Abstract. Dynamic Vision Sensors (DVSs) asynchronously stream events in correspondence of pixels subject to brightness changes. Differently from classic vision devices, they produce a sparse representation of the scene. Therefore, to apply standard computer vision algorithms, events need to be integrated into a frame or event-surface. This is usually attained through hand-crafted grids that reconstruct the frame using ad-hoc heuristics. In this paper, we propose Matrix-LSTM, a grid of Long Short-Term Memory (LSTM) cells that efficiently process events and learn end-to-end task-dependent event-surfaces. Compared to existing reconstruction approaches, our learned event-surface shows good flexibility and expressiveness on optical flow estimation on the MVSEC benchmark and it improves the state-of-the-art of event-based object classification on the N-Cars dataset.

Keywords: Event-based vision · Representation learning · LSTM · Classification · Optical flow

1 Introduction

Event-based cameras, such as dynamic vision sensors (DVSs) [2, 17, 25, 29], are bio-inspired devices that attempt to emulate the efficient data-driven communication mechanisms of the brain. Unlike conventional frame-based active pixel sensors (APS), which capture the scene at a predefined and constant frame-rate, these devices are composed of independent pixels that output sequences of asynchronous events, efficiently encoding pixel-level brightness changes caused by moving objects. This results in a sensor having a very high dynamic range (>120 dB) and high temporal resolution (in the order of microseconds), matched with low power consumption and minimal delay. All these characteristics are key features in challenging scenarios involving fast movements (e.g., drones or

moving cars), and abrupt brightness changes (e.g., when exiting a dark tunnel in a car). However, novel methods and hardware architectures need to be specifically designed to exploit these advantages and leverage their potential in complex tasks. Event-cameras only provide a timed sequence of changes that is not directly compatible with computer vision systems which typically work on frames.

Driven by the great success of frame-based deep learning architectures, that learn representations directly from standard APS signals, research in event-based processing is now focusing on how to effectively aggregate event information in grid-based representations which can be directly used, for instance, by convolutional deep learning models. Nevertheless, finding the best mechanism to extract information from event streams is not trivial. Multiple solutions have indeed emerged during the past few years, mostly employing hand-crafted mechanisms to accumulate events. Examples of such representations are mechanisms relying on exponential [6, 15, 31] and linear [4, 6] decays, “event-surfaces” storing the timestamp of the last received event in each pixel and extensions of such mechanism making use of memory cells [31] and voxel-grids [26, 36].

Only very recently deep learning techniques have been applied to learn such surfaces in a data-driven manner [10]. In this paper, we focus on this recent trend in event-based processing, and propose a mechanism to efficiently apply a Long Short-Term Memory (LSTM) network [12] as a convolutional filter over the 2D stream of events in order to accumulate pixel information through time and build 2D event representations. The reconstruction mechanism is end-to-end differentiable, meaning that it can be jointly trained with state-of-the-art frame-based architectures to learn event-surfaces specifically tailored for the task at hand. Most importantly, the mechanism specifically focuses on preserving sparsity during computation, enabling the reconstruction process to only focus on pixels receiving events and without requiring events to be densified in a dense tensor during the intermediate feature extraction steps, process that is otherwise necessary when applying standard computer vision approaches, such as ConvLSTM [30], in most of the cases.

Substituting hand-crafted event-surfaces with our trainable layer in state-of-the-art architectures improves their performance substantially without requiring particular effort in hyper-parameter tuning, enabling researchers to exploit event information effectively. The contributions of the paper are summarized as follows:

- We propose Matrix-LSTM, a task-independent mechanism to extract grid-like event representations from asynchronous streams of events. The framework is end-to-end differentiable, it can be used as input of any existing frame-based state-of-the-art architecture and jointly trained to extract the best representation from the events.
- Replacing input representations with a Matrix-LSTM layer in existing architectures, we show that it improves the state-of-the-art on event-based object classification on N-CARS [31] by 3.3% and performs better than hand-crafted features on N-Caltech101 [23]. Finally, it improves optical flow estimation on

the MVSEC benchmark [37] up to 30.76% over hand-crafted features [37] and up to 23.07% over end-to-end differentiable ones [10].

- We developed custom CUDA kernels, both in PyTorch [32] and TensorFlow [1], to efficiently aggregate events by position and perform a convolution-like operation on the stream of events using an LSTM as a convolutional filter¹.

2 Related Work

Event cameras provide outstanding advantages over ordinary devices in terms of time resolution and dynamic range. However, their potentialities are still unlocked, mainly due to the difficulty of building good representations from a sparser, asynchronous and much more rough source of information compared to frame-based data. In this section, we give a brief overview of related works, focusing on representations for event-based data and highlighting the differences and similarities with our work. We refer the reader to [8] for a thorough overview.

