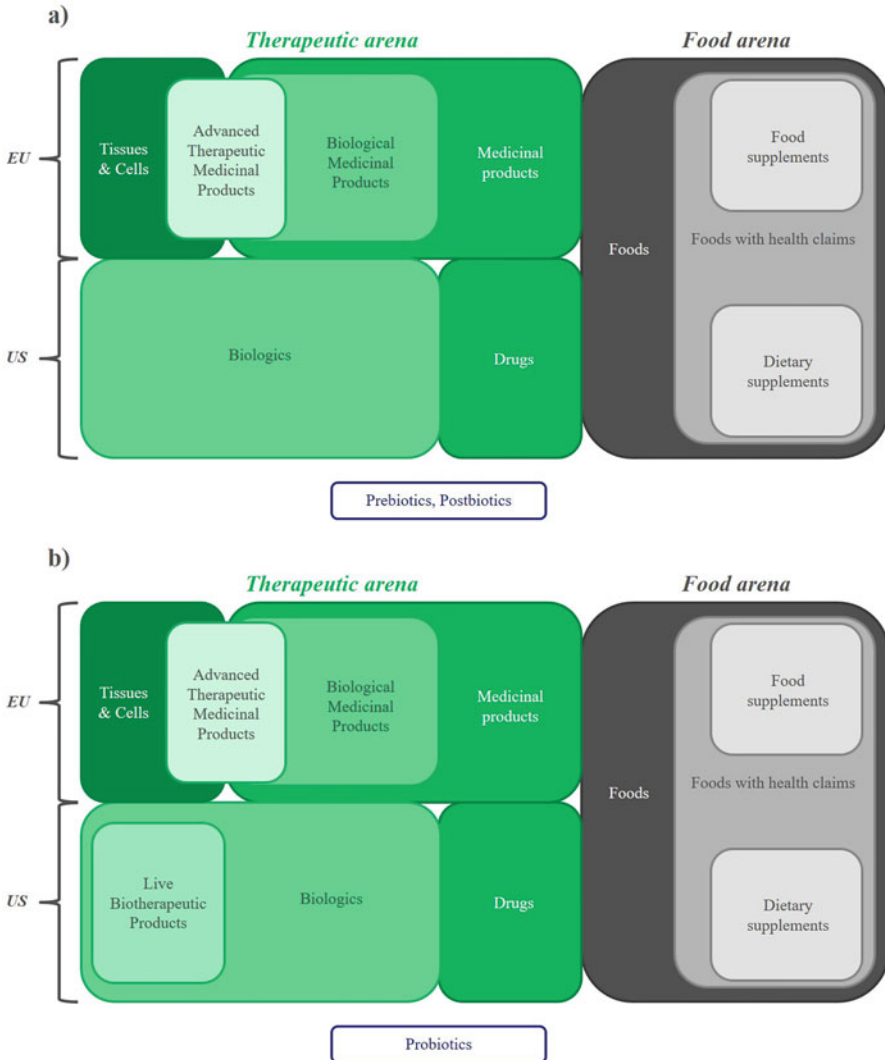

The potential regulatory scope of application for microbiome health products is outlined in Fig. 1.

The lay language used for microbiome products is not suitable with respect to regulatory considerations. Prebiotics and probiotics may both be developed as foods (e.g., functional foods or food supplements with health claims; specialized nutrition) as well as therapeutic products (e.g., drugs, biologics, tissues, and cells), and probiotics may in addition to these be developed as LBPs. Additional product characteristics must be taken into account to determine the applicable regulatory status and the associated requirements for development and marketing of a microbiome product in the EU and USA (e.g., intended use, presentation form, nature, and origin of components).

## Global Regulatory Framework in Place

A single guidance for all microbiome-related products would be impractical and potentially lead to generic recommendations with little added value. The different regulatory approaches for each status are reflected by the structure of the Authorities framework, either divided in multiple expertise centers (e.g., FDA Center for Biologics Evaluation and Research, Center for Food Safety and Applied Nutrition), or even distinct agencies (e.g., European Medicines Agency, European Food Safety Authorities, National Regulatory and Scientific Agencies).

On the global scale, only limited specific guidance is available to sponsors with regard to microbiome products development. The FDA has published two guidance documents dedicated to microbiome therapeutic products, namely: 1) live-biotherapeutic products (FDA 2016b), and 2) fecal microbiota transplantation (FDA 2016a). Additionally, an interagency Microbiome Working Group has been established in the USA, comprising members from various NIH Institutes and Centers and the FDA, to support discussion of microbiome-related topics and research.

**Fig. 1** Regulatory statuses potentially applicable to microbiome health products in the EU and the USA, in the food and therapeutic arenas. **(a)** Prebiotics and postbiotics may be food or drugs, depending in particular on their intended use. In the food arena, they may fall within any status where they may be considered as acceptable food components. They may also fall within many medicinal statuses, including biologicals. Prebiotics and postbiotics are not expected to be considered LBP; **(b)** Probiotics may fall within all of these same statuses and are additionally particularly prone to be considered LBPs in the USA

No comparable harmonized regulation has currently been established in the EU. Some national agencies have taken the initiative to provide national recommendations for products such as FMT, leading to regulatory discrepancies within the

European Community. Fecal microbiota is regarded as a medicinal product or as human material (ANSM 2016; Hoge Gezondheidsraad 2015; Peri et al. 2019). FMT is being regarded as a therapeutic intervention in some MS, explicitly not being subject to the national regulations applicable to drugs, medical devices, or transplantations (Kump et al. 2014). Hospital exemptions also allow custom-made ATMPs to be used in a hospital setting and under the responsibility of the medical practitioner, for a specific patient in individual EU member state, without the need for a marketing authorization (EMA 2018). While the need for an increased cooperation on classification of FMT has been acknowledged by many competent authorities (CAs) (EMA 2004), no common initiative has been initiated to date by the EU Authorities. Inversely, the current trends in the evolution of the regulatory framework for microbiome products are being settled on a national level, e.g., a law project is being evaluated in France which would regulate activities with regards to stool collection (Assemblée Nationale 2019).

The current regulatory framework dedicated to microbiome products is limited. Although the FDA and some EU national authorities have initiated drafting a framework for microbiome products, it remains restricted to therapeutic probiotics (LBPs, FMT). In the existing standards, the recommendations in terms of toxicological assessment remain high level. Prebiotics and postbiotics have not yet been subject to any standardization process. International dialogue between regulatory authorities still needs to be instigated to harmonize the regulation of microbiome products, as outlined by the OECD report on Microbiome Science (OECD 2017). Multiple associations and groups have emerged from research and industry to support and promote the development of microbiome products, such as the Intestinal Microbiome-based Medicines European Task Group (IMM-ETG), the International Probiotics Association, or the Microbiome Therapeutics Innovation Group, demonstrating the need for a globally harmonized standardization.

---

## Stakes and Hurdles of the Toxicological Assessment of Microbiome Products

Use of microbiome-based products could be distinguished in two main therapeutic approaches: 1) displacing pathogenic microorganisms and restoring symbiosis, and 2) delivering genetically modified bacteria to secrete and locally deliver active substance.

Before initiating any clinical studies, developers of microbiome-based products need to demonstrate product safety for their intended use. Yet, as products are typically composed of commensal or historically known living microorganisms, developers might mistakenly consider these microorganisms as safe by definition while neglecting that the formulation, route of administration, and dose can considerably influence the microorganism's activity with a potentially negative impact on the human organism. As example, the presence of the facultative anaerobic *E. coli* in the human gastrointestinal tract is estimated at  $10^{21}$  cells (Conway and Cohen 2015; Kittana et al. 2018). *E. coli* presents a large diversity of strains playing key roles in

the intestine and also encompasses pathogenic variants able to provoke severe intestinal or extraintestinal diseases in humans (Leimbach et al. 2013). Likewise, *Streptococcus pneumoniae* (*S. pneumoniae*) present in the commensal state in the human upper respiratory tract also has capability of becoming pathogenic after reaching normally sterile locations (e.g., lung, bloodstream) (Weiser 2010). Thus, a correct selection of the strain, the dose, and a complete control of the microbiome-based product are essential to ensure safety.

Developers might also consider that the historic use of microorganisms in the food field could be adequate to demonstrate the safety of the microbiome-based product. According to the European Food Safety Authority (EFSA), the Qualified Presumption of Safety (QPS) is based on reasonable evidence. Criteria for such qualification include taxonomic identification, established safety, and absence of pathogenic properties. If those criteria are met, the group of microorganisms evaluated is granted QPS status. A full safety assessment is not required for microorganism belonging to a group with QPS status (European Food Safety Authority (EFSA) 2020). In comparison, in the USA, substances that are reasonably expected to become components of foods are subject to premarket approval by the FDA, unless the substance is generally recognized as safe (GRAS). GRAS classification can be based on scientific procedures or on experience based on common use in food (FDA 2019b). The food regulatory landscape does not require monitoring nor vigilance of potential adverse events associated to food products. Developer may nevertheless find of interest to generate clinical data to support the health claims of their food products. However, clinical data generated for food products cannot be necessarily leveraged to support the use of their ingredients as medicinal products. In the therapeutic field, drug monitoring consists of various measurements, including pharmacokinetics, in order to assess if dosage needs adjustments (Kang and Lee 2009). This quantification is directly correlated to safety assessment, hence crucial even if the product cannot be directly measured in the blood. Thus, relying on experience from the food field to assess microorganism safety may not be sufficient to determine potential toxicological effects.

Hence, customized and reliable nonclinical models (in vitro, ex vivo, and in vivo (Table 1)) have been developed and/or optimized over the past decades by both sponsors and contract research organizations (CROs) to conduct pharmacological and toxicological assessment of microbiome-based products.

---

## Models for Toxicology Assessment

Given the need to support translation to the human situation, establishing models to reflect the complexity of the human microbiota, composed of approximately 100 trillion cells, is a challenge (Fritz et al. 2013). A nonexhaustive outline of currently available in vitro, ex vivo, and in vivo models is presented in Table 1.

In addition to classic animal models, nonclinical approaches include germ-free (GF, also referred as axenic animals) and gnotobiotic (from Greek “known” “life,” i.e., in this case, with defined microbiota) animals. Although the first GF animals

**Table 1** Overview of available nonclinical study models for microbiome research field

Type	Models	Clinical indication (s)	Target organs/systems	Advantages	Drawbacks	References
<b>In vitro models</b>	<b>SHIME</b> (Simulator of the Human Intestinal Microbial Ecosystem)	Chronic inflammatory diseases (e.g., inflammatory bowel disease, metabolic syndrome)	Mimics the human gut with five compartments simulating the stomach, small intestine, ascending, transverse, and descending colons	Able to simulate the entire intestinal tract. Highly reproducible and stable. Control the colon microbiome ecological aspects. Multiple adaptive models available (e.g., M-SHIME, TWIN-SHIME, TRIPLE-SHIME) allowing for example parallel testing (control vs. test). Long in vitro studies (from one to several weeks). Possibility to do metabolic studies.	The possibility to study the host-microbe interactions is lacking. Long adaptive period (14–21 days). Lack of dialysis.	Fritz et al. (2013), Pham and Mohajeri (2018), Van de Wiele et al. (2015), Chassaing et al. (2017)
	<b>PolyFermS</b> model – Fermentation model	Ecological and metabolic studies	Replicates the adult proximal colon	Simultaneous testing in comparison to a control reactor. Highly reproducible. Studies the impact of environmental parameters, dietary compounds, drugs, and microbes. Stable and reproducible.	The possibility to study the host-microbe interactions is lacking. Lack of dialysis.	Zihler Berner et al. (2013)
	<b>In vitro coculture models</b>	Host-microbe interaction studies	System allowing the separation of microbial and human cell cultures by semipermeable membranes	Avoid the interruption of cocultures of human and microbiota cells).	The possibility to study the host-microbe interactions is lacking. Risk of cross contamination. Strictly anaerobic microbiota setting up not possible.	Fritz et al. (2013), Pham and Mohajeri (2018), Castaneda et al. (2019), Pearce et al. (2018)

(continued)

**Table 1** (continued)

Type	Models	Clinical indication (s)	Target organs/systems	Advantages	Drawbacks	References
	<b>TNO gastro-intestinal model (TIM)</b> <b>TIMI/TIM2</b> models	Digestive processes studies	In vitro gastrointestinal tract system Stomach and small intestine (TIM1). Large intestine (TIM2).	Mimics the stimulations occurring in the stomach (including, e.g., water absorption, peristaltic mixing, fermentation processes). Allow metabolic studies. Replicate drug's bioavailability.	The possibility to study the host-microbe interactions is lacking. The luminal and mucosal microbiota cannot be separated.	Fritz et al. (2013), Pham and Mohajeri (2018), Keller et al. (2017), Pearce et al. (2018)
	<b>Human cells lines</b> (e.g., Caco-2 cell line, HT-29 cell line, IEC-6 and IEC-18 cell lines)	Gastrointestinal process, host-microbe interactions	Can be used in combination with in vitro fermentation models	Can be used for preliminary investigations. Rebuild a human bacterial microenvironment.	Not representative of GIT system by themselves – Need to be associated with an in vitro system.	Fritz et al. (2013), Pham and Mohajeri (2018)
<b>Ex vivo models</b>	<b>Explant cultures</b>	Inflammatory disease (e.g., ulcerative colitis, Crohn's disease)	Colon or rectum (e.g., organotypic slices from human colon biopsies)	Representative of human architecture and cells populations. Reflect in vivo situations by maintaining immune system components, epithelial organization, and metabolic activity.	Mucus layer damaged or removed during the surgical procedure. Artificial treatments (e.g., antibiotics) needed. Not possible to modulate cell populations. In vivo situations can be simulated for a short period of time only.	Fritz et al. (2013), Schwerdtfeger et al. (2019)

<b>In vivo models</b>	<b>Nematode worm</b> <i>Caenorhabditis elegans</i>	Discovery and study of fundamental microbiome biological mechanisms, immune responses	Host-microbiome interactions studies	Well-defined model. Possible to engineer GF and gnotobiotic subjects. Subjects optically transparent, allowing real-time visualization or fluorescence approaches.	Studies on GF subjects may be restricted to young larvae. Microbivores.	Douglas (2019)
	<b><i>Drosophila</i></b>	Discovery and study of fundamental microbiome biological mechanisms	Extensively used to study the immune system and the gut microbiota and host-microbiome interactions	Well-defined model. Possible to engineer GF and gnotobiotic subjects. Can be engineered and maintained over multiple generations. Can be engineered by showing a specific microbiota. Similarities with the human gut (e.g., gut divided into three sections). Relatively simple microbiota with only 5–30 taxa. Highly manageable, small size of animals, easy to store, and allowing large sample sizes (statistical precision).	Cannot be humanized by the colonization of human gut microbes (e.g., the <i>Drosophila</i> hindgut (third section of the gut, equivalent to the human colon) is not a fermentation chamber). Different diet as human. Studies on GF may be restricted to young larvae. Microbivores.	Douglas (2018), Kostic et al. (2013), Selkrig et al. (2018), Douglas (2019)

Table 1 (continued)

Type	Models	Clinical indication (s)	Target organs/systems	Advantages	Drawbacks	References
	<b>Zebrafish</b>	Microbiome ecological studies (e.g., impact of arsenic) and metabolic disorders (e.g., type 2 diabetes mellitus)	Mainly used to study host-microbe interactions	<p>Well-defined model. Possible to study host-microbiome interactions -GF and gnotobiotic subjects).</p> <p>Intestinal segmentation and architecture comparable with the mammalian intestine (e.g., similar gene expression and transcriptional regulation in intestinal epithelial cells, the presence of a common protective mucus layer (with mucin) in both zebrafish and mammalian GIT or the presence of an enteric nervous system (ENS). Subjects optically transparent, allowing real-time visualization or fluorescence approaches. Short generation time. Easy to store (measured 3–4 cm long). Fully sequenced genome. Biologically reproducible—Interesting for interindividual variation studies.</p>	<p>Mammalian GIT is divided into five distinct part (stomach, duodenum, jejunum, ileum, and colon), whereas the zebrafish is divided into three segments (anterior intestinal bulb, middle intestine, and posterior intestine).</p> <p>Zebrafish presents a less complex intestinal architecture as human. Lives in an aquatic environment. Difficult and costly to rear GF zebrafish into adults (90–100 days necessary to reach adulthood). Omnivores but different diet to humans (aquatic insects, crustaceans, and plant materials).</p>	<p>Flores et al. (2019), Fritz et al. (2013), Stephens et al. (2016), Dahan et al. (2018), Okazaki et al. (2019), Douglas (2019), Rawls et al. (2007)</p>

<b>Mouse</b>	Host-microbe interaction studies: Host nutrition and disease development	Allows to explore various interactions between the gut microbiota and, among others, mammalian physiological aspects such as: Brain development, obesity, malnutrition, and hepatic function	One of the most used in vivo animal models to study host-microbiota interactions. Anatomical, histological, and physiological similarities between mouse and human intestines. Genetic similarity between inbred strains allows the reproducibility of the experiments. Well-defined models. Genetic similarities between mice and human: 99% of mouse genes shared with human. Gnotobiotic <sup>a</sup> mice can be colonized with human gut microbiota and maintained over several generations with the defined microbiota. Mice have the same organs as human. Small size – low sheltering cost.	Different organ size scale size (e.g., the large intestine reaches up to 14 cm in mice and 105 cm in human). Small intestine of 33 cm in mice and 700 cm in human. Large intestine up to 14 cm in mice and 105 cm in human. Total transit can last 14–16 h in human vs. 6–7 h in mice. Mucus growth rate higher in the human colon than in the mouse colon (240 +/- 60 µm/h vs. 100 +/- 60 µm/h). Different metabolic rate. Different diet habits. Mice are hindgut fermenters with grain-based diets, humans are omnivores. Mice have a nonglandular forestomach, higher stomach pH in mice than in human (pH 2.7–4.1 vs. > pH 1). Mouse skin differs vs. human skin. Not fully relevant for skin, oral cavity, upper respiratory tract, and genitourinary tract studies.	Franklin and Ericsson (2017), Fritz et al. (2013), Hugenholtz and de Vos (2018), Kibe et al. (2005), Kostic et al. (2013), Lavin et al. (2018), Nagpal et al. (2018), Le Roy et al. (2019), Rosshart et al. (2019), Goodman et al. (2011)

Table 1 (continued)

Type	Models	Clinical indication (s)	Target organs/systems	Advantages	Drawbacks	References
	<b>Wilding mice</b> Laboratory mice embryos (C57BL/6) transferred into wild mice – Next generation	Immunological and microbiome-related disorders	Mice model counterbalancing the drawbacks of laboratory mice (e.g., variable microbiota)	Animals microbiota remain stable throughout generations. Animals remain robust against microbial, antibiotic, and dietary challenges. Animals have the same modifiable genetics of C57BL/6 mice. Good translation model into humans (e.g., immunological responses). Reproducible.	Human microbiota vs. mice microbiota differ in quantities. Approximately 80 microbial gut genera in common. Faecalibacterium, Succinivibrio and Dialister were not found in some laboratory mice. Different immune system – Difficult to predict humans' complex immune responses. Exclusive herbivores. Higher pH in the stomach. Laboratory mice may present different microbiota.	Rosshart et al. (2019)

<b>Rats</b>	Host-microbe interaction studies: Host nutrition and disease development	Gut microbiota	Rat microbiota better reflects the human microbiota than mice. Physiological and anatomic similarities with human GIT (organ, tissue, and cells). Large size facilitating the evaluation of metabolic parameters (e.g., blood pressure). Genome fully sequenced. Can better support human fecal microbiota than mice.	Exclusive herbivores. Higher pH in the stomach. Higher mucus growth rate in humans than in rats. Faster digestion as in humans. Low-fiber digestion capacity.	Flemer et al. (2017), Fritz et al. (2013), LLeal et al. (2019), Marques et al. (2015), Nagpal et al. (2018), Heinritz et al. (2013)
<b>Rabbits</b>	Sinusitis	Sinus microbiota	Similar sinonasal epithelium immunologic features. Sinusitis model well-defined.	Surgery and bacteria inoculation can enhance changes in mucociliary transport.	Cho et al. (2018)
<b>Dogs</b>	Gastrointestinal disorders (e.g., acute hemorrhagic / nonhemorrhagic diarrhea, idiopathic inflammatory bowel disease) Skin	Skin microbiota and gastrointestinal disorders	Skin conditions: Can develop atopic dermatitis similarly to humans. Possible to quantitate liver glucose levels. High fecundity. Diarrhea often occurs after weaning in research puppy colonies.	High mortality rates (high sensitivity to some disease models). Need extra care being domestic animals.	Kleinert et al. (2018), Burton et al. (2016), Rodrigues Hoffmann et al. (2014), Suchodolski et al. (2012), Coelho et al. (2018)

Type	Models	Clinical indication (s)	Target organs/systems	Advantages	Drawbacks	References
	<b>Pigs</b>	Gastrointestinal diseases (e.g., stress-induced intestinal dysfunction, intestinal ischemia / reperfusion injury, colorectal cancer, short-bowel syndrome, weaning diarrhea, necrotizing enterocolitis, obesity) Esophageal metaplasia and neoplasia Metabolic disorders (e.g., diabetes mellitus, obesity)	Particularly relevant to study esophageal disease, intestinal ischemia / reperfusion injury or even psychological stress-induced intestinal dysfunction	Anatomic, physiological, genomic (fully sequenced, with 60% of similarities with human), proteomic, immunologic, metabolic, and nutritional similarities with human. Esophagus (with the esophageal submucosal glands), stomach, structure of the small intestine, intestinal length and weight, and epithelial cell population are very close between the two species. Omnivore. Able to perform fermentation in their colon, which have sacculations and longitudinal muscular bands (like human colon). Close microbiota within their small and large intestine (mainly constituted of Firmicutes and Bacteroides, as humans). Comparable clinical signs and pathophysiological signs as human when submitted to stress. Well-developed central and peripheral nervous system enabling to integrate complex	Pigs have no appendix. Pigs cecum is much more developed and larger than the human cecum. Pigs have a different spinal arrangement in their colon. Slow reproduction rate (4 months gestation) compared to rodents.	Gonzalez et al. (2015), Ziegler et al. (2016), Crespo-Piazuelo et al. (2018), Heinritz et al. (2013), Zhang et al. (2013)

				stress signaling processes. High fecundity. Experimentally tractable animal model. Possible translation of the human microbiota into pigs.		
<b>Non-human Primates (NHP)</b>	Gastrointestinal disorders Metabolic disorders Pathogenesis and sexual infection transmissions (e.g., vaginal microbiota)	Ideal to study the vaginal and rectal microbiota	Behavioral, physiological, and genetic resemblances with humans. Widely used model in the medical research field – Well-known. Similar gut, skin, and genital microbiota when compared with other species (e.g., mice and rats).	Differences in the gut, vaginal, and saliva microbiota Higher quantities of Proteobacteria in rhesus macaques and baboons vs. higher quantities of Bacteroides and Firmicutes in human gut microbiota. Lower quantities of Lactobacillus in NHP than in human vaginal microbiota. Human and macaques saliva microbiota share three prevalent taxa: Streptococcus, Haemophilus, and Veillonella.	Chen et al. (2018), Nagpal Kennedy et al. (2018), Kleibert et al. (2018), Nugeyre et al. (2019)	

ENS Enteric Nervous System, GF germ-free, GIT Gastrointestinal Tract, NHP nonhuman primate(s)

<sup>a</sup>Gnotobiotic – Germ-free animals can become gnotobiotic models when colonized with specific and defined germs (Fritz et al. 2013; Pham and Mohajeri 2018)

were established in the late 1940s, their actual potential to conduct microbiome studies was recently implemented (Al-Asmakh and Zadjali 2015; Kennedy et al. 2018; Fritz et al. 2013; Pham and Mohajeri 2018). Gnotobiotic animal models evolved alongside the increasing understanding of the microbiota. They enable the conduct of studies to determine the functional impact of a defined microbiota on host physiology (Dewhirst et al. 1999; Marcobal et al. 2015; Martín et al. 2016; Basic and Bleich 2019). Despite obvious limitations, GF and gnotobiotic models have been broadly used to characterize patient – microbiota interactions in toxicology investigations and to investigate drug impact on host microbiota. Therefore, evolving models would need to focus on investigating microbiome-based products and their impact on both host health and host microbiota.

---

## Toxicological Assessment Strategy

Demonstrating safety and efficacy remains a prerequisite for all new medicinal product development, as well as determining an optimal dose and dosing regimen using nonclinical studies. The goals of nonclinical development as regard to microbiome-based products are the same, and so the strategy for demonstrating a positive outcome should be specifically tailored to the microbiome medicinal product. Using commensal bacteria is not an evidence per se of their safety, yet. The stakes are even higher for LBPs based on genetically modified bacteria or for therapies using phages to selectively re-program patient's targeted bacteria strain. The bacteria could be modified *ex vivo* through classic genetic engineering, or by the use of a new process involving clustered regularly interspaced short palindromic repeats (CRISPRs) and CRISPR-associated Cas proteins (Hamilton et al. 2019; Munck et al. 2020; Ramachandran and Bikard 2019). These genetically modified organisms (GMO) are usually designed to either selectively modify or eliminate members of the patient microbiota. Phage therapies implement bacteriophage (i.e., bacteria-specific viruses) natural competence to selectively target and kill bacteria and are aimed to be an alternative approach to the use of antibiotics (Paule et al. 2018; Divya Ganeshan and Hosseinidoust 2019; Vitetta et al. 2018). The sponsor needs to ensure the lack of toxicological effects of LBPs toward the patient both at local and systemic levels, and toward patient's microbiota to ensure a selective and controlled action. Of note, sponsors will also have to investigate risks associated to the propagation of the GMOs in the environment.

Toxicology assessment will have to focus both on the potential adverse effects of the microorganisms themselves and of the molecules derived from these microorganisms. Bacterial molecules (e.g., proteins or polysaccharides, lysates), surface molecules (e.g., surface markers, capsid proteins), or secreted molecules (e.g., proteins including but not limited to toxins and polysaccharides) could in fact have a direct or indirect impact on patient health. Therefore, the nonclinical strategy could then be compared to the strategy used to demonstrate safety and efficacy of cell and gene therapies. The sponsor will need to demonstrate safety of their microbiome-

based product and investigate pharmacokinetic (biodistribution, colonization, and elimination/shedding) and toxicology effects on the patient and his/her microbiota. Therefore, the choice of using one or two species (rodent and nonrodent) will also rely on which toxicological effect needs to be investigated. The guideline ICH M3R (2) will apply for products composed of molecules of bacteria or phage origin (secreted molecules or lysates) (ICH M3(R2) 2009). In the case of LBP, toxicology assessment strategy could be compared to what is done for cell and gene therapy products (see ► [Chap. 96, “Toxicological Aspects in the Regulation of Gene Therapy Medicinal Products”](#)). Given the large variety of microbiome-based products and targets, the toxicological assessment will have to be considered on a case-by-case basis. For instance, a sponsor developing bacteria-derived proteins will not investigate their toxicological potential for developing a LBP; nor would products aiming to eradicate bacteria be assessed the same way as products aiming to restore microbiota symbiosis.

## Distribution, Biodistribution, and Colonization

Even if not part of the toxicological assessment *per se*, distribution (of secreted molecules), biodistribution, and colonization/engraftment should be investigated as often correlated to potential toxicological effects. This is even more important when investigating LBPs which are usually aimed for long lasting effects to restore population balance in the patient microbiota. Therefore, the sponsor should ensure that these microorganisms reach the target site/organ appropriately and does not migrate to undesired sites. Their persistence should also be evaluated as these bacteria should accordingly colonize the targeted area but not over-proliferate within the host or in the environment.

## Immunogenicity/Immunotoxicity

All microbiome-based products may have a potential toward a drastic immunologic impact by different paths: they may elicit a host immune response toward bacterial molecules; they may also affect host immune system by altering host reactions; and/or they may affect the immune system by jeopardizing the patient homeostasis.

Gut microbiota are known to play a key role in the maintenance of homeostasis and health (Buret et al. 2019; Crespo-Piazuelo et al. 2018; Kostic et al. 2013; Martín et al. 2016; Vitetta et al. 2018). Same ascertainments have been made with other epithelium-associated microbiota such as skin (Johnson et al. 2018; Muszer et al. 2015; Nakamizo et al. 2015), oral (Solbiati and Frias-Lopez 2018), and vaginal (Chen et al. 2018; Nugeyre et al. 2019) microbiota. Clinical data suggest that probiotics and prebiotics may have immunomodulating capabilities by altering the intestinal microbial populations and tempering the activity of some resident bacteria (termed pathobionts) which have the potential to cause disease.

## Genotoxicity and Tumorigenicity

Genotoxicity and tumorigenicity potential assessment are expected for pharmaceutical products, even more so when the product itself has been genetically modified. Sponsors need to investigate the capability of their product to modify and/or damage the patient cell DNA by various mechanisms. However, developers of microbiome-based products are confronted with the lack of transposition of the standard regulatory guidelines for pharmaceuticals (ICH S2(R1) 2011) or for biotechnology-derived pharmaceuticals (ICH S6(R1) 2011). The requirement of genotoxicity and tumorigenicity studies may be waived if sponsors can demonstrate that tumor development, if any, cannot be correlated to microbiome products and/or associated secreted molecules during any of the pharmacology or toxicology studies. Hence for ATMPs, genotoxicity and tumorigenicity will be assessed on a case-by-case basis. However, carcinogenesis can be triggered by specific bacterial pathogens. For example, *Helicobacter pylori* (*H. pylori*) can develop gastric cancer in infected patients (Li and Perez Perez 2018; Tibbs et al. 2019; Francescone et al. 2014). *H. pylori* and other bacteria can also induce chronic inflammation and an associated increase in reactive oxygen species (ROS)-mediated genotoxicity (Tibbs et al. 2019; Francescone et al. 2014). Therefore, the investigation of both genotoxicity and tumorigenicity will be probably requested by the regulatory agencies, and sponsors are therefore expected to propose a nonclinical plan based on their product specific features and as appropriate for the intended clinical use (FDA 2016b). Methods to assess genotoxicity could eventually be transposed and adapted to microbiome-based products, with appropriate controls to be included to validate such assays (Federici et al. 2017; González Pereyra et al. 2014; Endres et al. 2009).

## Reprotoxicity

As for cell and gene therapies, reprotoxicity studies should be determined using a risk-based approach. Reprotoxicity risks could be identified from the intrinsic nature of the product, from preliminary findings on reproductive organ analysis, from the pharmacology and toxicology studies, and from the route of administration (e.g., vagina, urinary tract) (ICH M3(R2) 2009; ICH S5(R2) 2005). Reprotoxicity studies may then be deemed necessary. Of note, the guideline ICH S5 is currently under revision (ICH S5(R3)) since 2015, but it still does not take into consideration evaluation specific to microbiome-based medicinal products neither to cellular nor gene therapies, nor tissue-engineered products (ICH S5(R3) 2020).

