Fig. 33.2 A 43-year-old male with metastatic renal cell carcinoma, recent ground level fall with new inability to bear weight, with some preceding left hip pain. Initial X-rays show a displaced left femoral neck fracture, which could easily be mistaken for an osteoporotic fracture (**a**). CT scan illustrates a discrete metastatic lesion in the femoral neck that predisposed to this fracture (**b**). Patient underwent a left hip hemiarthroplasty (**c, d**)

Oncologic patients undergoing preoperative workup require additional special considerations. Orthogonal radiographs should be obtained of the entire bone, including the joints above and below the lesion. This clarifies the region of interest, identifies concomitant areas of concern, and aids in preoperative planning. Some patients have anemia, thrombocytopenia, or neutropenia. Extensive osseous metastasis can also cause marked hypercalcemia requiring pharmacologic correction [4]. Coagulopathy may be present because of cachexia, poor nutrition, or liver disease. Bedridden patients may be prone to venous thromboembolism. Cross-matched units of packed red blood cells need to be available, since metastatic lesions can bleed profusely intraoperatively. A chest X-ray prior to surgery can help screen for malignant pleural effusions.

When immediate surgery is not possible or prudent, appropriate immobilization is necessary. In general, long bone fractures should be immobilized in a well-padded splint that is not circumferential, to accommodate swelling. A joint above and joint below should be immobilized for mid-shaft fractures to prevent rotational stress. Exceptions to this include proximal humeral fractures and femoral fractures. Proximal humeral fractures can be immobilized in a cuff and collar or shoulder immobilizer. While some advocate Buck's traction for proximal femur fractures, current data do not indicate a clear benefit [5].

Surgical treatment of pathologic fractures has gradually become less invasive and stressful. In many instances, the fractures are amenable to intramedullary nailing, which can be placed percutaneously with minimal dissection. Nailing of proximal femoral metastases not involving the femoral head has been shown to be a reliable option with a 10% revision rate due to disease progression, breakage, and other reasons [6]. For pathologic fractures involving the femoral

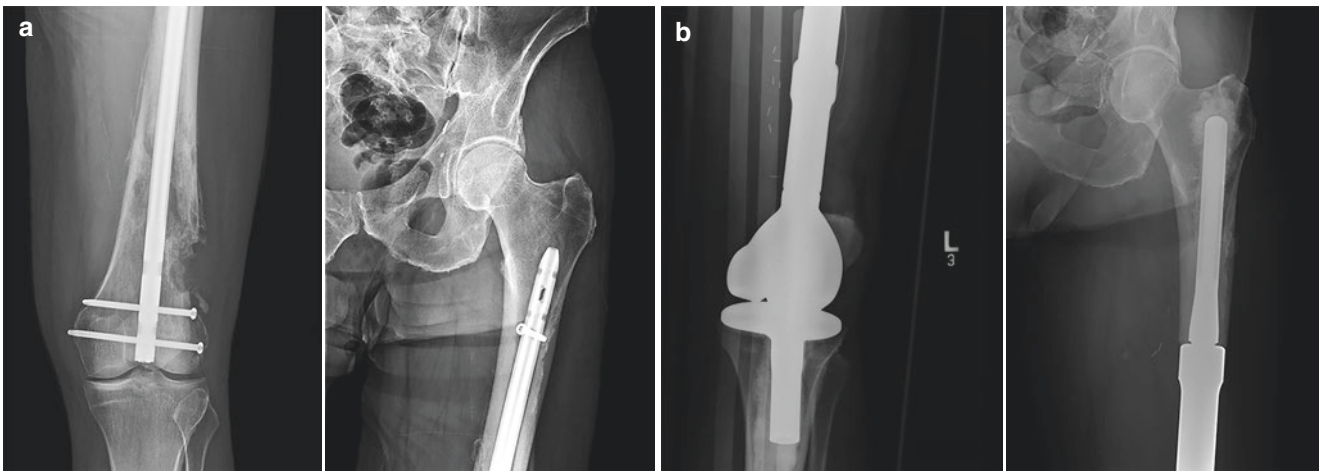

Fig. 33.3 A 61-year-old male with metastatic renal cell carcinoma to the left femur, 3 months status post intramedullary nailing at an outside facility, with progressive disease, difficulty ambulating, and persistent pain (**a**). The nail was removed and converted to a distal femur megaprosthesis (**b**), resulting in significant pain relief and improvement in function, as he was able to weight-bear immediately

neck and head, hip arthroplasty may be more secure than nails (see Figs. 33.1 and 33.2). These operations can also be done now through relatively small (10–15 cm) incisions. In the uncommon scenario where extensive bone destruction is present, larger segmental endoprostheses may be required, as nails may be structurally inadequate and fail to relieve symptoms (see Fig. 33.3).

Impending Pathologic Fractures

Impending fractures represent a form of orthopedic emergency, and, when diagnosed properly, are a best-case scenario. Prophylactic surgery prior to fracture results in less stress to the patient and a shorter hospital stay [7]. Additional benefits include improved pain control, diminished opioid use, better quality of life, simpler surgery, decreased operating time, and less blood loss [1]. For these reasons, emergency providers must be able to recognize the signs and symptoms of impending fractures.

Pain is the most common sign indicating an impending pathologic fracture. The degree of pain often correlates with degree of structural compromise of the bone. Patients may at first attribute pain to a presumed injury, but notice later that pain does not improve with time. Pain can be exacerbated by weight-bearing but is classically present at rest and at night [8]. In pelvic and femoral lesions, back and lower extremity pain is often coupled with mechanical instability [4].

The most common way to gauge the risk of impending fracture is Mirels' score, which incorporates four categories: pain, location, size, and radiographic appearance (see Fig. 33.1). Each category is given 1–3 points, depending upon the severity: pain (mild, moderate, functional), location (upper extremity, lower extremity, peritrochanteric in the proximal femur), size relative to bone diameter (<1/3, 1/3–2/3, >2/3), and radiographic appearance (osteoblastic, mixed, lytic). The total score ranges from 4 to 12. With a Mirels' score of ≥9, the risk of pathologic fracture is >33% and prophylactic surgery is recommended. A Mirels' score of ≤7 typically is treated nonsurgically with radiation. A Mirels' score of 8 is left up to surgeon discretion [9].

Mirels' score is widely employed, in part because it uses simple radiographs. However, reliance upon two-dimensional representation also limits its accuracy. In certain instances, CT scans can be helpful, since they provide three-dimensional detail regarding bone integrity and calcium density. While researchers have developed experimental methods of determining bone strength from CT scans that are more sensitive and specific in predicting pathologic fracture risk, these instruments are not yet available for widespread use [10].

In 22–30% of cases, patients with impending fractures do not have a known primary tumor at the time of presentation [2]. For adults over 40 years old, the differential diagnosis of a lytic lesion in bone includes metastatic disease, multiple myeloma, lymphoma, primary bone malignancy (sarcomas), destructive benign bone tumors (such as giant cell tumor of bone), and nonneoplastic conditions [8]. That being said, in this older age group, the most common malignant tumor of bone is metastatic disease, with the skeleton representing the third most frequent site of metastasis for carcinoma [2].

Open Fractures

While open injuries in cancer patients are mostly due to low-energy mechanisms, they should not be dismissed lightly, and it is important to follow Advanced Trauma Life Support (ATLS) protocols. Of those with open fracture, 30% have more than one injury [11]. One should check airway, breathing, and circulation, followed by a thorough head to toe exam after removing constricting clothing. The deadly triad of acidosis, hypothermia, and coagulopathy is common in these patients, and it is imperative to correct these abnormalities quickly. Open injuries should be scrutinized for signs of contamination and exposed bone. If a limb is grossly deformed, it should be gently reduced prior to splinting. In the absence of an open injury, but with significant skin tenting, causing vascular compromise to the skin, a reduction maneuver is also worth performing [11]. Patients should be examined for signs of vascular injury, which may include decreased/absent pulses, severe hemorrhage, expanding and pulsatile hematoma, bruit or thrill, numbness or neurologic deficit, decreased skin temperature, absent venous filling, absent pulse oximeter reading, or no capillary blanching [11]. If there is concern for vascular injury, a CT angiogram should be performed and a vascular surgery consultation obtained. All open wounds should be copiously irrigated prior to splinting, unless the patient is immediately being taken to the operating room. Due to environmental contamination, it is not recommended to obtain routine cultures from open wounds [11].

Early antibiotics are critical. Studies show that the most important factor in reducing infection rate for open fractures is early administration of intravenous antibiotics, ideally within 3 h of injury [12]. Open fractures are categorized by the Gustilo-Anderson classification: Type I (no gross contamination, laceration <1 cm, no significant muscle damage), Type II (+/− gross contamination, laceration 1-10 cm, no significant soft tissue crushing), and Type III (high energy, may have gross contamination, laceration >10 cm, extensive soft tissue injury). Type III is subdivided into types A (adequate soft tissue coverage), B (inadequate soft tissue coverage of bone), and C (vascular injury that requires repair). In general, Type I and II injuries are treated with a first-generation cephalosporin; for Type III injuries, add an aminoglycoside, and for farm injuries, add penicillin G. [13, 14]. All patients with open fractures must be asked about tetanus immunization history. Those who have had a booster in the past 5 years require no treatment. Those who have not had a booster in more than 5 years require tetanus toxoid plus human tetanus immunoglobulin (HTIG) if the wound is tetanus prone. Those who have not had a booster in more than 10 years or are immunocompromised require tetanus toxoid and HTIG [15].

Compartment Syndrome

Compartment syndrome is a problem that emergency providers must know how to identify, as it often demands immediate surgery. However, in the oncologic patient, compartment syndrome is usually not due to high-energy trauma but rather hematologic problems, and patients may not be good surgical candidates. The management thus has some unique features.

Compartment syndrome is a clinical diagnosis based on history and physical exam [16]. Fracture of the tibial diaphysis is the most common etiology, accounting for 36% of cases of acute compartment syndrome, with all four compartments frequently involved, but anterior compartment being most common [17]. Additional causes include blunt soft tissue injuries, burns, casts, venous thromboembolism, electromyelogram, extravasation of contrast, hematologic diseases, infection, hematomas, osteotomies, prolonged immobilization, and vascular procedures [18]. Pertinent laboratory values include creatine kinase, creatinine, BUN, potassium, urinalysis, and renal myoglobin. Rhabdomyolysis, which is frequent, causes renal insufficiency and hyperkalemia [18].

Classic findings include the 5Ps: pain, pulselessness, paralysis, paresthesia, and pallor. It should be stressed that excessive reliance upon the signs could lead to misdiagnosis since they may not be evident until late. Pain is usually the first symptom seen, typically due to ischemia and is often out of proportion to what is expected [19]. More specifically, pain occurs with passive stretch of the affected compartment (e.g., anterior compartment of tibia when ankle is passively plantar flexed). Marked firmness of the muscles, which is not one of the "Ps," is a reliable finding that is consistently present, but appreciation of muscle firmness requires some experience and can be difficult in obese or edematous limbs. Paralysis and pulselessness are usually very late findings after prolonged ischemia. Ironically, pulses may occasionally be bounding since the blood flow bypasses the capillaries in muscle, and this may lead the unwary clinician astray.

Although the diagnosis is usually evident from clinical examination, the findings are sometimes equivocal, especially for obtunded or mentally impaired patients. In these situations, an invasive diagnostic procedure can be performed to measure compartment pressures. A special manometer (i.e., Stryker Needle) is most commonly used. In the lower leg, all four compartments should be measured, ideally within 5 cm of the fracture site to improve diagnostic accuracy [20].

It is critical not to delay diagnosis or treatment. Duration of muscle ischemia predicts degree of muscle necrosis, and the damage to muscles becomes irreversible after 6 h of complete ischemia. On rare occasions, inflammatory response

that ensues can become systemic and ultimately lead to multiple organ failure [19]. Once diagnosis is established, the patient is taken to the operating room emergently for fasciotomy. The fasciotomy wounds are typically left open until the edema and swelling subside.

While compartment syndrome usually occurs after trauma in the general population, cancer patients more likely have a different etiology. Many have thrombocytopenia or coagulopathy secondary to either the disease or its treatment. When the platelet count is less than 10,000 per microliter, patients are at risk for spontaneous bleeding [21], which could cause acute compartment swelling.

Oncologic patients may not be appropriate for fasciotomies. Neutropenia, defined as absolute neutrophil count (ANC) of $<1.5 \times 10^9$/L, is one relative contra-indication to surgery and predisposes patients to wound infections [22, 23]. However, some clinical judgment must be exercised, and fasciotomies may be performed with mild degrees of neutropenia. A more problematic issue is a delayed diagnosis of compartment syndrome. For patients without clear trauma and fracture, this may not be recognized until days after onset, particularly when patients are heavily sedated in the ICU. If compartment syndrome is diagnosed late, after myonecrosis has already occurred, it may be a grave mistake to perform fasciotomies and to leave wounds open, as the dead tissue becomes prone to severe, deep infections. In this situation, surgeons may opt to delay intervention and address muscle contractures at a later date.

Infection

Orthopedic infections represent a major category of oncologic emergencies because many patients are immunocompromised. Not only does this make patients more susceptible to contracting infections, but also, the severity of infections can be much greater. Infections can involve soft tissue, bones, joints, or all three. In some cases, infection is insidious and indolent, but in others, it can be sudden and rapid. A prevailing theme in infection is that acute phase reactants can be a clue not only to presence of infection, but also to timing. In general, ESR has a high specificity for infection and malignancy, rises within 24–48 h of onset, and gradually resolves. CRP begins rising 12–24 h after onset and peaks in 2–3 days. Procalcitonin begins rising within 3–4 h and peaks within 6–24 h [24].

Cellulitis

Cellulitis is a diffuse, permeative infection of soft tissues that does not produce a loculated fluid collection or drainage. It presents as erythema, warmth, pain, swelling, and sometimes fever. Cellulitis is common in the oncologic population for several reasons, including immunosuppression and frequency of minor procedures, such as venipuncture. The differential diagnosis includes septic arthritis, necrotizing fasciitis, lymphangitis, insect bite, foreign body reaction, abscess, osteomyelitis, inflammatory conditions, muscle hemorrhage/hematoma, Sweets syndrome, and venous thromboembolism [25–27]. Noninfectious inflammatory conditions can be especially difficult to distinguish from cellulitis. These include gout, pseudogout, tenosynovitis, degenerative joint diseases, and rheumatologic conditions [25], all of which may be exacerbated acutely by chemotherapy.

Cellulitis is often a diagnosis of exclusion. Examination is useful for determining the likelihood of joint involvement and the presence of fluctuance. X-rays may help to rule out osteomyelitis [27], while ultrasound, MRI, and/or CT may be necessary to rule out loculated fluid collections and involvement of bone or joint. MRI characteristically shows diffuse edematous changes, bright on T2-weighted images, in cellulitis. Patients should be treated with empiric antibiotics since blood cultures are positive in <5% of patients [27]. The offending organism is most often streptococci or *Staphylococcus aureus,* and initial antibiotics should target Gram-positive bacteria [27]. Drawing a line around the region of erythema with indelible ink is helpful to track response to therapy. Depending on the degree of neutropenia, hospital admission for broad-spectrum intravenous antibiotics may be indicated.

Necrotizing Fasciitis

Necrotizing fasciitis is an acute, life-threatening infection that even among healthy individuals has a high mortality rate. It is imperative that this disease process be recognized early to maximize chances of survival. It is characterized by rapidly spreading inflammation followed by necrosis of fascial planes and surrounding soft tissue [28]. As many as 60% of patients have underlying diabetes [28]. Other risk factors include alcoholism, end stage renal disease, cardiopulmonary disease, peripheral vascular disease, advanced age, cancer/chemotherapy, immunosuppression, malnutrition, trauma, surgery, IV drug abuse, and smoking [28, 29]. Comorbid conditions that correlate with mortality include cancer, renal disease, and congestive heart failure [30]. Metastatic carcinoma has also been reported to cause a soft tissue abscess that ultimately led to development of necrotizing fasciitis [31].

Recognizing early signs and symptoms of necrotizing fasciitis is crucial but can be difficult, as pain frequently precedes overt findings [28]. Systemic symptoms include fever, chills, hypotension, and tachycardia. While patients may not have frank altered mental status, family mem-

bers often report that the patient is not behaving normally. Common skin findings, in addition to erythema and induration, are blisters and bullae that at first drain serosanguinous fluid and later become hemorrhagic. If there is associated soft tissue gas, crepitus will be present. A characteristic frequent finding of this disease is "dishwater pus," which describes the thin, watery, foul-smelling fluid produced consequent to necrosis of superficial fascia and fat [32]. The most common site of infection is the lower extremity, followed by the upper extremity and trunk [33].

Laboratory tests include CBC, comprehensive metabolic panel (CMP), ESR, and CRP. A useful diagnostic tool is the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) Score, which has a reported PPV of 92% and NPV of 96% [34]. The LRINEC score considers CRP (≥150 mg/L – 4 points); white blood cell (WBC) count (<15/mm^3 – 0 points, 15–25/mm^3 – 1 point, >25/mm^3 – 2 points); hemoglobin (>13 g/dL – 0 points, 11–13.5 g/dL – 1 point, <11 g/dL – 2 points); sodium (<135 mmol/L – 1 point); creatinine (>141/μmol/L – 2 points); and glucose (>10 mmol/L – 1 point). A total score of ≥6 is considered suspicious for the disease. While this may be true for the general population, the instrument must be used with caution and judiciously applied in the cancer population, which is replete with co-morbidities including chronic anemia, neutropenia, and renal insufficiency.

Plain films and CT scan classically show signs of gas in the soft tissue; however, gas tracking along fascial planes is only seen in 55% of CT scans. CT, however, will show asymmetric fascial thickening and fat stranding in 80% of cases [35]. A helpful bedside maneuver is the "finger test," whereby a 2-cm incision is made down to deep fascia and a gloved finger inserted to the base. A positive test is defined by dishwater pus, absence of skin bleeding, and lack of tissue resistance to blunt dissection [28]. The gold standard for diagnosis, however, remains fascial biopsy in the operating room.

Emergent surgery is required for any meaningful chance of survival. Prior to surgery, broad-spectrum antibiotics may be initiated to include coverage of streptococci, anaerobes, Gram-negative organisms, and Gram-positive bacilli [29]. More than 80% of cases are Type 1, defined as polymicrobial, whereas the remainder are Type 2 (Group A beta-hemolytic *Streptococcus* sp.) and Type 3 (marine *Vibrio* sp.) [28].

Other Soft Tissue Infections (Abscess, Bursitis, Tenosynovitis)

Unlike cellulitis, a deep tissue abscess is characterized by the presence of a purulent fluid-filled cavity, which can be documented by ultrasound, MRI, or CT scan. Drainage of the fluid, whether by aspiration, percutaneous drain placement, or surgery, is an essential aspect of treatment, since these infections typically do not resolve with antibiotics alone. It is important that fluid samples be obtained prior to initiation of antibiotics so that the organism can be isolated and tested for antibiotic susceptibility.

Synovial-lined spaces around tendons and bursa can potentially become infected and produce abscesses that need drainage or surgical debridement. Certain areas are especially prone to producing infected bursitis, including the olecranon and prepatellar bursas [36]. Although uncommon, flexor tenosynovitis in the hand is a true emergency that needs immediate attention, since this can result in rapid scarring and loss of function of the digit. The diagnosis is often made clinically based on examination and Kanavel's cardinal signs – flexion of the finger, fusiform swelling, tenderness along the flexor sheath, and pain with passive extension. Treatment is prompt surgical drainage, irrigation, and antibiotics [37].

Septic Arthritis

Septic arthritis can be defined as joint infection caused by pathogenic inoculation of the joint either directly or by hematogenous spread [38]. Risk factors for septic arthritis include presence of a prosthesis, intravenous drug use, alcoholism, diabetes, prior corticosteroid injection, and cutaneous ulcers. Immunosuppression resulting from chemotherapy or organ transplant can make patients particularly prone to septic arthritis [1].

A common proverb that underscores the urgency of septic arthritis is, "Time is cartilage." With time, bacterial toxins promote degradation of articular cartilage, mediated by proteolytic enzymes [1]. It is therefore imperative that it be diagnosed and treated in a timely manner, as irreversible joint damage and septicemia can even be seen in patients managed appropriately [38]. On physical exam, patients often are febrile with warmth and erythema about the joint with associated guarding. If the lower extremity is involved, they may have an antalgic gait. Patients tend to assume a position that minimizes pressure within the joint, which in the hip is a flexed, abducted, and externally rotated position, and in the knee or elbow is a slightly flexed position. It should be noted that in immunocompromised patients, fever and guarding may be diminished or absent [1].

Appropriate laboratory workup is critical. Initial labs should include CBC, CMP, ESR, and CRP. The gold standard for diagnosis of a septic joint is aspiration. This should be done after radiographs to evaluate for fracture or other pathologic processes. While the classic teaching is that synovial fluid with white cell count of >50,000 /mm^3 is synonymous with septic arthritis, this is an oversimplification. Coutlakis, et al. showed that a count of <50,000 was 5% sensitive, 50,000–100,000 was 47% sensitive, and >100,000 was 77% sensitive. In this study, crystalline arthropathies and rheumatoid arthritis accounted for 81% of patients with

white cell count in the 15,000–50,000 range, and 5/7 cases of septic arthritis with white cell count <20,000 grew atypical organisms [39]. Furthermore, patients with a polymorphonuclear (PMN) cell count of ≥90% are far more likely to have a septic joint than those <90% [40].

Antibiotics should be held until after joint aspiration in all medically stable patients. Following aspiration, initial antibiotics target common pathogens, with *S. aureus* and *Streptococcus* species accounting for more than 90% of cases [38]. That being said, atypical species such as Gram-negative organisms, *Mycobacterium,* and fungi can be seen in immunocompromised patients [1]. Antibiotics can be adjusted for susceptibilities and are typically continued for approximately 4–6 weeks [1]. Standard surgical care includes open or arthroscopic irrigation and debridement. In oncologic patients who are neutropenic or immunocompromised, alternatives include serial joint aspiration and bedside lavage.

Periprosthetic joint infections (PJIs) represent a different entity than septic arthritis of the native joint. However, timing remains critical. In acute infections, <4 weeks postoperatively, it may be possible to perform a surgical irrigation and debridement with modular component exchange (i.e., replacing easily removable parts such as plastic liners but leaving fixed hardware in place). In chronic infections, surgery entails removal of all components, insertion of an antibiotic spacer, an extended course of IV antibiotics, and a revision prosthesis.

On physical exam, PJIs can have similar findings to native septic joints. Additionally, there may be wound-related complications, such as dehiscence or drainage. However, PJIs sometimes show remarkably few signs, especially for chronic infections. While acute infections commonly show signs of rapid onset swelling, warmth and tenderness, chronic infections may be more subtle, with gradual, insidious pain, and no erythema or fever [41]. Radiographs are usually normal, but sometimes will show loosening of a previously well-fixed implant (especially if <5 years postoperative), subperiosteal elevation, or transcortical sinus tract [42]. Common risk factors include recent bacteremia, multiple prior surgeries, prior PJI, smoking, diabetes mellitus, cancer, inflammatory arthropathy, and immunosuppressive drugs [41, 42].

Laboratory cutoff values for PJI differ with respect to time. In patients who are <6 weeks postoperative, cutoffs are as follows: ESR has none, CRP >100 mg/L, synovial WBC count >10,000 cells/μL, PMN >90%. For patients >6 weeks postoperative, these values differ: ESR >30 mm/h, CRP >10 mg/L, synovial WBC count >3000 cells/μL, PMN >80% [42]. Diagnostic criteria are broken into major and minor. Major criteria include two positive cultures of the same organism or a sinus tract that communicates with the joint. Minor criteria include elevated CRP or D-dimer, elevated ESR, elevated synovial WBC, positive synovial alpha-defensin, elevated synovial PMN, and elevated synovial CRP. To confidently diagnose PJI, either 1 major or 6 minor criteria must be present [43].

Sinus tracts and open wounds should not be cultured in the ED, as they are more likely to grow colonized, nonpathogenic bacteria that confuse treatment goals. Following aspiration, empiric antibiotics should include MRSA coverage. In the uncommon scenario where the patient is unstable and septic, broad-spectrum antibiotics should be initiated prior to joint aspiration and blood cultures should be drawn [41].

Osteomyelitis

Osteomyelitis (OM) is defined as inflammation of the bone caused by an infecting organism [44]. Acute hematogenous OM is the most prevalent form. Patients typically present with fever and malaise. While WBC may be normal, inflammatory markers are usually elevated. Blood cultures should always be drawn, as the causative organism can be identified in approximately 50% of patients [44]. *S. aureus* accounts for the highest percentage of acute cases [45]. Radiographs often are unremarkable but can show soft tissue swelling after 1–3 days and periosteal elevation or bony destruction after 10–12 days [44]. MRI can be useful for diagnosis of OM and identification of associated abscesses. Empiric antibiotic coverage should include Gram-positive bacteria, Gram-negative bacteria, and potentially resistant organisms, depending on the patient's history [45]. The triad of fever, elevated CRP, and elevated absolute neutrophil count (ANC) correctly predicts methicillin-resistant *S. aureus* (MRSA) over methicillin-sensitive *S. aureus* (MSSA) in 87% of cases [46]. In leukemic patients, atypical bacteria or fungi have been isolated [47, 48]. Definitive treatment is with antibiotics. Some patients, particularly those with abscesses, may also require surgery.

Chronic OM is more indolent. Patients may have intermittent exacerbations over a course of years. Like acute cases, inflammatory markers are more sensitive than WBC count, which is elevated in only 35% of cases [44]. Those with chronic OM can have open wounds or sinus tracts communicating with deeper infection. It is not recommended to culture such wounds, as the isolates do not typically correlate with organisms that grow from an intraoperative bone biopsy [44]. In addition to X-rays, CT scan may help identify a sequestrum (infected, dead bone surrounded by new bone growth). Management requires a multidisciplinary approach, as the infection is typically difficult to eradicate, and associated comorbidities may preclude an aggressive debridement. Chronic OM can undergo malignant degeneration, most often as a squamous cell carcinoma (i.e., Marjolin ulcer) [49]. The latent period averages 27–30 years, with acute cases being very rare. Marjolin ulcers are characterized by drainage, foul odor, and a large, exophytic mass. Imaging should include X-rays, MRI, and a CT chest to evaluate for metastases. Diagnosis is confirmed by biopsy, and definitive treatment is wide excision or amputation [49].

Arthroplasty

Joint arthroplasty as a reconstructive modality has grown steadily with time. In years past, malignant primary bone tumors were routinely treated with amputation, but since the advent of effective chemotherapy, most sarcomas are now amenable to limb salvage [50]. The success of endoprosthetic reconstruction for primary bone sarcomas has led to its expanded use in benign and metastatic bone disease. While endoprostheses have consistently shown acceptable outcome in oncologic patients, the reported complication rates are 5–10 times higher than for routine, nononcologic joint arthroplasty [50].

Periprosthetic Fractures

Periprosthetic fractures are common but not always obvious since fractures may be minimally displaced. They are important to recognize early. The most significant negative prognostic indicator relating to early outcomes in periprosthetic hip fractures is delay to surgery [51]. The risk of periprosthetic fracture increases with chronic infection, poor bone quality, stress shielding, osteolysis, and oncologic resections [50, 52]. For oncologic patients, progression or relapse of disease in the bone surrounding the stem must be considered.

Common findings are pain, gross deformity, and swelling. A detailed exam of the entire extremity is important to rule out concomitant bony or neurovascular injury. Full-length orthogonal radiographs should always be obtained. Despite metallic streak artifacts, CT scans can be helpful when radiographs are equivocal.

The most common classification of periprosthetic hip fractures is the Vancouver classification: A (trochanteric), B (along the femoral stem, with 3 subtypes), and C (diaphyseal fracture distal to stem) (Fig. 33.4) [53]. Periprosthetic distal femur fractures are most commonly classified according to the Lewis and Rorabeck classification: I (nondisplaced fracture, intact prosthesis), II (displaced fracture, intact prosthesis), and III (loose or failing prosthesis) [54]. While these classification systems are designed for primary joints, the concepts of fracture location relative to the implant can be used for oncologic reconstructions as well [55].

Prosthetic Dislocation

The most common area for prosthetic dislocation is in the hip. In fact, dislocation accounts for >20% of revision hip surgery [56]. Dislocations can be attributed to one of three factors. Patient factors include older age, neurologic disease, cognitive impairment, spinal disease, and weak abductors [56, 57]. Implant factors include small head size and decreased offset. Surgeon factors include surgical approach (posterior approach most likely to dislocate) and component positioning.

Important details of the history include surgical approach, mechanism of dislocation, number of previous dislocations, and patient compliance with postoperative restrictions [58]. Location of surgical scars can serve as clues as to which approach was used. Posterior dislocations frequently occur when patients stand from a seated position. They result in an adducted, flexed, internally rotated, and shortened limb. Anterior dislocations result in abduction and external rota-

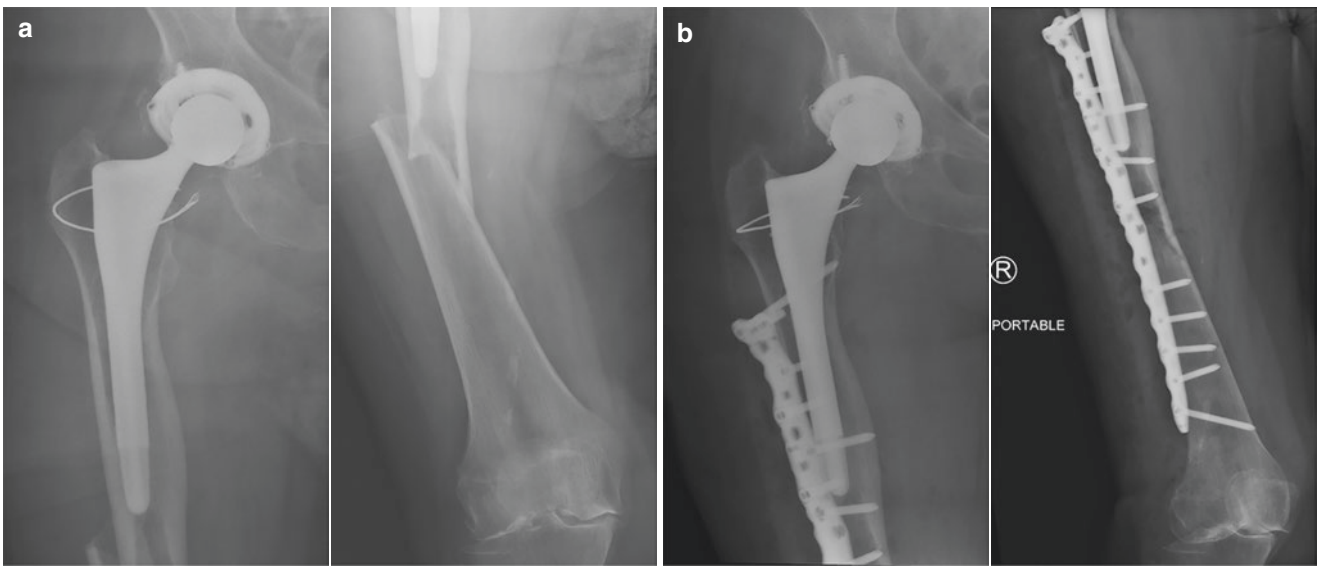

Fig. 33.4 (**a, b**) Preoperative and postoperative radiographs, respectively, of an 86-year-old female with multiple myeloma who sustained a pathologic periprosthetic femur fracture of the Vancouver C variety, for which she underwent open reduction with internal fixation

tion with either extension (pubic type) or flexion (obturator type) [58]. Evaluation of neurovascular status is important, as up to 10% of posterior dislocations can result in sciatic nerve palsy. Since infection can predispose to dislocation, laboratory workup should include a CBC, ESR, and CRP.

If an experienced emergency provider has adequate resources, a closed reduction may be attempted. While there are many techniques, the authors prefer the Waddell technique for posterior dislocations, whereby an assistant stabilizes the pelvis, and the provider straddles the patient's leg with the patient's hip and knee flexed, and exerts traction, with a combination of adduction and internal/external rotation [59]. Conscious sedation in the ED to reduce dislocated hips has been proven as a safe, effective method [60]. However, modular prostheses of the proximal femur in tumor patients have shown a re-dislocation rate following closed reduction of 58% compared to 11% of those that underwent an open reduction [61].

Complex arthroplasty for tumor patients is often performed with one of two methods to confer better stability: constrained liners or dual mobility systems. Constrained liners contain a metal ring to help stabilize the articulation between the head and the cup (Fig. 33.5). Dual mobility cups consist of a small metal/ceramic femoral head within a larger polyethylene head, which articulates with the acetabular component [58]. These are prone to what is called an intraprosthetic dislocation, whereby the polyethylene dissociates from the metal/ceramic head. While there are reports of successful closed reduction of dislocated constrained liners, it is typically recommended that the orthopedic surgeon perform open reduction of dislocations involving constrained liners or dual mobility cups [58, 62].

Pelvis

Patients with tumors of the bony pelvis and/or surrounding soft tissue represent a unique entity. The pelvis is the common pathway for all neurovascular structures supplying the lower extremities, genitalia, and perineum, thereby making surgery in this area complex and prone to complications. Hemipelvectomies performed for pelvic sarcomas are categorized by the area that is excised, but more broadly, are grouped as either internal (limb is preserved) or external (limb is amputated) [63]. One study showed a complication rate of 53% for external hemipelvectomies, most commonly due to wound infection and flap necrosis (Fig. 33.6) [64]. Other complications include ureteral injury, bladder fistula, strangulated incisional hernia, colocutaneous fistula, small bowel fistula, wound dehiscence, myocardial infarction, recurrent pulmonary emboli, and upper gastrointestinal bleed. In another study looking at both internal and external hemipelvectomies, wound infection occurred in 61.7% of cases [65]. Since these surgeries involve manipulation and/or reconstruction of large vessels, a possible dysvascular limb postoperatively should not be overlooked.

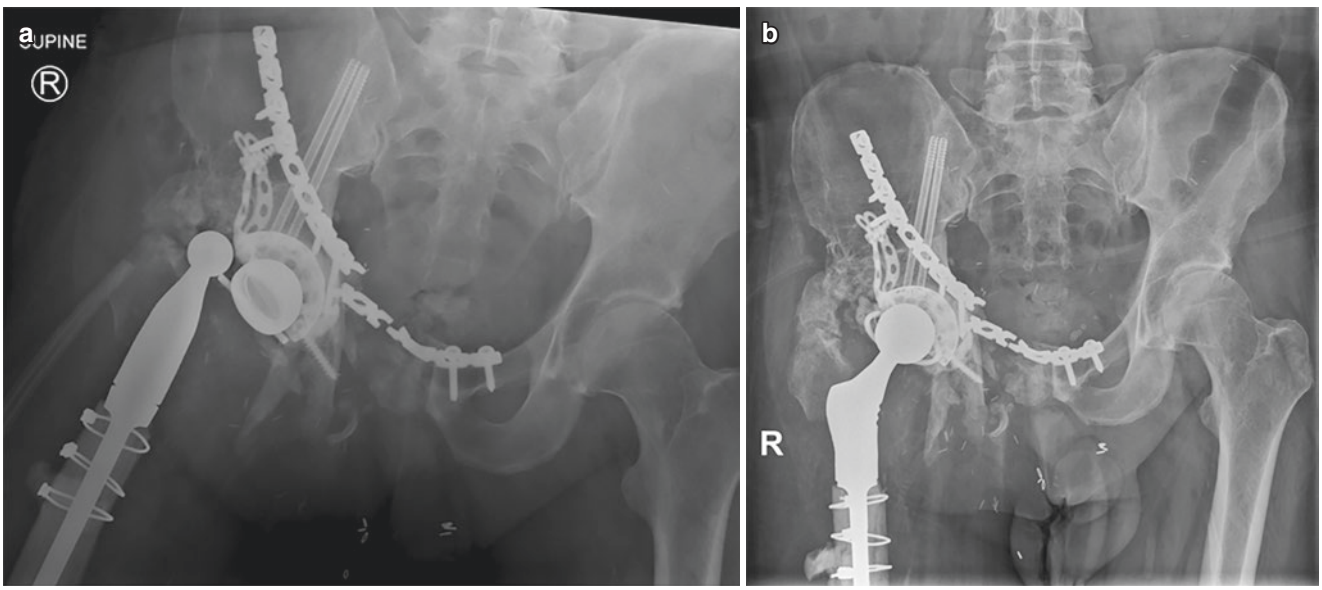

Fig. 33.5 A 53-year-old male with history of right pelvic chondrosarcoma 11 years status post internal hemipelvectomy and pelvic reconstruction with allograft prosthetic reconstruction with constrained liner total hip arthroplasty. Following a fall, the patient experienced a dislocation (**a**) that was revised to a new constrained liner in the operating room (**b**)

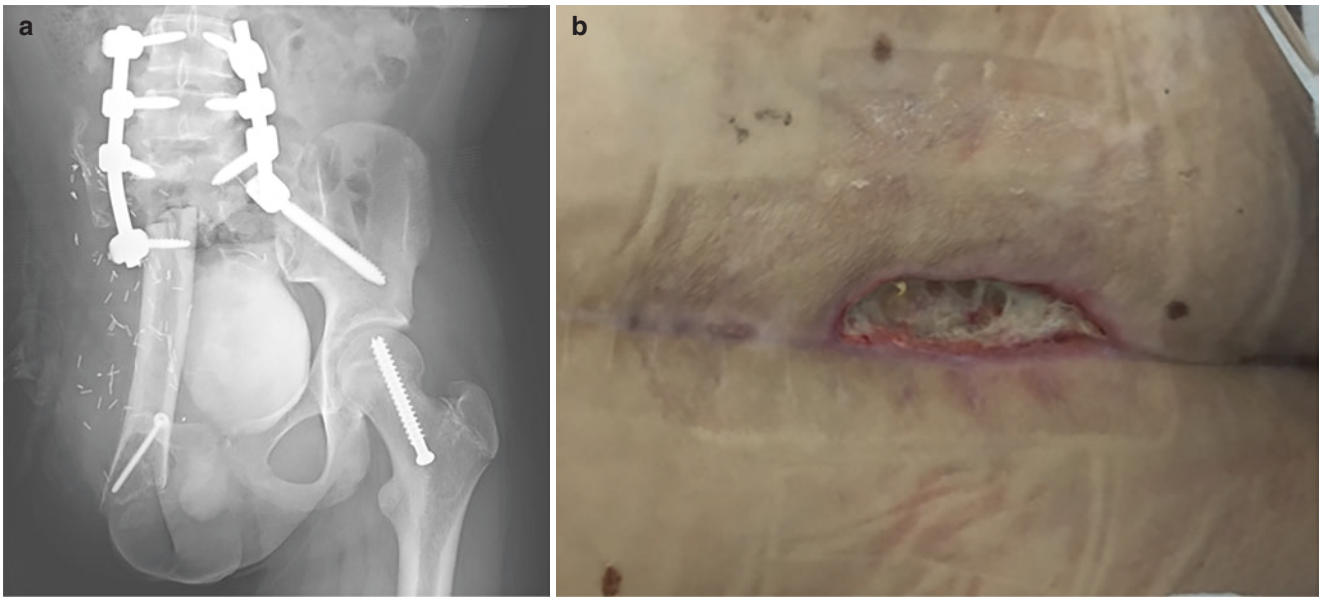

Fig. 33.6 A 15-year-old male who developed a radiation-induced pelvic osteosarcoma following treatment for neuroblastoma. He underwent a right external hemipelvectomy with reconstruction of the pelvic ring using the tibia of his amputated limb (**a**). Postoperatively, he developed a wound dehiscence and infection that required several months of antibiotics and wound care (**b**)

Dermatology

34

Joanna Harp and Alina Markova

Case Study

A 70-year-old man with metastatic melanoma started on ipilimumab with nivolumab 11 days ago presents to the emergency department with a 6-day history of a painful rash and mucositis. He reports initial sores in the oral and ocular mucosa and subsequent development of pain with urination. He then developed a red painful rash that continued to spread over the next few days. He denies any other new medications and known allergies include sulfa medications.

On exam he is well-appearing with stable vital signs with widespread erythematous macules and papules on 50% of his body some with central duskiness that resemble targetoid lesions on <10% of his body. He has hemorrhagic crusts and ulceration of the lips and oropharynx, as well as conjunctival injection and periurethral erythema. With lateral pressure on the dusky areas of the rash, he develops shearing of skin.

Metabolic panel reveals normal electrolytes, serum bicarbonate of 23 mEq/L, glucose of 113 mg/dL, BUN of 30 mg/dL (H), creatinine of 1.1 mg/dL, albumin of 3.4 g/dL (L), AST of 172 U/L (H), and ALT of 199 U/L (H). Mycoplasma respiratory PCR and serum IgM and IgG are ordered. A punch biopsy is performed, revealing a lichenoid and subepidermal vesicular dermatitis with full-thickness epidermal necrosis.

The patient is diagnosed with Stevens-Johnson syndrome-like rash, CTCAE grade 3, due to ipilimumab/nivolumab. He is admitted to the intensive care unit and started on cyclosporine 2.5 mg/kg twice daily for 10 days and then tapered by 1 mg/kg/week, as well as topical cyclosporine drops to both eyes, dexamethasone swish and spit for his mouth, topical steroids to his glans, and Foley catheter. Denuded areas are covered with non-adhesive silver nylon dressings.

During his hospitalization, he does not have further fevers, but develops additional areas of denudation (<10% BSA). After day 5 of cyclosporine, he no longer develops new areas of rash, by day 15 his rash begins to hyperpigment, by day 22 his mucositis resolves, transaminases downtrend, and he is discharged.

Introduction

Patients with cancer can present with a wide range of common, serious, and at times life-threatening dermatologic conditions related to their underlying malignancy or to its treatment. Additionally, they may be at increased risk for infections, including cutaneous infections, secondary to immunosuppression. Recognition of the morphology of skin lesions (i.e., color, texture, shape, distribution, etc.) is an important step in the evaluation of these patients as it can greatly aid in formulating a differential diagnosis for various cutaneous manifestations. It is particularly crucial for emergency physicians caring for oncologic patients to be aware of cutaneous manifestations that herald severe and life-threatening conditions to allow for quick recognition and initiation of the appropriate treatment. This chapter discusses the clinical presentation, pathophysiology, diagnosis, and management of these severe conditions organized by morphologic presentation (Table 34.1).

Maculopapular Eruptions

The differential diagnosis for maculopapular eruptions includes drug eruptions, viral exanthems, and, in the appropriate patient population, graft-versus-host disease.

Purpuric (non-blanching) eruptions

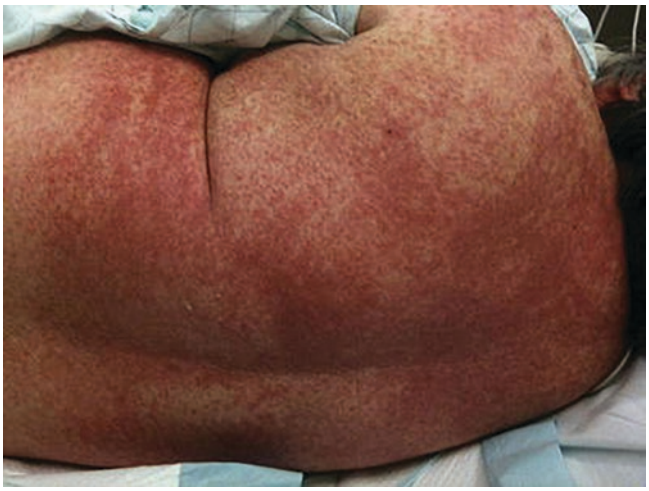

Fig. 34.1 Maculopapular eruption: diffuse erythematous macules and papules in a patient with DRESS secondary to allopurinol

Drug Eruptions

A maculopapular (exanthematous, morbilliform) rash (MPR) is the most common form of adverse drug reaction in hospitalized patients, occurring in 57% of patients with a drug eruption [1]. The eruption consists of erythematous macules and papules scattered diffusely over the body (often sparing the face) that may coalesce.

DRESS (Drug Reaction with Eosinophilia and Systemic Symptoms)/DIHS (Drug-Induced Hypersensitivity Syndromes)

Clinical Manifestations

When a maculopapular drug rash presents with fever, lymphadenopathy, or facial edema, drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) should be considered, and a work-up for systemic involvement should be performed. The cutaneous eruption is typically a MPR and rarely presents with purpura, vesicles, or pustules (Fig. 34.1). The liver is the most common site of visceral involvement, but other systemic findings include interstitial nephritis, pneumonitis, myocarditis, arthritis, cytopenias, atypical lymphocytosis, thyroiditis, and cerebritis. The clinical manifestations typically begin 2–6 weeks after initial exposure to the causative medication necessitating a drug history of the past several months when DRESS is suspected.

Pathophysiology/Etiology

DRESS is a delayed type IV hypersensitivity reaction that may involve impaired pharmacokinetics leading to the accumulation of drug metabolites. Genetic predisposition given the association with specific HLA alleles, viral reactivation, and the release of cytokines, including interleukin 5, may play a role [2]. Common etiologies include the anticonvulsants, sulfonamides, allopurinol, dapsone, and antiretroviral medications. A few anticancer drugs have also been associated including chlorambucil and lenalidomide.

Diagnosis

Diagnosis is made based on clinical findings of a MPR plus evidence of internal organ involvement, most commonly eosinophilia and transaminitis. However, any organ system may be involved, and eosinophilia is not required for diagnosis (thus the term drug-induced hypersensitivity syndrome (DIHS) is sometimes used). Biopsy findings are not specific for DRESS and show overlap features with simple drug eruptions.

Treatment

Early discontinuation of the suspected medication is necessary. Systemic corticosteroids (typically prednisone 1–2 mg/kg or equivalent) are the mainstay of treatment, and gradual taper with monitoring for flares is recommended to prevent relapse. The cutaneous and visceral manifestations may persist for weeks (rarely months), and patients should be monitored for late-onset thyroiditis and other autoimmune conditions.

Immune-Related Maculopapular Rash

Clinical Manifestations

Over 20% of patients treated with anti-cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) or anti-programmed death 1 (PD-1)/programmed death ligand 1 (PDL-1) and up to 72% with anti-CTLA-4/anti-PD-1 combination therapy develop immune-related cutaneous adverse events (ircAEs), most commonly pruritus and MPR [3, 4]. These ircAEs may be associated with prolonged progression-free survival and overall survival [4]. Unlike MPR to traditional medications, those to immunotherapy may develop at any time during or months after completion of therapy, with a median onset of 62 days (range 1–1676 days) after initiation of therapy [4]. Cutaneous morphology of immune-related MPR may be indistinguishable from that due to traditional medications or have overlap with lichenoid, psoriasiform, or eczematous rashes. Maculopapular rash

severity is classified via the National Cancer Institute: Common Terminology Criteria for Adverse Events (CTCAE) with Grade 1, macules/papules covering <10% body surface area (BSA); G2, macules/papules covering 10–30% BSA or rash >30% BSA with or without mild symptoms; and G3, macules/papules covering >30% BSA with moderate or severe symptoms [5]. Immune-related MPR with or without systemic involvement have a longer median duration of 37.5 days (range 1–700 days) than simple drug eruptions to traditional agents [6].

Pathophysiology/Etiology

Immune checkpoint inhibitors block CTLA-4, PD-1, and PDL-1 generating durable antitumor responses in several cancers [3]. Side effects of these agents may be attributed to a persistently stimulated immune system and are thus termed "immune-related adverse events" (irAE) [3]. Elevations in eosinophil counts, IL-6, IL-10, and IgE have been associated with grade 3 ircAEs, suggesting a pathogenic or correlative role, as well as potential targets for supportive care intervention.

Diagnosis

Diagnosis is made based on clinical findings of a MPR and history of current or prior immune checkpoint inhibitor (ICI) therapy. Biopsy findings are not specific for immune-related maculopapular rash and show overlap features with traditional drug eruptions.

Treatment

Goal of treatment of immune-related MPR is to minimize systemic immunosuppressive treatments while maintaining patient on current dose of ICI. Management of G1 MPR consists of high-potency topical corticosteroid twice daily [4]. For G2 MPR, systemic corticosteroids (prednisone 0.5–1 mg/kg) may be added [5]. For G3 or intolerable G2 MPR, ICI should be interrupted until MPR severity decreases to G0-1; and dose modified as per protocol; oral corticosteroids (prednisone 0.5–1 mg/kg) or biologics (infliximab, tocilizumab) are administered [3]. Patients should be reassessed every 2 weeks until improvement in grade. If reaction worsens or does not improve, dose reduction or discontinuation per protocol may be necessary. For corticosteroid-resistant MPR, check serum levels of IL-6 and TNF-α to assess for eligibility for targeted therapy (e.g., tocilizumab, infliximab) [4].

Viral Exanthems

Viral exanthems often present with a maculopapular eruption that can mimic drug eruptions. They are commonly seen in the pediatric population and immunocompromised adults who are at higher risk of viral infection and reactivation.

Clinical Manifestations

Although viral exanthems typically present with a MPR, they may also be scarlatiniform (diffuse small papules giving a sandpaper quality to the skin), petechial (non-blanching), or urticarial. Other clinical findings include fever, myalgias, arthralgias, nausea, vomiting, diarrhea, and malaise. SARS-CoV-2 infection can present with a variety of skin manifestations including MPR, macular erythema, urticaria, vesicles, livedo, and purpuric eruptions which tend to appear concurrently or after other viral symptoms [7].

Pathophysiology/Etiology

Causes of viral exanthems include Epstein-Barr virus, cytomegalovirus, enterovirus, adenovirus, human herpesvirus types 6 and 7, parvovirus B19, measles (rubeola), rubella, and early human immunodeficiency virus, among others. It is not known how viruses cause skin rashes, though it is likely related to immune system activation.

Diagnosis

It is not always possible to determine the exact viral cause; however, serologies, viral polymerase chain reaction assays, heterophile antibodies, and the presence of atypical lymphocytosis may be helpful. Skin biopsy may be useful in differentiating drug eruptions from viral exanthems; however, findings can be nonspecific.

Treatment

Viral exanthems are often self-limited with resolution after 1–2 weeks. Treatment includes symptom management and supportive care.

Graft-Versus-Host Disease (GVHD)

Acute graft-versus-host disease (GVHD) commonly appears as a diffuse MPR that classically presents in the early post-hematopoietic cell transplant period or after a reduction in immunosuppression (but can occur at any time after transplant). GVHD is most common after allogeneic hematopoietic stem cell transplant (alloHCT); however, it may be seen following autologous and solid organ transplant.

Clinical Manifestations

The skin is the most commonly affected organ in acute GVHD, presenting with a MPR. Individual lesions may be folliculocentric (centered upon a hair follicle) helping to distinguish from a drug or viral exanthem. A petechial component may be appreciated if the patient is thrombocytopenic. The liver and gastrointestinal systems are often also affected and, if severe, are associated with high morbidity and mortality. Chronic cutaneous GVHD has many clinical manifestations and can mimic lichen planus, lichen sclerosus, morphea,

and scleroderma. Engraftment syndrome presents around the time of neutrophil engraftment (ANC >500) with identical cutaneous manifestations as acute GVHD, as well as fever and evidence of capillary leak syndrome, and is more commonly seen after autologous transplant.

Pathophysiology/Etiology

In acute GVHD, alloHCT conditioning and damage to host tissues lead to the activation of host antigen-presenting cells. Donor T cells then proliferate in response to the activated antigen-presenting cells with subsequent activation of cytotoxic T lymphocytes and natural killer cells leading to tissue damage. Chronic GVHD is less well understood and is thought to involve donor T cells but also may involve B cells [8]. Risk factors associated with the development of GVHD include HLA incompatibility, unrelated donor, older age of recipient, peripheral blood stem cell source, and T-cell replete graft. In addition, the use of myeloablative-conditioning regimens is a specific risk factor for acute GVHD [9].

Diagnosis

The skin histology of acute GVHD shows varying degrees of keratinocyte necrosis, vacuolar changes at the dermal-epidermal junction, and a lymphohistiocytic infiltrate in the upper dermis, but a definitive diagnosis requires clinical correlation. The histology of chronic GVHD typically reflects the clinical pattern of the skin manifestations. Several serum biomarkers are also under active investigation to aid in the diagnosis of GVHD.

Treatment

Topical steroids are used to treat limited cutaneous acute GVHD; however, extensive cutaneous disease and other organ involvements often require systemic corticosteroids. Alternative and adjunct treatments for acute and chronic GVHD include phototherapy, other immunosuppressives including tacrolimus, mycophenolate mofetil, Janus kinase (JAK) inhibitors, Bruton tyrosine kinase inhibitors, and extracorporeal photopheresis among others.

Localized Erythema

Cellulitis

Cellulitis is a superficial, diffuse inflammation of the cutaneous dermis and subcutaneous fat secondary to an infectious process. Underlying immunosuppression and disruption of the skin barrier contribute to the development of cellulitis.

Table 34.2 Differential diagnosis for cellulitis in oncologic patients[a]

Abscess
Pyomyositis

[a]Expanded upon in text

Clinical Manifestations

Cellulitis presents with the acute onset of an erythematous, warm, tender plaque or plaques anywhere on the skin, usually over the lower extremities [10]. Cutaneous purpura may be present in the setting of thrombocytopenia or anticoagulation. Cutaneous edema can be severe leading to vesicle and blister formation. Cellulitis is almost always unilateral when located on an extremity. If findings are bilateral, an alternative diagnosis should be considered (Table 34.2). Patients are often afebrile, and increased white blood cell counts are seen in less than one-half of cases [10].

Pathophysiology

Cellulitis typically begins with organism entry through a disruption in the skin barrier especially in the setting of edema, trauma, ulceration, or a primary skin disorder, such as eczema or tinea pedis. The etiology is usually bacterial (most commonly *Streptococcus* genus followed by *Staphylococcus aureus*); however, cutaneous fungal infections including histoplasmosis and cryptococcosis can mimic bacterial cellulitis, especially in the immunocompromised host.

Diagnosis

Diagnosis is typically clinical. Skin biopsy is usually not helpful as histopathologic findings may be nonspecific, and tissue culture is positive for an organism in only about 20–30% of cases [10, 11]. However if cellulitis is worsening or not responding despite appropriate therapy, skin biopsy with tissue culture should be considered.

Treatment

Antibiotic therapy should be directed against streptococcal and staphylococcal organisms; however, broad-spectrum antibiotics including Gram-negative coverage are often warranted in the immunocompromised host. Adjunctive

Fig. 34.2 Necrotizing fasciitis: rapidly expanding erythema, purpura, and necrosis secondary to a polymicrobial deep soft tissue infection on the right leg

treatments including elevation and compression in the case of an involved extremity and treatment of concomitant skin conditions that disrupt the skin barrier should be initiated.

The differential diagnosis of cellulitis includes early necrotizing fasciitis, a rapidly progressive bacterial infection with necrosis of the deep subcutaneous tissue and fascia. Early infection presents with erythema and edema similar to cellulitis (often with pain out of proportion to exam); however, this is often quickly followed by the development of non-blanching purpura and hemorrhagic bulla that can progress to necrosis and gangrene within hours (Fig. 34.2). The most common etiology is group A *Streptococcus* though infections are often polymicrobial. Diagnosis is often made clinically, but imaging may demonstrate fascial thickening or air within the soft tissues. Treatment is emergent surgical debridement and broad-spectrum antimicrobials.

Toxic Erythema of Chemotherapy

Toxic erythema of chemotherapy (TEC) describes a spectrum of cutaneous eruptions that are thought to occur secondary to the cytotoxic effects of chemotherapy on the skin and sweat glands. Many terms have been used to describe these eruptions, including acral erythema, palmoplantar erythrodysesthesia, hand-foot syndrome, eccrine squamous syringometaplasia, Ara-C ears, and neutrophilic eccrine hidradenitis [12]. Skin findings in TEC include symmetric, erythematous, and purpuric (non-blanching) patches, which can be associated with erosions, bullae, and desquamation (Fig. 34.3) frequently noted in intertriginous areas, genital, overlying joints, and acrally. Patients often describe burning or pruritus.

TEC has been attributed to cytarabine, doxorubicin, 5-fluorouracil, capecitabine, methotrexate, bleomycin, carboplatin, cisplatin, etoposide, gemcitabine, receptor tyrosine kinase inhibitors, cyclophosphamide, and melphalan, among others [12]. Diagnosis is often made clinically. TEC is typically self-limited, and treatment is largely supportive and includes topical steroids, analgesics, and emollients. Rarely systemic steroids are needed in severe cases. Prevention includes dose reduction and lengthening dose intervals.

Fig. 34.3 Toxic erythema of chemotherapy: erythema and blisters secondary to sorafenib

Leukemia Cutis

Leukemia cutis is a skin eruption that results from cutaneous infiltration of malignant cells in the setting of leukemia, most commonly acute myeloid leukemia. Leukemia cutis classically presents with single or multiple raised red-purple (plum-colored) papules or nodules that can arise in any location [13]. Leukemia cutis may be the initial presenting manifestation of leukemia [14]. Skin biopsy should be performed to confirm the diagnosis and rule out clinical mimics including cutaneous infection and Sweet syndrome (acute febrile neutrophilic dermatosis). Management is aimed at treatment of the underlying leukemia. The development of leukemia cutis typically portends a poorer prognosis, with the exception of congenital leukemia with leukemia cutis [14].

Angioedema

Angioedema is the swelling of the deep dermis, subcutaneous, and submucosal tissues, most commonly on the eyelids, lips, and genitalia. It can involve the tongue and pharynx and, in such cases, become life-threatening.