Hand-Crafted Representations. Several hand-crafted event representations have been proposed over the years, ranging from biologically inspired, such as those used in Spiking Neural Networks [19], to more structured ones. Recently, the concept of *time-surface* was introduced [15,20], in which 2D surfaces are obtained by keeping track of the timestamp of the last event occurred in each location and by associating each event with features computed applying exponential kernels on the surface. An extension of these methods, called HATS [31], employs memory cells that retain temporal information from past events. Instead of building the surface using just the last event, too sensitive to noise, HATS uses a fixed-length memory. Histograms are then extracted from the surface and a SVM classifier is finally used for prediction. The use of a memory to compute the event-surface closely relates HATS with the solution presented in this paper. Crucially, the accumulation procedure employed in HATS is hand-crafted, while our work is end-to-end trainable thanks to a grid of LSTM cells [12], which enable to learn a better accumulation strategy directly from data.

In [36], the authors propose the EV-FlowNet network for optical flow estimation together with a new time-surface variant. Events of different polarities are kept separate to build a four-channel grid containing the number of events occurred in each location besides temporal information. A similar representation has also been used in [34]. To improve the temporal resolution of such representations, [38] suggests to discretize time into consecutive bins and accumulate events into a voxel-grid through a linearly weighted accumulation similar to bilinear interpolation. A similar time discretization has also been used in Events-to-Video [26], where the event representation is used within a recurrent-convolutional architecture to produce realistic video reconstructions of event sequences. Despite being slower, the quality of reconstructed frames closely

¹ Code available at <https://marcocannici.github.io/matrixlstm>.

resembles actual gray-scale frames, allowing the method to take full advantage from transferring feature representations trained on natural images.

End-to-End Representations. Most closely related to the current work, [10] learns a dense representation end-to-end directly from raw events. A multi-layer perceptron (MLP) is used to implement a trilinear filter that produces a voxel-grid of temporal features. The event time information of each event is encoded using the MLP network and the value obtained from events occurring in the same spatial location are summed up together to build the final feature. A look-up table is then used, after training, to speed-up the procedure. Events are processed independently as elements of a set, disregarding their sequentiality and preventing the network to modulate the information based on previous events. Our method, instead, by leveraging the memory mechanism of LSTM cells, can integrate information conditioned on the current state and can decide how much each event is relevant to perform the task, and how much information to retain from past events. A recent trend in event-based processing is studying mechanisms that do not require to construct intermediate explicit dense representations to perform the task at hand [3, 28, 33]. Among these, [22] uses a variant of the LSTM network, called PhasedLSTM, to learn the precise timings of events. While it integrates the events sequentially as in our work, PhasedLSTM employs a single cell on the entire stream of events and can be used only on very simple tasks [5]. The model, indeed, does not maintain the input spatial structure and condenses the 2D stream of events into a single feature vector, preventing the network to be used as input to standard CNNs. Finally, although it has never been adopted with event-based cameras, we also mention here the ConvLSTM [30] network, a convolutional variant of the LSTM that has previously been applied on several end-to-end prediction tasks. Despite its similarity with our method, since both implement the notion of convolution to LSTM cells, ConvLSTM is not straightforward to apply to sparse event-based streams and requires the input to be densified into frames before processing. This involves building very sparse frames of simultaneous events, mostly filled with padding, or dense frames containing uncorrelated events. Our formulation, instead, preserves sparsity during computation and does not require events to be densified, even when large receptive fields are considered.

3 Method

Event-based cameras are vision sensors composed of pixels able to work independently. Each pixel has its own exposure time and it is free to fire independently by producing an event as soon as it detects a significant change in brightness. Unlike conventional devices, no rolling shutter is used, instead, an asynchronous stream of events is generated describing what has changed in the scene. Each event e_i is a tuple $e_i = (x_i, y_i, t_i, p_i)$ specifying the time t_i , the location $(x, y)_i$ (within a $H \times W$ space) and the polarity $p_i \in \{-1, 1\}$ of the change (brightness increase or decrease). Therefore, given a time interval τ (i.e., the sample length), the set of events produced by the camera can be described as a sequence