The appropriate time-course should be established on a case-by-case basis and the assessment revisited throughout the development of the product. Endres et al. chose, for example, to investigate their LBP through combined overall toxicology assessment and reprotoxicity assessment (Endres et al. 2009; Endres et al. 2011). The requirement for reproductive toxicity studies may be waived if sponsors can demonstrate that the microbiome products and/or associated secreted molecules do not distribute in the gonads.

The relevance of such studies should be discussed early in the development with the agencies, and a follow-up discussion may eventually be needed depending on the nonclinical results collected prior the clinical phases.

## **New Nonclinical / Clinical Approach: In Silico Modeling and Simulation**

While new nonclinical models have been established to better understand the microbiome and develop microbiome-based medicinal products, *in silico* (meaning done with a computer) modeling and simulation (M&S) methods (Rousseau et al. 2019) have demonstrated to complement nonclinical and clinical studies. Historically, M&S was limited to early stage research analyses, to support medical device development, or to physiologically based pharmacokinetic modeling (PBPK) applied to small molecule development. However, in the past few years, developers as well as the agencies have started to acknowledge the potential of M&S contributing to product development by providing a new type of evidence: the digital evidence. Like microbiome science, M&S use is an emerging field for which the regulatory framework is currently being built. They will among other things support the development of applications to manipulate microbiome (OECD 2017). Nevertheless, researchers have already identified the potential use of M&S applied to the microbiome field (Moorthy and Eberl 2017; Borenstein 2012; Bauer and Thiele 2018; Greenhalgh et al. 2019; Michelini et al. 2018). Moorthy et al. proposed an *in silico* platform to investigate host microbiome, its interactions, and its role on the host health (Moorthy and Eberl 2017). Other research teams also developed M&S strategies to explore microbiome impact on immune system and even identify personalized microbiota (Bauer and Thiele 2018; Michelini et al. 2018).

In summary, conducting a toxicology assessment of microbiome-based products will most likely require sponsors to combine multiple nonclinical models, best determined based on each model's limitations.

---

## **Bench to Bedside Translation**

Translation challenges between nonclinical models and the human situation are acknowledged (OECD 2017). However, with the rise of microbiome-based medicinal products, new nonclinical models have been developed, as described in Table 1. Sponsors can therefore identify appropriate nonclinical model(s) from a panel of models to investigate their microbiome-based medicinal product. As mentioned in section “[Stakes and Hurdles of the Toxicological Assessment of Microbiome Products](#),” germ-free and gnotobiotic models offer broad possibilities to investigate various microbiome populations (Kennedy et al. 2018; Kittana et al. 2018; Lavin et al. 2018; Vlasova et al. 2018).

Microbiome-based products aim to modify/interact with the patient's microbiota and, therefore, are not designed to act toward the patient's cells/tissues.

Their action is indirect on the patient and contributes to modifying or eliminating target members of the patient's microbiome community. This paradox epitomizes the difficulty in classifying these products into a regulatory framework. Since they may be genetically modified microorganisms or perhaps, they might lead to genetic modification of the patient's microbiota, should they therefore be considered as gene therapies? By the same token, when products consist of selected bacteria populations aimed to colonize patients' tissues, would those products thus be considered cell therapies?

To optimize the bench to bedside translation, sponsors should consider an integrated approach with regards to the Chemistry, Manufacturing, Controls (CMC), and nonclinical and clinical development as this will directly impact non-clinical outcomes and their relevance toward the expected human outcomes.

---

## Conclusions

Microbiome-based products, as all health-care products, have to demonstrate that their quality, safety, and efficacy fit their intended use. Due to their large variety and mode of action, the nonclinical to clinical translation for microbiome-based products provides specific development challenges not typically encountered with other types of regulated healthcare products. This fact is also reflected in the difficulty for regulators and developers to classify them. Given the products' intrinsic features, nonclinical studies, and especially the toxicology assessment, should be tailored following a case-by-case approach. This can be supported by a vast spectrum of microbiome-adapted nonclinical models already well-developed and constantly improving.

Despite an increasing interest for such products, the regulatory framework is currently evolving alongside knowledge, with regulatory agencies and developers working in conjunction to build this regulatory framework (see also ► [Chaps. 39, "Biomolecules Versus Smaller Chemicals in Toxicology: ICH, EU, and US Recommendations,"](#) and ► [96, "Toxicological Aspects in the Regulation of Gene Therapy Medicinal Products"](#)). Therefore, it is of utmost interest for sponsors to reach out to regulatory agencies early on and during development to evaluate together the fitness and robustness of any proposed nonclinical and clinical development plans.

## Abstract

The safety of Gene Therapy Medicinal Product (GTMPs) is of paramount importance. Therefore, the European Medicines Agency (EMA), the US Food and Drug Administration (FDA), and other agencies in the world have issued regulatory guidelines/guidance. Nevertheless, as the field is evolving so fast and safer vectors being developed, a continuous adaptation of the regulation is needed, and not surprisingly, some nonclinical requirements deemed necessary only a few years ago (such as assessing the tumorigenicity of GTMPs *in vivo*), may appear less relevant today. As any GTMP has its own specificities, a “one-size fits all” toxicology development program cannot be routinely imposed by competent authorities. Rather, a scientifically driven and tailored approach, considering the choice of the delivery vector, the gene to be corrected, and the expected benefit/risk for the targeted indication is recommended for each GTMP. It is advised to present and discuss the development strategy early to regulatory agencies to agree upon the most appropriate design of the nonclinical studies to be conducted.

This chapter informs sponsors on the putative toxicological requirements for their specific GTMP. A review of the evolving regulatory toxicology landscape is provided, for both the EU and USA. To capitalize from the lessons learned from the past to illustrate potential toxicological requirements for new therapies, a benchmark of toxicology studies performed with the eight GTMPs approved by December 31, 2019, in the EU and/or USA is presented.

A hypothesis on the future regulation for the toxicological assessment of GTMPs is provided in the conclusion.

## Introduction

For those old enough to remember the limits of our phones and computers commercialized in the seventies, a parallel can be made to illustrate what is happening in the gene therapy arena: these technologies evolved remarkably during the last decades and both will undoubtedly continue to progress at increasing speed. Therefore, the safety for humans of gene therapies is mandatory, and regulatory agencies need to

adapt to continuous changes. Importantly, the standard regulatory guidelines applicable to, for example, “Pharmaceuticals” (i.e., ICH M3(R2) 2009) or “Biopharmaceuticals” (ICH S6(R1) 2011) cannot be fully transposed to gene therapies. For example, one major difference between GTMPs and conventional small molecule pharmaceuticals or other biological products is that once a GTMP has been administered it can be difficult to discontinue the effect of the expressed corrected protein or enzyme, especially when using integrative vectors.

Historically, it was only in 1990 that the first gene therapy trial approved by the US Federal Drug Administration (FDA) was launched when a four-year-old girl, named Ashanthi DeSilva, underwent a 12-day treatment for a rare genetic disease known as severe combined immunodeficiency (SCID) (Gruntman and Flotte 2018). This patient lacked the enzyme adenosine deaminase (ADA), a key enzyme for immune cells, and was successfully treated. Initial successes were however tempered by some abrupt but necessary slow-downs, for example, in 1999 after the death of an 18-year-old boy suffering from ornithine transcarbamylase deficiency (the patient experienced a severe immune reaction to the vector, (Sibbald 2001)), or when insertional oncogenesis was found in four young SCID-X1 patients and resulted in T cell leukemia after gene transfer of IL2R $\gamma$  via a Moloney murine leukemia virus (MoLV)-based gamma-retroviral vector into Hematopoietic Stem Cells (HSC) (Hacein-Bey-Abina et al. 2008; Couzin and Kaiser 2005).

These serious warnings allowed the emergence of safer vectors and improved techniques. Promising tools such as Clustered Regularly Interspaced Short Palindromic Repeats/Caspase 9 (CRISPR/Cas9)-based therapies are emerging, which not simply allow to incorporate a corrected gene into human cells, but also to replace a mutated “diseased” gene with its “healthy” counterpart. Thus, in 2019, the FDA has received more than 800 active Investigational New Drug (IND) applications involving GTMPs. At least eight gene therapies are currently approved between EU and USA (and four other in China, Philippines, and Russia), and it is extrapolated that 40 gene therapies should be approved by 2022 (Elverum and Whitman 2019).

---

## Main Gene Therapies and Associated Technologies

A series of definitions is provided in section “[Definitions and Associated Tests and Assays](#)” of this chapter for further guidance.

### Main Vectors for Gene Therapies (With or Without Ex Vivo Modified Cells)

Gene therapies can be achieved using genome nonintegrative or integrative approaches, with viral or nonviral vectors. The focus of this chapter is mainly on viral vectors. These vectors play a dual role in the context of gene therapies: either directly acting on the host genome or acting as delivery tools for gene editing systems (such as Clustered Regularly Interspaced Palindromic Repeats (CRISPR)/Cas9).

Gene therapies always involve the insertion of a correct copy of (at least) a defective gene, or a modification of a gene by correcting a mutation, or the inactivation of a gene. GTMPs in general aim to restore or inactivate (a) gene function(s) as cause of pathogenic symptoms. Gene therapies *sensus stricto* include (1) therapies in which the treatment consists of direct administration of only the vector containing the gene(s) of interest (i.e., without cells), and (2) gene-modified cell therapies (i.e., with cells, either from autologous or allogenic origin) in which target cells are modified *ex vivo*) using the vector containing the gene(s) of interest and then administered to the patient.

In any case, the transgenic expression should be sufficient in terms of level and duration to definitively correct the targeted disease. An ideal vector should be nonimmunogenic and safe and deliver the desired gene to a specific cell type or tissue. The benefit/risk balance of both nonintegrative or integrative (in the human genome) approaches and the associated gene transfer vectors (and technologies) need to be considered according to the planned clinical indication and the patients' population, taking into account previous knowledge and the safety assessments already reported in animals and humans with related vectors (and technologies).

Ideal vectors should be able to transport large therapeutic genes and achieve high transduction efficiency (Goswami et al. 2019). They should provide long-term and stable expression, as well as target specific cells and/organs, avoid random insertion of the therapeutic gene into the host genome, and modify mitotic as well as postmitotic cells. It should not be immunogenic nor pathogenic, nor cause inflammation and should possess the ability to be manufactured on a large scale.

The main advanced vectors for gene therapy can be grouped in the major classes shown in Table 1: plasmids and viral vectors derived from genetically modified natural viruses. The two main viral vector families currently used for gene therapy in clinical studies are recombinant adeno-associated viruses (rAAV) and retroviral/lentiviral vectors.

## Plasmids and Virus-Derived Vectors Overview

### Plasmids

Plasmids are closed, circular DNA strands and can be inserted directly into targeted tissues as naked-DNA, where they remain within the nucleus, thus limiting the risk of insertional mutagenesis. Since 1990s, the use of plasmids as nonviral (bacterial) vectors for gene delivery has been recognized (Wolff et al. 1990). A diversity of physical and chemical methods including for instance needles, electroporation, gene guns, ultrasounds, photoporation, magnetofection, hydroporation, mechanical massage, lipid, calcium phosphate, silica, and gold nanoparticles can be used to deliver the genetic material to target cells. Nonviral vectors such as plasmids also allow to select almost unlimited transgene size.

Because of their improved safety profile compared to viral vectors, plasmids have been widely tested in human clinical trials (Hardee et al. 2017). As they are poorly immunogenic, they can be administered via a dose-repeated regimen.

**Table 1** Overview of main vectors, associated features, and toxicological concerns

Gene therapy vectors	Structure/integration	Number of clinical trials	Pros	Cons
<b>Plasmids</b>	Circular DNA Nonintegrative, remain episomal in the nucleus	260 <sup>a</sup>	Less immunogenic than viral vectors Repeat administrations possible Can accept larger transgenes than rAAV and LV	Plasmids can be diluted during cell proliferation Low delivery efficiency requiring methods that may impact DNA integrity Risks of genome integration
<b>rAAV</b>	Single stranded DNA + capsid Considered as nonintegrative, the majority of AAV DNA remain episomal in the nucleus	202 AAV <sup>a</sup> + 49 rAAV <sup>a</sup>	Generally recognized as nonpathogenic and less immunogenic than other viral vectors (e.g., lentiviral vectors) Robust stability (i.e., shelf-life, little or no loss of activity with wide temperature and pH changes) <b>Tissue specificity (which may vary among species) can be achieved by selecting appropriate capsid sequence(s)</b> <b>AAV-1:</b> preferred tropism for neuronal, cardiac, and skeletal muscle cells in various animal models Used in 12 clinical trials (up to Feb 2020) and <b>for approved gene therapy Glybera</b> <b>AAV-2:</b> broad specificity Used in 63 clinical trials (up to Feb 2020) and <b>for approved gene therapy Luxturna</b> <b>AAV-5:</b> preferred tropism for airway, retinal receptors, pigmented epithelium, and CNS Used in 9 clinical trials (up to Feb 2020) <b>AAV-6:</b> Preferred tropism for skeletal muscle and lung <b>AAV-8:</b> preferred tropism for liver, heart, skeletal muscle, and pancreas Used in 20 clinical trials (up to Feb 2020) <b>AAV-9:</b> Preferred tropism for liver, heart and skeletal muscle,	Limited DNA size that can be inserted (generally 4.7 kb) Diluted during cell proliferation Preferred tropism of AAV may be species-dependent <b>Potential safety issues:</b> AAV's targeting liver may lead to hepatotoxicity Rare events of vector integration with a preference for sites close to active genes, ribosomal DNA, and CpG sequences Immunogenicity could be detected (preexisting immunogenicity to former AVV infection) AAV correlated with potential ocular toxicity ( <b>mainly AAV-2 and AAV-8</b> )

(continued)

Table 1 (continued)

Gene therapy vectors	Structure/integration	Number of clinical trials	Pros	Cons
<b>Lentiviral Vectors</b>	Double strand RNA + capsid + envelope Integrative at nontargeted site in the genome	198 lentiviral vector <sup>a</sup> + 87 labeled as retroviral vector <sup>a</sup>	<p>spinal cord, and brain</p> <p>Used in 9 clinical trials (up to Feb 2020)</p> <p>High efficiency of transduction on broad cell-types. Can accept transgenes above 4.7 kb (rAAV limit), however the transduction efficacy decreases with size</p> <p><b>1st Generation:</b> The vesicular stomatitis virus G protein (VSV-G) improves the stability and broadens the cellular tropism of the viral particles produced</p> <p><b>2nd Generation:</b> HIV accessory proteins not essential to the production of the LV particle have been removed. The lentiviral genes are split across at least three plasmids. The risk of generating RCL is lower</p> <p><b>3rd Generation (and Beyond):</b> Currently, the third-generation lentiviral vector system offers the best safety profile in terms of RCL generation because this vector requires only three HIV-1 genes (out of 9) (gag, pol, and rev) for production. The plasmid encoding the gene of interest contains lentiviral LTR sequences that have been altered to be self-inactivating (SIN) to prevent recombination.</p> <p>Effective delivery of genetic material and maintenance of long-term stable expression in target cells, delivery of larger amounts of genetic material than other methods, do not cause an inflammatory response in the recipient</p> <p><b>Used in approved gene therapies: Kymriah and Zynteglo</b></p>	<p>Potential risk of insertional mutagenesis (tumorigenesis), immunogenicity towards envelope protein limits repeat-dose administration</p> <p><b>1st Generation:</b> potential risk for the generation of Replication Competent Lentiviruses (RCL) especially if HIV positive human cell are used at the clinical stage. Potential risk of tumorigenesis</p> <p><b>2nd Generation:</b> Still extra-care is needed when working with proto-oncogenes or with human samples that have not been tested for HIV.</p> <p><b>3rd Generation (and Beyond):</b> Recognized safe for clinical development. However, as “Risk zero” level is impossible to achieve, decisions to treat patients should be based on reasonable benefit/risk considerations</p>

<sup>a</sup>Numbers of clinical trials identified on [www.clinicaltrials.gov](http://www.clinicaltrials.gov) consulted February 14, 2020

### Recombinant AAV Vectors

It is important to highlight that single-stranded DNA AAV (adeno-associated viral vectors) should not be confused with adenoviruses (double-stranded DNA), which resulted in the death of a patient who suffered from ornithine transcarbamylase deficiency, a rare X-linked genetic disease leading to metabolic disorder, during a gene therapy clinical trial in 1999 (Sibbald 2001). Indeed, despite the similarity in name, AAVs are fundamentally different from adenoviruses.

The amino acid sequence of the viral capsid proteins determines the serotype of AAV. Thirteen different AAV serotypes have been identified, which differ in their tropism and hence the target organ, tissue, or cell type (Srivastava 2016). This feature can be used to develop organ/tissue/cell type-specific gene therapy to control the delivery of the therapy after administration, limiting the risk of toxicity for an off-target organ/tissue/cell, as summarized in Table 1. To achieve such a broad tropism, AAVs require the expression of heparin sulfate proteoglycan, avb5 integrin, a5b1 integrin, fibroblast growth factor receptor 1, platelet-derived growth factor receptor, hepatocyte growth factor receptor, epidermal growth factor receptor, laminin receptor, and/or sialic acid moieties on the surface of target cells for efficient transduction and delivery (Goswami et al. 2019).

### Retroviral/Lentiviral Vectors

Retroviral vectors developed for gene therapy were initially derived from Moloney Murine Leukemia Virus (MoMLV). Viral particles were produced based on a two plasmids system: (1) the packaging plasmid containing the viral structural genes (*gag*, *pol*, *tat*, *rev*, and *env*), (2) the plasmid containing the target gene of interest and the sequence necessary to encapsulate the target gene into viral particles (Psi signal).

Retroviral vectors derive from RNA genome viruses and integrate permanently into the human genome via a reverse transcription mechanism. A delivered gene persists overtime and propagates through cell replication. Lentiviral vectors derived from Human Immunodeficiency Virus (HIV) belong to the family of retroviruses. A lentiviral vector can target broader cell types and therefore is considered as interesting tools for the development of gene therapy.

Efficacy of retroviral vectors in clinic has been demonstrated for ex vivo gene therapy in hematological diseases (Nienhuis 2013). Indeed, lentiviral vectors are considered as a tool of choice to develop gene therapy to target hematopoietic stem cells (HSC) (Morgan et al. 2017; White et al. 2017).

Despite leukemia being reported in patients treated with a retroviral vector for X-linked SCID (Hacein-Bey-Abina et al. 2008) and Wiskott-Aldrich syndromes (Braun et al. 2014), in 2016 the EMA granted its approval to Strimvelis<sup>®</sup>, a retrovirus expressing the Adenosine Deaminase (ADA) protein, for the treatment of ADA deficiency-associated SCID disease (Aiuti et al. 2017; Stirnadel-Farrant et al. 2018). The toxicology approach conducted with Strimvelis<sup>®</sup> is summarized in Table 2.

## CRISPR/Cas9 Technology

Recently new perspectives emerged with the development of genome editing tools such as CRISPR/Cas9 system. Genome editing offers a much more precise technology for altering genes. CRISPR/Cas9 is a genome editing technology developed to quickly, easily, and accurately correct gene mutation and to turn on or off gene function (Hsu et al. 2014; Estêvão et al. 2018). While CRISPR/Cas9 has mainly been studied in animals for the development of human disease models, it presents many potential human applications (Mokbel and Mokbel 2017), offering new perspective of gene therapy development to treat genetic disorders caused by single mutation, by deleting or inserting gene sequences.

CRISPR/Cas9 system is a prokaryotic enzymatic machinery that is reconstituted in mammalian cells using two essential components: (1) Cas9 (CRISPR-associated protein 9), an endonuclease that cuts DNA in a sequence-specific manner using (2) a single-guide (sg) RNA with a sequence that matches the target gene (Hsu et al. 2014). The resulting DNA double strand break (DSB) is then repaired by the DNA repair machinery. The genomic region is disrupted, and gene corrected for gain or loss of function. Plasmids containing the sequence of sgRNA and of *cas9* gene are usually used to deliver CRISPR/Cas9 tool within cells, although Cas9 protein can be delivered directly.

The current human clinical trials with CRISPR/Cas9 gene therapy are all at early stage, in three main areas: cancers, blood disorders and eye disease. The first, still ongoing US-based clinical trial uses *ex vivo* CRISPR/Cas9 technology (NCT03399448, (Baylis and McLeod 2017)) for the engineering of immunotherapy (e.g., CAR T-cells therapy). Cells from patients are transfected *in vitro* with plasmids encoding for sg RNA and Cas9 protein (or Cas9 protein directly delivered). *Ex vivo* genome editing enables to control that only targeted patient cells are in contact with the genome editing tool prior to being administered intravenously.

---

## Toxicological Aspects in the Regulation of GTMPs

Both the European Union (EU) and the United States (US) agencies have adopted guidance specific to gene therapy medicinal products. GTMPs include a broad variety of products including but not limited to plasmid DNA, viral and nonviral vectors, genetically modified viruses or cells that are developed for treatment or prevention of a variety of human diseases. EMA and FDA guidance has therefore evolved as scientific knowledge and experience have grown alongside of new therapies being developed. Indeed, product-specific and scientifically based deviations from established classical guidelines (initially implemented for small molecules) are increasingly needed to address the nonclinical development of innovative gene therapies.

In this rapidly evolving arena, the European Medicines Agency (EMA) has lately updated a guidance released in 1999 on the quality, nonclinical, and clinical aspects of gene therapy medicinal products for the purpose of Market Authorization

Application (MAA) (EMA 2019a). The FDA has recently published a draft guidance on interpreting the sameness of gene therapies under the orphan drug regulations (FDA 2020a), and several guidance documents specific to gene therapies in regards to Chemistry, Manufacturing, and Control (CMC) aspects relevant to gene therapies (FDA 2020b, f) and for various clinical indications such as hemophilia (FDA 2020c), retinal disorders (FDA 2020e), or “rare diseases” (FDA 2020d).

Though some differences exist between the EU and US guidelines, the approach is quite similar in the sense that a risk-based approach should be followed for the elaboration of the nonclinical and clinical development plan of GTMPs (EMA 2013a; FDA 2006). The extent of the toxicity studies as well as their design should be based on the vector selected (integrative; nonintegrative and discussion around the possibility of random integration; replication competent virus formation and insertional mutagenesis); preexisting data with similar vector backbone; use of cells modified *ex vivo*; route of administration; as well as dose/dosing regimen and number of administrations (e.g., discussion around the safety margin; repeat dose or not); indication targeted and the expected mode of action.

## General Toxicology

As a consequence of the human specificity of GTMPs, selecting nonclinical appropriate model(s) responding similarly to the human system is a true challenge and of utmost importance. In this context, both the EMA and FDA concur that the use of nonrelevant test systems and animal models (healthy or diseased, wild type or immunocompromised) should be avoided as this could lead to the wrong appraisal of the expected benefit/risk for patients. Since clinical trials (including first-in-human studies) with GTMPs are conducted in patients and not in healthy volunteers, the use, when available, of an animal model of disease for the safety evaluation of the therapy appears appropriate and can be recommended, as diseased animals may be closer to the patients expected to receive the gene therapy than wild-type animals. When possible, sponsors are even encouraged, in observance of the *3Rs* principle (Reduce/Refine/Replace), to optimize *in vivo* studies allowing extraction of multiple data (pharmacodynamics/biodistribution/toxicity) from a reasonable number of animals. In this context it is worth to mention that, in contrast to what is usually performed for the development of small molecules, it is not necessary to perform the toxicity studies in two different species (one rodent and one nonrodent). Usually rodents, that is, mice (or rat, more rarely), often immunocompromised NSG (NOD scid gamma) mice lacking mature T cells, B cells, and natural killer (NK) cells are selected to avoid rejection of human cells. In the facts it is rare to collect data for GTMPs in dogs or monkeys (one noticeable exception is Luxturna<sup>®</sup>, approved in 2018 and in 2017 in the EU and USA, respectively).

Although toxicity studies must be compliant with Good Laboratory Practices (GLP) and standards according to 21 CFR Part 58 and the WHO Handbook for Good Laboratory Practice, the regulators recognize that it may be difficult in some circumstances to perform all assessments under GLP compliance (e.g., disease

animal models are usually not available in GLP facilities) (World Health Organization 2009). When deviations are unavoidable, they should be properly justified in the dossier, including the impact on the data generated and conclusions. The EMA has released a short memo on GLP and Advanced Therapeutic Medicinal Products (ATMP) development (EMA 2017).

For nonclinical studies and more importantly for toxicity assessment, the investigational product used should be representative of the one that will be used in clinic (though not necessarily of Good Manufacturing Practices (GMP) grade); comparability/bridging studies are usually strongly advised to help the evaluation of its “representativeness” (FDA 2013). The product used in the toxicity study should have the same “potency” (biological activity) than the one to be used in clinic and should bare the same quality attributes as well as impurity profile. A specific paragraph on that matter is included in both the FDA guidance on nonclinical assessment of investigational cellular and GTMPs and on the EMA guideline on ATMPs, for the purpose of marketing application and investigational ATMPs. The EMA has also published in 2011 a reflection paper on modifications of GTMPs during development to share its views on potential impact of any changes in the development including nonclinical plan (EMA 2011). If a competent authority has any doubt regarding the comparability of the product used in the toxicity studies and the clinical batch, it may ask the developer to repeat the toxicity studies with a more representative batch. Hence, in case of doubt, it is strongly advised to seek advice from regulatory agencies before performing the GLP-compliant study.

The toxicity evaluation, as part of these studies, should assess local and systemic potential toxicity of the gene therapy and should be tailored to the intended clinical product. The use of the same animal model in both toxicology investigations and pharmacokinetics (biodistribution) studies is recommended, in particular when vector-related toxicity signals are observed (EMA 2018a). It is essential to emphasize that, for such product, the usual (expected) biological effect(s) and clinical benefit(s) are most likely on the long-term (lifelong). Hence, the duration of the general toxicity studies for gene therapies may be longer than for other investigational medicinal products, considering that usually only a single administration of the gene therapy is performed. However, when more than one administration is envisaged in humans, the number and timing of administrations in animals should at least be equal to and be representative of the intended clinical regimen. Also, it is acknowledged that usually the Maximum Feasible Dose (MFD) should be assessed during the toxicological evaluation, unless appropriately justified.

## **Biodistribution**

Classical Absorption-Distribution-Metabolism-Elimination (ADME) studies are not appropriate for GTMPs; however, the assessment of the biodistribution and potential shedding of the vector are expected. Biodistribution is not considered as part of the toxicology program of a gene therapy per se but is often linked to it. Biodistribution studies are most of the time mandatory for GTMPs, prior to the First-in-Human

administration, especially in the case of a novel backbone, change in the route of administration or significant change in the formulation as well as change in the dose/dose regimen (FDA 2013). The route of administration as well as the dose (including an appropriate safety margin that should be discussed with the Competent Authorities) and dose regimen should mimic as closely as possible the proposed clinical use. As stated in the Guideline on the quality, nonclinical, and clinical aspects of gene therapy medicinal (EMA 2018a), in addition to the proposed clinical route, it is sometimes useful to evaluate the maximum exposure via a systemic route of administration (e.g., intravenous in the case of an intramuscular administration).

Importantly for the future, ICH has released in November 2019 a concept paper for a new guidance, S12: Nonclinical Biodistribution Considerations for GTMPs. The objectives of this future guidance are to provide harmonization in the regions covered by the ICH on the definition of biodistribution; the need for and timing of the conduct of such studies as well as information on the methodologies and the data needed to justify the selection of most relevant species for pharmacology and safety studies; finally, discussion on the interpretation of the biodistribution data for clinical study design will be included. This guidance is expected to be released by 2023.

In addition to the regulatory texts, the readers are invited to consult a very informative review, presenting an EU perspective (Silva Lima and Videira 2018). To decrease the number of animals during the development, it may be useful and relevant to combine toxicity studies with biodistribution and shedding in accordance to the 3R's principle. This would also ease the assessment of the causality of any toxicity to the product.

Biodistribution is usually assessed by administering the GTMPs either in healthy animals, or in immunocompromised mice (e.g., NSG mice), or in an animal model of the disease (depending on model availability; and potential "impact" of the condition on the biodistribution). The animals (males and females) are sacrificed at different time points; organs and tissues sampled and prepared for qPCR specific to the vector or more generally to nucleic acid hybridization techniques (NAT). It is usually recommended to have at least two time-points (in NSG mice, the latest time point is frequently measured 4 months after the administration of the GTMP) demonstrating clearance or plateau of the distribution to be able to conclude.

Vector shedding (in the body fluids) is an important feature to assess during the development, especially in the case of a new vector construct (where it is strongly recommended to generate data prior to the first administration to human). Results of shedding studies will indeed have consequences on the clinical development to define the containment level in the clinical settings and the procedures for preparation, administration then waste management as well as the associated safety measures. Shedding can be evaluated along biodistribution (i.e., distribution of the gene therapy within the body) or toxicity studies, to avoid using specific animals for that matter in agreement with the 3R's principle. As for other evaluations, relevance of shedding studies and when these should be performed should be assessed on a case-by-case basis (*c.f.* EMA guidelines on (investigational) ATMPs (EMA 2018a, 2019a)).

For shedding studies, body fluids and/or excreta are collected at specific timepoints then typically quantitative (RT-)PCR or droplet digital PCR (ddPCR) being more sensitive can be performed to quantify the amount of vector present.

As regards the genomic distribution, it is crucial to assess the potential risks associated with the use of a defined vector, especially in the case of a new vector construct. To do so, integration site analysis is usually performed following *in vivo* administration of the gene therapy and sampling and preparation of DNA samples that are then digested and run through linear amplification mediated (LAM)-PCR.

Finally, biodistribution results in the gonads are important factors in assessing probability of germline transmission, as elaborated in the EMA guidance on non-clinical testing for inadvertent germline transmission of gene transfer vectors (EMA 2006).

## Insertional Capability

Relevance of performing insertional mutagenesis evaluation should be assessed on a case-by-case basis, depending on vector type; dose to be administered (the more vector copies, the higher the probability of insertional mutagenesis); cells or organs targeted; and the transgene expressed. Of note, previous use and knowledge of the vector should also be taken into account.

The most widely used test for assessing insertional mutagenesis is the *in vitro* immortalization assay (IVIM), based on *in vitro* culture of murine bone marrow lineage depleted cells (Modlich et al. 2006). In this assay, the replating frequency of transduced cells is measured and evaluated per vector copy number.

Due to genome integration and potential insertional mutagenesis, patients treated with lentiviral vectors are followed for any emergent signs of clonal cell proliferation. In addition, recombination between lentiviral vectors and wild-type lentivirus is a safety concern due to a potential risk for the generation of Replication Competent Lentiviruses (RCL), especially if HIV positive human cells are used at the clinical stage. One assay to assess the risk consists in infecting permissive lines with the vector followed by serial passaging and then PCR of specific regions. “Ideally, the capacity of tests to detect one replication competent lentivirus in a vector dose should be proven.” The FDA has released a guidance on the testing of replication-competent retroviruses that provides detailed information, including on the methods, amount of supernatant or product to be tested, and sensitivity of the assay (FDA 2020f).