Clinical Manifestations

The affected area is edematous and tender with the surface appearing normal or slightly pink. Angioedema can occur alone or simultaneously with hives. Patients with angioedema or hives must be monitored for signs and symptoms of anaphylaxis with evidence of respiratory compromise, hypotension, and shock.

Pathophysiology/Etiology

The etiology of angioedema is determined by the clinical manifestations and is critical for appropriate treatment. Angioedema that occurs with hives is due to an immediate type I hypersensitivity reaction mediated by IgE and mast cell degranulation. It can be triggered by infection, foods, and drugs or may be idiopathic. Angioedema that occurs without hives may be related to an inherited mutation or acquired in the presence of an underlying malignancy or autoimmune disorder. This pathway is driven by deficient or dysfunctional C1q esterase inhibitor, a critical enzyme in the complement and fibrinolytic cascade, leading to increased levels of bradykinin with resultant vasodilation and edema.

Diagnosis

Diagnosis of angioedema is often clinical; however, in the case of hereditary or acquired angioedema, low complement 4 (C4) level is seen both during and between attacks. C1q level is also low in acquired angioedema, helping to distinguish it from hereditary cases.

Treatment

Angioedema due to a type I hypersensitivity reaction may be treated with aggressive antihistamines and discontinuation of the offending agent if known. If there is concern for anaphylaxis, intramuscular or intravenous epinephrine should be used promptly. Recurring cases may require leukotriene receptor antagonists, immunosuppressants, and biologics [15].

Treatment for acute attacks in hereditary or acquired angioedema includes fresh frozen plasma, C1 inhibitor concentrate, kallikrein inhibitors, and bradykinin receptor antagonists [16].

Erythroderma

Erythroderma describes diffuse erythema of most if not the entire cutaneous surface often with exfoliative shedding of the skin. The differential diagnosis includes drug-induced, primary skin disorders, infectious etiologies, and paraneoplastic causes, among others (Table 34.3).

Table 34.3 Differential diagnosis for erythroderma

Drug-induced
Primary skin disorder
Psoriasis
Atopic dermatitis
Allergic contact dermatitis
Chronic actinic dermatitis
Pemphigus foliaceous
Infection
Toxic shock syndromes[a]
Generalized dermatophytosis
"Norwegian" crusted scabies
Viral exanthem
Neoplastic
Mycosis fungoides/Sézary syndrome[a]
Paraneoplastic phenomenon
Graft-versus-host disease
Others (rare): nutritional deficiencies, Kawasaki disease, cutaneous mastocytosis

[a]Expanded upon in text

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an acute, life-threatening infection due to a toxin-producing strand of *Staphylococcus* or *Streptococcus*. Patients with underlying chronic medical conditions including cancer are at higher risk for TSS.

Clinical Manifestations

In both staphylococcal and streptococcal TSS, patients become acutely ill with high fever, hypotension, and evidence of multiorgan system involvement. Influenza-like symptoms including chills, myalgias, headache, vomiting, and diarrhea are common. Cutaneous findings are relatively nonspecific including subtle, diffuse, blanchable erythema as well as edema and erythema of the palms and soles followed by prominent desquamation within 1–2 weeks. Mucosal findings include conjunctival erythema, anogenital erythema, and a strawberry tongue.

Pathophysiology/Etiology

In TSS, specific strands of *Staphylococcus* and *Streptococcus* produce toxins that act as superantigens leading to a widespread T-cell activation and cytokine release that cause fever, capillary leakage, and hypotension. Staphylococcal TSS is most often associated with focal infections including surgical wound infections, burns, osteomyelitis, sinusitis, septic arthritis, and tampon use in menstruating women [17]. Streptococcal TSS is more often seen in connection with bacteremia, cellulitis, or necrotizing fasciitis [18].

Diagnosis

Both staphylococcal and streptococcal TSS have specific diagnostic criteria required for diagnosis (Tables 34.4 and 34.5).

Table 34.4 Diagnostic criteria for staphylococcal toxic shock syndrome

Fever
Hypotension
Diffuse erythroderma
Desquamation (1–2 weeks after illness onset)
Three or more of the following:
Renal dysfunction
Gastrointestinal: vomiting or diarrhea
Hepatic dysfunction
Hematologic dysfunction
Severe myalgias or elevated creatinine phosphokinase
Altered mental status
Mucous membranes erythema
Negative results of following tests, if obtained:
Blood, throat, or cerebrospinal fluid cultures for another pathogen
Serologic tests for Rocky Mountain spotted fever, leptospirosis, measles

Data from the Centers for Disease Control. Wharton et al. [60] and Centers for Disease Control and Prevention [61]

Table 34.5 Diagnostic criteria for streptococcal toxic shock syndrome

Isolation of group A *Streptococcus*
Hypotension
Two or more of the following:
Pulmonary dysfunction
Liver dysfunction
Renal dysfunction
Coagulopathy
Erythroderma of the skin
Soft tissue necrosis (e.g., necrotizing fasciitis)

Data from: The Working Group on Severe Streptococcal Infections. [62]

Positive blood cultures are more frequently seen in streptococcal TSS than in staphylococcal TSS.

Treatment

Treatment includes rapid introduction of intravenous antibiotics against *Staphylococcus* and *Streptococcus*. Clindamycin has direct antitoxin properties and has been shown to improve patient outcomes in TSS [19]. The source of infection should be investigated and may be occult. Intravenous immunoglobulin (IVIG) and corticosteroids may be beneficial in severe and refractory cases [20, 21].

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides (MF) and Sézary syndrome (SS) are types of cutaneous T-cell lymphoma (CTCL), and both can present with erythroderma. MF is a T-cell lymphoma with initial presentation in the skin but with potential involvement of the lymph nodes, blood, and internal organs. SS is a distinctive type of CTCL with leukemic involvement of malignant T cells.

Fig. 34.4 Erythroderma: diffuse erythematous scaly plaques with small areas of sparing secondary to extensive mycosis fungoides

Clinical

MF typically presents with patches and plaques and may progress to tumors or erythroderma (Fig. 34.4). SS generally presents with erythroderma often in the setting of lymphadenopathy and indurated facial features from the infiltration of malignant cells [22].

Etiology

The etiology of cutaneous T-cell lymphoma is not entirely known. Hypotheses include chronic stimulation of circulating skin-homing lymphocyte subsets that cause transformation to a monoclonal population.

Diagnosis

Atypical lymphocytes within in the epidermis on skin biopsy are diagnostic of MF, though there may be overlap features with other chronic dermatoses. Diagnosis of SS requires the involvement of a clonal neoplastic T-cell population in the skin, lymph nodes, and blood.

Treatment

Patch stage MF may be treated with skin-targeted remedies such as topical steroids, topical nitrogen mustard, topical bexarotene, and phototherapy. Advanced MF presenting with erythroderma or systemic involvement and SS requires systemic therapies such as extracorporeal photopheresis, systemic retinoids, interferons, monoclonal antibodies, and chemotherapy regimens.

Table 34.6 Differential diagnosis for common causes of vesicular/pustular eruptions in oncologic patients

Drug
Acute generalized exanthematous pustulosis (AGEP)
Acneiform eruption secondary to epidermal growth factor receptor (EGFR) inhibitors
Steroid-induced acneiform eruption
Drug-induced autoimmune blistering disease (especially secondary to immunotherapy)
Inflammatory
Pustular psoriasis
Miliaria
Allergic/irritant contact dermatitis
Neutrophilic dermatoses
Infectious
Viral
Herpes simplex virus[a]
Varicella-zoster virus[a]
Coxsackie virus (hand, foot, and mouth disease)
SARS-CoV-2 (rare)

Others: rickettsialpox, nocardiosis, listeriosis
Fungal
Disseminated candidiasis[a]
Disseminated opportunistic fungal infection
Atypical mycobacteria

[a]Expanded upon in text

Vesicles and Pustules

The differential diagnosis for vesicular and/or pustular eruptions in oncologic patients is broad and includes infectious causes, inflammatory disorders, and drug reactions (Table 34.6).

Drug-Induced Autoimmune Blistering Disease

Immune-Related Bullous Pemphigoid-Like Eruption

Clinical Manifestations

Immune-related bullous pemphigoid-like (irBP) eruption due to ICI occurs in 1–5% of patients treated with anti-PD1 or anti-CTLA-4 and may develop during or months after completion of ICI with a median 190–298.5 days (range 31–2380 days) after initiation of therapy [3, 4, 23]. Development of irBP is associated with improved tumor response after PD-1 therapy [24]. Cutaneous morphology of irBP may be indistinguishable from idiopathic BP. Bullous dermatitis severity is classified via CTCAE with G1, asymptomatic, blisters covering <10% BSA; G2, blisters covering 10–30% BSA, painful blisters, limiting instrumental ADL; G3, blisters covering >30% BSA, limiting self-care ADL; and G4, blisters covering >30% BSA, associated with fluid or electrolyte abnormalities, ICU care, or burn unit indicated [5]. Median duration of irBP is 97.5 days (range 13–390 days) [4].

Pathophysiology/Etiology

The exact pathomechanism of irBP is not yet established. In idiopathic (non-drug-related) bullous pemphigoid, BP180, a transmembrane glycoprotein in the skin, serves as an autoantigen targeted by antibodies leading to dermal-epidermal separation and blister formation. BP180 is expressed in melanoma and non-small cell lung cancer, possibly serving as the target of antitumor antibodies that may concurrently bind to cutaneous BP180 [23].

Diagnosis

Diagnosis is made based on clinical findings of a tense bullae or urticarial plaques and history of current or prior immune checkpoint inhibitor (ICI) therapy. Differential diagnosis for irBP includes linear IgA bullous dermatosis (LABD), bullous lichen planus, lichen planus pemphigoides, bullous erythema multiforme, and epidermolysis bullosa acquisita. Serologic testing by ELISA for circulating autoantibodies against BP180 and BP230 may be used to confirm diagnosis, correlate with disease severity, or monitor response to treatment. Histology will reveal a subepidermal bullous dermatitis with eosinophils, and direct immunofluorescence (DIF) shows linear deposition of IgG and C3 at the basement membrane zone of the dermoepidermal junction [3]. Histologic and direct immunofluorescence findings will not differentiate between irBP and idiopathic BP, but will distinguish from the aforementioned bullous conditions which may also be immunotherapy associated.

Treatment

Goal of treatment of immune-related BP is to minimize systemic immunosuppressive treatments while maintaining the patient on the current dose of ICI. Management of G1 irBP consists of high-potency topical corticosteroid twice daily [2]. For G2 irBP, hold ICI until severity decreases to grade 0–1, and add systemic corticosteroids (prednisone 0.5–1 mg/kg) [5]. For G ≥3 or intolerable G2 irBP, oral corticosteroids (prednisone 0.5–1 mg/kg) and rituximab (+/− IVIG [4]) are added [3]. Patients should be reassessed every 2 weeks until improvement in grade. If reaction worsens or does not improve, dose reduction or discontinuation per protocol may be necessary.

Viral Infections

Varicella-Zoster Virus

Varicella-zoster virus (VZV) from the *Herpesviridae* family is the cause of varicella (chickenpox) and zoster (shingles). Herpes zoster is a common infection seen in the oncologic patient.

Clinical Presentation

Varicella begins with mild fever, malaise, and myalgias followed by an eruption of 2–4 mm clear vesicles with a red rim. Over the course of several days, the vesicles become pustular and often form a prominent central hemorrhagic crust. Varicella in adults and immunocompromised patients may be associated with higher risk of morbidity and mortality, often with more extensive crusting and risk of internal organ involvement.

Herpes zoster is the reactivation of latent VZV. Zoster initially presents with a prodrome of burning, tingling, and pruritus followed by the development of grouped vesicles on an erythematous base in a dermatomal distribution. When certain dermatomes are affected, extracutaneous complications can occur including ocular complications, facial paralysis, loss of taste, deafness, and temporary inability to urinate or defecate. In the immunocompromised, pain and post-herpetic neuralgia may be more severe [25].

Disseminated zoster is defined as more than 20 vesicles outside the primary or contiguous dermatome (Fig. 34.5). Visceral involvement including pulmonary, hepatic, and central nervous system can occur in approximately 10% of immunocompromised patients [26].

Pathophysiology/Etiology

Varicella is transmitted through airborne droplets or direct contact with vesicular fluid. After varicella infection, the virus travels to the dorsal root ganglion where it remains latent until reactivation. It is the reactivation of latent VZV that causes zoster (shingles), which may occur spontaneously or in the setting of stress, fever, local trauma, immunosuppression, or radiation.

Diagnosis

The diagnosis can be made clinically based on typical lesional morphology. Polymerase chain reaction (PCR) from lesional fluid has become the preferred method for confirmatory testing based on higher sensitivity and rapid results (often within 24 h). If not available, a Tzanck smear or direct fluorescence antibody (DFA) assay or viral culture can be used [27].

Fig. 34.5 Disseminated zoster: scattered vesicles on an erythematous base diffusely on the back with grouped vesicles in a dermatomal distribution on right mid-back

Treatment

Antivirals can be used for varicella and zoster in immunocompetent patients to decrease the duration and severity. Intravenous acyclovir is recommended for varicella in immunocompromised individuals and disseminated zoster. Postexposure prophylaxis with varicella-zoster immunoglobulin is recommended for immunocompromised individuals and nonimmune pregnant women.

Eczema Herpeticum (Kaposi's Varicelliform Eruption)

Eczema herpeticum is the cutaneous dissemination of herpes simplex virus (HSV) in areas of a preexisting dermatitis, such as atopic dermatitis (eczema), mycosis fungoides, or other skin conditions with impaired skin barrier.

Clinical Presentation

Eczema herpeticum appears clinically as discrete 2–3 mm punched-out erosions and circular hemorrhagic crusts con-

Fig. 34.6 Eczema herpeticum: diffuse 2–3 mm punched-out erosions within an area of eczema on the foot

centrated in areas of dermatitis (Fig. 34.6). Occasionally intact grouped vesicles or vesiculopustules may be seen, and the lesions may be superinfected with bacteria. Patients may have associated fever, malaise, and lymphadenopathy.

Pathophysiology/Etiology

Transmission of HSV1 is typically through direct contact with contaminated saliva, while HSV2 is transmitted through sexual contact. The virus then replicates at the site of infection and travels to the dorsal root ganglia, where it establishes latency until reactivation. Upon reactivation, the virus is able to spread via impaired skin leading to widespread involvement.

Diagnosis

As above, the preferred diagnostic technique is lesional PCR, though viral culture, DFA, and Tzanck smears may also be used.

Treatment

Treatment includes the use of antiviral therapy for 10–14 days, especially if immunocompromised, until all lesions are crusted over. Severe cases may require hospitalization with empiric intravenous acyclovir, while diagnostic studies are pending. Clinicians should also have a high suspicion for bacterial superinfection (especially with staphylococcal species) and low threshold to start concurrent antibiotics.

Fig. 34.7 Ecthyma: large pustules with central necrosis and crusting secondary to *S. aureus* bacteremia

Bacterial Infections

Ecthyma

Ecthyma is an ulcerative bacterial skin infection that can be localized or widespread with systemic manifestations. Ecthyma gangrenosum is a specific term for ecthyma skin lesions secondary to bacteremia with *Pseudomonas aeruginosa*.

Clinical Presentation

Ecthyma initially begins as single or multiple vesiculopustules that enlarge over several days. Lesions then ulcerate and develop central necrotic adherent crusts (Fig. 34.7). When multiple lesions are present, patients may have fever, chills, malaise, and, sometimes, hypotension and shock. Bacteremia should be strongly suspected.

Pathophysiology/Etiology

Ecthyma is secondary to a localized skin infection or secondary to bacteremia with cutaneous seeding. Ecthyma may be due to Gram-positive organisms including *Streptococcus* and *Staphylococcus* species and Gram-negative organisms such as *Pseudomonas*.

Diagnosis
The diagnosis can be made based on clinical appearance and Gram stain and culture of the purulent base. Skin biopsy and tissue culture can confirm the diagnosis and organism. Blood cultures should be ordered especially when multiple lesions are present.

Treatment
Treatment includes systemic antibiotics and wound care with soaking and gentle debridement of adherent crusts and topical antibiotic ointment. Hospitalization and intravenous antibiotics are indicated when multiple lesions are present or in immunocompromised patients.

Fungal Infections

Disseminated Candidiasis

Disseminated candidiasis is an infection most often seen in the immunocompromised host and can affect any organ system including the skin.

Clinical Manifestations
Cutaneous manifestations of disseminated candidiasis include pustules and scattered erythematous macules, papules, or nodules, often with a pale center. Other presentations include hemorrhagic bulla and purpura, especially in the setting of thrombocytopenia. Individuals are typically ill-appearing with tachycardia, hypotension, and fever.

Pathophysiology/Etiology
Candidal sepsis commonly occurs from *Candida* that has colonized the gastrointestinal tract or skin. *Candida albicans* is a common etiology of disseminated candidiasis, but *C. glabrata* and *C. tropicalis* can also be seen. *C. tropicalis* is more likely to produce cutaneous lesions and is common in patients with leukemia [28].

Diagnosis
Diagnosis can be established through skin biopsy and tissue culture or potassium hydroxide (KOH) preparation of purulent material. Budding yeast and pseudohyphae in the dermis are seen on skin biopsy. Evaluation also includes blood cultures, which may be negative, and evaluation for other organ involvement.

Treatment
In non-neutropenic patients, disseminated candidiasis can be treated with fluconazole. In neutropenic patients, amphotericin B, caspofungin, or voriconazole should be used. Any foci of infection such as lines and catheters should be removed.

Blistering Diseases

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe mucocutaneous reactions that are typically triggered by medications. SJS/TEN may be more frequent in the oncologic population with one study showing a high incidence of TEN (6%) in bone marrow transplant patients, though cases of TEN-like acute graft-versus-host disease (GVHD) were included [29].

Clinical Manifestations
SJS/TEN typically presents 1–3 weeks after initiation of the offending medication with blisters centered on non-blanching macules or atypical target lesions characterized by two distinct zones: a dark red center surrounded by a pale red outer ring (Fig. 34.8). The majority of immune checkpoint inhibitor (ICI)-associated SJS/TEN-like reactions begin after the first or second infusion of ICI; however, it may occur even 140 days after initiation of therapy or after discontinuation [30, 31]. Lesions tend to start proximally on the trunk and face and then spread distally. Individual lesions can rapidly coalesce followed by cutaneous necrosis and epidermal sloughing that can become widespread. ICI-associated SJS/TEN-like reactions may be preceded by days to months of slowly evolving maculopapular, psoriasiform, or lichenoid

Fig. 34.8 SJS: coalescing blisters centered on non-blanching macules on the chest

Fig. 34.9 (**a**) Generalized dusky red maculopapular eruption with scattered areas of erosions and hemorrhagic crusting, (**b**) cutaneous and mucosal lips with hemorrhagic mucositis, (**c**) confluent oral erosions with white fibrinous pseudomembranes

rashes, before developing denudation and mucosal involvement.

SJS/TEN exist on a spectrum defined by percentage body surface area (BSA) of epidermal detachment: SJS defined as <10% BSA, SJS/TEN as 10–30%, and TEN as >30%. ICI-associated SJS/TEN-like reactions severity is additionally graded via CTCAE starting with G3, skin sloughing covering <10% BSA with associated signs (e.g., erythema, purpura, epidermal detachment, and mucous membrane detachment); G4, skin sloughing covering 10–30% BSA with associated signs (e.g., erythema, purpura, epidermal detachment, and mucous membrane detachment); and G5, death [5] (Fig. 34.9).

Erythema multiforme (EM) was previously considered by many to exist on the spectrum of SJS and TEN but has more recently been classified as a separate entity with distinctive skin findings and etiology and a good prognosis [32].

Typically multiple mucosal sites (oral, ocular, and/or anogenital) are involved with erosions, ulcerations, and hemorrhagic crusting [33] (Fig. 34.10). In severe cases, gastrointestinal (GI) and pulmonary involvement occur. Patients are often febrile and can display signs of shock. Associated organ system involvement is frequently reported including hepatitis, acute renal failure, myocarditis, and bone marrow suppression. One study found the mean adjusted mortality rates between 2009 and 2012 in the United States were 4.8% for SJS, 19.4% for SJS/TEN, and 14.8% for TEN [34].

A validated scoring system has been developed to assess the severity of illness and predict mortality in SJS/TEN

Fig. 34.10 Mucosal findings in SJS: erosions and hemorrhagic crusting

Table 34.7 SCORTEN severity of illness score in Stevens-Johnson syndrome and toxic epidermal necrolysis (SJS/TEN)

One point for each of seven criteria if present on admission
Age >40 years
Presence of a malignancy (cancer)
Heart rate >120
Initial percentage of epidermal detachment >10%
Serum urea level >10 mmol/L
Serum glucose level >14 mmol/L
Serum bicarbonate level <20 mmol/L
SCORTEN predicted mortality rates
0–1: >3.2%
2: >12.1%
3: >35.3%
4: >58.3%
>=5: >90%

SCORTEN Score of toxic epidermal necrosis

(Table 34.7). However, with advances in wound care and treatment, the SCORe of Toxic Epidermal Necrosis (SCORTEN) may over-estimate mortality [35].

Pathophysiology

The pathophysiology of SJS/TEN is likely multifactorial involving cytotoxic T cells and soluble mediators including perforin, granzyme B, granulysin, and Fas-Fas ligand (FasL).

Table 34.8 Differential diagnosis for Stevens-johnson syndrome and toxic epidermal necrolysis (SJS/TEN)

Erythema multiforme[a]
Staphylococcal scalded skin syndrome
Pemphigus vulgaris/paraneoplastic pemphigus[a]
TEN-like acute graft-versus-host disease[a]
Linear IgA bullous dermatosis
Generalized bullous fixed drug eruption

[a]Expanded upon in text

Certain populations have specific human leukocyte antigen (HLA) types that are associated with a higher risk of development of SJS/TEN indicating a genetic component. Hundreds of medications have been associated with SJS/TEN, but the most common include allopurinol, aromatic anticonvulsants and lamotrigine, sulfa antibiotics, nevirapine, and nonsteroidal anti-inflammatory drugs (NSAIDs). In addition, many anticancer drugs have been associated with SJS/TEN including lenalidomide, thalidomide, docetaxel, and imatinib [36] and with SJS/TEN-like reactions including anti-CTLA-4, anti-PD-1, and anti-PDL-1 inhibitors [30]. The mechanism of SJS/TEN-like reactions is not yet established. Blockade of homeostatic PD-1/PD-L1 signaling, which maintains peripheral tolerance in the skin, may allow autoreactive CD8+ T cells targeting keratinocytes displaying self-antigens to become activated and proliferate leading to development of SJS/TEN-like reactions [37].

Diagnosis

Diagnosis can often be made clinically based on acute onset of blisters, targetoid (target-like) lesions, and epidermal detachment. Skin biopsy confirms the diagnosis and shows full-thickness epidermal necrosis. Where available, frozen sectioning of skin biopsy samples allows rapid diagnostic confirmation within hours. Direct immunofluorescence should also be done to rule out other etiologies of blistering disease, which is especially important for patients with history of ICI therapy given their predisposition for immunobullous disease (Table 34.8). SJS/TEN and ICI-associated SJS/TEN-like eruptions have overlapping histologic features.

Diagnosis may be more complicated in the setting of oncologic patients especially those who have undergone stem cell transplantation as severe acute GVHD can mimic SJS/TEN. Both diseases are at least partially mediated by cytotoxic T cells that target keratinocytes. Skin biopsies may be indistinguishable though the presence of eosinophils may be suggestive of GVHD.

Treatment

The most important interventions that have consistently been shown to improve survival in SJS/TEN is prompt

discontinuation of the offending medication and transfer to a burn unit, intensive care unit, or specialized care center. Supportive care consists of fluid and electrolyte balance, wound care, and monitoring for/early treatment of infection. An ophthalmology consult should be called whenever SJS/TEN is suspected. A urology and/or gynecology consult should also be considered. The use of prophylactic antibiotics is not recommended as no survival advantage has been shown [38].

A recent shift toward the use of cyclosporine and the tumor necrosis factor inhibitor etanercept has changed the landscape for treatment in patients with SJS/TEN. A 2018 meta-analysis of over 250 patients with SJS/TEN found that treatment with cyclosporine was associated with an approximately 70% decrease in mortality [39]. Typical recommended dose is 3 to 5 mg/kg/d divided bid for 7–10 days [39]. ICI-associated SJS/TEN-like eruptions may require longer therapeutic courses due to persistent immune activation and longer half-life of ICI when compared to traditional drug culprits. A 2018 randomized trial of 91 patients comparing etanercept versus systemic steroids showed improved clinical outcomes including decreased SCORTEN predicted mortality, decreased side effects, and more rapid re-epithelialization in the etanercept group [40]. While these results are encouraging, randomized, prospective trials are needed.

The use of systemic steroids in SJS/TEN (including recommended route of administration, dosage, and length of administration) remains controversial [35, 41–45]. While a recent 2017 meta-analysis [41] suggested decreased mortality rate, others have shown either no benefit or increased infection risk and length of hospital stay [35]. Some studies suggest a benefit especially if used earlier in the disease course, and at high dosages however, benefits must be weighed against increased infection risk and potential for delayed re-epithelialization [42, 43]. Intravenous immunoglobulin use in SJS/TEN is similarly controversial with some studies suggestive of benefit at higher dosages (over 2 gm/kg) [44], while a meta-analysis from the EuroSCAR group did not show survival benefit [45]. Despite this lack of clear supportive data, IVIG is still widely used for SJS/TEN in the United States [35]. Another important treatment consideration is the use of steroids and IVIG concurrently which also warrants additional study [35].

Paraneoplastic Pemphigus

Paraneoplastic pemphigus (PNP) is an autoimmune mucocutaneous blistering disease associated with an underlying neoplasm. PNP has been described in association with lymphoproliferative neoplasms including chronic lymphocytic leukemia, non-Hodgkin's lymphoma, and Castleman's disease, though solid organ tumors including thymomas have also been reported [46].

Clinical Manifestations

PNP is characterized by painful mucosal ulcerations and a polymorphous skin eruption with an associated neoplasm. Mucosal involvement typically affects the oral mucosa, especially the lips; however, the conjunctiva, anogenital region, nasopharynx, and esophagus may also be involved. Skin manifestations typically appear later and are varied including nonspecific erythematous papules, target-like lesions, and blisters. Internal organ involvement has also been reported including pulmonary (classically bronchiolitis obliterans), thyroid, renal, and gastrointestinal tract.

Pathophysiology

Autoantibodies against plakins (periplakin, envoplakin) are diagnostic of PNP. Plakins are important proteins found in hemidesmosomes and desmosomes, which serve as vital structures in keratinocyte adhesion to other keratinocytes and to the underlying basement membrane. In some cases, these autoantibodies have been shown to be produced directly by the associated neoplasm [47]. Additional autoantibodies involved in PNP are desmoplakins 1 and 2 and plectin.

Diagnosis

Currently no single established set of diagnostic criteria exists for PNP. Most proposed definitions include mucosal involvement, detection of autoantibodies via direct and/or indirect immunofluorescence antibody testing against envoplakin and/or periplakin, and the presence of an underlying neoplasm.

Treatment

PNP often improves after the removal or treatment of the underlying neoplasm. Rituximab is recommended as first-line treatment for PNP [48]. Other treatments including prednisone, cyclosporine, cyclophosphamide, and IVIG have also shown efficacy [46, 49].

Purpuric (Non-blanching) Eruptions

Purpuric eruptions describe non-blanching skin lesions secondary to hemorrhage into the skin. Purpuric lesions may be flat (macular purpura), small and raised (palpable purpura), or larger and netlike (retiform purpura). It is important to recognize the features of macular purpura, palpable purpura, and retiform purpura as the differential diagnosis varies based on these morphologic differences.

Table 34.9 Differential diagnosis for macular purpura

Platelet-related
Low platelets
Immune thrombocytopenic purpura (ITP)
Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS)
Disseminated intravascular coagulation (DIC)
Bone marrow failure
Drug-induced thrombocytopenia
Cirrhosis
Abnormal platelets
Congenital or hereditary platelet dysfunction
Nonsteroidal anti-inflammatory drugs
Renal disease
Thrombocytosis
Non-platelet-related
Trauma/Valsalva
Infections (Rocky Mountain spotted fever, parvovirus B19, disseminated strongyloidiasis)
Capillary fragility (actinic damage, Ehlers-Danlos syndrome)
Anticoagulant medications
Vitamin K deficiency
Vitamin C deficiency

Table 34.10 Differential diagnosis for palpable purpura (cutaneous small vessel vasculitis)

Inflammatory
Connective tissue disease-associated vasculitis
Mixed type II and III cryoglobulinemia
Henoch-Schonlein purpura (IgA vasculitis)
ANCA+ vasculitis
Infections (most commonly *Streptococcus*, HIV, hepatitis, tuberculosis)
Medications
Neoplastic (leukemic vasculitis, paraneoplastic phenomenon)
Idiopathic

Macular Purpura

Macular purpura describes flat areas of purpura of varying sizes. Lesions may be small (petechiae) or larger (ecchymoses). Macular purpura typically indicates hemorrhage into the skin secondary to low or dysfunctional platelets or vessel wall fragility in the absence of inflammation (Table 34.9).

Palpable Purpura

Palpable purpura describes small, raised, non-blanching lesions most commonly found on the lower extremities. Palpable purpura is the classic skin manifestation for cutaneous small vessel vasculitis (Table 34.10).

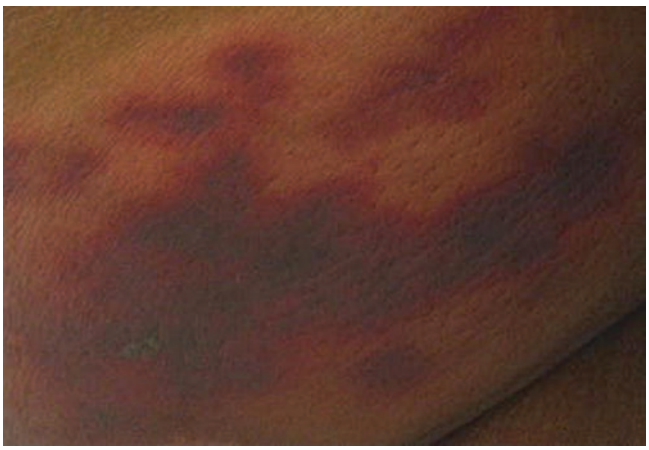

Fig. 34.11 Retiform purpura: netlike pattern of cutaneous purpura with central necrosis on the abdomen

Retiform Purpura

Retiform purpura describes cutaneous lesions that have a netlike or stellate (starlike) pattern of purpura often with central necrosis or ulceration, reflecting damage to larger vessels with resultant cutaneous ischemia and hemorrhage (Fig. 34.11). Damage to the vessel may occur through either infiltration of the vessel wall or occlusion of the vessel lumen (Table 34.11).

Acute Meningococcemia

Meningococcemia, a bloodstream infection with *Neisseria meningitidis*, is a rapidly progressive disease with a fatality rate of 7–11% [50]. Though its incidence is decreasing with increased vaccination in well-developed countries, its severity makes rapid recognition of paramount importance, especially in the immunocompromised host.

Clinical Manifestations

Acute infection results in a constellation of symptoms including high fever, myalgias, neck pain or stiffness, and headache. Skin findings typically manifest with a diffuse petechial rash that rapidly progresses to retiform purpura with a central "gun-metal gray" color and necrosis. Hypotension and shock may develop, and patients should be monitored for disseminated intravascular coagulation.

Pathophysiology/Etiology

Acute meningococcemia is caused by transmission via droplet of *Neisseria meningitidis*, a Gram-negative coccus. Disease typically develops 2 weeks after colonization of the pharyngeal mucosa. Cutaneous lesions of retiform purpura

Table 34.11 Differential diagnosis for retiform purpura

Vessel wall infiltration
Vasculitis
Septic vasculitis (bacterial, angioinvasive fungal)
Mixed type II and III cryoglobulinemia
Connective tissue disease-associated vasculitis
ANCA+ vasculitis
Leukemic vasculitis Polyarteritis nodosa Drug-induced vasculitis
Deposition (calciphylaxis, oxalosis)
Vessel lumen occlusion
Thrombotic
Abnormal coagulation
Hypercoagulable state (acquired or hereditary)
Warfarin-induced skin necrosis[a]
Disseminated intravascular coagulation/purpura fulminans
COVID-19-associated coagulopathy
Platelet plugging
Heparin-induced thrombocytopenia (HIT)[a]
Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS)
Paroxysmal nocturnal hemoglobinuria
Myeloproliferative disorders (essential thrombocytosis)
RBC occlusion (sickle cell, hereditary spherocytosis)
WBC occlusion (intravascular lymphoma)
Cold-related (type I cryoglobulinemia, cryofibrinogenemia)
Embolic: (septic, cholesterol, cardiac, air, fat emboli)

[a]Expanded upon in text

result from bacterial proliferation within the blood vessels creating vascular occlusion.

Diagnosis

Diagnosis of acute meningococcemia is clinical and should be suspected in any febrile patient with retiform purpura especially in the setting of headache and neck pain or stiffness. Treatment should be initiated prior to results of diagnostic testing to prevent rapid spread of infection. Cerebrospinal fluid (CSF) culture is superior to blood culture and positive in 90% of patients. PCR-based techniques on CSF approach a sensitivity of 100% [50]. Skin biopsy with tissue culture can be helpful to confirm the diagnosis.

Treatment

Neisseria meningitidis is highly sensitive to high-dose intravenous penicillin G, ceftriaxone, and cefotaxime, and treatment should be initiated within 1 h of presentation. Rifampin should be given to close contacts, and the vaccine is available for high-risk groups [51]. Adult oncologic patients are not routinely vaccinated unless a risk factor, such as previous splenectomy, is present.

Opportunistic Fungal Infections

Infections from the opportunistic dermatomycoses including aspergillosis, fusariosis, cryptococcosis, and zygomycosis can range from localized cutaneous infection to disseminated infection with multiorgan system involvement. Leukemia and lymphoma patients are most at risk for deep fungal infections when neutropenic.

Clinical Manifestations

Disseminated fungal infections can present with a wide range of cutaneous lesions including retiform purpura, papulonecrotic lesions, pustules, and hemorrhagic bulla [52]. *Cryptococcus* may present with umbilicated papules that resemble molluscum contagiosum. Patients are typically febrile and appear acutely ill.

Pathophysiology/Etiology

Systemic mycoses may begin with primary skin infection or spread to the skin from a distant site of infection. Disruption of skin barrier and mucosa from burns, trauma, and indwelling catheters, along with impaired immunity, are predisposing factors.

Diagnosis

Diagnosis can be established with skin biopsy, tissue culture, and microscopic examination of lesional fluid. Serum assays for components of the fungal cell wall, including 1,3-beta-D-glucan and galactomannan, can be used to screen for invasive fungal infection. Cryptococcal antigen is measurable in serum and correlates with fungal burden. Work-up should include chest X-ray and sputum culture to evaluate for pulmonary involvement.

Treatment

Expeditious treatment of deep fungal infection is key, and delay in treatment by as little as 2 h has shown to correlate with increasing mortality [53]. For many of the disseminated opportunistic mycoses, treatment is with intravenous amphotericin B. Voriconazole is first-line treatment for invasive aspergillosis. Prognosis is poor in disseminated disease but can be improved if neutropenia improves. Prophylactic treatment (agent of choice depends on the underlying malignancy, the length of expected neutropenia, etc.) may help reduce the risk of infection.

Anticoagulant-Induced Skin Necrosis

Anticoagulant-induced skin necrosis is a term that includes heparin-induced thrombocytopenia (HIT) and warfarin-induced skin necrosis (WISN).

Clinical Manifestations

Both HIT and WISN present with retiform purpura secondary to occlusion of cutaneous vessels. Necrosis may develop centrally secondary to tissue ischemia. HIT is most commonly found at sites of medication injection and typically develops within 5–10 days of starting heparin or within

Fig. 34.12 Heparin-induced thrombocytopenia: retiform purpura with central necrosis at the site of heparin injection on the abdomen

24 h in patients with recent exposure to heparin (Fig. 34.12). WISN typically develops 3–5 days after beginning warfarin, often on fatty sites, such as breasts, thighs, buttocks, and hips, and is preceded by pain.

Pathophysiology/Etiology

In HIT, circulating antibodies develop that simultaneously bind heparin and platelet factor 4 (PF4) causing platelet activation and subsequent aggregation leading to venous and arterial occlusion. For reasons that are not entirely clear, low-molecular-weight heparins are less likely to cause platelet activation than unfractionated heparins [54].

Warfarin-induced skin necrosis results from the temporary imbalance in pro- and anticoagulant factors upon initiation of warfarin. Warfarin functions by inhibiting vitamin K-dependent coagulation factors. Protein C, an anticoagulant, is more rapidly inhibited by warfarin than procoagulant factors II, VII, IX, and X, leading to a temporary prothrombotic state. Risk factors include obesity, perimenopausal age, viral infection, and underlying hypercoagulable state.

Diagnosis

In both HIT and WISN, skin biopsies reveal a pauci-inflammatory thrombotic vasculopathy secondary to vessel occlusion. Subtle histologic variations in platelet thrombi (white clots) in HIT versus fibrin thrombi (red clots) in WISN can aid in differentiating the two histologically similar conditions [55]. In HIT, a rapid drop in platelets is typical resulting in absolute thrombocytopenia or a drop in platelets by at least 50%. The diagnosis of HIT can be confirmed with HIT antibody testing including immunoassays and functional assays. WISN is typically a clinical diagnosis that requires a compatible histology and history of recent initiation or reintroduction of warfarin. Patients may also have a history of an underlying hypercoagulable state or a recent infection. Protein C and S analyses are not sensitive or specific markers [56].

Treatment

Treatment of HIT consists of immediate discontinuation of heparin and supplementation with an alternative anticoagulant, such as fondaparinux, danaparoid, apixaban, rivaroxaban, or argatroban. Warfarin should be avoided initially but may be used once the patient has stabilized and platelet counts have recovered. Treatment of WISN involves immediate discontinuation of warfarin and administration of vitamin K and infusion of heparin at therapeutic doses. Fresh frozen plasma and protein C concentrate have been used to restore protein C levels and may be considered in the setting of life-threatening coagulation [56, 57]. It is recommended to bridge initiation of warfarin with heparin to avoid this phenomenon.

DIC/Purpura Fulminans

Infection, trauma, and malignancy among other insults can lead to imbalances in the coagulation system causing disseminated intravascular coagulation (DIC) with resultant simultaneous hemorrhage and thrombosis. If clotting is severe, purpura fulminans with acute, widespread retiform purpura and gangrene of the skin can develop.

Clinical Manifestations

DIC presents with skin findings indicative of simultaneous bleeding and thrombosis including petechiae, ecchymoses, and mucosal bleeding as well as lesions of retiform purpura. Purpura fulminans presents with rapidly progressive, widespread retiform purpura, hemorrhagic bulla, and symmetrical gangrene especially acrally (Fig. 34.13). Patients are acutely ill often with fever, shock, and evidence of multiorgan system involvement [58].

Pathophysiology/Etiology

Disseminated intravascular coagulation (DIC) and purpura fulminans are conditions in which systemic activation of coagulation leads to widespread clotting, particularly in small- and medium-sized vessels. Excessive clotting then leads to a consumptive coagulopathy where clotting factors cannot be generated as quickly as they are consumed and a bleeding diathesis ensues.

Diagnosis

Cardinal lab findings in DIC and purpura fulminans are consistent, independent of cause, and consist of thrombocytopenia, reduced plasma fibrinogen concentrations, and increased fibrin and fibrin products, with prolonged clotting times. Skin biopsy may aid in diagnosis and shows a thrombotic vasculopathy [58].

Fig. 34.13 Purpura fulminans: retiform purpura, blistering, and distal necrosis/gangrene of the hand

Treatment

Treatment of DIC includes treatment of the underlying cause and aggressive management of hemodynamic stability. If serious bleeding is present, platelet transfusions and administration of fresh frozen plasma or cryoprecipitate may be indicated. The use of heparin is typically limited to patients with chronic, compensated DIC that have predominantly thrombotic manifestations. Protein C concentrate may be considered in cases of DIC secondary to hereditary or acquired protein C deficiency or in cases of purpura fulminans. Adjunctive hyperbaric oxygen and surgical debridement with skin grafting may prove beneficial in patients with extensive skin necrosis and gangrene [59].

Pediatrics

35

Kathleen M. Stephanos and Lindsey Picard

Introduction

Oncologic emergencies in pediatrics can be subdivided into presentation of disease and treatment of disease-associated emergencies. Each of these areas poses distinct risks and complications for the patient. This chapter will attempt to cover a multitude of different cancerous processes as well as their presentations. While many complications are similar to those in adults, the pathophysiology and resulting types of cancer can result in different treatment plans and prognostics. Many therapies are similar to those used in adults, with known adverse reactions, but their impact on the pediatric patient may result in more severe or long-term effects, a scenario which may become more common as cancer survivorship continues to improve.

Case Study

A 7-year-old female presents with 1 month of intermittent fevers, body aches, and left forearm pain. She has been seen by several providers since the onset of symptoms and diagnosed with viral illnesses. On the day of presentation, her parents described her as less alert throughout the day, so they brought her to the emergency department (ED). She has a temperature of 38.4, a heart rate of 130, a blood pressure of 85/50, a respiratory rate of 30, and an oxygen saturation of 100% on room air. On exam, she appears listless, with dry mucous membranes, her cardiopulmonary exam is normal other than the aforementioned vital signs, and she has diffuse lymphadenopathy and hepatosplenomegaly. What are the concerns for this patient? What is the differential diagnosis? What is the initial management?

The child in the case presents initially with symptoms suggestive of acute leukemia. Symptoms supportive of this are her hepatosplenomegaly, intermittent fevers, and changes in mental status. Acute mental status changes may signify that this patient is experiencing CNS involvement of her illness or that she has hyperleukocytosis causing hyperviscosity symptoms. It is important to recognize this as a pediatric emergency that will require admission to a pediatric hospital with oncologic coverage. Unlike adults, who (if not in a blast crisis or having other requirements for admission) can often be managed as an outpatient, children are often admitted for initial oncologic evaluation.

Two months later, she returns with 1 hour of fever. She has been on chemotherapy since her primary presentation. She was tolerating her treatment well, other than occasional nausea and vomiting, until the day of presentation when she developed abdominal pain and has not been able to eat or drink. When the fever occurred, she was instructed by her oncologist to come directly to the ED. On arrival, her temperature is 39.2, heart rate 120, blood pressure 90/55, and respiratory rate 22, and she has an oxygen saturation of 99% on room air. On exam she appears uncomfortable and has red cracked lips and a dry tongue. Her cardiopulmonary exam is notable only for the aforementioned vital signs. On abdominal exam, her hepatosplenomegaly has resolved, but she now has right lower quadrant tenderness with rebound and guarding. What is on the differential for this patient? What is the management?

On her return visit, there are many factors to consider; however, the most pressing are recognition of the possibility of both neutropenic fever and typhlitis, both of which can be rapidly fatal if not identified early. This patient requires prompt recognition and should not be in a waiting room for any duration of time. Other considerations include possible mucositis with dehydration or bowel perforation. She may also have appendicitis or even intussusception based on her pain. Her immunosuppressed state may have delayed the common symptoms of these, and her medications may have mimicked some of these symptoms as well causing family

and providers to attribute her recent nausea and vomiting due to medication effects rather than early signs of disease. Based on her presentation, intravenous fluid should be started, with antibiotics and imaging for better assessment of her abdomen.

History and Background

Overall incidence of pediatric cancer has not changed significantly over the past several decades; however, there has been one drastic change: on average, more than four out of every five children diagnosed with cancer can be expected to survive. A particular challenge of pediatric cancer is the small number of cases, resulting in limited testing and evaluation of new treatment options [1]. Pediatric cancers are managed several ways including multidisciplinary therapeutic strategies such as surgical intervention, cytotoxic chemotherapy, radiation therapy, and autologous as well as allogeneic bone marrow or stem cell transplants. More recent studies have begun to evaluate the efficacy of monoclonal antibody therapy, though this is not a commonly used therapy at the time of this publication [2, 3]. The treatment options are cancer specific, but nearly all pediatric cancers acquire some form of significant immunosuppression.

Anatomy

As with all oncologic processes, pediatric cancers are due to an unregulated overgrowth of mutated cells. The most common sites for this in children are bone marrow and central nervous system—specifically intracranial [4]. Therapy, therefore, targets these cells specifically.

Pathophysiology

New Onset

There are a variety of different pathophysiologic pathways depending on the type of pediatric cancer. In many pediatric cancers, the different hematopoietic cell lines are affected, which in turn leads to anemia, leukocytosis, and thrombocytopenia. A normocytic, normochromic anemia results from bone marrow infiltration (seen in leukemia), as an inflammatory process from cytokine release resulting in decreased production or from direct blood loss [5]. Similar effects are seen on platelets. Hyperleukocytosis can be seen in different pediatric cancers, defined as white blood cell count above 100,000 cells/mm^3. It can result in leukostasis leading to pulmonary and CNS complications [5].

Tumor lysis is another feature of cancer pathophysiology. It can occur as a result of high tumor burden and cell turnover or from initial treatment. It leads to the release of intracellular components into the blood, including DNA and electrolytes. Multiple electrolyte abnormalities are seen in tumor lysis syndrome. Renal failure, cardiac dysrhythmias, and seizures can result [6].

Undergoing Therapy

Treatment of disease targets the rapidly dividing mutated cells in order to prevent their further growth. This has known consequences on the surrounding cells, as well as other highly replicative cells within the human body including hair, blood, and mucosal, among others. Many chemotherapeutic agents result in severe, but often anticipated, adverse side effects. Common sequelae include alopecia, mucositis, vomiting, and diarrhea, accompanied by malnutrition. Often, these complications are managed in an outpatient setting. For example, prevention of emesis with 5-HT3 antagonists is common practice [7]. Pediatric infusion centers can administer intravenous fluids and prescribe antiemetics. For more severe emesis episodes, a child may require admission or presentation to an emergency department for management of hydration [8]. Immediately following initiation of chemotherapy, a patient may develop tumor lysis syndrome, as mentioned above. In known oncologic patients, this is typically seen on initiation of therapy only, during which the patient is already admitted and being monitored and would be an unanticipated finding in an ED. Beyond these anticipated outcomes, many of the current chemotherapeutic agents have severe impacts on organs throughout the body, some which are temporary and others that are more permanent [8].

Epidemiology

Pediatric cancers are the second most common cause of death due to disease in children and adolescents, behind only accidents. In 2018, there were over 10,000 new cancer diagnoses in children under age 14. Leukemias are the most common cancer diagnosis, followed by central nervous system (CNS) malignancies in young children. Adolescents have a different distribution; CNS cancers and lymphomas are the most common forms found in this age group [4].

Health Economics

A pediatric cancer admission costs roughly $40,000, which is five times more expensive than an average general pediatric hospital admission [9]. In addition to the medical costs from hospital admissions, cancer treatments, and outpatient follow-ups, many families experience increased financial

burdens as parents commonly experience employment disruptions [9]. A recent study demonstrated that advanced childhood cancer takes a disproportionate toll on family finances when compared to other complex chronic pediatric patients [10]. In one study, nearly 45% of families of pediatric patients had an identifiable socioeconomic or resource limitation hardship [11]. All of these contextual factors are important for the ED provider to appreciate for this patient cohort.

Presentation/Diagnosis

New Onset

Many initial cancer presentations in the pediatric population are nonspecific. Typically they present with vague symptoms, such as fatigue, headache, pallor, weight loss, unexplained bone pain, or fevers [12]. In young children, any unexplained weight loss is concerning, since children normally will follow a progressive growth curve. Even those children attempting to become less obese will target limiting weight gain rather than overt weight loss unless under specific guidance or weight loss planning. There are some more specific presentations to be aware of; for example, new-onset wheezing, particularly in school-aged children, can indicate a mediastinal mass [13]. Altered mental status, focal neurologic deficits, and seizures without return to baseline could be secondary to an intracranial malignancy [12]. This can also be due to spread of a hematologic malignancy or hyperleukocytosis. Metastatic brain lesions are an exceptionally uncommon presentation of disease in children, which is notably different than in adults. Unexplained bruising, bleeding, or petechiae are suggestive of thrombocytopenia, which could be from a malignant process. Intermittent abdominal pain, vomiting, constipation, or bloody stools could indicate intra-abdominal cancer pathology. Neuroblastoma may cause catecholamine-induced hypertension with cardiomyopathy or parasympathetic-driven refractory diarrhea, a-traumatic "raccoon eyes," or abnormal movements [14]. Superior vena cava syndrome may occur in children, though is less common than in adults, and can be due to thrombus or mass compression. This presents with cough, dyspnea, and swelling or color changes to the head and neck [6]. Tumor lysis may be found at presentation due to solid organ tumors. This is due to tumor involution and breakdown due to the tumor overgrowing its vascular supply, at which time tumor cells may rapidly break down, releasing electrolytes into the bloodstream. As the kidneys attempt to filter these lysed cells, renal function decreases, and the patient may suffer acute renal failure. Likewise, the released electrolytes, most specifically potassium and phosphorus, can have significant cardiac and other systemic effects [6] (Table 35.1).

Table 35.1 Common pediatric cancers and the symptoms associated with their diagnoses

Cancer	Symptoms
Leukemia, lymphoma	Fever, bone pain, bruising, bleeding, lymphadenopathy
Mediastinal masses	Wheezing, cough
Neuroblastoma	Diarrhea, hypertension, constipation, abdominal pain, periorbital ecchymosis, cardiomyopathy
Abdominal masses	Constipation, abdominal pain, vomiting, bloody stools
Intracranial masses	Altered mental status, seizures, neurologic deficits, headache, vomiting

Undergoing Therapy

There are a wide variety of complications due to cancer treatment. Surgical interventions may cause typical postsurgical issues including bleeding, pain, or infection. Medical treatments, however, may have systemic effects posing risks to nearly every organ system.

Blood dyscrasias are one of the most common side effects of chemotherapeutic agents and are typically the result of bone marrow suppression. These include leukopenia, thrombocytopenia, and anemia. Specifically, neutropenia may be severe resulting in increased risks for viral, bacterial, and fungal infections [15]. In these patients, fever can be the first sign of a severe systemic infection, which can, in turn, result in rapid and severe decompensation, particularly if not recognized and managed quickly [15]. Due to immunosuppression, patients may not show typical early signs of infection, including pain. Additionally, symptoms of infection may be mistaken for other common medication side effects, such as fatigue or pallor. Neutropenic fever comprised about 19% of post-diagnosis ED presentations in one study, and infections (or signs and symptoms of infection) accounted for over 40% of all visits [8].

Anemia may be the result of increased bleeding or bone marrow suppression [16]. Bleeding is commonly due to thrombocytopenia, though can also be due to coagulopathic side effects of medications [5]. Most oncologic patients have treatment-specific target transfusion criteria, though it is important to recognize that the need for frequent transfusions poses a risk for iron overload [12, 17].

While there is much focus on the bone marrow suppressive implications for the hematopoietic system, there is also a risk of hypercoagulation. Overall pulmonary embolism is very rare in children, but it has an incidence of 2% on routine CT (not specifically looking for pulmonary embolism) in oncologic patients. This hypercoagulopathic side effect also increases the risk of stroke, superior vena cava syndrome, as well as other ischemic diseases [12]. Thrombosis may also be related to indwelling central lines [16].

Hemoptysis may develop due to easy bleeding as a result of low platelets, pulmonary embolism, pulmonary edema, or, very commonly, infection. Diffuse alveolar hemorrhage may also occur and is associated with hematopoietic stem cell transplant [14]. This is also found in 40% of pediatric cancer autopsies and is the most frequently missed diagnosis in pediatric cancer deaths [18].

Cardiovascular compromise secondary to treatment may present early or be delayed. Pericardial effusion and cardiac tamponade may present, similar to adults, with chest pain, respiratory symptoms (such as cough or dyspnea), tachycardia, and occasionally pulsus paradoxus [19]. Specific therapies (e.g., anthracyclines) may also cause arrhythmias as well as heart failure resulting in long-term cardiac effects [20].

In the gastrointestinal tract, one of the most frequent side effects of cancer treatment is mucositis [16]. This is due to the breakdown of mucosal tissue throughout the intestinal tract, which is painful and increases the risk of bleeding, infection, and dehydration [21]. Bowel perforation may be found on presentation or due to treatment of disease. Steroids as well as chemotherapeutic agents increase the propensity for perforation due to structural effects on the bowel [21]. Patients may present with minimal initial symptoms due to immunosuppression. One of the most severe intra-abdominal complications of chemotherapy is neutropenic enterocolitis (also called typhlitis or ileocecal syndrome). This life-threatening disease process typically presents in severely neutropenic patients and is often associated with leukemia or lymphoma. Patients report abdominal pain, which is commonly located along the colon and often in the right lower quadrant. They may also have fever or diarrhea [22]. It is believed that this is due to chemotherapy causing friable mucosa vulnerable to infectious infiltration [22].

Pancreatitis can be caused by a variety of therapeutic agents including corticosteroids, trimethoprim-sulfamethoxazole (to prevent immunosuppression-related pneumocystis pneumonia), asparaginase, mercaptopurine, and cytarabine [14].

Renal system injuries are categorized as subacute and acute. Subacute injury is often due to treatment modalities and is less likely to present in extremis to the ED, as these patients are closely monitored for blood dyscrasias and electrolyte abnormalities during treatment [23]. Acutely, renal injury may occur due to tumor lysis syndrome. Hemorrhagic cystitis is a common complication of chemotherapy, specifically cyclophosphamide [24].

Graft-versus-host disease can cause a myriad of symptoms throughout the entire body. This typically occurs following allogeneic bone marrow transplantation. Symptoms may include skin findings, dyspnea, myalgias, fatigue, fever, liver disease, and other gastrointestinal effects [14].

Electrolyte abnormalities are also possible with a variety of chemotherapeutic agents (Table 35.2) [25–38]. Specifically vincristine, cyclophosphamide, and cisplatin are associated with syndrome of inappropriate anti-diuretic hormone (SIADH), resulting in hyponatremia [16].

Table 35.2 A review of common severe side effects for patients on various chemotherapeutic agents

Medication	Life-threatening complications
Asparaginase	Hemorrhage, coagulopathy (thrombosis, emboli) hypotension, pancreatitis, bronchospasm, decreased blood counts
Busulfan, myleran	Thrombosis, electrolyte abnormalities, severe fatigue, renal damage, decreased blood counts
Carboplatin	Renal damage, decreased blood counts, electrolyte abnormalities, bone marrow suppression
Cisplatin	Decreased blood counts, allergy, renal damage, electrolyte abnormalities, peripheral neuropathy
Cyclophosphamide	Bladder damage (hemorrhagic cystitis), oral sores, infertility
Cytarabine	Decreased blood counts, fever, flu-like symptoms, aseptic meningitis, neurotoxicity, intestinal necrosis, toxic megacolon, pancreatitis, rhabdomyolysis
Daunorubicin, doxorubicin	Decreased blood counts, heart failure, arrhythmias (note also changes in the color of sweat and urine)
Etoposide	Hypotension, peripheral neuropathy
Hydroxyurea	Decreased blood cell counts (macrocytosis, neutropenia), infection, severe central nervous system disease, thrombosis
Mercaptopurine	Decreased blood counts, fever, pancreatitis, renal toxicity, mucositis, pulmonary fibrosis
Methotrexate	Decreased blood counts, diabetes, intestinal perforation, dizziness, headache, focal neurologic findings, rashes, infertility, severe renal disease, intestinal bleeding, mucositis, tumor lysis syndrome, obstructive and restrictive lung diseases
Thioguanine	Decreased blood counts, portal hypertension, liver failure
Thiotepa	Intracranial hemorrhage, seizure, mucositis, decreased blood counts, infertility, asthma
Topotecan	Myalgias, decreased blood counts, dyspnea
Vincristine	Nerve injuries (central and peripheral), ischemic heart disease, decreased blood counts, intestinal perforation and necrosis, decreased blood counts. Hepatic sinusoidal obstruction

This list excludes common symptoms that are unlike to present to an emergency department or require significant intervention—such as nausea and vomiting [25–38]

Evaluation

New Onset

Given the typical, vague initial presentation for pediatric cancers, there is no set ED protocol for evaluation of these patients. Work-up should be based on history and physical

examination. Laboratory studies may include complete blood count with differential, electrolytes, renal function, lactate dehydrogenase, and uric acid. Imaging may be indicated, such as chest x-ray, head CT or MRI, abdominal ultrasound, or extremity imaging. Consultation with hematology/oncologic colleagues will help guide additional laboratory and imaging studies.

When there is concern for tumor lysis syndrome, lab work should focus on electrolytes, as well as lactate dehydrogenase, uric acid, calcium, and phosphate [6]. Elevated potassium, phosphate, urea nitrogen, uric acid, and lactate dehydrogenase, accompanied by low calcium, are supportive of this diagnosis [6].

Undergoing Therapy

Each therapeutic tool has different, treatment-specific risks. Radiation therapy typically causes local inflammatory reactions. While nearly all chemotherapeutic medications can result in decreased blood counts due to bone marrow suppression, as well as nausea, vomiting, anorexia, or alopecia, some have more severe complications specifically associated with their use. (See Table 35.2 for high-risk complications associated with specific medications.) Asking the patient or family member to identify the medications may help the provider assess for the risk for specific diagnoses.