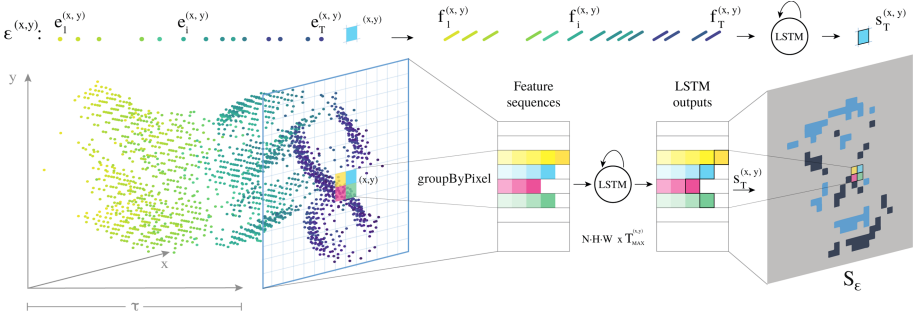

Fig. 1. Overview of Matrix-LSTM (figure adapted from [22]). Events in each pixel are first associated to a set of features $f_i^{(x,y)}$, and then processed by the LSTM. The last output, $s_T^{(x,y)}$, is finally used to construct \mathcal{S}_E . *GroupByPixel* is shown here on a single sample ($N = 1$) highlighting a 2×2 pixel region. Colors refer to pixel locations while intensity indicates time. For clarity, the features dimension is not shown in the figure (Color figure online)

$\mathcal{E} = \{(x_i, y_i, t_i, p_i) \mid t_i \in \tau\}$, ordered by the event timestamp. In principle, multiple events could be generated at the same timestamp. However, the grid representation of the events at a fixed timestamp t is likely to be very sparse, hence, an integrating procedure is necessary to reconstruct a dense representation \mathcal{S}_E before being processed by conventional frame-based algorithms.

Note that, in this work, we do not aim to reconstruct a frame that resembles the actual scene, such as a grey-scale or RGB image [26, 27], but instead to extract task-aware features regardless of their appearance. In the following, “*surface*”, “*reconstruction*” and “*representation*” are used with this meaning.

3.1 Matrix-LSTM

Analogously to [10], our goal is to learn end-to-end a fully parametric mapping $\mathcal{M} : \mathcal{E} \rightarrow \mathcal{S}_E \in \mathbb{R}^{H \times W \times C}$, between the event sequence and the corresponding dense representation, providing the best features for the task to optimize.

In this work, we propose to implement \mathcal{M} as an $H \times W$ matrix of LSTM cells [12] (see Fig. 1). Let’s define the ordered sequence of events $\mathcal{E}^{(x,y)}$ produced by the pixel (x, y) during interval τ as $\mathcal{E}^{(x,y)} = \{(x_i, y_i, t_i, p_i) \mid t_i \in \tau, x_i = x, y_i = y\} \subset \mathcal{E}$, and its length as $T^{(x,y)} = |\mathcal{E}^{(x,y)}|$, which may potentially be different for each location (x, y) . A set of features $f_i^{(x,y)} \in \mathbb{R}^F$ is first computed for each event occurring at location (x, y) , typically the polarity and one or multiple temporal features (see Sect. 4). At each location (x, y) , an $LSTM^{(x,y)}$ cell then processes these features asynchronously, keeping track of the current integration state and condensing all events into a single output vector $s^{(x,y)} \in \mathbb{R}^C$. In particular, at each time t , the $LSTM^{(x,y)}$ cell produces an intermediate representation $s_t^{(x,y)}$. Once all the events are processed, the last output of the LSTM cell compresses the dynamics of the entire sequence $\mathcal{E}^{(x,y)}$ into a fixed-length vector $s_T^{(x,y)}$ that

can be used as pixel feature (here we dropped the superscript (x,y) from T for readability). The final surface $\mathcal{S}_{\mathcal{E}}$ is finally built by collecting all LSTMs final outputs $s_T^{(x,y)}$ into a dense tensor of shape $H \times W \times C$. A fixed all-zeros output is used where the set of events $\mathcal{E}^{(x,y)}$ is empty.

Temporal Bins. Taking inspiration from previous methods [10, 26, 38] that discretize time into temporal bins, we also propose a variant of Matrix-LSTM that operates on successive time windows. Given a fixed number of bins B , the original event sequence is split into B consecutive windows $\mathcal{E}_{\tau_1}, \mathcal{E}_{\tau_2}, \dots, \mathcal{E}_{\tau_B}$. Each sequence is processed independently, i.e., the output of each LSTM at the end of each interval is used to construct a surface $\mathcal{S}_{\mathcal{E}_b}$ and the LSTMs state is re-initialized before the next sub-sequence starts. This gives rise of B different reconstructions $\mathcal{S}_{\mathcal{E}_b}$ that are concatenated to form the final surface $\mathcal{S}_{\mathcal{E}} \in \mathbb{R}^{H \times W \times B \cdot C}$. In this formulation, the LSTM input features $f_i^{(x,y)}$ usually contain both global temporal features (i.e., w.r.t. the original uncut sequence) and relative features (i.e., the event position in the sub-sequence). Although LSTMs should be able to retain memory over very long periods, we found that discretizing time into intervals helps, especially in tasks requiring precise time information such as optical flow estimation (see Sect. 4.2). A self-attention module [13] is then optionally applied on the reconstructed surface to correlate intervals (see Sect. 4.1).