Recombinant adeno-associated viruses (rAAV) developed for gene therapy are deleted for sequences encoding viral proteins necessary for their integration in the human genome, contrary to wild-type associated adenovirus (AAV). The majority of rAAV remain episomal after transduction (Schnepp et al. 2003, 2016). Therefore, they are considered to present a good safety profile with regards to potential risk

of insertional mutagenesis and then associated genotoxicity and tumorigenicity. However, recent nonclinical data gathered in murine model suggest that rAAV could also result in insertional mutagenesis leading to genotoxicity (Chandler et al. 2017).

## Genotoxicity and Tumorigenicity

Genotoxicity remains a crucial aspect of the toxicity program for gene therapies. Such nonstandard tailored evaluations are very different from what is classically required as per (ICH S2(R1) 2011) for small molecules. GTMPs can indeed have oncogenic activity. Genotoxicity studies can be performed *in silico*, *in vitro*, *ex vivo*, and/or *in vivo* (EMA 2008). Oncogenic potential of GTMPs should in principle be evaluated first *in silico* (e.g., presence of oncogene protein sequences, or mode of action of the GTMP in the genome).

The EMA Guideline on the quality, nonclinical, and clinical aspects of GTMPs (EMA 2018a) indicates that “standard life-time rodent carcinogenicity studies are usually not required in the nonclinical development” but rather suggests that an evaluation on their relevance should be based on several parameters including the mode of action of the GTMP and previous results such as insertional mutagenesis studies, hormonal perturbation or immune suppression and other relevant red flags. This is also indicated in the draft guideline on investigational ATMPs: “The need for additional toxicity studies for instance genotoxicity, tumorigenicity, reproductive and developmental toxicity, and immunotoxicity studies should be determined on a case by case basis taking into consideration the risks related to the nature and characteristics of the particular class of ATMP and the intended clinical use” (in Guideline on quality, nonclinical, and clinical requirements for investigational advanced therapy medicinal products in clinical trials (EMA 2019a)). When deemed necessary, tumorigenicity is usually assessed *in vivo*, by administration of the investigational drug in immune-deficient animals and then monitoring of the potential appearance of mass.

In summary, if an oncogenic potential has been identified *in silico*, then tumorigenicity should be evaluated in appropriate *in vitro* and/or *in vivo* models, for example, by analyzing first the proliferative capacity of the cells, response to apoptosis stimuli and genomic modification) (EMA 2008). The extent of studies for nonintegrative vectors can be certainly less than for integrative vectors. However, some data or thorough discussion will still be required to justify at least a low probability of insertional mutagenesis and tumorigenicity events. Only when deemed necessary following positive *in vitro* positive data, then developers should test tumorigenicity *in vivo*, in, for example, immunodeficient NSG mice for GTMPs consisting of *ex vivo* transduced cells to avoid immune rejection, to measure the occurrence of leukemia/lymphoma following administration of the cells. If rare events are detected, then additional analyses are needed to rule out that they were caused by the gene therapy.

## Off-Target Toxicological Effects: Case of Genome Editing CRISPR/Cas9 System

In addition to potential immunogenicity of the delivery system and Cas9 protein, the other main safety issue when using the CRISPR/Cas9 gene-editing tool is the possibility to observe off-target effects such as genome editing in off-target site, which may cause mutagenesis in normal genes or mis-repair of DNA double-strand breaks (DSB) leading to genetic instability and formation of chromosome aberrations. Hence, the use of CRISPR/Cas9 for the development of gene therapy in biomedical and clinical application raises safety concerns associated with potential tumor development (Albertson et al. 2003).

To minimize off target effects of CRISPR/Cas9, respective optimizations are ongoing (Zhang et al. 2015) and focus on (1) Specific design of single guide (sg) RNA sequence to limit the tolerance of base pair mismatches and the recognition of nontargeted region of the genome, (2) control of the concentration of Cas9 protein and sgRNA delivered to control the level of activity and anti-Cas9 immune reaction, (3) development of mutant versions of Cas9 protein to render the nuclease function even more specific.

### Immunogenicity (Immunotoxicity)

Preexisting exposure to Cas9 protein and to viral vectors such as AAV may result in immunogenicity after a single administration of the GTMP to patients. Therefore, new in vivo nonviral delivery systems are under development to decrease immune reaction and ensure efficient transport to the target cells (Shim et al. 2017).

Whatever the type of vector selected for a GTMP, an “immuno-toxicological” assessment will be required, by checking, for example, inflammatory responses, immunogenicity, and/or autoimmunity. Immunogenicity studies for gene therapies include also as appropriate humoral and cellular immune response endpoints to measure the potential innate and adaptive immune responses to the vector itself and/or the transgene. This is particularly important in the case of repeat administration to evaluate the potential immunogenicity.

Immunogenicity is a major aspect to be evaluated. Immunogenicity could be directly related to the composition of the vector or its packaging (e.g., capsid protein, cell proteins). In the case of rAAV vectors, host reaction towards the capsid proteins needs to be evaluated. Such reaction often translates in humans into a transient elevation of the liver transaminase level, indicating a liver damage. This transient change in liver physiologic parameters is due to the host immune reaction towards the AAV capsid protein and can be managed with a steroid treatment (Colella et al. 2018). As the transduction rate with AAV constructs appears lower than obtained with lentiviral vectors, AAV doses to achieve similar levels of gene expression should be higher, and this could potentially increase the risk of immunogenicity. Of note, retroviral vectors could as well be associated to autoimmune reactions (EMA 2016).

## Reprotoxicity

Reprotoxicity should be determined by a risk-based approach. Both the US and EU guidance indicate that if deemed necessary, reprotoxicity results should be provided before confirmatory/Phase 3 studies in which usually large populations are studied. The appropriate timepoint though should be established on a case-by-case basis and the assessment revisited throughout the development of the product. For instance, if the vector and gene products does not distribute in the gonads, the requirement for reproductive toxicity studies may be waived. In the same perspective, if no biodistribution is seen in the gonads, gene transfer studies in descendant animals may not be needed).

The EMA guideline on investigational ATMP states that “*if effects on reproductive function and/or development are anticipated relevant reproductive and developmental toxicity studies should be conducted before exposing larger patient populations*” (EMA 2019a). Though some flexibility is acknowledged in the EMA guideline on gene therapies for MAA, it is at the same time clearly stated that “*Embryo-fetal and perinatal toxicity studies and germline transmission studies should be provided, unless otherwise duly justified on the basis of the type of product concerned.*” Very interestingly, the draft guideline ICH S5(R3) on Detection of Toxicity to Reproduction for Human Pharmaceuticals (currently at stage 2 of the ICH review process) indicates it does not apply to Gene Therapies (ICH S5(R3) 2017).

It is worth mentioning that the risks associated with for instance lentiviral exposures have been described at length (Schlingens et al. 2016). This author does not cite “reprotoxicity” as a potential risk. In contrast, White et al. report that the standard battery of reproductive function tests as per (ICH S5(R2) 2005) is generally not required unless otherwise highlighted by specific features of a proposed therapy (e.g., if the gene therapy is specifically targeted toward the reproductive organs) (White et al. 2017).

However, developers should also consider the risks associated for the reproductive system with the potential overexpression and specificities of their transgene(s).

---

## Translational Risks from Bench to Clinic

Over the past two decades, gene therapy *sensus stricto* and gene-modified cell therapy product development has been increasing exponentially. The alliance for Regenerative Medicine reported 362 clinical trials for each of these approaches in its 2018 Annual Report (Alliance for Regenerative Medicine 2018), most of them being in Phase 1 or Phase 2 of their clinical development. Figures went up by Q3 2019 to 370 and 418, for gene therapy and gene-modified cell therapy, respectively (Alliance for Regenerative Medicine 2019). Nevertheless, translational research faces challenges such as how to demonstrate the reliability of nonclinical models towards what could be expected in First-in-Human (FIH), assessing the dose-efficacy relationship as well as risk/benefit ratio for patients.

Some of the risks associated to GTMPs are inherent to the products themselves. Nonclinical assessment should be therefore conducted on a risk-based approach while the nonclinical development plan will have to be tailored to the product to be evaluated. Ultimately, developers will have to demonstrate to the Regulatory Agencies that sufficient nonclinical data has been collected to support moving forward into a FIH study, and minimize the risks for patients. One common misconception is that one nonclinical model will have to be THE relevant model to address all safety concerns. Such a unique model is typically not available, as the nonclinical development must be tailored and adapted to the GTMP, combining several nonclinical models. Using *in vitro*, *ex vivo*, *in vivo* models, and even *in silico* modeling and simulation enhances the chance of ensuring successful translation to clinical studies. Lastly, the proper choice of negative (and positive) controls is of course crucial to assess the relevance of the data obtained.

All agencies agree on a key crucial point: sponsors have to demonstrate the relevance of the models they chose to investigate their product(s) and define any limitations of these models. Based on our experience, establishing the scientific validity of nonclinical data supporting the transition to a First-in-Human clinical trial is clearly more challenging for GTMPs when compared to traditional small molecules. To increase chances of translation to clinical setting, nonclinical development should be performed in alignment with the clinical intended use for the target population, while considering the specificities of the CMC of the GTMP.

Limitations of nonclinical models are acknowledged, and they may lead to clinical study failures (Couzin and Kaiser 2005). Sponsors need to demonstrate to the regulatory agencies the relevance and limitations of the selected model(s) and not overestimate the translation of the collected data for the human situation.

Finally, one of the primary risks associated with GTMPs lies in the effect and impact of overexpression or absence of expression of the protein/enzyme of interest. In such cases, understanding the distribution of the vector/gene within the whole body, and not only in the targeted organ(s) or tissue(s), becomes crucial.

---

## Benchmark with Approved Gene Therapies

From public information available in the Summary Basis for Approvals (SBAs) and European Public Assessment Reports (EPARs), we identified five GTMPs approved before the end of 2019 in the USA (Imlygic<sup>®</sup>, Kymriah<sup>®</sup>, Luxturna<sup>®</sup>, Yescarta<sup>®</sup>, and Zolgensma<sup>®</sup>), and seven in the EU (Imlygic<sup>®</sup>, Strimvelis<sup>®</sup>, Kymriah<sup>®</sup>, Luxturna<sup>®</sup>, Yescarta<sup>®</sup>, Zyntenglo<sup>®</sup>, and Zolgensma<sup>®</sup>), and in addition Glybera<sup>®</sup> was approved in the EU in 2012 but has been withdrawn from the market at the marketing holder's request (Paul-Ehrlich-Institut (PEI) 2020). A tabulated summary of toxicology investigations performed on various GTMPs is presented in Table 2.

In addition, four other gene therapies (not presented in Table 2) are authorized in other regions of the World (Goswami et al. 2019): Gencicine<sup>®</sup> (Head and Neck Cancer, since 2003 in China), Oncorine<sup>®</sup> (Nasopharyngeal Carcinoma, since 2005

**Table 2** Approved gene therapies in the EU and/or USA

Approved gene therapies <sup>a</sup>	Approval year	Sponsor/applicant	Indication	Vector and enzyme expressed	Toxicology and biodistribution studies conducted
Glybera <sup>®</sup> (EMA (2012b) only)	2012 ( <i>withdrawn from the market</i> )	uniQure biopharma B.V.	Treatment to reverse lipoprotein lipase deficiency. This therapy has been voluntary withdrawn from the market by the applicant	Replication-deficient adeno-associated virus type-1 (AAV1) vector expressing the human LPL gene variant LPLS447X	Five GLP-compliant <b>biodistribution</b> studies were conducted ( <b>mice, rabbits, cats</b> ). Shedding was addressed in clinical trials <b>GLP toxicity studies</b> (IM, single dose, up to 180 days) were performed in <b>mice</b> . Different doses were tested Studies on <b>insertional mutagenesis</b> done Female mice were treated 4 weeks prior to mating to <b>asses transmission of vector DNA to fetuses</b> <b>Reproductive toxicity</b> was studied in pregnant mice <b>Local tolerance</b> as part of toxicology studies
Imlygic <sup>®</sup> (EMA 2015; FDA)	2015	Amgen Europe B.V.	Treatment of melanoma that is regionally or distantly metastatic	An attenuated nonintegrating Herpes simplex virus type-1 (HSV-1) virus coding granulocyte macrophage colony-stimulating factor (GM-CSF)	<b>Biodistribution, viral shedding</b> (urine, feces, lachrymal glands, nasal mucosa, salivary glands), and <b>replication studies</b> conducted in <b>mice</b> <b>Toxicology studies</b> (up to 5 administrations) up to 12 weeks

Treatment of Non-Hodgkin's lymphomas	Retroviral vector PG13-CD19- H3 is a murine stem cell virus (MSCV)-based vector pseudotyped with the gibbon ape leukemia virus (GaLV) envelope	<b>Biodistribution and persistence</b> of the antimurine CD19 CAR T cells evaluated in the syngeneic mouse lymphoma model using flow cytometry analysis No standard single-dose or repeat-dose toxicity studies have been conducted, however <b>on-</b> <b>target/off-tumor toxicity</b> of CD19 CAR T cells in the syngeneic mouse lymphoma model, which has been <b>evaluated during the</b> <b>pharmacology study</b> in parallel with the anti-lymphoma effect and the persistence of the anti- murine CD19 CAR T cells

Zynteglo <sup>®</sup> (EMA 2019b)	2019	Bluebird bio B.V.	Treatment of $\beta$ -thalassaemia	A 3rd generation SIN LVV encoding $\beta^{A-187Q}$ -globin	<p><b>A pivotal combined therapeutic POC, pharmacology, single-dose toxicity and genotoxicity study in the <math>\beta</math>-thalassemic mice</b></p> <p><b>PK and biodistribution of BB305 LVV-transduced human healthy donor HSCs were also evaluated in NSG mice</b></p> <p><b>Four pivotal single-dose toxicity studies (including local tolerance) in primary and secondary recipient mice</b></p> <p><b>The biodistribution and SMN transgene expression profile of AVXS-101 were evaluated in neonatal FVB mice through 12 weeks</b></p> <p><b>Single-dose toxicology studies (IV) in neonatal FVB mice</b></p>
Zolgensma <sup>®</sup> (FDA)	2019	AveXis, Inc.	Treatment of spinal muscular atrophy (SMA)	An AAV9 vector encoding Human SMN gene	

<sup>a</sup>Only as of Dec 31, 2019

in China) and Rexin-G<sup>®</sup> (Pancreatic Cancer, since 2007 in the Philippines), and Neovasculogen<sup>®</sup> (Peripheral Artery Diseases, since 2011 in Russia).

The studies conducted reflect the specificity of each of the approved GTMPs. Interestingly, reprotoxicology evaluations were performed only with Glybera<sup>®</sup> and Imlygic<sup>®</sup>, the most ancient GTMPs approved, and such investigations were not requested for the most recent GTMPs, suggesting that the regulatory appraisal by the competent authorities is taking into account the nonclinical and clinical knowledge acquired through the years.

---

## Definitions and Associated Tests and Assays

### Autologous Versus Allogenic

Autologous cell therapy is a therapeutic intervention that uses the patient cells, which are cultured and expanded outside the body, and reintroduced into the donor. In contrast, allogenic product is usually used to refer to a source material from other human donors.

### Biodistribution, Persistence, Clearance

For small molecules, classical absorption, distribution, metabolism, and excretion (ADME) studies are usually performed. These studies are not appropriate for gene therapies, for which one rather assesses the biodistribution (of the cells, vector, and expressed transgene) in relevant organs, as well as the persistence, and clearance.

### CRISPR/Cas9

The CRISPR/Cas9 technology has emerged recently as a powerful tool to perform genome editing (as analogy, one can visualize this technique as the “copy/paste” shortcuts for text editing in Word). It originates from the natural immune system of bacteria, destroying infecting viruses. Briefly, the CRISPR sequence is composed of repeat nucleotides sequences and spacers. These “blocks” of sequences originate from viruses that previously infected the host. The second member of the CRISPR/Cas9 binomial is Caspase 9, an enzyme that is usually represented as “scissors” as it cuts specific sequences of DNA. Researchers have now developing improved and safer versions of CRISPR/Cas9.

### Gene Therapy

In Europe, the definition of a gene therapy medicinal product is provided in Annex I Part IV of Directive 2001/83/EC (EMA [2012a](#)):

Gene therapy medicinal product means a biological\* medicinal product which has the following characteristics:

- (a) It contains an active substance which contains or consists of a recombinant nucleic acid used in or administered to human beings with a view to regulating, repairing, replacing, adding, or deleting a genetic sequence.
- (b) Its therapeutic, prophylactic, or diagnostic effect relates directly to the recombinant nucleic acid sequence it contains, or to the product of genetic expression of this sequence.”

\*Biological is defined in Annex I Dir 2001/83/EC: “*A biological medicinal product is a product, the active substance of which is a biological substance. A biological substance is a substance that is produced by or extracted from a biological source.*” Consequently, the manufacturing process is crucial in determining the product classification

In the USA, the definition is included in federal register vol 58 N° 197 (FDA 1993):

GTMPs are defined as products containing genetic material administered to modify or manipulate the expression of genetic material or to alter the biological properties of living cells.

Gene therapy is a medical intervention based on modification of the genetic material of living cells. Cells may be modified *ex vivo* for subsequent administration or may be altered *in vivo* by GTMPs given directly to the subject. The genetic manipulation may be intended to prevent, treat, cure, diagnose, or mitigate disease or injuries in humans.

Importantly, both the EU and US definitions of gene therapies clearly indicate that *ex vivo* modified cells that are then (re) administered to a patient are considered as gene therapy medicinal products; one example is the CAR-T cells products, now approved on both sides of the Atlantic.

## Germline Transmission

Germline transmission (known as “*inadvertent gene transfer*” in the USA) is the vertical transmission of DNA sequence to offspring, something which is still clearly prohibited as per the EU legislation. Usually, factors such as the vector type route of administration, dosing, and importantly biodistribution results in the gonads are important factors in assessing probability of germline transmission.

The EMA guideline on nonclinical testing for inadvertent germline transmission of gene transfer vectors (EMA 2006) refers to this topic.

## Insertional Mutagenesis

Insertional mutagenesis is the creation of mutations in the host genome by addition of DNA base pairs. Insertional mutagenesis that may potentially lead to oncogenesis is a recognized safety concern of integrating vector-based gene therapies. However, even

for vectors that do not efficiently integrate, such as adeno-associated vectors (AAV), plasmids, or retroviral vectors modified to avoid integrations, insertions events can be detected (though very scarcely) and the risk should still be discussed and evaluated in some circumstances (refer to the Reflection paper on management of clinical risks deriving from insertional mutagenesis released by the CAT in 2013 (EMA 2013b)).

## **Integrative Versus Nonintegrative Vectors**

Some of the vectors used in gene therapy are integrative (e.g.,  $\gamma$ -retroviral vectors and lentiviral ones), whereas others are supposed to remain extra-chromosomal (“episomal”) such as AAVs though this feature is debated. While  $\gamma$ -retroviral vectors integrate preferentially at promoters and gene 5' ends, and clustering near genes controlling cell growth and proliferation has been reported, lentiviruses integrate preferentially in transcription units, avoiding regulatory 5' regions.

## **NSG Mice**

NOD *scid* gamma mice are preferred immunodeficient animals, lacking lymphoid cells with natural killer cell activity almost inexistent. They however display normal growth and are widely used especially in the context of research on hematopoietic stem cell transplantation and/or to assess the long-term toxicological effects of, for example, genetically modified human cells in another species.

## **Replication-Competent Virus (RCV)**

A replication competent vector is a vector able to replicate. Most (if not all) of the viral vectors used in gene therapy medicinal product manufacturing or as direct administration are designed to be replication incompetent for safety purposes. For such vectors, assessment of replication-competent vectors that might have been generated during the manufacturing process or in vivo (following administration) must be performed.

## **Tumorigenicity**

Tumorigenicity should be distinguished from carcinogenicity as the former focuses on the formation of a tumor (i.e., mass of cells), whereas the latter focuses on the development of cancer; though the authors agree that both terms are often used indistinctly.

## **Vector Mobilization**

Vector mobilization is the potentiation (or “rescue”) of the gene therapy by a wild-type virus in vivo that could lead to virus (uncontrolled) spread and potentially RCV.

Optimizations in vector design have significantly decreased the probability of vector mobilization by splitting the required sequences.

## Vector Shedding

Shedding is the dissemination of the vector through secretions and or excreta of the patient (or animal) (e.g., saliva, urine, feces).

---

## Conclusion and Perspectives

To date, only 12 different somatic gene therapies against cancer, blindness, immune, and neuronal disorders were approved worldwide, including eight in Europe and the United States. To achieve MAA/BLA, each sponsor had to overcome many specific hurdles applicable to their unique GTMP and to provide a strong nonclinical dossier, with comprehensive proof-of-concept, toxicology (usually in rodent only), biodistribution, shedding, and insertional mutagenesis, and sometimes (actually only for Glybera<sup>®</sup> and Imlygic<sup>®</sup>), repro-toxicity data. With the exception of Zolgensma<sup>®</sup>, nonclinical data were collected in adult animals.

These initial approvals should pave the way for many other MAAs / BLAs, as the possibilities for GTMPs appear endless as virtually every cell in the human body is a potential target for genetic manipulation. As for more established medicinal therapies, it appears possible that in the future the nonclinical studies for GTMPs may be abridged, based on the following hypotheses:

1. Only a restricted number of vectors and techniques with well-known benefit/risk profiles will be authorized for new GTMPs (it is our view that new vectors and techniques will however still need to go through an exhaustive nonclinical assessment before being approved for gene therapies, unless otherwise justified).
2. The scientific community and regulators are collecting large amounts of relevant nonclinical and clinical data which may render some of the nonclinical investigations unnecessary (e.g., demonstration of absence of insertional mutagenesis will not be needed anymore with “approved vectors”).
3. Finally, the emergence of *in silico* virtual assessments should considerably decrease the number of “real *in vivo* studies” to be conducted.

## Abstract

In this chapter, the expertise gathered in the broad area of toxicology and its implementation into the regulatory context is illustrated using the approval process of biocidal active substances as an example.

A brief overview of the relationship between biocidal active substances and product types is given followed by a description of the biocidal active substance approval process from the regulatory point of view. The different steps as well the timelines to be observed will be explained.

With a focus on the toxicological data requirements for biocidal active substances, the upcoming revisions of Annex II of the Biocidal Products Regulations as required by the mandatory assessment of potential endocrine-disrupting properties will be illustrated. The scientific criteria as well as the challenges encountered for the identification of potential endocrine-disrupting properties will be discussed.

Following thorough assessment of the toxicological data package submitted for active substance approval, the final and most important step in the approval

---

M. Werner (✉)  
Wöllstein, Germany

process consists of the derivation of reference values for systemic and local effects, depending on the effects and nature of the active substance. Consideration is given to the need and the type of the reference values usually derived for the purpose of the risk characterization in the intended uses of biocides, i.e., acceptable exposure levels (AELs) and acceptable exposure concentrations (AECs). As one further important pillar within the scope of active substance approval, the need for an exposure assessment with regard to the intended uses of biocidal products containing the active substance and the demonstration of acceptable risks will be addressed.

**Introduction**

The broad area of toxicology and its various disciplines focus primarily on the investigation of the potential detrimental effects of natural and synthetic substances on living systems.

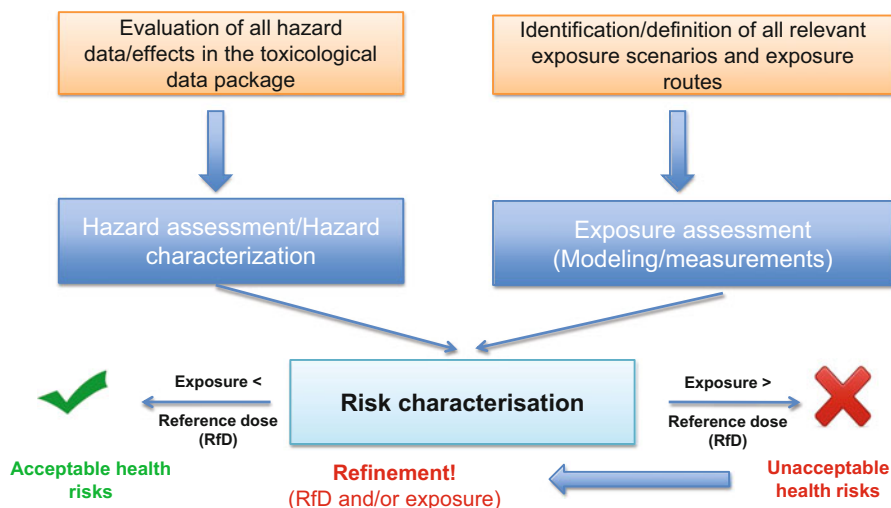

For this purpose, not only standardized studies but also studies with a “tailor-made design,” such as mechanistic studies, are performed toward the elucidation of the mode of action (MoA) and with a view to hazard characterization and hazard assessment.

Also *in vitro* studies (e.g., on mutagenicity/genotoxicity) form part of the establishment of a complete toxicological data package which in most of the cases is triggered by regulatory requirements of different (horizontal) legislations.

In this context, it is of particular note that especially “higher tier studies” such as repeated dose, developmental and reproductive toxicity, and carcinogenicity studies are usually performed in experimental animals *in vivo* according to recognized international standards such as the OECD guidelines for the Testing of Chemicals or the EPA OCSPP/OPPTs health effects testing guidelines for pesticides and toxic substances as *in vitro* or *in silico* methods are either not available yet or are not capable of completely and satisfactorily addressing these higher tier endpoints.

An integral part of mode of action (MoA) investigations is the clarification of the adverse outcome pathways (AOPs), comprising the determination of molecular initiating events (MIE) as well as the series of key events and their relationships to each other (KERs), finally leading to an adverse outcome (AO) on an organ and/or tissue level.

Following completion of the toxicological data package, a thorough evaluation of all studies and the effects observed therein is performed including a “weight-of-the-evidence (WoE) approach” in this assessment. In addition, the process of hazard

**Fig. 1** Overview of the general principles of hazard/exposure assessment and risk characterization

assessment on the one side and the following exposure and risk assessment on the other are very similar for all registration/authorization procedures irrespective of the regulatory context.

Considering the two main pillars of regulatory toxicology, namely (a) hazard characterization/hazard assessment and (b) exposure evaluation and risk characterization, two basic questions need to be answered:

- Are the effects observed in *in vivo* rodent and/or nonrodent studies as well as in *in vitro* systems generally transferable to humans, i.e., are they relevant for humans?
- Are the intended uses of a substance in industrial, professional, and non-professional applications safe for humans and, depending on the applications and relevance, also for animals (livestock, pets), i.e., is the anticipated exposure as estimated with accepted modes or by measurements not associated with an unacceptable health risk?

The principles of hazard and exposure assessment and the associated risk characterization which are generally valid in all regulatory areas are depicted in Fig. 1 below:

## Applied Regulatory Toxicology Using Biocides as an Example

The understanding and interpretation of effects observed in toxicological studies provide the basis for assessment and decision-making by regulators and risk assessors in the challenging field of regulatory toxicology.

To this end, scientific state-of-the-art knowledge and the expertise gathered in the interpretation of effects/findings in the various areas of toxicology are combined and integrated into the regulatory data requirements imposed by various horizontal legislations such as biocides, industrial chemicals, pharmaceutical drugs, and plant protection products, respectively.

The assessment of (active) substances with emphasis on the requirements on human health effects will be discussed in more detail using biocidal active substances and biocidal products containing these active substances as an example.

## Overview of the Regulatory Process Toward the Approval of Biocidal Active Substances and Authorization of Biocidal Products

The approval of biocidal active substances and authorization of biocidal products in the area of the European Union follow a “two-step concept”: Before a biocidal product can be placed on the market, the biocidal active substance needs to be approved first followed by the authorization of the biocidal product(s) containing the active substance (see Fig. 2).

The steps to be taken and requirements to be observed for approval of an active substance and authorizing a biocidal product are laid down in the “Biocidal Products Regulation” (BPR, Regulation (EU) No. 528/2012)

According to the definition of the BPR, an “**active substance**” means a substance or a microorganism that has an action on or against harmful organisms. These harmful organisms can be different types of bacteria, viruses, fungi, insects, or rodents which the active substance is efficacious against.

In general, it is not the biocidal active substances on their own but rather a **biocidal product** containing the active substances which is applied for the intended uses of the products. Within the meaning of Article 3(1)(a) of the BPR, a biocidal product means the following:

- Any substance or mixture, in the form in which it is supplied to the user, consisting of, containing or generating one or more active substances, with the intention of destroying, deterring, rendering harmless, preventing the action of, or otherwise exerting a controlling effect on, any harmful organism by any means other than mere physical or mechanical action
- Any substance or mixture, generated from substances or mixtures which do not themselves fall under the first indent, to be used with the intention of destroying, deterring, rendering harmless, preventing the action of, or otherwise exerting a

**Fig. 2** Two-step process for biocidal active substance approval and biocidal product authorization

controlling effect on any harmful organism by any means other than mere physical or mechanical action

However, there are some exceptions and applications where the active substance is applied in the pure form which means that in these particular cases the biocidal active substance and the biocidal product are identical.

Furthermore, there is a range of active substances which possess so called “dual uses,” i.e., these active substances are applied and regulated under two or more horizontal legislations. For instance, an active substance used as an insecticide can be applied both as a biocidal active substance in stables, as an active substance to protect plants, or even as a veterinary drug for the treatment/protection of pets or livestock animals. The decision which legislations will become applicable for the respective products containing the active substance of interest depends on the claim made by applicants. For instance, if an active substance is intended to protect plants or plant products against insects, this substance is regulated under the plant protection regulation (Regulation (EC) No. 1107/2009), while the application of the same active substance in domestic settings for controlling an insect infestation in homes or to protect livestock animals used for food production is being dealt with under the BPR. Finally, there are some borderline cases where a clear decision on the applicable legislation cannot be made. These cases are to be presented to and discussed with the competent authorities responsible for different legislations. It could also happen that for a particular application, more than only one regulation is to be complied with by the prospective applicant.

Within the framework of active substance approvals under the BPR, the assessment of hazardous properties of the active substance and derivation of acceptable exposure levels (AELs) in relation to different exposure durations (e.g., acute, medium-term, and long-term AELs) are in the focus of the toxicology section of biocidal active substance dossiers. In contrast, the determination of the acute toxicity, primary irritation, and skin sensitization as well as the assessment of the potential endocrine-disrupting properties of nonactive substances contained in the biocidal products stands in the foreground in the toxicology section of biocidal product dossiers in addition to the demonstration of safe exposures and risks in the intended uses of biocidal products. With regard to exposure and risk assessments, it is also necessary to demonstrate a safe use of the active substance during the active substance approval process. In this case, however, the level of detail is not as extensive as during biocidal product authorization, and only one safe use is sufficient for active substance approval. Nevertheless, during biocidal product authorization, all intended uses of the concerned biocidal product(s) are to be considered and an acceptable risk to be shown either by modeling or exposure measurements in order to attain a positive decision during the authorization process.