In general, patients with oncologic processes who are undergoing treatment require rapid ED assessment and prompt placement in a treatment room isolated from other patients and more specifically from patients with infectious symptoms [39]. These oncologic patients typically warrant blood work including complete blood counts with differential, allowing assessment for neutropenia, anemia, and thrombocytopenia. Absolute neutrophil count should be determined using the following formula: (percent neutrophils + percent bands) × white blood cells × 100 [40]. A neutrophil count below 1000 cells/mm^3 is considered neutropenic, and below 500 cells/mm^3, severely neutropenic [4]. A basic metabolic panel assesses hydration and electrolyte status. Finally, liver function testing and pancreatic tests, specifically lipase, are often warranted in patients with nonspecific infection symptoms and should be obtained in patients with any gastrointestinal symptoms [16]. The emergency physician should communicate with the patient's oncologist or a member of their team early in evaluation and management to ensure appropriate medications and treatments are given and risk factors are identified. Infectious evaluation of pediatric patients should include complete blood counts, cultures (including cultures from any central access points), urinalysis, and urine culture. If there is concern for neutropenia, urine should not be obtained via catheter due to the risk for introduction of infection. Concern for meningitis may require meningitic dosing of antibiotics and avoidance of lumbar puncture in a thrombocytopenic patient [15].

Diffuse alveolar hemorrhage may manifest as bilateral opacities on chest x-ray or ground-glass opacities on CT. Chest radiographs may reveal cardiogenic pulmonary edema and cardiomegaly [14]. For pulmonary embolism, CT angiography is the test of choice. MRA, while having some utility in adult patients, has not been assessed for pediatrics and therefore has an unclear role. Nuclear medicine or interventional radiology studies are rarely utilized in children [14].

If there is concern for pericardial effusion and/or tamponade, chest x-ray may reveal a water-bottle heart appearance; though this has some specificity, its sensitivity is poor [12]. Echocardiography is the test of choice to evaluate pericardial effusion.

Plain abdominal radiographs may find thickened bowel walls or air-fluid levels, suggesting graft-versus-host disease, typhlitis, or other intra-abdominal pathology. Ultrasound may also be utilized in pediatric patients to assess bowel wall thickness, with levels over 3 mm suggestive of thickening [14]. Ultrasound avoids radiation and allows more accurate measurement of bowel wall thickness than CT. Pneumatosis intestinalis indicating typhlitis may be seen on a screening x-ray, but CT should be performed as well, assuming the patient is stable enough for transport.

Patients with pancreatitis do not necessarily require emergent imaging; however, ultrasound is the evaluation of choice. Again, radiation is limited, and an enlarged or hypoechoic pancreas, including pseudocysts, may be seen. For patients in whom ultrasound is equivocal or unavailable, CT scan is an appropriate modality for assessment [14]. Of course, pediatric cancer patients may have typical diseases of childhood (e.g., appendicitis, intussusception) and should have standard of care performed for these diagnoses as well.

Management

New Onset

The management of new cancer diagnoses in the ED is most frequently supportive. As mentioned above, consultation with pediatric hematology and oncologic is important. Their expertise will guide the emergency physician through the necessary primary evaluation. Initial presentations can include tumor lysis and hyperleukocytosis, both of which are treated initially with intravenous fluids. Allopurinol and rasburicase can be added as needed to treat tumor lysis [6]. Hyperleukocytosis may require leukapheresis and high volume intravenous fluids [12]. These additional medications should only be added when discussed with pediatric hematology and oncologic.

Patients with mediastinal masses with concern for airway compression may require intubation. These patients also highlight the importance of imaging for new wheezing. Management should not include steroids as this can impact the tissue and limit the ability to make an accurate diagnosis on biopsy.

Neuroblastoma patients may require blood pressure management, when experiencing blood pressure elevations above the 95th percentile for age and height or if it is associated with end-organ dysfunction.

A key component to the initial management of a new cancer diagnosis is the discussion with the patient and their family. Discussing the diagnosis first with the parents is vital as it allows the parents to cope with this life-changing news. In addition, it allows for the parents and physician to consider the most appropriate way to tell the patient. The patient should be informed using age-appropriate terminology. A child life specialist may assist in this discussion with the patient and family when one is available. Ideally, children who are old enough to understand would be informed of the diagnosis shortly after parents are notified. There is evidence that delays in informing children can result in distrust of both parents and the medical system [41].

Undergoing Therapy

Patients presenting with isolated blood dyscrasias may require transfusion to meet the goals of their therapeutic plan. Blood should be irradiated and leukocyte reduced [17]. Additionally, cytomegalovirus (CMV) is less common in pediatric than adult patients, and CMV-negative blood products should be administered unless there is documentation that the patient has tested positive for CMV antibodies [5]. Transfusions in pediatrics are typically administered based on weight, 10 ml/kg up to 250–300 ml (the typical adult unit of blood), and can be expected to raise hemoglobin levels by 2–3 g/dL [16].

Coagulopathy resulting in increased clot burden may require anticoagulants. This must be done cautiously in order to avoid bleeding and worsening anemia [5].

Fever in the setting of known or possible neutropenia is considered an emergency, and these patients require prompt antibiotic therapy. While ampicillin-sulbactam and cefepime are often cited as the antibiotics of choice, therapy should be tailored to the patient's past sensitivity and resistance patterns when possible [15, 16]. If this information is not readily available to the emergency provider, the patient's oncologist should be consulted. In ill-appearing patients, the addition of vancomycin should be added to management early in treatment [15].

Pericardial effusion may require placement of a pericardial drain or surgical intervention with a pericardial window [19]. In cases of tamponade physiology with cardiovascular collapse, emergent pericardiocentesis may be indicated [29].

Pancreatitis is treated similarly in children as in adults, with initiation of intravenous fluids and bowel rest [42]. Intra-abdominal processes such as typhlitis or graft-versus-host disease require the initiation of antibiotics and surgical consultation [22].

Electrolyte repletion should be monitored closely and based on the severity of the imbalance [16].

Of note, the specific diagnosis of COVID-19 has not been shown to have significant morbidity and mortality in pediatric oncologic patients to date, though understanding of this disease and its impact on this patient population is actively changing [43].

Disposition/Follow-Up

New Onset

Unlike the adult population, new cancer diagnoses in pediatric patients typically require hospital admission. During the admission, thorough work-up of the new cancer will occur with discussions of management options. Depending on the cancer type, initiation of treatment may occur during this admission. Coordination of care is key during the admission to facilitate accurate diagnosis and treatment, as well as provide the necessary patient and family support.

Undergoing Therapy

The majority of pediatric patients who present to an ED while undergoing chemotherapy will require hospital admission [8]. Some exceptions include those who require simple transfusions or patients with concern for neutropenic fever who both appear well and are not found to have neutropenia. Disposition of all patients with treatment-associated complications should be in conjunction with the patient's primary oncologic team.

Prognosis/Treatment

Over 80% of children will pass the 5-year survivor mark. In a 2020 review by Horn et al., the overall mortality rate of pediatric patients with a cancer diagnosis was estimated to be 23% with 73% of deaths resulting from their primary cancer and 27% from a competing cause [44]. Deaths from competing causes were most closely associated with Hodgkin lymphoma and gonadal germ cell tumors, both highly treatable with current chemotherapeutic agents. In both of these cancers, as well as with osteosarcoma, the cause of death is often a secondary cancer that may be treatment-related [44].

Complications

With rapid advances in therapy, many more pediatric patients may survive into adulthood. Long-term sequelae of some treatments used in children are still being discovered. It is known that some patients have secondary treatment-related cancers, as well as long-term cardiac effects [44]. It is also important to note that pediatric cancer survivors have a higher than typical risk of suicide. This typically occurs in the third or fourth decade of life, indicating a need for long-term psychosocial support, and not just during active treatment [44]. It is important for emergency physicians to be aware of this and consider previous cancer as a risk factor when screening children and adults in the ED.

Common Pitfalls

New Onset

The most common pitfall of diagnosis is not considering an oncologic process in the differential of a vague complaint. A missed diagnosis can delay care or in severe cases be fatal. Additionally it is important avoid steroids in patients who present with new-onset wheezing without considering the possibility of a mediastinal mass.

Undergoing Therapy

The most common pitfall in patients receiving treatment is not recognizing the severe impact chemotherapeutic agents have on typical symptom presentations. The immunosuppressive therapies may also suppress typical systemic symptoms of disease.

Prevention/Upstream Drivers

Unlike many adult oncologic processes, there are very few pediatric cancers with specific, preventable causes. There is a significant increase in cancer among pediatric patients receiving organ transplants, primarily due to Epstein-Barr virus infection in conjunction with immunosuppression to prevent rejection [45]. Socioeconomics has not been linked to leukemic processes [46]. While some studies speculate that children born via artificial reproductive technologies have a higher risk of cancer, some recent studies refute this claim [47, 48]. Birth defects are associated with increased cancer risk, with some defects related to specific cancers [49]. Overall, genetic predisposition is believed to be the more common cause of disease than specific environmental exposures [50]. Prevention and recognition of secondary treatment-related complications should be enhanced with close monitoring by the patient's oncologist.

Future Needs/Vision

Pediatric oncologic is a rapidly changing field of medicine. Within the past 20 years, survival rates continue to improve. The rise of monoclonal antibody use in adults may soon be employed in pediatrics as well, with studies already being conducted with neuroblastoma [2, 3]. Emergency physicians should be aware that the complications of these medications in children are not well known; however, they may be similar to those in adults. Current studies suggest that the same weight-based dosing results in lower plasma levels in infants and children, which must be taken into consideration for future management [51].

Health Services/Resource Utilization

Studies show that, even with the same malignancy, pediatric patients, and specifically adolescent patients, have higher costs associated with treatment compared to adults. These increased costs are likely related to increased rates of hospitalization [52].

Policy/Legislative

Medicolegal

The most important component of ED management of patients with known oncologic processes is rapid evaluation. In these patients, as with every neutropenic fever patient, time is essential for infection control and hemorrhage management [15]. When available, notification prior to arrival with pre-ordering treatment for specific diagnoses, such as neutropenic fever, may improve time to administration of live-saving antibiotics.

Documentation/Quality Indicators

The main quality indicators in pediatric oncologic are focused on time to antibiotics in the setting of neutropenic fever. It is important to document the initial examination in detail as it may change rapidly, as well as repeat examinations that give a clear picture of any changes that occur.

Key Points/Pearls

Pattern recognition is key in pediatric cancer diagnosis. Staying vigilant is vital to avoid missing key diagnoses. Weight loss in children, unexplained bruising or bleeding, persistent and unexplained pain in back or extremities, new-onset wheezing, and mental status changes are particularly pertinent to cancer diagnoses.

The emergency provider should maintain a low threshold for detailed evaluation of the oncologic patient undergoing active therapy.

Hyperleukocytosis and Leukostasis

36

Sharleen Yuan, Samantha J. Yarmis, and Kami M. Hu

Case Study

A 78-year-old male with a history of hypertension, coronary artery disease, and acute myelogenous leukemia is brought in by family for altered mental status. His family members state that he has not acted like himself for the last few days and has had a steady functional decline for the last few weeks to months. Additionally, he has experienced worsening shortness of breath with a fever of 101.2 degrees Fahrenheit (°F) that developed "the other day." The patient is alert but only oriented to self, which is inconsistent with his baseline. He has had no known sick contacts and is up to date on his immunizations. The patient denies any chest pain, upper respiratory symptoms, nausea, vomiting, diarrhea, numbness, tingling, or weakness. He has no history of alcohol or drug use. The rest of his history is unremarkable.

Physical Exam

Vitals: Temp 100.8 °F, BP 150/75 mmHg, HR 98 bpm, RR 32/min, O_2 saturation 89% on room air. General: Patient alert, but not oriented to place or time. Appears tachypneic when speaking but is in no acute distress. HEENT: Normal sclera, intact extraocular movements, pupils equal and reactive to light. Petechiae noted on buccal mucosa intraorally. Tympanic membranes are normal. Trachea midline. Cardiovascular: Regular rate and rhythm, with good S1 and S2. No murmurs, rubs, or gallops. Pulses 2+ bilaterally. Pulmonary: Rales bilaterally with faint expiratory wheezes throughout. Abdomen: Normoactive bowel sounds. Nontender, non-distended, with the spleen tip palpable 3 cm below the costal margin. Neuro: Cranial nerves intact to testing. Motor strength and sensation intact. Negative Romberg, normal gait. Skin: Scattered petechiae over bilateral upper and lower extremities. Extremities: Warm, well-perfused, without edema.

Laboratory Values

White blood cell count, 125 × 10^3/μ[micro]L (89% blasts); hemoglobin, 6.6 g/dL; hematocrit, 19.9%; platelets, 9 × 10^3/μ[micro]L; sodium, 137 mmol/L; potassium, 5.3 mmol/L; chloride, 104 mmol/L; bicarbonate, 22 mmol/L; blood urea nitrogen, 25 mg/dL; creatinine, 2.4 μ[micro]mol/L; calcium, 9 mg/dL; magnesium, 2.9 mg/dL; phosphorus, 4 mg/dL; troponin, <0.04 ng/mL; uric acid, 5.5 mg/dL; lactate dehydrogenase, 432 IU/L.

Imaging

Chest radiograph: Bilateral interstitial infiltrates without cardiomegaly, masses or effusions.

Management

The patient was determined to have hyperleukocytosis causing cerebral leukostasis. He received isotonic intravenous (IV) fluids in the emergency department (ED) and was transfused 1 unit of packed red blood cells and 1 pack of platelets. The on-call oncologist was consulted and hydroxyurea was started with a plan for leukapheresis given his altered mental status and worsening WBC count. He was admitted to the cancer service to further monitor his symptoms and was also treated with allopurinol for mild tumor lysis syndrome. By early the next morning, the patient had demonstrated a

mild decrease in WBC count with the hydroxyurea alone, and there were extensive conversations with the patient's family regarding placement of a leukopheresis catheter and overall goals of care. In the end, the family decided on palliative measures and the patient was transitioned to inpatient hospice care.

Introduction

The leukemias are a broad group of hematologic malignancies encompassing acute myeloid leukemia (AML), chronic myeloid leukemia (CML), acute lymphoblastic leukemia/lymphoma (ALL), and chronic lymphocytic leukemia (CLL) [1]. Given the prevalence of these malignancies, it is highly likely that the average emergency physician will encounter a patient at their first presentation for medical care. This chapter will discuss the ED management of hyperleukocytosis and resulting leukostasis, providing insights into necessary diagnostics and crucial steps for treatment. Other complications of leukemia are discussed elsewhere in the text.

Hyperleukocytosis is most often defined as a white blood cell (WBC) count of greater than 50,000 or 100,000 cells/microliter, but complications can occur at lower numbers, and absolute WBC count does not correlate directly with symptoms [2]. Although coined specifically to refer to the acute phase of CML, the term "blast crisis" is sometimes used to describe any hyperleukocytosis with predominant blasts. Hyperleukocytosis causes symptoms when the high concentration of circulating cells leads to leukostasis and impaired microvascular circulation causing organ damage, most commonly affecting the lungs and brain. Additional complications of hyperleukocytosis include tumor lysis syndrome (TLS) and disseminated intravascular coagulation (DIC), both independently life-threatening entities. Early recognition and treatment of this disease process is crucial to minimize the morbidity and mortality of these patients and to optimize them for attempts to cure of malignancy.

Epidemiology

Globally, leukemias are the eighth most commonly diagnosed cancer with 600,000 new cases annually and the ninth most common cause of cancer mortality with 353,000 deaths each year [3]. Of these, AML and CLL have the highest annual incidence rates with 190,000 and 191,000 new cases, respectively, while ALL carries the highest yearly mortality with approximately 110,000 deaths annually [3]. The overall incidence of leukemias has increased by 26% from 2005 to 2015, largely due to an aging global population as well as overall population growth [3]. With respect to pediatric patients, leukemias are the most common childhood cancer and the leading cause of both childhood and young adult (age 15–29 years) cancer deaths worldwide [3].

In the United States, leukemias are the 11th most commonly diagnosed cancer [3] with a 1.5% lifetime risk of developing any type of leukemia [4] and the sixth most common cause of cancer deaths each year. While there is a relatively even distribution between acute and chronic leukemia diagnoses annually, when divided by type, CLL is the most commonly diagnosed leukemia, followed by AML, CML, and ALL. The overall number of annual deaths from acute leukemia is two-thirds higher than those from chronic leukemias [5, 6] with AML responsible for the most deaths, followed by CLL, ALL, and CML [3].

Rates of leukemia vary by age and by ethnicity. Overall, acute leukemias are more common in non-Hispanic whites than in other ethnicities [7]. In terms of age, AML demonstrates a bimodal distribution, with a peak in infancy followed by a second peak beginning in young adulthood, with a median age at diagnosis of 69 years [8]. ALL also has a bimodal distribution with a slightly later peak in childhood and then a smaller second peak after the age of 60 [7], with a median age at diagnosis of 15 years. The median age at diagnosis is 65 years for CML and 70 years for CLL [8].

Overall survival for all forms of leukemia has improved, from 33% in 1975 to 59% in 2005 [4], but these gains in survival have been unevenly distributed with the greatest gains for patients with ALL, patients in younger age groups, and patients who are white. For the acute leukemias, the poorest survival is in those under 1 year of age, after which point the likelihood of survival is highest in older children and young adults and subsequently decreases with age [7]. Survival also varies widely by location; childhood ALL, for example, carries an overall survival rate ranging from 15% to 90% depending on the country, reflecting disparities in access to care [3]. As survival from childhood leukemias has improved, treatment-related mortality has accounted for an increased number of deaths, especially from ALL [9]. There are over 450,000 leukemia survivors in the United States [8], with several factors contributing to the increased survival over time. These factors include more intensive and standardized protocols for pediatric patients, the development of tyrosine kinase inhibitors (TKIs) and stem cell transplantation, and improved techniques for diagnosis and residual monitoring, including flow cytometry, polymerase chain reaction (PCR), and fluorescence in situ hybridization (FISH) testing [1, 4, 6].

Epidemiologic data on frequencies of ED presentations by patients with leukemia are scarce. A 2017 analysis of the Nationwide Emergency Department Sample found that of

the 29.5 million ED visits by patients with a cancer diagnosis over a 7-year period, 3.1% of those were by patients with a diagnosis of leukemia [10]. The existing published data on general ED usage indicates that solid tumors make up a larger contingency of ED visits [10, 11], but a case series from MD Anderson Cancer Center found that patients with leukemia accounted for the second highest percentage of annual visits by cancer patients (12.7%) with the highest admission rate for a specific cancer (83%) [12].

The incidences of hyperleukocytosis and leukostasis are dependent on the type of leukemia, and the presence or absence of certain genetic mutations affects an individual's risk. Perhaps because myeloid cells are larger than lymphoid cells, leukostasis occurs most often in AML and CML and can occur at lower white blood cell counts in the lymphocytic leukemias [13]. The incidence of hyperleukocytosis in adult patients with AML ranges from 5% to 13%, while it ranges from 10% to 30% for patients with ALL. While hyperleukocytosis is common in CLL, leukostasis itself is rare [14]. Hyperleukocytosis is similarly common in CML, but with more frequent clinical leukostasis occurring most often during blast crisis. Hyperleukocytosis is associated with markedly higher early mortality (approximately 20% in the first week) and modestly reduced 5-year overall survival for those who survive the initial phase [2].

Health Economics

The cost of general cancer care is rising rapidly [12, 15], and the management of leukemia is no exception. There are multiple drivers of healthcare expenditures in treating leukemia, including the cost of medications, the costs associated with the provision of both clinic and in-hospital care, and the costs related to the management of both expected and unexpected treatment-related complications [15, 16]. Treatment strategies for leukemia have expanded to include targeted oral chemotherapies and immunotherapies which often carry decreased treatment-related morbidity and mortality and the potential for increased longevity. These medications are often much more expensive than traditional chemotherapy, however, and are a significant driver of the increased costs of modern leukemia management, as exemplified by the 300% increase in per-patient lifetime cost of CLL treatment since the development of newer oral targeted therapies [15].

Treatment costs vary by leukemia subtype and type of treatment. Costs to the healthcare system range from approximately $88,000 per chronic leukemia patient to more than $450,000 per acute leukemia patient over the first year after diagnosis, with highly variable costs to patients themselves [17]. The need for inpatient care is a major driver, accounting for 55–70% of costs in the United States, depending on leukemia type [17–19], and hospitalizations for leukemia cost more per stay than any other type of cancer [20]. Direct cancer treatment, specifically anticancer drugs and hematopoietic stem cell transplantation (HSCT), accounts for a large portion of healthcare costs [17, 19].

For patients with incurable malignancy or poor prognosis, severe comorbid illness, and poor functional status or who have goals of care that focus on comfort rather than aggressive measures, palliative care consultation is associated with lower rates of intensive care unit (ICU) admission and lower healthcare costs, although such consultations rarely occur early [12, 21, 22].

ED visits are common among leukemia patients; in one study, 81% of patients with acute leukemias had at least one unplanned ED visit and/or hospitalization within the first year [23]. Common reasons for ED visits include fever, bleeding, gastrointestinal complaints, and respiratory symptoms [18]. Robust data on the cost of these unplanned visits as a portion of total leukemia healthcare expenditures is lacking.

Pathophysiology of Leukemia and Leukostasis

Both acute and chronic leukemias arise from abnormalities in hematopoiesis that lead to the proliferation of abnormal cells. The pathophysiology of each will be briefly discussed with the acknowledgement that the processes are complex and not yet fully understood. The increased availability of molecular techniques has led to recognition of greater heterogeneity among the leukemia subtypes than was previously known, and different subtypes of each disease may have different causal mechanisms [18].

In normal hematopoiesis, pluripotent hematopoietic stem cells in the bone marrow give rise to all hematologic cells, with various biochemical factors influencing their differentiation into common lymphoid or common myeloid progenitor cells [24]. Common lymphoid precursors mature within the lymphoid organs to become natural killer cells, T lymphocytes, and B lymphocytes [25], while common myeloid progenitor cells eventually give rise to basophils, neutrophils, eosinophils, macrophage, platelets, and erythrocytes [24]. Blast cells are the early manifestations of both lymphoid and myeloid cells. In healthy individuals, they comprise less than 5% of the cells in the bone marrow and should not be found in the peripheral blood.

In CML, there is abnormal proliferation of the myeloid lineage. The initial chronic phase, characterized by the accumulation of myeloid progenitors and mature myeloid cells in the blood and extramedullary tissues, is followed after 3 to 4 years by arrest of myeloid cell maturation and a transition to blast crisis [26]. Blast crisis is technically defined as the presence of greater than 20% blasts in the blood or bone

marrow with demonstration of extramedullary blast accumulation [1, 27, 28]. In over 90% of cases, patients have a characteristic acquired genetic abnormality, the Philadelphia chromosome, which is the result of translocation between the long arms of chromosomes 9 and 22 [t(9;22)], resulting in the creation of the BCR-ABL fusion gene [26].

AML, as its name suggests, does not have the initial indolent phase seen in CML. It is characterized by uncontrolled clonal expansion of myeloid progenitor cells, i.e., blasts. The accumulation of blasts interferes with the production of normal blood cells of all lineages – red blood cells, platelets, and normal white blood cells – leading to the common signs and symptoms of fatigue, easy bleeding and bruising, and fever and infection, secondary to anemia, thrombocytopenia, and neutropenia, respectively [16, 29]. Acute promyelocytic leukemia (APL, APML), an important subtype of AML with its own prognosis, complications, and specific treatment considerations, accounts for 5–10% of cases and is characterized by the translocation t(15;17) [30]. Several other mutations and cytogenetic abnormalities play key roles in recent targeted therapies [31].

A related malignancy, myelodysplastic syndrome (MDS), is characterized by cytopenias resulting from abnormal, ineffective bone marrow [24, 32]. An enormous variety of genetic mutations have been implicated in the development of MDS, with varying effects on prognosis [32]. Some subtypes of MDS are associated with excess, but fewer than 20%, blasts. The presence of greater than 20% blasts defines AML, and, in fact, having MDS dramatically increases the risk of developing AML [1, 33].

ALL occurs due to the clonal expansion of lymphoid progenitor cells which proliferate and accumulate in the bone marrow and other tissues [34]. Different subtypes are characterized by the type of lymphocytes involved, i.e., B or T cells, as well as the specific causative cytogenetic abnormalities, which have important prognostic and therapeutic implications. A complex interplay between multiple genetic mutations and environmental factors ultimately results in the development of ALL [35].

CLL is characterized by the accumulation of mature-appearing B lymphocytes in the blood, bone marrow, or other lymphoid tissues [36]. As in ALL, multiple incompletely understood genetic mutations and other factors result in CLL and determine severity and prognosis [37].

As already mentioned, hyperleukocytosis can cause a hyperviscous state and decreased tissue perfusion, although the fact that particularly high WBC counts may not always cause symptoms is still not fully explained. Theories regarding specific pathophysiology include the consideration that progenitor cells (blasts) are generally larger and less flexible than mature cells, making them more likely to block microvasculature. It has also been proposed that the rapid division of malignant cells, potentially in combination with the body's response to microvascular ischemia, releases specific cytokines and chemoattractants that further attract blast cells and activate the coagulation cascade, worsening the overall prothrombotic milieu [13]. The ongoing cell turnover of such a high volume of cells often leads to a pre-chemotherapy "spontaneous" tumor lysis syndrome. This turnover is also thought to increase the circulating concentration of tissue factor, a procoagulant, with ongoing endothelial damage and hypoxic events predisposing to the development of disseminated intravascular coagulation [2, 13].

Presentation

Leukostasis can be difficult to recognize, as its clinical manifestations mimic other common conditions such as infection, intoxication, acute cerebrovascular accident, and myocardial infarction [2]. The most common presenting symptoms are those of respiratory or neurologic involvement. Patients with pulmonary complaints may present with symptoms ranging from mild dyspnea on exertion to respiratory distress and hypoxia requiring mechanical ventilation. The pulmonary exam, similarly, may range from relatively normal to demonstrating focal findings or widespread abnormalities. Neurologic symptoms can range from focal neurologic deficits to generalized confusion or weakness, blurred vision, or decreased alertness, and a fundoscopic examination may reveal retinal hemorrhages or papilledema. Despite an elevated white count, patients with hyperleukocytosis actually have a functional neutropenia due to decrease in the amount of normal white blood cells, and up to 80% of patients with leukostasis develop fevers, most likely due to increased inflammation as well as high risk of concurrent infection given the patient's immunosuppressed state [28]. The electrolyte abnormalities associated with TLS may cause patients to present with arrhythmia, palpitations, or [pre]syncope, although these are not classic presentations of hyperleukocytosis. Leukostasis can affect any part of the body; the emergency physician should be wary of other organ system dysfunction such as renal insufficiency or myocardial ischemia and perform a thorough physical exam and appropriate diagnostics once hyperleukocytosis is identified [38]. Some common manifestations of leukostasis are listed in Fig. 36.1.

ED Evaluation

Because of the nonspecific nature of these patients' presenting symptoms, the diagnosis of leukemia and leukostasis are often not considered until bloodwork returns with an elevated WBC count, but once hyperleukocytosis is recognized, it is important to revisit the patient's presentation. Ensuring a thorough history is key, utilizing collateral from chart review

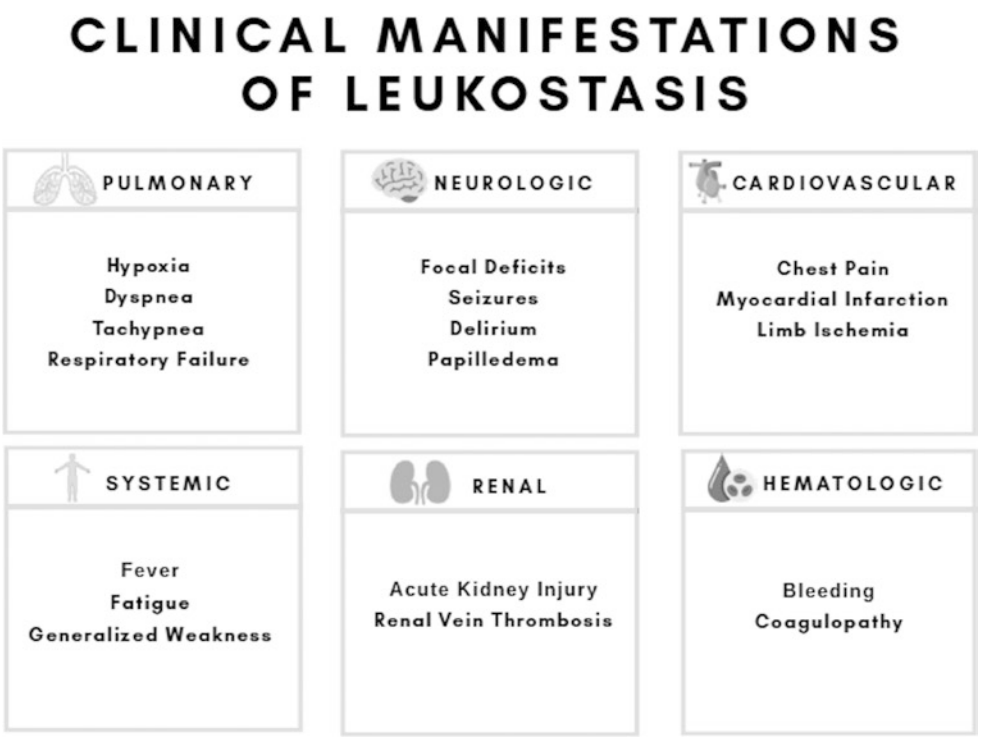

Fig. 36.1 Common manifestations of leukostasis

and available family or friends if the patient is unable to provide it. It may also be necessary to reexamine the patient to ensure all signs of potential organ dysfunction have been identified.

The gold standard diagnostic test for leukostasis is tissue biopsy demonstrating leukocyte-clogged blood vessels [39]. but this test is rarely performed. The diagnosis is now most often made based on a combination of clinical findings and diagnostics indicative of organ dysfunction in the setting of hyperleukocytosis. Laboratory testing in the ED should include a complete blood count (CBC) with differential, peripheral blood smear, complete metabolic panel (CMP) including magnesium and phosphorus levels, prothrombin time with international normalized ratio (PT/INR), partial thromboplastin time (PTT), fibrinogen, D-dimer, fibrin-split products, uric acid, lactate dehydrogenase (LDH), and type and screen. A troponin should be collected in patients with chest discomfort or other concern for myocardial ischemia, and a blood gas obtained for pH determination in patients with metabolic acidosis and acute renal failure. A venous blood gas (VBG) is usually the most appropriate as arterial blood gas (ABG) oxygenation values are inaccurate due to ongoing oxygen consumption by the many leukocytes in the blood collection tube [28]. This "pseudohypoxemia" can be partially mitigated by sending the ABG to the lab on ice. Blood cultures should be obtained in febrile patients, with urine culture added if urinalysis is consistent with infection and sputum culture if patient has a productive cough. An electrocardiogram should be obtained to evaluate for signs of leukostasis-induced ischemia or other pathology secondary to metabolic abnormalities.

Imaging should target the symptoms exhibited by the patient. In patients with respiratory complaints, a chest x-ray should be obtained, and if clear, a non-contrast computed tomography (CT) scan of the chest should be pursued. Chest imaging may demonstrate a wide range of abnormalities, including interstitial edema, consolidation, focal or diffuse airspace opacities, and effusion or other infiltrates [40]. While malignancy is generally associated with an increased risk of venous thromboembolism, patients presenting with new leukemia and hyperleukocytosis prior to treatment are much more likely to have pulmonary leukostasis (reported incidence of 30–34% in AML) [41, 42] than pulmonary embolism (PE) (reported incidence of 3.4% to 5% for all leukemias) [43]. Indiscriminate evaluation by contrasted CT angiography should therefore be avoided if possible, given the high risk of renal dysfunction in this population. Although specific leukemias, such as CML and APL, carry higher risks for the development of venous thromboemboli (VTE), they are most often treatment-related, whether associated with the presence of a central venous catheter or the chemotherapy used [43, 44]. In cases of legitimately high concern for PE, CT must be pursued as ventilation-perfusion (VQ) scans have limited ability to discriminate between VQ mismatch caused by leukostasis versus embolism [45]. A non-contrast CT of

the head should be included if there are neurologic symptoms, and it may demonstrate ischemia, hemorrhage, or intracranial mass [46–48]. Depending on the neurologic deficits present, a nondiagnostic CT may indicate a need for further evaluation with magnetic resonance imaging (MRI). The presence of abdominal tenderness on exam may warrant imaging of the abdomen, whether by ultrasound or CT.

ED Management

The mainstay of ED leukostasis management is supportive therapy adhering to the ABCs – or CABs – of emergency medical care, as well as management of concomitant TLS or DIC, if present. While the basics of TLS and DIC treatment will be touched upon here, more thorough discussion can be found elsewhere in the text, and a summary of treatments can be found in Fig. 36.2.

Circulation

Hypotension is not classically seen in this patient population unless they also have severe metabolic acidosis or shock due to another etiology, but isotonic crystalloid IV fluids are a key component of leukostasis treatment for the purpose of hemodilution to decrease blood viscosity. Intravenous fluid administration also helps manage concomitant TLS and preserve kidney function. In patients without a reduced ejection fraction, it is recommended that IV fluids be given to a target urine output of 2 ml/kg/hr [49]. The use of furosemide may be considered if urine output falls below 100 ml/hr, in order to allow continued IV fluid administration, but should be used with caution as diuretics can worsen hyperviscosity and are relatively contraindicated in hypotension unrelated to cardiac volume overload. If the blood pressure is not adequately supported with hydration, a vasopressor such as norepinephrine should be used to maintain a mean arterial pressure (MAP) of greater than 65 mmHg. In patients with decompensated heart failure, use of an inotrope such as epinephrine is more appropriate, keeping in mind that at higher doses (above 0.05 mcg/kg/min) there is more alpha-1-receptor effect and pulmonary vasoconstriction may ensue, worsening potential cardiopulmonary instability.

There should be high suspicion for DIC in patients experiencing hemorrhage, whether pulmonary, intracranial, or another source. If the patient is not bleeding or is hemodynamically stable with small volume blood loss, aggressive packed red blood cell transfusion is not recommended due to its likelihood of worsening hyperviscosity. In patients without hemorrhage, early platelet transfusions should be performed to maintain platelet counts greater than 20,000 µ[micro]L to avoid spontaneous bleeding [50]. If the patient has CNS or intraocular hemorrhage, the platelet goal should be greater than 100,000 µ[micro]L, with a goal of 50,000 µ[micro]L for bleeding at other sites. Patients with DIC and fibrinogen levels less than 150 mg/dL should receive cryoprecipitate transfusion [51].

Patients with acute renal failure, whether secondary to renal ischemia from leukostasis, the renotoxic effects of lysed cell contents, or a combination of both, may exhibit a severe metabolic acidosis depending on the severity of renal injury, with secondary vasodilation and hypotension [52]. Consultation to the nephrology team may be indicated for emergent renal replacement therapy if there is not marked improvement with IV fluids, but the patient with hemody-

Emergency Department Leukostasis Mangement

Leukostasis	Intravenous Fluids	Hydroxyurea	Leukapheresis
Tumor lysis	Intravenous fluids	Address electrolyte abnormalities	Allopurinol +/– Rasburicase
DIC	Cryoprecipitate	Platelets (If below goal)	Red blood cells*

Fig. 36.2 Summary of ED treatments for leukostasis management. DIC = diffuse intravascular coagulation. *Red blood cell transfusion for hemorrhagic shock only, until white blood cell count decreased

namic instability and metabolic acidosis with a pH less than 7.2 should be temporized with IV sodium bicarbonate infusion [53] in addition to support with vasopressors if needed.

Airway/Breathing

The most acutely pressing issue for patients with leukostasis can be mild hypoxia or respiratory failure, both of which should be managed with the appropriate respiratory support from simple nasal cannula up to and including intubation if necessary. Patients may also present with increased work of breathing without pulmonary leukostasis secondary to respiratory compensation for metabolic acidosis. Strong consideration should be given to intubation in these patients, in order to decrease their metabolic workload and prevent decompensation when their respiratory muscles fatigue. It is crucial to remember to match their minute ventilation while still paralyzed post-intubation to avoid loss of their compensatory alkalosis and subsequent hemodynamic decompensation.

Other Treatment Considerations

Patients with leukostasis and TLS, characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia with or without acute kidney injury, should receive allopurinol, dosed appropriately according to renal function, in addition to IV fluids. If uric acid levels are high, typically greater than 8 mg/dL, a single dose of rasburicase, an effective uric acid-lowering agent [54], may be given in the ED. The electrolyte derangements should be managed as usual, with severe hyperkalemia sometimes requiring emergent dialysis if unresponsive to standard measures. The hypocalcemia that may be seen in parallel to hyperphosphatemia is due to phosphate binding with calcium and, as such, should not be repleted unless the patient is symptomatic or the hyperphosphatemia has been corrected, as IV calcium may cause intravascular calcium-phosphate crystal precipitation and renal failure.

Emergency physicians should maintain a low threshold to obtain cultures and administer empiric antibiotics in patients with hyperleukocytosis and fever, as they are functionally neutropenic [28]. Although these patients are in a hypercoagulable state, without a clear diagnosis of life-threatening venous thromboembolism, prophylactic antiplatelet and anticoagulant medications should not be given due to the patient's high risk of bleeding. It is recommended that patients with identified TLS or DIC or who are unstable should have a CBC, BMP with magnesium and phosphorus, uric acid and coagulation panel, including fibrinogen, with consideration given to pH monitoring as well, measured every 4 to 6 hours while in the ED [55].

Definitive Treatment

The definitive management of hyperleukocytosis and leukostasis is leukocytoreduction, which can be achieved by three methods: administration of hydroxyurea, leukapheresis, and initiation of appropriate chemotherapy. Emergent consultation with the oncologist is crucial to determine the plan for cytoreduction. While hydroxyurea is generally widely available and effective and in most instances should be started immediately, it can take 24 to 48 hours to demonstrate its cytoreductive effect. On the other hand, leukapheresis is rapidly effective but in most cases requires central venous access and is not performed at all centers, potentially requiring transfer to another facility. If the patient is symptomatic, emergent leukapheresis for leukocytoreduction is the treatment of choice, although there is no consistent data to indicate that it improves overall mortality [13]. The emergency physician should note that if placement of a central line is required during their care of the patient, it is helpful to avoid the right internal jugular in case leukapheresis or emergent hemodialysis is indicated, as it is the preferred site for apheresis/dialysis catheter placement.

Disposition and Prognosis

Leukostasis is a medical emergency. Without immediate recognition and treatment, a patient presenting with new onset leukemia and leukostasis with both pulmonary and neurologic symptoms has a 1-week mortality rate of 90% [56]. Pulmonary involvement is an independent predictor of hospital mortality and has been identified as the single worst prognosticator for overall morbidity and mortality [41]. Although other predictors of in-hospital death include altered mental status and non-white race [12], overall mortality of individuals with leukostasis is 40%. A diagnosis of leukostasis requires admission to an inpatient team; the level of care is determined by the patient's clinical stability and hospital resources and protocols.

In consultation with the oncologist, the management of stable, asymptomatic patients sent to the ED for lab abnormalities who exhibit hyperleukocytosis without leukostasis is often less "exciting." These patients can be started on hydroxyurea and IV fluids without much fanfare, depending on the level of hyperleukocytosis, and admitted to the inpatient service. Stable tumor lysis syndrome without life-threatening electrolyte derangements or metabolic acidosis can similarly be started on allopurinol and/or rasburicase

with IV hydration and appropriate lab monitoring. The presence of DIC, even without hemorrhage, warrants closer monitoring as serious bleeding can develop quickly.

For patients with severe medical comorbidities or poor baseline functional status, initiation of palliative services in the ED may be warranted. An increasing number of cancer patients die in the hospital, and leukemia has the second highest in-hospital mortality rate at 16%. Early initiation of palliative care, especially in the ED, has been associated with improved patient symptom management, decreased utilization of hospital resources, and decreased hospital costs [12, 21, 22, 57, 58].

Future Research

Most of the research regarding economic impact and ED utilization is small-scale and limited with respect to the leukemias specifically. Further research into cost and number of and reasons for ED visits, with and without subsequent hospitalization, would be helpful in defining the scope of the problem, assessing changes over time and investigating interventions to decrease healthcare costs and ED utilization.

Only 2–4% of palliative care consults for cancer patients take place in the ED, and consultation often occurs close to the time of death [12]. Research into factors leading to late palliative consultation and factors influencing ED referrals could have a significant impact on the quality of life of leukemia patients, as well as avoiding unnecessary and/or unwanted hospitalizations in these patients. The development of predictive models to determine hospital mortality for patients with leukemia, which could be applied in the ED, could be useful for both patients and physicians.

Several subgroups of patients have been underrepresented in large clinical trials, which may contribute to disparities in care. These include racial minorities and elderly patients [8, 15, 18]. As patient populations continue to increase in age and medical complexity over time, more specific research into both curative and palliative treatments for these sicker patients is needed.

Conclusion

The collective leukemias are some of the most common malignancies worldwide, resulting in more than half a million new cases yearly. Leukostasis is a medical emergency that must be promptly recognized by the emergency physician and is commonly accompanied by other potentially life-threatening disease processes such as tumor lysis syndrome and disseminated intravascular coagulation. Leukostasis presents nonspecifically and may mimic other disorders. High clinical suspicion is warranted if the patient has a history of hematologic malignancy, and the diagnosis should be quickly identified once hyperleukocytosis is detected. Patients with leukostasis not only require supportive care but also directed therapies to improve outcomes, making it crucial for emergency clinicians to not only be aware of this process but to also know how to take the appropriate steps to manage it.

Pearls

- Leukostasis refers to the clinical effects of blood hyperviscosity and impaired tissue perfusion secondary to hyperleukocytosis and can present with a broad range of symptoms, most often respiratory or neurologic.
- The mainstays of leukostasis management include hemodilution with IV fluids, supportive therapy including respiratory and hemodynamic support if needed, leukocytoreduction with hydroxyurea +/− leukapheresis, and ultimately chemotherapy.
- Pulse oximetry is more accurate than ABGs for assessment of oxygenation, as there is continued oxygen consumption by the leukocytes in the ABG syringe.
- Patients with hyperleukocytosis should be screened for TLS and DIC, which increase mortality and should be quickly addressed. If the patient is unstable and remains in the ED for an extended period, labs should be obtained every 4 to 6 hours.
- Packed red blood cell transfusion should be avoided in relatively stable patients as it worsens viscosity and can further impair perfusion.
- Hydroxyurea is indicated even for asymptomatic or mild symptoms, starting at 50–100 mg/kg/day until WBC decreases appropriately.

Bleeding and Thrombosis

37

Thomas G. DeLoughery

Case Study

A 67-year-old man was receiving gemcitabine for metastatic pancreatic cancer. He has noticed after the fourth cycle of treatment his blood pressure was starting to rise. When he presented for his sixth cycle of therapy, his oncologist noted that his platelets were decreased to 50,000/uL. Review of the blood smear showed 2–3 schistocytes per high-power field. His creatinine had risen to 2.3 mg/dL and LDH was five times normal. A diagnosis of gemcitabine-induced thrombotic microangiopathy was made. Despite holding gemcitabine, his laboratory findings continued to worsen. Anti-complement therapy with eculizumab was started with a loading dose of 900 mg weekly and then 1200 mg every other week. Within 2 weeks, his platelets started to rise and his LDH fell. By 2 months, his creatinine had normalized. Given complete resolution of his thrombotic microangiopathy, his anti-complement therapy was stopped. At 1-year follow-up, he had no signs of recurrence of his thrombotic microangiopathy.

Introduction

Cancer patients can suffer both bleeding and thrombotic complications, which can impair both quality of life and survival. These complications can be due to the effects of the cancer itself or its therapy. This chapter will review these complications and offer guidance to diagnosis and treatment.

Bleeding

Bleeding Related to Coagulation Factors

Acquired von Willebrand Disease Acquired von Willebrand disease (VWD) can complicate hematological malignancies – lymphomas, myeloproliferative neoplasms, myeloma, and monoclonal gammopathies [1]. Acquired VWD should be considered when a patient with these types of tumors presents with excess bleeding – especially nosebleeds or gastrointestinal bleeding [2]. Both type 1 (decreased total von Willebrand protein) and type 2 (loss of high molecular weight multimers) VWD can be seen.

Patients with acquired VWD have variable responses to therapy for acute bleeding [3]. Desmopressin is effective for patients with acquired VWD types 1 and 2, but the magnitude and duration of effect are often reduced. For bleeding or for surgical procedures, high doses of the von Willebrand concentrate Humate-P or recombinant von Willebrand factor are indicated with careful monitoring of levels. For patients with very strong inhibitors that factor concentrates cannot overcome or those with life-threatening bleeding, rVIIa may prove useful.

Acquired Factor VIII Inhibitors Factor VIII deficiency is the most frequent acquired coagulation factor deficiency seen in cancer patients [4]. There are also cases reported after use of checkpoint inhibitors [5, 6]. Patients will have prolonged aPTTs, a positive screening test for a factor inhibitor, and a low factor VIII level. For severe or life-threatening bleeding, recombinant VIIa is the treatment of choice [7]. The dose is 90 ug/kg repeated every 2–3 h until bleeding has stopped. The key step beside controlling bleeding is to eliminate the autoantibody with immunosuppression starting with prednisone 60 mg/day and adding oral cyclophosphamide 100 mg po plus rituximab either 375 mg/m^2 weekly × 4 or 1000 mg separated by 14 days. Eradication of the autoantibody does not require successful tumor treatment

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_37

and should be attempted before major procedures such as tumor resection are planned.

Bleeding Related to Platelet Number and Function

Immune Thrombocytopenia Immune thrombocytopenic purpura (ITP) has been reported in 2–4% of patients with chronic lymphocytic leukemia, myeloma, and Hodgkin's disease [8]. ITP can occur during any part of the course of the tumor including when the patient has responded to antineoplastic therapy. The presentation of ITP in cancer patients is not different than in those with other conditions; patients present with petechia and other stigmata of bleeding. Why ITP occurs during the course of lymphoproliferative disease is not well understood, although a disturbed immune system could possibly predispose patients both to the lymphoproliferative disorder and to thrombocytopenia [9, 10]. Increasingly, ITP and other autoimmune cytopenias are being reported as complications of the use of checkpoint inhibitors [11]. Therapy for the ITP that complicates tumors/checkpoint therapy is the same as that for classic immune thrombocytopenia. High-dose corticosteroids such as pulse dexamethasone 40 mg/day × 4 days (plus immunoglobulin 1 gram/kg IV if necessary) are given first, but if an adequate platelet count cannot be maintained, then the choice is between splenectomy, thrombopoietin agonists, and rituximab.

Thrombotic Thrombocytopenic Purpura Thrombotic thrombocytopenic purpura (TTP) should be suspected when a patient presents thrombocytopenia, microangiopathic hemolytic anemia (schistocytes and signs of hemolysis), and any evidence of end-organ damage [12]. Diagnosis is confirmed by finding a low ADAMT13 level (<10%). TTP has a unique presentation in cancer patients with evidence of metastatic cancer in the bone marrow and lungs [13, 14]. These patients can have extensive intravascular tumor leading to thrombocytopenia and schistocytes. Plasma exchange is ineffective in these patients, but resolution of the TTP has been reported if the tumor is responsive to antineoplastic therapy.

Therapy-Related Thrombotic Microangiopathy Thrombotic microangiopathies (TM) can complicate a variety of therapies such as calcineurin inhibitors, proteasome inhibitors [15], and gemcitabine [16]. The most common antineoplastic drug causing TM is gemcitabine with an incidence of 0.1–1% [17, 18]. The appearance of the TM syndrome associated with gemcitabine can be delayed, and the condition often is fatal. Severe hypertension often precedes the clinical appearance of the TM. The use of plasma exchange is waning due to lack of effectiveness, and there are increasing reports of the successful use of the complement inhibitor eculizumab [19].

TMs can complicate stem cell marrow transplants [20, 21]. The incidence ranges from 15% for allogeneic to 5% for autologous bone marrow transplants. Several types of TMs are recognized in bone marrow transplantations. One is "multi-organ fulminant" which occurs early (20–60 days) with the evolution of multi-organ system involvement and is often fatal. Another type of TM is similar to calcineurin inhibitors TMs. This occurs within days after the agent is started with the appearance of a falling platelet count, falling hematocrit, and rising serum LDH level [22]. With withdrawing the agent, the TM resolves. A "conditioning" TM, which occurs 6 months or more after total body irradiation, is associated with primary renal involvement. Finally, patients with systemic CMV infections can present with a TM syndrome related to vascular infection with CMV. The etiology of bone marrow transplant-related TM appears to be different from that of "classic" TTP since alterations of ADAMTS13 have not been found in stem cell transplant-related TTP implicated therapy-related vascular damage. There is increasing evidence that disorders of complement regulation may be the etiology of early stem cell transplant TM. Although plasma exchange is often tried, response is poor for TTP/HUS. There are increasing reports of successful use of the complement inhibitor eculizumab, and this agent should be used, especially if there are signs of complement dysregulation such as high C5-9 levels [23, 24].

Specific Hematological Cancers Associated with Bleeding

Acute Promyelocytic Leukemia (APL)

Patients with APL have a higher risk of hemorrhagic death during induction therapy when compared with patients with other forms of leukemia [25]. The hemostatic defects in patients with APL are multiple with most having evidence of DIC at the time of diagnosis with bleeding still being the major cause of early death [26]. Life-threatening bleeding such as intracranial hemorrhage may occur at any time until the APL is put into remission. The etiology of the hemostatic defects in APL is complex and is thought to be the result of DIC, fibrinolysis, and the release of other procoagulant enzymes [25–27]. Therapy of APL involves treating both the leukemia and the coagulopathy (Table 37.1). Currently the standard treatment for APL is trans-retinoic acid (ATRA) in combination with chemotherapy or arsenic [28, 29]. This will induce remission in over 90% of patients, and a sizable majority of these patients will be cured of their APL. ATRA

Table 37.1 Acute promyelocytic leukemia

Consider diagnosis in any patient with leukemia presenting with coagulopathy
Start empiric all-trans-retinoic acid 45 mg/m^2/day in two divided doses while performing work-up
Coagulation goals
Fibrinogen greater than 150 mg/dL
Platelets greater than 50 × 10^9/L

therapy will also lead to the early correction of the coagulation defects, often within the first week of therapy. Given the marked beneficial effect of ATRA on the coagulopathy of APL and its low toxicity, it should be empirically started for any patient suspected of having APL, while specific testing is being performed. Therapy for the coagulation defects consists of aggressive transfusion to maintain the fibrinogen level at over 150 mg/dL and the platelet count at over 50 × 109/L.

Myeloproliferative Neoplasms

Bleeding can be seen in many of the myeloproliferative neoplasms, but rarely results in major morbidity [30, 31]. In patients with essential thrombocytosis, the risk of bleeding appears to increase with platelet counts above one million – perhaps due to the large amount of platelets absorbing von Willebrand factor. Most bleeding in myeloproliferative neoplasms consists of platelet-type bleeding – mucocutaneous bleeding or bruising with only a few reports of major bleeding. The use of drugs that inhibit platelet function such as aspirin is associated with a higher incidence of bleeding. Patients with extreme thrombocytosis and bleeding will respond to lowering the counts to below 1000 × 109/L [1]. Patients with myeloproliferative neoplasms should be screened for VWD before surgery or starting antiplatelet therapy. Rare patients with myeloproliferative neoplasms will have an acquired factor V deficiency with symptomatic patients presenting with bleeding and variable elevation of the INR and/or aPTT [32, 33].

Dysproteinemia

Multiple coagulation abnormalities have been described in patients with dysproteinemia, which can lead to severe bleeding [34, 35]:

- Abnormal clot retraction
- Abnormal fibrin clot
- Anti-glycoprotein IIb/IIIa antibodies
- Factor VIII inhibitor
- Heparin-like anticoagulation
- Impaired fibrin polymerization
- Inhibition of thrombin time

Therapy for the hemostatic defects in the dysproteinemic syndromes includes removal of the offending protein, either by reducing synthesis by treating the myeloma with aggressive chemotherapy or by plasmapheresis if the patient is having acute symptoms.

Patients with amyloidosis can have a marked increase in easy bruising and other bleeding symptoms which may be the first clue to diagnosis [36]. The most common defect is an elevation in the thrombin time which is seen in 30–80% of cases. A rare but important cause of bleeding in patients is systemic fibrinolysis. The patients may have decreased levels of alpha-2-antiplasmin and an abnormal euglobulin clot lysis time. The use of fibrinolytic inhibitors such as tranexamic acid has both corrected laboratory tests of fibrinolysis and reduced bleeding symptoms. Like with myeloma, treatment of the amyloid will correct the bleeding diathesis.

Coagulation Defect Due to Therapy

Bleeding has been reported with the use of tyrosine kinase inhibitors used in CML therapy, but it's unclear if this is due to the drug effect or the underlying disease. Many of these agents have been reported to lead to in vitro platelet dysfunction, but for most patients this does not appear to be clinically significant [37]. Bleeding has also been reported with inhibitors of VEGF [38]. Bevacizumab in particular is associated with bleeding – especially after surgery or with treatment of squamous cell carcinoma of the lung. In these cases, the bleeding may be more related to lack of wound healing and tumor necrosis. The BTK inhibitor ibrutinib is associated with a 5% incidence of bleeding including subdural hematoma, with the mechanism appearing to be via decreased platelet aggregation [39–41]. The new BTK inhibitor acalabrutinib – being more selective – may be associated with less bleeding [42].

Cancer and Thrombosis

Epidemiology

Thrombosis can be the presenting sign of cancer [43, 44]. As many as 10–20% of older patients who present with an idiopathic deep venous thrombosis will be found to have cancer on initial evaluation. Furthermore, over the next 2 years, up to 25% of these patients will develop cancer. Certain presentations of thrombosis are more worrisome for underlying cancer as a cause of the thrombosis: warfarin-refractory thrombosis, idiopathic bilateral deep vein thrombosis, or

both arterial and venous thrombosis. The cancers most frequently associated with thrombosis are adenocarcinoma of the lung and gastrointestinal cancers, especially pancreatic. Primary brain tumors are also associated with a higher risk of thrombosis as well as kidney, ovarian, and uterine cancers [43]. Thrombosis rates for breast and prostate cancer are not as extreme [45]. The co-existence of cancer and thrombosis has implications for both disease processes [46]. Cancer raises the risk of both anticoagulant-induced bleeding and breakthrough thrombosis, while the presence of a thrombosis worsens the cancer prognosis.

Given the data that thrombosis can be an early sign of cancer, one question that commonly arises is "Should a patient who presents with an idiopathic thrombosis be aggressively worked up for cancer?" Studies to date have not shown benefit of extensive evaluations of these patients for cancer, and current recommendations are age-appropriate cancer screening and complete work-up of any worrisome signs – such as guaiac-positive stools.

Increasingly common in cancer patients is the finding of an "incidental" pulmonary embolism on a CT obtained for tumor staging or evaluation of response to chemotherapy. Despite the "incidental" nature of finding the thrombosis, the prognosis is just as ominous as any cancer-related thrombosis, and these need to be aggressively treated with anticoagulation [47]. Also in cancer patients, distal vein thrombosis has a high recurrence rates and mandates long-term anticoagulation [48].

Rare patients can present with thrombosis and associated disseminated intravascular coagulation. These patients with tumor-related DIC have thrombosis in the setting of low platelets and decrease coagulation factors. These patients may also develop a non-bacterial thrombotic endocarditis and have multiple arterial embolic events.

The etiology of the cancer-related thrombosis is complex with many factors potentially playing a role [49, 50]. Tumors may directly activate factor VII by tumor-expressed tissue factor, as well as factor X. Patients with cancer have elevations of inflammatory cytokines that can further augment the hypercoagulable state. Treatment of the cancer can also lead to thrombosis. As discussed below, chemotherapy – especially cisplatinum, fluorouracil, and asparaginase – increases the risk of thrombosis. Biological agents such as thalidomide and lenalidomide also increase thrombosis risk. Surgery for cancer patients increases the risk of thrombosis threefold over similar operations in non-cancer patients [51].

Treatment

Cancer-related thrombosis requires aggressive anticoagulation [52, 53]. While in the past low molecular weight heparin (LMWH) was the treatment of choice, this has now shifted to the direct oral anticoagulants (DOAC). There are three large clinical trials of LMWH vs DOAC that show that DOACs are as effective, if not more effective, in the prevention of recurrent thrombosis with a slighter higher risk of bleeding [54–56]. This higher bleeding risk is only seen with upper gastrointestinal cancers and not with the use of apixaban. Two clinical trials have also shown the benefit of prophylactic dosing of DOAC by preventing the first cancer thrombosis in higher thrombotic risk patients [57, 58]. However, given the low absolute risk reduction in thrombosis, widespread use remains controversial.

Patients who have recurrent thrombosis while taking direct oral anticoagulants need to be treated indefinitely with LMWH. The rare patient who fails LMWH may benefit either from raising the dose by 25% or changing to fondaparinux [59].

Brain tumors or brain metastases are not a contraindication to anticoagulation. The only exceptions are brain metastases from thyroid cancer, melanoma, renal cancer, or choriocarcinoma, as these tumor metastases have a high rate of bleeding [60]. It should be remembered that placement of an inferior vena cava filter without concurrent anticoagulation is associated with an unacceptable rate of complications, including death from massive thrombosis.

Specific Situations

Myeloproliferative Neoplasms

Thrombosis is the most common cause of death in the myeloproliferative neoplasms [31, 61]. Correlation of thrombosis with blood counts depends on the underlying disease – patients with polycythemia rubra vera are at risk of thrombosis with hematocrits over 45%, but those with essential thrombocytosis can have thrombosis with platelets in the 4–600 × 109/L and as noted before may have greater risk of bleeding with counts greater than 1000 × 109/L. Patients with myeloproliferative neoplasms have a higher risk of thrombosis even with relatively normal blood counts, suggesting an intrinsic defect in the blood cell or vascular endothelium leading to thrombosis.