Parameters Sharing. Inspired by the convolution operation defined on images, we designed Matrix-LSTM to enjoy translation invariance. This is implemented by sharing the parameters across all the LSTM cells, as in a convolutional kernel. Sharing parameters not only drastically reduces the number of parameters in the network, but it also allows us to transfer a learned transformation to higher or lower resolutions as in fully-convolutional networks [18].

We highlight that such an interpretation of the Matrix-LSTM functioning also fits the framework proposed in [10], in which popular event densification mechanisms are rephrased as kernel convolutions on the *event field*, i.e., a discretized four-dimensional manifold spanning x and y , and the time and polarity dimensions. We finally report that this formulation is equivalent to a 1×1 ConvLSTM [30] applied on a dense tensor where events are stacked in pixel locations by arrival order. However, as reported in Sect. 4.1, this formulation has better space and time performance on sparse event sequences. Moreover, in the next section, an extension to larger receptive fields with better accuracy performance on asynchronous event data compared to ConvLSTM, is also proposed.

Receptive Field Size. As in a conventional convolution operation, Matrix-LSTM can be convolved on the input space using different strides and kernel dimensions. In particular, given a receptive field of size $K_H \times K_W$, each LSTM cell processes a local neighborhood of asynchronous events $\mathcal{E}^{(x,y)} = \{(x_i, y_i, t_i, p_i) \mid t_i \in \tau, |x - x_i| < K_W - 1, |y - y_i| < K_H - 1\}$. Events features are computed as in the original formulation, however, an additional coordinate feature (p_x, p_y) is also added specifying the relative position of each event within the receptive field. Coordinate features are range-normalized in such a way that an event

occurring in the top-left pixel of the receptive field has feature $(0, 0)$, whereas one occurring in the bottom-right position has features $(1, 1)$. Events belonging to multiple receptive fields (e.g., when the LSTM is convolved with a stride 1×1 and receptive field greater than 1×1) are processed multiple times, independently.

Implementation. The convolution-like operation described in the previous section can be implemented efficiently by means of two carefully designed event grouping operations. Rather than replicating the LSTM unit multiple times on each spatial location, a single recurrent unit is applied over different $\mathcal{E}^{(x,y)}$ sequences in parallel. This requires a reshape operation, i.e., *groupByPixel*, that splits events based on their pixel location maintaining the events relative ordering within each sub-sequence. A similar procedure, i.e., *groupByTime*, is employed to efficiently split events into consecutive temporal windows without making use of expensive masking operations. An example of the *groupByPixel* operation is provided in Fig. 1 while implementation details of both operations, implemented as custom CUDA kernels, are provided in the supplementary materials. We finally highlight that these operations are not specific to Matrix-LSTM, since grouping events by pixel index is a common operation in event-based processing, and could indeed benefit other implementations making use of GPUs.

4 Evaluation

We test the proposed mechanism on two different tasks: object classification (see Sect. 4.1) and optical flow estimation (see Sect. 4.2), where the network is required to extract effective temporal features. We evaluated the goodness of Matrix-LSTM features indirectly: a state-of-the-art architecture is taken as a reference and the proposed method is evaluated in terms of the gain in performance obtained by replacing the network representation with a Matrix-LSTM.

4.1 Object Classification

We evaluated the model on the classification task using two publicly available event-based collections, namely the N-Cars [31] and the N-Caltech101 [23] datasets, which represent to date the most complex benchmarks for event-based classification. N-Cars is a collection of urban scenes recordings (lasting 100ms each) captured with a DVS sensor and showing two object categories: cars and urban background. The dataset comes already split into 7,940 car and 7,482 background training samples, and 4,396 car and 4,211 background testing samples. The N-Caltech101 collection is an event-based conversion of the popular Caltech-101 [16] dataset obtained by moving an event-based camera in front of a still monitor showing one of the original RGB images. Like the original version, the dataset contains objects from 101 classes distributed amongst 8,246 samples.

Network Architectures. We used two network configurations to test Matrix-LSTM on both datasets, namely the classifier used in Events-to-Video [26], and the one used to evaluate the EST [10] reconstruction. Both are based on

Table 1. Results on N-Cars: (a) ResNet18–Ev2Vid, variable time encoding, and normalization; (b) ResNet18–EST, variable time encoding and number of bins

		(a)						
					ts glob+loc	-	93.46 ± 0.84%	93.21 ± 0.49%
					local	92.65 ± 0.78%	92.75 ± 1.38%	93.12 ± 0.68%
							(b)	

ResNet [11] backbones and pre-trained on ImageNet [7]. Events-to-Video [26] uses a ResNet18 configuration maintaining the first 3 channels convolution (since reconstructed images are RGB) while adding an extra fully-connected layer to account for the different number of classes in both N-Caltech101 and N-Cars (we refer to this configuration as *ResNet–Ev2Vid*). EST [10] instead uses a ResNet34 backbone and replaces both the first and last layers respectively, with a convolution matching the input features, and a fully-connected layer with the proper number of neurons (we refer to this configuration as *ResNet–EST*).