In the context of the evaluation of biocidal active substances and the products containing these active substances, it is of particular note that the assessment of both active substances and the intended uses of biocidal products is always performed in connection with so-called product types (PTs) the active substances were originally notified for (see Commission Regulation (EC) No. 1451/2007 and Commission

Delegated Regulation (EU) No. 1062/2014 for the list of notified biocidal active substances and the product types they were notified for). An overview of the different product types for biocides including their scope and function is presented in Table 1 below:

When compared to the extent of human health hazard data required for biocidal products according to Annex III of the BPR, the data requirements for the human health hazard assessment of biocidal active substances as given in Annex II of the BPR are by far more comprehensive as all aspects of toxicity need to be addressed for a thorough and satisfactory appraisal of the toxicological profile. For this reason, the following subchapters are primarily dedicated to the illustration of the evaluation procedure and the toxicological data requirements in the process of the approval of biocidal active substances.

### **Approval Process for Biocidal Active Substances**

Within the framework of the active substance approval process, the official assessment of biocidal active substances falls within the remit of an evaluating competent authority (eCA) of a EU member state. For this purpose, applicants for a biocidal active substance are required to prepare an active substance dossier observing the data requirements laid down in Annex II of the BPR and biocides dossier formats (“draft risk assessment report” for active substances) which are made available on the website of the ECHA (European Chemicals Agency).

Following submission of an application for active substance approval to the eCA, the dossier assessment process consists of two steps, namely “**validation**” and “**evaluation.**”

In the validation step, the eCA investigates whether all data and information requirements in accordance with Annex II of the BPR have been provided for all section points of the active substance dossier. This step is, therefore, regarded as a completeness check, however, without performing a detailed assessment of the quality of the data submitted. Data gaps identified during the validation procedure need to be closed by the applicant within the time frames given in Art. 7 of the BPR and which normally should not exceed 90 days. Once the validation step has been passed and the dossier has been accepted by the eCA, the process moves on to the next stage which is the evaluation phase. This is the most important phase as the eCA will perform an in-depth evaluation of the quality/acceptability of the data submitted for all section points of the active substance including the acceptability of the methods and models used for exposure and risk assessments on the intended uses of the biocidal products containing the active substance.

It is of particular note that not all toxicological endpoints of Section 8 of Annex II of the BPR need to be addressed by study data, i.e., by the performance of *in vitro* and *in vivo* studies for the active substance of interest. The biocides regime offers the possibility of the preparation of “waivers” or “justifications for non-submission of data” in accordance with Article 6 (2)(a)–(c) and as detailed in Annex IV “General Rules for the Adaptation of the Data Requirements” of the BPR. This means that in justified cases, the generation of data on the active substance is not required if

**Table 1** Overview of biocidal product types and their descriptions as referred to in Article 2(1) of the Biocidal Products Regulation (Regulation (EU) No 528/2012; 2012)

PT Number	Product type	Description
<b>Main group 1: Disinfectants</b>		
These product types exclude cleaning products that are not intended to have a biocidal effect, including washing liquids, powders, and similar products.		
1	Human hygiene	Human hygiene purposes: Application on or in contact with human skin or scalps for the primary purpose of disinfecting the skin or scalp
2	Disinfectants and algicides not intended for direct application to humans or animals	Disinfection of: Surfaces, materials, equipment, and furniture which are not used for direct contact with food or feeding stuffs Air, water not used for human or animal consumption, chemical toilets, waste water, hospital waste, and soil Use area(s): Swimming pools, aquariums, bathing, and other waters; air conditioning systems; and walls and floors in private, public, industrial areas, and in other areas for professional activities Algicides for treatment of swimming pools, aquariums, other waters, and for remedial treatment of construction materials Incorporation in textiles, tissues, masks, paints, and other articles or materials with the purpose of producing treated articles with disinfecting properties
3	Veterinary hygiene	Use area(s): Disinfectants, disinfecting soaps, oral or corporal hygiene products, or with antimicrobial function for veterinary hygiene purposes Disinfection of materials and surfaces associated with the housing or transportation of animals
4	Food and feed area	Uses area(s): Disinfection of equipment, containers, consumption utensils, surfaces or pipework associated with the production, transport, and storage or consumption of food or feed (including drinking water) for humans and animals. Impregnation of materials which may enter into contact with food

(continued)

**Table 1** (continued)

PT Number	Product type	Description
5	Drinking water	Disinfection of human and animal drinking water
<b>Main group 2: Preservatives</b>		
Unless otherwise stated, these product types include only products to prevent microbial and algal development.		
6	Preservatives for products during storage	Use area(s): Preservation of manufactured products, other than foodstuffs, feeding stuffs, cosmetics or medicinal products, or medical devices by the control of microbial deterioration to ensure their shelf life Preservatives for the storage or use of rodenticide, insecticide, or other baits
7	Film preservatives	Use area(s): Preservation of films or coatings by the control of microbial deterioration or algal growth for protecting the initial properties of the surface of materials or objects such as paints, plastics, sealants, wall adhesives, binders, papers, and art works
8	Wood preservatives	Use area(s): Preservation of wood, from and including the saw-mill stage, or wood products by the control of wood-destroying or wood-disfiguring organisms, including insects in both preventive and curative applications
9	Fiber, leather, rubber, and polymerized materials preservatives	Use area(s): Preservation of fibrous or polymerized materials, such as leather, rubber or paper, or textile products by the control of microbiological deterioration
10	Construction material preservatives	Use area(s): Preservation of masonry, composite materials, or other construction materials other than wood by the control of microbiological and algal attack
11	Preservatives for liquid-cooling and processing systems	Use area(s): Preservation of water or other liquids used in cooling and processing systems by the control of harmful organisms such as microbes, algae, and mussels
12	Slimicides	Use area(s): Prevention or control of slime growth on materials, equipment, and structures, used in industrial processes, e.g., on wood and

PT Number	Product type	Description
		aquaculture equipment, or other structures used in water
22	Embalming and taxidermist fluids	Use area(s): Disinfection and preservation of human or animal corpses, or parts thereof.

### 1. Testing Does Not Appear to Be Scientifically Necessary

- By using already existing data which on their own, or in the context with other available independent sources of information and applying a WoE approach, are sufficiently reliable for classification and labeling and the key parameters are adequately covered.
- By using a grouping/read-across approach to reliable data on substances of similar structure and properties (“reference substances”); the validity of such an approach needs to be proven by the comparison of data on available reference points.
- If available data of sufficient reliability/validity cover the exposure durations foreseen in the intended applications of biocidal products containing the concerned active substance.
- If QSAR (qualitative or quantitative structure-activity relationship) methods provide reliable and adequate information on the endpoint to be waived.
- If it can be shown by reliable data that due to its high reactivity and associated rapid degradation, an active substance does not become systemically available; in this case, investigations directed to local effects may be sufficient.

### 2. Testing Is Technically Not Possible

- If based on the physico-chemical properties of the substance, study data cannot be established, e.g., oral/dermal testing of highly volatile substances or testing of highly reactive or unstable substances in general.

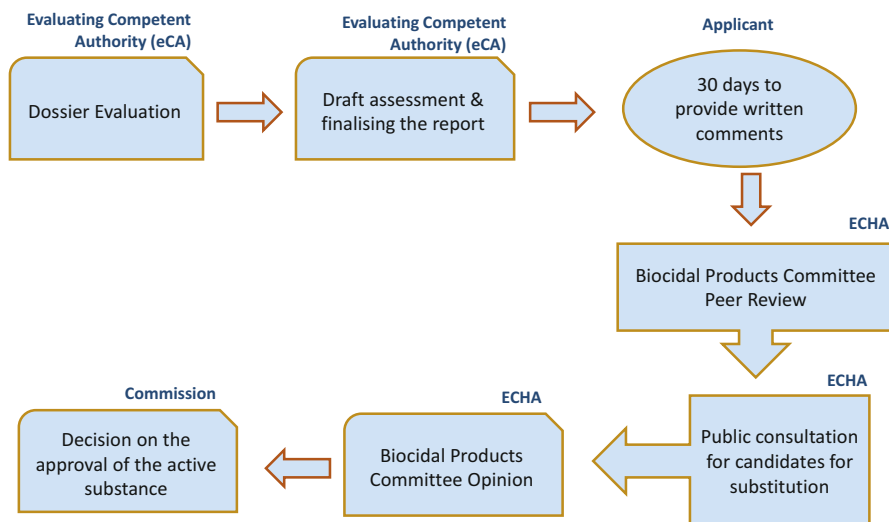

Although a third-waiving option based on exposure considerations is provided for in the BPR (“Product-Tailored Exposure-Driven Testing”), this option is rarely applicable in the biocides area as the application of biocides in general will in the majority of cases be associated with an exposure of various population subgroups. Use of this option can, therefore, only be made on a case-by-case basis considering details of the intended biocidal application(s).

## Evaluation and Defense of Biocidal Active Substances During the Approval Process

The most challenging part of the active substance approval process is represented by the evaluation phase with a focus on the defense of the active substance dossier as submitted by an applicant. This stage involves both the applicant and

the selected eCA as well as the corresponding experts of all EU biocides authorities which are explained in more detail in the following:

1. According to BPR Article 8 “Evaluation of applications,” the eCA is required to complete its evaluation of the active substance within 365 days of the validation of an application. In case the eCA had further requirements during the evaluation phase, e.g., the need to revise the assessment of study reports or exposure and risk assessments, an extension could be granted which usually shall not exceed a “stop of the clock” period of 180 days.
2. After completion of the evaluation of the active substance dossier by the eCA, it prepares a “draft competent authority report” (dCAR). In this dCAR, the results of the evaluation are summarized. In a first step, the dCAR and the comments of the eCA are sent to the applicant. The applicant is granted a period of 30 days to comment on and clarify outstanding issues identified by the eCA by submitting scientifically robust reasonings in the form of, e.g., expert statements/position papers.
3. Thereafter, the conclusions of the evaluation of the eCA together with a discussion table listing unresolved comments/open points identified during the evaluation are sent to the European Chemical Agency (ECHA) where they are subject to a peer review by the “Biocidal Products Committee” (BPC). The BPC Tox Working Group (WG) comprising human health experts of all EU biocides authorities is responsible for the assessment of human health hazards, exposure and risk characterization of the concerned active substance.
4. The conclusions of the BPC Tox WG and the open issues which could not be solved in the WG discussions are passed on to the Biocidal Products Committee (BPC) which aims at a conclusion on all section points of the active substance. The results of the BPC discussions will be adopted in a BPC Opinion which contains also further elements to be taken into account when authorizing products in the products types applied for and which do not prevent the active substance from being approved. The decisions made on the assessment of the active substance and the reasons for the conclusions drawn are summarized in the BPC Opinion on the active substance in its respective products types. The BPC phase for discussing the evaluation and concluding on the approval or nonapproval of the active substance shall not exceed a period of 270 days.
5. The outcomes of the BPC conclusions will be implemented by the eCA in a revised version of the Assessment Report. If in the subsequent comitology procedure of the Standing Committee on Biocidal Products of the European Commission there are no objections on the decisions made in the BPC, the active substance approval process is finalized. The BPC opinion together with the Assessment Report of the active substance in its respective product types will be published on the ECHA website and the active substance included in the Union list of approved active substances.

**Fig. 3** Overview of the evaluation process for biocidal active substances by the eCA, Applicant, BPC, and the Commission (<https://echa.europa.eu/regulations/biocidal-products-regulation/approval-of-active-substances/existing-active-substance/evaluation-process-for-active-substances-under-the-review-programme>)

An overview of the active substance approval process is depicted in Fig. 3 below.

A biocidal active substance is approved for a maximum period of 10 years. Thereafter, the approval is to be renewed on the basis of the data/studies originally submitted and taking into a consideration new data requirements which may have been drawn up in the meantime.

If active substances reveal certain hazardous properties, the exclusion criteria according to Art. 5(1) or the criteria for candidates for substitution (CfS) according to Art. 10(1) of the BPR may apply. Most importantly, active substances fulfilling the exclusion criteria will in principle not be approved.

Both the criteria for exclusion and substitution are strictly based on the intrinsic hazardous properties in combination with the use without taking into consideration any aspects related to exposure and risks.

An active substance will be considered as meeting the criteria for exclusion or substitution if any of the following hazardous properties are identified during evaluation:

### 1. Active Substances Fulfilling the Exclusion Criteria

- Carcinogens, mutagens, and reprotoxic substances categories 1A or 1B according to the CLP Regulation
- Endocrine disruptors
- Persistent, bioaccumulative, and toxic (PBT) substances
- Very persistent and very bioaccumulative (vPvB) substances

### 2. Active Substances Which Are Candidates for Substitution

- Active substances fulfilling the exclusion criteria.
- Active substances classified as a respiratory sensitizer.

- Toxicological reference values of the active substance are significantly lower than those of the majority of approved active substances for the same product type and use.
- Active substances meeting two of the PBT criteria.
- Active substances causing concerns for human or animal health and for the environment even with very restrictive risk management measures.
- Active substances containing a significant proportion of nonactive isomers or impurities.

### **Toxicological Data Requirements of Biocidal Active Substances According to the Provisions of the Biocidal Products Regulation**

One major pillar in the approval process of biocidal active substances is represented by the toxicological data package to be established in relation to the human health hazard assessment with the aim to enable a) classification and labeling of the substance, and b) derivation of tolerable reference values for systemic and local effects.

The data package to be prepared is comprised of studies on the following human health-related endpoint studies (not exhaustive):

- Acute toxicity studies (oral, dermal, and inhalation)
- Primary irritation studies (skin and eye)
- Skin and respiratory sensitization
- Repeated dose toxicity (RDT) studies: 28-/90-day studies in rodents (e.g., rats), 90-day/1 year studies in nonrodents (mostly dogs)
- Carcinogenicity studies in rodents (rats and mice)
- Developmental toxicity and reproductive toxicity studies (“DART” studies)
  - Reproductive toxicity studies: Two-generation reproductive toxicity studies (TGRTS) or extended one generation study (EOGRTS) in rats
  - Developmental toxicity and teratogenicity studies in rats and rabbits
- Acute/subchronic neurotoxicity and delayed neurotoxicity studies
- Developmental neurotoxicity (DNT) and developmental immunotoxicity (DIT) studies as (optional) parts of the EOGRTS
- Dedicated *in vitro* and *in vivo* studies on the elucidation of the potential endocrine-disrupting (ED) properties with a focus on endocrine activity and related adverse effects

The toxicological data requirements distinguish endpoints pertaining to the Core Data Set (CDS) or Additional Data Set (ADS).

Data assigned to the CDS are to be regarded as basic data which should, in principle, be provided for all active substances. In case there are grounds for deviating from the CDS and an endpoint is waived, a scientifically sound explanation on the nonsubmission of the respective data needs to be provided.

Data, assigned to the ADS, are to be provided by taking into account, for instance, the physical and chemical properties of the substance, existing data, and information which is part of the CDS, the types of products in which the active substance will be used and the exposure patterns related to these uses.

With the application of the most recent “ECHA/EFSA Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009,” there is now a need to assess the potential endocrine-disrupting properties of biocidal active substances before a final conclusion on the approval or nonapproval of an active substance can be drawn. As a consequence, the data requirements in Annex II and III of the current version of the BPR need to be adapted to the scientific and technical progress in relation to the determination of endocrine-disrupting properties both for active substances and biocidal products (for details, please refer to most recent Competent Authority document “CA-Feb20-Doc.3.1.b – Rev BPR annexes.docx”).

The most profound revisions on the toxicological data requirements in Section 8 of Annex II of the BPR concern reproductive toxicity (8.10) and the newly introduced endpoint endocrine disruption (8.13.3).

For reproductive toxicity examination, preference is given to the EOGRTS using cohorts 1A and 1B for effects on reproduction/fertility and effects on a pup/litter level. In addition, the EOGRTS offers a number of advantages in comparison to the TGRTS as it assesses in addition to effects on the male and female reproductive system more toxicological effects linked to endocrine-disrupting modes of action.

In relation to the (separate) assessment of endocrine-disrupting properties, a whole battery of *in vitro* and *in vivo* tests needs to be performed comprising studies on the mechanism of action and adversity.

Another endpoint which is affected by the revision of the Annex II concerns studies on the investigation of potential developmental neurotoxicity (DNT) which will be changed from an ADS to a CDS and becomes, thus, a mandatory data requirement in the proposal for an update of Annex II of the BPR. This investigation shall be integrated as cohorts 2A and 2B of the EOGRTS as the preferred study type for the examination of potential reproductive toxicity.

Table 2 summarizes the data requirements and specific rules for adaptation of the selected endpoints mentioned above.

## Assessment of Potential Endocrine Disruption

### WHO Definition of an Endocrine Disruptor

With the entry into force and application of the ECHA/EFSA guidance document on the assessment of potential endocrine-disrupting (ED) properties of active substances used in biocidal and plant protection products, the assessment and conclusion on the potential ED properties became a mandatory data requirement within the scope of the approval of biocidal active substances.

The basis of the determination of potential ED properties of biocidal active substances is based on the WHO definition of an endocrine disruptor (WHO 2002). According to this definition, a substance shall be considered as having endocrine-disrupting properties that may cause adverse effect in humans if it is a substance that meets all of the following criteria, unless there is evidence demonstrating that the adverse effects identified are not relevant to humans:

**Table 2** Selection of proposed amendments on the toxicological data requirements for active substances according to Annex II of the BPR with a focus on CDS for reproductive toxicity, developmental neurotoxicity, and endocrine disruption (CA-Feb20-Doc.3.1.b – Rev BPR annexes.docx; CIRCA BC, 2020)

Endpoint	Specific rules for adaptation from column 1
<b>8.10 Reproductive toxicity</b>	The studies do not need to be conducted if:
For evaluation of consumer and animal safety of active substances that may end up in food or feed, it is necessary to conduct toxicity studies by the oral route.	<p>The substance meets the criteria to be classified as a genotoxic carcinogen (classified both as germ cell mutagen category 2, 1A or 1B, and carcinogenic category 1A or 1B), and appropriate risk management measures are implemented including measures related to reproductive toxicity</p>
	<p>The substance meets the criteria to be classified as a germ cell mutagen category 1A or 1B, and appropriate risk management measures are implemented including measures related to reproductive toxicity</p>
	<p>The substance is of low toxicological activity (no evidence of toxicity seen in any of the tests available provided that the dataset is sufficiently comprehensive and informative); it can be proven from toxicokinetic data that no systemic absorption occurs via relevant routes of exposure (e.g., plasma or blood concentrations below detection limit using a sensitive method and absence of the substance and of metabolites of the substance in urine, bile, or exhaled air), and the pattern of use indicates there is no or negligible significant human or animal exposure</p>
	<p>The substance meets the criteria to be classified as reproductive toxicity category 1A or 1B: may damage fertility (H360F), and the available data are adequate to support a robust risk assessment, then no further testing for sexual function and fertility will be necessary. A full justification must be provided and documented if investigations for developmental toxicity are not conducted or</p>
	<p>The substance is known to cause developmental toxicity, meeting the criteria for classification as reproductive toxicity category 1A or 1B: may damage the unborn child (H360D), and the available data are adequate to support a robust risk assessment, then no further testing for developmental toxicity will be necessary. A full justification must be provided and documented if investigations for sexual function and fertility are not conducted</p>
	<p>Notwithstanding the provisions of this column of this subsection, studies on reproductive toxicity may need to be conducted to obtain</p>

Endpoint	Specific rules for adaptation from column 1
	information on endocrine-disrupting properties as laid down in 8.13.3.1.
<p><b>8.10.2 Extended One-Generation Reproductive Toxicity Study (OECD TG 443),</b></p> <p>with cohorts 1A and 1B and extension of cohort 1B to include the F2 generation with the aim to produce 20 litters per dose group, F2 pups must be followed to weaning and investigated similarly as F1 pups. Rat is the preferred species, and oral route of administration is the preferred route.</p> <p>The highest dose level should be based on toxicity and selected with the aim to induce reproductive and/or other systemic toxicity.</p>	<p>A two-generation reproductive toxicity study conducted in accordance with OECD TG 416 (adopted 2001 or later) or equivalent information shall be considered appropriate to address this information requirement, if the study is available and was initiated before . . . (<i>OJ please insert the date of application of this amending Regulation</i>).</p>
<p><b>8.10.3 Developmental neurotoxicity</b></p>	<p>The study shall not be conducted if the available data:</p>
<p>Developmental Neurotoxicity Study in accordance with OECD TG 426, or any relevant study (set) providing equivalent information, or by cohorts 2A and 2B of an Extended One-Generation Reproductive Toxicity study (OECD TG 443) with additional investigation for cognitive functions</p>	<p>Indicate that the substance causes developmental toxicity and meets the criteria to be classified as toxic for reproduction category 1A or 1B: may damage the unborn child (H360D)</p> <p>Are adequate to support a robust risk assessment</p>
<p><b>8.13.3 Endocrine disruption</b></p>	<p>Where sufficient weight of evidence to conclude on the presence or absence of a particular endocrine-disrupting mode of action is available:</p>
<p>The assessment of endocrine disruption shall comprise the following tiers:</p>	<p>Further testing on vertebrate animals for that effect shall be omitted for that mode of action</p>
<p>(a) An assessment of the available information from the following studies and any other relevant information, including <i>in vitro</i> and <i>in silico</i> methods:</p>	<p>Further testing not involving vertebrate animals may be omitted for that mode of action.</p>
<p>(i) 8.9.1 A 28-day oral study in rodents (OECD TG 407)</p>	<p>In all cases, adequate and reliable documentation shall be provided.</p>
<p>(ii) 8.9.2 A 90-day oral study in rodents (OECD TG 408)</p>	
<p>(iii) 8.9.4 A repeated dose oral study in nonrodents (OECD TG 409)</p>	
<p>(iv) 8.10.1 A prenatal developmental toxicity study (OECD TG 414)</p>	
<p>(v) 8.10.2 An extended one-generation reproductive toxicity study (OECD TG 443) or two-generation reproductive toxicity study (OECD TG 416)</p>	
<p>(vi) 8.10.3 A developmental neurotoxicity study (OECD TG 426)</p>	

(continued)

**Table 2** (continued)

Endpoint	Specific rules for adaptation from column 1
(vii) 8.11.1 A combined carcinogenicity study and long-term repeated dose toxicity study (OECD TG 451-3)	
(viii) A systematic review of the literature including studies on mammals and nonmammalian organisms	
(b) If there is any information suggesting that the active substance may have endocrine-disrupting properties, or if there is incomplete information on key parameters relevant for concluding on endocrine disruption, then additional information or specific studies shall be required to elucidate any of the following:	
(1) the mode or the mechanism of action	
(2) potentially relevant adverse effects in humans or animals	
For evaluation of consumer safety of active substances that may end up in food or feed, it is necessary to consider the oral route and conduct animal studies by the oral route.	
<b>8.13.3.1 Specific additional studies to investigate potential endocrine-disrupting properties may include, but are not limited to the following:</b>	
(a) the mammalian toxicity studies listed in 8.13.3 (a)	
(b) the <i>in vitro</i> assays:	
(i) Estrogen receptor transactivation assay (OECD TG 455)	
(ii) Androgen receptor transactivation assay, (OECD TG 458)	
(iii) H295R steroidogenesis assay (OECD TG 456)	
(iv) the Aromatase assay (human recombinant) OPPTS 890.1200	
(c) Uterotrophic bioassay in rodents (OECD TG 440) and Hershberger bioassay in rats (OECD TG 441)	
(d) Pubertal development and thyroid function in intact juvenile or peripubertal male rats (OPPTS 890.1500)	
The decision to carry out studies in mammals shall be taken based on all available information, including a systematic review of the literature (including information on endocrine-disrupting effects in nontarget organisms) and the availability of suitable <i>in silico</i> or <i>in vitro</i> methods.	

- Observation of an adverse effect in an intact organism or its progeny (change in the morphology, physiology, growth, development, reproduction, or life span of an organism, system, or (sub)population that results in an impairment of functional capacity, an impairment of the capacity to compensate for additional stress, or an increase in susceptibility to other influences).
- Identification of an endocrine mode of action (altering the function(s) of the endocrine system).
- Adverse effect is a consequence of the endocrine mode of action.

### **Scientific Criteria for the Determination of Endocrine-Disrupting Properties**

Scientific criteria for the determination of endocrine-disrupting properties were not available within the process of the approval of biocidal active substances until recently. Therefore, a major task consisted in the definition of such criteria which became available with the application of the Commission Delegated Regulation (EU) No. 2017/2100.

The scientific criteria differentiate between criteria for the determination of potential ED properties in humans in Section A and on nontarget organisms in part B of the regulation.

The following main elements which need to be taken into consideration in the process of the determination of potential ED properties in humans comprise the following aspects:

- Gathering of all relevant scientific ED-related data (in vivo, in vitro, in silico)
- Assessment of all relevant scientific ED-related data applying a WoE approach considering:
  - Positive/negative results
  - Relevance of study design, quality, and consistency of data
  - Exposure route and toxicokinetics
  - Limit dose/MTD (maximum tolerated dose) effects
  - Adverse effects of nonspecific consequences of toxicity which are not to be considered/not relevant for the determination of potential ED properties

All of the above listed criteria are to be met in order to conclude on the presence or absence of potential ED properties of a biocidal active substance.

### **Main Elements of the ECHA/EFSA Guidance for the Identification of Endocrine Disruptors**

Since the assessment of potential ED properties was not part of biocidal active substance dossiers before the application of the ED guidance document and as in most cases no attention was paid to possible endocrine-mediated effects, all study data and information submitted in relation to active substance approval have to be reassessed with a particular focus on potential ED effects.

In the ECHA/EFSA guidance document, focus is placed on ED properties based on “EATS (Estrogen, Androgen, Thyroid and Steroid)-mediated effects.” To date, these endpoints are best understood from the mechanistic point of view and

standardized *in vitro/in vivo* test methods and guidelines are available on these endpoints with broad scientific agreement on the interpretation of the effects observed on the investigated parameters. The available test methods are provided for in the OECD Guidance Document on Standardised Test Guidelines for Evaluating Chemicals for Endocrine Disruption (OECD GD 150) which includes the “OECD Conceptual Framework (OECD CF) for Testing and Assessment of Endocrine Disruptors” providing a grouping of the studies into five levels according to the kind of information provided.

For the assessment of the potential ED properties of an active substance, a grouping is performed in the evaluation of the scientific evidence when identifying substances with ED properties which comprises:

- ***In vitro* mechanistic:** *In vitro* parameters of OECD CF level 2 providing information on a potential endocrine mechanism (i.e., receptor binding/activation, interaction with hormone production)
- ***In vivo* mechanistic:** *In vivo* parameters of OECD CF level 3 providing information on usually nonadverse endocrine activity
- **EATS-mediated:** *In vivo* parameters contributing to the evaluation of adversity, while at the same time they are also considered indicative of an EATS mode of action and imply underlying *in vivo* mechanistic information
- **Sensitive to, but not diagnostic of, EATS:** *In vivo* parameters from OECD CF levels 3–5 which contribute to the evaluation of adversity, but are not sufficiently indicative on their own of any one of the EATS modalities

In accordance with the ECHA/EFSA ED guidance document, the ED assessment comprises the five following stages toward assessment of ED properties which are briefly summarized below and are based on the strategy for the assessment of potential ED properties of active substances used in biocidal and plant protection products as provided for in the ED guidance document (Fig. 4):

### 1. Gathering of All Relevant Information/Parameters Relevant for ED Assessment

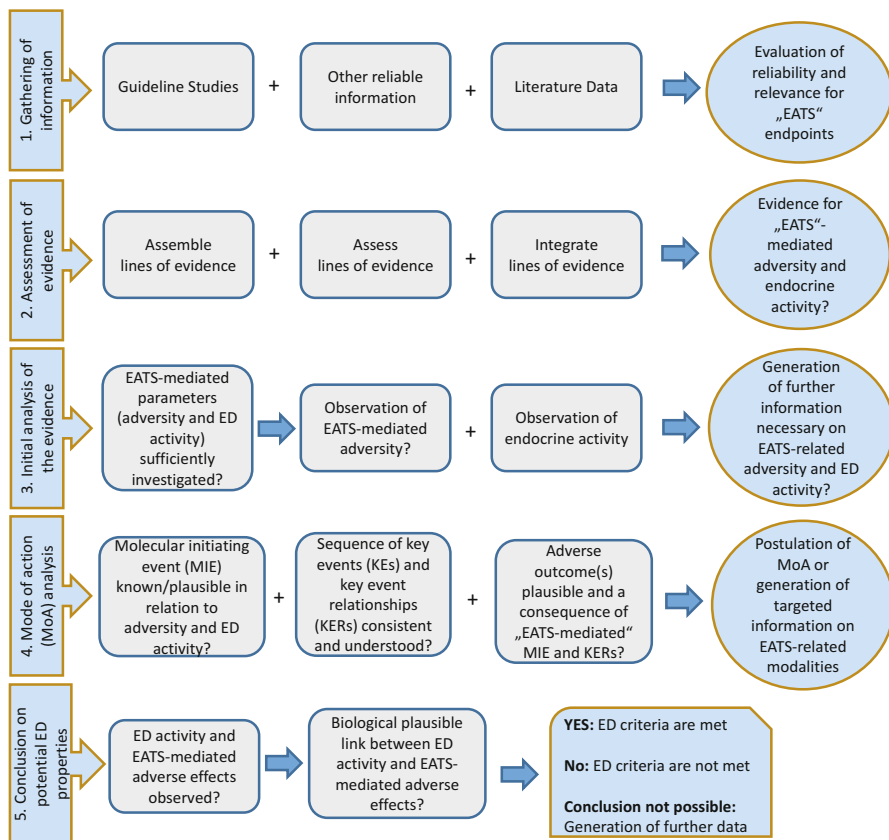

- *In vivo/in vitro* mechanistic data (Levels 2 + 3 of OECD CF)
- EATS-mediated parameters (Levels 4 + 5 of OECD CF)
- Sensitive to, but not diagnostic of, EATS parameters (Levels 3–5 of OECD CF)

### 2. Assembling, Assessing, and Integrating the Lines of Evidence

- Assessment of adverse effects with a view to ED relevance (“EATS-mediated parameters” and “sensitive to, but not diagnostic of, EATS parameters”)
- Assessment of available information on ED activity (*in vivo/in vitro* mechanistic data, EATS parameters)

### 3. Initial Analysis of the Evidence

- Judgement if EATS-mediated parameters/ED activities are sufficiently investigated and a potential biological plausible link between (EATS-mediated) adversity and potential ED activity is established.