Patients with myeloproliferative neoplasms have a predilection for several types of thrombosis. Patients with Budd-Chiari and other visceral vein thromboses have a high incidence of underlying myeloproliferative syndromes [62]. Patients with essential thrombocytosis can also have platelet occlusion of the small digital vessels leading to erythromelalgia. These patients will have swollen, red, and very painful digits. The patients may only have slightly elevated platelet counts and are often misdiagnosed with arthritis. A diagnostic clue is that these patients will respond dramatically to a single aspirin per day.

Certain patients, especially those with Budd-Chiari syndrome, may have an "occult" myeloproliferative syndrome with maybe no evidence of any hematological disorder but have genetic evidence of myeloproliferative disease with

positive testing for the *JAK2* mutation. Interestingly, the *CALR* mutation – seen in 30–50% of patients with essential thrombocytosis – has not been associated with visceral vein thrombosis in patients with normal blood counts [63].

Heparin followed by warfarin or direct oral anticoagulants is indicated for most patients with acute venous thromboembolism complicating the myeloproliferative disorders. In a few instances, liver transplantation has been successful in treating liver failure due to Budd-Chiari syndrome – but these patients require long-term anticoagulation.

Antiplatelet therapy is recommended for treatment of patients with arterial thrombosis. Low doses of aspirin (81 mg/d) are preferable in patients with myeloproliferative neoplasms because the risk of bleeding with aspirin is dose related. There is increasing data that dosing 81 mg bid may be more effective [64, 65]. There is currently no data concerning the use of newer agents such as clopidogrel, but it may be reasonable for patients allergic to aspirin.

In addition to antithrombotic therapy, treating elevated blood counts is also important for patients with a history of thrombosis [66, 67]. For patients with thrombocytosis, hydroxyurea (1 gm daily to start) is the preferred therapy as trials have shown antithrombotic benefit. For younger patients who have concerns about hydroxyurea, weekly PEGylated interferon starting at 45–90 ug is another consideration. For patients with polycythemia, reduction of the hematocrit to under 45% with phlebotomy, hydroxyurea, or interferon is crucial [68]. There is increasing data for using the *JAK2* inhibitor ruxolitinib for blood count control in patients intolerant of other therapy, and this is another treatment option with retrospective data showing reduction in thrombosis [69, 70].

A common issue is whether to reduce platelet counts or to give aspirin to patients with thrombocytosis who do not have a history of thrombosis. Platelet reduction with hydroxyurea or interferon should be considered in asymptomatic patient if they are older (>65 years) or they have atherosclerosis, risk factors for arterial disease or symptoms of vascular ischemia. Some studies indicate that an elevated white count or the presence of the *JAK2* mutation may also be a risk factor for thrombosis [71]. All patients diagnosed with polycythemia should have their hematocrits reduced to less than 45% with either phlebotomy or cytoreduction [68]. Aspirin should be used in all patients with polycythemia (unless they have a bleeding diathesis). For patients with thrombocytosis, those at low risk of thrombosis do not benefit from aspirin [72].

Paroxysmal Nocturnal Hemoglobinuria (PNH)

One of the leading causes of morbidity and mortality in patients with PNH is thrombosis with patients presenting with either venous or arterial disease [73, 74]. PNH is also associated with a high incidence of visceral vein thrombosis. The cause of the hypercoagulable state is unknown, but complement-activated platelets have been implicated. In two large series pre-dating specific anti-compliment therapy, the rate of thrombosis in PNH was 28–39% with thrombosis leading to death in 58% [73, 75]. The development of the complement inhibitor eculizumab has led to control of the hemolysis in most patients with PNH, and there is strong evidence it also reduces thrombosis rates [76]. Eculizumab or ravulizumab [77] should be used in any patient with PNH who has had thrombosis, severe hemolysis, or a significant PNH clone (>50%). Although PNH is rare, patients with visceral vein thrombosis, thrombosis with unexplained high LDH levels, recurrent or warfarin-refractory thrombosis, or thrombosis in the setting of pancytopenia should be screened for PNH.

Venous Catheter Thrombosis

Central venous catheters are essential to many aspects of cancer therapy, but the clinically apparent thrombosis incidence for catheters is estimated to be 3–6% [78]. The signs of catheter thrombosis are non-specific, and the incidence of thrombosis is thought to be underestimated (Table 37.2).

Patients with catheter-related thrombosis often notice arm pain and swelling. Diagnosis of the thrombosis is made by Doppler, but some patients may only have central vein thrombosis and may require venography or CT angiography to make the diagnosis. Many patients have the diagnosis found while undergoing imaging for other reasons.

Therapy is not well defined. Data is increasing for peripherally inserted central catheters that simply removing the catheter may be the safest approach as the risk of bleeding with anticoagulation is high – reserving anticoagulation for the severely symptomatic [79]. For thrombosis with tunneled lines, anticoagulation should be given – unless the risk of bleeding is substantial. One trial does show that one can keep the catheter in place with 3 months of anticoagulation [80]. Prevention of catheter thrombosis is difficult as prophylaxis has not been shown to be a benefit.

Table 37.2 Options for catheter thrombosis

Peripheral inserted central catheters
Removal of catheter
Reserve anticoagulation for very symptomatic patients
Tunneled central catheters
Evaluated if line is needed
If removed, short-term anticoagulation if no bleeding risk factors
If kept in place, 3 months of anticoagulation

Antineoplastic Therapy

Adjuvant chemotherapy for breast cancer has been associated with an increased risk of both arterial and venous thromboembolism (in 5–7% of patients) [81]. The thrombogenic stimulus is not clear, but this could reflect vascular damage by the chemotherapeutic agents or perhaps a reduction in natural anticoagulants, such as protein C or protein S concentrations.

L-Asparaginase – an effective therapy for acute lymphocytic leukemia – is associated with thrombosis [82, 83]. The overall rate of thrombosis in children is 5% but may be as high as 36% if asymptomatic thromboses are included and can range from 5% to 20% in adult. The rate of potentially devastating CNS thrombosis is approximately 1–2% of patients with childhood ALL and up to 4% of adults. Thrombosis usually occurs 2–3 weeks after the start of a course of therapy. Most patients recover, although serious neurologic defects or even death can occur.

The pathogenesis of the thrombotic complications of L-asparaginase may be related to decreased levels of natural anticoagulants antithrombin III, protein C, protein S, and plasminogen via general inhibition hepatic protein synthesis by L-asparaginase.

Patients with acute thrombosis should have levels of fibrinogen and antithrombin drawn before anticoagulation and if deficient supplemented to keep fibrinogen greater than 150 mg/dL and antithrombin greater than 80%. Platelets need to be kept greater than 50 × 109/L during acute anticoagulation.

There remains no consensus on prevention of thrombosis given varying results of clinical trials. There is increasing evidence that LMWH prophylaxis at either 40 mg/day or 1 mg/kg/day is effective at preventing thrombosis [84].

The anti-myeloma agents thalidomide and lenalidomide are both associated with substantial rates of thrombosis that can be as high as 36–75% [85]. The incidence is higher with the use of dexamethasone and with chemotherapy, especially doxorubicin. These agents may have a direct toxic effect on the vascular endothelium promoting a prothrombotic state. Aspirin appears useful for thrombosis prevention in low-risk patients, while those who have had previous thrombosis, receiving dexamethasone or chemotherapy, or have central lines may benefit from warfarin or LMWH prophylaxis.

Targeted antineoplastic therapy also increases the risk of thrombosis. Bevacizumab has been associated with a ~two-fold increase in arterial thrombosis [86] but not venous disease [87]. This may be a class effect of VEGF inhibition as the VEGF tyrosine kinase inhibitors such as sorafenib and sunitinib also increase arterial thrombosis 2.2-fold [88]. Several of the new tyrosine kinase inhibitors developed for treatment of chronic myelogenous leukemia also increase the risk of arterial thrombosis – the most pronounce risk with ponatinib with an incidence ratio of 40.7 per 100 patient years [89, 90].

Use of Anticoagulants in Thrombocytopenic Patients

A common issue for which there is little guidance is management of anticoagulation in patients who are or are at risk of becoming thrombocytopenic [91, 92]. For venous thrombosis, full-dose heparin/DOAC can be given to a platelet count of 50,000/uL and prophylactic dosing down to 20 × 109/L [93]. Aspirin given for primary prevention can be held until therapy is over. For secondary prevention, one would hold aspirin when platelets decrease to under 50 × 109/L. For acute coronary events, patients should receive aspirin no matter what their platelet counts are [94].

Infectious Disease

38

Nathanial S. Nolan, Michael J. Kim, and Stephen Y. Liang

Introduction

While the emergency physician specializes in evaluating and managing patients with undifferentiated illness, those with cancer and undergoing treatment represent a unique challenge due to their immunocompromised state, lack of typical inflammatory signs and symptoms, and atypical clinical presentations. In such cases, fever may be the only presenting symptom of infection; however, even lack of fever cannot preclude an infectious disease emergency. Malignancies and their treatment modify immune defenses in many ways, and frequent healthcare interventions, including central venous catheterization, further add to the risk of infection. Cytotoxic chemotherapy often results in disruption of mucosal barriers and reduction in functional neutrophils, both of which are critical components of the innate immune system.

Febrile neutropenia in a patient with cancer is an oncologic emergency. While many advances have been made in prevention and management of febrile neutropenia syndromes, infection remains a serious cause of morbidity and mortality in oncologic patients. Major complications (e.g., hypotension, acute renal failure, respiratory failure) in the context of febrile neutropenia occur at a rate of approximately 25–30% with mortality rates as high as 11%; in the setting of severe sepsis or septic shock, mortality can approach 50% [1–3]. Rapid assessment and timely interventions, including the initiation of empiric antibiotics, can be crucial in preventing complications and deterioration in a patient's clinical course. Therefore, emergency physicians must maintain a high index of suspicion for infection in any oncologic patient presenting to the emergency department (ED) with acute illness.

Risk Factors and Immune Compromise

Oncologic patients have many risk factors for infection. Malignancy frequently causes immune compromise, particularly those malignancies affecting the hematopoietic system. Cancers can be inflammatory, releasing cytokines resulting in disordered immune responses. Primary or metastatic tumors can result in anatomic defects promoting infection, such as an endobronchial lesion predisposing a patient to post-obstructive pneumonia. Furthermore, many cancer treatments result in unintended adverse effects, including neutropenia and mucositis. Surgical interventions and procedures, such as port placement, can be complicated by subsequent infection. Due to immune impairment, many oncologic patients may lack classic symptoms of infection (e.g., fever, signs of inflammation). Therefore, a strong clinical suspicion for infection should be maintained during assessment of the acutely ill oncologic patient presenting for ED care.

The spectrum of infectious diseases seen in oncologic patients can be broadly categorized based on primary immune dysfunction (Table 38.1) [4, 5]. For example, patients with primary neutropenia are most susceptible to infection from bacteria they are already colonized with or those found in their environment. These patients frequently develop bacteremia from gastrointestinal pathogens (due to gut translocation), oral pathogens (due to mucositis), or skin flora (due to skin breakdown and/or sites of central venous access). They are also at high risk for infection due to fungi, including *Candida*, *Aspergillus*, and other molds [4].

Patients who have lymphomas, those receiving T-cell-targeting therapies, or those taking high-dose steroids are considered to have dysfunction of cellular-mediated

Table 38.1 Immune defects and their associated pathogens [5]

Immune dysfunction	Associated conditions	At-risk pathogens
Neutrophil defects	Cytotoxic chemotherapy Hematologic malignancy Marrow infiltration Drug-induced neutropenia	Bacteria: *Staphylococcus aureus*, *Viridans streptococci*, *Pseudomonas*, *Stenotrophomonas*, *Enterobacteriaceae*, *Clostridium* Fungi: *Candida*, *Aspergillus*, *Fusarium*, *Zygomycetes*, *Trichosporon*
Cellular immunity defects	Stem cell transplantation Chronic immunosuppressive therapy Hodgkin's lymphoma HIV infection Irradiation	Bacteria: *Mycobacteria*, atypical bacteria (*Nocardia*, *Legionella*, *Listeria*), zoonoses (*Bartonella*, *Brucella*) Fungi: endemic mycoses (*Histoplasma*, *Blastomyces*, *Coccidioides*, *Paracoccidioides*, *Penicillium*), *Pneumocystis jirovecii*, *Cryptococcus*, *Candida*, *Aspergillus* Viruses: herpesviruses (CMV, HSV, VZV, EBV, HHV-6), HPV, community-acquired viral infections Parasites: *Toxoplasma*, *Strongyloides*, *Leishmania*, *Cryptosporidium*
Humoral immunity defects	Drug-induced B-lymphocyte depletion Splenectomy or functional asplenia Hematopoietic stem cell transplantation Paraproteinemias Non-Hodgkin's lymphoma	Bacteria: *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*, *Capnocytophaga* (particularly if receiving rituximab or alemtuzumab) Viruses: Enteroviruses Parasites: *Giardia*, *Plasmodium*, *Babesia*

CMV cytomegalovirus, *HSV* herpes simplex virus, *VZV* varicella-zoster virus [VZV], *EBV* Epstein-Barr virus, *HHV* human herpes virus

immunity. They are particularly vulnerable to infection due to mycobacteria and atypical bacteria, such as *Nocardia*, *Legionella*, and *Listeria*, as well as viruses, including herpesviruses (i.e., cytomegalovirus [CMV], herpes simplex virus [HSV], varicella-zoster virus [VZV], and Epstein-Barr virus [EBV]). They are also more susceptible to infection due to fungi, including dimorphic molds such as *Histoplasma*, *Coccidioides*, and *Blastomyces*, as well as *Pneumocystis jirovecii*, *Aspergillus*, and *Cryptococcus* [4]. Finally, those with therapies targeting B-cells (e.g., monoclonal antibodies against CD-20 surface proteins), hypogammaglobulinemia secondary to malignancy, or those post-splenectomy are considered to have deficits of humoral immunity, placing them at increased risk for infection due to encapsulated bacteria including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. These patients also have an increased risk of parasitic infection.

Antimicrobial Prophylaxis for Cancer Patients

Prophylactic antimicrobial, antifungal, and antiviral therapies are often employed to mitigate the risk of infection associated with necessary and life-saving cancer treatments. Prophylaxis is tailored to an individual patient's risks and is frequently left to the discretion of the oncologic provider. Hospitals and healthcare systems often have their own internal policies or guidelines, and it is useful to be familiar with these. Herein are the most common oncologic scenarios in which patients receive antimicrobial prophylaxis and the underlying reasoning for doing so. Understanding the rationale for commonly prescribed antimicrobial prophylaxis can help emergency physicians better navigate the differential diagnosis of infection in an acutely ill oncologic patient.

Hematopoietic Stem Cell Transplantation (HSCT)

HSCT is a life-saving procedure for patients with hematologic malignancy. However, this treatment often comes with risk of infection from a variety of pathogens. The process of HSCT (whether allogeneic or autologous) requires a cytotoxic conditioning regimen that produces a period of time in which the patient does not have a completely functional immune system. The degree of immunosuppression will depend on the conditioning regimen and the time it takes to achieve engraftment of stem cells. Further immune compromise is common in allogeneic HSCT patients who suffer from graft-vs-host disease (GVHD). The immunosuppression required to treat this condition often further impairs an already fragile immune system.

The role for prophylaxis in HSCT is well established [6, 7]. Prior to HSCT, the recipient and donor often undergo screening as a means to risk stratify and tailor post-transplant antimicrobial prophylaxis for the recipient. For example, a recipient with existing IgG antibodies to CMV will receive antiviral prophylaxis with a drug that is active against CMV, such as valganciclovir, as opposed to prophylaxis with acyclovir, which targets only HSV and VZV. Likewise, a prior history of invasive mold infection can prompt initiation of mold active antifungal prophylaxis. In general, most prophylaxis is aimed at bacteria commonly found on mucosal surfaces or the gastrointestinal tract (e.g., Gram-negative rods including *Pseudomonas aeruginosa*), fungi (e.g., *Candida*, *Aspergillus*), and herpesviruses.

Table 38.2 Antimicrobial prophylaxis in the HSCT patient

	Pre-engraftment phase	Early post-engraftment phase	Late post-engraftment phase
Pathogens with the greatest risk	Gram-negative bacilli (including *Pseudomonas*), Gram- positive cocci, HSV, *Candida* spp., *Aspergillus*	Gram-negative bacilli (including *Pseudomonas*), Gram-positive cocci, HSV, CMV, *Candida* spp., *Aspergillus*	Encapsulated bacteria, VZV, *Aspergillus*, *Pneumocystis jirovecii*
Antibacterial prophylaxis	Fluoroquinolones (ciprofloxacin or levofloxacin)	Penicillin, amoxicillin, or trimethoprim-sulfamethoxazole	Penicillin, amoxicillin, or trimethoprim-sulfamethoxazole
Antifungal prophylaxis	Fluconazole; if increased risk for mold infection, voriconazole, or posaconazole	Fluconazole, trimethoprim-sulfamethoxazole	
Antiviral prophylaxis	Valacyclovir; if CMV IgG positive, valganciclovir	Valacyclovir vs valganciclovir	Valacyclovir – many institutions continue for 1 year

HSCT hematopoietic stem cell transplantation *CMV* cytomegalovirus virus, *HSV* herpes simplex virus, *VZV* varicella-zoster virus

Infectious risk for patients is often dependent on their phase of recovery following HSCT (Table 38.2). In the pre-engraftment phase immediately post-transplantation, typically the first 30 days, patients are in various stages of engrafting new stem cells. Patients are generally profoundly neutropenic and often have mucosal barrier disruption. Studies have suggested that antimicrobial prophylaxis with fluoroquinolones (ciprofloxacin or levofloxacin) can reduce the rate of infections with Gram-negative organisms [8, 9]. During this neutropenic phase, HSCT patients also have a risk of invasive fungal infection, most notably with *Candida*. Antifungal prophylaxis is often targeted toward *Candida*, consisting of daily fluconazole. However, some institutions and/or protocols may favor the use of antifungals such as voriconazole or posaconazole with expanded mold coverage depending on the type of transplant and expected duration of neutropenia. Antiviral prophylaxis is typically directed against human herpesviruses.

A brief discussion of risk for CMV reactivation is worthwhile, as this may seem counterintuitive in HSCT. A high-risk patient is a recipient who is CMV IgG positive at the time of transplant [10]. This high-risk status exists regardless of the donor's status; however, a stem cell transplant from a CMV IgG-positive donor may be protective. As CMV infection is typically a disease of reactivation in HSCT, transplantation from a seronegative donor into a seropositive recipient effectively provides a high-risk recipient with an immune system that has not previously encountered CMV. Various strategies for the management of CMV reactivation exist. Some institutions surveille for reactivation and then provide treatment as needed. Frequently, institutions provide pre-emptive CMV prophylaxis based on recipient seropositive status [11]. Valganciclovir [12] and letermovir [13] have been demonstrated to reduce the risk of CMV disease in seropositive HSCT patients.

Engraftment of the transplant is evident when the patient is able to maintain a neutrophil count from their own hematopoiesis. Despite the development of improved (and sometimes normal) neutrophil counts, HSCT patients remain immunosuppressed due to impaired activity of B-cells and T-cells. This impaired immune function can last for years in allogeneic HSCT patients. The early post-engraftment phase is often arbitrarily defined as the time of engraftment around day 30 until day 100. Following engraftment, antimicrobial prophylaxis targets encapsulated bacteria, particularly *S. pneumoniae* [6]. Based on local protocols, patients may continue on fluoroquinolones, trimethoprim-sulfamethoxazole, or penicillin. The benefit of trimethoprim-sulfamethoxazole is that it also serves as prophylaxis against *P. jirovecii*, a pathogen known to affect HSCT patients [14]. *P. jirovecii* prophylaxis is generally started after engraftment due to concern for bone marrow suppression with trimethoprim-sulfamethoxazole. Antifungal prophylaxis against *Candida* is typically continued during this phase for up to 75–100 days [15].

The late post-engraftment phase refers to the period of time from 100 days until 1-year post-transplant. In this phase, cellular immunity remains impaired. Antibiotic prophylaxis against encapsulated bacteria, specifically *S. pneumoniae*, is typically continued for up to a year. There is evidence to support the role of prophylaxis against HSV and VZV for up to a year to prevent infection [16]. Currently, CMV prophylaxis is not recommended in the late post-engraftment phase [17].

Graft-vs-host disease (GVHD) occurs when transplanted immune cells (from the stem cell transplant) react to recipient tissues. Manifestations of GVHD vary among HSCT recipients. Treatment of GVHD often consists of steroids and frequently escalates to involve immunosuppression with JAK inhibitors or calcineurin inhibitors. In patients with GVHD, prophylaxis often intensifies based on patient risk factors. Some institutions transition antifungal coverage to include mold coverage, if the patient was not already on this. There is some data to suggest that in GVHD, posaconazole and, theoretically, voriconazole decrease the risk for invasive aspergillosis and death [18]. Antibiotic prophylaxis is often continued and will include trimethoprim-sulfamethoxazole for *P. jirovecii* prophylaxis. Antivirals will continue as previously prescribed. In patients with GVHD, antimicrobial prophylaxis often continues until immunosuppression is decreased.

Chemotherapy-Induced Neutropenia

Cytotoxic chemotherapy is a frequent cause of bone marrow suppression and subsequent neutropenia. The risk of infection associated with neutropenia is related to the severity (i.e., how low the neutrophil count is) and the duration of neutropenia. Severe neutropenia is defined as an absolute neutrophil count less than 500 cells/μL. Patients with severe neutropenia for a duration of more than 7 days are considered to be high risk for infection.

Recent guidelines suggest that prophylaxis for neutropenia should be targeted and based on the patient's risk for neutropenia-related infection [19]. For patients with risk of severe neutropenia, current evidence suggests benefit with fluoroquinolone antibiotic prophylaxis [20, 21]. Levofloxacin is often preferred due to its spectrum of activity against *Streptococci* and *P. aeruginosa*. Ciprofloxacin may also be considered. Antifungal prophylaxis with fluconazole, or other triazoles, is recommended in patients who are expected to have severe neutropenia [19]. Prophylaxis against *P. jirovecii*, with trimethoprim-sulfamethoxazole, is also recommended if the risk of *Pneumocystis* pneumonia is felt to be high (typically based on use of high-dose corticosteroids or purine analog therapy) [19]. Of note, use of trimethoprim-sulfamethoxazole alone as prophylaxis against *Pneumocystis* and bacterial pathogens is not recommended due to their limited spectrum of activity compared to fluoroquinolones.

Chemotherapy and Immunotherapy Against Solid Organ Tumors

Though chemotherapy for treatment of solid organ tumors risks depressing the immune system, routine prophylaxis is generally not given. Based on current guidelines, the decision to use fluoroquinolones for prophylaxis in solid organ tumor patients receiving cytotoxic chemotherapy with severe neutropenia should be made on a case-by-case basis [22]. In patients who will be treated with high-dose steroids (≥20 mg of prednisone daily for ≥4 weeks), consideration should be given to *P. jirovecii* prophylaxis using trimethoprim-sulfamethoxazole. Newer immune system-modulating therapies used in cancer treatments may promote risk for invasive infections [23]. Adverse effects of these medications are frequently treated with immune-suppressing therapies (such as corticosteroids). At this time, no guidance on routine prophylaxis before their use exists.

Evaluation of the Oncologic Patient with Infection

When approaching care of the acutely ill oncologic patient in the ED, providers must decipher signs and symptoms that frequently overlap infectious and malignant syndromes. While a fever in an oncologic patient usually indicates infection, it may also result from medications, venous thromboembolism, or the malignancy itself [24].

Fever can be a paraneoplastic syndrome in a wide range of tumor types, from hematologic cancers such as lymphoma and leukemia to solid cancers such as renal cell carcinoma, glioblastoma multiforme, and ovarian carcinoma [25]. While the exact mechanisms of how malignancy induces fever are not fully understood, it is theorized that the release of pyrogenic cytokines directly from tumor cells, or from macrophages responding to the tumor, can induce prostaglandin E2, which acts on the hypothalamus and causes a change in the thermostatic set point. These cytokines – IL-1, IL-2, IL-6, IL-12, TNF, and interferon – also play a crucial role in driving the inflammatory response to infection [25, 26]. Other theories have focused on activation of cytokines by mutated receptors such as RAS; and IL-6 levels are often associated with driving outcomes in lymphomas and renal cell carcinoma [27]. Because the inflammatory states of both neoplastic and infectious origins share similar cytokines, clinical presentations may be indistinguishable between the two, requiring a careful and thorough workup to differentiate them. However, there are differences in the clinical features of fever caused by malignancy compared to infection (Fig. 38.1). Systemic signs and symptoms such as rigors, chills, tachycardia, or hypotension are often muted with malignancy compared to infectious fever. Further, neoplastic fevers are often not relieved by acetaminophen [27].

When approaching a fever of unclear etiology, the first priority of the emergency physician is to treat any presumed underly-

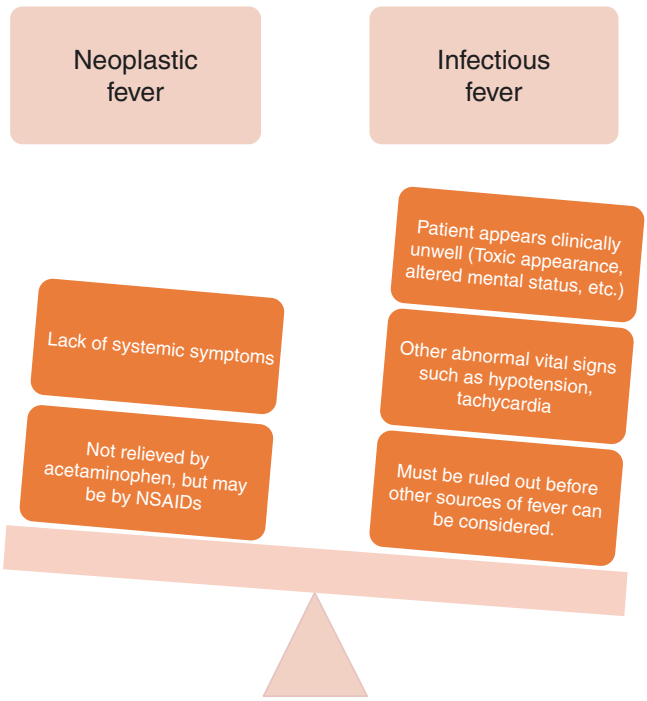

Fig. 38.1 A comparison of neoplastic and infectious fever

ing infection. A fever of unclear etiology in an oncologic patient should be treated as infectious until proven otherwise based on careful examination, laboratory data, and imaging. Neoplastic fever should only be considered once other diagnoses have been thoroughly excluded. The evolving story of SARS-CoV-2 is covered in a separate chapter of this text.

Febrile Neutropenia: An Oncologic Emergency

A frequently encountered syndrome in patients receiving cytotoxic chemotherapy (and sometimes in patients with hematologic malignancies) is neutropenic fever, which is considered an oncologic emergency. This is defined as a temperature ≥38.3 °C once or ≥38.0 °C sustained over an hour in the setting of absolute neutrophil count (ANC) <500 cells/μL or an ANC <1000 with predicted nadir <500 cells/μL [28]. Neutropenic fever requires prompt evaluation and empiric antimicrobial treatment as indicated. The choice of antibiotics and location of treatment is based on underlying risk factors [22, 28]. Patients with comorbid conditions, those with severe neutropenia (ANC <100 cells/μL), and those with neutropenia that will last ≥7 days are at greatest risk for febrile neutropenia.

History and Physical Examination

A careful review of the patient's history and a thorough physical examination should be undertaken. When evaluating an oncologic patient in the ED, it is helpful to sort out the following information:

- Location of the tumor and/or metastases with attention to potential anatomic changes as a result (e.g., does the patient have metastases that could cause urinary, respiratory, bowel, or biliary obstruction?)
- What foreign objects does the patient have inside them (e.g., do they have a central venous catheter, implantable port, urinary catheter, drain, or other implantable device?)
- What therapies are being used to treat the patient and when did he/she last receive them? (e.g., did the patient receive outpatient chemotherapy or are they receiving immunotherapy?)
- What infections has the patient had and/or what infections are they currently being treated for? (e.g., does the patient have a history of a multidrug-resistant organism? Are they currently receiving antimicrobial prophylaxis?)
- What other comorbidities (e.g., diabetes, end-stage renal disease) does the patient have that may increase their risk for infection or worsen clinical outcomes?

While these points do not constitute all of the history that should be obtained, they can help narrow the differential diagnosis. A thorough physical examination can also elucidate supporting signs and symptoms for a suspected infection. Assessing the patient's overall clinical appearance can be the first step in establishing a clinical gestalt – does the patient appear sick or unwell? Has there been a change from their baseline mental status? Central venous catheters, implantable ports, and surgical sites should be inspected for any signs of infection that could lead to bacteremia or wound infection. A tender, distended abdomen in a patient with liver cancer and ascites can suggest peritonitis. Decreased breath sounds and rales in a lung cancer patient may indicate a developing pneumonia or empyema. Early determination of these factors can help guide initial management, including administration of fluids and empiric antibiotics, and inform clinical decision-making regarding the need for imaging.

Initial Diagnostic Workup

All patients with known malignancy and fever require a full infectious workup (Fig. 38.2). Though most patients with neutropenic fever may never have a diagnosed etiology, all patients presenting with febrile neutropenia should be treated as if they have true infection. After 48–72 h of continuous fever without positive culture data or response to antibiotics, alternative infectious etiologies should be considered including less common fungal, viral, and parasitic organisms.

Initial workup of an oncologic patient presenting with fever should include but is not limited to:

- Thorough history and physical examination to identify possible infectious sources including wounds, surgical sites, and indwelling central venous catheters and urinary catheters
- Complete blood count with differential, complete metabolic panel including hepatic function panels, other electrolytes, and serum lactate
- At least two sets of blood cultures from different sites, with consideration of obtaining a set from current indwelling central venous catheter or implantable port (if there is concern for infection involving the device)
- Microbiologic cultures from other sites including sputum, tracheostomy tubes, wounds, surgical incisions, CSF, and stool as applicable
- Urinalysis and urine cultures
- Chest radiography for the patient presenting with hypoxia, new oxygen requirements, or respiratory symptoms
- Brain imaging and lumbar puncture in a patient with altered mental status or neurological symptoms

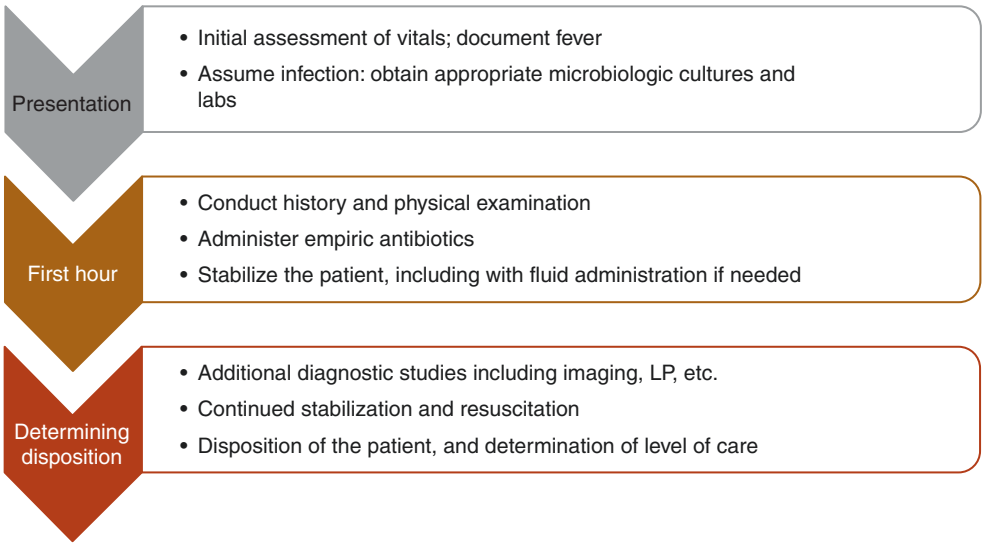

Fig. 38.2 An approach to evaluation of the oncologic patient with neutropenic fever and/or suspected infection in the emergency department

Table 38.3 MASCC risk assessment [29]

Factors	Score
Burden of disease	
No or mild symptoms	5
Moderate symptoms	3
Severe symptoms	0
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or hematologic malignancy without previous fungal infection	4
No dehydration	3
Outpatient status at onset of fever	3
Age of <60 years	2
Total score of 21 or higher means that the patient is considered as low risk for complication	

MASCC Multinational Association for Supportive Care in Cancer

- Nasopharyngeal swabs for patients with flu-like symptoms in the setting of community-acquired respiratory illnesses such as influenza or COVID-19

Ideally, patient assessment should be performed as soon as possible as delays in treatment can adversely affect outcomes. The goal of the emergency physician is not to identify a specific infectious diagnosis, but to maximize the chances of establishing clinical and microbiologic diagnoses later in the patient's clinical course that may affect treatment, including antibiotic choice and prognosis. In this same vein, the emergency physician must assess the patient's risk for infectious complications. Different risk stratification scoring systems have been proposed – the Multinational Association for Supportive Care in Cancer (MASCC) score is based on seven clinical factors derived and validated from prospective analyses (Table 38.3) [29].

While low-risk patients may be considered for outpatient therapy, high-risk patients will most likely require empiric intravenous antibiotics and hospitalization. Identifying a patient's risk for infectious complications is an important skill for the emergency physician as it ultimately determines the disposition of the patient and the level of care they will receive during their hospital course.

Treatment and Management

Guidelines from the American Society of Clinical Oncologic (ASCO) and Infectious Diseases Society of America (IDSA) for empiric treatment recommend the early use of broad-spectrum antibiotics when treating febrile neutropenia [22, 28]. Stabilization of the sick patient is the critical goal for the emergency physician. Early aggressive fluid resuscitation should be considered in patients presenting with sepsis and/or septic shock. Early blood products may also be required due to the marrow suppressing nature of cytotoxic chemotherapy. Obtaining central venous access, if not already present, and initiating vasopressor therapy can be crucial in preserving hemodynamics. Source control through removal of an infected central venous catheter or urinary catheter or drainage of an infected fluid collection (e.g., abscess) may be necessary. Early communication with the patient's oncologist or an on-call oncologist can help facilitate disposition and ensure proper next steps in management and follow-up.

Gram-positive or Gram-negative bacteria account for more than 90% of the causes for a first febrile episode in neutropenic patients [4]; therefore, empiric antibiotic regimens must be broad-spectrum and bactericidal and achieve therapeutic levels quickly (Fig. 38.3). Based on IDSA guidelines, patients should receive at least monotherapy with an antibiotic that empirically covers *P. aeruginosa* [28]. Reasonable choices therefore include an anti-pseudomonal fourth-generation cephalosporin (cefepime), β-lactam/β--

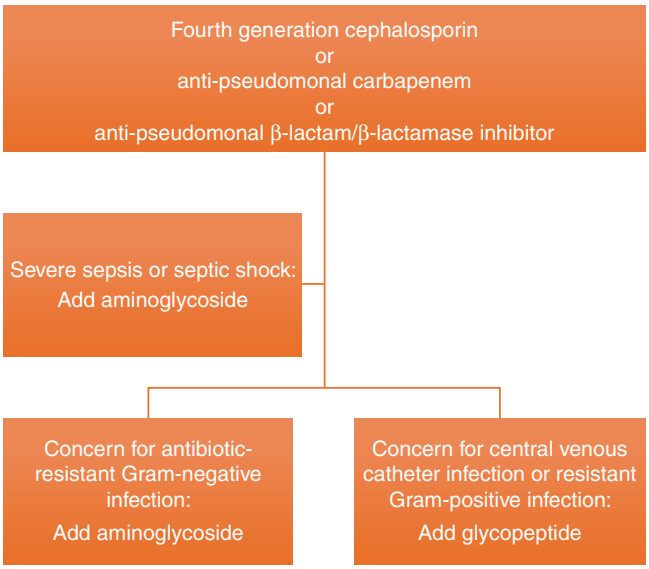

Fig. 38.3 Empiric antibiotic therapy for suspected infection in high-risk oncologic patients

lactamase inhibitor (piperacillin-tazobactam), or carbapenem (meropenem). Vancomycin, or other agents targeted against resistant Gram-positives (linezolid, daptomycin), should be considered in patients who have suspected central venous catheter infection or severe skin and soft tissue infection. Septic patients may also require treatment with an aminoglycoside, especially when there is a history of resistant Gram-negative infection. Additional empiric coverage directed toward fungi and viruses can be considered based on the clinical context (e.g., previous fungal infection, previous isolation of multidrug-resistant organisms) and local antibiogram data [28].

Recent ASCO/IDSA guidelines have outlined a population of patients who may be safely treated for neutropenic fever outside of the hospital setting. Again, validated tools such as the MASCC index or the Clinical Index of Stable Febrile Neutropenia (CISNE) can aid decision-making [29, 30]. In stable, low-risk patients felt to be candidates for outpatient treatment, the current recommended antibiotic regimen includes fluoroquinolones active against *Pseudomonas* plus amoxicillin/clavulanate or clindamycin [22].

Case Study 1: An Oncologic Patient with Fever and Neutropenia

A 62-year-old woman with hypertension, COPD, and diffuse large B-cell lymphoma presents to the ED via *private vehicle with fever. She first felt "hot" earlier this morning and found her temperature to be 102 °F. She has not had any other symptoms and feels well overall. She completed her first cycle of chemotherapy with R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone) 2 weeks ago. She does not report any recent travel.*

On arrival to the ED, the patient's vital signs are notable for a temperature of 102.5 °F, a heart rate of 98 beats per minute, and a blood pressure of 88/60 mmHg. A head-to-toe physical examination finds a well-appearing female with clear lung sounds, a non-tender abdomen, and good pulses in all her extremities. Initial laboratory assessment demonstrates a hemoglobin of 12.1 mg/dL and a white blood cell count of 1700 cells/μL. The laboratory calls the emergency physician with a critical lab result from the white blood cell differential – the absolute neutrophil count is 200 cells/μL. Given concern for neutropenic fever, the emergency physician obtains two sets of blood cultures and a urine culture and starts the patient empirically on intravenous cefepime, all within 1 h of her presentation to the ED. A chest radiograph shows no evidence of pneumonia and a urinalysis is within normal limits. The emergency physician determines that the patient is at high risk for infectious complications with a MASCC score of 15. She notifies the oncologist of the patient's neutropenic fever and recommends admission for further workup and observation. The oncologist concurs and is appreciative of the call.

During the hospitalization, the patient's blood and urine cultures show no growth. The oncologic team decides to administer granulocyte colony-stimulating factor. Three days later, her fever has resolved, and her absolute neutrophil count has increased to 500 cells/μL. She is discharged on oral ciprofloxacin and amoxicillin/clavulanate and is scheduled follow-up in 2 days with her oncologist. This case demonstrates the importance of early recognition of neutropenic fever, appropriate microbiological culture collection, and prompt initiation of empiric antibiotics, even in the absence of other localizing symptoms. Risk stratification tools such as the MASCC score and close communication with a patient's oncologist can help in clinical decision-making and securing timely outpatient follow-up once the patient has been discharged.

Special Considerations

Syndromic Approaches

Specific history and physical examination findings can help one to narrow their approach when diagnosing the cause of a fever in an oncologic patient. The following is a brief review of specific clinical syndromes and how one might approach them when it comes to infection.

Pulmonary syndromes usually manifest by increased work of breathing, hypoxia, and cough with or without sputum production. In neutropenic or stem cell transplant patients, pneumonia carries a high rate of mortality. Infiltrates

may not be prominent on routine chest radiography; thus computed tomography should be obtained in those who have clinical symptoms but a seemingly clear chest x-ray. Bacterial pathogens, such as *S. pneumoniae*, *Staphylococcus aureus*, and *P. aeruginosa*, predominate as causes of pneumonia in immunosuppressed oncologic patients [31, 32]. Given their frequent encounters with healthcare, resistant Gram-negative organisms are also frequently isolated, including *Stenotrophomonas maltophilia*, *Acinetobacter* spp., *Klebsiella pneumoniae*, etc. [31]. A high index of suspicion must also be maintained for fungi such as *Aspergillus* spp. and *P. jirovecii* [32]. In immunosuppressed patients, community respiratory viruses can cause pulmonary infiltrates on chest x-ray and result in significant morbidity. Influenza, respiratory syncytial virus, parainfluenza, and SARS-CoV-2 are among the many circulating viruses that can cause serious respiratory syndromes. Assessment should include routine labs and sputum culture, if the patient is making sputum. In critically ill patients who do not respond to empiric antibiotic therapy, bronchoalveolar lavage with microbiologic culture can help further guide coverage.

Skin and soft tissue infections have a broad differential in the immunosuppressed patient. The classic erythema, pain, warmth, and swelling of cellulitis may be less prominent than in immunocompetent patients. Clinicians should have a high index of suspicion for necrotizing infections, especially when patients have significant pain out of proportion to the exam. It is also important to recognize that in neutropenic or immunosuppressed patients, skin lesions are frequent manifestations of disseminated disease [5]. When evaluating skin infections, it is important not to overlook mucous membranes, which may help to differentiate cutaneous syndromes vs. systemic processes (such as disseminated viral processes). Vesicular, crusted, or shallow ulcerative lesions may suggest a viral process, such as disseminated zoster or herpes simplex virus. Nodular lesions may be suggestive of fungal or mycobacterial processes. Erythematous skin lesions with central necrosis can also signify a fungal process. Unfortunately, many non-infectious processes, including Sweet's syndrome, can mimic cutaneous infection. The diagnosis of these infections often relies on not only routine laboratory tests and blood cultures but frequently skin biopsy for pathology and special stains (e.g., Gram stain, GMS stain, Fite stain).

Gastrointestinal syndromes manifest as abdominal pain, nausea, vomiting, and diarrhea. Given their frequent exposure to healthcare and antibiotics, oncologic patients are at increased risk for *Clostridioides difficile* infection [33]. They are also at risk for a range of bacterial infections, including *E. coli*, *Salmonella*, *Shigella*, and *Campylobacter* [34]. Viral (CMV, norovirus) and parasitic (e.g., *Cryptosporidium*, *Strongyloides*, *Entamoeba*) causes should also be considered in immunosuppressed patients with unexplained diarrhea. Typhlitis is a life-threatening condition due to neutropenia resulting in necrotizing enterocolitis, predominantly affecting the cecum. This most often manifests as right lower quadrant abdominal pain, many times with associated bloody diarrhea [35]. This can be readily diagnosed on CT scan. Patients who have pain or difficulty swallowing should be evaluated for esophagitis, which may be due to *Candida*, CMV, or HSV infection. The approach to an immunosuppressed patient with abdominal pain often includes routine laboratory tests, including liver function testing, pancreatic enzymes, and stool studies (for *C. difficile* toxin or polymerase chain reaction, fecal leukocytes, and stool culture). When patients have significant pain, early CT scan should be considered. It should be noted that oncologic patients are also at risk for non-infectious causes of gastrointestinal illness, including tumor effects, medication effects, and, in HSCT patients, gastrointestinal graft-vs-host disease.

Central nervous system infections should be considered not only in patients with classic meningeal symptoms but also in those who are altered or obtunded. Emergency physicians should have a low threshold for evaluating patients for neurologic infections. Patients with symptoms concerning for focal neurologic deficits or meningoencephalitis should undergo imaging and early lumbar puncture as indicated, with appropriately recorded opening pressure. In addition to typical meningitis pathogens, such as *S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*, immunosuppressed oncologic patients are at increased risk of infection due to pathogens such as *Listeria monocytogenes*, *Cryptococcus neoformans*, and herpesviruses (HSV/VZV) [35]. Those with a history of neurosurgical procedures have an increased risk for coagulase-negative staphylococci, *S. aureus*, and Gram-negative rods [36]. Early pathogen identification can improve time to life-saving therapies. Intracranial mass lesions can have many etiologies, including bacterial abscess, fungal infection, or *Toxoplasma*. The workup for these will often depend on imaging characteristics. Fungal sinusitis is a diagnosis that can mimic a neurologic syndrome based on severe headache and ocular nerve palsies. This is a diagnosis not to miss as the associated mortality is very high [37].

Healthcare-associated infections can arise from any number of interventions associated with cancer care. Central venous catheters and implantable ports are frequently used to provide chemotherapy, intravenous fluids, blood product transfusions, and other treatments. A central line-associated bloodstream infection (CLABSI) is defined by the Centers for Disease Control and Prevention as a primary bloodstream infection in a patient who has had a central venous catheter in place for more than 48 h with a bacterial or fungal pathogen isolated from one or more blood cultures unrelated to another source of infection [38]. While surveillance and clinical definitions may vary, a CLABSI can contribute significant morbidity and mortality, particularly in patients who

have undergone HSCT [39, 40]. Coagulase-negative staphylococci, *S. aureus*, *Enterococcus faecium*, *E. coli*, and *Candida* are common causative organisms, with antibiotic-resistant organisms increasingly implicated [41, 42]. Fever, chills, and rigors may not always be present, particularly with infection due to coagulase-negative staphylococci. Erythema, induration, and purulence at the insertion site for the central venous catheter or overlying the pocket of an implantable port should raise suspicion that this device could be a potential source of infection. At least two sets of blood cultures should be obtained preferably from two separate peripheral sites; one set can be drawn from the central venous catheter or implantable port when necessary. When clinical suspicion for CLABSI or implantable port infection is high, device removal is preferred [42, 43]; this decision should be made in consultation with the patient's oncologist. Presence of an indwelling urinary catheter in an oncologic patient presenting with fever, suprapubic tenderness, costovertebral angle tenderness, or urinary symptoms should raise concern for a catheter-associated urinary tract infection (CAUTI). Urinalysis and urine culture help establish the diagnosis and guide antibiotic therapy; catheter removal is strongly recommended. Avoidance of unnecessary urinary catheterization, including in the ED, should remain a major strategy to prevent CAUTI [44].

Case Study 2: A Thorough Examination Uncovers the Source of Fever in an Ill Oncologic Patient

A 73-year-old man with hypertension, coronary disease, and small-cell lung cancer presents to the ED via *emergency medical services for altered mentation and hypotension. Approximately 12 h prior to admission, the patient developed fever at home, and his mental status subsequently declined throughout the day. His wife eventually called EMS and on arrival he is obtunded and hypotensive.*

In the ED, the patient is febrile to 101.3 °F with a heart rate of 120 beats per minute and a blood pressure of 73/29 mmHg. A head-to-toe physical examination is performed. He is obtunded but has no focal deficits and is protecting his airway. His heart and lung exam are significant for crackles in the lung bases. Abdominal examination is benign. On exposure of the chest during a complete skin examination, mild erythema and induration are visualized overlying the site of his implantable port. Initial laboratory assessment demonstrates anemia (hemoglobin 9.7 mg/dL), thrombocytopenia (platelet count 129 × 10^9/L), and a white blood cell count of 6000 cells/μL. Two sets of blood cultures are obtained, and the patient is started empirically on intravenous vancomycin. A central venous catheter is placed and vasoactive agents are started. It is noted the patient recently completed cycle 3 of cisplatin and etoposide for his cancer. He has not had any recent procedures.

The patient is admitted to the oncologic ICU. Twelve hours into his stay, blood cultures are reported as positive for Gram-positive cocci in clusters. The following day, his implantable port is removed. The organisms in blood cultures are identified as methicillin-resistant Staphylococcus aureus. Two days later, he is improved and able to transition out of the ICU. This case demonstrates the importance of a thorough physical examination in identifying potential sources of fever in an oncologic patient, including evaluation of vascular access devices commonly used for cancer treatment.

Future Issues and Considerations

In the United States, there are over 14 million people who have been treated for cancer sometime during their life [44]. While outpatient therapy is the mainstay of cancer management, the ED is the first destination for many patients with acute complications. National data suggests that patients with cancer make up approximately 3% of all ED visits with an admission rate that is much higher than that of the general ED population; future studies should focus on improving emergency care, especially with regard to febrile neutropenia [45]. As stated before, guidelines recommend early administration of empiric antibiotics for patients who present with neutropenic fever. However, in the setting of ED overcrowding and prolonged boarding times, significant delays in initiating treatment have been observed, with some studies reporting a median time to initial antibiotics ranging from 102 to 300 min [46]. Understanding the barriers that prevent prompt treatment and care can provide systemic targets for improving overall patient flow in the ED. Another consideration is the continued efforts to develop risk stratification methods to identify patients with the highest risk of serious infection and need for immediate assessment. As protocols and systems have developed to improve intervention times of other emergent presentations such as myocardial infarction and stroke, similar systems can be developed to reduce the time to initial antibiotic treatment. However, these strategies must be based on adequately powered and valid studies with convincing evidence of positive clinical effects and outcomes [45].

As physicians wage a never-ending arms race against evolving multidrug-resistant bacteria, it is important to consider the potential ramifications of continuing broad-spectrum antibiotics when it comes to antibiotic stewardship. While inadequate antibiotic treatment can lead to worse clinical outcomes in oncologic patients, continued use of broad-spectrum therapy when not indicated promotes selection of antibiotic-resistant bacteria. As the use of antibiotics has evolved over time, causative organisms associated with

febrile neutropenia have shifted from Gram-negative bacteria in the 1960s and 1970s to Gram-positive bacteria in the 1980s and now to antibiotic-resistant Gram-negative and Gram-positive bacteria in recent years [47]. Multidrug-resistant organisms including *K. pneumoniae, P. aeruginosa*, and MRSA are associated with considerable mortality in patients with and without neutropenia, although data regarding oncologic patients is limited [48]. Risk assessment for multidrug-resistant infection should be considered for every oncologic patient, particularly those with a history of frequent hospital admissions. While empiric broad-spectrum antibiotic therapy is warranted in the management of undifferentiated infection in a cancer patient, emergency physicians have an important role to play in promoting antibiotic stewardship through responsible prescribing. Selecting the right *d*rug (targeting the most likely organisms with as narrow a spectrum as allowable; using hospital antibiograms to guide antibiotic selection based on trends in local antibiotic resistance), administering that drug at the right *d*ose (e.g., accounting for hepatic and/or renal clearance) for the right *d*uration (shortest time needed to appropriately treat the infection), enabling opportunities to *d*e-escalate antibiotic therapy based on microbiologic cultures, and making sure a drug is prescribed for the right *d*iagnosis in the ED (avoiding antibiotic use when a viral infection is suspected) constitute the 5 Ds of antibiotic stewardship in emergency medicine [41].

Summary and Key Points

The oncologic patient presents a diagnostic challenge to the emergency physician due to their immunocompromised state, lack of typical inflammatory signs and symptoms, and potential for atypical clinical presentations. Fever in a neutropenic patient is an oncologic emergency that necessitates immediate, thorough assessment and early, empiric treatment. When evaluating these patients, the following key points should be remembered:

- Neutropenic fever is defined as a temperature ≥38.3 °C once or ≥38.0 °C sustained over an hour in the setting of absolute neutrophil count (ANC) <500 cells/μL or an ANC <1000 with predicted nadir <500 cells/μL.
- Malignancies can also cause fever, but all fevers must be treated as infectious until proven otherwise.
- Understanding the rationale for antimicrobial prophylaxis in a cancer patient can help narrow the diagnostic possibilities when ill oncologic patients present to the ED.
- A thorough history and physical examination can help uncover subtle signs and symptoms of infection.
- A broad workup should be performed to help maximize the chances of establishing a clinical and microbiological diagnosis.
- Blood cultures should be obtained and empiric broad-spectrum antibiotics started within 1 h of presentation.
- Validated tools such as the MASCC index or the Clinical Index of Stable Febrile Neutropenia (CISNE) can help with risk stratification and determination of disposition.
- Future studies should focus on improving time to antibiotics, risk stratification, and addressing the growing challenge of multidrug-resistant bacteria.

Febrile Neutropenia

39

Christopher J. Coyne and Rahul V. Nene

Case Study

A 54-year-old female with a history of breast cancer presents to the ED with a low-grade fever (38.3 °C) and myalgias. She denies cough, shortness of breath, chest pain, abdominal pain, dysuria, sore throat, or mouth sores. Her physical exam is non-focal and does not reveal a potential source of infection. The patient has a past medical history of essential hypertension, though is otherwise healthy and exercises every day. Her labs are significant for an absolute neutrophil count of 300 cells/mm^3 and an absolute monocyte count of 600 cells/mm^3. All additional labs including a complete metabolic panel, lactate, and urinalysis are within normal limits. She receives a chest x-ray that is read as negative for acute cardiopulmonary disease. Blood cultures, a urine culture, and a respiratory viral panel are sent and pending.

Given the reassuring clinical picture, the emergency physician applies the Clinical Index of Stable Febrile Neutropenia (CISNE) score to assist with risk stratification. The patient is found to have a CISNE score of zero and is therefore considered low risk of developing severe disease. She is placed in observation status and receives an initial dose of amoxicillin/clavulanate and ciprofloxacin. The patient remains stable for several hours while in the ED. After a discussion between the emergency physician and the patient's primary oncologist, the patient is cleared for discharge home with a plan for expedited follow-up. She will continue oral antibiotic therapy and she will return if any new or concerning issues arise.

Introduction

Infectious complications related to cancer and cytotoxic chemotherapy remain common. A particular disease process that has the potential for significant morbidity and mortality is febrile neutropenia. Appropriate identification and management of this condition is critical given that major complications (e.g., end-organ damage, need for mechanical ventilation) occur in up to 30% of patients and the reported mortality may approach 11% [1–3]. Unfortunately, the classic signs and symptoms of infection in patients with neutropenia are often absent or muted, with fever being the only presenting symptom in many cases [4]. This makes it difficult for the treating clinician to diagnose the underlying cause and provide directed therapy against potential infectious agents. Almost universally, patients are treated for potentially serious and life-threatening bacterial infections. Many patients, however, may suffer from viral or fungal pathogens, while others may experience fever due to underlying malignancy and/or therapeutic agents. Due to this diagnostic dilemma, the ultimate disposition of these patients becomes quite challenging. Which patients can safely be discharged and which require hospitalization?

In this chapter, we will address the most recent literature and recommendations relating to the diagnosis and treatment of febrile neutropenia in the acute setting. We will discuss the current best-practice guidelines in the identification of a low-risk patient cohort, who may be safely treated in the outpatient setting. Finally, we will discuss future considerations in febrile neutropenia diagnosis and risk stratification.

Definition

Febrile neutropenia is a vitally important complication of chemotherapy. Neutrophils are an essential component of the immune response, especially against bacteria and fungi, and febrile neutropenia may be the only sign of a serious infection in an immunocompromised patient [1, 5]. Neutropenia

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_39

is typically categorized as mild, with an absolute neutrophil count (ANC) 1000–1500 cell/μL; moderate, with an ANC 500–1000 cells/μL; and severe, with an ANC <500 cells/μL [6]. Per the American Society of Clinical Oncologic (ASCO) and Infectious Diseases Society of America (IDSA), febrile neutropenia is defined as a single oral temperature (either obtained in a healthcare setting or self-reported) of ≥38.3 °C (101°F) or a sustained temperature of ≥38.0 °C (100.4°F) for 1 h, with an ANC <500 or an ANC expected to decrease to <500 in the next 48 h [5, 7].

Pathophysiology

Many cytotoxic chemotherapy regimens work by targeting rapidly dividing cancer cells, but in the process also damage the patient's normal cells, including those that make up the immune system and mucosal linings. Not only does this leave the patient immunocompromised, but the breakdown of mucosa anywhere along the gastrointestinal tract allows for seeding of the bloodstream with endogenous flora; this is thought to cause the majority of febrile neutropenia cases [4]. Patients may also be more susceptible to infection because of the underlying cancer. Hematologic malignancies by definition have a defect in some aspect of the immune system. Solid tumors can also cause obstruction to the hepatobiliary, gastrointestinal, bronchial, and renal tracts, which can serve as a nidus for infection. Surgery and the presence of implantable venous access devices also pose a risk of infection.

Neutropenia normally occurs 5–10 days after chemotherapy [8]. Patients with solid tumors undergoing cytotoxic chemotherapy typically still have healthy bone marrow, and neutropenia generally lasts less than 7 days. In contrast, patients with hematologic malignancies undergoing chemotherapy and/or hematopoietic stem cell transplantation (HSCT) may have extended periods of neutropenia lasting more than 14 days [9, 10]. It is estimated that 5–30% of patients receiving chemotherapy for solid tumors will develop febrile neutropenia, while the rate of this complication is >80% for patients with leukemia or those undergoing HSCT 5. Other factors that increase the risk of febrile neutropenia include metastatic cancer, mucositis, chronic obstructive pulmonary disease, and advanced age [11]. The cytotoxic chemotherapies associated with the highest risk of neutropenia include anthracyclines, taxanes, platinums, ifosfamide, cyclophosphamide, etoposide, and cytarabine [11, 12].

An infectious source is identified in only 40–50% of febrile neutropenia cases, with bacteremia identified in 10–25% [7, 13]. An additional 20–25% of patients have an identifiable site of infection (e.g., pneumonia, cellulitis), but no identifiable causative organism [10]. Less than 5% of cases have a non-infectious cause of fever, such as drug fever or tumor fever; as such, this should be a diagnosis of exclusion [14]. It is suspected 80% of infections arise from endogenous flora. Interestingly, over time there have been changes in the most common identified pathogens. Historically until the 1980s, gram-negative bacilli predominated, particularly *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species [10, 15]. Since then, gram-positive cocci have become more common, particularly *Staphylococcus epidermidis*, and, to a lesser extent, *Staphylococcus aureus*, and streptococci [16, 17]. It is suspected the cause of this transition is the increasing prevalence of implantable venous access devices, as well as the use of prophylactic fluoroquinolone antibiotics, which are primarily active against gram-negative species. More recently however, there has been a trend back toward gram-negative bacteremia, particularly multidrug-resistant organisms [18].