To perform a fair comparison we replicated the two settings, using the same number of channels in the event representation (although we also tried different channel values) and data augmentation procedures (random horizontal flips and crops of 224×224 pixels). We perform early stopping on a validation set in all experiments, using 20% of the training on N-Cars and using the splits provided by the EST official code repository [9] for N-Caltech101. ADAM [14] was used as optimizer for all experiments with a learning rate of 10^{-4} . Finally, we use a batch size of 64 and a constant learning rate on N-Cars in both configurations. On N-Caltech101, instead, we use a batch size of 16 while decaying the learning rate by a factor of 0.8 after each epoch when testing on *ResNet–Ev2Vid*, and a batch size of 100 with no decay with the *ResNet–EST* setup. Finally, to perform a robust evaluation, we compute the mean and standard deviation values using five different seeds in all the experiments reported in this section.

Results. The empirical evaluation is organized as it follows for both *ResNet–Ev2Vid* and *ResNet–EST*. We always perform hyper-parameters search using ResNet18 on N-Cars, being faster to train and thus allowing to explore a larger parameter space. We then select the best configuration to train the remaining architectures, i.e., ResNet34 on N-Cars and both variants on N-Caltech101.

Matrix-LSTM + ResNet–Ev2Vid. We start out with the *ResNet–Ev2Vid* baseline (setting up the Matrix-LSTM to output 3 channels) by identifying the optimal time feature to provide as input to the LSTM, as reported in Table 1a. We distinguish between *ts* and *delay* features and between *absolute* and *relative* scope. The first distinction refers to the type of time encoding, i.e., the timestamp of each event in the case of *ts* feature, or the delay between an event and the previous one in case of *delay*. Time features are always range-normalized between 0 and 1, with the scope distinction differentiating if the normalization takes place before splitting events into pixels (*absolute* feature) or after (*relative* feature).

Table 2. Results on N-Cars with ResNet18-EST: **(a)** *polarity + global ts + local ts* encoding, optional SELayer and variable number of bins; **(b)** *polarity + global ts + local ts* encoding, SELayer and variable number of channels

SE	2 bins	4 bins	9 bins	16 bins	bins	Channels		
						4	8	16
✓	93.46 ± 0.84%	92.68 ± 0.62%	93.21 ± 0.49%	92.01 ± 0.45%	1	93.88 ± 0.87%	93.60 ± 0.30%	94.37 ± 0.40%
	93.71 ± 0.93%	92.90 ± 0.62%	93.30 ± 0.47%	92.44 ± 0.43%	2	93.05 ± 0.92%	93.97 ± 0.52%	94.09 ± 0.29%
		(a)			bins	4	7	8
					9	92.42 ± 0.65%	93.56 ± 0.46%	93.49 ± 0.84%
							(b)	

In the case of *ts*, *absolute* means that the first and last events in the sequence have time feature 0 and 1, respectively, regardless of their position, whereas *relative* means that the previous condition holds for each position (x, y) . Note that we only consider relative delays since it is only meaningful to compute them between events of the same pixel. Finally, we always add the polarity, obtaining a 2-value feature $f_i^{(x,y)}$. *Delay relative* and *ts absolute* are those providing the best results, with *ts relative* having higher variance. We select *delay relative* as the best configuration. In Table 1a we also show the effect of applying the same frame normalization used while pre-training the ResNet backbone on ImageNet also to the Matrix-LSTM output. While performing normalization makes sense when training images are very similar to those used in pre-training, as in Events-to-Video [26], we found out that in our case, where no constraint is imposed on the appearance of reconstructions, this does not improve the performance.

Matrix-LSTM + ResNet-EST. We continue the experiments on N-Cars by considering *ResNet-EST* as baseline, where we explore the effect of using bins, i.e., intervals, on the quality of Matrix-LSTM surfaces. Since multiple intervals are involved, we distinguish between *global* and *local* temporal features. The first type is computed on the original sequence \mathcal{E} , before splitting events into intervals, whereas the latter locally, within the interval scope \mathcal{E}_{τ_b} . For local features we consider the best options we identified on ResNet-Ev2Vid, namely *delay relative* and *ts absolute*, while we only consider *ts* as global feature since a global delay loses meaning after interval splitting. Results are reported in Table 1b where values for single bin are missing since there is no distinction between *global* and *local* scope. Adding a global feature consistently improves performance. This can indeed help the LSTM network in performing integration conditioned on a global timescale and thus enabling the extraction of temporal consistent features. We use *global ts + local ts* features in next experiments, since this provides better performance and reduced variance, and always add the polarity feature.