**Fig. 4** Flowchart on the assessment strategy for potential ED properties of active substances used in biocidal and plant protection products

#### 4. Mode of Action Analysis

- If EATS-mediated adversity and/or ED activity is observed, an in-depth analysis of the mode of action and the cascade MIE → KE1-n → AO is needed (MIE: molecular initiating event; KE: key event; AO: Adverse outcome).

#### 5. Conclusion Whether the Substance Meets the ED Criteria

- A conclusion on a positive/negative ED potential is always required. If a conclusion is not possible, the need and a strategy for the generation of further *in vitro/in vivo* data are to be considered.

The reassessment of all available information with a particular focus on ED properties and establishment of a biologically plausible link between potential ED activity and observed adverse effects is associated with high efforts and requires a high level of expertise in order to:

- Reevaluate and assess the available study data

- (b) Postulate/elucidate a potential endocrine mode of action
- (c) Decide on further ED-specific testing taking into account integrated approaches for testing and assessment
- (d) Draw a final conclusion on the absence or presence of potential ED properties of the active substance

### **Derivation of Acceptable Exposure Levels (AELs)/Concentrations (AECs) for Biocidal Active Substances**

Besides the demonstration of safe uses in the intended application of biocidal products and the active substances contained therein, the derivation of acceptable reference values both for systemic and local effects represents the final objective of the toxicological hazard characterization process during active substance approval. The deduction of a reference value for an active substance is a crucial step in the evaluation procedure as the reference values constitutes a crucial determinant in the risk characterization process.

Depending on the effects observed in the available or generated toxicological data package, it needs to be differentiated between substances exerting a systemic and/or local mode of action. According to the terminology for biocides, acceptable exposure levels (AELs) are derived for substances with systemic effects, while for local effects, acceptable exposure concentrations (AECs) are derived.

Usually, the most relevant and sensitive endpoints identified in the toxicological data package serve as the point of departure (i.e., no-observed-adverse-effect-level, NOAEL) for reference value deduction including the application of uncertainty factors to correct the NOAEL for inter-/intraspecies variabilities in toxicodynamic and toxicokinetics and to adjust for bioavailability and/or exposure duration. Further uncertainty factors may have to be applied for the extrapolation from a lowest-observed-adverse-effect-level (LOAEL) to a no-observed-adverse-effect-level if only a LOAEL could be derived from the data/studies available. Most importantly, if more than one “key study” is available for reference value setting, a weight-of-the evidence approach is used with a view to the identification of the most relevant and most sensitive point of departure.

This process affords a high level of expertise and experience by undertaking considerations on, e.g., dose setting, dosing duration, effects observed at or above the maximum tolerated dose (MTD effects), and relevance of the findings made for humans. Furthermore, with a view to the exposure and risk assessment in the intended uses of an active substance which exerts systemic effects, the foreseen exposure duration for an application may trigger the need for the derivation of acceptable exposure levels for different time frames. Exposure-related information is, therefore, crucial for the adjustment of human health risk assessment to varying time frames for professional as well as consumer exposure.

With regard to the derivation of reference values for local effects (“AECs”), the regulatory process differentiates between

- Local effects via the dermal route and
- Local effects directed toward the respiratory tract

The common understanding in the derivation of AECs for biocidal active substance is that these effects are concentration-related rather than dosage-related. In general, if local effects are independent of metabolic processes, considerations on toxicokinetics for the correction of the NOAEC (i.e., a no-observable-adverse-effect concentration) as the starting point are not required, and only uncertainty factors to account for inter- and intraspecies differences in toxicodynamics are applied. However, in the course of the defense of active substances, a point of discussion is always related to the uncertainty factor to be applied for the derivation of reference values for local effect via the inhalation route. Based on the inhalation NOAEC, the following types of correction are considered in this particular case:

- Inter- and intraspecies differences for toxicodynamics
- Intraspecies differences in toxicokinetics
- Exposure duration in the study vs. anticipated exposure duration during application

Especially the need to correct the NOAEC for exposure duration has to be carefully considered and to be decided upon on a case-by-case basis taking into account the available data.

The type of assessment/uncertainty factor as well as the extrapolation factors usually applied in the derivation of reference values for systemic and local effects of biocidal active substances is given in Table 3:

Finally, after having identified the most appropriate point of departure(s) and following a correction of the starting point(s) by the application of the required uncertainty factors, the corresponding reference values, i.e., AELs/AECs, are derived. Table 4 below provides an overview of the different types of reference values for biocidal active substances and their relationship to diverse categories of users.

The type of AEL derived is largely depending on the intended application of the active substance and the category of users applying the biocidal products containing the active substance. In Table 5 below, the relationship between duration of human exposure and the studies required for hazard identification and derivation of the relevant points of departure as retrieved from the Guidance on BPR: Volume III Parts B+C (Version 4.0 December 2017), are summarized.

More details and specific needs in relation to the derivation of acceptable exposure levels and concentrations as well as uncertainty/correction factors to be applied can be found in Volume III, Part B+C of the ECHA Guidance on the assessment for human health (Guidance on the Biocidal Products Regulation 2017).

**Table 3** Default uncertainty/correction factors in the derivation of AELs/AECs for biocidal active substances

Type of uncertainty	Default uncertainty factor	Remark
<u>Interspecies differences – systemic effects:</u>		Allometric scaling factors:
Toxicodynamics	2.5	Dog: 1.4
Toxicokinetics (allometric scaling)	1.4–7 (species specific)	Rat: 4 Mouse: 7
<u>Intraspecies differences – systemic effects:</u>		Adjustment of allometric scaling factors in humans if substance-specific data are available
Toxicodynamics	3.16	
Toxicokinetics (allometric scaling)	3.16	
<u>Interspecies differences – local dermal effects:</u>		Factor of 2.5 is required if dermal effects are dependent on local metabolism
Toxicodynamics	1–2.5	
Toxicokinetics (allometric scaling)	1	
<u>Intraspecies differences – local dermal effects:</u>		Expert judgment
Toxicodynamics	1–3.16	
Toxicokinetics (allometric scaling)	1–3.16	
<u>Interspecies differences – local effects respiratory tract:</u>		Expert judgment in case workplace measurements in humans is available
Toxicodynamics	2.5	
Toxicokinetics (allometric scaling)	1	
<u>Intraspecies differences – local effects respiratory tract:</u>		Expert judgment in case workplace measurements in humans is available
Toxicodynamics	3.16	
Toxicokinetics (allometric scaling)	3.16	
<u>Exposure duration (systemic and local inhalation effects)</u>		
Subchronic to chronic	2	
Subacute to subchronic	3	
Subacute to chronic	6	
LOAEL-NOAEL extrapolation	2–10	Expert judgment based on dose-response considerations applying weight of the evidence approach

**Table 4** Overview of toxicological reference values for active substances in relation to the concerned user categories

Reference value type	User categories
<b>Systemic effects</b>	
AEL <sub>acute/short-term</sub>	Nonprofessional users/bystanders
AEL <sub>medium-term</sub>	Industrial/professional/ nonprofessional users
AEL <sub>long-term</sub>	Industrial/professional users
(AELs needed in case of systemic effects following dermal/ inhalation exposure; for oral exposure, the acceptable intake (ADI) is preferred although an AEL could be used as surrogate following correction of oral exposure by systemic availability)	
<b>Local effects</b>	
AEC <sub>dermal</sub>	Industrial/professional/ nonprofessional users/bystanders
AEC <sub>inhal</sub>	Industrial/professional/ nonprofessional users/bystanders
(AECs are needed in case the active substance exerts local effects via the dermal and/or inhalation routes of exposure)	

**Table 5** Relationship between duration of human exposure and the studies required for hazard identification and derivation of the relevant points of departure

Anticipated duration of human exposure	Relevant toxicity studies to be selected	Relevant point(s) of departure for AEL derivation
≤24 h	Single-dose studies designed to determine points of departure <sup>a</sup> or repeated dose studies demonstrating relevant acute effects, e.g.,	Toxic effects relevant for acute exposure
	acute neurotoxicity studies	
	28-d/90-d repeated-dose studies, acute effects	
>24 h – 3 months (max. 6 months)	developmental toxicity studies, acute effects	Toxic effects relevant for medium-term exposure
	Repeated-dose studies designed to determine dose descriptors, e.g.,	
	28-d/90-d repeated-dose studies	
	90-d neurotoxicity studies	
	12-m dog studies, depending on the nature of effects	
>6 months (min. 3 months)	developmental toxicity studies	Toxic effects relevant for long-term exposure
	2-generation studies	
	Chronic studies or repeated dose studies designed to determine dose descriptors and demonstrating relevant chronic effects, e.g.,	
	18-m/24-m chronic/carcinogenicity studies	

<sup>a</sup>Data from LD<sub>50</sub> studies can be considered supportive if appropriate acute effects were investigated

## Exposure Assessment and Risk Characterization for Biocides

### General Principles on Exposure and Risk Assessment

The focus of the approval process of biocidal active substances lies on the assessment of the intrinsic hazardous properties by gathering and evaluating all available data and study information of the concerned active substance to enable the following:

- (a) Classification and labeling of the active substance
- (b) Derivation of tolerable reference values for systemic and/or local effects

A further important cornerstone in the approval of biocidal active substances constitutes the demonstration of safe uses in the product type-dependent intended applications of the biocidal products containing the active substance.

This process encompasses the identification of the relevant exposure scenarios, exposure assessment, and risk characterization with the objective to demonstrate that the estimated exposure is acceptable and does not lead to an exceedance of the relevant reference values derived for the active substance from the most relevant study and most sensitive animal species.

The scope of exposure and risk assessments in general is described by the following elements:

- Estimation of the potential dermal, inhalation, and, where relevant, the oral exposure following application of a substance in its intended use(s)
- Characterization and identification of the potential risks associated with handling and use, i.e., comparison of the estimated exposure with a “tolerable exposure level” derived for the active substance based on the most sensitive endpoint from the most relevant toxicity study in experimental animals
- Demonstration of safe uses and absence of unacceptable health risks for workers, consumers, and/or the general population (including the young and elderly persons)

During active substance approval, however, not all uses which the biocidal product is intended to be applied for need to be addressed. In the context of the safe use concept, it is sufficient at this stage to show that one intended use is safe from the risk assessment point of view. However, all other uses of the biocidal product which were not covered in the active substance dossier need to be addressed at the biocidal product authorization stage at the latest.

Irrespective of the approach chosen during active substance approval in relation to the intended uses, the following stepwise approach applies in general to all exposure assessments which need to be performed on the biocidal product containing the active substance:

1. Determination of the relevant product types and formulations the biocidal active substance is intended to be used for

2. Identification of the exposed type of population which could comprise the following:
  - Industrial users
  - Professional users
  - Nonprofessional/amateur users
  - The general public including children and the elderly
3. Identification of the exposure scenarios which are composed of the following:
  - Use pattern for each identified population subgroup, i.e., definition of the different tasks/working procedures to be performed for a specific application
  - Routes of exposure (e.g., inhalation, dermal, and oral route)
  - Frequency and duration of the concerned use(s)
  - Determination of primary and secondary exposure scenarios
4. Estimation of exposure by the following:
  - Using exposure models agreed upon by the human exposure working groups of the BPC
  - Building of justified generic exposure scenarios including a reasoning on their applicability
  - Using available measured data for specific use scenarios if relevant, reliable, and valid

With a view to the performance of exposure assessments for biocides, a differentiation needs to be made between primary and secondary exposure. This difference will have a decisive impact on the type of population exposed and the feasibility of the implementation of risk mitigation measures, i.e., the possibility of the use of personal/respiratory protective equipment (PPE/RPE) such as gloves, coveralls, or respirators, respectively.

### **Primary Exposure**

Primary exposure is related to those individuals applying the active substance and the biocidal product containing it in its intended application(s). In this respect, a refinement of the exposure estimations by taking into consideration PPE/RPE is only possible for industrial or professional workers. This group of operators is usually trained in the applications to be performed and have knowledge on worker protection. In contrast, nonprofessional workers apply biocidal products less frequently, are less skilled, and usually have no or only little knowledge on the use of PPE/RPE. For this reason, any kind of PPE/RPE can usually not be taken into account in the estimation of the primary exposure of nonprofessional users.

### **Secondary Exposure**

Secondary exposure will be encountered during and after application by those individuals not directly involved in the application itself. However, also the individual having performed the application could additionally be secondarily exposed once the application has been completed and treated areas are reentered or surfaces are being touched for instance. In these particular exposure situations, exposure-reducing measures such as PPE/RPE will not be taken into account

unless specific instructions have been released in industrial and/or professional work areas.

### **Exposure Modeling for Biocides**

With respect to the performance of exposure estimations for biocidal active substances, significant progress has been made in recent years in relation to the release or revision of guidance documents. The comprehensive guidances, opinions, or recommendations available are intended to assist applicants in the identification of exposure models most appropriate for their intended applications. These exposure models are largely based on assumptions with respect to exposure durations and indicative exposure values which were compiled in the framework of surveys performed under real application conditions. The following documents are generally used and accepted by regulatory authorities in the exposure assessment of biocidal active substances/biocidal products with respect to the identification of exposure models for specific applications and application types:

- User Guidance – Version 1 (TNsG 2002)
- Technical Notes For Guidance 2007 (TNsG 2007)
- Opinions of the Human Exposure Expert Group (HEEG)
- Recommendations of the Ad hoc Working Group on Human Exposure (HEAdhoc)
- Biocides Human Health Exposure Methodology Document (BHHEM 2015)
- DRAFT Guidance on Estimating Dietary Risk from Transfer of Biocidal Active Substances into Foods – Nonprofessional Uses
- BPR Guidance Volume III Human Health Parts B+C (Guidance on the Biocidal Products Regulation 2017)

In some instances, however, an acceptable exposure cannot be demonstrated on the basis of exposure modeling even if all feasible exposure refinement options have been exhausted. In these situations, the applicant needs to decide on whether to withdraw the concerned use or to perform exposure measurements under representative application conditions. The latter option is very demanding and requires a high degree of expertise including an intensive preparation in relation to planning and design as well as documentation and evaluation of the results of the operator exposure study.

### **Substances of Concern and Cumulative Risk Assessment**

In the biocides area, the exposure and risk assessment process is not restricted to the active substance(s) only but needs also to consider “Substances of Concern” (SoCs). SoCs are understood as nonactive substances in a biocidal product which due to their intrinsic hazardous properties trigger or contribute to the classification of a biocidal product or substances which have been assigned a “IOELV” (Indicative Occupational Exposure Limit Value or Community workplace exposure limits). The latter type of substances requires a quantitative risk

characterization for local effects via the inhalation route in the intended applications. A further group of SoCs comprises substances which are active substances on their own but which have no biocidal function in the concerned biocidal product but rather function as a coformulant such as solvents. For this kind of SoCs, a quantitative risk characterization for systemic and/or local effects will be required in the biocidal product authorization process. Moreover, depending on the toxicological properties of both the active substance and the SoCs, the performance of a cumulative risk assessment may become necessary if common target organs/tissues or modes of action are identified in the respective toxicological data packages.

If the performance of a cumulative risk assessment will be needed, the overall risk, expressed as the “Hazard Index” (HI), is determined. This is accomplished by adding up the individual “Hazard Quotients” (HQ); the latter of which is formed by calculating the ratio of the estimated exposure and the respective reference dose (RfD) for the concerned substance with a view to the demonstration of acceptable risks in the intended biocidal application(s):

$$\text{HI} = \text{HQ}_A(\text{Exposure}_A/\text{RfD}_A) + \text{HQ}_B(\text{Exposure}_B/\text{RfD}_B) + \text{HQ}_C(\text{Exposure}_C/\text{RfD}_C) + \dots$$

Regardless of the substances concerned in the overall exposure and risk assessment process, the following outcomes will be obtained:

- $\text{HI} < 1$  (exposure  $<$  AEL/AEC): safe use and no unacceptable health risk identified
- $\text{HI} > 1$  (exposure  $>$  AEL/AEC): no safe use, i.e., identified health risk not acceptable

In the latter case, a refinement of the risk characterization process is triggered with a focus on the following:

- (a) Revisit of the toxicological data package with a view to increasing the reference values
- (b) Refinement of the exposure assessment by taking into considerations application-specific information on in-use concentrations, application duration, and frequency including considerations on the conduct of use-specific operator exposure (OPEX) studies

### Addendum: Tables and Lists

# Checklist: Toxicological Risk Assessment in Practice **98**

Michael Schwenk and H. Paul A. Illing

## Contents

Introduction .....	1492
Checklist and Comments .....	1492
Cross-References .....	1496
References .....	1496

## Abstract

The checklist gives brief practical hints for all those who are occasionally or professionally involved in toxicological risk assessment, risk management, and risk regulation, for example: when dealing with a new substance; a chemical incident; a pollution situation, where the full identity of the substances is unknown initially; a situation where human exposure exceeds guideline levels. It names typical questions arising in such situations, concerning the toxicological profile of the chemical, exposure levels, and risk. The checklist should be helpful in finding adequate solutions for many kinds of scenarios.

## Keywords

Exposure assessment · Hazard identification · Internal exposure · Risk management · Safety factor · Toxic effect · Threshold · Toxicodynamics · Toxicokinetics · Vulnerable individuals

## Introduction

Each industrial chemical and pharmaceutical product has its specific hazard and risk profile that has been characterized in the premarket period using harmonized test methods and guidelines. Once on the market, the safety data sheet (for chemicals) and the package leaflets (for pharmaceuticals) provide information for safe and correct handling. When incidents nevertheless happen, all relevant information must be collected as base for risk assessment, without any delay.

Toxicological considerations in the development phase of a chemical/pharmaceutical resemble those, made in chemical emergencies. They include technical aspects like physicochemical features, toxic profile, exposure route, and risk estimation but also aspects of risk communication and risk management.

The checklist below deals with some key questions to be asked in specific situations. The left column depicts items that should be considered, when dealing with such questions. The right column (comments) provides some additional explanatory remarks.

## Checklist and Comments

Checklist	Comments
<b>Which are the steps of the risk regulation process?</b>	
The WHO-IPCS document (IPCS 1994) identifies these as: <b>Risk assessment</b> (in four steps): Hazard identification Hazard characterization (including dose–response relationship) Exposure assessment Risk characterization <b>Risk management</b> Risk evaluation Emission and exposure control Risk monitoring	Risk assessments are made on the basis of a scientific examination of toxicity and exposure, leading to a risk characterization. The risk management process is aimed at developing an appropriate response (regulatory, technical, legal) to the hazard. Risk (or risk-benefit) evaluation, the first step in risk management, establishes a qualitative or quantitative relationship between risks and benefits of exposure to an agent and the influence of possible control measures on that evaluation. It may be necessary to examine relative risk and benefit for different agents used for the same purpose.
<b>What data on toxic properties are needed for risk assessment?</b>	
<b>Chemistry</b> Basic physical and chemical properties. Structure–activity relationships (if available) for the test substance and related substances. Chemical analysis	By proper assessment of the physicochemical properties (e.g., fat solubility, volatility, size of nanoparticles), it is often possible to get a first estimate of the risk level. This should soon be verified by analytical procedures.
<b>Identification of toxic effects</b> Animal testing results (acute, subacute, and chronic toxicity; carcinogenicity; and toxicity to reproduction) Evidence of irritation and sensitization Genotoxicity	Data quality (this includes whether appropriate protocols and audit procedures were employed) must be considered. For chemical assessment, Klimisch gradings are often used (Klimisch et al. 1997). The overall picture will emerge only from the

(continued)

Checklist	Comments
Results from in vitro tests Molecular mechanism of action Experience in humans (case reports, epidemiological studies, and experimental studies)	sum of all available information and will need reevaluation at periodic intervals and when new control measures are implemented. If in doubt, additional information/studies must be asked from poison control centers, manufacturers, and others.
<b>Toxicodynamics</b> Targeted organs, biomolecules Type of cell damage and repair Dose–response relationships (size of response). Rates of development and duration of effects.	Reversible or irreversible effect? Additive effects of mixtures (e.g., neurotoxicity)?
<b>Toxicokinetics</b> Absorption rates (oral, inhalation, dermal) Distribution Half-life Metabolites Routes and rates of elimination Experience with humans	Toxicokinetic data are often ignored in risk assessments – Which is a fault. Toxicokinetics determine levels and duration of organ exposure.
<b>What information is provided by the dose–response relationship?</b>	
<b>Dose–response diagram</b> Shows threshold above which effects can be observed (NOAEL/LOAEL/BMD). If the dose–response relationship is very steep, there is a very small safety margin. Shape of the curve influences values obtained by extrapolation to low doses (e.g., unit risk).	Non-sigmoidal dose–response relationship increases the uncertainty in extrapolation to low concentrations. NOAEL values of different studies often differ as they are the dose below the dose at which effects were seen and therefore depend on the dose intervals between doses in the study. They also depend on what parameters were measured in the studies. If in doubt, it should be checked as to whether one of the studies is better suited for a particular risk assessment.
<b>How is an exposure assessment made?</b>	
<b>Source and external exposure</b>	
Measurement or estimation of the extent of external exposure (in the intake, in the medium [air, water, food basket], or, using more complicated models, in the input to the medium [e.g., water] from the source [e.g., outlet sewer of chemical factory/sewage treatment works]). Observe all routes of exposure (oral, inhalation, dermal). Consider sensitive persons.	Exposure estimates can be extremely uncertain. Scenarios (models) should be clearly set out and estimates calculated according to standardized procedures. Estimates should not contain multiple “worst-case” assumptions (if the <i>P</i> value of 0.1 [i.e., 1 in 10 will show the effect] is applied three times, this gives a <i>P</i> value of 0.001 [1 in 1000]). Monte Carlo analysis is essential in these circumstances.
<b>Internal exposure</b>	
Calculation of the assumed maximum uptake on the basis of (worst-case) scenarios. Probabilistic assessment of the different routes of intake. Measurement of the internal concentration (human biomonitoring).	Human biomonitoring is the method of choice for internal exposure assessment – If available. It analyzes the substance in human body fluids of exposed versus unexposed (control) groups.

(continued)

Checklist	Comments
<b>Which safety factors are often used?</b>	
<p>Usual safety factor for extrapolation for a threshold effect from a good animal data to a general human population = 100 (depends on circumstances).</p> <p>Some regulatory agencies use safety factors up to 10,000 (see, e.g., IPCS 1994).</p>	<p>Depending on the size of the selected safety factors, risk assessments can vary enormously even when the experimental database is identical. This can easily lead to dispute.</p>
<b>Why does epidemiology rarely find a threshold value?</b>	
<p><b>Uncertainty</b> in the estimation of exposure of the effects at low doses</p> <p><b>Variability</b> for example, due to polymorphism and age</p>	<p>Lack of thresholds in epidemiological studies may be artificially caused by the multiplication of several uncertainty factors plus interindividual variability of toxicodynamics and/or toxicokinetics.</p>
<b>Who belong to the vulnerable groups?</b>	
<p>Pregnant women (organogenesis of the embryo), infants, and children (organ development, toxicokinetics)</p> <p>Elderly and sick people (low functional reserves, low repair capacity)</p> <p>Allergic people (hypersensitivity)</p>	<p>Often, sensitive groups are given special regulatory protection in various laws (occupational safety, baby food, allergens, etc.). This must be considered in the risk management process.</p>
<b>What else must be considered in risk management?</b>	
<p>Protection philosophy for the population at risk (nature and extent of population covered, use of personal protective equipment, etc.)</p> <p>Guideline values and their rationale. Are they applicable?</p> <p>Verification of measurement results</p> <p>Quality assurance of the process</p>	<p>The safety philosophy may be for good hygiene practice, precautionary, or danger-oriented. It may be for a fit, working population or include vulnerable groups. In order that a risk assessment finds acceptance, it is important to understand the origin of existing regulations as well as the present state of scientific interpretation of the toxicological data.</p>
<b>What does “traffic light principle” mean in regulation?</b>	
<p><b>Green:</b> No effect and no action required</p> <p><b>Yellow:</b> Slightly below threshold level.</p> <p>Adequate action: Monitoring</p> <p><b>Red:</b> Above the threshold of action. Swift action to reduce exposure and/or institute suitable control measures</p>	<p>Multistage systems such as the traffic light system are more flexible. Where only a single limit value exists, a brief or minor overrun may cause action or legal consequences, even if the excess is toxicologically irrelevant</p>
<b>When is a disease due to toxic substances?</b>	
<p>Causality can be assumed if exposure levels and exposure duration were sufficient and the response spectrum (the affected organ, expression) characteristic for a compound. The rarer the symptoms occur in daily life, the more secure a causal relationship can be assumed.</p> <p>Criteria to be considered are given in Hill</p>	<p>The causality principle is often presumed for toxic substances. But it is not easy to prove causality.</p> <p>With many drugs, possible unwanted effects are often overlooked. And the dramatic health effects of smoking and alcohol are often socially trivialized and ignored.</p> <p>Some dangerous substances produce very</p>

(continued)

Checklist	Comments
(1965) and are applicable to all toxicological data, not only epidemiological data	specific disease patterns (e.g., asbestos and mesothelioma).
<b>In which way can the modes of thinking influence the risk awareness?</b>	
<b>Scientific way of thinking (“objective risk”)</b> Risk assessment Risk comparison Risk management (technical)	Many social groups (toxicologists, engineers, politicians, stakeholders, arbitrator, government representatives, etc.) are potentially involved in risk communication and risk management.
<b>Emotional way of thinking, e.g., by the general public (perceived risk)</b> Risk acceptance or nonacceptance	In this process, it often happens that different ways of thinking collide. This leads to inner discomfort and confrontation. Knowledge of the various ways of thinking of the general public, as described by psychologists and sociologists, can reduce conflict.
<b>Political way of thinking (perceived risk)</b> Risk exaggeration (phantom risk) Risk trivializing Conclusion: Understanding the sociological and psychological aspects of risk perception and communication is critical to effective risk management.	A good moderator can help overcome these hurdles. Note: The eloquent charlatan and the lobbyist usually receive more credibility than the highly educated toxicologist and the regulator.
<b>How to deal with knowledge gaps?</b>	
<b>During development of chemicals and pharmaceuticals</b> Perform missing studies according to the needs and guidelines.	Check the current guidelines (guidelines are often updated); get information on the current state of expert discussions, notably in novel fields like biopharmaceuticals and nanoparticles.
<b>In chemical emergencies such as uncontrolled emissions, spills, and accidents</b> Protect humans and the environment, as adequate. Consider use of personal protection clothing. Organize medical assessment of exposed persons and treatment of injured individuals. Read safety data sheet. Contact regional poison center. Involve analytical laboratory. Check toxicological literature and current guidelines. Design an information sheet for the public. Advise the risk managing committee. Take measures for risk reduction and sanitation. Arrange follow-up study with measurement of exposure levels and disease parameters, and – Where possible – Measurement of the internal load of exposed vs unexposed persons.	Police, fire department, and medical first aid are the first to get alarmed; they organize initial rescue steps. Toxicologists may get involved early as well. They should then have knowledge about their responsibilities in the team. It may be favorable to involve additional experts who have experience with this kind of scenario. Rapid action and at the same time sensible dealing with uncertainties can be challenging. In cases where the identity of the contaminating/intoxicating substance is not clear, investigations should be made to reconstruct the cause of the incident and/or find the contamination source. Early support by an experienced trace-analysis laboratory is required. Repeated sampling and measurements allow to detect whether the chemical persists.

**Abstract**

Depending on the matrix (e.g., water, air) and the classification of a substance (e.g., contaminant), a multitude of limits and guidelines has been defined. The motivation for defining such a limit or guideline can be different. The most important reason is to protect the population from adverse health effects such as acute chronic toxicity or cancer. Another reason could be the protection of ecosystems which could be more vulnerable than humans. Moreover, aesthetic considerations, like the taste and/or odor of drinking water, can result in limitations of chemicals. In the following chapter, definitions of and examples for limits in water, air, or occupational environments are given. These lists are by no means exhaustible.

---

**Introduction**

Reference doses are important points of departure (POD) for calculating acceptable concentrations of contaminants in different media, e.g., food, water, or air. Since they are given on a per kg bodyweight base, sensitive population groups such as infants can be taken into account when necessary.

---

**Reference Doses****Acceptable Daily Intake (ADI) Values**

The World Health Organization (WHO) defined Acceptable Daily Intake (ADI) values for pesticides, food additives, and veterinary pharmaceuticals. The ADI values form the basis for the maximum concentration of contaminations in food. These values can be considered safe, even if a lifetime exposure is assumed (see Table 1 or references mentioned “Resources”).

**Acute Reference Dose (Acute RfD)**

In order to avoid health risks caused by a single exposure exceeding the ADI, the WHO has established acute reference doses (acute RfD; see Table 1) for some pesticides. This is supposed to help local authorities to deal with spills or accidents.

**Contaminants**

If the uptake of a contaminant is per definition of the WHO acceptable, because the contaminant is useful, these contaminations become “tolerable.” Early on (since 1972), provisional tolerable weekly intake (PTWI) values were defined for metals,

which accumulate in the human body due to their ubiquity. The definition of a tolerable weekly intake is motivated by the fact that one increased intake per week caused, for example, by certain foods is irrelevant. An example for this can be the uptake of methylmercury via fish. Later on, this concept was extended to substances (e.g., mycotoxins) that are not accumulating in the human body or that can diffuse into foods from packaging materials. In some cases, the limit was referred to a daily intake (PMTDI = provisional maximum tolerable daily intake). For pesticides which are banned but still contaminants of food products, the original ADI value was transferred into a PTDI value (provisional tolerable daily intake). MTDI (maximum tolerable daily intake) values were derived for substances that are essential for human nutrition but for which the range between physiological needs and toxic dose is very small, e.g., copper or iron. *TDI* (tolerable daily intake) values are the basis of the WHO's drinking water guidelines. Table 2 depicts tolerable intake values of some chemicals.

### Tolerable Absorbed Doses (TRD)

For chemicals that are also important contaminants in soil, the so-called tolerable absorbed doses ("tolerierbare resorbierte Dosis," TRD) were derived by the Research and Advisory Institute for Hazardous Substances ("Forschungs- und Beratungsinstitut Giftstoffe," FoBiG) based in Freiburg, Germany. The values given in Table 3 are calculated for safe, lifetime exposure, either after oral or

respiratory intake. In order to compare those values with other limits like ADI, the absorption rate has to be taken into account.

## Reference Dose and Reference Concentration (RfD, RfC)

The US Environmental Protection Agency (US-EPA) has established dose limits for oral (reference dose, RfD) or respiratory (reference concentration, RfC) uptake of many chemicals. Based on these values, the US limits for air, water, and food were defined. Listing all of these would exceed the scope of the book. The list can be found on the Internet at <http://www.epa.gov/iris>.