Fungal pathogens can also cause neutropenic fever, though they are rarely associated with the first episode [10]. The risk of fungal infection increases with the duration and severity of the neutropenia, particularly with profound neutropenia lasting more than 10–15 days [19]. Most commonly, *Candida* species were identified in central venous catheter-associated infections and gastrointestinal tract colonization, while *Aspergillus* was identified more commonly with respiratory tract infections [20]. Severely immunocompromised patients are also at risk for mucormycosis, invasive *Fusarium* infection, and new infection or reactivation of endemic fungi such as *Coccidioides*, *Histoplasma*, and *Blastomyces* [10, 20]. Other opportunistic infections should also be considered, including tuberculosis, *Pneumocystis jirovecii*, and *Mycobacterium avium complex*.

Viral infections are also a common cause of febrile neutropenia. Community-acquired respiratory viruses are of particular concern and have been documented with increasing frequency in neutropenic patients, particularly seasonal influenza, respiratory syncytial virus, parainfluenza, adenovirus, rhinoviruses, human metapneumovirus, and coronaviruses, including the novel corona virus, COVID-19 [21, 22]. Reactivation of human herpesviruses, particularly herpes simplex virus-1 and 2, and herpes zoster, is also very common, however typically only in those with hematologic malignancies and prolonged neutropenia. As a result, it is standard practice to start empiric antiviral prophylaxis on most patients with hematologic malignancies prior to the commencement of chemotherapy [7, 23].

Assessment

A patient with febrile neutropenia may present with vague nonspecific complaints [24]. Due to the muted inflammatory response in an immunocompromised patient, fever may often be the only presenting sign or symptom. The assessment of temperature can be particularly tricky and is often the turning point between discharging a patient home or starting broad-spectrum antibiotics in the hopes of not missing life-threatening illness. An oral temperature is the preferred method, though care should be taken in those with significant oral mucositis, which may also falsely elevate the temperature [25]. Rectal thermometry is not recommended in neutropenic patients due to the potential risk of mucosal injury leading to bacteremia.

A thorough history should be obtained to evaluate the risk of serious complications and help determine the potential site of infection [7]. Important factors to assess include medical comorbidities, a thorough review of systems, chemotherapeutic regimen and timing of last cycle, use of antibiotic prophylaxis or recent antibiotic treatment, and history of prior infections or colonization with multidrug-resistant organisms. A careful physical examination should be performed, with special attention to the skin, biopsy sites, catheter sites, oropharynx, lungs, abdomen, genitals and perianal area, and decubitus sites.

Patients with febrile neutropenia require a broad diagnostic workup, consisting of a complete blood cell count with differential, a complete metabolic panel with liver function tests, and an evaluation of all possible sources of infection. This includes, but is not limited to, urinalysis, urine culture, two blood cultures obtained from peripheral sites and additional blood cultures from each central venous catheter, sputum culture for respiratory symptoms, and stool sample for gastrointestinal symptoms. Consider lumbar puncture and cerebrospinal fluid (CSF) cell count, culture, and PCR testing if there is a high index of suspicion for meningitis or encephalitis. Consider fungal blood cultures, fungal serum markers, and a beta-D-glucan assay in patients with persistent neutropenic fever or a history of prior invasive fungal infection. Have a low threshold for respiratory viral testing, especially during influenza season or other viral epidemic. However, caution should be exercised when interpreting any of these tests in a neutropenic patient; the absence of typical laboratory findings does not exclude infection in the immunocompromised patient.

Patients with respiratory symptoms should have a chest radiograph, with a low threshold to proceed to chest computed tomography (CT) given the high prevalence of occult pneumonia [26]. Additional advanced imaging can be obtained according to suggestive symptoms (e.g., head, sinuses). Of particular note is CT of the abdomen/pelvis, with contrast when possible, which should be obtained for patients with any abdominal complaints, especially if there is a concern for neutropenic enterocolitis (Table 39.1).

Table 39.1 Diagnostic evaluation of febrile neutropenia

Should obtain for all patients
CBC with diff
CMP
Peripheral blood cultures × 2
Urinalysis and urine culture
Chest x-ray
Strongly consider for all patients
Viral respiratory pathogen panel
Patient-specific additional testing
Additional blood cultures from each CVC
Sputum culture
Stool culture
Fungal cultures
Beta-D-glucan
CSF cell count and culture
CT chest/abdomen/pelvis

CBC complete blood count, *CMP* complete metabolic panel, *CVC* central venous catheter, *CSF* cerebrospinal fluid

Management

Classically, the management of febrile neutropenia has included broad-spectrum antibiotics and hospital admission. This approach minimizes morbidity and mortality by providing aggressive empirical care prior to obtaining microbiological isolates. Since the 1960s, this approach has been supported by a large body of literature in the fields of oncologic, infectious diseases, and emergency medicine [27, 28]. Additionally, hospitalization was classically continued until fevers resolved and neutrophil counts recovered. Subsequent literature, however, suggested that a more nuanced, less aggressive approach may be appropriate for a subset of low-risk patients [29, 30]. This section will first cover febrile neutropenia risk stratification, followed by a discussion on empiric antibiotic therapy and disposition considerations.

Risk Stratification

The risk of severe disease among patients with febrile neutropenia depends on several factors, including the cancer type, medical comorbidities, and a variety of findings on history and physical exam. Patients with a prior history of opportunistic infections, those with anticipated prolonged neutropenia (>7 days less than 100 ANC), or those who have received more intense cytotoxic chemotherapy are known to be of higher risk. Patients with risk of prolonged neutropenia include those who have received several courses of

Table 39.2 MASCC Risk Index Score ≥21 indicates that the patient is low risk for complications

Characteristic	Weight
Burden of illness with no or mild symptoms	5
Burden of illness with moderate symptoms	3
No hypotension (systolic blood pressure >90 mm Hg)	5
No chronic obstructive pulmonary disease	4
Solid tumor or no previous fungal infection	4
No dehydration requiring parental fluids	3
Outpatient status at onset of fever	3
Age <60 years	2

MASCC Multinational Association for Supportive Care in Cancer

Table 39.3 Clinical Index of Stable Febrile Neutropenia (CISNE) score

Characteristic	Points
ECOG PS ≥2	2
Stress-induced hyperglycemia	2

Chronic cardiovascular disease	1
Mucositis National Cancer Institute grade ≥2	1
Absolute monocyte count <200 μL	1

ECOG PS Eastern Cooperative Oncologic Group Performance Scale

myelosuppressive chemotherapy, allogeneic stem cell recipients, patients with bone marrow metastases, and those who have received radiation to the pelvis or long bones [31]. Additionally, those patients who receive alemtuzumab are known to be at particular high risk. Patients with a lower baseline functional status (Eastern Cooperative Oncologic Group Performance Scale [ECOG PS] ≥2) are more likely to develop severe disease. Other indicators of high-risk febrile neutropenia include hepatic or renal insufficiency, uncontrolled or progressive cancer, grade 3–4 mucositis, or those with more life-threatening infectious sources (pneumonia, meningitis, encephalitis, etc.) [31].

One of the most widely accepted tools to aid clinicians in the risk stratification of patients with febrile neutropenia is the Multinational Association for Supportive Care in Cancer (MASCC) score. First published in 2000 by Klastersky et al., the MASCC score synthesizes of variety of clinical and historical data to produce a neutropenic fever risk score (Table 39.2) [30]. Points are assigned based on the lack of high-risk features with a score ≥21 considered as low risk and potentially appropriate for outpatient management (maximum score of 26). Of note, this score was only validated in the adult population and should not be used to risk stratify children.

A more recent risk stratification tool, the Clinical Index of Stable Febrile Neutropenia (CISNE) score, was validated in 2015 by Carmona-Bayonas et al. and specifically targets those patients with solid tumor malignancies (Table 39.3) [2]. This score utilizes similar historical risk factors as the MASCC score but eliminates symptom burden and adds certain laboratory values (absolute monocyte count, presence of hyperglycemia) as well as functional status (ECOG PS). In studies that compared the CISNE and MASCC scores, the CISNE score appeared to have a greater sensitivity in the identification of a low-risk cohort, with fewer patients misclassified as low risk [32, 33]. The most recent American Society of Clinical Oncologic (ASCO) and Infectious Diseases Society of America (IDSA) Joint guideline on the safe discharge of low-risk patients with febrile neutropenia supported the application of the CISNE score to patients with solid tumor malignancy who have received mild- to moderate-intensity chemotherapy. Studies evaluating these risk stratification tools in the ED have similarly supported utilizing the CISNE score to identify low-risk febrile neutropenia patients with solid malignancy who may be suitable for outpatient management [34].

Table 39.4 ASCO/IDSA safe discharge criteria for patients with febrile neutropenia

Residence ≤1 h or ≤30 miles (48 km) from clinic or hospital
Patient's primary care physician or oncologist agrees to outpatient management
Able to comply with logistic requirements, including frequent clinic visits
Family member or caregiver at home 24 h/d
Access to a telephone and transportation 24 h/d
No history of noncompliance with treatment protocols
The following additional measures are recommended:
Frequent evaluation for at least 3 days in clinic or at home
Daily or frequent telephone contact to verify (by home thermometry) that fever resolves
Monitoring of ANC and platelet count for myeloid reconstitution
Frequent return visits to clinic

With regard to febrile neutropenia risk stratification in the pediatric population, there is no universally accepted risk stratification tool. To date, there have been at least 27 attempts to derive a validated score to appropriately categorize pediatric patients as low or high risk; however, none of these scores have achieved adequate sensitivity or specificity [35–38].

Finally, there are several social considerations that must be addressed prior to safely discharging low-risk febrile neutropenic patients. The ASCO/IDSA safe-discharge criteria are listed in Table 39.4 [1].

Antibiotic Therapy

It is recommended that all patients presenting with febrile neutropenia rapidly receive broad-spectrum empiric antibiotics. The joint ASCO/IDSA guidelines state that all patients with febrile neutropenia should receive appropriate antibiotic therapy within 1 h of triage [1]. Perron et al. demon-

strated that early antibiotics significantly decreased hospital length of stay for patients with febrile neutropenia who received early antibiotics. Rosa et al. found there to be a decrease in 28-day mortality for patients who received early antibiotic therapy (within 30 min), with an increase in 28-day mortality by 18% for each hour that antibiotics were delayed [39, 40]. A more recent, well-powered study by Daniels et al., however, demonstrated that only more significant delays in antibiotic administration (>3 h) were associated with increased length of stay and 30-day mortality [41].

Several factors must be considered when choosing the initial antibiotic course including previous culture data, the presence of indwelling catheters, site of infection, organ dysfunction, drug allergy, previous antibiotic therapy, and local antibiograms/sensitivities. Choosing the correct empiric antibiotic is likely the most important modifiable factor affecting the morbidity and mortality of a patient with febrile neutropenia [42, 43]. Previous literature has demonstrated that inappropriate empiric antibiotics may lead to a significant increase in mortality, especially in cases of *Pseudomonas aeruginosa* [44]. Consensus guidelines have been published by the National Comprehensive Cancer Network (NCCN) to guide clinicians in the initial selection of antibiotics for patients with febrile neutropenia (Table 39.5) [31]. Note, however, that one should synthesize all available information (previous cultures, specific risk factors, etc.) before choosing an initial antibiotic.

In an era of increasing antibiotic resistance, there are emerging data that suggest alternating first-line therapies may be beneficial to decrease antibiotic resistance. This strategy has been shown to be effective in increasing antibiotic heterogeneity without worsening outcomes [45, 46]. A recent study among pediatric patients with febrile neutropenia specifically demonstrated a significant decrease in extended-spectrum β-lactamase producers in blood and stool cultures after implementation of antibiotic cycling over a 3-year period [47].

Table 39.5 Typical empiric antibiotic therapy for patients with febrile neutropenia

Inpatient therapy (intravenous)	Outpatient therapy (low risk) (per os)
Cefepime	Ciprofloxacin[a] + amoxicillin/clavulanate
Imipenem/cilastatin	Moxifloxacin[a]
Meropenem	Levofloxacin[a]
Piperacillin/tazobactam	
Ceftazidime[b]	
Vancomycin[c]	

[a]Patients previously on fluoroquinolone prophylactic therapy are not candidates for oral antibiotic therapy

[b]Weak gram-positive coverage may limit utility

[c]Consider vancomycin in patients who have a history of methicillin-resistant *Staphylococcus aureus* (MRSA) colonization, clinical instability, soft tissue infection with high risk of MRSA, or indwelling intravenous catheters

If a patient is risk-stratified into a low-risk cohort after utilizing a validated scoring method, it is appropriate to consider treatment with oral antibiotics. First-line oral therapy typically consists of ciprofloxacin and amoxicillin/clavulanate. Alternative monotherapies with either moxifloxacin or levofloxacin are acceptable. Of note, if a patient was on prophylactic therapy with a fluoroquinolone prior to presentation, these oral regiments should not be utilized. Several studies have demonstrated non-inferiority of oral versus intravenous antibiotics in low-risk patients with febrile neutropenia [48–50]. Given increasing reports of adverse reactions to fluoroquinolone therapy (tendinopathies, CNS complications, etc.), it is important to discuss these potential risks with patients discharged on these oral agents [51, 52]. It is recommended that patients who are identified as potential candidates for home therapy are observed for a period of time in the ED prior to discharge (4–12 h).

Antifungal Therapy

Empiric antifungal therapy is not typically recommended in the acute setting, unless the patient has known invasive fungal disease or has physical exam findings suggestive of invasive fungal disease (i.e., mucormycosis). In general, antifungal therapy is initiated only after 4 or more days (average 7–10 days) of persistent fevers despite broad-spectrum antibiotic therapy [53, 54]. Those with the highest risk of mold infections (neutropenia >10 days, allogenic stem cell recipient, prolonged steroid use) should receive early antifungal coverage (4 days of persistent fever), unless they are already on prophylactic antifungal medications [55].

Antiviral Therapy

Similar to antifungal therapy, antiviral therapy is not typically recommended in the acute setting, unless there is clear indication of a viral infection prompting treatment (i.e., HSV, VZV). It is prudent to assess for common viral upper respiratory infections with a respiratory viral polymerase chain reaction (PCR) swab. Additionally, assessing and treating for influenza may be indicated, especially if a patient presents with the appropriate constellation of symptoms [7].

Granulocyte Colony-Stimulating Factor (GCSF)

Although there is a role for the use of GCSF to prevent febrile neutropenia in patients receiving myelosuppressive therapy, the use of GCSF in patients with established febrile neutropenia has been controversial. Overall, the medication appears to have a negligible effect on patient-centered out-

comes [56]. Specifically, GCSF given during febrile neutropenia does not improve overall patient mortality [57]. Conversely, patients receiving GCSF typically have a shorter duration of neutropenia, faster recovery from fever, and shorter duration of antibiotic use.

Future Considerations

Biomarkers

A significant proportion of patients with febrile neutropenia have little or no symptoms to assist clinicians in making a definitive diagnosis. Although some patients may have non-infectious causes of fever (tumor fever, drug fever) or minor viral infections, there is a subset of febrile neutropenic patients who appear clinically well, despite bacteremia. Unfortunately, blood cultures are classically insensitive and are prone to false positives due to contamination with skin flora. This has led researchers to explore several biomarkers as potential risk stratifications tools to predict poor outcomes in patients with febrile neutropenia.

Procalcitonin (PCT) has emerged as a valuable biomarker to help clinicians differentiate between bacterial illness and alternative causes of inflammation/infection. Unfortunately, previous literature has demonstrated a high variability in PCT levels among patients with febrile neutropenia, and there have been reports of bacteremia in patients with low procalcitonin levels [58, 59]. Serial PCT levels may provide improved discriminatory power [60].

CRP has also been proposed as a possible biomarker to aide in risk stratification. Overall, CRP may have a slightly higher sensitivity than procalcitonin (using a cutoff of >20 mg/L for CRP and >0.2 ng/ml for PCT). However, this sensitivity (0.82, 95% CI) is still too low to safely utilize CRP alone to risk stratify patients. Additionally, PCT appeared to be more discriminatory than CRP at time of disposition.

Interleukin-6 (IL-6) and interleukin-8 (IL-8) may also provide some insight into the risk of severe febrile neutropenia. Both IL-6 and IL-8 appear to have better predictive value than CRP for high-risk febrile neutropenia, with one study reporting that low IL-8 levels predicted patients at low risk for bacteremia with a sensitivity of 0.9 and a negative predictive value of 0.98 [61, 62].

Overall, biomarkers may prove to be very important in differentiating high- vs low-risk febrile neutropenia. Currently, however, the body of literature is lacking, and more evidence is needed before utilizing a single biomarker (or a combination of biomarkers) to definitely risk stratify patients.

Conclusion

Febrile neutropenia is a common complication of cytotoxic chemotherapy, and despite decades of study, it continues to present challenges for acute care providers. It is imperative to initiate a broad workup for these patients and provide rapid, broad-spectrum antibiotic therapy. For clinically stable patients, it is appropriate to apply validated risk stratification tools to identify a low-risk cohort appropriate for discharge. For patients qualifying for outpatient management, one must assure that the proper outpatient structure is in place prior to discharge. Treatment with antibiotics should cover both typical and atypical organisms and should account for previous cultures as well as the bacterial sensitivities of a particular hospital or region. As biomarkers for disease severity are developed and validated, we may more objectively identify patients at higher or lower risk for severe disease.

Neutropenic Enterocolitis

40

Steven McGaughey and Robert L. Cloutier

Case Study

A 70-year-old man with acute myeloid leukemia on daunorubicin and cytarabine for induction therapy presents to the emergency department (ED) after suddenly developing fever, diffuse abdominal pain, and diarrhea. On review of his chart, it is noted that he has been neutropenic (absolute neutrophil count (ANC) = 350/dL) since 9 days prior to presentation. Today, vitals are notable for a respiratory rate of 19 breaths per minute, sinus tachycardia of 120 beats/min, and blood pressure of 105/60 mmHg. On exam, he has right lower quadrant abdominal pain with associated involuntary guarding. Laboratory evaluation reveals a white blood cell count of 1200 cells/μL (ANC = 100/dL), a hematocrit of 23%, and 40,000 platelets/μL. Computed tomography (CT) scan of the abdomen and pelvis shows thickening of the colonic wall with diffuse pericolic edema and pneumatosis. Since the differential diagnosis includes a strong suggestion of neutropenic enterocolitis, the hematology and surgical teams are promptly consulted. The patient is admitted and started on intravenous fluids, ceftazidime and metronidazole, as well as granulocyte colony-stimulating factor (G-CSF). The next day, the patient becomes hemodynamically unstable and is transferred to the intensive care unit where he remains on broad-spectrum antibiotics with close monitoring. On hospital day 5, he shows clinical improvement. Blood cultures remain no growth, and stool studies are negative for Clostridium difficile (C. difficile) or other enteropathogenic organisms. With continued conservative management, the patient had full resolution of symptoms following 14 days of treatment.

Introduction

Neutropenic enterocolitis (NE) is a poorly understood and life-threatening complication of severe neutropenia [1]. While it is most often seen in patients with hematologic malignancies, it can be seen in a wide range of disease processes. NE was first reported as a complication of treatment of childhood leukemias and remains most common in pediatric patients [2]. However, NE is increasingly documented in adults as well, especially in those patients on intensive chemotherapies for hematologic malignancies. Incidence is variable with rates ranging from 0.8% to 26% with a pooled incidence rate of 5.3% [3–5]. Clinical manifestations of NE include fever, abdominal pain or distension, diarrhea, and intestinal bleeding. There are no pathognomonic manifestations or strict diagnostic criteria; thus, a high level of clinical acumen is required to make a prompt diagnosis and start appropriate treatment [1].

NE most commonly occurs 2–3 weeks after chemotherapy is initiated. At this time, a combination of impaired mucosal defense and intestinal injury leaves the bowel susceptible to bacterial invasion with possible progression to perforation [1, 6, 7]. If untreated, these patients can quickly progress to sepsis syndrome with resultant multisystem organ failure. Early reports of NE in the 1960s were almost uniformly fatal. Over the subsequent decades, outcomes have improved; however, morbidity and mortality remain high at between 50% and 100% [8–12].

With the advent of new chemotherapies, more patients than ever are at risk for developing NE, including those with both hematologic malignancies and solid tumors [1, 13]. Emergency physicians and other frontline medical professionals are critical in rapidly identifying and treating neutropenic patients. Given the high morbidity of NE, it is essential that these clinicians have familiarity with this disease process to allow them to more promptly detect and treat these patients appropriately.

This chapter will discuss the background, clinical presentation, diagnostic criteria, risk factors, pathophysiology,

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_40

workup, and management of NE. We note that the nomenclature of NE is heterogeneous; typhlitis, ileocecitis, and cecitis have all been used synonymously in the literature to describe NE. For clarity, we have chosen to use the term NE exclusively in this chapter. This should not be confused with necrotizing enterocolitis or NEC, a separate and unrelated neonatal disease.

Background and State of the Evidence

The first description of NE dates back at to 1933, when Cooke noted submucosal hemorrhage and appendiceal perforation in children with leukemia [2]. More contemporary reports date to 1962, with a case series by Amromin and Salomon [14]. As noted in a review by Cunningham, these patients almost uniformly experienced abdominal pain, distension, leukopenia, and intestinal necrosis with histologic evidence of bacterial invasion of the mucosal and submucosal bowel wall [8]. These patients characteristically developed necrotizing enteric lesions shortly after intensive chemotherapy. These lesions developed regardless of whether the patient responded to chemotherapy. In fact, most patients with NE actually experience excellent therapeutic response prior to developing NE. Unfortunately, the subsequent clinical course in patients diagnosed with NE in the 1960s was marked by hemodynamic collapse and death.

Since then, there have been numerous reports of NE across a spectrum of patients, both with and without cancer. However, the current literature suffers from many limitations. First, these articles have mainly been restricted to case reports and series. A recent review by Gorschlüter noted that, of the 145 papers on neutropenic enterocolitis, there were no clinical trials or case-control studies. The few remaining prospective studies have significant limitations and meet only level 3b evidence according to the Oxford Center for Evidence-Based Medicine [5]. Second, there are no unified diagnostic criteria for NE. As a result, the overall grade of the evidence in neutropenic enterocolitis is low. An editorial by Gorbach summed up the challenges of understanding NE: "the diversity of the pathology is matched by the difficulty in establishing the diagnosis on the basis of only clinical findings" [9]. Despite these challenges, clinicians have made progress in early recognition and treatment of NE, leading to meaningful improvements in patient outcomes [1].

Clinical Presentation

Most patients with NE will present with a combination of diffuse crampy abdominal pain, vomiting, abdominal distension, and diarrhea [1, 10, 15, 16]. The location of abdominal pain is most often diffuse with or without rebound tenderness. Some patients do have localized abdominal pain when NE affects a specific segment of bowel. For example, patients frequently experience right lower quadrant pain which may be due to distension of, and limited blood supply to, the cecum [10, 15]. Patients can have hematochezia or melanotic stools; however, the frequency of these presentations is varied [7, 11, 17, 18]. Peritoneal signs, such as abdominal rebound, guarding, or abdominal distension, may be present if patients develop intestinal perforation. While fever is common, it may be absent in severely immunocompromised patients [10, 15, 16, 19, 20].

Table 40.1 Common signs and symptoms of neutropenic enterocolitis

Vague diffuse crampy abdominal pain
With or without peritoneal signs including rebound and/or guarding
If localizes: more commonly to the right lower quadrant
Abdominal distension
Diarrhea
Fever
Melanotic stools or hematochezia

Overall, the clinical presentation of NE is variable with significant overlap between NE and many other abdominal pathologies representing infectious, chemotherapeutic, and malignancy-induced as well as primary and surgical conditions or causes. The differential diagnosis includes infections, such as *C. difficile* colitis, and chemotherapy-induced conditions, such as mucositis, mycophenolate injury, as well as graft-versus-host disease (GVHD); malignancy-induced conditions, such as recurrent lymphoma and leukemic infiltration; and, lastly, surgical conditions, such as appendicitis or intussusception [1, 7, 12, 21]. Clinically, it is difficult to differentiate between these conditions; thus, prompt imaging is crucial to diagnose NE.

Common presenting signs and symptoms are summarized in Table 40.1.

Diagnostic Criteria

There are currently no universal diagnostic criteria for NE. This is largely due to the vast heterogeneity in pathological, radiographic, and clinical diagnostic criteria across the literature. In 2005, Gorschlüter published a systematic review of NE literature and proposed the diagnostic criteria listed in Table 40.2 [5], which include clinical signs, such as fever and abdominal pain, in combination with imaging findings. While these criteria have been generally accepted, some suggest refining the criteria to include the presence of neutropenia (ANC < 500 × 106 cells/L) and to rule out alternative conditions, such as GVHD, *C. difficile* colitis, and appendicitis [1]. Still others debate including fever as a

Table 40.2 Suggested diagnostic criteria for neutropenic enterocolitis

Presence of fever (axillary temperature >38.0 °C or rectal temperature >38.5 °C)
Abdominal pain (at least degree 3 determined by the patient using a visual analogous scale pain score ranging from degree 1 to 10)
Demonstration of the bowel wall thickening of more than 4 mm (transversal scan) over more than 30 mm (longitudinal scan) in any segment by US or CT

From Gorschlüter et al. [5], with permission John Wiley
US ultrasound, *CT* computed tomography

criteria given how poorly fever correlates with the ultimate diagnosis of NE [22]. Regardless, most authors broadly agree that a combination of clinical signs and symptoms with bowel wall thickening (BWT) on imaging is most appropriate to ultimately diagnose NE.

NE remains a difficult diagnosis for frontline clinicians, including emergency physicians. Neutropenic patients on chemotherapy are at high risk to develop many possible complications. Consequently, clinicians must perform a thoughtful and thorough evaluation and have a high index of suspicion for NE in neutropenic patients presenting with abdominal pain.

Risk Factors

There are several risk factors for developing NE. Numerous chemotherapeutic agents are strongly associated with NE. Cyclophosphamide, 5-fluorouracil, and its prodrug capecitabine, ifosfamide, cisplatin, carboplatin, gemcitabine, cytosine arabinoside, vincristine, doxorubicin, idarubicin, leucovorin, and daunorubicin are all associated with NE [10, 13, 15, 23–25]. Additionally, taxanes (docetaxel, paclitaxel) and vinorelbine, which are used for solid tumors, have been implicated in recent reports [1].

Beyond the chemotherapeutic agents themselves, the risk of a patient developing NE changes depending on the timing of chemotherapy and the resultant duration of neutropenia. The average time between chemotherapy and development of NE ranges from 12 to 17 days. It is during this time frame when cytotoxic chemotherapy causes maximal injury of the mucosal barrier and makes NE possible [26–28]. Some patients will develop NE later in their chemotherapeutic course; however, most NE patients will have neutropenia 2–9 days before developing symptoms [7, 11, 15]. While later onset is less common, this specific population is at an increased risk of death [11]. Other factors associated with increased mortality include older age, more severe and prolonged neutropenia, and concomitant systemic infections [11].

Lastly, there is an association between the type of malignancy and NE. Early cases of NE were found almost exclusively in pediatric leukemias. Today, while the majority of cases of NE are still found in patients with leukemia and lymphoma, a growing number of NE cases are found in patients with solid tumors including breast, lung, colorectal, and ovarian cancer [10, 13, 23, 24]. Overall, patients with hematologic malignancies who develop NE portend a worse overall survival. This may be linked to the longer duration and more profound neutropenia seen with these malignancies and their associated treatments [11].

While most NE is associated with specific chemotherapies, there are a small number of reported cases in patients prior to initiation of treatment [17, 29, 30]. Additionally, there are rare cases of non-oncologic conditions leading to NE. A single trauma patient developed NE in the setting of reversible neutropenia secondary to nafcillin therapy for osteomyelitis [19]. Other cases have been reported in the setting of aplastic anemia, cyclic neutropenia, acquired immunodeficiency syndrome, and immune-suppression for bone marrow or renal transplantation [19, 20]. Overall, any condition which causes prolonged neutropenia places patients at risk for developing NE.

Pathophysiology

The pathophysiology of NE is multifactorial and incompletely understood. The primary effects of neutropenia decrease the immunologic response against intestinal invasion, making the patient more susceptible to infection. Secondly, the intestinal wall is damaged through a number of mechanisms: direct destruction due to chemotherapy and/or radiation, leukemic or lymphomatous infiltrates, or intramural hemorrhage secondary to severe thrombocytopenia. This compromised mucosa ultimately allows translocation of normal gut microbial flora [1, 6, 7, 11, 31]. Innate immunity of the submucosal tissue and proinflammatory mediators leads to a cascade of events culminating in epithelial cell apoptosis and mucosal permeability. Visualized bowel is thickened and edematous with hemorrhage and ulceration [1]. As noted previously, the cecum is particularly susceptible to injury secondary to its more limited blood supply. However, while NE most commonly affects the cecum, this condition may affect any portion of the intestinal tract.

The combination of mucosal injury and neutropenia places patients at high risk of developing bacteremia from gut flora, including *Enterococcus*, *Klebsiella*, and coagulase-negative *Staphylococcus* [11, 12]. In addition, *C. difficile* is commonly seen in NE, but it is generally not thought to be pathogenic as there is no mortality difference in patients with or without this pathogen [32]. Invasive fungal infections, mostly commonly by *Candida*, occur in approximately 5% of cases [33]. Bacteremia is more common, with positive blood cultures found in 28–80% of definite cases of

NE [7, 15, 34]. Overall, while the most common single isolate from blood cultures are aerobic gram-negative bacilli, most cultures show polymicrobial infections [7, 11, 35]. There is no data to suggest that a specific organism or combination of pathogens is associated with NE.

Pediatric Considerations

Considerations in the pediatric population closely mirror those of adults. Hematopoietic malignancies such as acute lymphoid leukemia (ALL) and acute myeloid leukemia (AML) are most commonly associated with NE in the pediatric population [36, 37]. The incidence has been reported to be higher in pediatric patients, varying between 2.6% and 16.2%, which may reflect the highly aggressive malignancies and associated intensive chemotherapy regimens used for treatment [36–39]. A study by McCarville characterizing NE in pediatric patients noted that, similar to adults, diagnosing NE in children based on symptoms alone, is challenging [37]. The clinical presentation of NE in pediatric patients is similar to adults and includes abdominal tenderness, fever, diarrhea, and nausea. However, in 9–16% of cases, typical signs and symptoms, including abdominal pain, fever, and neutropenia, were absent [37]. Overall age, race, and gender are poorly associated with risk of NE; however, patients older than 16 years had an increased odds ratio of NE and had poorer response to therapy than younger patients. Medications and chemotherapeutic agents associated with pediatric NE include GCS-F, topotecan, atovaquone, PEG-L-asparaginase, idarubicin, cytosine arabinoside, hydrocortisone, methotrexate, and carboplatin. Additionally, treatment with cytarabine and presenting with abdominal distention are poor prognostic factors, which are associated with increased mortality [36].

Workup

Initial workup for NE requires ruling out other common conditions, including *C. difficile* colitis, GVHD, and other abdominal pathology, while meaningfully addressing the broader threats posed by potential neutropenia. Thus, initial laboratory testing, including complete blood count, coagulation studies, chemistry panel, and *C. difficile* toxin or polymerase chain reaction (PCR) assay, is recommended. While no laboratory tests will confirm the diagnosis of NE, presence of neutropenia in the absence of other abdominal pathologies strongly suggests a patient is at risk for NE. In these patients, additional imaging is critical in making the correct diagnosis and starting appropriate treatment.

The Role of Diagnostic Imaging: CT and Ultrasound

Because the clinical presentation is nonspecific, imaging is essential in the diagnosis of NE. Computed tomography (CT) and ultrasonography (US) are the most common modalities for diagnosing NE. Conversely, plain radiographs are of limited utility; while positive findings, such as paucity of air in the cecum with associated pneumatosis, can be helpful, most x-rays are nonspecific or normal.

Many clinicians favor CT to evaluate for NE. CT provides a more detailed view of bowel integrity and better characterizes surrounding abdominal inflammation and bowel wall thickening (BWT) (Fig. 40.1) [12, 16, 27, 40, 41]. In addition, CT provides better visualization of other radiographic features of abdominal pathology, including pneumatosis and nodularity. This becomes clinically important when trying to differentiate between NE and other mimics. A retrospective

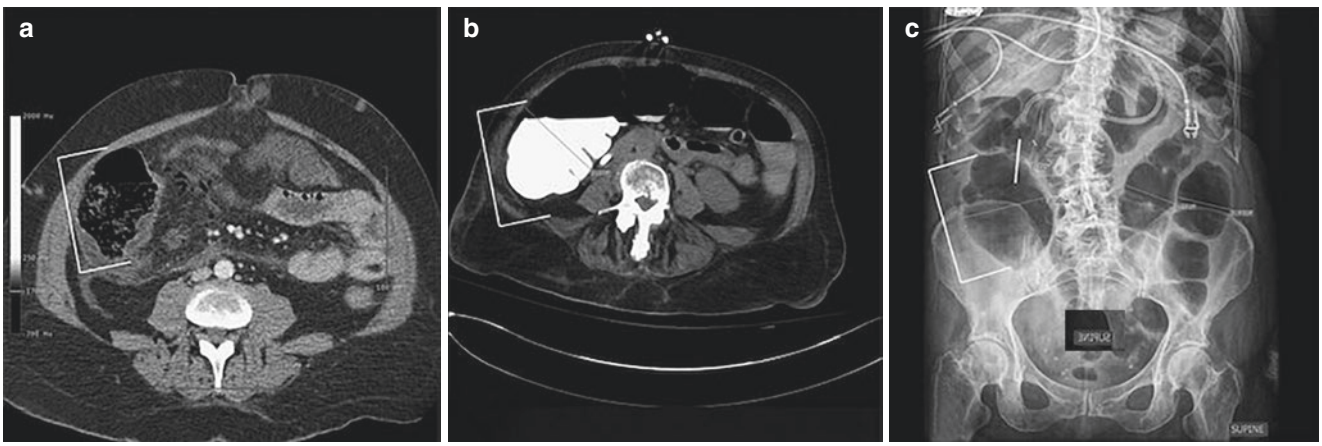

Fig. 40.1 NE imaging findings. (**a**, **b**) Computed tomography images from two different patients with NE; both show cecal wall thickening and dilation (*brackets*). (**c**) Colonic dilatation on an abdominal radiograph; findings are most prominent in the cecum (*bracket*). (From Sachak et al. [12], with permission Wolters Kluwer)

study characterized the CT features of neutropenic patients with radiographic bowel abnormalities—noting specific patterns of BWT, pneumatosis, and nodularity on CT—useful in distinguishing NE from other pathologies, including GVHD, cytomegalovirus colitis, and *C. difficile* colitis [41]. NE was also best characterized by its predilection for the right colon and cecum, with occasional involvement of the small bowel. Lastly, NE exhibited the greatest degree of pneumatosis and mesenteric stranding when compared with GVHD or *C. difficile* colitis [41].

While CT provides highly detailed images, ultrasound can be deployed more quickly and avoids radiation. In an emergent setting, ultrasound-derived BWT measurements can be used to help support the diagnosis of NE or rule out other diagnoses. Measurement criteria for BWT vary due to differences in the sensitivity of sonographic machines and the small number of published studies. Nonetheless, ≥3–5 mm (outer wall to luminal surface) has often been defined as abnormal in pediatric and adult patients [10, 27, 36–38, 40, 42, 43]. Though most authors would agree that BWT of greater than 5 mm is abnormal, the prognostic significance of BWT remains unclear. A few studies, however, report that measurements of greater than 10 mm portend a poor outcome [15, 16, 27]. US is a particularly useful and radiation-free option in the pediatric population. In addition to more well-known signs, a unique finding in the pediatric population, pneumatosis intestinalis with portal venous gas, can be suggestive of pan-intestinal involvement [25].

US may also be useful as an efficient and inexpensive screening tool to initiate antibiotic therapy in the appropriate patient [44]. In a recent study, the authors used US to screen all hospitalized neutropenic patients with fever and abdominal pain and/or diarrhea to evaluate for signs of BWT. If present, they promptly started patients on antifungal agents, antibiotics, and granulocyte colony-stimulating factor. Their mortality of post-chemotherapy patients drastically reduced from 45% pre-intervention to 0% afterward, and mean diagnosis time after fever decreased from 9 days to 3 days [45].

For the emergency clinician, the most appropriate imaging modality will depend upon the hemodynamic stability of the patient. If a patient is safe to transport, he or she will benefit from a CT as this will provide more diagnostic information and help to differentiate from other serious complications of chemotherapy. However, in patients who are hemodynamically unstable, US is a powerful screening tool to evaluate for BWT at the bedside. For any patient who is critically ill, the emergency clinician should request emergent surgical consultation for possible operative resection of necrotic bowel.

Treatment

Medical Versus Surgical

There is no clear consensus on the most appropriate management of NE. Most patients will require supportive measures, including bowel rest, parenteral nutrition, and intravenous (IV) fluid support. Clinicians should also evaluate for and correct severe thrombocytopenia and coagulopathies [1]. In addition, we recommend the prudent advice by Gorschlüter: "to follow a pragmatic strategy analogous to neutropenic [fever of unknown origin], which is always treated as an infectious disease even if sometimes non-infectious causes are present" [5]. Unfortunately, there are no unified recommendations on the most appropriate antibiotics for NE patients [42, 46–49]. We recommend selecting antibiotics that cover a broad spectrum of gram-positive and gram-negative organisms as well as *Pseudomonas* and *C. difficile*. Monotherapies, such as piperacillin-tazobactam or imipenem-cilastatin, are reasonable initial choices. Duo therapies, combining another beta-lactam antipseudomonal agent with an aminoglycoside or, alternatively, cefepime or ceftazidime coupled with metronidazole, are also acceptable. Anaerobic coverage is important primarily when using a cephalosporin monotherapy [5]. Recommended doses for adults and children are summarized in Table 40.3 [51]. In

Table 40.3 Antibiotics for empiric treatment of adult and pediatric neutropenic enterocolitis

Antibiotics for empiric treatment	Dosages
In adult neutropenic enterocolitis	
Monotherapy	
Piperacillin-tazobactam	3.375 g IV Q6 h
Imipenem-cilastatin	500 mg IV Q6 h or 1 g IV Q6–8 h
Duo therapy	
Ceftazidime	1 g IV Q8–12 h ***or***
Cefepime	2 g IV Q8 h ***plus***
Metronidazole	1 g IV Q6 h
In pediatric (1–12 y of age) neutropenic enterocolitis	
Monotherapy	
Piperacillin-tazobactam	(>9 mo and <40 kg) 300 mg/kg/d IV divided Q8 h
Imipenem-cilastatin	(>3 mo) 60–100 mg/kg/d IV divided Q6 h, max 2–4 g/d
Duo therapy	
Ceftazidime	90–150 mg/kg/d IV divided Q8 h max 6 g/d ***or***
Cefepime	50 mg/kg IV Q8 h, max 2 g/dose ***plus***
Metronidazole	30 mg/kg/d IV divided Q6 h max 4 g/d

their invited review, Nesher discourages empiric use of antifungal medications as the frequency of invasive fungemia is only 5%. They further summarized their workup and treatment algorithm which is outlined in Fig. 40.2 [1, 33].

Surgical Intervention

Historically, autopsies of patients with NE showed high rates of transmural bowel necrosis and perforation [15]. Based on this, surgical intervention with bowel resection became first-line therapy, and early studies showed this reduced overall mortality. However, the clinical presentation of NE is heterogeneous, and experts today disagree on the necessity of early surgical intervention [5, 16, 51]. More recently, as clinicians gain more experience with NE, a greater proportion of patients have been successfully managed medically with broad-spectrum antibiotic therapy [5, 15, 16]. Now, surgery is typically reserved for more severe cases, as summarized in Table 40.4; however, there is still wide variation between institutions [1, 11, 12, 49, 52]. If a patient does require non-emergent surgical management, a recent review by Badgwell

Table 40.4 Criteria for surgical intervention

Persistent gastrointestinal bleeding despite correction of coagulopathies, thrombocytopenia, and neutropenia
Intraperitoneal free air
Deterioration despite sufficient medical management, suggesting sepsis
Development of other surgical indications

suggests delaying surgery until neutropenia resolves as this lowers the overall mortality rate [22]. Overall, these recommendations are based on small case series studies; larger prospective studies are required to provide more definitive recommendations on medical versus surgical management.

If the emergency clinician suspects NE in a patient, he or she should organize critical care resources and consult surgery services early. Patients with NE are medically tenuous and have high potential to decompensate and require operative intervention.

Additional Therapy

Recombinant granulocyte colony-stimulating factor (G-CSF) has recently gained more widespread use to hasten bowel healing. In theory, G-CSF causes more rapid recovery of neutropenia which would therefore improve clinical outcomes [5, 10]. However, the data on G-CSF remains mixed. A recent large cohort study by Abu-Sbeih found that while G-CSF shortens the median time of neutropenia, it does not alter frequency of NE-related complications or mortality rates [11]. The American Society of Clinical Oncologic Clinical Practice Guidelines only recommend using a combination of antibiotics and empiric G-CSF in febrile neutropenic patients with high-risk factors including expected prolonged (>10 days) and profound (<0.1 × 109/L) neutropenia, age > 65 years, sepsis syndrome, or hospitalization at the time of fever development [53].

Despite recent gains in outcomes, morbidity and mortality remain high for NE. Treatment for a patient with NE is the same as that for other patients at risk for acute sepsis and hemodynamic collapse. An appropriate initial assessment should include venous access to support aggressive fluid support in addition to broad-spectrum antibiotics. Central venous access and an arterial line may be necessary for goal-directed therapy for sepsis. Lastly, clinicians should remain vigilant and monitor carefully for surgical indications, such as signs of an acute abdomen or hemodynamic compromise.

Summary

NE is a relatively rare but potentially devastating disease most often seen in neutropenic patients after chemotherapy. It is critical that emergency clinicians promptly identify and triage at-risk patients. Early recognition and intervention are essential to minimize morbidity and mortality in patients with NE. NE should be suspected in any neutropenic patient with abdominal pain. Patients who recently received chemotherapy are at particularly high risk. We recommend laboratory testing, including complete blood count to evaluate for neutropenia and thrombocytopenia, coagulation studies to evaluate for reversible coagulopathies, chemistry panel, and *C. difficile* toxin or PCR assay. In addition, we recommend rapid abdominal imaging. In a stable patient, CT can provide highly detailed information on bowel wall thickening which can help to differentiate between NE and other mimics. However, in the unstable patient, ultrasound may be appropriate as a fast, effective means to evaluate the bowel wall. Treatment includes bowel rest, parenteral nutrition, IV fluids, and correction of severe thrombocytopenia and coagulopathies. Broad-spectrum antibiotics with adequate coverage for intra-abdominal pathogens should be utilized. G-CSF may be beneficial in high-risk patients. Surgery services should be consulted early as NE patients can deteriorate rapidly.

Sickle Cell Disease

41

Harsh P. Sule, Novneet N. Sahu, and Bernard L. Lopez

Case Study

A 25-year-old female with history of sickle cell disease (SCD) presents to the emergency department reporting 10/10 dull, aching pain in her back and hips. She has been taking her home regimen of morphine around the clock without relief. She took her last dose of medication just prior to arrival. She states that this is typical of prior episodes where she has needed care in the emergency department. Her vital signs are temperature of 37.2 °C, heart rate of 80 beats per minute, blood pressure of 112/72, and oxygen saturation of 99% on room air. She has a normal exam, and you do not suspect dehydration, organ failure, or neurological complications. Her old records are reviewed, and she has been previously given higher doses of morphine in the emergency department with relief. You suspect an acute painful episode associated with vaso-occlusive crisis and provide her repeat doses of pain medication. Her symptoms improve after the third dose of pain medication and she feels well. You discharge her home to continue her outpatient regimen and she will follow up with her hematologist.

Introduction

Emergency physicians (EPs) practicing in North America must be familiar with SCD and its complications. SCD is the most common inherited blood disorder in the United States [1]: 1 in 13 African American newborns has sickle cell trait, while 1 in 365 African Americans has the disease [2]. In SCD, hemoglobin molecules have a propensity to aggregate into rigid polymers, particularly under conditions of low oxygen tension, resulting in the characteristic sickle-shaped erythrocytes that cause vaso-occlusion and ischemia. The clinical hallmark of SCD is episodes of acute pain, and this is by far the most common reason for emergency department (ED) visits and inpatient admissions by SCD patients [3–6]. In addition to managing these acute pain episodes, the EP must be alert to other manifestations, complications, and comorbidities of the disease, some of which carry significant risk for morbidity and mortality.

This chapter describes the clinical presentations and management of SCD in the ED while delving into key decisions and current controversies.

Pathophysiology

SCD was first described in the Western medical literature by James B. Herrick in 1910 [7]. In 1949 James V. Neel described the pattern of inheritance, with individuals who were heterozygous for the responsible gene having sickle cell trait (SCT) and homozygous individuals having SCD [8]. SCD was the first human anemia defined at the amino acid level [9].

Human hemoglobin (Hb) molecules are typically tetramers comprising four subunit proteins (two α and two β subunits) [10]. The exact composition of the peptide chains determines the specific shape into which the molecule can fold. Hemoglobin S (HbS) is the result of a glutamic acid to valine substitution at the β6 amino acid position [11, 12]. The result is polymerization due to a hydrophobic interaction between the altered, deoxygenated molecule and other hemoglobin molecules [11]. As a consequence, there are a change in the shape and reduction in the critical ability of erythrocytes to deform [11, 12]. While initially thought that the ensuing change in flow characteristics and erythrocyte aggregation alone caused vaso-occlusion, the root cause is multi-factorial. Initial endothelial activation with increased adhesion of erythrocytes and leukocytes is followed by

formation of heterocellular aggregates that then physically result in occlusion and local hypoxia [11]. This triggers a vicious cycle of increased HbS formation due to hypoxia, presence of inflammatory mediators, free radicals, and reperfusion injury. Hemoglobin also binds nitric oxide (NO), a potent vasodilator, and releases it with oxygen [10]. Ineffective binding and release of NO along with hemolysis and erythrocyte lysis further reduce NO production and result in persistent tissue hypoxia [10, 11, 13]. Finally, erythrocytes are more likely to sickle and become rigid the more dehydrated they get. This is in large part due to changes in cation homeostasis – specifically, increased potassium and water efflux mediated by potassium-chloride co-transport and Gardos channels (Ca^{++}-dependent K^+ channel) [11, 14]. Figure 41.1 [12] displays the pathophysiology of sickle cell disease.

Sickle cell disease is commonly represented by the primary HbSS genotype. There are also five other genotypes that are associated with varying clinical severity, and all have a majority of their hemoglobin as HbS [13]. HbSS, commonly referred to as sickle cell SS disease, is the most severe clinically, with the heterozygous HbS/β^o thalassemia genotype being similarly severe. HbSC has intermediate severity, HbS/β^+ has mild to moderate severity, and HbS/HPFH (hereditary persistence of HbF) and HbS/HbE demonstrate mild to no symptoms [14]. There exist several other genotypes that are exceedingly rare but do cause disease of varying severity. Those with sickle cell trait (heterozygous with HbA) have hemoglobin that is majority HbA [13]. Table 41.1 [15] displays the genotypes and phenotypes of different sickling disorders.

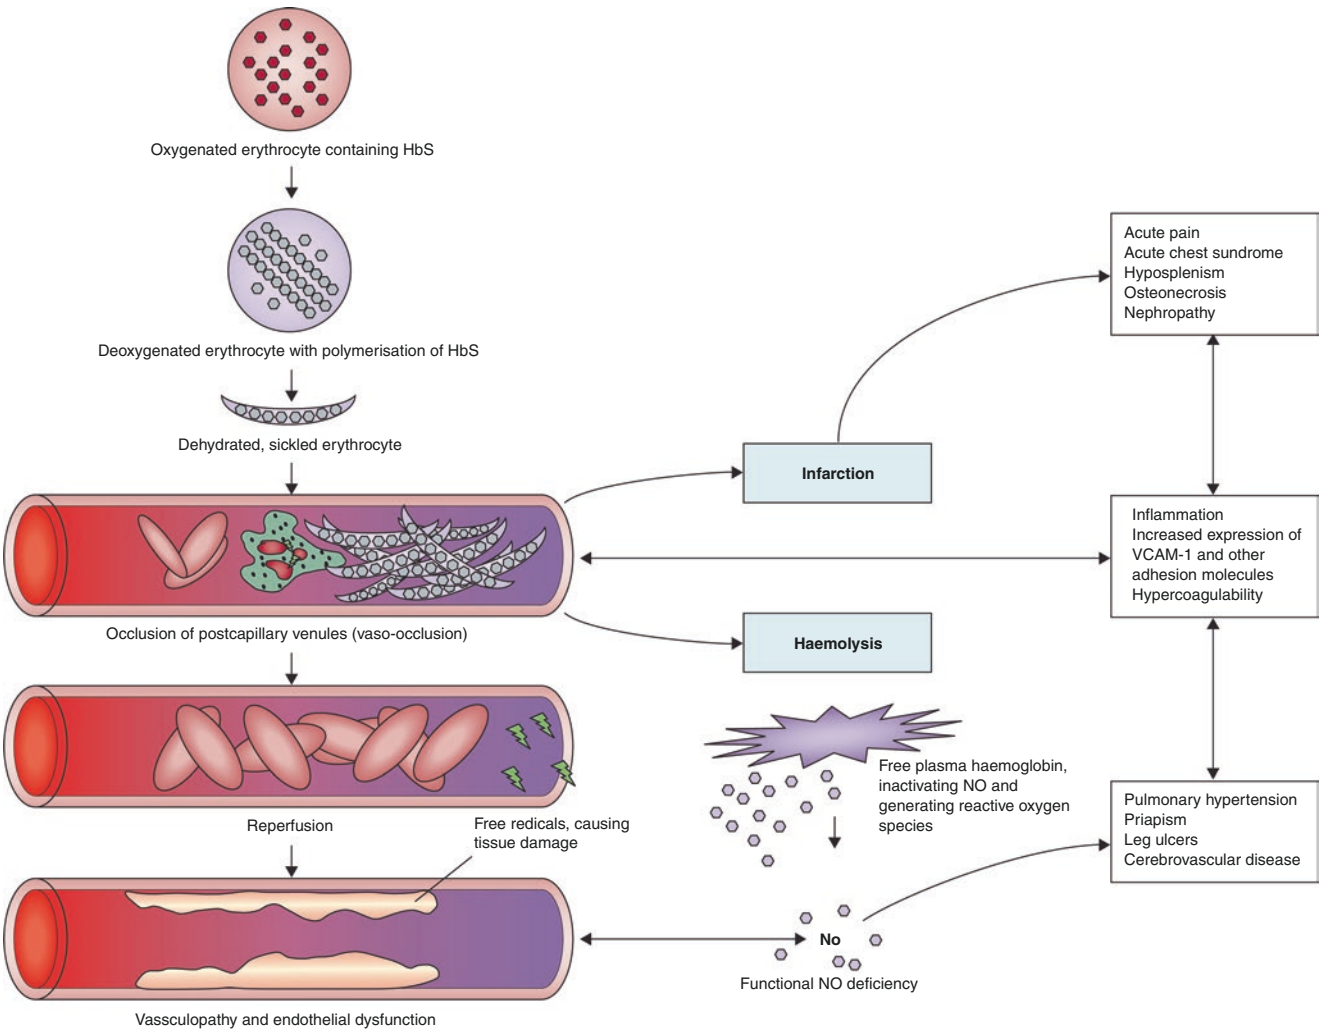

Fig. 41.1 Pathophysiology of sickle cell disease. (From Rees et al. [12], with permission of The Lancet and Elsevier)

Table 41.1 Genotypes and characteristics of different sickling disorders

	HbA (%)	HbS (%)	HbC (%)	HbF (%)	HbA_2 (%)	Clinical course
Normal	95–98	0	0	<1	<3.5	–
Trait conditions						
Sickle trait HbAS	55–65	30–40	0	<1	<3.5	Benign
Hemoglobin C trait	55–65	0	30–40%	<1	<3.5	Benign
β-Thalassemia trait	90–95	0	0	1–3	>3.5	Benign
Disease conditions						
Sickle cell anemia	0	80–95	0	5–15	<3.5	Severe
Sickle C disease	0	50–55	40–45%	<3	<3.5	Moderate
S/β^0 thalassemia	0	80–90	0	5–15	>3.5	Severe
S/β^+ thalassemia	10–25	70–80	0	<3	>3.5	Mild
S/other (Hb variant)	0	50–60	0	Variable	<3.5	Variable

Epidemiology

Based on geographical distribution and genetic studies, the sickle cell gene is thought to provide protection against malaria infection by *Plasmodium falciparum* in heterozygotes [16]. Despite the length of time since this association was first proposed, the exact cellular mechanisms for this protection remain unclear [17]. Geographic distribution of HbS genotypes is based on the presence of malaria in a region and ensuing migration trends. While SCD is most common among people of African descent, it is also found among people of South Asian, Middle Eastern, and Mediterranean descent [18]. There are four African haplotypes and one Arab-Indian haplotype [12].

In the United States, prevalence of SCD is highest in the African American population (1 in 365 Black or African American) with the average age of death in all patients with SCD being 39 years [19]. With advances in medical care, survival to the age of 18 is now 93.9% with a mortality rate in pediatric patients of 0.52 per 100 patient years [20].

Clinical Presentations in the ED

Table 41.2 summarizes the various acute and chronic clinical presentations of sickle cell anemia [21]. Figure 41.2 shows the biochemical targets of potential treatments for SCD [21].

Pain in Sickle Cell Disease

While EPs most frequently encounter acute pain associated with SCD, they must become familiar with other types of pain that occur in patients with SCD (Table 41.3) [22]. The EP faces three important challenges. First, the EP must recognize other causes of pain that may masquerade as vaso-occlusive crisis (VOC) pain, in some instances representing dangerous conditions such as acute chest syndrome (abbreviated here as AChS to avoid confusion with acute coronary syndrome). However, adult patients with SCD can reasonably differentiate their VOC-related pain from other causes [23]. Second, the EP must be alert to other dangerous conditions that are not painful and are masked by the patient's preoccupation with their acute pain. Third, the EP must

Table 41.2 Clinical manifestations of sickle cell anemia

	Complication	Characteristics
Acute	Acute pain episodes (vaso-occlusive events)	Most common complication of SCD. Severity varies and may be manageable at home or require hospitalization
	Acute chest syndrome	Development of chest pain accompanied by fever, respiratory symptoms, and a chest X-ray with a new pulmonary opacity; associated with hypoxemia in severe cases
	Stroke	Both ischemic and hemorrhagic stokes may occur in adult SCD
	Thrombosis	Can occur in adult SCD, particularly during pregnancy and post-partum
	Liver complications	Acute pain in the right upper quadrant with jaundice requires workup to distinguish between acute cholecystitis, acute viral hepatitis, hepatic sequestration, and sickle cell intra-hepatic cholestasis
	Infections	Most frequently pneumonia, osteomyelitis, and urinary infections; may progress to or present primarily as sepsis
	Priapism	Compartment syndrome of the penis causing "stuttering" (short-lived, intermittent) or prolonged (lasting over 4 h) painful penile erections; can cause permanent erectile dysfunction
	Aplastic crisis	Exacerbated anemia accompanied by reticulocytopenia, usually caused by parvovirus B19 infection

(continued)

Table 41.2 (continued)

	Complication	Characteristics
Chronic	Hemolytic anemia	Normocytic, normochromic anemia; hemoglobin levels may vary between 6 and 10 g/dL, accompanied by reticulocytosis
	Functional asplenia	Splenic dysfunction and eventual autosplenectomy secondary to the splenic infarction that usually occurs during childhood
	Avascular necrosis	Can affect hip(s) or shoulder(s) causing early osteoarthritis and chronic pain
	Osteopenia and osteoporosis	Reduction of bone mass density occurs earlier than in the general population; is progressive and associated with hemolysis in SCD
	Pulmonary arterial hypertension	Exertional dyspnea or fatigue with chronic oxygen desaturation, caused by pulmonary artery lumen restriction and wall stiffening, linked to hemolysis, and associated with poor prognosis
	Gallstones/ cholelithiasis	Caused by augmented heme breakdown due to hemolysis
	Retinopathy	Proliferative retinopathy is relatively frequent, especially in HbSC disease and may cause blindness
	Nephropathy	Hyperfiltration and hyposthenuria occur early; incidence of microalbuminuria increases with patient age and can result in end-stage kidney disease
	Heart disease	Includes diastolic dysfunction with increased mortality, overt heart failure, and under-recognized acute myocardial infarction
	Leg ulcers	Development of ulcers in the maleolar and distal leg skin can be a recurring complication. These ulcers are painful, disfiguring, and are difficult to heal
	Neurological complications	Neurocognitive impairment is frequent, particularly in patients with previous stroke. Moyamoya syndrome may also occur, with proliferation of intracerebral blood vessels caused by stenosis or occlusion of cerebral arteries, increasing risk for acute cerebrovascular events

Table 41.3 Types of pain in sickle cell disease

Intermittent pain syndromes
VOC with pain-free periods between recurrent episodes
Priapism
ACS
Splenic sequestration
Hepatic sequestration
Intrahepatic cholestasis
Dactylitis (hand-foot syndrome)
Intractable VOC with persistent pain between VOCs
Due to activation of the NMDA receptor
Due to central sensitization
Due to glial activation
Chronic pain syndromes
Leg ulcers
AVN
Chronic osteomyelitis
Osteoporosis/osteopenia
Neuropathy/neuropathic pain
Pain due to comorbidities
Mixed syndromes including two or more of the above types

From Ballas [22], with permission John Wiley & Sons
ACS acute chest syndrome, *AVN* avascular necrosis, *NMDA* N-methyl-D-aspartate, *VOC* vaso-occlusive crisis

promptly initiate analgesia and other therapy for the acute painful episode.