The next set of experiments was designed to select the optimal number of bins, searching for the best $B = 2, 4, 9, 16$ as done in EST, while using a fixed *polarity + global ts + local ts* configuration. In these experiments, we also make use of the SELayer [13], a self-attention operation specifically designed to correlate channels. Being the number of channels limited, we always use a reduction factor of 1. Please refer to the paper [13] for more details. As reported in Table 2a, adding the layer consistently improves performance. We explain this by noticing

		3x3	5x5
Matrix-LSTM	delay rel	95.05 ± 0.96%	93.38 ± 0.64%
	ts abs	94.92 ± 0.74%	94.34 ± 0.94%

	ts abs	93.97 ± 1.30%	93.61 ± 1.59%

(a)

(b)

Fig. 2. (a) Comparison between Matrix-LSTM and ConvLSTM on N-Cars. (b) Space and time relative improvements of Matrix-LSTM over ConvLSTM as a function of input density (from 10% to 100% with 30% steps). Colors refer to different density, from low density (dark colors) to high density (light colors) (Color figure online)

that surfaces computed on successive intervals are naturally correlated and, thus, explicitly modeling this behavior helps in extracting richer features. Finally, we perform the last set of experiments to select the Matrix-LSTM hidden size (which also controls the number of output channels). Results are reported in Table 2b. Note that we only consider 4, 7, 8 channels with 9 bins to limit the total number of channels after concatenation.

Matrix-LSTM vs. ConvLSTM. In Table 2a we compare Matrix-LSTM with ConvLSTM [30] for different choices of kernel size on the N-Cars [31] dataset using the Ev2Vid-ResNet18 backbone. When using ConvLSTM, events are densified in a volume $\tilde{\mathcal{E}}_{dense}$ of shape $N \times T_{max}^{(x,y)} \times H \times W \times F$. Matrix-LSTM performs better on all configurations, despite achieving worst performance than the 1×1 Matrix-LSTM best configuration in Table 1a. Event surfaces produced by the Matrix-LSTM layer are indeed more blurry with larger receptive fields and this may prevent the subsequent ResNet backbone from extracting effective features. Using a 1×1 kernel enables to focus on temporal information while the subsequent convolutional layers deal with spatial correlation.

ConvLSTM, instead, does not properly handle asynchronous data when large receptive fields are considered, and this may explain the performance difference with Matrix-LSTM. Indeed, since pixels at different locations most often fire at different times and with different frequencies, the $\tilde{\mathcal{E}}_{dense}[n, i, :, :, :]$ slice processed by the ConvLSTM in each iteration does not contain all simultaneous events. Using a large ConvLSTM receptive field means to compare a neighborhood of events occurred at different timestamps and therefore not necessarily correlated. Contrary to ConvLSTM, Matrix-LSTM allows for a greater flexibility when large receptive fields are considered since the original events arrival order is preserved and we do not require events to be densified during intermediate steps. We do not compare the two LSTMs on the 1×1 configuration since, when using $\tilde{\mathcal{E}}_{dense}$ as input to ConvLSTM, the two configurations compute the same transformation,

despite ConvLSTM having to process more padded values. The two settings are indeed computationally equivalent only in the worst case in which all pixels in the batch happen to receive at least one event (i.e., $P = N \cdot H \cdot W$).

The 1×1 configurations are compared in terms of space and time efficiency in Fig. 2b. We use the two layers to extract a 224×224 frame from artificially generated events with increasing density, i.e., the ratio of pixels receiving at least one event. The reconstruction is performed using PyTorch [32] on a 12 GB Titan Xp, by varying the batch size, the LSTM hidden size and the number of events in each active pixel (starting from 1 and increasing by a factor of 2 for the hidden size, while increasing by a factor of 10 for the number of events, until allowed by GPU memory constraints). We compute the relative improvement of Matrix-LSTM in terms of sample reconstruction time and peak processing space (i.e., excluding model and input space) during both forward and backward passes, and finally aggregate the results by batch size computing the mean improvement over all the trials. Matrix-LSTM performs better than ConvLSTM on prediction time, with the time efficiency improving as the batch size increases, while worst than ConvLSTM on memory efficiency in very dense surfaces ($>70\%$ density). However, this situation is quite uncommon in event-cameras since they only generate events when brightness changes are detected. Uniform parts of the scene that remain unchanged, despite the camera movement, do not appear in the event stream. For instance, the background sky and road in MVSEC [37] make *outdoor_day* sequences only have an average 10% of active pixels.