## Occupational Safety and Health

According to the World Health Organization (see WHO in “Resources”), “occupational health deals with all aspects of health and safety in the workplace and has a strong focus on primary prevention of hazards. The health of the workers

$$^a \left( \sum \left( \frac{\alpha HCH}{5} + \beta HCH + \frac{\gamma HCH}{16} \right) \right)$$

has several determinants, including risk factors at the workplace leading to cancers, accidents, musculoskeletal diseases, respiratory diseases, hearing loss, circulatory diseases, stress related disorders and communicable diseases and others.” Therefore, the European Union (EU) established the Occupational Safety and Health Agency to protect workers from occupational health hazards. Its abbreviation is “EU-OSHA” to be distinguishable from its sister agency in the USA, which is referred to as “OSHA.” Every country of the EU and the EFTA (European Free Trade Association) has its own so-called focal points, which make up the national partners of EU-OSHA. Five priority groups were formed to satisfy the special needs of some of the most vulnerable workers: young workers, women, people with disabilities, migrant workers, and aging workers. To facilitate the implementation of EU directives on a national basis, the EU-OSHA passed several guidelines for topics such as workplaces, personal equipment, chemical agents, or physical hazards (see “Resources”). In Germany, the Federal Agency for Occupational Safety and Medicine (AGS 2020) has passed several technical guidelines (TRGS 900, 903, and 905) to implement the directive (EG) Nr. 1272/2008 (CLP) on classification, packaging, and labeling of dangerous substances. The guideline TRGS 900, for example, regulates the limits of

**Table 4** Workplace limits of selected chemicals in Germany (TRGS 900) and the USA (OSHA)

Substance	TRGS 900	US-OSHA
	Concentration [mg/m <sup>3</sup> ]	Concentration [mg/m <sup>3</sup> ] <sup>a</sup>

<sup>a</sup>Since most values provided by OSHA are given in ppm, transformation into mg/m<sup>3</sup> was based on a pressure of 1013 hPa and a temperature of 20 °C

<sup>b</sup>OSHA did not establish an exposure limit for dichloromethane. This value was established by the American Conference of Governmental Industrial Hygienists (ACGIH) and is quoted by OSHA

exposure against some 350 chemicals (AGS 2019). Similar regulations were passed in every member state of the EU, the USA (for link see “Resources”), and other countries. In all regulations, different aspects of toxicology, i.e., acute and chronic exposure or carcinogenic potential, are considered. From 1995 to 2018, the Scientific Committee on Occupational Exposure Limits (SCOEL) assisted the European Commission in assessing chemicals and their effects on workers on the European level. Since 2019, this task is fulfilled by the ECHA Risk Assessment Committee (RAC). Information about the activities of the RAC can be found on the web (for link see “Resources” – ECHA and RAC 2020). Currently, five opinions on occupational exposure limits (OEL) have been adopted, and another two are pending. Although the lists of substances that are regulated in Europe and the USA are quite similar, the limits can vary considerably as can be seen from Table 4.

---

## Drinking Water

### WHO Guidelines for Drinking Water Quality (WHO-GLDWQ)

The WHO recommends limits for organic as well as inorganic chemicals in its “Guidelines for Drinking-water Quality,” which are not legally binding (see Table 5 or WHO 2017). Especially in countries without national regulations on drinking water, they can be used as guidelines. They are mostly derived from toxicological data, and the quality of the water bodies themselves is given only limited consideration. The European drinking water directive is currently revised, and new parameter values for lead, chromium, and perfluorinated chemicals will be implemented.

**Table 5** Comparison between the WHO guidelines on drinking water quality and the limits in the German drinking water regulation (TrinkwV 2019)

Trichloroacetic acid	0.20	
Trichloroacetonitrile	i.d.	

*n.l.c.n.* no limit considered necessary; *t.m.* more toxic metabolites, but insufficient data on them; *i.d.* insufficient data

<sup>a</sup>Additional risk for skin cancer  $10^{-4}$

<sup>b</sup>Limit of 0.025 mg/l until 11/30/2013, 0.010 mg/l from 12/01/2013

<sup>c</sup>Additional risk for cancer  $10^{-5}$

<sup>d</sup>Sum of the following substances: benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[ghi]perylene, indeno[1,2,3-cd]pyrene

<sup>e</sup>General limit for pesticides in German drinking water, when no lower value is necessary, sum 0.5 µg/l

<sup>f</sup>For authorities wishing to establish a total THM standard to account for additive toxicity, the following fractionation approach could be taken: the sum the value of each THM divided by this guideline value has to be <1

## German Regulation on Drinking Water

The German drinking water regulation (“Trinkwasserverordnung,” TrinkwV) was ratified in February 2001 and entered into force on January 1, 2003. It was last modified on January 3, 2018. Most of the limits are based on the guidelines of WHO. Exceptions are the limits for pesticides. The WHO states a health-based limit for each pesticide, whereas in the EU and thus also in Germany, the drinking water limit of 0.1 µg/L is politically motivated. In addition, the EU has set a limit for the sum of all pesticides (i.e., 0.5 µg/l; see Table 5).

## Air

### World Health Organization (WHO) Air Quality Guidelines

Clean air is a basic need for human well-being and health. The World Health Organization (WHO) therefore first published its Air Quality Guidelines for Europe in 1987, and a second edition was issued in 2000 (WHO 2000). Within these guidelines, guideline values for various inorganic, organic, and so-called classical pollutants (i.e., nitrogen dioxide, ozone, particulate matter, and sulfur dioxide) for air outdoors were established. Moreover, guideline values for indoor air pollutants were

**Table 6** Air quality guideline values as provided in the second air quality guidelines for Europe, the global update in 2005 and guidelines for indoor air quality: selected pollutants (WHO 2010)

Substance	Concentration [ $\mu\text{g}/\text{m}^3$ , if not otherwise indicated] or unit risk (UR) <sup>a</sup>	Averaging period
<b>Classical pollutants</b>		
Sulfur dioxide (SO <sub>2</sub> )	20	24 h
	500	10 min
Nitrogen dioxide (NO <sub>2</sub> )	40	Year
	200	1 h
PM <sub>10</sub> <sup>b</sup>	20	Year
	50	24 h <sup>c</sup>
PM <sub>2.5</sub> <sup>b</sup>	10	Year
	25	24 h <sup>c</sup>
Ozone <sup>b</sup>	100	Daily maximum 8-h mean
<b>Organic pollutants</b>		
Acrylonitrile	UR: $2 \times 10^{-5}$ (lung)	
Benzene	UR: $6 \times 10^{-6}$ (blood: leukemia)	
Carbon disulfide	100	24 h
Carbon monoxide	7 mg/m <sup>3</sup>	24 h
	10 mg/m <sup>3</sup>	8 h
	35 mg/m <sup>3</sup>	1 h
	100 mg/m <sup>3</sup>	15 min
1,2-Dichloroethane	700	24 h
Dichloromethane	450	1 week
	3,000	24 h
Formaldehyde	100	30 min
Polycyclic aromatic hydrocarbons <sup>d</sup>	UR: $8,75 \times 10^{-5}$ (lung)	
Styrene	260	1 week
Tetrachloroethylene	250	Year
Toluene	260	1 week
Trichloroethylene	UR: $4.3 \times 10^{-7}$ (lung, testis)	
Vinyl chloride	UR: $1 \times 10^6$ (lung and other sites)	
<b>Inorganic pollutants</b>		
Arsenic	UR: $1.5 \times 10^{-3}$ (lung)	
Asbestos	At a concentration of 500 fibers <sup>e</sup> /m <sup>3</sup> , the following ranges of lifetime risk estimates are made: $10^{-6}$ to $10^{-5}$ (lung cancer in a population where 30% are smokers) $10^{-5}$ to $10^{-4}$ (mesothelioma)	
Cadmium	0.005	Year
Chromium (VI)	UR: $4 \times 10^{-2}$ (lung)	
Hydrogen sulfide	150	24 h
Lead	0.5	Year
Manganese	0.15	Year

(continued)

**Table 6** (continued)

Substance	Concentration [ $\mu\text{g}/\text{m}^3$ , if not otherwise indicated] or unit risk (UR) <sup>a</sup>	Averaging period
Mercury	1	Year
Nickel	UR: $4 \times 10^{-4}$ (lung)	
Platinum		
Refractory ceramic fibers	UR: $1 \times 10^{-6}$ (fiber/l) <sup>-1</sup> (lung)	
Vanadium	1	24 h
<b>Indoor air pollutants</b>		
Environmental tobacco smoke	UR: approximately $1 \times 10^{-3}$	
Man-made vitreous fibers	See above (refractory ceramic fibers, for most other MMVF data are considered inadequate to establish AQG)	
Radon	Reference level: 100 Bq/m <sup>3</sup> (a)	Year
	300 Bq/m <sup>3</sup> (b)	Year
	UR <sup>f</sup> : $0.6 \times 10^{-5}$ per Bq/m <sup>3</sup> (nonsmokers)	
	UR <sup>f</sup> : $15 \times 10^{-5}$ per Bq/m <sup>3</sup> (smokers)	
Naphthalene	10	Year

<sup>a</sup>Unit risk: Cancer risk estimates for lifetime exposure to concentration of  $1 \mu\text{g}/\text{m}^3$

<sup>b</sup>Air quality guideline (AQG) values

<sup>c</sup>24-h concentration: 99th percentile (3 days/year)

<sup>d</sup>Based on benzo[a]pyrene

<sup>e</sup>Fibers measured by optical methods

<sup>f</sup>Excess lifetime risks (by the age of 75 years) for lung cancer of lifelong nonsmokers or current smokers (15–24 cigarettes/day)

1. To minimize health hazards due to indoor radon exposure

2. Applies only if the Reference Level mentioned in (a) cannot be reached under the common country-specific conditions

provided. In 2005, a global update became available for the classical pollutants (WHO 2006). There are also guidelines for emissions of gases and chemicals from furnishings and building materials that collect indoors (WHO 2010), and the most recent WHO guideline deals with indoor air quality – household fuel combustion (WHO 2014). In this guideline, no need for review of the evidence informing the published WHO guidelines for air quality (AQG) was identified. Currently available air quality guideline values are provided within Table 6.

### Immission Values Based on EU Directives

Within the European Union, there are directives dealing with several air pollutants (e.g., nitrogen dioxide, particulate matter, lead, and sulfur dioxide), which provide immission limit values. They are mostly based on the recommendations of the WHO

**Table 7** Immission limit values and target values for protection of human health taken from 39th BImSchVO, which represents national implementation of current European legislation

Substance	Concentration [ $\mu\text{g}/\text{m}^3$ ]	Averaging period	Allowed frequency of excess per year
Sulfur dioxide (SO <sub>2</sub> )	125	Day	3
	350	1 h	24
Nitrogen dioxide (NO <sub>2</sub> )	40	Year	–
	200	1 h	18
PM <sub>10</sub>	40	Year	–
	50	Day	35
PM <sub>2.5</sub> <sup>a, b</sup>	25	Year	
Ozone <sup>c</sup>	120	Daily maximum 8-h mean	25
Lead	0.5	Year	
Benzene	5	Year	
Carbon monoxide (CO)	10,000	Daily maximum 8-h mean	
Arsenic <sup>d</sup>	6 ng/m <sup>3</sup>	Year (total content in PM <sub>10</sub> fraction)	
Cadmium <sup>d</sup>	5 ng/m <sup>3</sup>		
Nickel <sup>d</sup>	20 ng/m <sup>3</sup>		
Benzo[a]pyrene <sup>d</sup>	1 ng/m <sup>3</sup>		

<sup>a</sup>Immission limit value, but starting from January 1, 2020, further reduction of PM<sub>2.5</sub> exposure according to national target value is foreseen. This target value depends on the value of the indicator for the average PM<sub>2.5</sub> exposure according to §15 in the reference year 2010. The assessment shall be carried out by the German Environment Agency in accordance with Annex 12, Section B

<sup>b</sup>This commitment was also included in the recast of the National Emission Ceilings Directive (NEC Directive) adopted in 2016 and supplemented by a target for 2030 (EC 2001, 2016). By that date, German PM<sub>2.5</sub> emissions must be reduced by 43% compared to 2005 (for link see “Resources”)

<sup>c</sup>Target value, which will be the long-range target value without allowance of excess

<sup>d</sup>Target values which will be valid from January 1, 2013 onward

(see above) and are designed to protect human health from harmful environmental influences. In Germany, the respective legislation is based on the Federal Immission Control Act (“Bundes-Immissionsschutzgesetz,” BImSchG, last updated in 2011). Limit values were defined earlier within the 22<sup>nd</sup> Regulation of Federal Immission Control (22. BImSchVO as of October 26, 1993). In 1996, the Framework Directive 96/62/EC entered into force and subsequently various sub-directives (“daughter directives” in Annex I of Framework Directive; 1999/30/EC; 2000/69/EC; 2002/3/EC; 2004/107/EC), in which immission limit values were described to ensure protection of human health, as well as protection of the environment (ecosystems and vegetation). For implementation of revisions made, the European Directive 2008/50/EC entered into force (May 21, 2008). Afterward in Germany, the 22<sup>nd</sup> amended BImSchVO was withdrawn and newly regulated on a national level via the 39<sup>th</sup> Regulation of Federal Immission Control (39. BImSchVO as of August 2, 2010; see Table 7 and for link see “Resources”). In case of carcinogenic substances (e.g., benzene), the limit values are set to an extra risk of  $1:1 \times 10^{-6}$ .

**Table 8** Immission limit values for protection from hazard to human health according to “TA Luft”

Substance	Concentration [ $\mu\text{g}/\text{m}^3$ ]	Averaging period	Allowed frequency of excess per year
Sulfur dioxide (SO <sub>2</sub> )	50	Year	–
	125	24 h	3
	350	1 h	24
Nitrogen dioxide (NO <sub>2</sub> )	40	Year	–
	200	1 h	18
PM <sub>10</sub>	40	Year	–
	50	24 h	35
Lead <sup>a</sup>	0.5	Year	
Benzene	5	Year	
Tetrachloroethylene	10	Year	

<sup>a</sup>Lead and its inorganic compounds as part of particulate matter (PM<sub>10</sub>), given as Pb

### Technical Instruction on Air Quality Control (“TA Luft”)

Based on the Federal Immission Control Act (“Bundes-Immissionsschutzgesetz,” BImSchG, last updated in 2011), an administrative act was issued. This was the technical instruction on air quality control (“TA Luft” as of July 24, 2002, which replaces the “TA Luft” from 1986). Within this updated administrative act, emission and immission values are provided. They are used to control for construction and operation of industrial sites, which are subjects of approval. Emission values are precautionary values in order to protect against detrimental environmental influences. Immission values shall protect from hazard to human health (see Table 8) as well as from major disturbance or disadvantages.

### Indoor Air Guide Values

Besides the WHO air quality guideline values indicated above (see Table 6), which can be used for indoor air as well, national committees are in place to establish guideline values for indoor air (see Table 9). In Germany, since 1993, there is a Committee on Indoor Guide Values (“Ausschuss für Innenraumrichtwerte,” AIR, formerly “ad hoc working group”). AIR consists of technical experts from the Indoor Air Hygiene Commission (IRK) of the German Environment Agency and the Permanent Working Group of the Highest State Health Authorities (“Arbeitsgemeinschaft der Obersten Landesgesundheitsbehörden,” AOLG). Until now, guide values for various organic compounds, hydrocarbons used as solvents, mercury vapors, and the inorganic gases carbon monoxide and nitrogen dioxide have been derived. There are two categories of guideline values: *RW-I* and *RW-II* (RW = “Richtwert” = guide value).

**Table 9** Guide values of the last 5 years from AIR

Substance	RW-II <sup>a</sup> [µg/m <sup>3</sup> ]	RW-I <sup>a</sup> [µg/m <sup>3</sup> ]	Year of designation by AIR
Nitrogen dioxide (NO <sub>2</sub> ) (CAS no. 10102-44-0)	250 (60 min)	80 (60 min)	2018
2-Phenoxyethanol (CAS no. 122-99-6)	100	30	2018
Tetrachloroethene (CAS no. 127-18-4)	1,000	100	2017
Propan-1,2-diol (CAS no. 57-55-6)	600	60	2017
C7-C8-alkylbenzenes – total guide values: toluene, xylene, ethylbenzene	See comment b below		2016
Toluene (CAS no. 108-88-3)	3,000	300	2016
Formaldehyde (CAS no. 50-00-0)	Not derived	100	2016
Xylene total (CAS no. 95-47-6; 108-38-3; 106-42-3; 1330-20-7)	800	100	2015
2-Butanone oxime (CAS no. 96-29-7)	60	20	2015
2-Chloropropane (CAS no. 75-29-6)	8,000	800	2015

Further values are available, Resources: “Umweltbundesamt 2020” <https://www.umweltbundesamt.de/themen/gesundheit/kommissionen-arbeitsgruppen/ausschuss-fuer-innenraumrichtwerte-vormals-ad-hoc>

<sup>a</sup>Usually, these guidelines are given as long-term values. Averaging periods deviating from this are given in brackets, e.g., 60 min

<sup>b</sup>For each substance *i*, the ratio  $R_i$ :  $R_i = c_i/RW_i$  is formed. In this,  $c_i$  is the concentration of the respective substance in indoor air and  $RW_i$  is the corresponding guide value. The respective  $R_i$  are then added to an  $R$ :  $R = \sum R_i = \sum c_i/RW_i$ . If  $R$  is exceeding the value of 1, the respective total reference value is exceeded. Applicable guide values:

Substance	RW-II a [µg/m <sup>3</sup> ]	RW-I a [µg/m <sup>3</sup> ]
Ethylbenzene	2000	200
Xylene total	800	100
Toluene	3000	300

RW-I is a precautionary guideline. It is anticipated that even with lifelong exposure below the RW-I concentration, no adverse effects on human health are to be expected. If the threshold is exceeded, additional and non-usual burden might be the case. If the measured concentration is between RW-I and RW-II, precautionary measures shall be taken (either by changing the consumer behavior or by technical or construction measures). RW-I guideline values can be used as target values for remediation purposes.

RW-II values are effect-related values, which are derived from current toxicological and epidemiological data on the respective substance taking assessment factors into account. Depending on the mode of action, the RW-II values might refer to short-term (RW-II-K) or long-term values (RW-II-L). In case that the RW-II value is reached or even exceeded, an acute need for action is indicated.

## Food

### **Maximum Residual Levels (MRLs): International, European, and National Standards and Regulations**

As fruits and vegetables are prone to various detrimental effects (e.g., diseases and pests), pesticides are used to ward off or at least minimize these negative consequences. On the other hand, it must be granted that plant protection products have no adverse effects on human health. Therefore, maximum residual levels (MRLs) are in place in order to prevent consumers from adverse health effects. Within Europe, maximum residue levels are defined as “upper levels of pesticide residues that are legally permissible in or on food or animal feed, based on good agricultural practice and the lowest consumer exposure necessary to protect vulnerable consumers.” Most of the values are based on the ALARA principle (as low as reasonably achievable). If the MRL within one foodstuff is exceeded, trading might be forbidden, even if there is no adverse health effect yet.

The WHO and the FAO (Food and Agriculture Organization of the United Nations) jointly publish the *CODEX Alimentarius*, which provides international food standards for pesticides (also for veterinary drugs and food additives). The CODEX standards contribute to the safety, quality, and fairness of the international food trade. They are only recommendations but may often serve as a basis for national legislations. The standards are not listed here as they can easily be searched within the given Internet source (see “Resources”).

In Europe, in 2005, a harmonized regulation was being introduced with Regulation (EC) No 396/2005 which entered into force in 2008. The text of the regulation is given on the homepage of the Federal Office of Consumer Protection and Food Safety, which includes the currently valid MRLs in Annex II, IIIA, and IIIB. As the list of regulated substances is quite extensive and would not fit into this chapter, we refer to the list as provided within the regulation. Moreover, an EU Pesticides Database was established in order to perform searches for MRLs (for link see “Resources”). In cases where no specific MRL was determined, a general level of 0.01 mg/kg has to be met.

Even though the European Regulation overrules the former, valid German Regulation on maximum residual levels (“Rückstands-Höchstmengenverordnung,” RHmV, 1994, last updated in 2010), which was the national implementation of various former EU Directives (i.e., 90/642/EEC, 93/57/EEC, 93/58/EEC), this regulation still is in force concerning certain areas, for example, for safeners and synergists which are relevant co-formulants in plant protection products, or in case of category 11 (fish, fish products, shellfish, mollusks, and products of other freshwater or seawater fish). In case of group 12 (exclusive use as feeding stuff), still the German Regulation on Feeding stuff (“Futtermittelverordnung,” FuttMV, 1981, last updated in 2018) is in place.

### **European Maximum Levels for Certain Contaminants in Foodstuffs**

Contaminants are substances that have not intentionally been added to food. In general, they negatively influence the quality of food and may cause harm to

human health in certain cases. Basic principles are therefore regulated within Council Regulation 315/93/EEC, stating that food containing unacceptable amounts of contaminants based on considerations for the human health shall not be placed on the market, the level shall be kept as low as reasonably achievable (ALARA principle), and maximum levels must be set. These maximum levels are given in the Commission Regulation (EC) No 1881/2006, which entered into force in 2007 and was amended afterward several times. Currently, there are community measures for the following contaminants: mycotoxins (aflatoxins, ochratoxin A, *Fusarium* toxins, patulin, citrinin, ergot sclerotia, and ergot alkaloids), metals (cadmium, lead, mercury, inorganic tin), dioxins and PCBs, polycyclic aromatic hydrocarbons (PAH), 3-monochloropropanediol (3-MCPD) and glycidyl fatty acid ester, nitrates, and plant toxins (erucic acid, tropane alkaloids, and prussic acid). Even though only a small number of contaminants are regulated, the list is quite extensive as foodstuff description is detailed, and therefore here it is referred to the list included in the Commission Regulation (EC) No 1881/2006 and its amendments (for information please see Resources: European Commission).

---

## Soil

Germany adopted a legislation to protect soil in 1998 (so-called Bundes-Bodenschutzgesetz, BBodSchG). Based on this legislation, the federal regulation on soil conservation and contaminated sites was adopted in 1999 (“Bundesbodenschutzverordnung,” BBodSchV; see also “Resources”). Within this regulation, there are *precautionary values*, *trigger values*, and *action values* (i.e., “Vorsorge, Prüf- und Maßnahmenwerte”). These values are designed to apply for different routes of exposure (i.e., soil to humans, soil to plants, soil to groundwater). The values established for direct interaction (soil to humans) are the most relevant from the toxicological point of view (see Table 10). These values always consider different exposure scenarios (i.e., playground, residential area, park and recreation area, industrial sites) and are usually derived from the *TRD* values (tolerable absorbed dose; cf. paragraph on Tolerable Absorbed Doses (*TRD*)). In case of carcinogenic substances, an additional risk of  $>5 \times 10^{-5}$  is assumed to be no more tolerable under defined exposure assumptions for trigger as well as action values.

When a trigger value is exceeded, a site-specific assessment has to be performed, in order to investigate if a detrimental effect to soil quality or even a hazardous waste site may be present. This site-specific determination allows the respective authority to decide if further action to reduce exposure is necessary.

In general, if action values specified for a certain exposure scenario (e.g., playground) are exceeded, it is assumed that detrimental effects to soil quality occurred or a hazardous waste site was identified, and an immediate need for action to reduce exposure exists. Action values are only available for polychlorinated dibenzodioxins or dibenzofurans.

**Table 10** Trigger and action values for substances mentioned in Annex 2 of the “BBodSchV” (exposure pathway: soil to humans)

Trigger values [mg/kg dry weight]				
Substance	Playground	Residential area	Park and recreation area	Industrial site
Arsenic	25	50	125	140
Lead	200	400	1,000	2,000
Cadmium	10 <sup>a</sup>	20 <sup>a</sup>	50	60
Cyanides	50	50	50	100
Chromium	200	400	1,000	1,000
Nickel	70	140	350	900
Mercury	10	20	50	80
Aldrin	2	4	10	–
Benzo[a]pyrene	2	4	10	12
DDT	40	80	200	–
Hexachlorobenzene	4	8	20	200
Hexachlorocyclohexane (HCH mixtures or beta HCH)	5	10	25	400
Pentachlorophenol (PCP)	50	100	250	250
Polychlorinated biphenyls (PCB) <sub>6</sub> <sup>b</sup>	0.4	0.8	2	40
Action values [ng I-TEQ/kg dry weight] <sup>c</sup>				
Polychlorinated dibenzodioxins/dibenzofurans (PCDD/F)	100	1,000	1,000	10,000

<sup>a</sup>In garden plots, which can be occupied by children and are used for growing food plants, a guidance value of 2 mg cadmium per kg dry weight has to be applied

<sup>b</sup>In case total amount of PCBs are determined, the measured values have to be divided by 5

<sup>c</sup>Total amount of 2,3,7,8-TCDD toxicity equivalents (according to NATO Committee on the Challenges of Modern Society)

A volume entitled “Calculation of guidance values for assessment of hazardous waste sites” is dedicated to the protection of soil and was published by the German Environment Agency (Bachmann et al. 2007). This supplementary volume includes the underlying calculations for all legally binding trigger values presented in Table 10. Moreover, references for further trigger values are given for approximately 50 additional substances, relevant for hazardous waste sites, especially abandoned military sites.

## Body Burden

The Human Biomonitoring Commission is part of the German Environment Agency (“Umweltbundesamt,” UBA). Members are recruited from federal and regional authorities, as well as from academia (universities, institutes of hygiene, medicinal clinics). The work of the commission was to establish various reference

**Table 11** Reference values and Human Biomonitoring (HBM) values for various substances in urine or blood

Substance and matrix	Reference values		Human biomonitoring (HBM) values		
	Subpopulation	Reference value	Subpopulation	HBM-I	HBM-II
Lead (blood)	Children (girls 3–17 y, boys 11–17 y)	15 µg/l	Children ≤12 years and females of reproductive age Other persons	Suspended	Suspended
	Children (boys 3–10 y)	20 µg/l			
Cadmium (urine)	Females (18–69 y)	30 µg/l	Children and adolescents Adults	0.5 µg/l 1 µg/l	2 µg/l 4 µg/l

<sup>a</sup>*Crea creatinine*

<sup>b</sup>Derived from females in reproductive age. The use is recommended for other groups

<sup>c</sup>No reference value, but should there be analytical reliable and confirmed concentrations above the mentioned value, a special exposure must be expected

<sup>d</sup>Subpopulation only refers to adults who were living in homes where no wood preservatives had been used

<sup>e</sup>Possible sensitization not considered

**Table 12** Reference values for persistent organic pollutants in whole blood [ $\mu\text{g/l}$ ]

Age (years)	PCB 138	PCB 153	PCB 180	$\Sigma$ PCB (138 + 153 + 180)	$\beta$ -HCH	HCB	DDE	
							Germany	
							East	West
7–14	0.3	0.4	0.3	1.0	0.1	0.2	1.4	0.7
18–19	0.4	0.6	0.3	1.1	0.3	0.4	3	1.5
20–29	0.6	0.9	0.6	2.0	0.3	0.5	5	2
30–39	0.9	1.6	1.0	3.2	0.3	1.0	11	4
40–49	1.4	2.2	1.6	5.1	0.3	2.5	18	7
50–59	1.7	2.8	2.1	6.4	0.5	3.3	31	8
60–69	2.2	3.3	2.4	7.8	0.9	5.8	31	11

Note: Values for PCB 138, PCB 153, and PCB 180 and the sum of these PCBs are no longer listed on the homepage of the German Environment Agency (“Umweltbundesamt”)

**Table 13** Reference values for some polychlorinated biphenyls (PCB) and organochlorines in human breast milk [mg/kg fat]

Total DDT (applies only to women in western Germany)	Total PCB (138 + 153 + 180) <sup>a</sup>	$\beta$ -HCH	HCB
0.5	0.5	0.07	0.06

<sup>a</sup>Total PCB = 1.64\*(PCB 138 + PCB 153 + PCB180)

and Human Biomonitoring values for different toxic substances in various body fluids, which are further exemplified below (Tables 11, 12, and 13 and Resources “HBM-Commission”).

The reference value describes the exposure of individuals or population groups compared to the ubiquitous background exposure (they are checked and updated continuously). The reference value for a specific chemical is established only on a statistical basis, after having collected a representative series of measurements (from a defined group of the general population). These values therefore have not been derived with respect to protecting human health.

In contrast to that, Human Biomonitoring (HBM)-I and HBM-II values are based on toxicological and epidemiological data. The derivation of HBM values relied on studies that allowed correlating the concentration of a substance or its metabolites in human body fluids and the occurrence of adverse effects. Such studies are lacking for most of the substances. Thus, since 2014, the HBM Commission also derives HBM values based on toxicologically justified tolerable daily intakes or other suitable parameters from animal experiments. Known uncertainties of this approach are weighed against urgently required HBM values for substances or their metabolites for which no suitable studies on health effects of low-dose environmental exposure are currently available.

According to the current opinion of the HBM committee, HBM-I values represent the concentration of a chemical in a defined biological material, below which no adverse health effect is expected and therefore no actions have to be taken. In case the *HBM-I value* is exceeded, but is still lower than the *HBM-II value*, further

measurements have to be performed, and the possible source of exposure should be identified. Moreover, the exposure to the source should be minimized. The HBM-I value thus represents a verification or control value.

HBM-II values represent the concentration above which a high possibility of an adverse health effect exists, thus resulting in acute need for action (i.e., reduction of exposure and biomedical care (advice)). The HBM-II value therefore represents an intervention or action value.

# Regulatory Toxicology: Glossary

Franz-Xaver -X. Reichl and Gisela Degen

**Abuse** Improper and excessive use of drugs or stimulants (e.g., alcohol, tobacco) and the use of pharmaceutical products without medical indication or in exceeding doses.

**Acceptable Risk** This is a risk management term (for a given risk level). Risk levels used for risk evaluations can only be sociopolitically established rather than scientifically substantiated. Numerous criteria have to be taken into account apart from risk perception, e.g., severity of health damage, the possible extent of damage (type of damage and/or number of persons affected), relation to other comparable risks, direct benefit, and actual and possible risk reduction measures. According to a concept adopted in 2007 by the German Committee on Hazardous Substances (AGS), an *acceptable* and a *tolerable* risk level serves to derive exposure-risk relations for carcinogenic chemicals at the workplace. This concept for setting risk-based occupational exposure limits is linked to a set of risk reduction measures.

**Accumulation** Enrichment of a substance in a medium or environmental compartment. Bioaccumulation is the successive enrichment of a repeatedly administered chemical in an organism when the half-life is very long due to minor metabolism and slow excretion. Accumulation occurs often in specific organs, e.g., cadmium in kidney, lead in bone, and PCDD in fat tissue. Body burden.

**Acute Toxicity** Adverse effect occurring within a short time of exposure (up to max. 14 days) after a single (high) dose (see also (Sub)chronic Toxicity).

**Acute Toxicity Test** Test with an observation time up to 14 days after a single dose. The toxic class method (for estimating LD50) requires a clearly reduced number of animals.