Chronic Pain in Sickle Cell Disease The Pain in Sickle Cell Epidemiology Study (PiSCES) found that in adult patients pain was reported in 56% of patient-days, with 29.3% of patients reporting pain on more than 95% of days logged [24]. Furthermore, this study identified that only 3.5% of patient-days were associated with utilization of healthcare services. These numbers are important to recognize in terms of reducing the biases that healthcare providers often harbor toward patients with SCD. The Analgesic, Anesthetic, and Addiction Clinical Trial Translations Innovations Opportunities and Networks-American Pain Society Pain Taxonomy (AAPT) initiative has developed diagnostic criteria for chronic sickle cell disease pain involving five dimensions [23]. These should be reviewed by providers in ED observation units and day units for sickle patients to gain familiarity with the spectrum of pain SCD patients experience. Table 41.4 outlines the AAPT criteria [23].

Table 41.4 American Pain Society Pain Taxonomy diagnostic criteria for chronic pain associated with sickle cell disease (SCD)

Dimension 1: Core diagnostic criteria
1. Diagnosis of SCD confirmed by laboratory testing
2. Reports of ongoing pain present on most days over the past 6 months either in a single location or in multiple locations
3. Must display *at least 1* sign:
Palpation of the region of reported pain elicits focal pain or tenderness
Movement of the region of reported pain elicits focal pain
Decreased range of motion or weakness in the region of reported pain
Evidence of skin ulcer in the region of reported pain
Evidence of hepatobiliary or splenic imaging abnormalities (e.g., splenic infarct, chronic pancreatitis) consistent with the region of reported pain
Evidence of imaging abnormalities consistent with bone infarction or avascular necrosis in the region of reported pain
4. There is no other diagnosis that better explains the signs and symptoms
Chronic SCD pain diagnostic modifiers:
We propose three diagnostic modifiers to indicate subtypes of chronic SCD pain
1. Chronic SCD pain without contributory disease complications is used if there is no evidence of contributory SCD complications on the basis of either clinical signs (e.g., presence of leg ulcers) or test results (e.g., imaging abnormalities)
2. Chronic SCD pain with contributory disease complications should be used if there is evidence of contributory SCD complications on the basis of clinical signs or test results
3. Chronic SCD pain with mixed pain types should be used if there is evidence of contributory SCD complications (e.g., avascular necrosis) on the basis of clinical signs or test results and there is pain also occurring in unrelated sites (e.g., arms, back, chest, or abdominal pain)

From Dampier et al. [23], with permission Elsevier

Vaso-occlusive Crisis and Acute Painful Episodes Vaso-occlusive crisis (VOC) is the most common ED presentation of SCD. Patients with HbSS or HbSβ0 experience frequent VOCs, while those with sickle cell trait do not experience typical VOCs [25]. Microvascular occlusion (the cardinal pathophysiologic cause of acute pain) leads to ischemia and hypoxia. This is followed by tissue and vascular damage and inflammation, with release of inflammatory mediators, all of which activate nociceptors [22, 26]. Reperfusion intensifies the inflammation and resultant pain [3, 4, 6]. Patients experiencing frequent pain crises (more than three per year) are at higher risk for complications including a higher mortality rate [23].

Classically, acute pain from VOC is described in the back or extremities, although it may occur elsewhere. It may be migratory and is usually continuous and progressive. VOC pain occurs less frequently elsewhere, such as in the chest, where it may create diagnostic overlap with acute chest syndrome and other causes of chest pain. Pain from VOC should be distinguished from two other patterns of pain experienced by patients with SCD: acute flare of chronic pain and neuropathic pain. Generally, the major focus for the EP is upon management of acute painful episodes caused by VOC.

There are no reliable signs or tests to indicate the presence or absence of VOC or pain associated with VOC. Patients' self-reported pain scores do not reliably correlate with changes in vital signs, such as tachycardia, hypertension, or tachypnea, that may be associated with pain in other clinical contexts. Hemoglobin, hematocrit, and reticulocyte measurements do not serve as markers for pain; neither do some more recent tests such as inflammatory cytokines [26]. Further, patients may exhibit behavior which EPs consider inconsistent with pain, including walking, engaging in conversations, or having a calm appearance while still reporting high levels of pain [3, 5, 27]. Laboratory tests should be ordered for patients who are being admitted and for other indications that may be considered.

Opioids have been the mainstay of analgesia for acute painful episodes over the past century. Meperidine was commonly used in the past but is no longer a commonly available or utilized medication because it is metabolized to normeperidine and has been linked to emotional and behavioral changes as well as seizures due to renal excretion and a long half-life [28–30]. More recently morphine, fentanyl, and hydromorphone became the medications of choice in EDs. However, with the recent opioid crisis and related stigma and addiction concerns, there is an emphasis on using these in an incremental and targeted manner.

Contemporary management of acute painful episodes is outlined in Table 41.5. Key goals include prioritization of these patients in triage, early and adequate analgesia, and frequent repeat dosing until pain is controlled [3, 22, 25–31].

Table 41.5 Emergency department (ED) management of sickle cell disease-related pain

Triage
Triage as high priority ESI level 2
Assess for complications and administer first dose of analgesic within 30 min of triage or within 60 min of registration
Route of administration
Oral route preferred for initial dose
Intranasal can be an alternative for appropriate medication
Intravenous should be used for second-line therapy
Avoid intramuscular route due to unpredictable pharmacokinetics
Medications
Opioid naïve: NSAIDs such as ibuprofen and ketorolac for mild-moderate pain, with oral immediate-release morphine or intranasal fentanyl for severe pain
Opioid tolerant: Oral immediate-release morphine based on home dose, with intranasal fentanyl as an alternative
Intravenous morphine if unable to tolerate or failed oral administration
Pain/sub-dissociative dose ketamine for persistent/uncontrolled pain
Avoid meperidine and hydromorphone
Reassessment
Within 30 min
Use capnography if available before initiating additional or higher doses of morphine
Consider admission or placement in observation unit if pain is not controlled within 90 min with adequate dosing
Adjuncts
Ondansetron for nausea or vomiting
Oral diphenhydramine for itching associated with opioids (with first dose only)
Acetaminophen as an adjunct for pain relief
Consider non-pharmacologic approaches such as heat, acupuncture, etc.
Other therapies
Intravenous fluids: routine fluids not indicated in the ED if euvolemic – bolus only if hypovolemic
Oxygen: only if hypoxic (oxygen saturation less than 92%)
Nitric oxide: vasodilatory effect, but limited data on benefits with potential risks
Hydroxyurea: increased HbF and reduces frequency of VOC

ESI Emergency Severity Index, *NSAID* non-steroidal anti-inflammatory drug, *VOC* vaso-occlusive crisis

Avoid using the intramuscular route and administer fluids only to patients who are hypovolemic.

Patients with acute painful episodes may be discharged if their pain is adequately controlled and they expect, based on past individual experience, that it will remain adequately controlled with ongoing use of their outpatient analgesic regimen. There is no evidence-based fixed number of doses of opioid medication established as a threshold for admission decisions, and EPs should judge the necessity of admission on clinical grounds, balancing the benefits of pain control with parenteral opioids and adjuvants against the well-known risks of hospitalization.

Day clinics are a complement and alternative to traditional inpatient therapy for acute painful episodes [5, 31]. Day clinics are less resource intensive than EDs, with less associated pressure on length of stay and more room to achieve pain control and discharge to home without repeat presentation. Day clinics can additionally complement outpatient hematology clinics as part of a medical home for patients with SCD, providing a multidisciplinary approach beyond acute pain management.

Acute Chest Syndrome

Acute chest syndrome (AChS) is defined as the appearance of a new pulmonary infiltrate on chest radiography accompanied by a fever and respiratory symptoms including cough, tachypnea, and chest pain [32, 33]. It is hypothesized that AChS is the result of hypoxia and an inflammatory mediator-induced increase in adhesion of the pulmonary microvasculature to sickled erythrocytes. This is coupled with a reduction in NO that would normally counteract this [34, 35]. The most common symptoms in patients with AChS are fever (80%) and cough (62–74%), with rales being the most common finding on physical exam (48–76%) [33]. Table 41.6 displays clinical and laboratory characteristics of acute chest syndrome [33].

Table 41.6 Select clinical and laboratory characteristics at diagnosis of acute chest syndrome

	CSSCD	MACSSD

While a significant portion (45.7%) of cases of AChS are due to unknown etiologies, 30% of AChS cases yield a documented infection, and about 9% are attributed to a pulmonary fat embolism (which in turn could be due to infection) and 16% to pulmonary infarction (not caused by infection or fat embolism) [35]. Hypoventilation due to two common clinical scenarios puts the patient at risk for AChS: splinting (pain) and/or opioid analgesic side effects (somnolence) [33]. Pulmonary edema caused by intravenous hydration may lead to AChS, but the data is not conclusive. Pulmonary thrombosis occurs in about 17% of cases with AChS, but it is unclear if it is a cause of AChS [36]. Additionally, the use of clinical decision rules such as the revised Geneva score and d-dimer testing have not been found to be useful in patients with AChS [36].

Initial management of AChS includes empiric antibiotics (cephalosporin and macrolide – to ensure coverage of chlamydia and mycoplasma); however, antibiotics do not appear to have a significant effect on patient outcomes [25]. In a single, small randomized controlled trial, dexamethasone use was shown to have a short-term benefit on hospital length of stay, need for transfusions, number of opioid doses, and clinical condition [37]; however, with longer follow-up, results were inconsistent. There is wide variability in dexamethasone use between hospitals, and in the absence of larger randomized clinical trials, it is difficult to determine its efficacy with any precision [38]. Incentive spirometry plays a significant role in the prophylaxis and treatment of AChS [25]. Pain medications and intravenous hydration should be administered judiciously due to their risk of worsening the condition.

Blood transfusion has been used effectively in the United States for treatment of AChS, but a significant improvement in mortality rate has not been noted when compared to Europe, where it is not used as routinely [35]. Additionally, substantial increases in hemoglobin levels can increase viscosity, thereby raising the risk of complications. Exchange transfusion may be considered in patients with a baseline "high" hemoglobin or those with "multilobe involvement, persistent or worsening hypoxemia, neurologic abnormalities, or multi-organ failure" but has also had mixed results [25, 35, 39, 40]. Both transfusions retain a "Strong Recommendation" from the National Heart, Lung, and Blood Institute's Expert Panel but with low-quality evidence [25].

The role of anti-coagulation in AChS patients with pulmonary thrombosis remains unclear, but EPs would be hard-pressed to avoid anti-coagulation if CT findings are consistent with a pulmonary artery occlusion. Nitric oxide inhalation and steroids may also be used in the management of AChS, but at present, these therapies should be considered experimental [35].

Disposition of these patients should be dictated by their clinical status. While increasing age is associated with worse outcomes (adults generally do worse than pediatric patients) and up to 3% of patients with AChS die, absolute predictors of bad outcomes are difficult to define. The best predictors of bad outcome are extensive lung involvement on x-ray, a platelet count of less than 199,000/mm^3, and cardiac disease as a comorbidity [35]. All patients with AChS should initially be admitted to a monitored setting (not necessarily an intensive care unit).

Fever and Infection

Patients with SCD are at high risk for infections with encapsulated organisms due to functional asplenia, as well as a functionally immunocompromised state (increased bone marrow turnover and altered complement activation) [4]. Penicillin prophylaxis in children and widespread use of the pneumococcal vaccine have made tremendous headway in reducing the incidence of bacterial infections and sepsis [25]. However, EPs must remain aggressive in working up any SCD patient presenting with a fever while keeping in mind that their reduced ability to mount an inflammatory response may limit leukocytosis or even an elevated temperature.

A low threshold should be employed to order a complete blood count (CBC), chest x-ray, and urinalysis at minimum. If no source if identified, consideration should be given to obtaining blood and urine cultures, performing a lumbar puncture, evaluating for potential arthrocentesis, and initiating empiric antibiotics. Workup and treatment should be even more aggressive in pediatric patients since the risk of overwhelming *Streptococcus pneumoniae* sepsis is high [25, 41].

Admission to the hospital should be strongly considered for ill-appearing patients with SCD and a temperature ≥103.1 °F (39.5 °C) [25]. Outpatient management with administration of parenteral long-acting antibiotics may be considered in select patients with reliable follow-up (within 24 h) as long as they defervesce, have never been septic, and have a normal chest radiograph, oxygen saturation, baseline white blood cell (WBC) count, platelet count, and hemoglobin.

Pulmonary Hypertension

Pulmonary hypertension (PHTN) has an incidence of 6–10% and a mortality rate of 2–5% [13]. PHTN is thought to be due in large part to changes in medial smooth muscle and endothelial cells. The key clinical finding is reduced exercise

capacity (45% of patients are New York Heart Association class III or IV) [13]. Diagnostic findings include an elevated N-terminal pro-brain natriuretic peptide (NT-proBNP), an elevated tricuspid valve regurgitant jet velocity on echocardiography, and elevated pulmonary pressures on right heart catheterization.

Currently there is no approved and effective therapy to manage PHTN in SCD patients. Sildenafil, used in non-SCD-related PHTN, has been studied but was found to increase acute pain episodes [13].

Cerebrovascular Accident

While strokes are unusual entities in the general pediatric population, they are relatively frequent in children with SCD and more common in children than adults with SCD [12, 13]. Cerebrovascular accidents (CVA) can occur in children as young as 2 years of age, with 11% of patients with SCD having a stroke by 20 years of age [12]. However, silent cerebral infarcts (SCI) associated with small-vessel disease are more common than overt strokes with 34% of SCD patients having evidence of SCI by age 14 [13]. Symptomatic patients exhibit vasculopathy primarily in the distribution of mid- to large-sized arteries (distal internal carotid and middle cerebral arteries) which is triggered by anemia, leukocytosis, hypoxia, and impaired regulation of blood flow [12, 13].

The Stroke Prevention Trial in Sickle Cell Anemia (STOP) study showed that in patients with elevated transcranial Doppler velocities, prophylactic blood transfusion to maintain HbS less than 30% could reduce the risk of stroke to less than 1% [42]. Exchange transfusion is recommended in SCD patients with an image-confirmed acute CVA [25, 43]. Additionally, myeloablative bone marrow transplant appears to offer a significant benefit in limiting cerebral vasculopathy and, in turn, risk for a CVA [13]. Tissue plasminogen activator (tPA) has not been studied specifically in patients with SCD. Therefore, the determination of whether to treat SCD patients presenting with a CVA with tPA should be made in consultation with a neurologist and hematologist [4].

Pulmonary Embolism

Patients with SCD should intuitively seem susceptible to venous thromboembolism (VTE) given their increased coagulability, endothelial dysfunction, and impaired blood flow (Virchow's triad) [44, 45]. Indeed, the incidence of pulmonary embolism (PE) is higher in patients with SCD. There is a 50–100-fold increase in annual incidence in inpatients with SCD compared to those without SCD [44, 46, 47]. VTE is present in 50% of autopsies of patients with SCD, and yet only 5% of these are detected clinically [46]. Additionally, patients with AChS have a reported PE prevalence rate approaching 17%, and PE may be a contributing factor to the pulmonary hypertension seen in patients with SCD [36]. Despite this, inpatients with SCD undergo fewer chest computed tomography (CT) angiography tests for PE compared to those without SCD [46].

Unfortunately, several clinical prediction rules for VTE are unreliable in the setting of SCD since symptoms of AChS and VOC may overlap with those of VTE. D-dimer testing is also of limited utility since elevated D-dimer levels are found in the vast majority (92%) of patients with VOC [44, 45].

Therefore, a high index of suspicion for VTE must be maintained when evaluating patients with SCD. Computed tomography pulmonary angiography (CTPA) and ventilation-perfusion scanning are both reasonable options for the further workup of pulmonary embolism [48, 49]. Despite concerns and reports regarding intravenous contrast inducing nephropathy and/or increasing sickling of erythrocytes, there is data indicating no difference in adverse events compared to patients without SCD. Lower extremity venous duplex evaluation should also be considered to reduce radiation risk and the risk of other complications in patients with VOC.

Acute Coronary Syndrome

The literature indicates that patients with SCD have minimal atherosclerosis of the large coronary arteries [50–53]. This is despite case reports and autopsy series which reveal findings of myocardial infarction presumably from vaso-occlusive effects on coronary microcirculation [53–55]. Therefore, acute coronary syndrome (ACS) should be considered in the differential for patients with SCD presenting with cardiac symptoms regardless of age (since VOC at the microvascular level is not age dependent).

Since SCD by itself does not result in a baseline increase in cardiac biomarkers (troponin-I, troponin-T, and creatinine kinase isoenzyme MB) [53, 56], an appropriate strategy would be to evaluate patients that are deemed at risk for ACS with serial electrocardiograms and serial cardiac biomarkers. Stress testing or cardiac CT angiography (CCTA) should be considered based on national guidelines.

The treatment of acute ST-elevation myocardial infarction should err on the side of interventional treatment since thrombolytics have not been studied specifically in patients with SCD. However, when interventional options are unavailable in a timely manner, thrombolytics should be considered in consultation with a hematologist and cardiologist when possible.

Renal Complications

Renal complications are extremely common in SCD with 30% of adults developing chronic renal failure [13]. Pre-renal, post-renal, and intrinsic renal factors all contribute to this dysfunction. Acute kidney injury can occur during an acute VOC due to low partial pressure of oxygen, low pH, and high osmolality in the renal medulla which all contribute to erythrocyte dehydration and vaso-occlusion [12, 25]. Diffuse vaso-occlusion can result in multisystem organ failure including renal complications.

Microalbuminuria and proteinuria are common diagnostic findings [14, 25]. It is important to avoid nephrotoxic drugs and monitor renal function on a regular basis. ACE inhibitors are used prophylactically (including in children) to reduce the progression of disease, while transplantation has significant benefits in survival over dialysis [12].

Ocular Complications

Proliferative retinopathy is the most common ophthalmologic complication of SCD (more common in HbSC – as high as 70%) and results from occlusion of the peripheral retinal vasculature [13, 14]. Permanent loss of vision can occur from ocular complications not only due to progression of this proliferative sickle retinopathy but also from complications of trauma, infection, and VOC.

Hyphema can lead to significant complications in patients with SCD and also with sickle cell trait since sickling is more likely to occur in the hypoxic and acidotic anterior chamber with resultant outflow tract obstruction. The elevated intraocular pressure (IOP) that results can cause central retinal artery occlusion and infarction of the optic nerve [57, 58]. Presence of a significant hyphema warrants ophthalmologic consultation with possible surgical drainage [59, 60].

Orbital infarction, although rare, can also occur in SCD patients experiencing a VOC, and compression of the optic nerve as well as nerves affecting extraocular movements are also possible [61, 62]. Surgical intervention is indicated if symptoms progress rapidly.

Splenic Sequestration

Splenic sequestration is a potentially catastrophic complication of SCD and is characterized by an acute drop in hemoglobin that can cause circulatory collapse. It is more common in the pediatric population, especially with HbSS, since they have not yet auto-infarcted their spleen [14, 41]. The mechanism for this entity involves sickled erythrocytes becoming trapped within the spleen and thereby being removed from the circulatory system, manifested in laboratory testing as a profound anemia.

EPs must consider this entity when presented with an adult or child with acute splenic enlargement and circulatory collapse. Splenic sequestration can be differentiated from other causes of anemia associated with SCD (hemolysis, red cell aplasia) based on a combination of laboratory tests: severe anemia, elevated reticulocyte count, and findings of hemolysis (elevated indirect bilirubin, ALT, and LDH) [41]. Guidance regarding the management of SCD patients with splenic sequestration is limited, but transfusion (without over-transfusion) and splenectomy are being advised, in addition to observation based on the patient's clinical status [25]. Eventually a splenectomy is critical since splenic sequestration recurs at a rate of nearly 50% [14].

Priapism

Priapism associated with SCD is typically of the low-flow type associated with stasis, hypoxia, and ischemia, with about 35% of boys/men affected [14, 63]. Conservative management with fluid hydration and analgesia are an appropriate first step, with medical management including injection of phenylephrine into the corpora cavernosa, subcutaneous terbutaline, and/or oral pseudoephedrine. Interventional approaches such as aspiration and irrigation with alpha-adrenergic agents are an appropriate next step. If these therapies are unsuccessful, then emergent urologic consultation for possible shunting is recommended.

Hepatobiliary

Biliary sludge and cholelithiasis/choledocholithiasis are common in SCD patients due to chronic hemolysis and increased bilirubin turnover [64]. Gallstones are noted on ultrasound in up to 70% of patients [25]. Asymptomatic patients should be managed conservatively, while surgical cholecystectomy, including laparoscopic approaches, has good outcomes [65].

As with splenic sequestration, hepatic crisis and hepatic sequestration can occur and require aggressive management with hydration, rest, and close observation [25]. Exchange transfusion has demonstrated positive results [66]. Of note, frequent transfusions can also result in hemosiderosis or hemochromatosis.

Avascular Necrosis (AVN)

Sickling results in occlusion of capillaries which in turn causes inadequate blood supply with consequential bone

death. The femoral heads are common sites of this osteonecrosis. About 50% of patients with HbSS demonstrate some avascular necrosis by age 33 [67]. Pain control and physical therapy are the mainstays of treatment, with surgical treatment for symptomatic patients with advanced AVN [25].

Aplastic Crises

Commonly seen in children, aplastic crisis presents with gradual onset fatigue, shortness of breath, and fever. Patients can present with tachycardia and even florid heart failure. Parvovirus B19 has been identified as the inciting infection [68], causing an interruption of erythropoiesis via destruction of erythrocyte precursors and resulting in severe anemia and cardiovascular decompensation. This self-limited infection typically lasts 7–10 days and results in lifelong immunity [14].

Controversies in the Management of Sickle Cell Disease

Acute Pain

Unfortunately, stigma and judgment often influence the diagnosis and management of SCD patients who present to the ED in pain. It is important to remember that these patients can experience similar painful disease processes as patients without SCD and failure to recognize non-SCD-related conditions can result in poor outcomes. As mentioned previously, patients are generally able to ascertain if the acute pain they are feeling is typical of prior VOC episodes. Additional testing should be considered when patients complain that a painful episode is different in character (not just severity) from typical episodes. In some cases, VOC may be triggered by an unrelated diagnosis, but the acute pain from the VOC may mask this underlying condition. Therefore, it is important that EPs proactively set aside their biases and approach patients with SCD in an open-minded and non-judgmental manner.

Physicians treating patients with SCD are at specific risk for cognitive biases, also known as cognitive dispositions to respond. Examples of cognitive bias include being overcommitted to a given diagnosis, failure to consider alternative diagnoses, continuing with a diagnosis reached by others, being overly influenced by past patient experiences, ending the diagnostic workup prematurely, and being influenced by context or patient characteristics [69, 70].

Opioid Crisis and Implications for the Care of Patients with SCD

Over the past 10 years, the opioid crisis in the United States has received increasing attention. Given that that from 1999 to 2018 over 400,000 people died from an opioid overdose, that 2 out of 3 drug overdose deaths in 2018 involved an opioid, that nearly 47,000 people died from opioid overdoses in 2018, and that 32% of those deaths involved prescription opioids [71, 72], there is immense pressure on emergency physicians to curtail the use and prescription of opioids. However, the challenges related to the objective assessment of pain as well as pressures related to patient satisfaction scores and the emphasis on early pain management by regulatory agencies have placed emergency physicians in a quandary regarding the appropriate management of SCD patients presenting with acute pain.

However, prudent strategies can guide emergency departments and EPs in this regard. First, it is helpful to develop departmental and/or institutional evidence-based guidelines in a collaborative manner with a variety of personnel involved in the care of patients with SCD. Second, these guidelines should recognize the need to differentiate opioid-naive from opioid-tolerant patients while also acknowledging that the latter group is not simply "addicted" to opioids but that there is a physiologic basis for the dependence that has developed over time. Finally, prudent limitations such as avoidance of intramuscular administration and minimizing use of intravenous hydromorphone and diphenhydramine while still utilizing opioids in the management can guide EPs in appropriately caring for patients with VOC.

Additionally, high utilizers of emergency department services should be managed proactively with a diverse care team and individualized care plans to ensure that the patient's needs are met while being judicious in the use of opioid medications. Increasing interoperability of electronic medical records and prescription drug monitoring programs are helpful in assessing a patient's use of healthcare resources and potential overuse of opioids. Goals driven by care plans and collaborations between EPs and outpatient physicians are shown in Table 41.7 [73].

Intravenous Fluids

Given that erythrocyte dehydration plays a significant role in the pathophysiology of SCD, hydration has long been a com-

Table 41.7 Goals in promoting care coordination and continuity

Patient received coordinated, comprehensive care
Patient keeps regular appointments (for patients with three or more ED visits per year, it is recommended they have at least four scheduled outpatient appointments per year, with a goal of not missing more than one appointment except when missed because of hospitalization)
Patient is compliant with health promotion and disease management programs
Patient abstains from using illicit opioids
Patient obtains opioid prescriptions from a single practice

From Lovett et al. [73], with permission Elsevier

ponent of therapy. However, while isolated and suboptimal studies have shown a potential benefit to intravenous hydration during VOC and for other complications, there is inadequate data to assess the safety of aggressive hydration [74]. Additionally, there are reports linking excessive fluid administration to the development of atelectasis [75], and this in turn to AChS. Thus, it is recommended that boluses of intravenous fluids be reserved for suspected or proven hypovolemia or hypertonicity [4].

Blood Transfusion

Erythrocyte transfusions, with the goal of reducing HbS to less than 30%, are indicated in the urgent management of acute anemia, AChS, acute neurological deficits, multi-organ failure, and perioperative management [12, 25, 76]. However, care must be taken to avoid volume overload and increased blood viscosity associated with transfusion. Transfusion is not recommended in patients with asymptomatic anemia and those with acute kidney injury in the absence of multisystem organ failure [25].

Transfusions may be considered in patients hospitalized with complications of SCD (e.g., AChS, cerebral infarction, ACS) but not simple VOC. Anemia should not be overcorrected with a goal of no more than 10 g/dL with care be taken to use leukocyte-reduced blood that is matched for all relevant antigens (Rh, C, E, and Kell) [25, 33]. Regular, long-term transfusions are beneficial in the prevention of strokes in pediatric patients, but carry risks of alloimmunization and iron overload, and hence should be coordinated with the patient's hematologist [20, 25]. Figure 41.3 represents

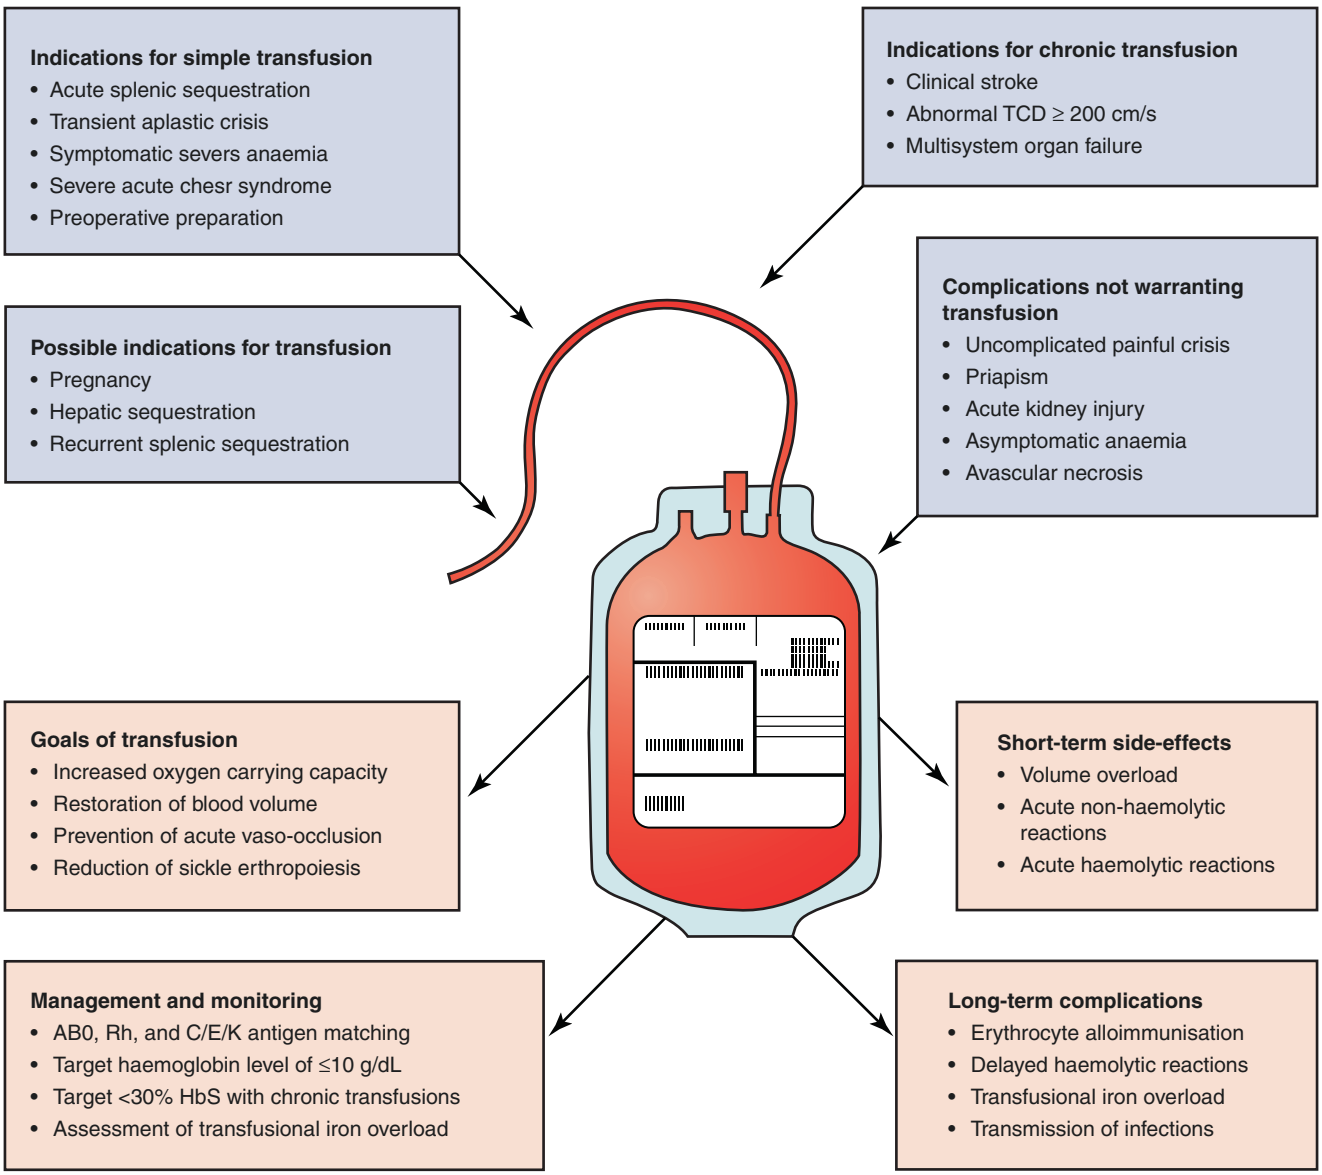

Fig. 41.3 Indications and goals for blood transfusion. (From Ware et al. [15], with permission The Lancet and Elsevier)

current recommendations regarding transfusion therapy for acute complications of SCD [15].

Hydroxyurea (Hydroxycarbamide)

Hydroxyurea is a ribonucleotide reductase inhibitor that can increase HbF levels, in turn inhibiting polymerization of deoxygenated HbS [77–79]. Additionally, it triggers increased donation of NO and a reduction in erythrocyte adhesiveness and leukocyte count [13, 25, 79]. Results of the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH) were promising with a 50% reduction in painful episodes, reduced need for blood transfusions, and lower mortality rate at 9 years [80]. While a potentially effective therapy, it requires time to trigger an increase in HbF and should be given per a standardized protocol – it is therefore not a realistic option for acute ED management, but should be strongly considered if the patient is being cared for in an ED observation unit [25].

Looking Ahead

It is striking to note the dearth of high-quality evidence, especially randomized controlled trials (RCTs), related to the management of SCD. Sickle cell disease exemplifies the potential racial and ethnic disparities that exist in healthcare spending and research, as well as stigmas associated with patients afflicted with it. The most tangible hope for a cure exists with hematopoietic stem cell transplantation (HSCT) but is feasible in only a small proportion of patients with SCD [81].

Several other therapies are under early investigation (phase 1 and 2 trials) [15], and gene therapy has shown promise; however, introduction to clinical practice remains years away [82].

Summary

Sickle cell disease is a genetic disorder commonly encountered by ED providers. Acute painful episodes are by far the most common reason for ED visits. Early and aggressive pain management is a key priority in these visits; however, EPs must also actively seek to diagnose other emergent diagnoses in patients with SCD, including AChS and infection, and differentiate them from VOC. EPs should be especially aware of cognitive biases that may misdirect the diagnostic process.

Bolus administration of intravenous fluids should be considered only for hypovolemic patients. Blood transfusion may be considered to reduce the percentage of HbS, but close attention must be given to its associated risks – impact on volume status and viscosity. Conditions such as acute coronary syndrome, pulmonary embolism, and cerebrovascular accident must be considered in the evaluation of patients with SCD, and while management is guided by the standard of care for the individual conditions, early consultation with hematology is imperative.

Finally, we cannot over-emphasize the importance of coordinating care with hematology and the outpatient team in the effective emergency and long-term management of patients with sickle cell disease.

Radiological and Nuclear Terrorism

42

Carol J. Iddins, Jason E. Davis, Ronald E. Goans, and Cullen Case Jr.

Introduction

Recent world events and political tensions are again bringing attention to the possibility of a nuclear incident, including a detonation. Radiological materials are ubiquitous and are found in most cities throughout the country at academic institutions, hospitals, and many businesses and in industrial settings. Nuclear materials are more difficult to access because of their scarce nature and the security of the settings in which they are found. A significant radiological or nuclear (R/N) incident in the Unites States will require activation of local, state, territory, regional, and national government assets. Initially, ad hoc triage and treatment areas will rise up in the moderately to lightly damaged zones. Patients will undergo mass casualty triage and stabilization before medical evacuation to subsequent higher levels of care. This will require subject matter expert advice and response as the size and circumstances of the incident unfold. Initial mass casualty triage should be done to sort the populations who will require minor interventions, admission to the hospital, and possibly eventual intensive care and those who may have an extremely dire prognosis and may require comfort or hospice care. The hematologist-oncologist will be among those with the expertise to effectively treat those patients who will experience bone marrow aplasia as part of radiation exposure that is higher than 1–2 Gray (Gy). Acute radiation syndrome (ARS) is the complex of organ system injuries that occur from the radiation exposure. The organ systems show a classical clinical prodrome that correlates to radiation exposure dose. This syndrome will affect bone marrow, gastrointestinal, cutaneous, pulmonary, and neurovascular systems. These patients will require the expertise of intensivists and those experienced in managing systemic inflammatory response syndrome (SIRS), multiple organ dysfunction (MOD), and multiple organ failure (MOF) that may result. This chapter provides an overview for the hematologist-oncologist in managing patients who may present after an R/N incident.

Some understanding of the mechanisms of damage incurred from radiation is helpful in managing these patients. This is not routinely included in our medical or graduate medical education. Many oncologists and radiation oncologists deal with radiotherapy adverse effects, but, otherwise, most physicians never manage a patient from a radiological incident. A review of some important terms and topics is included for better understanding of the disease processes.

Radiological materials have many uses in academia, medicine, and industry. They may be used in the initiation or attempted initiation of an energetic chain reaction of fissionable materials. Small quantities of fissionable nuclear materials generally pose more of a chemical hazard than a radiological hazard. If sufficient quantities of fissionable material are present in the correct geometry, a chain reaction is initiated resulting in the release of immense amounts of energy and the production of highly radioactive isotopes. Nuclear fission supplies the destructive potential of improvised nuclear devices (IND) (a terrorist nuclear bomb) and more sophisticated nuclear weapons. Fission is also the process used to generate heat for the production of electricity in nuclear power plants (NPPs). In fission reactors, steam generated from the nuclear process is used to turn a turbine which, in turn, rotates a generator [1].

Measurement of Radioactivity Radioactivity, the activity of a radiation source, is the term used to describe how much

energy is being released by radioactive material in a given time. Radioactivity or activity is measured in curies (Ci) in the English measurement system or the becquerel (Bq) in the SI system (SI = International System of Units or Système International). A Bq is equivalent to one disintegration of an atomic nucleus per second. A Ci is equivalent to 3.7×10^{10} disintegrations per second (dps) and is based on the decay rate of radium-226. A Bq is so small that it is much more common to see units in multiples of Bq such as megabecquerels (MBq), gigabecquerels (GBq), etc. Likewise, a curie is so large that it is much more common to see units in fractions of Ci such as millicuries (mCi), microcuries (μCi), etc.

Units of Dose Measurement The unit rad is often used in the English system to describe the amount of ionizing radiation that is absorbed in a cell, tissue, organ, or the body. It is equivalent to 100 ergs of energy deposited in 1 g of tissue. The gray (Gy) is equivalent to 1 J of energy deposited in 1 kg of tissue. One Gy is equivalent to 100 rad. The rem (roentgen equivalent man) is a unit of equivalent dose which is used to measure the long-term biological risk related to ionizing radiation exposure (in the USA). The sievert (Sv) is the international unit (SI) for equivalent dose. One Sv is equivalent to 100 rem. The terms Gy and Sv will be used.

Radiological and Nuclear Scenarios of Concern

Key to understanding radiological and nuclear incidents are the types of injuries and illnesses that they can cause. There are many occupational and medical exposures occurring with more frequency. However, the following radiation scenarios are of concern for emergency care responders:

- Radiological exposure device (RED)
- Radiological dispersal device (RDD)
- Improvised nuclear device (IND)
- Nuclear weapon detonation (NWD)
- Nuclear power plant (NPP) incident

Radiological Exposure Device (RED)

A RED is any radioactive material or an object containing radioactive material that can expose people to radiation without their knowledge. These materials may be inadvertently left in an accessible area or may be intentionally placed in a public space with the intent to cause harm to one or more people. The radiation-induced injuries and illnesses that may result from exposure or touching the source vary, depending upon the nature of the source, the radiation emitted, and the energy of the radiation emitted. It is possible for an RED to cause severe damage up to, and including, ARS, as well as cutaneous radiation injuries (CRI) with damage to the skin and deeper tissues and organs.

Radiological Dispersal Device (RDD)

A radiological dispersal device (RDD) is any device that spreads radioactive material in the environment with the intent to cause panic, destruction, damage, or injury. A "dirty bomb" is one type of RDD, in which explosives are used as the mechanism to disperse the radioactive material. Radioactive materials needed to produce an RDD can be obtained from industrial, commercial, medical, and research applications. An explosive RDD may result in the immediate threat to human life. Hazards will occur from fire, smoke, shock (physical, or thermal), and debris from the explosion. The long-term consequences of an explosive RDD could involve increased risk of cancer to exposed individuals resulting from direct exposure to radioactive materials, the inhalation of radioactive materials, and potential contact with other hazardous materials present at the scene. In most plausible scenarios, the radioactive material would not result in acutely harmful radiation doses.

Improvised Nuclear Device (IND) and Nuclear Weapon Detonation (NWD)

An improvised nuclear device (IND) can be described as a homemade atomic bomb in which the most likely configuration includes two subcritical masses of a fissile material that are quickly and forcefully brought together. Bringing these masses together allows for an uncontrolled fission reaction to occur, resulting in a massive release of energy in the form of thermal radiation, ionizing radiation, and a forceful pressure wave. Improvised nuclear devices are likely to cause more nuclear fallout because of incomplete fission due to a number of engineering complexities. They are also likely to be exploded at ground level rather than at an altitude, which causes ground materials to be irradiated and drawn up into the sky by the lifting of heated gases. Mistakes in the design and timing of the device may also result in a fizzle, where the criticality is too short-lived to consume all of the fuel or the device fails to achieve criticality, resulting in the fuel being dispersed without being consumed. The primary distinction between an IND and a traditional nuclear weapon is the sophistication of the manufactured device.

The nuclear weapons detonated over Japan during World War II were on the order of 10–15 kilotons (KT) of TNT and involved the use of only a few pounds of U-235 or Pu-238. Weapons developed later during the Cold War were on the order of megatons. When discussing nuclear weapons, it is important to realize that they are designed and manufactured

with very sophisticated nuclear, chemical, and electrical engineering skills and techniques. The detonation of a nuclear weapon would be devastating, with massive infrastructure damage and massive numbers of casualties. The fallout of radioactive material descending to the ground after being blown into the atmosphere by the detonation can result in significant radiation exposures. The acute and subacute consequences of such detonations will involve physical trauma and thermal burns, as well as radiation-induced illnesses/injuries.

Nuclear Power Plant (NPP) Incidents

NPP incidents are rare and historically have produced variable outcomes. Not all of these outcomes manifest physically. Sometimes the psychological or social impact can be equally devastating, and health effects may be more related to lack of daily necessities rather than radiation. The Chernobyl (1986) and Fukushima (2011) incidents resulted in multiple human health effects as a result of the incidents. Chernobyl resulted in 28 acute deaths from ARS, primarily related to exposures to, and contamination with, radioactive materials [2]. At Fukushima, the public health emergency from the Great East Japan Earthquake and tsunami resulted in many health effects and deaths; however, none of these were related to acute radiation effects. The Three Mile Island incident in 1976 also had no associated adverse human health effects from radiation. However, all incidents have had significant impact on psychological health and the environment.

Radiation-Induced Injuries and Illnesses

Internal Contamination

After a nuclear detonation or NPP incident, there may be radioactive fallout that can become widespread. This fallout may externally and internally contaminate (NPP only) both casualties and persons within the plume. External decontamination is accomplished through removing the contaminant by either wet or dry means, depending on the chemical composition. Internal contamination may be removed from the body or blocked to the organ of uptake. This should be done urgently, to avoid dose to organs/tissues. Knowledge of this for the oncologist is important as the internally contaminated patient may require therapy for a prolonged amount of time, i.e., after reaching definitive medical care. Following an R/N incident, consult the Radiation Emergency Assistance Center/Training Site by phone (24/7 emergency number, 865-576-1005) or access the REAC/TS RadMed Application, to assist with management of internal contamination with radioactive materials [3].

Acute Radiation Syndrome

Ionizing radiation has many mechanisms that induce injuries and illnesses. These mechanisms may cause direct or indirect injuries. For example, the energy from one ionization event is sufficient to directly break the chemical bonds of macromolecules, including DNA. Ionizing radiation generates free radicals, causing oxidation and oxidative stress, lipid peroxidation, and nitrosative stress, all indirectly injuring molecules and cells. The damage, indirect or direct, to DNA results in either single-strand or double-strand breaks, with the latter often misrejoining, leading to genetic changes including cell death. All of these processes, particularly in the more radiosensitive cells, will manifest as cellular, tissue, vascular, and, ultimately, organ damage. The noxious stimuli of radiation will cause nausea, protracted emesis, and, sometimes, fever as a prodrome. This usually lasts for ~ 48 h; however, higher acute exposures will have a shortened or absent prodrome.

As the dose of the exposure increases, the deterministic effects are seen in their classic syndrome, known as acute radiation syndrome (ARS). ARS is broken down into organ syndromes according to classic presentation at the organ's dose threshold. The earliest observations on the effect of acute radiation exposure on the various organs occurred after the atomic weapon detonations in Japan in August of 1945. In work starting in 1997, the Commission of the European Communities initiated a "Concerted Action" to give a scientific basis and synopsis for deciding the most appropriate medical interventions for ARS. Depending on radiation dose, clinical findings assigned to an organ system may occur concurrently or sequentially with those assigned to the other systems. The signs and symptoms of each of the resulting four organ syndromes of ARS (hematopoietic, gastrointestinal, cutaneous, and neurovascular) are summarized in tables below. The severity of signs and symptoms for each organ system is quantified as degrees of toxicity (degree 1, 2, 3, or 4). The response category (grade 1, 2, 3, or 4) correlates with overall severity of ARS and is determined by the highest degree of toxicity within any of the organ systems [4].

The hematopoietic syndrome (HS) shows classic expression with an acute, whole body (or a large portion of the body) exposure greater than 2 Gray (Gy). This is the identified triage decision point for US guidelines, though other countries use equal to or greater than 3 Gy. The mature lymphocytes are the most sensitive cell type to ionizing radiation. This makes this a helpful tool for triage. Most individuals will fully recover their bone marrow at the 2 Gy level. However, colony-stimulating factors (CSFs) are recommended to more quickly recover the bone marrow and avoid morbidity from infection. The classic HS is lymphopenia, followed by neutropenia, thrombocytopenia, and, eventually, pancytopenia with exposure to greater than 2 Gy.

The nadir of neutropenia is generally 3–4 weeks with a classic HS.

The gastrointestinal syndrome (GS) shows classic expression with an acute exposure to the whole/partial body, to include the torso, in the range of 6–8 Gy. The presentation is nausea, protracted emesis, diarrhea, gastrointestinal bleeding, bacterial translocation, and loss of absorptive capability of the intestines. Frank bowel necrosis may occur in the upper range of exposed dose. Acute renal dysfunction/failure may accompany GS.

The cutaneous syndrome (CS) classically begins expression with exposure to 6 Gy or higher. This syndrome presents with erythema, edema, desquamation, and, at higher doses, blistering, ulceration, and necrosis. At the dose threshold for deep ulceration and necrosis, these become complex and often non-healing or recurring wounds.

The neurovascular or cerebrovascular syndrome (NS) presents with acute exposure to doses of 10 Gy and up. This syndrome may present with nausea and protracted emesis within minutes, alteration of mental status or loss of consciousness, ataxia, high fever, fluid shifts and third spacing, seizures, cerebral edema, and coma (especially above 10 Gy). Neurovascular syndrome is not compatible with long-term survivability. Acute renal failure and pulmonary involvement may be concurrent. In acute doses in the 8–30 Gy range, pulmonary edema, pneumonitis, and fibrosis may occur.

Clinical Evaluation of Acute Radiation Injury

Clinical History and Laboratory

Proper application of a well-structured interview technique can contribute to an accurate diagnosis of radiation injury. Patients presenting with nausea, vomiting, and diarrhea may have many etiologies and may be misdiagnosed unless seen in conjunction with a known missing radiological source or incident. Evaluation of a patient suspected of a radiological exposure consists of a thorough event history, including geographic location at the time of the incident; how long the patient was in that location; was the patient sheltered and, if so, what kind of structure and location (basement, windows, etc.); if they exited the area, what pathway was taken and what form of transport was utilized; have they removed clothing/showered; did they have any signs of symptoms; a complete medical/surgical history; and a thorough physical examination. It would also be helpful to know if anyone else was co-located with them and, if so, if that individual is exhibiting similar signs and symptoms.

Laboratory evaluation should include a baseline and serial complete blood cell count with differential (CBC with diff) every 6–12 h to monitor for a decline in the absolute lymphocyte count. In papers by Goans et al., a simple prediction algorithm was presented to estimate effective whole-body dose within 8–12 h after moderate- and high-level gamma accidents and after criticality accidents [5–7]. The algorithm is based on the observation that lymphocyte depletion follows first-order kinetics after high-level gamma accidents. Using historical data from both gamma and criticality accidents, lymphocytes are observed to follow approximately an exponential decline in time within the first 24–48 h. This algorithm has been incorporated into the Armed Forces Radiobiology Research Institute (AFRRI) Biodosimetry Assessment Tool (BAT) program and the WinFrat tool [8] (Table 42.1).

Table 42.1 Absolute lymphocyte count decrease and approximate estimate of absorbed dose (R.E. Goans, personal data, 2014)

Absolute count 8–12 h post-event	*Rough estimate of absorbed dose*
1700–2500/mm^3	0–4 Gy
1200–1700/mm^3	4–8 Gy
<1000/mm^3	>8 Gy
Absolute lymphocyte count 48 h postexposure	*Absorbed dose estimate*
1000–1500/mm^3	1–2 Gy
500–1000/mm^3	2–4 Gy
100–500/mm^3	4–8 Gy
<100/mm^3	>8 Gy

A whole-body dose of 1 Gy or less should not noticeably depress the lymphocyte count below the normal range taken as 1500–3500/mm^3

An additional tube (green top, preferred lithium heparin) of blood should be collected for biodosimetry. This tube does not need refrigeration or centrifugation. This tube can be held for several days before being sent to the Radiation Emergency Assistance Center/Training Site (REAC/TS) Cytogenetic Biodosimetry Laboratory (CBL) for dicentric chromosome analysis (see Biodosimetry). A serum amylase may be helpful, as well as a C-reactive protein (CRP) which may be grossly elevated after a whole body exposure.

Blood typing and cross-match may be delayed unless needed for other medical/surgical indications. However, human leukocyte antigen (HLA) typing should be done immediately if the patient is a potential candidate for bone marrow transplantation (see National Network for Management of Mass Radiation Casualties), as it may take time to find a donor match.

Clinical Prodrome

Observation for any of the signs and symptoms of organ system involvement of ARS should be done for smaller incidents. In a mass casualty, patients presenting greater than 4–6 h after the incident who are symptom-free will be triaged as delayed and may follow up later with a community

reception center (CRC), private healthcare provider, or public health point of dispensing (POD). An early sign of significant, potentially non-survivable ARS is early, protracted emesis, not to be confused with a single episode from psychosomatic or sympathetic emesis. Anti-emetics, 5-HT3 receptor antagonists (ondansetron, granisetron), and dopamine antagonist (metoclopramide) are indicated for relief of emesis [4].

In work performed at Oak Ridge Associated Universities (ORAU) from 1964 to 1975, with patients undergoing long-term radiation therapy at a relatively low-dose rate ($n=502$ patients, 0.8–90 R/h), 50 percentile frequency doses were obtained as follows: ED50 = 1.08 Gy for anorexia, ED50 = 1.58 Gy for nausea, and ED50 = 2.40 Gy for emesis. A trend is noted whereby the time to emesis decreases with increasing dose [9, 10] though there is much variability among individuals and circumstances using this as a sole biodosimeter. The presence of early nausea, protracted emesis, diarrhea, and fever may correlate with the general range of exposure dose, approximately 100% of patients with whole-body dose greater than the LD50 or the dose required to cause mortality in 50% of the population (approximately 3.5–4.0 Gy without treatment) [11]. In addition, Hartmann et al. have noted an increased body temperature for effective whole-body dose >2.5 Gy and acute diarrhea for dose >9 Gy [12]. Other organ dysfunction clinical indicators that may be present up to 4 weeks or later after an terrorist or other incident include:

- Hematologic: lymphopenia, neutropenia, thrombocytopenia with resulting immunocompromise, petechial hemorrhages, and/or mucosal bleeding
- Gastrointestinal: emesis, diarrhea with or without bleeding, fluid loss with dehydration, subsequent renal dysfunction, and potential cardiovascular dysfunction
- Neurovascular or cerebrovascular: mental status changes, cerebral edema, possible seizures, and coma

Cytogenetic Biodosimetry

Since 1963, the dicentric chromosome assay (DCA) has been extensively developed, researched, and validated in numerous incidents to be the global gold standard for biodosimetry [13]. Researchers at AFRRI and REAC/TS have established the conventional lymphocyte metaphase-spread dicentric assay and have applied it to the clinical management of several overexposure incidents. The DCA is radiation-specific, is sensitive as low as 0.2 Gy, and is not affected by ethnicity or gender. REAC/TS is automating much of the process, and Columbia University has a completely automated system to perform the DCA. One of the limitations of DCA is that it is not available as a point-of-care (POC) test and may take several days for results. Another limitation is the upper end of dose assessment is approximately 5 Gy. Techniques such as premature chromosome condensation (PCC) assay are a good addition to DCA in extending the dose range above the NS syndrome.

Recently, it was suggested that the dicentric assay may be adapted for the triage of mass casualties [14–16]. Lloyd et al. described an in vivo simulation of an accident with mass casualties receiving whole- or partial-body irradiation in the 0–8 Gy range [14]. Faced with an urgent need for rapid results, clinical triage was accomplished by scoring as low as 20 metaphase spreads per subject, compared with the typical 500–1000 spreads scored in routine analyses for estimating dose. However, Lloyd et al. suggested increasing the analyses to 50 metaphase spreads when there is disagreement with the initial assessment or when there is evidence of significant inhomogeneous exposure [14, 17] (Table 42.2).

There are other biodosimetric techniques being researched with point-of-care testing potential. Many of these look for metabolomics and show promise for the future.

Table 42.2 Proposed biodosimetry technique as a function of expected dose

Dose range (Gy)	Proposed validated dosimetry method	Prodromal effects	Manifest symptoms	Survival expectancy
0.1–1	Dicentric/PCC	None to mild (1–48 h)	None to slight decrease in blood count	Almost certain
1.0–3.5	Lymphocyte depletion kinetics/ dicentrics/PCC	Mild to moderate (1–48 h)	Mild to severe bone marrow damage	0–10% death
3.5–7.5	Lymphocyte depletion kinetics/PCC	Severe (1–48 h)	Pancytopenia, mild to moderate GI damage	10–100% death within 2–6 weeks
7.5–10.0	Lymphocyte depletion kinetics/PCC	Severe (<1–48 h)	Combined BM and GI damage	90–100% death within 1–3 weeks
>10.0	PCC	Severe (minutes to <48 h)	GI, neurological, cardiovascular damage	100% death (within 2–12 days)

PCC premature chromosome concentration

Acute Radiation Syndrome (ARS)

The timing and severity of ARS depend upon the radiation quality, dose, dose rate, and irradiated area(s) (organs). Clinical findings associated with an organ system may occur concurrently or sequentially with those assigned to the other systems.

Hematopoietic Syndrome (HS)

Hematopoietic stem/progenitor cells in the bone marrow and circulation are particularly sensitive to ionizing radiation with a dose (D0) of approximately 1 Gy at a dose rate of 0.8 Gy/min [18] (Table 42.3). At doses of 2–3 Gy, hematopoietic stem/progenitor cells exhibit reduced capacity to divide. Morphological changes in interphase cells of the bone marrow include nuclear karyorrhexis, cytoplasmic fragments, nuclear and intercellular bridging, multinuclearity, and pseudo-Pelger-Huet anomaly [19, 20]. Chromosomal bridges and fragments are seen in actively dividing cells of the marrow. Bone marrow hypoplasia and/or aplasia may develop at doses >5–7 Gy, resulting in severe pancytopenia weeks to months after exposure [21]. The pathophysiologic mechanisms underlying these radiation-induced effects on the bone marrow involve dose-dependent and clonal elimination of stem/progenitor cell populations and their progeny [22, 23]. Various degrees of pancytopenia develop several weeks after exposure and need serial CBC and differential every 12–24 hours, as opposed to the more frequent monitoring of the early lymphopenia in the first 24–48 hours post incident [24, 25].

Table 42.3 Hematopoietic syndrome modified from Fliedner, et al. [4]

	Degree 1	Degree 2	Degree 3	Degree 4
	Mild damage	Moderate damage	Severe damage	Fatal damage
Hematopoietic system				
Lymphocyte count[a]	At/above **1.5** × 10^9 cells/L	**1.0–1.5** × 10^9 cells/L	**0.5–1.0** × 10^9 cells/L	Below **0.5** × 10^9 cells/L
Granulocyte count[b]	At or above **2** × 10^9 cells/L	**1–2** × 10^9 cells/L	**0.5–1.0** × 10^9 cells/L	Below **0.5** × 10^9 cells/L
Thrombocyte count[c]	At or above **100** × 10^9 cells/L	**50–100** × 10^9 cells/L	**20–50** × 10^9 cells/L	Below **20** × 10^9 cells/L
Hemoglobin	Normal	Decreases 0–9%	Decreases 10–20%	Decreases more than 20%

Note: Reference values will vary by laboratory
Values are in SI units
10^9/L = 10^9 cells/L = 10^3 cells/μL = 10^3 cells/mm^3 (cubic millimeter)
[a]Reference value: (1.5–4) × 10^9 cells/L
[b]Reference value: (4–9) × 10^9 cells/L
[c]Reference value: (140–400) × 10^9cells/L

Lymphocytes are the most radiosensitive of the circulating blood cells in spite of their being terminally differentiated and largely mitotically inactive. Radiation may alter recirculation properties and surface antigen expression of lymphocytes [4, 26]. The rate of decline in lymphocytes is directly dependent on the absorbed radiation dose.

Other hematological findings include a decline in the absolute neutrophil count (ANC) and the platelet count. The ANC may briefly increase within hours after exposure, a phenomenon first described by Fliedner as an abortive rise [4]. The abortive rise is believed to be due to migration of preformed myeloid elements across the marrow-blood barrier into the circulation, although demargination cannot be excluded as a mechanism for this transient effect. Thereafter, the ANC declines over several days to weeks, depending on radiation dose. The abortive rise is typically seen with HS-1 and HS-2 and appears to indicate reversible marrow damage from a survivable exposure. The absence of an abortive rise in ANC is observed in HS-3 and HS-4 and appears to indicate irreversible bone marrow damage. Neutropenia and thrombocytopenia reach a nadir at 1–2 weeks after exposure to >3–4 Gy. Anemia follows due to impaired erythropoiesis and severe bleeding may occur secondary to thrombocytopenia.

The most significant consequences of lymphopenia and neutropenia are disruption of immune defenses and predisposition to life-threatening infections. ANCs of <500–1000 cells/mm^3 (HS-3 and HS-4) are associated with bacterial, viral, and fungal infections, similar to what occurs in the setting of neutropenia and lymphopenia from any other cause. Management of febrile neutropenia should follow guidelines recommended by the Infectious Diseases Society of America (IDSA), using broad-spectrum prophylactic and therapeutic antimicrobial agents [27].