Discussion. Results of the top performing configurations for both *ResNet-Ev2Vid* and *ResNet-EST* variants on both N-Cars and N-Caltech101 are reported in Table 3. We use *relative delay* with *ResNet-Ev2Vid* and *global ts + local ts* with *ResNet-EST*. Through an extensive evaluation, we show that using Matrix-LSTM representation as input to the baseline networks and training them jointly improves performance by a good margin. Indeed, using the ResNet34-Ev2Vid setup, our solution sets a new state-of-the-art on N-Cars, even surpassing the Events-to-Video model that was trained to extract realistic reconstructions. The same does not happen on N-Caltech101, whose performance usually greatly depends on pre-training also on the original image-based version, and where Events-to-Video has therefore advantage. Despite this, our model only performs 0.9% worse than the baseline. On the ResNet-EST configuration, the model performs consistently better on N-Cars, while slightly worse on N-Caltech101 on most configurations. However, we remark that search for the best configuration was indeed performed on N-Cars, while a hyper-parameter search directly performed on N-Caltech101 would have probably lead to better results.

4.2 Optical Flow Prediction

For the evaluation of optical flow prediction we used the MVSEC [37] suite. Fusing event-data with lidar, IMU, motion capture and GPS sources, MVSEC is the first event-based dataset to provide a solid benchmark in real urban conditions. The dataset provides ground truth information for depth and vehicle

Table 3. Matrix-LSTM best configurations compared to state-of-the-art

Method	Classifier	Channels (bins)	N-Cars	N-Caltech101
H-First [24]	Spike-based	-	56.1	0.54
HOTS [15]	Histogram similarity	-	62.4	21.0
Gabor-SNN [31]	SVM	-	78.9	19.6
HATS [31]	SVM	-	90.2	64.2
	ResNet34-EST [10]	-	90.9	69.1
	ResNet18-Ev2Vid [26]	-	90.4	70.0
Ev2Vid [26]	ResNet18-Ev2Vid	3	91.0	86.6
Matrix-LSTM (Ours)	ResNet18-Ev2Vid	3 (1)	95.80 ± 0.53	84.12 ± 0.84
	ResNet34-Ev2Vid	3 (1)	95.65 ± 0.46	85.72 ± 0.37
EST [10]	ResNet34-EST	2 (9)	92.5	81.7
	ResNet34-EST	2 (16)	92.3	83.7
Matrix-LSTM (Ours)	ResNet18-EST	16 (1)	94.37 ± 0.40	81.24 ± 1.31
	ResNet34-EST	16 (1)	94.31 ± 0.43	78.98 ± 0.54
	ResNet18-EST	16 (2)	94.09 ± 0.29	83.42 ± 0.80
	ResNet34-EST	16 (2)	94.31 ± 0.44	80.45 ± 0.55
	ResNet18-EST	2 (16)	92.58 ± 0.68	84.31 ± 0.59
	ResNet34-EST	2 (16)	92.15 ± 0.73	83.50 ± 1.24

pose and was later extended in [36] with optical flow information extracted from depth-maps. The dataset has been recorded on a range of different vehicles and features both indoor and outdoor scenarios and different lighting conditions.

Network Architecture. We used the EV-FlowNet [36] architecture as reference model. To perform a fair comparison between Matrix-LSTM and the original hand-crafted features, we built our model on top of its publicly available code-base [35]. The code contains few minor upgrades over the paper version, which we made sure to remove as reported in the supplementary materials.

The original network uses a 4-channels event-surface, collecting in pairs of separate channels based on the event polarity, the timestamp of the most recent event, and the number of events occurred in every spatial location. We replaced this representation with a Matrix-LSTM making use of 4 output channels, as well. We trained the model on the *outdoor_day1* and *outdoor_day2* sequences for 300,000 iterations, as in the original paper. We used the ADAM optimizer with batch size 8, and an initial learning rate of 10^{-5} , exponentially decayed every 4 epochs by a factor of 0.8. We noticed that EV-FlowNet is quite unstable at higher learning rates, while Matrix-LSTM could benefit from larger rates, so we multiply its learning rate, i.e., the Matrix-LSTM gradients, by a factor of 10 during training. Test was performed on a separate set of recordings, namely *indoor_flying1*, *indoor_flying2* and *indoor_flying3*, which are visually different from the training data. The network performance is measured in terms of average endpoint error (AEE), defined as the distance between the endpoints of the predicted and ground truth flow vectors. In addition, as proposed in the KITTI benchmark [21] and as done in [36], we report the percentage of outliers, namely points with endpoint error greater than 3 pixels and 5% of the magnitude ground

truth vector. Finally, following the procedure used in [36], we only report the error computed in spatial locations where at least one event was generated.