---

F.-X. -X. Reichl  
LMU Munich, Munich, Germany

G. Degen  
Leibniz Research Centre for Working Environment and Human Factors, Dortmund, Germany  
e-mail: [degen@ifado.de](mailto:degen@ifado.de)

**Adaptation** Compensatory change in an organism, in response to certain environmental conditions, which occurs without disruption of the biological system and without exceeding the homeostatic capacities of its response.

**Added Risk** Difference between the incidence of an adverse effect on a treated group of organisms or a group of exposed humans and a control group.

**Additive Effect** An effect which is the simple sum of the effects of two or more chemicals acting independently (see also Combined Chemical Effects).

**ADI (Acceptable Daily Intake)** Dose of an agent (amount expressed on a body mass basis) to which an individual in a (sub)population may be exposed daily over its lifetime without an appreciable health risk. The WHO sets ADI values for food additives and tolerable daily intakes (TDI) for contaminants; they are calculated by division of the *NO(A)EL* with a *safety factor* (see also Reference Dose and TDI).

**Adverse Effect** “Change in the morphology, physiology, growth, development, reproduction or life span of an organism, system, or (sub)population that results in an impairment of functional capacity, an impairment of the capacity to compensate for additional stress or an increase in susceptibility to other influences. Decision on whether or not any effect is adverse requires expert judgement” (according to IPCS/WHO 1994). A biochemical change, functional impairment, or pathologic lesion that affects the performance of the whole organism or reduces an organism’s ability to respond to an additional environmental challenge.

**Agent** Something (chemically, physically, or biologically active principle) capable of producing an effect.

**Aggrieved Party** Any natural person or legal entity or rather a group of persons whose interests or values can be affected (derogated) by the impact of risks or by risk reduction measures.

**Agonist** Chemical that can activate a receptor similar to a physiological mediator.

**AGS** Ausschuss für Gefahrstoffe, the German Committee on Hazardous Substances. The AGS gives advice to the German Federal Ministry of Labour and Social Affairs regarding regulation of workplace chemicals.

**AGW** Arbeitsplatzgrenzwert: A health-based OEL for a substance in workplace air set by the German Committee on Hazardous Substances (AGS) according to criteria of BekGS 901 and published in the TRGS 900. The AGS evaluates OELs proposed by the German MAK commission, by SCOEL, and by other scientific advisory bodies (DECOS, TLV committee).

**ALARA** Acronym for “as low as reasonably achievable”; a term from the US Nuclear Regulatory Commission. It means “making every reasonable effort to maintain exposures to ionizing radiation as far below the dose limits as practical, consistent with the purpose for which the licensed activity is undertaken, taking into account the state of technology, the economics of improvements in relation to state of technology, the economics of improvements in relation to benefits to the public health and safety, and other societal and socioeconomic considerations, and in relation to utilization of nuclear energy and licensed materials in the public interest.” The ALARA principle is a regulatory tool in the risk management of substances (when a regular risk assessment is not available) (see also Precautionary Principle).

- Allergen** Any substance that can cause an allergy. Antigens which cause an allergic reaction (hypersensitivity of type I) by stimulating immunoglobulin E (IgE) responses upon contact with skin and/or mucous membranes. Allergens are often compounds, polypeptides, or proteins, the sensitizing potential of which depends on chemical structure and the presence of allergenic determinants (epitopes).
- Allergy** An (acquired) hypersensitivity disorder of the immune system against environmental (normally harmless) substances. Allergic reactions (to an allergen) involve excessive activation of mast cells and basophils by IgE antibodies. Symptoms occur on the skin, in mucous membranes, and in the respiratory tract (e.g., urticaria, eczema, edema, conjunctivitis, hay fever, asthma) of sensitized individuals.
- Ames Assay** In vitro assay (developed by Bruce Ames) for the detection of mutagenic effects of chemicals in bacteria (*Salmonella* test strains). As it reveals mutagenic effects of, e.g., cigarette smoke components and of a high percentage of known mutagenic carcinogenic substances, the Ames assay is usually a starting point in genotoxicity testing.
- Aneuploidy** Deviation from the number of the normal (euploid) chromosome set by one or several chromosomes.
- Annoyance** An unpleasant (mental) state that is characterized by such effects as irritation and distraction. Annoyance can result from (various) environmental stimuli (e.g., noise, odor) perceived as unpleasant or pestering by the recipient(s). The property of being easily annoyed is called irritability.
- Antagonism** The property of a chemical to counteract the effect of another; e.g., in the case of co-exposure to two chemicals when the resulting effect is less than the simple sum of their independent effects (see also Antagonist).
- Antagonist** Chemical (or drug) which fits into the inactive conformation of a receptor and thereby diminishes or prevents its activation by another chemical, an agonist.
- Antigen** A substance which elicits a specific immune response (e.g., formation of antibodies) when introduced into an organism.
- Antioxidants** Substances that inhibit or prevent oxidation processes which result in undesirable changes of biomolecules.
- Antitoxins** Antibodies (often immunoglobulins of the IgG class) which can neutralize toxins of microbial, plant, or animal origin (e.g., snake venom).
- Application** Administration of substances to an organism. Common routes of application are: p.o. = per os (via the gastrointestinal tract), s.c. = subcutaneous (injection under the skin), i.m. = intramuscular (in the skeletal muscle), i.p. = intraperitoneal (injection in the abdominal cavity), i.v. = intravenous (injection in veins).
- Assessment Endpoint** Qualitative/quantitative expression of a specific factor (a response) with which a risk may be associated through an appropriate risk assessment.
- Assessment Factor** Numerical adjustment used to extrapolate from experimentally determined dose-response relationships to estimate the agent exposure below which an adverse effect is not likely to occur (see also Safety and Uncertainty Factor).
- Atopic Persons** Individuals with a predisposition for developing an allergy.

**Background Burden/Exposure** Substance concentrations in biological samples of humans as a result of normal conditions (without known additional exposure).

**BAT Value** German “Biologischer Arbeitsstoff-Toleranzwert” for biological tolerance value (BLV) for occupational exposures; defined as the maximum permissible quantity of a chemical substance or its metabolites or the maximum permissible deviation from the norm of biological parameters induced by these substances in exposed humans. As with MAK values, BAT values are established on the assumption that persons are exposed at work for at most 8 h daily and 40 h weekly (see also BEI and EKA).

**BEI** Biological Exposure Indices: used in the USA analogous to BAT values in Germany.

**Benchmark Approach/Dose** Adjustment of a mathematical model to the data obtained in a study for the dose-response relationship. The benchmark approach is an instrument to determine a *point of departure* for quantitative risk assessments. The dose that leads to an effect with a certain likelihood can be estimated for a defined frequency (for quantal data) or a defined effect measure (for continuous data), i.e., a benchmark response (BMR). This dose is referred to as benchmark dose (BMD). A  $BMD_{10}$  indicates the dose at which there is a 10% risk that the effect concerned would likely occur. The reliability of assessing dose-response relationships is quantified by specifying a confidence interval. The value of the lower (generally 90% or 95%) confidence interval is referred to as benchmark dose lower bound (BMDL).

**Bioactivation** Conversion of xenobiotics (e.g., by enzymes) to biologically reactive, toxic, or carcinogenic metabolites.

**Bioassay** An assay for determining the potency (or concentration) of a substance that causes a biological change in experimental animals and living systems.

**Bioavailability** The fraction of a chemical or drug that can be absorbed by the body through the gastrointestinal system, the pulmonary system, or the skin and is systemically available. By definition, when a medication is administered intravenously, its bioavailability is 100%. Upon administration by other routes, its bioavailability generally decreases (due to incomplete absorption and first-pass metabolism) or may vary from person to person.

**Biocide** A selectively acting toxic substance that is used to destroy harmful organisms (see *Pesticide*).

**Biological Limit Values** For occupational health purposes, special human biomonitoring (limit) values have been established, such as Biologischer Arbeitsstoff-Toleranzwert (BAT) and Biologische Leitwerte (BLW) by the German MAK commission or Biological Exposure Indices (BEI) by the AGCIH. These values are meant to allow evaluating the risk to an individual’s health that results from exposure to a substance at the workplace (by inhalation and/or dermal uptake) and to protect the health of the employee at the workplace.

**Biomonitoring** In a broader sense, all biological monitoring methods used to investigate the (complex) relationship between external and internal exposure and, thereby, the potential adverse health and environmental effects. In ambient monitoring, living organisms are used as “sensors” in water/sediment quality

surveillance and compliance to detect changes in an effluent or water body and to indicate whether aquatic life may be endangered. In health monitoring, biomonitoring is a general term for the following subcategories: (a) biological monitoring applying biomarkers of exposure such as internal dose or body burden, (b) biochemical effect monitoring with biomarkers of effective dose (e.g., adduct levels and also tissue dose), (c) biological effect monitoring with biomarkers of effect (e.g., micronuclei), and (d) clinical parameters – biomarkers of disease. Most common in human biomonitoring are studies with biomarkers of exposure and biochemical effects aimed to establish distribution of exposure among the general population (including trends and changes in exposure), identify vulnerable groups and populations with higher exposures, identify new chemical exposures, and identify environmental risks at specific contaminated sites or at workplaces.

**Biotransformation** Enzymatic conversion of xenobiotics in an organism; metabolism (biotransformation) usually results in products that are less toxic, more water soluble, and readily excreted from the organism. But with some chemicals, biotransformation results in bioactivation and thus an increased toxicity.

**Body Burden** The total amount of a substance in the body. Some substances build up in the body because they are stored (e.g., in fat or bone) or because they leave the organism very slowly. In such cases, the blood concentration does not reflect the amount stored in the body. Body burden must be measured with independent methods.

**Brownfields** Sites or soil polluted with hazardous substances (e.g., abandoned or existing waste deposits and/or production sites).

**Cancer** Disease which results from the development of a malignant tumor and its spreading into surrounding tissues.

**Carcinogen** An agent capable of inducing cancer. A substance or mixture (e.g., coal tar) which causes tumors (cancer) in animals or humans.

**Carcinogenesis** The development of cancer, a disease of heritable, somatic mutations affecting cell growth and differentiation, characterized by an abnormal, uncontrolled growth of cells. In chemical carcinogenesis, several steps are defined: initiation, promotion, and progression. Any chemical which can cause cancer is said to be carcinogenic.

**Carcinogenicity Test** A form of chronic toxicity testing directed to detect carcinogenic effects of chemicals: The test substance is applied to rodents for 18–24 months, usually five times a week, at several dose levels. The appearance of tumors is assessed upon necropsy and compared to the frequency in a nonexposed control group.

**Cell Culture** The maintenance and propagation of previously isolated cells in a suitable nutrient (culture) medium. Cell cultures are used for various in vitro toxicity tests. Other than primary cells, cell lines can be kept in culture for long periods and passaged numerous times.

**Chromosomal Aberration** An abnormality in chromosome number or structure.

**Chromosome** The heredity-bearing gene carrier in the cell nucleus, composed of DNA and protein.

**Chronic Toxicity** Refers to long-term adverse effects in an organism after dosing of a toxicant over an extended time period. Long-term effects relate to changes in, e.g., growth, reproduction, or the ability to survive. Examples in humans are cardiovascular diseases and cancer from smoking and liver disease from alcohol abuse.

**Chronic Toxicity Test** Experimental studies with repeated application of a substance over an extended period of time (at least 3 months), usually at several dose levels, to gain information on, e.g., organ toxicity, tumor formation, and dose-effect relationships.

**Clastogens** Agents which cause chromosomes to break. This may be a result of direct damage to the DNA or by indirect mechanisms, e.g., inhibition of topoisomerases.

**Clearance** The process of losing a substance from the body. Total clearance (Cl<sub>tot</sub>) is a measure for the ability of an organism to eliminate a given substance by both renal and extrarenal clearance. Renal clearance (Cl<sub>R</sub>) is a function of glomerular filtration, secretion from the peritubular secretion of the nephron, and reabsorption from the nephron back to these blood vessels. Another major route for elimination of foreign compounds is their uptake by liver cells and secretion into bile.

**CLP** Acronym for Regulation on Classification, Labelling, and Packaging of chemical substances and mixtures (see also ECHA and REACH).

**Combined Chemical Effects** Chemicals that act by the same mode of action and/or at the same target cell or tissue often act in a (potency-corrected) “dose-additive” manner. Where chemicals act independently, by discrete modes of action or at different target cells or tissues, the effects may be additive (“effects additive” or “response additive”). Alternatively, chemicals may interact to produce an effect, such that their combined effect “departs from dose additivity.” Such departures comprise “synergy,” where the effect is greater than that predicted on the basis of additivity, and “antagonism,” where the effect is less than that predicted on the basis of additivity. Related terms are “mixture toxicity,” additive effect, antagonism, and synergism.

**Compartment** In pharmaco- and toxicokinetics, a compartment is a defined volume of body fluids. Major body compartments are blood plasma, interstitial fluid, fat tissue, and intracellular and transcellular fluid. With the exception of blood, where the volume is rather well defined, other “compartments” are of less distinct size, because the volume for distribution of a given substance can comprise various body fluids and tissues. In pharmaco-/toxicokinetics, “compartments” are separated entities which have a defined volume and defined rates of influx and efflux. These interact with each other in a dynamic way. There are one-, two-, or multi-compartment mathematical models. The models are a practical approach to a much more complex reality.

**Concentration-Effect Relationship** Relationship between the exposure, expressed in concentration, of a given organism, system, or (sub)population to an agent in a specific pattern during a given time and the magnitude of a continuously graded effect to that organism, system, or (sub)population.

- Concern Level** Concentration of an environmental chemical expected/suspected to cause harm to a population in field experiments.
- Congeners** Substances whose structure, function, or origin is similar to others and may match the same structure-activity relationship (SAR). Examples are polyhalogenated dibenzodioxins and -furans (dioxins) which can have diverse toxicological properties.
- Consumer Protection** All areas of legislation and policy which serve to protect citizens (private persons) who are buying or consuming goods or demanding services. Protecting the health of consumers involves mainly issues of food safety, product safety (e.g., personal care products, detergents and household cleaners, textiles, toys), and other consumer goods.
- Contamination** In general, the presence of a minor or unwanted constituent (contaminant) in a material (physical or body tissue), the environment, at a workplace, etc. In food and medicinal chemistry, the term contamination usually refers to the presence of toxic substances or pathogens.
- Course of Action** Variants of possible actions in risk management to reduce risks, including the option for nonaction (for minimal risks). In the case of action, there may be also options for different risk reduction measures.
- Cross-reactivity** Immunological reaction of specific antibodies or specifically sensitized T-lymphocytes with compounds having similar or identical determinants as the so-called homologous antigen.
- Cytochrome P-450** A family of heme containing enzymes that transfer oxygen to chemicals (old term mixed-function oxidases) involved in phase I reactions of xenobiotics. They are located on microsomes and have a light absorption peak near 450 nm.
- Cytotoxicity** Ability of an agent to cause disturbance to cellular structure or function, often leading to cell death.
- DDT** Dichloro-diphenyl-trichloroethane (Chlorphenotan). Contact insecticide, now widely banned because of its high persistence in the environment and accumulation in the food chain.
- Decontamination** Removal of hazardous substances, e.g., from materials, from soil, or from dead and living tissues.
- Default** Statistically supported standard value or assumption that is to be used in the absence of substance-specific or species-specific data. A default is a means to describe systems despite incomplete knowledge of their characteristics.
- Deposition** Sedimentation of solid, liquid, or volatile particles in the organism.
- Desoxyribonucleic Acid** That constituent of cells which stores the hereditary information of an organism in the form of a sequence of nitrogenous bases. Much of this information relates to the synthesis of proteins. Damage of DNA can result in a mutation.
- Detergent** A cleaning or wetting agent which possesses polar and nonpolar functional groups or surfaces allowing interaction with nonpolar molecules making them miscible with a polar solvent.
- Detoxification** (a) A process which renders a toxic molecule less toxic by biotransformation, removal, or the masking of active functional groups, and (b) the

treatment of patients suffering from poisoning in order to reduce the probability or severity of harmful effects.

**Dioxin(s)** Systematic term for a twofold unsaturated six-membered ring system with two oxygens in the ring. Dioxin is used colloquially for the group of polychlorinated dibenzodioxins (PCDD) and sometimes also the polychlorinated dibenzofurans (PCDF); in the first group, there are 75, and in the latter, 135 isomers (congeners). The most famous dioxin, the “Seveso-poison,” i.e., 2,3,7,8-tetrachlordibenzo[1,4,]dioxin (2,3,7,8-TCDD) is far more toxic than all other congeners.

**Disinfectants** Substances/preparations used to reduce or eliminate (pathogenic) microorganisms on skin and other surfaces. Examples are ethanol, phenol, soaps, and tensides which act against bacteria.

**Distribution** Dispersal of a xenobiotic and its derivatives throughout an organism or environmental matrix, including tissue binding and localization. In toxicokinetics, this includes the passage of a substance from one compartment (e.g., blood, extracellular fluid) to another (e.g., fat tissue), moving towards an equilibrium.

**Dose** Total amount of an agent administered to, taken up, or absorbed by an organism, system, or (sub)population. Administered doses are often given in mg/kg of body weight.

**Dose-Effect Relationship** The (functional) relationship between the dose and the magnitude of a continuously graded effect in an organism, system, or (sub) population (see also Dose-Response Relationship).

**Dose-Response Relationship** Relationship between the total amount of an agent (the dose) and responses in an organism, system, or (sub)population in reaction to that agent (see also Dose-Effect Relationship).

**Dust** Fine, dry powder consisting of inorganic particles (e.g., ash, clay, rock chip, sand) and/or organic material (e.g., fungal spores, microorganisms, mites, feather or plant fragments, sooty particles), matter lying on the ground or on surfaces or carried in the air. Dusts are generated by work processes such as cutting, crushing, detonation, grinding, and handling of organic and inorganic matter such as coal, grain, metal, ore, rock, and wood, but may also occur naturally (e.g., pollens, volcanic ashes, sandstorms). The term “airborne dust” often refers to airborne particulate matter ranging in diameter from 1 to 100  $\mu\text{m}$ , which differs in deposition in the respiratory tract. Very small particles (fine and ultrafine, less than 5  $\mu\text{m}$ ) are of concern as they deposit in the tracheobronchial and alveolar regions. Fibrous dusts, such as asbestos and other such materials, have been shown to present special health problems primarily related to the shape of the particles (see also Fibers).

**EC50** Effective concentration which affects 50% of a test population after a specified exposure time.

**ECHA** European Chemical Agency (in Helsinki, Finland) with the task of implementing the EU’s chemical legislation. The mission of ECHA is to manage all REACH and CLP tasks by carrying out or coordinating the necessary activities, ensure a consistent implementation at the community level, and provide

member states and the European institutions with the best possible scientific advice on questions related to the safety and the socioeconomic aspects of the use of chemicals.

**Ecotoxicology** The study of effects of toxic chemicals on biological organisms, mainly at the population, community, and ecosystem levels. A multidisciplinary field which integrates toxicology and ecology, with the aim to predict the effects of pollution and to gather information as to the best course of action to restore already affected ecosystems. Ecotoxicology differs from environmental toxicology in that it integrates the effects of stressors across all levels of the biological organization, whereas environmental toxicology focuses upon effects at the level of individual species and the occurrence and fate of anthropogenic chemicals in the environment.

**ECVAM** European Centre for the Validation of Alternative Methods.

**ED50** Dose that affects a designated criterion in 50% of the population observed. Also known as median effect concentration/dose.

**Effect** A change in the state or dynamics of an organism, system, or (sub)population caused by exposure to an agent.

**EIA** Environmental Impact Assessment.

**EINECS** European Inventory of Existing Commercial Substances.

**EKA Value** Exposure equivalents for carcinogenic substances at the workplace (see also BAT Value).

**Elimination** The combined process of metabolism and excretion which results in the removal of a substance from an organism.

**ELINCS** European List of Notified Chemical Substances.

**Embryotoxicity** Damage to the embryo (the undeveloped animal or individual), e.g., by chemicals, which results in early death, delays in development, impaired organ function, or malformations (see also Teratogenicity).

**Emission** Release of a substance (or radiation) from a source, including discharges into the wider environment.

**Endogenous** Arising within or derived from the organism.

**Environmental Health** A branch of public health related to all aspects of the natural and built environment that may affect human health. The term “environmental hygiene” is used synonymous with environmental health.

**Environmental Impact Assessment** EIA: A procedural step – introduced by an amendment to Federal Act on EIA in 2001 in Germany – for a screening process (“case-by-case examination”) in order to determine whether for a given project (e.g., new streets, train tracks) an EIA is required in the authorization procedure. With regard to chemicals, toxicity testing in nonmammalian species is part of the required hazard assessment under ecological aspects.

**Environmental Medicine** A field of medicine which studies the interaction between environment and human health and the role of the environmental factors in causing or mediating disease in patients (i.e., in a clinical setting) and, thereby, differs from environmental health.

**Environmental Protection** A wide range of societal and individual “measures” aimed to prevent or remediate interferences with ecosystems, e.g., in raising

consciousness by information campaigns, labeling of “eco-friendly” products, or setting of standards for hazardous chemicals and pollutants or use restrictions and bans of particularly hazardous agents (such as DDT, vPvB).

**Environmental Toxicology** A field of toxicology which focuses upon the occurrence and fate of anthropogenic chemicals in the environment and the effects of pollutants at the level of individual species (see also Ecotoxicology).

**EPA** Environmental Protection Agency (in the USA, also in Denmark and elsewhere; in Germany, UBA).

**Epidemiology** The study of the incidence, distribution, and causes of disease or the statistical study of categories of persons and the patterns of diseases from which they suffer in order to determine the events or circumstances causing the diseases.

**Epoxide** Highly reactive metabolites with the ability to bind to cell components. Epoxides are held responsible for the toxic and carcinogenic effects of, e.g., polycyclic aromatic hydrocarbons and certain other organic compounds.

**Excretion** Removal of a substance or its metabolites from an organism by the discharge of biological material, including urine, feces, expired air, mucus, milk, eggs, and perspiration.

**Existing Chemicals** Chemicals which have been available in an EC member state between 1971 and 1981 – prior to the introduction of legal obligations for testing them for hazardous properties – and have been listed in EINECS (see also REACH).

**Exogenous** Resulting from events or derived from materials external to an organism.

**Expert Judgment** The opinion of an authoritative person on a particular subject.

**Exposure** The concentration or amount of a particular agent that reaches a target organism, system, or (sub)population at a specific frequency for a defined duration.

**Exposure Assessment** Evaluation of the exposure of an organism, system, or (sub) population to an agent (and its derivatives). Exposure assessment is a key step in the process of risk assessment.

**Exposure Routes** External routes by which a chemical exposure of the organism can occur (e.g., by inhalation, dermal contact, or oral intake) from air, food, water, or soil.

**Extrapolation** An estimation of a numerical value of an empirical (measured) function at a point outside the range of data used to calibrate the function or the use of data derived from observations to estimate values for unobserved entities or conditions....

**Fecundity** (1) Potential to produce offspring frequently and in large numbers, and (2) in demography, the physical ability to reproduce. A lack of fecundity is called sterility.

**Fertility** In humans and mammals, the natural capability to produce offspring. Fertility in a stricter sense differs from fecundity which is defined as the potential for reproduction and influenced by gamete production (sperm, eggs), fertilization, and carrying a pregnancy to term.

- Fetotoxicity** Damage to mammals in the womb, after completion of organogenesis. In humans, this stage is reached after about 3 months of pregnancy. Prior to this, the developing mammal is in the embryo stage (see also Embryotoxicity).
- Fibers** In relation to health, particles with a diameter  $< 3$   $\mu\text{m}$ , length  $> 5$   $\mu\text{m}$ , and aspect ratio (length to width) greater than or equal to 3 to 1 are classified as “fibers” (WHO 1997). Examples of fibers include asbestos (comprising two groups of minerals: the serpentines, e.g., chrysotile, and the amphiboles, e.g., crocidolite – “blue asbestos”). Other examples include synthetic fibrous materials, such as rock wool (or stone wool) and glass wool, as well as ceramic, aramid, nylon, and carbon and silicon carbide fibers.
- First-Pass Effect** The metabolism that an ingested compound undergoes in its passage through the gut and liver before reaching the systemic circulation.
- Fly Ash** (Or flue-ash): Residues generated during combustion of coal which comprise fine particles that rise with the flue gases. Depending on the specific type of coal burnt, fly ash can contain highly toxic materials (arsenic, heavy metals, along with dioxins and PAH); these are concentrated in filter devices (which have to be treated as hazardous waste).
- Food Chain** A sequence of links in a food web between different trophic species, starting, for instance, with basal species such as producers of fine organic matter (plants) and continuing with consumer organisms (herbivores and carnivores). Persistent lipophilic substances (e.g., pesticides) can accumulate in the course of the food chain (see Bioaccumulation).
- Genotoxicity** Ability to cause damage to the genetic material or an adverse effect in the genome, e.g., a gene mutation, chromosomal aberration, or aneuploidy. Genotoxicity is a broader term and refers also to processes which alter the genetic material, yet are not necessarily associated with mutagenicity. Thus, tests for genotoxicity include tests which provide an indication of induced damage to DNA (but no direct evidence of mutation), e.g., increases in unscheduled DNA synthesis or sister chromatid exchange, DNA strand breaks, DNA adduct formation, as well as tests for mutagenicity.
- GHS** The Global Harmonized System for classification and labeling of chemicals (CLP) of the UN, implemented under Regulation (EC) No. 1272/2008.
- GLP** Good Laboratory Practice, a quality assurance system.
- Guidance Value** Value, such as concentration in air or water, which is derived after allocation of the reference dose among the different possible media (routes) of exposure. The aim of the guidance is to provide quantitative information from risk assessment to risk managers to enable them to make decisions (see also Reference Dose).
- Half-life** The time interval (commonly denoted as  $t_{1/2}$ ) that corresponds to a concentration decrease by a factor of 2. After five half-lives, the blood level will be 3% of the initial concentration, a decrease due to metabolism or excretion. Compounds with a long half-life can accumulate upon repeated intake. Environmental half-life data generally reflect the rate of disappearance from a medium without identifying the mechanism of chemical loss.

**Half-life, Biological** Time interval after administration of a substance to an organism in which half of the originally present dose is eliminated, i.e., metabolized or excreted.

**Harm** Physical injury or mental damage; actual or potential ill effects or danger. For example, "smoking when pregnant can harm your baby."

**Hazard** (1) A potential source of harm. (2) The inherent property of an agent or a situation having the potential to cause adverse effects in organisms or individuals.

**Hazard Assessment** A process designed to determine the possible adverse effects of an agent (or situation) to which an organism could be exposed. The process includes hazard identification and hazard characterization. The process focuses on hazard in contrast to *risk assessment* where exposure assessment is a distinct additional step.

**Hazard Characterization** The qualitative and, wherever possible, quantitative description of the inherent properties of an agent (or situation) having the potential to cause adverse effects. It is a stage in hazard assessment and the second step in risk assessment (see also Concentration/Dose-Effect Relationship).

**Hazard Identification** The identification of the type and nature of adverse effects that an agent can elicit in an organism. Hazard identification is the first stage in the process of hazard assessment and the first in the process of risk assessment.

**Hazardous Situation** Circumstances of danger for a given object (see also Risk).

**HBM Value** Human biomonitoring values I and II

**HCH** Acronym for six chlorine substituted cyclohexanes; the most common form is gamma-HCH (lindane).

**HCp (HC5) Value** Hazardous concentration for p % (5%) of the species, derived by means of statistical extrapolation for acceptable levels in ecotoxicology.

**Health** As defined by the WHO, health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.

**Health Damage/Impairment** All temporary or permanent undesirable changes triggered by, e.g., chemicals, radiation, accidents, or lifestyle factors.

**Health Protection** All measures taken to protect the health and well-being of the population against harmful factors, such as hazardous chemicals, infectious agents, and radiation. Preventive health protection aims to keep the possible impact low by means of exposure reduction and education measures.

**Health Risk** The probability (likelihood) that damage to health will occur in a population with exposure to a harmful agent or factor. This depends upon the intensity and duration of exposure to a hazardous compound or factor and its activity/affectivity.

**HPVC** High Production Volume Chemical.

**Human Equivalent Dose** The human concentration (for inhalation exposure) or dose (for other routes of exposure) of an agent that is believed to induce the same magnitude of toxic effect as the experimental animal species concentration or dose. This adjustment may incorporate toxicokinetic information on the particular agent, if available, or use a default procedure, such as assuming that daily oral doses experienced for a lifetime are proportional to body weight raised to the power of 0.75.

**Human Biomonitoring Values I and II (HBM I and II)** The Human Biomonitoring (HBM) Commission of the German Federal Environmental Agency (UBA) defines two different types of HBM values: HBM I and HBM II. HBM I describes the concentration in the body matrix of a substance below which, according to the Commission's current assessment, no adverse health effect should be expected. The HBM II value represents the concentration above which there is an increased risk for adverse health effects; it is thus regarded an intervention or "action" level. HBM I and II values are set on the basis of health risk assessments and are thereby clearly distinct from reference values (RV95). RV values (derived according to a defined statistical method from a series of analytical results) are statistical descriptions of the ranges of concentrations typically seen in a specified reference population, but which have no direct relationship to health effects or risk assessment.

**i.v.** Intravenous administration (injection).

**ICH** The International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use. A source for toxicity test guidelines in drug development.

**Immunotoxicity** Adverse effects of chemicals (or other agents) on components/function of the immune system.

**In Vitro/In Vitro Test** In glass; refers to studies and tests in the laboratory usually involving isolated organs, tissues, cells, or biochemical systems.

**In Vivo/In Vivo Test** Within the living organisms; refers to studies and tests of chemicals in laboratory animals.

**Incidence** The number of newly diagnosed cases of a certain disease within a given period of time; epidemiological measure to characterize disease trends in a certain population.

**Incidence Rate** The ratio of new cases within a population to the total population at risk given a specified period of time.

**Incorporation** The entry/uptake of a (hazardous) substance in an organism or a compartment (e.g., lung, gastrointestinal tract).

**Interest Group** Parts of the population organized as a group that holds and presents a common view.

**Interspecies Dose Conversion** The process of extrapolating from animal doses to human equivalent doses.

**Intervention Value** A value discussed in the context of chemical residues and contaminants of food which is lower than the respective (maximal) limit values. When the intervention value is exceeded, appropriate measures should be taken to reduce emissions of this substance in the environment and thereby prevent contamination of food commodities.

**Intolerance** (Med.) Varied (nonallergic) responses to drugs (drug sensitivity) or food ingredients (e.g., lactose)...

**Intoxication** (Poisoning): Impact of usually chemically defined, toxic agents. These substances may also be of mineral, plant, animal, or viral origin. They can "enter" the body via the gastrointestinal tract, the respiratory system, the intact skin, but also via wounds or injection. The severity of an illness depends upon the toxicity,

the amount (dose), the duration of exposure, and the susceptibility of the afflicted individual. Poisoned persons often show typical symptoms.