Managing HS includes administration of granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) when the dose is expected to be >2 Gy and/or when it is anticipated that the ANC will decline to <500 cells/mm^3 for 7 days or longer [28]. The Food and Drug Administration (FDA) has approved these myeloid colony-stimulating factors for use in a radiological incident. Initiate CSF therapy within 24 h of exposure and continue until the ANC reaches and maintains a level of >1000 cells/mm^3 in the absence of active infection. For individuals with active infection, continue cytokines together with antimicrobial agents, according to guidelines of the IDSA [27].

Erythroid-stimulating agents (ESAs) may be used as clinically indicated [28]. The rationale for ESA therapy is avoiding need for red blood cell infusion. The lowest dosage that induces a hemoglobin level of >9–10 g/dL is appropriate. Iron supplementation may also be used in conjunction with ESA therapy.

Other growth factors, including stem cell factor, interleukin-3, and the pegylated form of erythropoietin and G-CSF, have been administered sequentially or concomitantly with G-CSF and/or GM-CSF to victims of a radiological incident [28]. These growth factors and new thrombopoietic factors may be useful as in aplastic anemia; however, there is no evidence-based recommendation at this time [29].

Because radiation injury to the bone marrow is typically heterogeneous, leaving areas of unirradiated or minimally irradiated/damaged marrow that are capable of reconstituting lymphohematopoiesis over time, a watch-and-wait approach is recommended after initiating myeloid growth factor therapy. Administration of hematopoietic stem cells (HSCs) should be considered only after failure of a 2–3-week trial of cytokine treatment has been demonstrated [28]. A review of 31 patients undergoing HSC transplantation for accidental radiation injury found that 27 patients died and the remaining 4 patients survived with a rejected allograft [30]. Causes of death after therapeutic HSC transplantation include burns (55%), hemorrhage (41%), infection (15%), and acute respiratory distress syndrome (ARDS) (15%) [31]. Since survival outcomes are poor among HSC transplant recipients with radiation burns, GS, renal failure, and/or adult ARDS, HSC transplantation should not be performed in individuals with non-hematopoietic organ failure and/or active infection [28, 32]. In the case of a large radiological incident, the Radiation Injury Treatment Network (RITN), a voluntary consortium consisting of >70 transplant centers, donor centers, and umbilical cord blood banks, will be activated (see National Network for Management of Mass Radiation Casualties) [33, 34].

When transfusion is indicated for severe cytopenia, blood products should be irradiated (25 Gy) to prevent transfusion-associated graft-versus-host disease (TA-GVHD). Since TA-GVHD is almost universally fatal in this population, its prevention by prior irradiation of blood products is mandatory. Leukoreduction may lessen febrile reactions and the immunosuppressive effects of blood transfusion, limit platelet alloimmunization, and reduce CMV infection [35, 36]. Leukoreduction is recommended whenever feasible.

National Network for Management of Mass Radiation Casualties

In the USA, a network has been developed that includes transplant centers, hospitals, blood donation centers, and stem cell banks to provide resource-intense medical management of mass casualties from a radiological event. The Radiation Injury Treatment Network (RITN) provides comprehensive evaluation and treatment for victims of radiation exposure or other marrow toxic injuries (like those caused by mustard agent). Many of the casualties with radiation injury will be salvageable but require specialized outpatient and/or inpatient care. Recognizing this need, the US National Marrow Donor Program/Be The Match Marrow Registry, the US Navy, and the American Society for Transplantation and Cellular Therapy (formerly known as American Society for Blood and Marrow Transplantation) collaboratively organized RITN, which provides expertise in the management of bone marrow failure, blood component therapy, stem cell collection, and umbilical cord blood banking around the globe.

The RITN is preparing for the resulting medical surge of radiation casualties from the detonation of an improvised nuclear device.

The goals of RITN are:

- To develop treatment guidelines for managing hematologic toxicity among victims of radiation exposure
- To educate healthcare professionals about pertinent aspects of radiation exposure management through training and exercises
- To help coordinate the medical response to radiation events
- To provide comprehensive evaluation and treatment for victims at participating centers

The RITN collaborates with the Department of Health and Human Services-Assistant Secretary for Preparedness and Response to ensure coordination following a mass casualty marrow toxic incident that would require their involvement in a national response. The RITN has developed ARS Treatment Guidelines, Referral Guidelines, as well as web-based training materials for hospitals that receive individuals who show early signs of ARS [37]. In addition, the RITN regularly collaborates with organizations to expand the availability of treatment materials. Through a collaboration with Epic Software Systems, RITN developed Adult and Pediatric Medical Order Sets to be available through the Epic electronic health record system for any hospital that utilizes the system. In collaboration with staff managing the Radiation Emergency Medical Management (REMM) website, RITN developed treatment orders for adults and children [38], and RITN has ongoing efforts with the American Burn Association to formalize combined practice guidelines to meet the needs of caring for patients with combined injuries of trauma and radiation.

The RITN estimates that, of survivors from an IND detonation, only 1% of radiation casualties will be candidates for hematopoietic stem cell transplantation. Approximately 30% of casualties are expected to require specialized supportive care in an inpatient setting that involves isolation to protect individuals with febrile neutropenia. Finally, nearly 70% of casualties are expected to require ambulatory care for treatments such as administration of cytokines and antimicrobials, serial assessment of the CBC, and calculation of the absolute lymphocyte count [37].

RITN medical staff are specialists in hematology and oncologic who have daily experience in treating patients with hematologic signs and symptoms that characterize HS. Hospitals that participate in RITN have established standard operating procedures (SOPs) for managing mass casualties. They coordinate locally with emergency management personnel and public health officials and conduct annual training and exercises to constantly improve their level of preparedness.

Cutaneous Subsyndrome (CS)

Injury to the skin and subcutaneous tissues is highly dependent on localized radiation dose [39–41] (Table 42.4). The external dose thresholds at which the deterministic effect manifest begin at 6 Gy with erythema. A transient epilation may occur at Gy but permanent epilation occurs around the Gy threshold. Desquamation, both dry and moist, will occur at ranges of 10–15 and 15–20 Gy, respectively. At doses greater than 25 Gy, ulceration of deeper tissues and necrosis may occur. Prodromal pain, erythema, and edema may occur for 24–48 h. At higher doses, the prodrome will be shorter or absent. The damage to subcutaneous tissues is highly dependent upon the type and energy of the radiation, as well as the duration of irradiation. These wounds will differ from thermal burns in the pathophysiology. The repeated release of proinflammatory mediators will result in a wound that evolves over weeks, months, or even years. The complex wounds seen at necrosis threshold ranges will often heal with repeated recurrence or not heal completely, often resulting in surgeries and possible amputation. It is important for the hematologist-oncologist to recognize that, when the involved total body surface area is greater than 40%, these may cause great morbidity and mortality. Of the 28 acute deaths in the Chernobyl incident, the primary cause of death for 16 of these patients was CS, according to Gottlöber et al. [42]. It is of extreme importance to realize that these cutaneous syndromes and complex wounds may not fully manifest for 3–4 weeks after an incident, after arrival to a definitive care treatment facility.

Managing CS includes topicals: Class II and III steroids, antihistamines, and antibiotics [4, 43]. The REAC/TS past and present experience has found that hyperbaric oxygen therapy, pentoxifylline with topical and/or oral alpha-tocopherol, and artificial skin constructs are helpful. Newer silver-based treatments should be considered. Systemic steroids should be decided on a case-by-case basis. Surgical debridement, wide local excision, skin grafts/flaps, or amputation may be necessary [44]. Newer techniques, mesenchymal stem cell [45, 46] or adipose-derived stromal vascular fraction injections [47], with or without surgery, may lead to more long-term healing and relief from intractable pain from compression of cutaneous nerve bundles. Clinical trials using these techniques with thermal burns are underway in the USA. Other countries have both bench research and clinical trials with these therapies; however, lack long-term follow-up is still necessary [45–48].

Gastrointestinal Subsyndrome (GS)

The rapid turnover of the extremely radiosensitive epithelial cells lining the gastrointestinal tract demands that the stem cells in the crypts of Lieberkuhn are functional. The hematologist-oncologist is certainly familiar with the noxious stimuli of various chemotherapy and radiotherapy regimens inducing nausea, anorexia, and, possibly, protracted emesis. This is similar to the prodrome seen with ARS. If nausea and emesis occur within the first hour of exposure and, if accompanied by diarrhea, is likely from both central and peripheral nervous system and is indicative of a potentially non-survivable dose [4]. At doses of 5–6 Gy or greater, damage occurs to stem cells in the crypts, leaving the lining of the gastrointestinal (GI) tract denuded [24, 25]. These findings may be accompanied over time by hematemesis,

Table 42.4 Cutaneous syndrome modified from Fliedner, et al. [4]

	Degree 1	Degree 2	Degree 3	Degree 4
Symptom or sign	Mild damage	Moderate damage	Severe damage	Critical/fatal damage
Cutaneous system				
Erythema[a]	Minimal; transient	Isolated patches 0–9% TBSA[b]	Marked erythema, may have some confluence 10–40% TBSA	Severe; may have confluence >40% TBSA
Pain	None, may have pruritus	Slight	Moderate and persistent	Severe and intractable pain
Blistering and desquamation	Rare, sterile fluid	Rare blister; dry desquamation	Bullae; moist desquamation	Bullae with bleeding; moist desquamation
Deep ulceration/ necrosis		Dermal	Subcutaneous tissue	Muscle, organ, or bone involvement

[a]Extent of the TBSA is decisive
[b]*TBSA* total body surface area

hematochezia, frank bloody emesis or diarrhea, fluid and electrolyte shifts, hypovolemia with eventual renal failure, and cardiovascular collapse (Table 42.5).

Sloughing of the lining of the GI tract removes the barrier to bacterial translocation from the intestinal lumen to the bloodstream. Bacterial translocation occurs at a time of immunocompromise from neutropenia and lymphopenia, predisposing to sepsis [49].

Managing GS includes antimicrobial prophylaxis and therapy to achieve therapeutic drug levels (rather than bowel decontamination), replacement of fluids and electrolytes, loperamide, and a serotonin receptor antagonist to control emesis [4, 43].

Neurovascular Subsyndrome (NS)

Neurovascular syndrome (NS), characterized by acute, irreversible neurotoxicity, occurs at whole-body doses of >10 Gy (Table 42.6). Abnormalities in EEG may occur after low doses of radiation, and a milder NS may occur at 3–4 Gy, with mild headache, limited emesis, and hypotension. The prodrome begins as noxious stimuli gain access to blood and cerebrospinal fluid and may result in anorexia, nausea, and emesis. The signs and symptoms of moderate- to high-dose exposure include mental status changes, fatigue, dizziness, hypotension, syncope ataxia, seizures, and coma. Managing NS includes serotonin receptor antagonists, mannitol, furosemide, anti-seizure medications, and analgesics [4, 43]. In a mass casualty, resource-scarce setting, these patients would initially be put in an expectant category. Comfort or hospice care should be provided for these patients.

Other Considerations

Involvement of the tracheobronchial tree and lungs is observed at 1–6 months following exposure to a high radiation dose [50]. Edema and leukocyte infiltration of the lung parenchyma occur during the initial day to week after exposure. An acute exudate occurs after 1–3 months, followed by collagen deposition and fibrosis after months to years. Pulmonary edema and acute respiratory distress syndrome (ARDS) may be delayed and seen after high doses [4]. Interstitial pneumonitis accompanied by a restrictive ventilatory defect may lead to death. Management of respiratory failure includes ventilatory support with a lung protection strategy, using the lowest possible inhaled oxygen concentration to maintain an arterial oxygen saturation of >90% [43]. Radiation damage may occur in other organ systems, including the renal, vascular, and cardiac systems. Multiorgan failure (MOF) can be an intermediate- to long-term complication of radiation exposure with significant morbidity and mortality [51, 52]. Vigilance for damage to other organ systems must be maintained throughout medical care.

Table 42.5 Gastrointestinal syndrome modified from Fliedner, et al. [4]

	Degree 1	Degree 2	Degree 3	Degree 4
Symptom or sign	Mild damage	Mild-moderate damage	Severe damage	Serious/fatal damage
Gastrointestinal system				
Diarrhea				
Frequency/ bleeding	2–3 stools/d; occult blood	4–6 stools/d; some blood	7–9 stools/d; bloody	Refractory, watery diarrhea; "gross hemorrhage"
Mucosal loss/day	Intermittent	Large and intermittent	Persistent	Large, persistent

Table 42.6 Neurovascular syndrome modified from Fliedner, et al. [4]

	Degree 1	Degree 2	Degree 3	Degree 4
Symptom or sign	Mild damage	Moderate damage	Severe damage	Fatal damage
Neurovascular system				
Vomiting	Occasional	Intermittent	Persistent	Refractory
Temperature °F/°C	<100.4/38	100.4–104/38–40	>104/40 <24 h	>104/40 >24 h
Hypotension (mm/Hg)	~ normal >100/70	<100/70	<90/60	<80/
Fatigue/ neurologic deficit[a]	Performs activities	Interferes with work/performs activities with noticeable deficit	Assistance for daily activities/cannot perform normal activities; prominent deficit	No activities/loss of consciousness; "life-threatening" neurologic signs
Cognitive deficits	Minor	Moderate	Major impairment since exposure	Complete impairment

[a]Neurological deficits: Reflex status including reflexes of the eye, ophthalmoscopy (edema of papilla), fainting, dizziness, ataxia, and other motor signs and sensory signs

Summary

A myriad of specialists, especially those well versed in hematologic abnormalities, will be required for any significant ionizing radiation injury to the whole body, or a significant portion thereof, because of the potential for injury to circulating WBCs or the bone marrow. In fact, inappropriate management of the HS will almost certainly result in elevated morbidity, if not mortality, from the HS itself or damage to other organ systems. The manifestations of immunologic incompetence, including the spectrum of infectious diseases, must be treated properly in order to improve patient survival. Practitioners must be also vigilant for multiple organ dysfunction/failure secondary to ionizing radiation exposure.

Delirium

43

Zahra Alhajji and Ahmed Elsayem

Case Study

A 65-year-old woman with advanced uterine cancer presented to the emergency department (ED) with increasing abdominal pain, lethargy, and insomnia. She received her last round of chemotherapy treatment 5 days earlier and takes morphine 15 mg every 4 hours as needed for pain. She had taken the maximum dose for the previous 3 days and was unable to sleep because of increasing pain and anxiety. Her son stated that she was unable to eat or drink (except when taking her pain medication) because of drowsiness. Physical examination demonstrated a chronically ill-appearing patient with dehydration and cachexia. Her abdomen was soft, with generalized tenderness and no rigidity. She was easily arousable and, when asked, reported pain intensity of 10 out of 10. She was tachycardic, but other vital signs were normal. Her son, who was exhausted, left her in the ED and went home. Initial laboratory tests revealed a high blood urea nitrogen level. Intravenous hydration was initiated, and the patient received intravenous morphine 4 mg every hour as needed for severe pain. Shortly after, the patient was taken to radiology for abdominal and head computed tomography. She became agitated, pulled on her IV lines, and began bleeding. She hit the radiology technician, and the ED was notified. The patient was given lorazepam IV to control her agitation, and a 24-hour sitter was ordered. The patient was admitted to the hospital, and palliative care was consulted. Pain medications were changed to fentanyl, and haloperidol was ordered for agitation. Further evaluation revealed cancer progression. A family meeting was held, and the patient was discharged to hospice care.

Introduction

Delirium is a common neuropsychiatric syndrome among patients with cancer, particularly in elderly patients, those receiving opioids, and those with advanced disease. Over 80% of patients with advanced cancer will develop delirium in the last hours and days before death. Approximately 50% of episodes are reversible [1]. Delirium is a predictor of short survival and is a significant cause of distress among patients, family members, and healthcare providers [2, 3].

Definitions

Terms used in relation to delirium may be imprecise and nonspecific. We will use the following definitions:

- Altered mental status (AMS): A broad term encompasses all manifestations of brain dysfunction, including confusion, clouding of consciousness, disorientation, inattention, altered behavior, or drowsiness [4].
- Confusion: The quality or state of being bewildered or unclear. Confusion is usually a symptom of delirium or dementia [5].
- Delirium: A more specific term commonly used to describe an acute state of confusion resulting from organic brain dysfunction. Delirium is characterized by an acute onset of fluctuating levels of consciousness and severe disturbance of mental abilities which results in confused thinking and reduced awareness of the environment [5–8].

Epidemiology

The exact prevalence of delirium in ED patients with advanced cancer is unknown. We found a frequency of 9% among patients with advanced cancer presenting to the MD Anderson Cancer Center ED [9]. The literature supports rates of 8% to 17% among all elderly patients seen in general EDs

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_43

[10–12]. Among emergently transferred and hospitalized nursing-home elderly, 38% will develop delirium [12]. The highest rates of delirium are seen near the end of life; in one study, 88% of patients with advanced cancer treated in an inpatient palliative care unit experienced terminal delirium. Among hospitalized patients with cognitive impairment, such as dementia, almost half will develop delirium [13]. Siddiqi et al. conducted a systematic review of 42 cohorts and found the prevalence of delirium at admission ranged from 10% to 31%, with the incidence per admission ranging from 3% to 29% and occurrence rates per admission from 11% to 42% [14]. In another systematic review, Gibb et al. reported a delirium frequency of 23% in hospitalized patients [15].

Delirium is even more prevalent among patients with advanced cancer, particularly patients receiving palliative care [16, 17]. In a systematic review of 42 studies, Wattet et al. reported a prevalence ranging from 44% to 88% across all palliative care settings [16]. Fann et al. reported a 50% cumulative incidence of delirium over 30 days following hematopoietic stem cell transplant [18].

Etiology and Pathophysiology

The precise cause of delirium is unknown, but the syndrome tends to occur in predisposed individuals who have underlying comorbid conditions and experience additional insults [1, 19, 20]. Evidence suggests that delirium is a multifactorial condition resulting from structural or nonstructural brain pathology.

Doriathet et al. reported that toxic metabolic factors (frequently multifactorial) are the most common causes of delirium [21]. The most common contributing factors are medications, infection, electrolyte abnormalities, renal insufficiency, liver dysfunction, anticancer drugs, infections, and opioids [22–24].

Tuma and DeAngelis reported that the causes of delirium were multiple in about two-thirds of cases. Only 15% had structural lesions as a cause of AMS [25]. Doriathet et al. studied 100 consecutive patients with confusion, finding that 36% were due to structural causes [21]. Other overlooked but important factors are loneliness and unfamiliar environments, which add to the psychological stress afflicting cancer patients. Given the complex nature of delirium and its multifactorial etiologies, it is difficult to subsume delirium under one heading.

Table 43.1 lists conditions that can cause or contribute to delirium. Medications, particularly opioids, are a frequent proximal cause of delirium in patients with advanced cancer [26, 27]. Table 43.2 lists medications that can contribute to delirium.

Neurotoxicity is a known complication of chronic opioid therapy and may be manifested by delirium, hallucinations (particularly visual hallucinations), myoclonus, and hyperalgesia. Chronic high-dose opioid therapy and coadministration of opioids and other psychoactive drugs, such as benzodiazepines, are common predisposing factors for delirium. Opioid-induced neurotoxicity is believed to be caused by opioid end products, such as morphine-3-glucuronide (in the case of morphine) [23, 28, 29]. The majority of opioids have similar active metabolites. These opioid metabolites are usually excreted by the kidneys and accumulate with renal insufficiency; therefore, dehydration and acute or chronic renal failure may decrease their clearance.

Opioids may exert their toxic effects via the cholinergic system [23]. Central neurotransmitter disturbances are believed to be the final common pathophysiologic mechanism causing delirium. Most of these theories, reviewed by Maldonado, center on neurotransmitter roles, inflammatory cytokines, and blood-brain barrier integrity in delirium development. The neurotransmitter hypothesis

Table 43.1 Common conditions that could contribute to delirium

Conditions that contribute to delirium	Examples
Medications	Mainly opioids, benzodiazepines, steroids, some antiemetics, certain chemotherapies
Infection	Urinary tract infection, pneumonia, sepsis
Organ failure	Renal, hepatic, pulmonary, cardiac
Primary CNS insult	Primary or metastatic brain tumors, cerebrovascular accidents, leptomeningeal disease
Withdrawal from medications	Alcohol, benzodiazepines
Electrolyte imbalance	Hyponatremia, hypercalcemia
Metabolic/endocrine	Hypothyroidism, paraneoplastic syndrome,
Others	Uncontrolled pain, dehydration, malnutrition, change in environment/ stimulation

Table 43.2 Common medications that could contribute to delirium

Medication category	Examples
Opioids analgesia	Morphine, hydromorphone, oxycodone, fentanyl
Antiemetics	Prochlorperazine, promethazine
Antibiotics	Fluoroquinolones; gemifloxacin, levofloxacin, moxifloxacin
Antivirals	Acyclovir
Sedatives	Benzodiazepines; lorazepam, diazepam, midazolam
Muscle relaxants	Baclofen,
Antihistamines	Diphenhydramine, dimenhydrinate, hydroxyzine
Antidepressants and mood stabilizer	TCAs, SSRIs, lithium
Cardiac medications	Antiarrhythmics, digitalis
Chemotherapy	Ifosfamide, 5-fluorouracil, paclitaxel, vincristine, cisplatin, cytosine arabinoside

TCA tricyclic antidepressant, *SSRI* selective serotonin reuptake inhibitor

builds upon the role of neurotransmitter changes in the development and treatment of delirium and AMS.

Other neurotransmitter abnormalities that may contribute to delirium include excess serotonin and cortisol levels, as well as reductions in GABA (γ-aminobutyric acid) levels [30]. More recently, increasing attention has been given to the role of cytokines, such as interleukins 1 and 6, tumor necrosis factor, and pro-inflammatory markers, such as C-reactive protein, in causing delirium. These are consistent with the neuro-inflammatory hypothesis, which implies that peripheral inflammation results in the activation of CNS parenchymal cells, which produces inflammatory cytokines that alter the normal functioning of neuronal synapses. This hypothesis could explain the "sickness behavior" seen in patients with inflammation or infections [31, 32].

Clinical Personation and Diagnosis

Three clinical subtypes of delirium have been described, classified by the patient's psychomotor activity and arousal level [33]:

- Hyperactive: confusion + agitation ± hallucinations ± delusions ± myoclonus ± hyperalgesia. The patient may fidget around the room, attempt to pull out lines, repeat movements and names, etc. Its features mimic those seen in psychosis, mania, or extrapyramidal side effects of medications.
- Hypoactive: confusion + somnolence ± withdrawal. Usually manifests with withdrawal, psychomotor retardation or lack of movement, lack of orientation, paucity of speech, and unresponsiveness. This type of delirium may mimic a depressed mood.
- Mixed: alternating symptoms of both hyperactive and hypoactive delirium. This form is the most common in advanced cancer patients.

The gold standard for diagnosing delirium is psychiatric evaluation based on criteria set forth by the Diagnostic and Statistical Manual of Mental Disorders (DSM-V). Based on these criteria, diagnosing delirium will require all of the following [34, 35]:

A. A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).
B. The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.
C. An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception).
D. The disturbances in Criteria A and C are not explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma.
E. There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin or is due to multiple etiologies.

Patient Evaluation

The clinician should maintain a high index of suspicion and look for clues within the patient's presentation, such as new-onset agitation that peaks at night or variations in sleep patterns (generally sundowning) in which patients sleep during the day and remain awake at night. Also, patients will have memory deficit and difficulty mentioning names of people and places. Relatively acute onset of symptoms with a fluctuating pattern helps distinguish delirium from more chronic conditions such as dementia, which occurs gradually over months and years. Ask the patient specifically about hallucinations (they are more often tactile than visual) and delusional thoughts. Look for clinical signs of sepsis, opioid toxicity, dehydration, metabolic abnormalities, or other potential causes of delirium. Family members or other surrogates may provide valuable information such as changes in cognition, memory, or behaviors. Inattention is a vital finding to observe while assessing delirious patients.

Screening Tools

Multiple tools have been developed in order to facilitate the detection of delirium. Most of these tools used for screening and diagnosis of delirium are based on the DSM criteria. LaMantia conducted a systematic review and concluded that although several tools were used in the ED, only one was validated and, because of limited information, there are no specific recommendations for screening of delirium in ED [36].

The CAM (Confusion Assessment Method) is the most validated screening tool for delirium in the ED [37]. The CAM for the Intensive Care Unit (CAM-ICU) has also been evaluated as an ED screening tool with good reported accuracy [38–40]. In a systematic review, Mariz et al. [41] suggest that the CAM-ICU has potential to be the reference for diagnosing delirium in ED. The Single Question in Delirium is an easy and quick tool to screen for delirium [42].

Table 43.3 lists some commonly used screening and diagnostic tools. Some patients with delirium may appear cog-

Table 43.3 Delirium screening and diagnostic tools

Tool	Purpose	Main Features
Nu-DESC [43]	Screening	Used by nurses at the bedside Brief (5 items, requires <2 min)
MMSE [32]	Screening	Test of cognitive failure 30 items (score <24 signifies greater cognitive failure) Commonly used for dementia but may be used as a screening tool for delirium
CAM [37]	Screening and diagnostic	Based on DSM-III-R [34] criteria Brief (four features, could be completed in <5 min) Simple, but users need training Does not rate the severity
Single Question in Delirium [42]	Screening	Simple and brief Easy to administer
MDAS [44]	Severity rating	Differentiates among subtypes of delirium Easy to administer by a non-medically trained person Ten items, 30-point scale (higher scores signify greater severity) Some groups use cutoff score >7 to diagnose delirium [44]
CAM-ICU [40]	Diagnosis in ICU, screening in ED	Based on CAM Originally validated to assess delirium in ICU Evaluated in ED setting

Nu-DESC Nursing Delirium Screening Scale, *MMSE* Mini-Mental State Examination, *CAM* Confusion Assessment Method, *DSM-III-R* Diagnostic and Statistical Manual of Mental Disorders, Third Edition–Revised, *ED* emergency department, *MDAS* Memorial Delirium Assessment Scale, *CAM-ICU* Confusion Assessment Method for the Intensive Care Unit

nitively normal and follow commands appropriately; thus, using a screening tool can provide valuable guidance toward an accurate diagnosis of the condition. Because of time constraints in the ED, a shorter screening tool may be more practical [43]. The single question delirium screen is a short and practical ED screening tool when answered by the patient and surrogate [34]. However, further research is needed to evaluate its utility. The Memorial Delirium Assessment Scale (MDAS) is easy to administer by a lay-trained person, but it is time-consuming [44]. The MDAS may be more sensitive than CAM in diagnosing ED delirium [45].

Diagnosing delirium superimposed on dementia is challenging. Family identification of delirium using CAM instrument (FAM-CAM) is an informant-based delirium assessment that may help overcome the barriers to delirium screening in patients with dementia [46]. The FAM-CAM consists of 11 items that characterize changes in attention, speech, arousal, and orientation; a patient's family member or caregiver who knows the patient's baseline mental and cognitive status well completes it. To improve delirium recognition in the ED, however, we must move beyond just conducting research and take a more active approach to diagnosing delirium while incorporating implementation science principles.

Differential Diagnosis

Depression and dementia may complicate the differential diagnosis of delirium, and hypoactive delirium may be misdiagnosed as depression, with resultant inappropriate treatment. Agitated delirium may be wrongly assessed as anxiety, insomnia, or psychosis and treated with benzodiazepines. The presence of grimacing or moaning may be interpreted as inadequate pain resulting in inappropriately opioid dosing. Urinary retention and constipation can aggravate agitation. Previously unrecognized cognitive dysfunction may manifest itself as delirium during cancer treatment. Patients may have episodic lucid intervals marked by the clearing of their sensorium.

Management

Step 1. Assessing the Patient

Maintain a high index of suspicion. Ask family members or the nurse caring for the patient about new symptoms, especially symptoms at night.

Use a screening tool such as CAM, MDAS, Clock-making, or Mini-Mental State Examination (identifies cognitive impairment only). These screening tools should be used even in patients with no overt signs of delirium to make an early diagnosis. Ask specifically about hallucinations (they are more often tactile than visual) and delusional thoughts. Look for clinical signs of sepsis, opioid toxicity, dehydration, metabolic abnormalities, or other potential delirium causes [47, 48].

Order appropriate laboratory tests early, such as a complete blood count, electrolytes, calcium (with albumin), and renal and liver function. Imaging tests that may help include chest x-ray, brain CT/MRI, and O2 saturation, with other tests ordered as clinically indicated.

Step 2. Reviewing the Environment

- Ensure a physically safe environment and minimize noise and excessive light.
- Provide the presence of familiar objects and a visible clock and calendar.
- Include the family by asking them to assist with reorientation.
- Pain levels and the patient's need to use the bathroom should be addressed.

- The bed should be lowered to minimize fall-related injury.
- The patient and surrogate should be advised to call the nurse if the patient wants to leave the bed for any reason, including going to the restroom.
- If no caregiver is available, a sitter should be assigned to assist the patient; however, a familiar face is preferable to a stranger [49, 50].
- Use of restraints or any tethering agent, such as Foley catheters, ECG leads, and oxygen saturation or blood pressure monitor lines, is discouraged. These items may worsen agitation in the delirious patient. Familiar items such as photographs of family members may help calm the patient [47, 51–53].

Step 3. Treating the Symptoms of Delirium

Agitation and Hallucinations Haloperidol is the drug of the first choice. Treatment can be started with haloperidol 0.5 = 1 mg PO/SC/IV q6h and 1–2 mg PO/SC/IV q2h as needed. To bring severe agitation rapidly under control, it may be necessary to give haloperidol more frequently initially (e.g., 1–2 mg q30 min SC/IV as needed during the first hour and q1h prn after that).

The oral bioavailability of haloperidol is approximately 60–70%, and this should be taken into account when converting from the oral to the parenteral route and vice versa. It is essential to bring agitated delirium under control as rapidly as possible to prevent patient, family, and staff distress or injuries. Once symptoms are under control, start reducing the dose to the minimal effective quantity [54, 55]. One of haloperidol's main side effects is extrapyramidal symptoms, which could be confused with worsening agitation [56].

If agitation persists with increasing haloperidol doses, agents providing more sedation, such as chlorpromazine or an atypical antipsychotic (e.g., olanzapine), may be considered. Studies have shown some promise using subcutaneous olanzapine to treat agitated delirium in the advanced cancer patient population [57]. Sometimes an infusion of haloperidol or more sedating neuroleptic medication (such as chlorpromazine) may be required, at which time we encourage palliative care or psychiatric consultation [27, 58, 59]. Table 43.4 lists common medications used in the management of delirium and their main side effects [57, 60, 61].

Chlorpromazine is a more sedating antipsychotic, but its use is limited by significant side effects, such as orthostatic hypotension and anticholinergic effects. Benzodiazepines are not recommended (except in alcohol withdrawal) or if antipsychotic medications are contraindicated or associated with significant side effects (seizures, extrapyramidal side effects, or severe arrhythmia). In such cases, consultation to palliative care, psychiatry, or neurology specialists is recommended [62–64].

Table 43.4 Common medications for management of agitated delirium

Medication	Main receptors affected	Available forms	Major side effects
Haloperidol	Dopamine D2, D1	Oral Subcutaneous Intramuscular Intravenous	Extrapyramidal QT-interval prolongation Seizure *Use lower doses in elderly or frail patients
Chlorpromazine	Dopamine D2, D1 α1-Adrenergic	Oral Rectal Intravenous Intramuscular	Orthostatic hypotension Anticholinergic QT-interval prolongation Arrhythmia
Risperidone	Serotonin 5-HT2A α1-,α2- Adrenergic Histamine H1	Oral	Arrhythmia Dysphagia Seizure Expensive *Use with caution in patients with severe hepatic or renal dysfunction Use lower doses in elderly or frail patients
Olanzapine	Serotonin 5HT2A Histamine H1 Muscarinic M1	Oral Subcutaneous Intramuscular	Arrhythmia Weight gain Sedation Expensive *Use with caution in patients with hepatic dysfunction
Quetiapine	Serotonin 5-HT2A Dopamine D2	Oral	Arrhythmia Orthostatic hypotension Expensive
Ziprasidone	Serotonin 5-HT2A Dopamine D2	Oral Intramuscular	Drowsiness Sedation Headache Metabolic disturbances Extrapyramidal symptoms

The atypical antipsychotics have gained attention in the management of delirium; however, most of these agents are unavailable in parenteral form. For atypical antipsychotic agents available in the parenteral form, such as olanzapine and ziprasidone, administration via intramuscular injection is recommended. Such routes may not be suitable for the advanced cancer patient, who frequently suffers from muscle wasting and cachexia or has thrombocytopenia or other hematologic abnormalities. Antipsychotic side effects depend on the receptor targeted or blocked by the medication. For example, chlorpromazine's action on histamine and α1-adrenergic receptors results in more sedation and orthostatic hypotension, respectively, than does haloperidol. Conversely, haloperidol has more extrapyramidal side effects because of its action at dopamine receptors [63, 65, 66].

Some studies have reported increased mortality in elderly patients receiving atypical antipsychotic medications, resulting from their effect on cardiac conduction. This mortality may be due to prolonged QT intervals and resultant arrhythmias. Therefore, it is vital to obtain a baseline ECG, if possible. If conduction abnormalities are evident at baseline, antipsychotics should be used sparingly.

Step 4. Treating the Underlying Cause

Opioid Toxicity Rotate (switch) opioids from one type to another based on the morphine equivalent dose of the new opioid and reduce the dose of the new drug as recommended for pain management. If the ED physician lacks experience in pain management, consider pain or palliative care consultation. Hydration may be required to clear active metabolites.

Sepsis Start intravenous fluids and appropriate antibiotics as soon as possible.

Other Drugs Discontinue all possible implicated medications, especially benzodiazepines, anticholinergics, corticosteroids, antidepressants, certain antiemetics and antivirals, antibiotics (quinolones), cimetidine, and ranitidine.

Dehydration Start intravenous or subcutaneous hydration as soon as possible. In the home or hospice settings, fluids may be given under the skin (hypodermoclysis) with normal saline at 60–100 ml/hour or give boluses of 500 cc administered over 1 hour, three or four times daily.

Hypercalcemia Treat with hydration with saline and bisphosphonates.

Hypoxia Treat the underlying cause and administer oxygen.

Table 43.5 Interventions to correct common underlying causes of delirium

Condition	Treatment
Side effect of a medication (e.g., opioids, benzodiazepines)	Stop offending drug (with opioids, consider reducing dose/switching to a different opioid)
Alcohol or benzodiazepine withdrawal	Benzodiazepines
Dehydration	Intravenous fluid hydration
Infection/sepsis	Antibiotics
Hypercalcemia	Hydration, bisphosphonate, or calcitonin (for hypercalcemia)
Brain metastasis	Corticosteroids (consider radiation therapy or chemotherapy)

Brain Tumor or Metastasis Consider high-dose corticosteroids. Radiation or surgery may be required. Table 43.5 lists possible interventions to correct the underlying cause of delirium.

Step 5. Counseling the Patient's Family and Healthcare Professionals

Confusion and agitation are expressions of brain malfunction and not necessarily of discomfort or suffering. Disinhibition is one of the main components of delirium and may result in two possibly distressing phenomena:

- *A dramatic expression of previously well-controlled physical symptoms by grimacing or moaning*: Family or staff may interpret this as aggravating symptoms rather than merely increased expression. In addition to observer distress, this can lead to excessive use of opioids and adjuvant drugs, as well as the accompanying potential for delirium exacerbation.
- *Unreasonable requests of family or staff* (e.g., "I want to go home now."): If these requests are not immediately addressed, the patient may become hostile. Unless appropriately explained to the patient's family, this disinhibited behavior may be quite distressing. Research has shown that up to 74% of patients recall their symptoms after delirium resolution and up to 81% of those recall associated distress [67]. Hypoactive delirium is as distressing for patients as hyperactive delirium.

Palliative Sedation

Palliative sedation (PS) is defined as "the monitored use of sedative medication to reduce patients' awareness of intractable and refractory symptoms near the end of life, when other interventions have failed to control them." Clinicians should attempt all available symptom-specific measures,

including specialists' consultation before labeling a symptom as refractory. Refractory delirium is the most common indication for PS [68].

The goal of PS is to control distressing symptoms and not to hasten death. Consciousness should be maintained if possible. PS should be differentiated from physician-assisted death or euthanasia. Therefore, we do not recommend PS for existential distress. Reasons and goals of PS should be discussed with the family and patient (if possible) and well documented in the medical record [68].

Midazolam is the drug of the first choice. Use the lowest dose possible to provide comfort, e.g., commence a continuous SC or IV infusion of midazolam at 1 mg/hour, titrated according to clinical response.

Prognosis

Mortality risk varies depending on the delirium subtype, as well as potential etiological factors involved. The hypoactive subtype of delirium is associated with a higher mortality rate and a shorter mean survival time [17].

Delirium is associated with increased risks of complications, more extended hospital stays, prolonged mechanical ventilation, and increased mortality rates. Delirium has also been suggested as a risk factor for the future development of dementia. Patients who do not recover fully continue to show signs of cognitive impairment and functional decline over time [69].

Suicide

44

Anis Rashid

Introduction

Suicide is the intentional act of taking one's own life. The traits dependent on heritable factors related to suicidal psychopathology are complex. The triggers leading to suicide vary from severe depression to loss of a loved one, loss of a job, hopelessness, substance misuse, chronic or incurable illness, and even uncontrollable anger due to an underlying clinical or psychiatric illness. According to the World Health Organization, about 800,000 people die by suicide worldwide every year [1]. Suicide is the second leading cause of death in individuals aged 18–24 years and the fourth leading cause of death in older populations [2].

Cancer patients have a four times higher risk of suicide as compared to the general population [3]. One study found that 8% of patients attending an oncology clinic reported ongoing passive suicidal thoughts [4]. Chochinov et al. documented that up to 44% of terminally ill cancer patients expressed fleeting suicidal thoughts [5]. Cancer patients are at high risk for suicide as they are burdened with cancer-specific risk factors in addition to the general risk factors for suicide. Major risk factors specific to cancer patients include pain, physical dysfunction/dependence, and a fear of abandonment [6]. Literature indicates that the risk of suicide is highest in the first year and the relative risk is highest in the first month after a cancer diagnosis but decreases significantly over time [6]. Increased risk may resurface with advanced stage or recurrent disease. A higher risk of suicide has been reported in patients with certain cancer types such as lung cancer, head and neck cancers, Hodgkin lymphoma, testicular cancer, and bladder cancers [3]. Studies have shown that elderly, white, unmarried men are at greater risk than other patient groups [3] and as compared to patients with spousal support [7].

Whether in the general population or in an oncology setting, the act of suicide has a traumatic effect not only on the person's family, relatives, close friends, and caregivers but also on coworkers, colleagues, organizations the person was part of, and even the entire community. Caregivers of cancer patients may be more traumatized, as in addition to grief they may feel they have failed in providing proper emotional and physical support to the patients [8]. Suicide has repercussions far beyond the affected individual. In summary, the act of suicide has negative ripple effects throughout society. Confidentiality is the key to preservation of trust between clinicians and patients, but when there is a threat of harm to self or others, clinicians have a duty to breach confidentiality and take necessary actions to protect identifiable individuals. Recognizing and reporting suicidal individuals whose job functions could endanger the safety of others is crucial.

A few years ago, one such suicide changed the dynamics of the airline industry, with global repercussions. On March 24, 2015, Germanwings Flight 9525, an Airbus 320, took off for a two-hour flight from Barcelona to Dusseldorf. An hour and half into the flight, the Airbus 320 crashed into the Alps 100 kilometers northwest from Niles killing all 150 people on board. The cause of the crash, determined by an investigation, was an act of suicide committed by the copilot, 27-year-old Andreas Lubitz. The suicide shook the airline industry worldwide. Subsequently, it was determined through an investigation that the copilot had a long history of severe depression and was on several psychotropic medications. He had seen his psychiatrist 2 weeks before the incident. German privacy laws prevented this information from being shared with his employer. This lack of information prevented any timely intervention by his employer or a third party. The result was a terrible suicide that took both his life and that of 149 innocent people. It also brought into focus the question of privacy laws in relation to conditions relevant to critical job functions.

In the United States, the patient physician relationship is confidential, and the Health Insurance Portability and Accountability Act (HIPAA) protects the confidentiality of health records, including therapy and mental health infor-

mation, but with certain exceptions. Confidentiality can be breached if the patient is a threat to his/her own safety and safety of others [9].

Despite advances in cancer treatment and success in novel approaches of treatment with immunotherapy, the diagnosis of cancer can still feel like a death sentence to some patients. Patients can feel anxiety, depression, and compromised quality of life due to the sheer burden of undergoing cancer treatment. Regular support, reassurance, and medication management by mental health providers give them hope, improve their quality of life, and keep them adherent to medical treatment. Continuity of care and empowering them with emotion-based coping strategies are essential for their stability.

Case Study: Refractory Hodgkin Lymphoma

Mr. B, a 40-year-old gentleman with refractory Hodgkin lymphoma, was seen over several years in the psychiatry clinic for anxiety and depression. He was stable with medications and psychotherapy. However, Mr. B lost his mental health insurance and was not seen in the clinic for several months. One afternoon a social worker from the lymphoma team contacted the psychiatry clinic, explaining that Mr. B is extremely distressed, is back on mental health coverage, and needs to be seen urgently. Mr. B walked into the psychiatry clinic limping, with his head down, and spoke in a low tone. He stated he was miserable due to CAR T-cell toxicities and feels he is better off being dead. He denied any active suicidal thoughts or plans but reported he cannot live like this and intends to stop the treatment. He came to psychiatry clinic at the social worker's insistence.

Mr. B had failed several lines of chemotherapy and stem cell transplant. The disease progressed, and he was then started on immune checkpoint inhibitor. Mr. B developed severe toxicities related to the treatment which compromised his quality of life. He was fatigued and developed bilateral lower limb vasculitis with open wounds, abdominal pain, diarrhea, bilateral hip pain, neuropathy in hands and feet, and a wrist drop. He became severely depressed and started having fleeting suicidal thoughts. Mr. B reconnected with his psychiatrist and assured her that he would not harm himself because of his faith. As he had no active suicidal thoughts, no past history of suicidal attempt, and a good support system, he did not seem to be at acute risk for suicide. He was discharged home with close follow-up and was given suicide hotline numbers and the social worker's direct contact information. Social work's timely intervention and support from psychiatry services, as well as a modification in his cancer treatment regimen, has stabilized Mr. B. He is back to his baseline mood, compliant with his cancer treatment, and stable enough to enjoy company of his friends and his favorite television programs.

It has been well established that not all individuals who commit suicide truly want to die. Most suicidal patients have a desire to live; they either cannot see past their distress to the options available or have lost hope of changing their situation. It is important to be able to assess who will commit suicide and who is just thinking about it. The relationship between depression and suicide has been well documented in the literature; however, not everyone with depression wants to die or attempts suicide. This suggests that depression is not fully adequate as a causal explanation and that additional factors play a role in suicide. Although the act of suicide is complex, several theories have been described to explain the extent of deep emotional pain and reasoning that triggers the act. In this chapter, we describe these theories and the biopsychosocial model of suicide. We then discuss risk factors specific to cancer patients and management of suicidal patients in oncology settings. Finally, we propose directions for future research.

Theories of Suicide

Mental health providers have been trained to understand the psychopathology underlying suicidal thoughts. Psychoanalysts have several theories regarding suicidal ideations and gestures. According to Freud, suicide is aggression turned inward [10]. He believed that patients internalize and connect with an object (person) so deeply that they and the object become one entity. If in their minds that object betrays them, they become angry and believe that the only way to get rid of the object is to get rid of themselves [10]. Karl Menninger claimed suicide reflects murderous wishes of individuals who kill themselves [11]. Edwin Shneidman described the unbearable psychological pain and suffering that exists in the mind of a suicidal person [12]. He talked about the imbalance between belongings and the burden. He believed that individuals with major losses and failures in life may feel overpowered by psychological demands that are above their tolerance threshold. This intense psychological energy can lead to an impulsive desire to change the unbearable situation [12]. Aaron Beck's theory of suicide is about hopelessness: that nothing will change for the better no matter what an individual does [13]. Another theory of suicide by Roy Baumeister is based on persistent negative experiences in life leading to negative self-perception and self-hate, with the only escape being suicide [14].

Biopsychosocial Model of Suicide

Introduced about 45 years ago, the biopsychosocial model was developed to better understand patients by using a more holistic approach with less emphasis on biomedicine. This model,

which captures the interaction of biological, psychological, and social factors underlying illness, can help nonpsychiatric clinicians understand the underlying complex psychopathology that may manifest as physical symptoms in their patients [15]. With time, the biopsychosocial model became very popular and currently has become the standard of practice in teaching programs for medical students and residents.

Unfortunately, the concept and practice of this model have changed overtime and have now drawn an artificial distinction between biology and psychology. Psychiatrists have become psychopharmacologists, and the role of psychotherapy has been taken over by psychologists. One of the reasons for this divide is the difference in reimbursement from insurance companies for pharmacological management versus psychotherapy.

Trained in the concept that any psychopathology may have biological and social influences, mental health providers are highly interested in examining **three** domains: **predisposing, precipitating**, and **perpetuating** risk factors for suicide. Predisposing factors include patients' genetic makeup, temperament, and social factors during early childhood. Precipitating factors include stressful life events and losses affecting psychology. Perpetuating factors are ongoing life challenges [16]. The biopsychosocial formulation gives clinicians a deeper understanding of such factors as patients' unhappy childhoods, poor social support and relationships, anger, negative cognitive style, and impulsivity.

Predisposing Factors: Genetic Makeup

Serotonin

One of the complex aspects of the neurobiology of suicide is that of serotonin. Dysregulation of serotonergic receptors in the brain plays an important role in depression and suicidal behavior. Serotonin is the main neurotransmitter that plays an important role in mood [17], appetite, sleep, and memory [18]. It has been well documented that cerebrospinal fluid in depressed patients who committed suicide contained lower levels of 5-hydroxyindoleacetic acid, which is the major metabolite of serotonin, as well as lower levels of homovanillic acid, a metabolite of dopamine [19]. Lower levels of serotonin could be due to upregulation of serotonin receptors [19]. In order to compensate for lower serotonin levels, the body attempts to enhance serotoninergic activity at nerve terminals by increasing central serotonergic neurons and the levels of key enzymes required for serotonin synthesis. This complex phenomenon is still not clearly understood.

Hypothalamus-Pituitary-Adrenal Axis

A more recent study focused on the hypothalamus-pituitary-adrenal axis in depressed patients and confirmed hyperfunctioning of the axis in depression and return to normal functioning when symptoms improved. The study used the dexamethasone suppression test and found a much higher positive rate in depressed patients with suicidal behavior vs. depressed patients with no previous suicidal thoughts. This indicates suicide-specific characteristics that may differentiate depressed patients with suicidal behavior from those without such behavior [20]. Further work is needed in the area.

Childhood Trauma

Other associated factors affecting suicidal thought include adverse childhood experiences in the absence of protective factors. Children raised in a household with parental substance use or incarceration and divorce or domestic violence or those who experience childhood sexual, emotional, or physical abuse develop a sense of insecurity, mistrust, and anger [21]. It has been shown that childhood trauma alters stress reactivity of the hypothalamus-pituitary-adrenal axis [22]. As adults, these individuals may develop physical, mental, and behavioral disorders with poor coping skills and feel very angry with themselves and society. Depression may result, and when individuals have other risk factors such as substance misuse, mistrust, and poor social support, they are at high risk for suicide.

Anger and Impulsive Behavior

Another well-known risk factor for suicide is anger and impulsiveness in individuals. These characteristics can play an important role in enhancing the risk of suicide [23, 24]. Teenagers and young adults are more impulsive, which may increase the risk of suicidal behavior [25]. This may be due to poor self-control and urgency to act on thoughts, disregarding implications and consequences.

Precipitating Factors

Mood Disorders

A strong association between suicide and depression has been documented [26]. The literature suggests that almost 90% of people who commit suicide have a mental disorder but only 5% of people with a mental disorder die by suicide [27]. Thus, depression in itself does not always lead to suicide. The stress-diathesis model describes the tendency to act upon suicidal ideations as based on multiple factors and not just the presence of a mental disorder such as depression [27]. Sometimes, unpleasant life events such as loss of a loved one or a relationship with extreme hopelessness may be so devastating that they lead to suicide [28].

Substance Misuse is an independent risk factor for suicide. Compared to the general population, people with alcohol and drug use disorders have a 10–14 times higher risk of suicide [29].

Chronic Illness

Patients with chronic illnesses, such as rheumatoid arthritis, diabetes, or cancer, may grieve for the loss of the life they experienced before being sick. Adjusting to the prolonged illness and effects, such as loss of employment, financial distress, or poor quality of life, is difficult. Such individuals may have protracted distress, develop depression and suicidal thoughts, and may even attempt suicide. Patients with chronic illness who have poor social support and quality of life are at high risk for suicide [30].

Challenges Faced by Military Veterans

The majority of first suicide attempts in veterans occur after separation from military service; veterans may find it difficult to adjust to civilian life due to relationship conflict, social isolation, pain from war injuries, and symptoms of post-traumatic stress disorder [31].

A 2019 report released by the Veterans Administration stated that the suicide rate among veterans is 1.5 times higher than among nonveterans [32, 33]. The literature indicates that major factors responsible for the high suicide rate in veterans are habituation and the acquired capability to attempt suicide [34]. Through repeated exposure to trauma or near-death experiences while serving on the front lines, soldiers may become habituated to trauma, injury, and death, and the fear of death may fade away. Another risk factor in this setting is survivors' guilt [35].

Financial Crisis/Loss of Job

Economic trends and industry shifts, such as corporate mergers and sale of companies in capitalistic economies or changing market forces, can cause major upheavals in individual lives through unemployment, loss of business, and failure to be able to support oneself. Many poor countries in Africa, South America, and Southern Asia are also known to have high suicide rates due to chronic hopelessness associated with the failure to earn enough income to raise a family or take care of the sick and elderly [36]. Again, the will to survive can vanish, propelling individuals in a highly distressed society to attempt suicide as a way to escape their financial conditions.

Environmental Factors

Environmental influences are well known to play a role in suicidal thoughts. Changes in human behavior triggered by negative external events can strongly affect the body's stress system and responses. These epigenetic changes influence psychiatric disorders and may lead to suicide attempts [37].

Perpetuating Factors

According to the stress-diathesis model, an ongoing biological or psychological factor in the absence of an acute event may not influence the individual toward a suicidal attempt. However, stressful acute events, such as divorce, rejection, or loss of a loved one, can cause a strong emotional experience of hopelessness and, when combined with impulsiveness, propel an individual toward suicide.

Suicide Risk Factors Specific to Cancer Patients

Although the literature documents a high risk of suicide in cancer patients, thus far, there is no clear documentation that cancer, *in and of itself,* is a risk factor for suicide in the absence of any psychopathology [38]. The risk of suicide in this patient population is high, however, since, in addition to general risk factors discussed above, cancer patients face other risk factors, including disease burden and life-changing adverse effects of cancer treatment. In the initial stage of disease, patients are anxious and fearful, with uncertainty of treatment outcome, and may experience treatment side effects, including nausea, poor energy, and sleep disturbances. As the disease progresses or treatment intensifies, patients may experience extreme fatigue, poor appetite, vomiting/diarrhea, neuropathy, and physical changes such as loss of muscle mass, loss of hair, and discoloration of skin and nail beds. Patients may lose their jobs and their physical independence. Depression may set in as the patient becomes more dependent on others. Role reversal within the family that comes with loss of independence, job loss, financial distress, and the potential guilt of being a burden on the family can intensify symptoms of depression.

In addition to hopelessness and fear of abandonment, one of the major risk factors for suicide in cancer patients is intolerable pain and suffering. Reports have documented that cancer patients do not always experience good pain control; for example, oncologists may fear prescribing opioids to emaciated or ill cancer patients with compromised liver, kidney, or respiratory functions.

Management of Suicidal Cancer Patients

Currently, the best screening tool is the clinical judgment of mental health providers and their expert opinions regarding suicide risk. Such providers working with these patients try to understand the root cause of these symptoms and provide support and management strategies. When a patient with cancer reports suicidal thoughts, it should be given serious consideration. It is important to determine whether such thoughts are due to physical challenges, such as unbearable pain, or because of hopelessness and depression. Many symptoms of depression, such as poor sleep, fatigue, and loss of appetite, are similar to those of cancer and the side

effects of cancer treatment. Hopelessness, loss of meaning in life, despair, and suicidal thoughts are alarming signs [39]. Cancer patients with a history of psychopathology, previous suicide attempts, or a family history of mental illness are at high risk for suicide. Recognizing clinical depression in cancer patients is very important as depression is treatable; treatment may uplift patients' mood, giving them hope and motivating them to continue treatment.

Management of Suicidal Oncology Patients in the Emergency Department

About 8% of emergency department (ED) patients have suicidal thoughts, which they may not share unless asked [40]. It is important for the emergency physician to explore any suicidal thoughts from a patient with a history of mental illness. Based on the initial assessment, the clinician may need to consult the psychiatry service for a full evaluation and management. Management of suicidal oncology patients in the emergency department is a challenge due to time constraints, medical comorbidities needing immediate attention, the potential need to find availability of psychiatry beds in a med-psych facility, arranging transport to the appropriate hospital, and completing paperwork for involuntary admission, if the patient is not willing to go voluntarily.

The first step in management is to implement a proper safety protocol and protect the patient from self-harm. Patients with suicidal thoughts should not be allowed to leave the emergency department until they have had a complete evaluation by a mental health provider [41]. Medical staff should closely observe the patient, and the room should be searched for items that could be used as a weapon, such as a belt, wires, any sharp object, or glass medicine bottles [41].

Patients with vague suicidal thoughts but no plans, no previous attempts, no history of mental illness, no substance use, no agitation or confusion, and with good social support may be allowed to leave but with a firm follow-up plan [42], as the days after discharge from the emergency center are a high-risk period [40]. Patients who have any unbearable physical symptoms such as pain or severe nausea and vomiting should be admitted to the medical ward for stabilization and control of these symptoms.

Cancer patients with active suicidal thoughts who are undergoing active treatment or with medical comorbidities should be admitted to a hospital where they can be monitored closely until stabilized and their treatment continued. Daily assessment by a mental health provider, appropriate medication, and support are required. After discharge from the hospital, the patient should follow up with a psychiatrist for continued care.

It is important to determine if the suicidal thoughts are due to unbearable physical symptoms, such as severe pain or intractable nausea/vomiting, which should be addressed and managed properly. Inadequate pain management in oncology is a multidimensional problem. It is a devastating symptom that many cancer patients suffer. Since the publication of the analgesic ladder in 1986, pain management has improved, but many cancer patients still do not receive proper pain control [43]. High pain levels, especially in advanced cancer stages, lead to suicidal thoughts. Pain symptoms should be properly managed by the palliative care team [7] during hospitalization, and patients should be discharged with adequate analgesics. Any other physical symptom should be properly investigated and managed.

Management of Suicidal Patients in the Oncology Clinic

Patients with active suicidal thoughts or plans to act on them require full evaluation by a mental health provider and should be admitted to a psychiatric facility for safety until stabilized. Patients with passive suicidal thoughts, with no plans and means to act on them, and with no major risk factors but good social support may be allowed to go home after thorough evaluation. With the patient's permission, a family member or a close friend can be involved who will monitor the patient's safety and adherence to treatment [42]. Such patients should be monitored through regular follow-up with a mental health provider and medication management as indicated.

Most suicidal patients do not want to end their lives; rather, they want to end their emotional pain and unbearable suffering. Talking about suicide does not trigger a suicidal attempt. Instead, it gives the patient a chance to discuss his/her fears and may help them find a source for sharing their feelings. Clinicians work in a collaborative model, walking with the patient on difficult roads to understand their emotional pain and suffering, validating their emotional turmoil, and helping them find alternative ways to cope. They assure these patients that the solution to their problems lies within them and they can work together to find those solutions [44]. They help raise patients' pain threshold and coping skills. Regular follow-up with a mental health provider for support and to learn and sustain coping strategies is key. The mental health provider develops a suicide-specific treatment plan and clinically tracks and documents ongoing suicidal risk. They also monitor medication compliance, side effects, and response. Most important is to empathize with the suicidal wish, identify protective factors, and work in a collaborative model.

The literature documents that combination therapy with medication and psychotherapy gives better results in managing depression [45]. This approach shortens the time until symptom control and increases adherence to medical treatment. Cognitive behavioral therapy and dialectal behavioral

therapy have shown good results to reduce suicidal thinking, as they address cognitive and behavioral aspects of suicide.

Antidepressants for the Treatment of Depression in Cancer Patients

Depression is the most common psychological symptom in cancer patients. It is often underdiagnosed or misdiagnosed because its symptoms overlap the physical symptoms of cancer and its treatment. The most frequent and common example of this misdiagnosis is hypoactive delirium. Prescribing an antidepressant or a stimulant to a delirious patient may exacerbate the condition [46]; hence, proper diagnosis and management of depression by a mental health provider is important. There are not enough data available to assess the efficacy and tolerability of antidepressants in the oncology setting, and no one antidepressant has been proven superior to another [47]. The most commonly prescribed antidepressants in the oncology setting are specific serotonin reuptake inhibitors (SSRIs). These drugs have a good safety profile with a minimum of drug interactions. The choice of antidepressant should be individualized to the specific symptoms in cancer patients. Patients with depression and poor sleep may be given antidepressants with sedative properties [48]. Depressed patients with pain symptoms may benefit from the choice of duloxetine. Cancer patients with nausea and poor appetite may benefit from mirtazapine; this drug not only helps with mood symptoms but also controls nausea and promotes appetite. It is important to understand that antidepressants take a few weeks to control symptoms. Psychostimulants deserve special consideration in terminally ill patients when a quick response is needed, as they provide a rapid effect [49]. Choosing an antidepressant becomes challenging when patients are on certain protocols with restrictions on the choice of antidepressant or when they are unable to swallow a pill. Communicating with the primary oncology team before starting an antidepressant, monitoring the side effects profile of the drug, and having a sound knowledge of drug-drug interactions is important.