Table 4. Optical flow estimation on MVSEC

Method		<i>indoor_flying1</i>		<i>indoor_flying2</i>		<i>indoor_flying3</i>	
		AEE	%Outlier	AEE	%Outlier	AEE	%Outlier
Two-Channel Image [20]		1.21	4.49	2.03	22.8	1.84	17.7
EV-FlowNet [36]		1.03	2.20	1.72	15.1	1.53	11.9
Voxel Grid [38]		0.96	1.47	1.65	14.6	1.45	11.4
EST [10]	Exp. kernel	0.96	1.27	1.58	10.5	1.40	9.44
	Learnt kernel	0.97	0.91	1.38	8.20	1.43	6.47
Matrix-LSTM (Ours)	1 bin	1.017	2.071	1.642	13.88	1.432	10.44
	2 bins	0.829	0.471	1.194	5.341	1.083	4.390
	4 bins	0.969	1.781	1.505	11.63	1.507	12.97
	8 bins	0.881	0.672	1.292	6.594	1.181	5.389
	2 bins + SELayer	0.821	0.534	1.191	5.590	1.077	4.805

Results. In the previous classification experiments, we observed that the type of temporal features and the number of bins play an important role in extracting effective representations. We expect time resolution to be a key factor of performance in optical flow, hence, we focus here on measuring how different interval choices impact on the flow prediction. We decided to always use the *polarity + global ts + local ts* configuration, which worked well on N-Cars while considering different bin setups. Results are reported in Table 4.

As performed on classification, we study the effect of adding a SELayer on the best performing configuration. Correlating the intervals slightly improves the AEE metric in all test sequences but increases the number of outliers. As expected, varying the number of bins has a great impact on performance. The AEE metric, indeed, greatly reduces by simply considering two intervals instead of one. Interestingly, we achieved the best performance by considering only 2 intervals, as adding more bins hurts performance. We believe this behavior resides on the nature of optical flow prediction, where the network is implicitly asked to compare two distinct temporal instants. This configuration consistently improves the baseline up to 30.76% on *indoor_flying2*, highlighting the capability of the Matrix-LSTM to adapt also to low-level tasks.

4.3 Time Performance Analysis

We compared the time performance of Matrix-LSTM with other event representations following EST [10] and HATS [31] evaluation procedure. In Table 3b we report the time required to compute features on a sample averaged over the whole N-Cars training dataset for both ResNet-Ev2Vid and ResNet-EST configurations. Our surface achieves similar time performance than both HATS and EST, performing only ~ 2 ms slower than EST on the same setting (9 bins

Fig. 3. (a) Accuracy as a function of latency (adapted from [31]). (b) Average sample computation time on N-Cars and number of events processed per second. (c) Average time to reconstruct the event surface in MVSEC test sequences

and 2 channels). Similarly, in Table 3c, we compute the mean surface reconstruction time for MVSEC *indoor_flying* test sequences. While EST can exploit parallel batch computation of events within the same sample, since each event feature is processed independently, Matrix-LSTM relies on sequential computation to reconstruct the surface. The custom CUDA kernels we designed, however, enable bins and pixel sequences to be processed in parallel, drastically reducing the processing time. Please, refer to the additional materials for more details. All evaluations are performed with PyTorch on a GeForce GTX 1080Ti GPU.

In Fig. 3a we analyze the accuracy-vs-latency trade-off on the N-Cars dataset, as proposed in [31], using the ResNet18-Ev2Vid configuration. While the performance of the model, trained on 100 ms sequences, significantly drops when very few milliseconds of events are considered, the proposed method still shows good generalization, achieving better performance than the baselines when more than 20 ms of events are used. However, fixing the performance loss on small latencies is just a matter of training augmentation: by randomly cropping sequences to variable lengths (from 5 ms to 100 ms), our method consistently improves the baselines, dynamically adapting to sequences of different lengths.

5 Conclusion

We proposed Matrix-LSTM, an effective method for learning dense event representations from event-based data. By modeling the reconstruction with a spatially shared LSTM we obtained a fully differentiable procedure that can be trained end-to-end to extract the event representation that best fits the task at hand. Focusing on efficiently handling asynchronous data, Matrix-LSTM preserves sparsity during computation and surpasses other popular LSTM variants on space and time efficiency when processing sparse inputs. In this regard, we

proposed an efficient implementation of the method that exploits parallel batch-wise computation and demonstrated the effectiveness of the Matrix-LSTM layer on multiple tasks, improving the state-of-the-art of object classification on N-Cars by 3.3% and the performance on optical flow prediction on MVSEC by up to 23.07% over previous differentiable techniques [10]. Although we only integrate windows of events, the proposed mechanism can be extended to process a continuous streams thanks to the LSTM memory that is able to update its representation as soon as a new event arrives. As a future line of research, we plan to explore the use of Matrix-LSTM for more complex tasks such as gray-scale frame reconstruction [26], ego-motion and depth estimation [34,38].

Acknowledgments. We thank Alex Zihao Zhu for his help on replicating Ev-FlowNet results and the ISPL group at Politecnico di Milano for GPU support.