**Invasion** Passage of an incorporated substance into the circulation (e.g., blood or lymph); resorption and distribution in the body.

**IPCS** International Programme on Chemical Safety of the WHO.

**IRIS** Acronym for Integrated Risk Information System. More information (list of substances and documents/reviews) is available on the EPA page: <http://www.epa.gov/iris/intro.htm>

**Irritants** Substances which cause local reactions (e.g., erythema) on skin or mucous membranes upon prolonged contact due to irritant properties. Agents with corrosive properties (e.g., strong acids or bases) cause more severe damage.

**JECFA** Joint FAO/WHO Expert Committee for Food Additives (and Veterinary Drugs and Contaminants). An international committee that sets ADI and TDI values.

**Latency Period** The time between first exposure to an agent and manifestation or detection of a health effect of interest.

**LC50 (Lethal Concentration)** Concentration of an agent in the surrounding atmosphere, respectively for aquatic organisms in water, which results in the death of 50% of the exposed individuals.

**LD50 (Lethal Dose)** The median lethal dose that is estimated to cause death of 50% of the test organisms.

**Limit Values** Limit values (maximal permissible concentrations) for hazardous chemicals are set to protect humans and the environment against harmful effects. Examples of toxicologically founded limit values are maximal residual levels for pesticide contaminants in food or MAK values and other OELs for industrial chemicals at the workplace. Limit values are quantitative standards where non-compliance triggers legal consequences while a "guidance" value has to be observed only when this is possible.

**Lindane** 1,2,3,4,5,6-Hexachlorocyclohexane (gamma-HCH), a pesticide.

**Linear Dose Response** A pattern of frequency or severity of biological response that varies directly with the amount of dose of an agent.

**LO(A)EL (Lowest Observed (Adverse) Effect Level)** LOEL: In a study, the lowest dose or exposure level at which a statistically or biologically significant effect is observed in the exposed population compared with an appropriate unexposed control group. LOAEL: The lowest exposure level at which there are biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group.

**LOEC** The lowest concentration at which a statistically or biologically significant effect is observed in the exposed population compared with an appropriate unexposed control group.

**MAC and MAK Value** Regulatory value (MAC) defining the concentration which if inhaled daily (for workers: 8 h/day over a working week of 40 h; for the general population: 24 h/day) does not appear capable of causing appreciable harm in the light of the present knowledge. In Germany, MAK values (*Maximale*

*Arbeitsplatz-Konzentration*) for volatile chemicals and dusts are proposed by the Senate Commission of the German Research Foundation Council (DFG) on the basis of toxicological data and workplace-related observations. The MAK Commission also draws up proposals for BAT values (biological tolerance values) and develops procedures to analyze chemical substances in the air and in biological materials. The list of MAK and BAT values is published annually and presented to the German Federal Ministry of Labour and Social Affairs. The Ministry's Committee on Hazardous Substances (AGS) subsequently reviews the proposals and makes recommendations for their inclusion in the Hazardous Substances Ordinance.

**Malignant Tumor** An abnormal growth of tissue which can invade adjacent or distant tissue.

**Margin of Exposure (MOE)** Ratio of the no observed adverse effect levels (the NOAEL or other point of departure) for the critical effect to the theoretical, predicted, or estimated dose or concentration. The MOE is a tool used by risk assessors to consider possible safety concerns arising from the presence in food and feed of substances which are both genotoxic (i.e., which may damage DNA, the genetic material of cells) and carcinogenic (see also Margin of Safety (for noncarcinogenic substances)).

**Margin of Safety (MOS)** For some experts, the MOS has the same meaning as the MOE (margin of exposure), while for others, the MOS means the margin between the reference dose and the actual exposure dose or concentration.

**Mechanism of Action** The interpretation of pharmacological or toxicological effects on the basis of biochemical and molecular data; a sufficient understanding of the molecular basis for an effect so that causation can be established. Compare Mode of Action.

**Medicine** The applied science or practice of the diagnosis, treatment, and prevention of disease.

**Metabolic Activation** See Bioactivation.

**Metabolism** In toxicology, the term refers to the conversion of xenobiotics by endogenous enzymes (see Biotransformation).

**Metabolite** The product from a biotransformation process of xenobiotics.

**Minimal Risk Level** An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. The substance-specific estimates, which are intended to serve as screening levels, are used by the US Agency for Toxic Substances and Disease Registry (ATSDR) health assessors and other responders to identify contaminants and potential health effects that may be of concern at hazardous waste sites.

**Mode of Action** A postulated MoA for a chemical is a plausible sequence of key events leading to an observed effect, supported by robust experimental observations and mechanistic data. Both MoA and mechanistic data can be important elements in chemical risk characterization, e.g., with regard to the question whether an adverse effect is thresholded or not.

**MOE** See Margin of Exposure.

**Monitoring** Repeated measurements, observations, and evaluation of specified properties of the environment, in order to define the current state and establish trends over time. Surveys and surveillance are used to achieve this objective and/or study the situation after taking measures to reduce risk, e.g., from contaminants.

**Morbidity** The state of disease or illness within a population; the morbidity rate is given as incidence and prevalence. Compare also Mortality.

**Mortality (Rate)** The state of death; mortality rate is a measure of the number of deaths (in general or due to a specific cause) in a population, scaled to the size of that population, per unit of time.

**MRL** See Minimal Risk Level.

**Mutagenicity** The ability of a substance (or agent) to induce a *mutation*.

**Mutagenicity Testing** Studies on mutagenic properties of chemicals: Several in vitro assays (tests in bacteria, such as Ames assay and mammalian cells) or in vivo assays are used for the identification of agents that can induce or increase the frequency of mutation in an organism (see also Genotoxicity).

**Mutation** A change in the amount or structure of the genetic material (DNA) of cells or organisms. Changes may involve a single gene or gene segment, a block of genes, or chromosomes. Mutagenicity refers to the induction of permanent transmissible changes either in somatic cells or in germ cells (see also *Genotoxicity*).

**N(O)EC** No (observed) effect concentration. The highest concentration of a material or substance in a toxicity test that has no statistically significant adverse effects on the exposed population of test organisms compared with the control group.

**NAS** National Academy of Science in the USA.

**Necrosis** Cell death or death of areas of tissue, usually surrounded by healthy tissue. Necrosis (caused by trauma or toxic chemicals) results in an unregulated digestion of cell components. It differs from apoptosis, a programmed and targeted cause of cell death in multicellular organisms.

**Neurotoxicity** Toxicity on any aspect of the central or peripheral nervous system. Adverse effects may be observed as functional changes (behavioral or neurological abnormalities) or as neurochemical, biochemical, physiological, or morphological changes.

**NOAEL** No observed adverse effect level. The highest exposure level at which there are no biologically significant increases in the frequency or severity of adverse effects between the exposed population and its appropriate control group; some effects may be produced at this level, but they are not considered adverse or precursors of adverse effects.

**Nocebo** In medicine, a nocebo reaction is the harmful, unpleasant, or undesirable effect seen in a subject who received an inert tablet (e.g., sugar pill) and may be also observed in persons with exposure to chemicals at irrelevant levels. Nocebo responses are due to the subject's pessimistic belief and expectation that the inert drug (or the chemical) will produce negative consequences. The opposite of *placebo*.

**NOEL** No observed (adverse) effect level. An exposure level at which there are no statistically or biologically significant increases in the frequency or severity of any effect between the exposed population and its appropriate control group.

**Notified Substance** According to REACH, a substance for which a notification has been submitted and which could be placed on the market in accordance with Directive 76/548/EEC. In the EC, “new chemicals” were those produced since 1981 and not listed on the EINECS.

**Objective (Protection Goal)** The goal to be reached with respect to a desired level of protection. The framework for risk regulation often sets the objective, i.e., a level of protection adequate for averting a danger (i.e., hazard control) or for prevention.

**Occupational Disease** An official list of diseases which have been recognized to be caused by specific influences at the workplace. The list is used – along with several criteria for causation (i.e., occupational history, conditions at the workplace, exposure measurements) – in legal procedures to establish (or refute) cases claiming compensation.

**Occupational Medicine** Applied science dealing with occupational diseases, workplace accidents, questions of occupational hygiene, and toxicology.

**Occupational Safety** All measures to protect workers against accidents and diseases in conjunction with the workplace. Important elements of occupational safety are on-the-job safety requirements and company medical doctors. OEL and MAK values limit exposure to hazardous chemicals.

**Odds Ratio (OR)** A relative measure of the difference in exposure between the diseased (cases) and not diseased (controls) individuals in a case-control study. The OR is interpreted similarly to the relative risk.

**OEL** Occupational Exposure Limit; expressed as concentration of a substance in the air at the workplace.

**Oral Slope Factor** An upper bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low-dose region of the dose-response relationship, i.e., for exposures corresponding to risks less than 1 in 100.

**Overadditive Effects** See Synergism.

**PAH** Polycyclic aromatic hydrocarbons.

**PBPK** Physiologically Based Pharmacokinetic Model. A model that estimates the dose to a target tissue or organ by taking into account the rate of absorption into the body, distribution among target organs and tissues, metabolism, and excretion.

**PCB** Polychlorinated Biphenyls. An important group of environmental chemicals, some of which tend to persist in the environment and to accumulate in the human body.

**PCDD** Acronym for poly-chlorinated dibenzo-1,4-dioxins; a class of 75 chemicals with several highly toxic compounds. The best known example of these ubiquitously found “environmental chemicals” is 2,3,7,8-tetrachloro-dibenzo-1,4-dioxin, colloquially termed dioxin.

**PCDF** Polychlorinated dibenzofurans (see also PCDD and Dioxin).

**PCP** Pentachlorophenol, previously widely used for preservation of wood, textiles, and leather and as disinfectant.

**PEL** Permissible Exposure Limit. In the USA, a legal limit for exposure of an employee to a chemical substance or a physical agent. PEL values, established by OSHA, are usually expressed in ppm or mg/m<sup>3</sup> (see also MAC/MAK values).

**per os (p.o.)** Administration via the mouth, e.g., by gavage (bolus) or with food.

**Pesticide(s)** Chemicals used in agriculture and other areas to control the severity and incidence of pests and diseases. Pesticides (or “biocides”) are used to control bacteria, fungi, algae, higher plants, nematodes, molluscs, mites and ticks, insects, rodents, and other organisms. The generic term is also used to cover bactericides, fungicides, algicides, herbicides, nematocides, molluscicides, acaricides, insecticides, and rodenticides.

**Pharmacodynamics** See Toxicodynamics.

**Phase-I (Reactions)** First step in biotransformation. Modification of a molecule (drug or other chemical) by oxidation, reduction, hydrolysis, hydration, dechlorination, or other reactions which are catalyzed by enzymes, mainly xenobiotic metabolizing enzymes of the endoplasmic reticulum (microsomal) or cytosolic enzymes (see also Cytochrome P450).

**Phase-II (Reactions)** Step in the biotransformation of a substance or its phase-I reaction product by enzyme families which catalyze either acetylation, glucuronidation, sulfation, or conjugation with glutathione. This results in the formation of more water-soluble metabolites which can be excreted in urine or bile.

**Placebo** Latin: “I shall please.” A simulated treatment or an inert drug given in medical research as control treatment. Interestingly, patients receiving a placebo may feel or show an (actual) improvement in their condition, a phenomenon known as the “placebo effect.” The opposite phenomenon is known as nocebo effect.

**Point of Departure (POD)** The dose-response point that marks the beginning of a low-dose extrapolation. This point can be the lower bound on dose for an estimated incidence or a change in response level from a dose-response model (BMD), or a NOAEL or LOAEL for an observed incidence or a change in response level (see also Benchmark Approach/Dose).

**Point Source** Emission source(s), either single or multiple, which can be quantified by means of location and the amount of substance emitted per source and emission unit (e.g., amount per time).

**Poison** Compound of which a certain dose can elicit toxic effects and, possibly, death. A poison may be a mixture of various toxic substances: Natural poisons (e.g., bee or snake venom) are often secretion products and consist of numerous components, i.e., toxins and/or (toxic) enzymes as well as poisonous plant extracts.

**Pollution** Release to or presence in the environment of a chemical, physical, or biological agent (a pollutant) that has the potential to damage the health of humans or other organisms.

- Polymorphism** The existence of interindividual differences in DNA sequences coding for one specific gene. The effects of such differences may vary, from fully intact protein to inactive protein or lack of synthesis of this protein. In the context of pharmacology and toxicology, genetic polymorphisms of xenobiotic metabolizing enzymes are of special interest, as certain (iso)enzymes which are expressed at higher or lower levels or missing in individuals may predispose them to adverse effects (see also Susceptibility and Biotransformation).
- POP(s)** Persistent organic pollutant(s). PCDDs, PCDFs, and PCBs are persistent organic pollutants (POPs) under the Stockholm Convention on Persistent Organic Pollutants (<http://www.pops.int/>) and are omnipresent in the global environment.
- ppb** A unit of measure expressed as parts per billion. Equivalent to  $1 \times 10^{-9}$ , e.g., mg per kg.
- ppm** A unit of measure expressed as parts per million. Equivalent to  $1 \times 10^{-6}$ , e.g., mg per kg.
- Prevalence** The proportion of disease cases that exist within a population at a specific point in time, relative to the number of individuals within that population at the same point in time.
- Prioritization** Setting priorities in the sequential risk assessment of (numerous) agents under consideration according to their perceived importance.
- Probability** A quantitative statement about the likelihood of a specific outcome. Probability values can range from 0 to 1.
- Proliferation** Multiplication, i.e., an increase by frequent and repeated reproduction or growth by cell division.
- Promotion** Phase of proliferation of carcinogen-initiated cells in the context of carcinogenesis.
- Promotor** An agent that is not carcinogenic in itself, but when administered after an initiator of carcinogenesis stimulates the clonal expansion of the initiated cell to produce a neoplasm.
- PTWI (Provisional Tolerable Weekly Intake)** The weekly dose of a contaminant which an individual may ingest over its lifetime without an appreciable health risk, according to current knowledge (thus provisional). The WHO sets PTWI values for food contaminants (see also ADI and TDI).
- QSAR** Quantitative structure-activity relationship. A quantitative relationship between a biological activity (e.g., toxicity) and one or more molecular descriptors that are used to predict the activity (see also Structure-Activity Relationship).
- REACH** Registration, Evaluation, Authorisation and Restriction of Chemicals – the new chemical legislation of the European Union (Regulation No. 907/2006) which came into force in 2007. It replaces about 40 directives and regulations and erases the former regulatory distinction between newly notified substances and existing chemical substances. REACH does not touch special regulations for drugs, biocides, radioactive compounds, and food and feed additives.
- Reference Dose** Acronym: RfD. “An estimate (with uncertainty perhaps spanning an order of magnitude) of a daily oral exposure to the human population (including sensitive subpopulations) that is likely to be without an appreciable risk of deleterious effects during a lifetime. It can be derived from a NOAEL, LOAEL,

or benchmark dose, with uncertainty factors generally applied to reflect limitations of the data used” (WHO/IPCS 2004) (see also Reference Values).

**Reference Values (RfD or RfC and RV95)** An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. It is derived from a BMDL, a NOAEL, a LOAEL, or another suitable point of departure, with uncertainty/variability factors applied to reflect limitations of the data used. Reference value, a generic term as used by EPA (2002), is not specific to a given route of exposure. EPA develops numerical toxicity values for the reference dose (RfD) and reference concentration (RfC), usually for non-cancer health assessments. The term “reference value” is also used in human biomonitoring: Here,  $RV_{95}$  are statistical descriptions of the range of concentrations typically seen in a specified reference population, but which have no direct relationship to health effects or risk assessment. But,  $RV_{95}$  are an important tool for prevention to assess whether populations (or individuals) are more exposed when compared to the environmental background exposure. Compare also Human Biomonitoring Values I and II (HBM I and II).

**Relative Risk** The relative measure of the difference in risk between the exposed and unexposed populations in a cohort study. The relative risk is defined as the rate of disease among the exposed divided by the rate of disease among the unexposed. A relative risk of 2 means that the exposed group has twice the disease risk as the unexposed group.

**Reproductive Toxicology** The study of the adverse effects of chemicals (and medicinal drugs) on the embryo, fetus, neonate, and prepubertal animal and the adult reproductive and neuroendocrine systems. Reproductive toxins comprise both agents which impair the fertility of adult organisms and/or those which can adversely affect the developing organisms (see also Embryotoxicity and Teratogenicity).

**RfD** See Reference Dose.

**Risk** The probability of an adverse effect in an organism, system, or (sub)population caused under specific circumstances, e.g., by exposure to an agent and/or a situation.

**Risk (Human Health)** The Regulation EC 178/2002 defines risk as “a function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard.” For some areas, different definitions have been established in legislation or by relevant international authorities. Although most definitions of “risk” have a common core (probability of adverse effects resulting from. . .), they differ in various disciplines (e.g., epidemiology, economics, sociology, toxicology).

**Risk Analysis** This term is not well defined in toxicology. Some consider it as a process consisting of three components: risk assessment, risk management, and risk communication.

**Risk Assessment (Human Health)** The evaluation of scientific information on the hazardous properties of environmental agents (hazard characterization), the dose-

response relationship (dose-response assessment), and the extent of human exposure to those agents (exposure assessment). The product of the risk assessment is a statement regarding the probability that populations or individuals so exposed will be harmed and to what degree (risk characterization).

**Risk Characterization** The integration of information on hazard, exposure, and dose response to provide an estimate of the likelihood that any of the identified adverse effects will occur in exposed people. The *Codex Alimentarius* definition: “The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization and exposure assessment.”

**Risk Communication** An interactive process of exchanging information and views on risks between scientific experts, risk managers (at federal or state agencies), consumers, and the interested public.

**Risk Evaluation** Establishment of a qualitative or quantitative relationship between risks and benefits of exposure to an agent, involving the complex process of determining the significance of the identified hazards and estimated risks to the system concerned or affected by the exposure as well as the significance of the benefits brought about by the agent. It is an element of risk management. Risk evaluation is synonymous with risk-benefit evaluation.

**Risk Management (Human Health)** A decision-making process that accounts for political, social, economic, and engineering implications together with risk-related information in order to develop, analyze, and compare management options and select the appropriate managerial response to a potential chronic health hazard.

**Risk Management Measures (RMMs)** Measures in the control strategy for a hazardous substance that reduce the emission of and exposure to a substance, thereby reducing the risk to human health and the environment.

**Risk Perception** An integral part of risk evaluation. The subjective perception of the gravity or importance of the risk based on an individual’s knowledge of different risks and the moral and political judgment attached to them and their importance.

**Safety** Practical certainty that adverse effects will not result from exposure to an agent under defined circumstances. It is the reciprocal of risk. Toxicological “safety” is defined as a high probability that adverse effects will not result from exposure to a chemical under specific conditions of quantity and manner of use.

**Safety Factor** Composite (reductive) factor by which an observed or estimated NOAEL is divided to arrive at a criterion or standard that is considered safe or without appreciable risk (see also Assessment Factor and Uncertainty Factor).

**SAR** Structure-activity relationship.

**SCOEL** The Scientific Committee for Occupational Exposure Limit values with the mandate to advise the European Commission on occupational exposure limits for chemicals at the workplace.

**Sensibility** An acute perception or responsiveness of an individual toward something, such as the emotions of another person or to environmental factors, e.g., noise or chemicals.

**Sensitivity** Personal susceptibility of an individual to a stimulus. The concept “multiple chemical sensitivity” assumes that some individuals are more susceptible to low-dose toxic effects of chemicals than others.

**Sensitivity and Specificity** Statistical terms used to describe the ability of a test to correctly identify true positives and negatives. For instance, in medical diagnostics, test sensitivity is the ability of a test to correctly identify those with the disease (true positive rate), whereas test specificity is the ability of the test to correctly identify those without the disease (true negative rate).

**Short-Term Exposure Limits** Acronym: STEL. For a number of workplace chemicals, peak exposure or ceiling limits for short-term exposure are set, in addition to the 8-h time-weighted average (TWA) exposure limits (MAK or TLV values). According to STEL, exposure should not be longer than 15 min and should not be repeated more than four times per day. The “excursion” factor ( $>1$ ) by which the STEL can exceed the TWA depends upon the chemical concerned and takes into account certain properties such as irritation.

**Smog** A word coined for air pollution from smoke and fog. Smog is a problem in many cities, aggravated by inversion weather conditions (which traps pollution close to the ground), and continues to harm human health. When limit values for smog are reached, warnings are given to the public.

**SMR** Standardized mortality ratio. This is the relative measure of the difference in risk between the exposed and unexposed populations in a cohort study. The SMR is similar to the relative risk in both definition and interpretation. This measure is usually standardized to control for any differences in age, sex, and/or race between the exposed and reference populations. It is frequently converted to a percent by multiplying the ratio by 100 (see also Mortality Rate).

**Specificity** The term has context-dependent meanings. In chemistry, the ability to identify and quantify the target analyte in the presence of chemically similar interfering compounds. In medicine, the ability to exclusively detect persons with a particular disease; ratio of persons with a negative test result to nondiseased persons.

**Standard** An environmental quality standard is the limiting concentration of a chemical (or other adverse condition, e.g., pH) permitted in a given compartment (soil, effluent, water). All standards are established for regulatory purposes and set on the basis of a judgment of a number of criteria involved: The standard is dependent on the use (e.g., drinking water or agricultural water for irrigation), the subject of protection, and the objective (protection goal).

**STEL** See Short-Term Exposure Limit.

**Stochastic Effects** The term stochastic indicates that the occurrence of effects so named would be random (with a probability  $<1$  and  $>0$ ), meaning – even for an individual – there is no threshold of dose below which the effect will not occur and the chance of experiencing the effect increases with increasing dose.

Hereditary effects and cancer induced by radiation are considered to be stochastic effects.

**Stress-Strain Concept** Concept in occupational medicine that describes how mechanical stress at the workplace will result in an overstraining of the musculoskeletal system. This concept is also useful for nonmechanical stress factors, such as exposures to toxicants or radioactive compounds and the resulting effects on health.

**Structural Alert** A molecular (sub)structure associated with the presence of a biological activity (e.g., genotoxicity).

**Structure-Activity Relationship SAR:** The correlation between the chemical or 3D structure of a molecule and its physicochemical properties or its biological activity. SAR analysis can help to determine chemical groups responsible for evoking a biological effect. This allows (targeted) modification of the effect or potency of a bioactive compound (e.g., a drug) by changing its chemical structure. The method has been refined to build mathematical models for the prediction of quantitative relationships between structure and biological activity (see QSAR).

**Subchronic Exposure (Toxicity Study)** Repeated exposure by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10% of the life span in humans (more than 30 days up to approximately 90 days in typically used laboratory animal species) (see also Chronic Toxicity Study).

**Subject of Protection** The target object (e.g., human population, subgroup, or environment) to be protected by risk reduction measures.

**Susceptibility** The state or fact of being likely or liable to be influenced or harmed by a particular thing. In epidemiology or toxicology, susceptible individuals are members who are more prone to develop an illness than the (average) population at risk.

**Symptoms** Signs of disease. They are usually characteristic of a specific type of disease and also of a specific toxic agent.

**Synergism** A phenomenon in which the toxicity of a mixture of chemicals is greater than that which would be expected from the total toxicity of the individual chemicals present in the mixture (see also Combined Chemical Effects).

**Systemic Toxicity** Toxic effects as a result of absorption and distribution of a toxicant to a site distant from its entry point.

**Target Organ** The biological organ(s) most adversely affected by exposure to a chemical, physical, or biological agent.

**TCCD** Acronym for trichlorodibenzo[1,4]dioxin(s) or for tetrachloro-dibenzo [1,4]dioxin(s); mostly for 2,3,7,8-tetrachlorodibenzo[1,4]dioxin (see Dioxins).

**TCDF** Acronym for trichlorodibenzofuran(s) and for tetrachlorodibenzofuran(s) (see Dioxin).

**TDI** Tolerable Daily Intake; analogous to acceptable daily intake (ADI). The term "tolerable" is used for agents that are not deliberately added, such as contaminants in food.

**TEF** See Toxicity Equivalency Factor.

**Teratogen** Agent which when administered prenatally to the mother induces permanent structural malformations or defects in the offspring. The most widely known example of a teratogen is thalidomide (Contergan) which can cause severe malformations of internal organs, but mainly of extremities (limbs).

**Teratogenicity** Structural developmental defects due to exposure to a chemical agent during formation of individual organs.

**Threshold** The dose or exposure below which no deleterious effect is expected to occur.

**Threshold Limit Value (TLV)** Values for occupational exposure to airborne substances published by the American Conference of Governmental Industrial Hygienists (ACGIH). TLVs represent the average concentration in  $\text{mg}/\text{m}^3$  for an 8-h workday and a 40-h work week to which nearly all workers may be repeatedly exposed, day after day, without adverse effect.

**Tolerable Risk** A risk which may be tolerated for transient exposure, but requires further risk reduction measures to achieve lower risk levels (see Acceptable Risk).

**Toxicant** An agent or material capable of producing an adverse response (effect) in a biological system, seriously injuring structure and/or function or causing death.

**Toxicity** Inherent property of an agent to cause an adverse biological effect. Toxicity is a general term for all undesirable or detrimental health effects of a substance and depends upon dose and properties of the substance. Based on the effect, one distinguishes between, e.g., organ toxicity, carcinogenicity, mutagenicity, embryotoxicity, and teratogenicity.

**Toxicity Equivalency Factor** TEF. Factor used in risk assessment to estimate the toxicity of a complex mixture, most commonly a mixture of chlorinated dibenzo-p-dioxins, furans, and biphenyls; in this case, TEF is based on relative toxicity to 2,3,7,8-tetrachlorodibenzo-p-dioxin.

**Toxicity Tests** Determination of the effect of a substance on a group of selected organisms under defined conditions. A toxicity test usually measures either the proportion of organisms affected (quantal) or the degree of effect shown (graded or quantitative) after exposure to specific levels of a stimulus (concentration or dose, or mixture of chemicals) for a given period of time.

**Toxicodynamics** The determination and quantification of the sequence of events at the cellular and molecular levels leading to a toxic response to a chemical agent. In the context of medicinal drugs, this is referred to as pharmacodynamics.

**Toxicokinetics** The field of toxicology dealing with the determination and quantification of the time course of absorption, distribution, biotransformation (metabolism), and excretion of hazardous chemicals in the body. In the context of medicinal drugs, this is referred to as pharmacokinetics.

**Toxicology** The discipline of the adverse effects of chemical substances on living organisms. Basic toxicology characterizes the type of effects observed at different doses as well as the cellular, biochemical, and molecular mechanisms of action and the toxicokinetics. Clinical toxicology deals with the diagnosis and treatment of human and animal intoxications. Regulatory toxicology sets rules with the aim to prevent unwanted effects of chemicals.

**Toxin(s)** Natural poison(s); toxic organic substance(s) produced by a living organism, e.g., mycotoxins of fungi, phytotoxins of plants, or venoms of animals, often agents with partly highly specific mechanisms of action.

**Toxinology** The science that deals with toxins of plant, animal, and microbial origin. Toxin.

**Transcriptomics** Techniques available to identify the mRNA from actively transcribed genes, e.g., used to compare patterns in treated and untreated cells/organisms.

**Transfer** Term in environmental toxicology for the passage of a substance (e.g., cadmium) from one medium (e.g., soil) in plants.

**Tumor** An abnormal, uncontrolled growth of cells (synonym: neoplasm). A benign tumor is defined as a tumor that does not spread to a secondary localization, but may impair normal biological function through obstruction or may progress to malignancy later.

**UBA** German: Umweltbundesamt, the Federal Environmental Protection Agency.

**Uncertainty** Imperfect knowledge concerning the present or future state of an organism, system, or (sub)population under consideration. Lack of knowledge about variability in specific parameters in a risk assessment. Uncertainty is not the same as variability. For example, a risk assessor may be very certain that different people drink different amounts of water but may be uncertain about how much variability there is in water intakes within the population. Uncertainty can often be reduced by collecting more and better data, whereas variability is an inherent property of the population being evaluated. Variability can be better characterized with more data, but it cannot be reduced or eliminated. Efforts to clearly distinguish between variability and uncertainty are important for both risk assessment and risk characterization (see also Uncertainty Factors).

**Uncertainty Factor(s)** One of several, often tenfold, default factors used in operationally deriving the RfD and RfC from experimental data. The factors are intended to account for (1) variation in susceptibility among the members of the human population (i.e., interindividual or intraspecies variability); (2) uncertainty in extrapolating animal data to humans (i.e., interspecies uncertainty); (3) uncertainty in extrapolating from data obtained in a study with less-than-lifetime exposure (i.e., extrapolating from subchronic to chronic exposure); (4) uncertainty in extrapolating from a LOAEL rather than from a NOAEL; and (5) uncertainty associated with extrapolation when the database is incomplete.

**Unit Risk** The upper-bound excess lifetime cancer risk estimated to result from continuous exposure to an agent at a concentration of 1 mg/L in water, or 1 mg/m<sup>3</sup> in air. The interpretation of unit risk would be as follows: If unit risk  $\frac{1}{4} 2 \times 10^{-6}$  per mg/L, then two excess cancer cases (upper bound estimate) are expected to develop per 1,000,000 people if exposed daily for a lifetime to 1 mg of the chemical per liter of drinking water.

**Validation** Process by which the reliability and relevance of a particular approach, method, process, or assessment is established for a defined purpose. Different parties define "reliability" as establishing the reproducibility or outcome of the

approach, method, process, or assessment over time. “Relevance” is defined as establishing the meaningfulness and usefulness of the approach, etc., for a defined purpose. Validation is a process required, e.g., for alternative test methods to replace for toxicity tests in animals.

**Virtually Safe Dose** The VSD, derived from the unit risk for a carcinogenic chemical, denotes the dose which could cause one additional case of cancer in 1,000,000 persons with lifetime exposure. In practical terms, VSD denotes a “safe” dose.

**vPvB** Acronym for “very persistent, very bioaccumulative.” There are restrictions for compounds with such properties due to high concerns for the environment and human health.

**Weight-of-Evidence (WoE) for Carcinogenicity** A system used by the US EPA (and others) for characterizing the extent to which the available data support the hypothesis that an agent causes cancer in humans. The approach outlined in EPA’s guidelines for carcinogen risk assessment (2005) considers all scientific information in determining whether and under what conditions an agent may cause cancer in humans and provides a narrative approach to characterize carcinogenicity rather than categories. Five standard weight-of-evidence descriptors are used as part of the narrative.

**WHO** World Health Organization. An independent organization of the United Nations (UN) with advisory functions, e.g., publication of guidance documents on hazardous chemicals in air, water, and food and recommendations on maximal levels in food commodities (see also ADI and PTWI).

**Xenobiotic(s)** A term for man-made (manufactured) chemical(s) not produced in nature and not normally considered a constituent component of a specified biological system. With regard to the latter, also phytochemicals (of natural origin but “foreign” for the mammalian organism) can be considered as xenobiotics for humans.