Future Research

Patients with biopsychosocial risk factors and suicidal thoughts and behaviors may show a specific neural circuitry picture. Previous work on brain scans has identified specific circuits associated with executive functions, impulsivity, and mood [50]. Recently, it has been shown that every idea or thought has a specific pattern in the brain; these patterns can be identified through brain scans showing color changes in the brain neurons. Researchers have been working to identify suicidal thoughts through brain scans with the goal of determining who could attempt suicide in the future. People with active suicidal thoughts exhibit increased brain activity in the areas associated with emotions and thoughts about self, which can be identified using functional MRI [51]. This work is still in the initial stages but seems promising. If thought processes reflecting risk factors of suicide can be identified and associated with interventions, a reduction in suicide attempts could result.

Conclusion

Suicide remains among the leading causes of death in the United States. The management of suicidal patients is a psychiatric emergency and the most challenging task faced by mental health providers. Through an empathic and collaborative approach, clinicians in the emergency department and mental health providers can prevent future injury and death. Emergency physicians, social workers, and mental health providers should work as a team to ensure the safety of suicidal patients, reduce emotional pain, address any acute medical condition leading to suicidal thoughts, and make appropriate treatment plans. Ensuring that treatment and safety plans are followed during transitions of care, when patients are transferred to another facility or referred for follow-up appointments, is essential to providing superior care and sustained stabilization.

Substance Abuse

45

Adam Rzetelny, Tatiana Starr Kreitzer, Maria A. Farberov, and Steven D. Passik

Introduction

Until very recently, discussing the problem of substance abuse in people with cancer might have been seen as having only minor clinical relevance. Certainly, the relief of anxiety, pain, and other distressing symptoms has been identified as a top priority for oncologic clinicians, and the use of medications, even those with abuse potential, has been deemed essential. Much of the literature on this subject suggests that problems of substance abuse are only infrequently encountered in oncologic. Perhaps this underestimation of the problem stems from the fact that much of this academic work has come from tertiary care settings—where those with histories of addiction are less frequently encountered because of barriers to care in the form of economic issues, lack of insurance coverage, and estrangement from healthcare providers who might diagnose and refer patients to such centers. Or perhaps it has been that cancer typically remains a disease of the sixth decade of life and beyond, whereas addiction overwhelmingly manifests earlier in life, making it unlikely to emerge de novo in a person first exposed to substances with abuse potential when they are older and ill [1, 2]. Or perhaps it has been because cancer used to follow an almost uniformly fast and fatal trajectory, and so any exposure to controlled substances was likely to be brief and occur during a period of time when the person was becoming increasingly disabled and less likely to engage in practices related to the obtaining and use of illicit drugs. Thus, even if the exposure to such drugs might trigger a relapse in a person who suffered with the disease of addiction before they became ill with cancer, the dysfunctional behaviors that might have been set in motion would be mediated and limited by the relentless impact of the cancer itself. Or perhaps it was simply the trivialization of addiction that characterized the early rhetoric accompanying the increase in opioid prescribing that led to this being such a neglected topic [3].

In response to the public health crisis that is chronic pain in our aging society, the prescribing of opioids and other controlled substances increased dramatically. Unfortunately, a parallel set of public health crises arose: the problems of prescription drug abuse, diversion, overdose, and death. Although a substantial portion of the problem of opioid-related overdoses now appears to be fueled by the prevalence of illicitly manufactured fentanyl, prescription opioids remain a central concern [4]. Given that people with cancer are living longer at all stages of disease, including those with painful but stable disease and those who go onto remission but are left with chronic pain issues from chemotherapy and other factors, exposures to controlled substances are considerably longer than they once were, and thus there is greater opportunity for those who come to the disease with a history of substance use disorder (SUD) to lose control and overuse or even have the problem of addiction fully rekindled [5, 6]. Thus, it is not surprising that there has been a substantial increase in the number of opioid-related emergency department (ED) visits from patients with cancer [7], with nearly a fifth of cancer patients in the ED admitting to past or current misuse and a third at high risk of misusing their opioid prescriptions [8].

The recently exacerbated problems of opioid abuse and overdose also affect patients who do not themselves suffer from these problems. A growing concern for those prescribing controlled substances and treating pain, anxiety, and other symptoms in people with cancer, including older patients, is that their medications are increasingly sought after by younger individuals with substance abuse problems

in their family or social environment (including grandchildren and caregivers). Additionally, recent data suggests that some parents of children with cancer do not manage their children's opioids safely, at times giving them to another person or even taking the opioid themselves [9]. Thus, it is not surprising that in the midst of the current opioid crisis, new restrictions and limits have emerged on the prescribing of opioids, including in the ED [10]. Although the intended aim of these restrictions is to address the management of acute, non-cancer pain, cancer patients in the ED and elsewhere may be impacted. An unintended consequence of the recent well-intended restrictions has been to increase the stigmatization of patients in pain, with deleterious effects on healthcare outcomes [11, 12]. Cancer patients are not immune to this burden, as evident in the lack of adequate pain control experienced by some opioid-tolerant cancer patients in the ED [13]. Mitigating the impact of stigma on pain and opioids requires a better understanding of addiction.

Thus, it is not only important for oncologic professionals of every stripe to have a working knowledge of addiction medicine principles and practices but particularly the oncologic ED professional. In the ED, consequences of drug abuse—from the older person with cancer presenting in withdrawal because family members have stolen their medication to the younger person whose addiction has been rekindled by the need for pain medication—are likely to be common. Common doesn't mean obvious, however, and it is important to dispel myths about the relative absence of addiction issues in cancer to help emergency care providers anticipate such problems and learn to manage them.

The increasing use of opioids in non-cancer pain grew out of recognition that people with cancer pain (at least those seeking treatment at tertiary care facilities) appeared to be able to take these medications with generally positive results. That is, their pain was controlled, side effects manageable, functional status improved or stabilized, and problems of misuse or addiction minimal. Opioid prescribing then increased dramatically, particularly in North America, to the much more diverse population of those with chronic pain—more diverse in terms of age, psychiatric, and addiction histories and comorbidities, as well as in duration of exposure [14]. Not surprisingly, the results of this effort were mixed. Cancer pain management with opioids follows a basically self-titration model consistent with an assumption that risk of misuse and addiction is uniformly minimal across patients. When this method of delivering opioid therapy in non-cancer pain began to meet with problems of abuse and diversion, a risk stratification model began to emerge. Younger age, personal or family history of addiction, history of sexual trauma, and active psychiatric comorbidity were seen as risks for a poor outcome in opioid therapy, unless the delivery of this therapy was tailored to the needs of the individual (with the employment of safeguards such as urine drug testing, prescription monitoring programs, and the like, as well as consultations with psychiatric and addiction professionals to assure safety). There is a certain irony in the fact that oncologic pain management must now take a page from the non-cancer pain "playbook." This type of risk stratification is somewhat foreign to oncologic pain management, but it seems that the time is right to close the loop and for the therapy that initially influenced non-cancer pain practice to adopt strategies developed therein, especially now that many of the differences between cancer and non-cancer pain patients have narrowed [15].

Pain and anxiety management are not the only aspects of cancer care affected by the presence of a SUD. Indeed, because unchecked drug or alcohol abuse can cause spotty or complete nonadherence to potentially lifesaving cancer treatments, virtually every step along the disease trajectory, from diagnosis to palliative care, can be threatened. Thus, the "downstream" complications of substance abuse can lead to a person with cancer presenting in the ED with problems related to nonadherence of every variety. A question is whether the ED professional will recognize them as such. And if the ED professional is working outside of a tertiary care academic center, the frequency with which they will be confronted with SUDs is shockingly high, due to the high base rate of these disorders in this population which is so much more reflective of the population as a whole. Particularly when one considers that substance use can be a risk factor for cancer, one would expect substance abusers to be over- and not underrepresented in the oncologic population. Many oncologic ED professionals from nearly all of the disciplines represented in this group of practitioners are lacking in their knowledge of addictions. There is an enormous gap between the prevalence of these problems and the expertise available to care for cancer patients who are struggling with them. It is hoped that this chapter helps bridge this gap for oncologic emergency medicine.

Scope of the Problem

Substance Use Disorder

Substance use disorders are a consistent phenomenon in the USA over time, with estimated base rates of 6–15% [16–20]. This prevalence of drug abuse certainly touches medically ill patients and can negatively influence how patients are treated. Although few studies have been conducted to evaluate the epidemiology of substance abuse in patients with advanced illness, these disorders have been reported to be relatively rare within the tertiary care population with cancer and other advanced diseases [21–23]. However, the prevalence of alcoholism in major cancer centers is most likely underestimated. A study by Bruera and colleagues [24] of

100 terminally ill alcoholic cancer patients found that despite multiple hospital admissions and screenings, only one-third had documentation of alcoholism in their medical records. How then would the ED professional know to anticipate and plan for emergent problems related to alcohol abuse in a person presenting in their setting?

The belief that drug habits diminish and vanish with age is no longer held with the certainty of past belief. An early study supporting this belief reported that 50% of individuals addicted to narcotics were no longer active drug users by age 32 and over 99% were no longer users by age 67 [25]. However, as the "baby boom" cohort ages, the extent of alcohol and medication misuse is predicted to increase significantly because of the combined effect of the growing population of older adults and cohort-related differences in lifestyles and attitudes [26]. One study suggested that the number of illicit drug users aged 50 years or older will double from the year 2000 to the year 2020 because of an anticipated 52% increase in this segment of the population and the attendant shift in attitudes and historical experiences with substance use in this cohort [27].

Prescription Drug Abuse

The use of illicit drugs and the nonmedical use of prescription opioids have increased significantly in the general population over the last decade, though it has begun to decline in the just the past few years, and the highest prevalence remains among younger adult men [16, 28]. Such estimates, however, belie alarming trends emerging among older adults. Among adults aged 50 or older, nearly five million, roughly 5% of that age group, report using illicit drugs in the past year [20]. Marijuana is the most abused drug in the USA, but among adults aged 60 or older, the abuse of prescription drugs is equally common. A changing pattern of cannabis use among older adults suggests that as an individual ages, the social incentive to smoke marijuana decreases, while the attempt to use it medicinally increases [29]. In the oncologic setting, this might include an attempt to self-medicate for nausea, anorexia, pain, and anxiety or combinations of these common symptoms [30]. More alarming than rates of cannabis use, ED visits related to pharmaceutical abuse more than doubled from 2004 to 2008 among adults aged 50 or older, and a fifth of these was among adults aged 70 or older [31]. Prescription opioids were the most common culprit, followed by benzodiazepines. Although ED visits in 2008 related to illicit drug use among adults 50 and older were a little less than half that of pharmaceuticals (118,495 vs. 256,097 visits), they were not uncommon [31, 32]. The majority of those visits were related to cocaine, followed by heroin. Consistent with this, one study demonstrated marijuana, cocaine, and opioid use in 2.4%, 1.9%, and 11.6% of elderly men, respectively [33]. Substance use treatment admissions among adults aged 50 and older have nearly doubled in recent years, from 6.6% of all admissions in 1992 to 12.7% in 2009 [34]. During this same time period, alcohol as the only substance of abuse being treated decreased from 87.6% to 58.0%, while the addition of other drugs to alcohol increased from 12.4% to 42.0%. Also around this time, treatment admissions involving heroin more than doubled, from 7.2% to 16.0%, and those reporting multiple drugs of abuse nearly tripled [35].

Even as the baby boomer population ages and more frequently experiences pain, there is a paucity of information on older patients and the risk of comorbid pain and SUDs. A survey in Denmark revealed that 22.5% of men and 27.8% of women aged 65 and older reported chronic pain [36]. Of these men and women, 35% of them were not satisfied with their pain treatment. This can lead to alternative methods for relieving pain such as taking non-prescribed medications. In one study of 100 patients with chronic pain (average age near 50), 23 tested positive for illicit drugs, and 12 tested positive for opioids, even though they had no prescription and denied taking opioids [37]. In another study of primary care patients in a Veterans Affairs facility who were receiving opioids for the treatment of chronic pain (average age 59), 78% reported at least one indicator of medication misuse during the prior year, with significantly more of those who misused pain medications reporting comorbid SUD [38]. This is consistent with a more recent examination of a subset of data from the Researched Abuse, Diversion and Addiction-Related Surveillance (RADARS) system's finding that though severe chronic pain is common in adults entering treatment for prescription opioid abuse, it is exponentially more prevalent in adults older than 45 years (70%) relative to the 18–24-year age group (45%) [1]. Clearly, to the extent that chronic pain and SUDs are comorbid or mutually exacerbating problems, older adults are a particularly vulnerable population. This might be especially true in the oncologic culture, wherein performing a risk assessment has been historically uncommon and decreasing patients' wariness about using opioids aggressively when needed has been the biggest concern.

Thus, the emerging pattern, consistent with the aging of the "baby boom" generation and their greater likelihood of exposure to various types of drugs, is that illicit and prescription drug misuse and abuse, along with the need for treatment, is expected to double by 2020 (relative to the 1990s prevalence estimates) among older adults [27, 39], with the greatest changes reflecting the increasing rates of ED visits and treatment admissions related to prescription opioids, benzodiazepines, heroin, and cocaine. Knowledge of these trends should assist oncologic providers in identifying and managing problems in a more age-appropriate manner.

Alcohol

There have been relatively few studies examining the prevalence of alcoholism in an oncologic population. The prevalence likely varies widely from one cancer to another with the highest rate in the head and neck cancer population. One study found that greater than 25% of patients admitted to a palliative care unit had problems with alcohol abuse [24]. Socioeconomic barriers such as low income or unemployment, lack of health insurance, and possibly even attempts to self-medicate early symptoms of cancer may preclude patients from seeking care at tertiary care centers. Furthermore, alcohol abuse complicates cancer care. For example, postsurgical withdrawal and delirium tremens (DTs) can be life-threatening. Unfortunately, many patients are unrecognized prior to undergoing surgery. Integrating screening for alcoholism and offering detoxification ahead of surgery are underutilized opportunities, discussed in detail later in this chapter.

Diagnostic and Treatment Issues

Defining Substance Use Disorder and Addiction in the Medically Ill

It is difficult to define substance use disorder (SUD) and addiction in patients with cancer, as the definitions of terms have been adopted from populations that do not necessarily have a medical illness. Furthermore, the pharmacological phenomena of tolerance and withdrawal may be present in SUD but are distinct from it, and it is important that clinicians understand the difference. To complicate the matter further, the use of these terms is inconsistent across settings and is so influenced by sociocultural considerations that it may lead to confusion in the clinical setting. In some settings, the terms "abuse" and "addiction" have been shunned in favor of the less stigmatizing "substance use disorder." (In this chapter, we use these terms somewhat interchangeably.) What these concepts have in common is some degree of the use of illicit drugs or the non-medical use of prescription medications, and at the most severe end of the spectrum there is craving and continued or compulsive use despite harms. Harms may be social, physical, psychological, or vocational in nature. The severity of the SUD depends, in part, on the harms and whether those harms are actual or potential. For example, a patient who continues to smoke following a lung cancer diagnosis likely has a more severe addiction than a smoker without cancer, even though they may smoke the same daily amount. This distinction is clinically relevant because understanding the severity helps determine the needed level of medical response. A thorough review of this topic is beyond the scope of this chapter, but we hope that some clarification of the terminology will help improve the diagnosis and management of substance abuse when treating patients with advanced disease [40, 41].

Physical Dependence: An expected biological adaptation to a drug that results in tolerance and withdrawal. Physical dependence is distinct from SUD or addiction which may involve craving and continued or compulsive use despite harms.

- "Tolerance" occurs when a higher dosage of a drug is required over time to achieve the same effect.
- "Withdrawal" occurs when rapid discontinuation of a medication leads to a sequalae of adverse symptoms.

Because substance use is increasingly widespread in the population at large, patients with cancer who have used illicit drugs are more frequently encountered in medical settings. Illicit drug use, actual or suspected misuse of prescribed medication, or actual SUDs create the most serious difficulties in the clinical setting, complicating the treatment of pain. However, the management of SUD is fundamental to medical therapy adherence and safety during treatment. Also, adverse interactions between illicit drugs and medications prescribed as part of the patient's treatment can be dangerous. The presence of a SUD may alienate or weaken an already tenuous social support network that is crucial for alleviating the chronic stressors associated with advanced disease and its treatment. Therefore, a history of substance use can impede treatment and pain management and increase the risk of hastening morbidity and mortality among those with advanced cancer, which can only be alleviated by a therapeutic approach that addresses drug-taking behavior while expediting the treatment of the malignancy and distressing symptoms, as well as addiction [21, 22].

Important factors when assessing drug-taking behavior in cancer patients:

- Undertreatment of associated issues, particularly pain disorders.
- Sociocultural differences in defining "aberrant" drug taking.

Varied and repeated observations over a period of time may be necessary to categorize questionable behaviors properly (Table 45.1). Perceptive psychiatric assessment is crucial and may require evaluation by consultants who can elucidate the complex interactions among personality factors and psychiatric illness.

Patients with borderline personality disorders, for example, may impulsively use prescription medications that regulate inner tension or improve chronic emptiness or boredom

Table 45.1 Differential diagnoses to consider when interpreting aberrant drug-taking behaviors

Possible alternate diagnoses for aberrant drug-taking behaviors
Anxiety
Depression
Insomnia
Problems of adjustment (such as boredom caused by decreased ability to engage in usual activities)
Borderline personality disorder

Table 45.2 Examples of aberrant drug-taking behaviors and severity

Examples of clearly aberrant behaviors	Examples of potentially aberrant behaviors
Illicit drug use	Requests for early medication refills
Intravenous injection of oral formulations	Requesting specific medications
Recurrent prescription "losses"	Patient taking extra doses of medication

and express anger at physicians, friends, or family. Psychiatric assessment is vitally important for both the population without a prior history of substance abuse and the population of known substance abusers who have a high incidence of psychiatric comorbidity [51].

Pseudoaddiction

Various studies have provided compelling evidence that pain is poorly treated in many oncologic patients [42–44]. Clinical experience indicates that the inadequate management of symptoms and related pain may be the motivation for aberrant drug-taking behaviors.

Pseudoaddiction: distress and aberrant drug-seeking behaviors that produce a similar pattern as individuals with substance use disorders; however, these behaviors actually stem from the patient seeking relief from untreated pain [45]:

- Patients are often attempting to "self-medicate," and behaviors can be considered pseudoaddictive if sufficient pain relief eliminates these behaviors.
- Physical dependence can often lead to pseudoaddictive behaviors, as clinicians do not compensate for growing tolerance to medications and therefore underdose patients.

More recent scientific advances have also provided new insight into behaviors that may be considered pseudoaddiction. Pharmacogenetic variances in the enzymes that metabolize pain medications help to explain individual differences in medication response and side effects experienced. If a patient is an ultrarapid metabolizer, they may complain that the medication is effective for a shorter period of time than is common for that medication. If a patient is a poor metabolizer, they may complain that the medication is not working or possibly continue to ask for increased amount of medication. Pharmacogenetic variations should be considered and pharmacogenetic testing implemented when a patient has an unusual response to a medication, more than expected side effect profile, and/or inefficacy at usual dosages [46].

The potential for pseudoaddiction creates a challenge for the assessment of a patient with both a substance use disorder and an advanced illness. Clinical evidence indicates that aberrant behaviors impelled by unrelieved pain can become so dramatic in this population that some patients appear to return to illicit drug use as a means of self-medication. Others use more covert patterns of behavior, which may also cause concerns regarding the possibility of true addiction.

Aberrant behaviors set in motion by poorly relieved pain can, in vulnerable patients, lead to actual loss of control of their opioids and/or other controlled substances, and so pseudoaddiction and abuse or addiction should not be considered mutually exclusive. Pseudoaddiction might be best thought of as akin to the problem of secondary alcoholism in response, for example, to an untreated panic disorder. If self-medication of panic disorder is persistent for some duration, before long a patient will likely have both problems—panic disorder and alcoholism. People taking liberties with their opioid dosing should be considered for a parallel diagnosis of addiction if attempts to improve analgesia do not lead to a relatively rapid cessation of the problematic behaviors [45]. Although it may not be obvious that drug-related behaviors are aberrant, the meaning of these behaviors may be difficult to discern in the context of unrelieved symptoms [21–23]. This can be a particularly vexing issue when the person with cancer presents in the ED. Is the presentation related to poor pain control or substance abuse, or both?

Aberrant Drug-Taking Behaviors

When a drug is prescribed for a medically diagnosed purpose, less assuredness exists as to the behaviors that could be deemed aberrant, thereby increasing the potential for a diagnosis of drug abuse or addiction. The ability to categorize these questionable behaviors as apart from social or cultural norms is also based on the assumption that certain parameters of normative behavior exist. Although it is useful to consider the degree of aberrancy of a given behavior, it is important to recognize that these behaviors exist along a continuum, with certain behaviors being less aberrant (such as aggressively requesting medication) and other behaviors more aberrant (such as injection of oral formulations) (Table 45.2). If a large portion of patients were found to

engage in a certain behavior, it may be normative, and judgments regarding aberrancy should be influenced accordingly [21–23].

We know more scientifically about aberrant behaviors, their prevalence, and meaning today than we did in the mid-1990s. We know that many patients will have at least a few aberrant behaviors in a 6-month period [47]. We also know that once a patient has demonstrated four behaviors in their lifetime, they have an 85% likelihood of meeting diagnostic criteria for substance use disorder [48]. But there is still much to be learned, confirmed, replicated, and studied.

Disease-Related Variables

Changes caused by progressive diseases, such as cancer, also challenge the principal concepts used to define addiction. Alterations in physical and psychosocial functioning caused by advanced illness and its treatment may be difficult to distinguish from the morbidity associated with drug abuse. In particular, alterations in functioning may complicate the ability to evaluate a concept that is vital to the diagnosis of addiction: "use despite harm." For example, discerning the questionable behaviors can be difficult in a patient who develops social withdrawal or cognitive changes after brain irradiation for metastases. Even if diminished cognition is clearly related to pain medication used in treatment, this effect might only reflect a narrow therapeutic window rather than the patient's use of analgesic to acquire these psychic effects [40, 41, 48]. To accurately assess drug-related behaviors in patients with advanced disease, explicit information is usually required regarding the role of the drug in the patient's life. Therefore, the presence of mild mental clouding or the time spent out of bed may have less meaning than other outcomes, such as noncompliance with primary therapy related to drug use or behaviors that threaten relationships with physicians, other healthcare professionals, and family members [40, 41, 49].

Risks in Patients with Current or Remote Histories of Drug Abuse

There is a lack of information regarding the risk of abuse or addiction during or subsequent to the therapeutic administration of potentially abusable drugs to medically ill patients with a current or remote history of abuse or addiction [40, 41]. The possibility of successful long-term opioid therapy in patients with cancer or chronic nonmalignant pain has been indicated by anecdotal reports, particularly if the abuse or addiction is remote [52–54].

Because it is commonly accepted that the likelihood of aberrant drug-related behavior occurring during treatment for medical illness will be greater for those with a remote or current history of substance abuse, it is reasonable to consider the possibility of abuse behaviors occurring when using different therapies. For example, although no clinical evidence exists to support the notion that the use of short-acting drugs or the parenteral route is more likely to cause questionable drug-related behaviors than other therapeutic strategies, it may be prudent to avoid such therapies in patients with histories of drug abuse [40, 41].

Clinical Management of Substance use Disorders in Oncologic

The greatest challenges in caring for patients with SUDs and cancer typically arise when these patients are actively abusing alcohol or other drugs. This is in part because they experience more difficulty in managing pain [55]. Patients may become caught in a cycle where pain functions as a barrier to seeking treatment for addiction possibly complicating treatment for chronic pain [56]. Also, because pain is undertreated, the risk of bingeing with prescription medications and/or other substances increases for drug-abusing patients [55]. The implementation of a more comprehensive treatment plan for such patients may indeed only be initiated after ED visit(s) bring the need for such a labor-intensive program to light.

General Recommendations

The following guidelines can be beneficial, whether the patient is actively abusing drugs or has a history of substance abuse. The principles outlined assist clinicians in establishing structure, control, and monitoring of addiction-related behaviors, which may be helpful and necessary at times in all pain treatment [21].

Recommendations for the long-term administration of potentially abusable drugs, such as opioids, to patients with a history of substance abuse are based exclusively on clinical experience. Research is needed to ascertain the most effective strategies and to empirically identify patient subgroups which may be most responsive to different approaches. The following guidelines broadly reflect the types of interventions that might be considered in this clinical context [37, 49, 57].

Multidisciplinary Approach

Pain and symptom management is often complicated by various medical, psychosocial, and administrative issues in the population of advanced patients with a substance use disorder. The most effective team may include a physician with expertise in pain/palliative care, nurses, social workers, and, when possible, a mental healthcare provider with expertise in the area of addiction medicine [21, 22].

Assessment of Substance Use History

In an effort to not offend, threaten, or anger patients, clinicians frequently avoid asking patients about drug abuse. There is also often the expectation that patients will not answer truthfully. However, obtaining a detailed history of duration, frequency, and desired effect of drug use is vital. Adopting a nonjudgmental position and communicating in an empathetic and truthful manner is the best strategy when taking patients' substance abuse histories [21–23]. Avoid stigmatizing terms such as "abuse." Do not rush through a substance use assessment: It helps to make eye contact and show the patient that you really care about their answers. Patients can be quite candid about their drug and alcohol use, though even then it is not unusual for them to underreport or minimize their problems.

In anticipating defensiveness on part of the patient, it can be helpful for clinicians to mention that patients often misrepresent their drug use for logical reasons, such as stigmatization, mistrust of the interviewer, or concerns regarding fears of undertreatment. It is also wise for clinicians to explain that in an effort to keep the patient as comfortable as possible, by preventing withdrawal states and prescribing sufficient medication for pain and symptom control, an accurate account of drug use is necessary [21–23].

Taking an accurate, detailed history from the patient is essential for the proper assessment and treatment of alcohol and drug abuse as well as any comorbid psychiatric disorders. It is also important to ask about the duration, frequency, and desired effect of drug or alcohol consumption. In the wake of current pressures to treat the majority of patients in ambulatory settings and to admit patients on the morning of major surgery, the quick identification of alcoholism and initiation of plans for social, medical, and physiological needs of the patient must begin upon initial contact.

The use of a careful, graduated-style interview can be beneficial in slowly introducing the assessment of drug abuse. This approach begins with broad and general inquiries regarding the role of drugs in the patient's life, such as caffeine and nicotine, and gradually proceeds to more specific questions regarding illicit drugs. This interview style can also assist in discerning any coexisting psychiatric disorders, which can significantly contribute to aberrant drug-taking behavior. Once identified, treatment of comorbid psychiatric disorders can greatly enhance management strategies and decrease the risk of relapse [21–23].

Use of Risk Assessment Tools

As stated above, potential opioid use must be accompanied by risk stratification and management. Given time constraints, a full psychiatric interview may not be feasible, and thus time-sensitive measures are clearly needed to help in this endeavor. Many screening tools contain items on personal and family history of addiction as well as other history-related risk factors, such as preadolescent sexual abuse, age, and psychological disease. These are tools for clinical decision-making and should not be viewed as necessarily diagnostically accurate [58, 59]. Whatever tool the clinician chooses, it is advised that the screening process be presented to the patient with the assurance that no answers will negatively influence effective treatment. One risk factor unique to the oncologic setting is the economic pressure that accompanies the disease and its treatment. The depletion of savings over time can be a huge stress, and for some the temptation to divert medications with a street value may be seen as a matter of survival.

Setting Realistic Goals for Therapy

The rate of recurrence for drug abuse and addiction is high in general. The stress associated with cancer and the easy availability of centrally acting drugs increase this risk. Therefore, total prevention of relapse may be impossible in this type of setting. Gaining an understanding that compliance and abstinence are not realistic goals may decrease conflicts with staff members in terms of management goals. Instead, the goals might be perceived as the creation of a structure for therapy that includes ample social/emotional support and limit setting to control the harm done by relapse [21–23].

There may be some subgroups of patients who are unable to comply with the requirements of therapy because of severe substance use disorders and comorbid psychiatric diagnoses. In these instances, clinicians must modify limits on various occasions and endeavor to develop a greater variety and intensity of supports. This may necessitate frequent team meetings and consultations with other clinicians; however, pertinent expectations must be clarified, and therapy that is not successful should be modified [21–23].

Evaluation and Treatment of Comorbid Psychiatric Disorders

Extremely high comorbidities of personality disorders, depression, and anxiety disorders exist in alcoholics and other patients with substance abuse histories [51]. Individuals with a history of alcohol abuse have been found to be at higher risk for other psychiatric disorders [60]. The most common comorbid mental disorders associated with alcoholism are anxiety disorders (19.4%), antisocial personality disorder (14.3%), affective disorder (13.4%), and schizophrenia (3.8%) [61]. The occurrence of comorbid mental disorders in alcoholics may contribute to poor treatment compliance and success due to cognitive limitations and premorbid (in relation to the diagnosis of cancer) pain and neurological deficits. The same is true of opioid abuse where 85% of addicts have a comorbid, nondrug abuse-related psychological disorder [51]. Thus, the ED professional assessing the cancer patient with addiction or alcoholism must anticipate and identify for treatment or referral any comorbid disorders present. The treatment of depression and anxiety can increase patient comfort and decrease the risk of relapse or aberrant drug taking [21–23].

Preventing and Minimizing Withdrawal Symptoms

Assessing and treating withdrawal can help mitigate the immediate harms, as well as preventing substance use relapse. Identifying withdrawal, as with uncovering substance misuse, is an opportunity to initiate a useful discussion with the patient. Because patients with drug abuse histories often use multiple drugs, it is necessary to conduct a complete drug-use history to prepare for the possibility of withdrawal. A thorough discussion of this topic is beyond the scope of this chapter, but we will briefly discuss opioid and alcohol withdrawal, as they can be particularly consequential and likely to be encountered in the ED. Opioid withdrawal can be extremely unpleasant but rarely results in death. However, for a patient on long-term opioid therapy for pain, withdrawal can precipitate a severe exacerbation of pain, and in an individual with an opioid use disorder (OUD), withdrawal also increases the risk of a relapse, which can sometimes be fatal [62]. Perhaps more commonly, withdrawal (and indeed sometimes the ED visit itself) can indicate that the patient may have increased their use of prescription opioids, running out early. In this case, an important question is whether there has been an exacerbation of pain secondary to a change in the disease progression. Accurately assessing withdrawal can be challenging, as the symptoms associated with different types of withdrawal can overlap. To aid in assessing withdrawal, it is helpful to utilize the substance use history, conducted in a nonjudgmental manner so as not to evoke shame and silence. Simply noticing some possible symptoms of withdrawal and inquiring with the patient can sometimes open up useful discussions. When a patient is unwilling or unable to provide this information, the clinician may rely more on the presenting symptoms, information obtained from family or friends, results of toxicology reports, and review of prescription drug monitoring programs. Some symptoms of opioid withdrawal include pain, anxiety/restlessness, insomnia, excessive sweating, dilated pupils, diarrhea/abdominal pain, flu-like symptoms, goose bumps, tremor, and yawning [63].

Alcohol Withdrawal Syndrome

Alcohol withdrawal is dangerous and can seriously complicate cancer treatment. In some instances, it is fatal. The first symptoms of withdrawal typically appear in the first few hours following the cessation of alcohol consumption and may consist of tremors, agitation, and insomnia. In cases of mild to moderate withdrawal, these symptoms tend to dissipate within 1–2 days without recurrence. However, in cases of severe withdrawal, autonomic hyperactivity, hallucinations, and disorientation may follow. The onset of delirium tremens marks the individual's progression from the withdrawal state to a state of delirium that represents a serious medical emergency.

Delirium tremens (*DTs*): characterized by agitation, hallucination, delusions, incoherence, and disorientation, typically within the first 72–96 h of withdrawal

- Occurs in approximately 5–15% of patients with alcohol withdrawal [64].
- Is self-limiting and often ends with the patient entering a deep sleep with amnesia for most of the episode.
- DTs can increase the risk of further complications in medically ill patients.

Wernicke-Korsakoff syndrome: indicative of thiamine deficiency that causes permanent cognitive impairment

- Frequently underdiagnosed.
- Symptoms.
  - Fixed upward gaze.
  - Alcoholic neuropathy.
  - "Stocking-glove" paresthesia
  - Autonomic instability.
- Delirium encephalopathy.

Medical Treatment of Alcohol Withdrawal

While a full discussion of the pharmacological approach to alcohol withdrawal is beyond the scope of this chapter, a

basic approach to its treatment is given. The use of hydration, benzodiazepines, and, in some cases, neuroleptics is appropriate for the management of alcohol withdrawal syndrome (Table 45.3). The administration of a vitamin-mineral solution is indicated to counteract the effects of malnutrition that results from the alcohol itself and poor eating habits. Thiamine 100 mg administered intramuscularly or intravenously for 3 days before switching to oral administration for the duration of treatment will prevent the development of Korsakoff syndrome and alcoholic dementia. A daily oral dose of folate 1 mg should also be given throughout the course of treatment. In cases of mild withdrawal, hydration alone may be sufficient. Benzodiazepines (lorazepam, midazolam, diazepam, and chlordiazepoxide) are the drugs of choice for the management of alcohol withdrawal because of their sedative effects (Table 45.4) [65, 66]. Careful consideration must be given to route, absorption, potency, and dose of benzodiazepine prescribed. Dose should be based upon estimated alcohol consumption and the type of detoxification setting (see below). Insufficient administration of benzodiazepines (too low dose or too rapid taper) may allow the progression of withdrawal to a state of delirium tremens. The development of seizures is life-threatening, and they may repeatedly recur in the patient while unconscious. The nonbenzodiazepine anticonvulsants are not prescribed prophylactically. In cases of severe withdrawal and confusion, neuroleptics (i.e., haloperidol 0.5–5.0 mg IV every 8 h) are added to the treatment regimen. Commonly, alcoholic patients report to the hospital either intoxicated or in the early stages of withdrawal. From a surgical perspective, serious complications can arise from the presence of alcohol withdrawal, and its acute management is the primary treatment goal. Unfortunately, clinicians are frequently provided insufficient lead time to properly detoxify the patient prior to surgery (typically less than 24 h), and the patient is at an increased risk for the postoperative development of organic mental disorders, seizure, and delirium tremens. Since alcoholic cancer patients are already at high risk for delirium postoperatively due to poor nutrition, prior head trauma, and brain injury from excessive alcohol consumption, the development of seizures and delirium tremens adds to the risk of fatality. It is important to note that since it is desirable for the patient to be alert postoperatively for ambulation and use of pulmonary toilet, the amount of sedation required for detoxification is much lower than the desired level of sedation in a nonsurgical alcoholic patient.

Table 45.3 Guidelines for the treatment of alcohol withdrawal

Continual close monitoring of withdrawal status
Utilization of benzodiazepines
Taper dose slowly (generally not by more than 25% per 24-h period)
Administration of thiamine 100 mg IM or IV qid
Administration of folate 1 mg po qid
Monitor for signs of the potential onset of delirium tremens
Consideration should be given to a loading dose of phenytoin for patients with a history of withdrawal seizures or for patients in whom seizures are likely (i.e., patients with brain metastases)

Table 45.4 Types and characteristics of benzodiazepines for treatment of alcohol withdrawal

Drug	Dose	Duration of action	Half-life (h)
Chlordiazepoxide	25–100 mg every 3 h IV	Short	5–30
Diazepam	10–20 mg every 1–4 h IV	Short	20–100
Lorazepam	1–2 mg every 1–4 h IV	Intermediate	10–20
Midazolam	1–5 mg every 1–2 h IV	Very short	1–4

Considering the Therapeutic Impact of Tolerance

Patients who are active substance abusers may be tolerant to drugs administered for therapy, making pain management more difficult. The magnitude of this tolerance is never known. Therefore, it is best to begin with a conservative dose of therapeutic drug and then rapidly titrate the dose, with frequent reassessments, until the patient is comfortable [40, 41, 54]. Cancer patients and those with progressive disease can be treated with gradually increasing doses, and opioids can still be titrated to effect or toxicity with no arbitrary number of milligrams constituting a limit. Tolerance to a variety of opioid effects can be reliably observed in animal models [67], and tolerance to non-analgesic effects, such as respiratory depression and cognitive impairment [68], occurs regularly in the clinical setting. However, analgesic tolerance does not appear to routinely interfere with the clinical efficacy of opioid drugs.

Psychopharmacology Approaches

Disulfiram (Antabuse) is a pharmacological agent that has been approved by the Food and Drug Administration (FDA) since 1951 for the treatment of alcoholism. Antabuse serves as a deterrent by inducing an unpleasant physical state characterized by nausea or vomiting when alcohol is consumed, thus ideally leading to alcohol cessation [69]. The practicality and effectiveness of Antabuse is questionable however, since its use has been limited by difficulties with patient adherence for continued use of the drug [70].

There have been a number of studies shedding light on subgroups of patients who have been shown to benefit the most from treatment with Antabuse. The findings have shown that patients with the following characteristics generally

experience the most long-term benefits from Antabuse: (1) older than 40 years of age, (2) longer drinking histories, (3) socially stable, (4) highly motivated, (5) prior attendance of Alcoholics Anonymous, (6) cognitively intact, and (7) able to maintain and tolerate dependent or treatment relationships [71–73]. Further research is needed to ascertain what factors and patient characteristics will increase the likelihood of successful treatment. A greater understanding has the potential to significantly enhance clinicians' ability to select those patients who will experience optimal effectiveness.

Methadone Maintenance

Methadone maintenance therapy (MMT) is superior to illegal heroin use, in part, because the extreme highs and lows felt by heroin users (related to the waxing and waning of serum heroin levels) are avoided by the long-acting properties of methadone. The term "agonist blockade" was coined to describe the phenomenon of significantly limited or blunted effects after administration of "usual" doses of mu-opioid agonists to subjects on high-dose methadone (e.g., 80–120 mg/day).

In humans, all opioids suppress the hypothalamic-pituitary-adrenal (HPA) axis when given acutely, and this effect persists during chronic, intermittent exposure to short-acting opioids during chronic cycles of heroin addiction [74].

The endogenous mu-opioid receptor-mediated opioid system in humans appears to constitutively provide tonic inhibition of the HPA axis [74, 75]. Thus, administration of mu-opioid receptor antagonists to healthy human volunteers leads to activation of the HPA axis [75–79]. Similarly, the HPA axis is activated in opioid withdrawal (for which clonidine may be helpful [62]), or with administration of mu-opioid receptor antagonists to opioid-dependent individuals, or during acute cocaine or alcohol consumption [75, 78].

Kreek and colleagues [80] proposed that suppression of the HPA axis through administration of intermittent or binge-type short-acting opioids (e.g., heroin) and then with repeated alternating short cycling of suppression (e.g., with heroin administration), followed by activation (e.g., with heroin withdrawal [i.e., just before next dose]), may lead to and/or exacerbate atypical responsivity to stress/stressors, as well as addictive-type behavior (with resultant self-administration/relapse). Adequate methadone maintenance treatment permits normalization of the HPA axis—including response to a chemically induced stress of metyrapone challenge [81, 82]. In an optimal situation, stabilized methadone-maintained former heroin addicts treated in high-quality methadone maintenance treatment programs (e.g., associated with psychosocial interventions) with effective methadone doses experience the following: markedly reduced drug craving; reduced or eliminated heroin use; improved or normalized stress-responsive hypothalamic-pituitary-adrenal axis; and reproductive, gastrointestinal, and immunologic functions with relatively normal responses to acute pain [83, 84].

Buprenorphine and Naltrexone

Two other therapies used in the medication-assisted treatment (MAT) of those with opioid addiction and alcoholism are not without their complexities if they are to be used in people with cancer.

Buprenorphine is a partial opioid agonist that has significantly advanced MAT for opioid addiction on an international level. Available as a pill, sublingual film (with and without naltrexone), and as an implant for addiction treatment, its use in people with cancer can complicate the treatment of pain in the setting of disease progression and require dose escalation that could "bump up against" the drug's ceiling effect or in the treatment of acute pain requiring the use of a pure mu-agonist. However, there are also reports of the successful use of oral and transdermal buprenorphine for chronic and breakthrough cancer pain in nonaddicts [85]. If a person with cancer also has a history of opioid addiction and is to be managed with continuation of their buprenorphine treatment, consultation should be sought from an addiction medicine expert (who also has the appropriate certification to prescribe it where necessary). Options for managing pain exacerbations may include increasing the total daily dose and dividing the buprenorphine dose into 6- to 8-hour intervals, adding and titrating a short-acting and potent mu-agonist such as fentanyl, or discontinuing and switching buprenorphine to a full mu-opioid agonist. Emerging evidence supports that patients with opioid use disorders continue with buprenorphine treatment while the acute pain is being managed [86].

The oral opioid antagonist naltrexone is used to treat alcohol cravings and opioid addiction and is also available as a monthly depot injection for addiction treatment. While ultralow-dose naltrexone has been used to augment opioids for cancer-related pain and for the treatment of side effects such as constipation, little has been written about the use of this therapy for addiction treatment in people with cancer. While one can imagine antagonist therapy having a role in, for example, people surviving cancer who struggle with addiction (and in whom pain severe enough to require opioids is not part of the clinical picture) and in those with pain and with active disease, its role is limited. There is a paucity of data and direct clinical experience on which specific recommendations might be made. These medications can cause difficulties for the ED professionals as they might, for instance, need to intervene for acute pain in the ED setting,

the management of which is complex in persons on antagonist therapy.

Selecting Appropriate Drugs and Route of Administration for the Symptom and Setting

The use of long-acting analgesics in sufficient amounts may help to minimize the number of rescue doses needed, lessen cravings, and decrease the risk of abuse of prescribed medications, given the possible difficulty of using short-acting formulations in patients with substance abuse histories. Rather than being overly concerned regarding the choice of drug or route of administration, the prescription of opioids and other potentially abusable drugs should be carried out with limits and guidelines [21–23].

Many clinicians now respond to particularly high-opioid-dose requirements with rotation to another opioid. This practice capitalizes on incomplete cross-tolerance, or the unique pharmacology of methadone in particular, to bring doses down while maintaining or improving efficacy and changing the balance of efficacy to toxicity [87, 88]. Some clinicians set arbitrary dose limits for the various opioids. Others stop using certain opioids they perceive as of higher risk or street value. Still others became so disillusioned as to stop using opioids altogether.

Recognizing Specific Drug Abuse Behaviors

In an effort to monitor the development of aberrant drug-taking behaviors, all patients who are prescribed potentially abusable drugs must be evaluated over time. This is particularly true for those patients with a remote or current history of drug abuse, including alcohol abuse. Should a high level of concern exist regarding such behaviors, frequent visits and regular assessments of significant others who can contribute information regarding the patient's drug use may be required. To promote early recognition of aberrant drug-related behaviors, it may also be necessary to have patients with histories of recent active abuse to submit urine specimens for regular screening of illicit, or licit but non-prescribed, drugs. When informing the patient of this approach, explain that it is a method of monitoring that helps the clinician keep the patient safe and provides a foundation for aggressive symptom-oriented treatment, thus enhancing the therapeutic alliance with the patient [21–23].

Using Nondrug Approaches as Appropriate

The most effective psychotherapeutic treatment approach with medically ill people appears to be one that focuses on the development of effective coping skills, relapse prevention, and, most importantly, treatment compliance. Alcohol or the specific substance being abused represents one of the dependent patient's primary, albeit maladaptive, coping tools. As a result, the improvement of coping skills in these individuals is critical. When compounded with the stress associated with cancer, substance abuse cessation can be overwhelming and contribute to noncompliance and discontinuation of treatment. Teaching specific, illness-related coping methods with an emphasis upon containing episodes of consumption is essential. Further, the recognition and treatment of anxiety and depression may decrease the patients' need and desire for alcohol or substances. As an alternative to the abstinence approach, a harm reduction with crisis intervention as a central component should be utilized. The fundamental aims of this approach are enhancement of social support, maximization of treatment compliance, and containing harm associated with episodic relapses. Further, minimizing the frequency and intensity of the patients' use and consumption is the broad goal of treatment. Therefore, further damage to the patient will be reduced as well as the facilitation of treatment compliance.

Other psychotherapeutic approaches beneficial for this population are support groups and 12-step programs. The problem lies in that traditional 12-step groups are based on an abstinence-only policy. This poses a problem for patients who are being treated with opioids for pain-related syndromes. More recently, support groups have been tailored for this specific population.

Many nondrug approaches exist to assist patients in coping with chronic pain in advanced illness. Such educational interventions may include relaxation techniques, ways of thinking of and describing the experience of pain, and methods of communicating physical and emotional distress to staff members. Although nondrug interventions are adjuvants to management, they should not be perceived as substitutes for drugs targeting pain or other physical or psychological symptoms [21–23].

Developing the Treatment Plan

Inpatient Management Plan

In designing the inpatient management of an actively abusing patient with advanced illness, it is helpful to use structured treatment guidelines. Although the applicability of these guidelines may vary from setting to setting, they provide a set of strategies that can ensure the safety of the patient and staff, control possible manipulative behaviors, allow for supervision of illicit drug use, enhance appropriate use of medications for pain and symptom control, and communicate an understanding of pain and substance abuse management [21–23].

Under certain circumstances, such as actively abusing patients who are scheduled for surgery, patients should be admitted several days in advance, when possible, to allow for stabilization of the drug regimen. This time can also be used to avoid withdrawal and to provide an opportunity to assess whether modifications of an established plan are necessary [21, 22].

Once established, the structured treatment plan for the management of active abuse must proceed conscientiously. In an effort to assess and manage symptoms, frequent visits are usually necessary. It is also important to avoid drug withdrawal, and, to the extent possible, prescribed drugs for symptom control should be administered on a regularly scheduled basis. This helps to eliminate repetitive encounters with staff that center on the desire to obtain drugs [21–23].

Treatment management plans must be designed to represent the clinician's assessment of the severity of drug abuse. Open and honest communication between clinician and patient to stress that the guidelines were established in the best interest of the patient is often helpful. However, in cases where patients are unable to follow these guidelines despite repeated interventions from the staff, discharge should be considered. Clinicians should discuss this decision for patient discharge with the staff and administration while considering the ethical and legal ramifications of this action [21–23].

Outpatient Management Plan

Alternative guidelines may be used in the management of the actively abusing patient with advanced illness who is being treated on an outpatient basis. In some instances, the treatment plan can be coordinated with referral to a drug rehabilitation program. However, patients who are facing end-of-life issues may have difficulty participating in such programs. Using the following approaches may be helpful for managing the complex and more difficult-to-control aspects of care.

Case Study

*A 36-year-old white male with stage IV lung cancer (Pancoast tumor) that was locally advanced and widely metastatic presented late after a 35-lb weight loss. His sister had died of the same disease at age 35, and he had a history of significant substance abuse and drug dealing. The patient complained of out-of-control pain and lack of willingness of any local providers to prescribe pain medication. The patient was inflexible about acceptance of any other treatments (*i.e., *nerve block, epidural) other than OxyContin™. The patient's pain was 10/10 from brachial plexopathy with mixed neuropathic/somatic/visceral components.*

Patient was titrated to effect over time. The maximum dose reached 800 mg bid at the time of death with 100 mg liquid MS04 q1h rescues. Although the patient was dying, structured management was required because of his history. The structured management plan was as follows: hospice nurses delivered one-day supply, unscheduled visits for pill counts, urine screens, and a reliable family member was identified to lock up pain medication supply.

The patient settled down and with renewed trust was willing to add nortriptyline, which helped with neuropathic pain, as well as steroids for nausea, cachexia, and fatigue.

Recommendations for Prescribing

Patients who are actively abusing must be seen weekly to build a good rapport with staff and afford evaluation of symptom control and addiction-related concerns. Frequent visits allow the opportunity to prescribe small quantities of drugs, which may decrease the temptation to divert and provide a motive for not missing appointments [21–23].

Procedures for prescription loss or replacement should be explicitly explained to the patient, with the stipulation that no renewals will be given if appointments are missed. The patient should also be informed that any dose changes require prior communication with the clinician. Additionally, clinicians who are covering for the primary care provider must be advised of the guidelines that have been established for each patient with a substance abuse history to avoid conflict and disruption of the treatment plan [21–23].

Twelve-Step Programs

Depending on the patient's stage of advanced illness and functional status, the clinician may consider referring the patient to a 12-step program with the stipulation that attendance be documented for ongoing prescription purposes. If the patient has one, the clinician may contact the patient's sponsor, depending on the stage of illness and individual capabilities, in an effort to disclose the patient's illness, and that medication is required in the treatment of the illness. This contact will also help decrease the risk of stigmatizing the patient as being noncompliant with the ideals of the 12-step program [21–23]. If the patient is unable to participate in a 12-step program, other psychosocial and/or spiritual team members can provide care that supports sobriety.

Urine Drug Testing and Prescription Drug Monitoring Programs

One of the most commonly utilized risk management tools in chronic non-cancer pain management and adherence monitoring/sobriety in addiction treatment is urine drug testing (UDT). Depending on the method employed, UDT can be used to gauge whether the patient is adherent to their prescribed medication, whether or not they are also taking non-prescribed licit medications, and/or whether they are using illicit drugs and alcohol [89]. Indeed, one study in which primary care doctors were taught to employ a "menu" of risk management techniques (including UDT) and then studied over time to examine their use of them found that UDT was the most commonly retained practice element on 6-month follow-up [90].

UDT is underutilized in the management of cancer-related pain with opioids [91]. Perhaps oncologic ED professionals, due to their lack of familiarity with the evolution in methods and mind-set that had occurred in the laboratory and clinic in the last decade, think of UDT in only its forensic incarnation. In that view, UDT is a means out of finding if "bad people" are "doing bad things," as seen in a prior chart review study [92]. Thus, because of this stigma, they are fearful that introducing UDT to their patients and integrating it into patient management will be offensive, and they may lack an approach for discussing it in a non-shaming manner with their patients. However, recent research in addiction treatment suggests that UDT can be utilized with patients in a non-stigmatizing manner when clinicians take the perspective that patients with substance abuse problems deserve help, and UDT is seen as a supportive tool for the patient's benefit [93]. The forensic method, from which more modern clinical testing sprung, tends to rely on immunoassay (IA) testing which offers fast but only class-level (not drug-specific) results with high cutoffs. It is meant to detect recent use of classes of drugs that would impair, for example, a truck driver from driving. Cutoffs are high because of the legal and other consequences that could follow and to avoid falsely accusing people. In recent years, gas chromatography and liquid chromatography with mass spectrometry are capable of giving highly accurate drug-specific results and return them in a timely fashion (1–2 days as opposed to 10 days–2 weeks). Such results can be used to determine whether a patient is misusing a range of drugs or alcohol and gauge their adherence with specific medication and controlled substance regimens. More data is needed in this area [91], but the use of UDT for those with pain and/or substance use disorder is well documented [94–98].

Oncologic personnel in the ED should routinely access prescription drug monitoring program (PDMP) prior to prescribing a scheduled medication. Checking PDMPs can identify patients who may be receiving overlapping prescriptions, obtaining prescriptions from multiple prescribers, or misusing their scheduled medications [99]. A point that is often overlooked is that patients in oncologic settings can benefit from the clinician's use of PDMPs as much as in any chronic pain setting. Patients being treated for cancer are more likely than with some other chronic pain conditions to have multiple prescribers. Coordinating care can be a challenge, and patients are at risk for being overmedicated. Although not intended for patients with cancer, clinicians should be aware of the Center for Disease Control and Prevention guidelines [100], which recommend checking the PDMP prior to initiating a scheduled medication and at least every 3 months thereafter.

Family Sessions and Meetings

The clinician, in an effort to increase support and function, should involve family members and friends in the treatment plan. These meetings allow the clinician and other team members to become familiar with the family and additionally help the team identify family members who are using illicit drugs. Offering referral of these identified family members to drug treatment can be portrayed as a method of gathering support for the patient. The patient should also be prepared to cope with family members or friends who may attempt to buy or sell the patient's medications. These meetings will also assist the team in identifying dependable individuals who can serve as a source of strength and support for the patient during treatment [21–23]. These published guidelines generally advocate an approach to UDT based on risk stratification (i.e., frequency of testing and choice of methods are aimed at matching the approach to the level of risk of abuse, addiction, and diversion in an individualized way to each patient). Such an approach seeks to maximize the benefit of testing while also managing cost. As oncologic professionals learn to integrate UDT into treatment of the person with cancer and addiction or the management of chronic opioid therapy, there is no reason to think that the adaptation of a similar approach might not be a reasonable way to proceed.

Conclusion

Treating oncologic patients with chronic pain and substance use disorders is both complicated and challenging, as each can significantly complicate the other. Whether our patients respond to cancer treatments or have life-limiting disease, we can no longer justify high-dose opioid therapy in a vacuum without trying to assess and manage addiction and abuse behaviors. Using a treatment plan that involves a team

approach to recognize and respond to these complex needs is the optimum treatment strategy. While pain management may remain challenging even when all treatment plan procedures are implemented, the healthcare team's goal should be providing the highest level of pain management for all patients with substance use disorders.

Introduction

Oncologic emergencies encompass a wide spectrum of pathology and can affect any organ system. These can be divided into metabolic, hematologic, and structural emergencies [1]. Metabolic and hematologic conditions are frequently diagnosed based on clinical and laboratory findings, often with only incidental imaging support. Structural emergencies are those arising from mass effect, tissue infiltration, tumor hemorrhage, vascular invasion with resulting occlusion or hemorrhage, and organ drainage pathway obstruction. Diagnostic imaging can also provide a "road map" for subsequent image-guided interventional and noninvasive therapies.

Imaging Modalities

There is a wide array of diagnostic imaging options available for evaluating oncologic emergencies. Selecting the appropriate imaging modality requires consideration of availability, speed, patient-specific factors, and anticipated diagnostic yield.

Plain Radiography Rapid, universally available, low-cost screening modality. Core utility is for osseous and pulmonary evaluation and to screen for intestinal obstruction and pneumoperitoneum. Particularly useful in trauma to the appendicular skeleton. Less sensitive in the diagnosis of axial and spinal trauma, although still used as a screening tool.

Computed Tomography (CT) Rapid and highly available. Mainstay in the emergent evaluation of the head, neck, chest, abdomen, and pelvis. Modern multidetector CT technology allows for thin X-ray beam collimation to 0.625 mm, allowing for isotropic image acquisition and post-processing capabilities, including orthogonal and curved planar reformations, as well as 3D surface rendering [2].

The diagnostic value of CT derives from its ability to discriminate tissues based on physical density, measured in Hounsfield units (HU) and displayed in gray scale on a picturing and archiving communication system (PACS) workstation. By convention, water has a density of 0 HU and appears intermediate in gray scale. Air has a density of approximately −1000 HU and appears relatively dark (hypodense or hypoattenuating). Bone and calcium have densities in the range of +1000 HU and appear relatively bright (hyperdense or hyperattenuating). Intravascular or unclotted extravascular blood, for example, has a density of around 30–45 HU but increases in attenuation to 45–70 HU as clot develops [3]. Administration of iodine-based nonionic intravenous (IV) contrast increases soft tissue and vascular conspicuity, further improving diagnostic yield. Most malignancies display predictable enhancement characteristics, and the use of IV contrast often permits accurate diagnosis. In oncologic emergencies, routine use of IV contrast is suggested for the neck, chest, abdomen, and pelvis, primarily for soft tissue evaluation. However, ED personnel evaluating female patients with pelvic pain should refrain from ordering an abdominal or pelvic CT scan without first consulting the gynecologic oncologic team, as such scans are often of low yield [4]. For the evaluation of osseous pathology, IV contrast is not usually necessary. Most intracranial emergencies are imaged with head CT without IV contrast, as opacified intracranial vessels may obscure extra-axial hemorrhage. Optimizing arterial or venous enhancement by adjusting the timing of image acquisition allows for an assessment of vascular abnormalities, such as dural venous sinus or cortical vein thrombosis (on CT venogram) or vasospasm (on CT angiogram). Recent advances in CT technology have led to increased utilization of dual-energy CT in clinical practice. Dual-energy CT assesses attenuation at two

different energy levels, usually at low energy (80–100 kVp) and high energy (140–150 kVp). Based on atomic interactions between imaged tissue and X-rays at low and high energy levels, it is often possible to determine the type of material in each voxel, improving tissue contrast beyond conventional single-energy CT [5]. This approach may help to distinguish between traumatic and pathologic bone fractures [6].

Magnetic Resonance Imaging (MRI) May not be accessible after-hours at many centers. MRI requires a greater degree of patient stability and compliance than does CT and entails longer imaging times. Due to the powerful magnet used in MRI, ferromagnetic metal-containing objects inside the body can pose significant risk to the patient, as they may heat up or migrate during the exam. As a result, the presence of ferromagnetic metal-containing devices within the patient is an absolute contraindication for MRI. In addition, implanted cardiac devices may malfunction in a strong magnet and are often contraindicated for MRI. The core utility for MRI in the emergent setting is for intracranial (e.g., acute stroke, tumor burden, dural venous sinus thrombosis) and spine (e.g., cord compression, cord edema, epidural tumor, and osseous involvement) evaluation. Gadolinium-based IV contrast aids in quantifying the extent of malignant disease and can potentially characterize soft tissue tumors. As with CT, IV contrast is typically not essential for osseous evaluation but may be helpful in characterizing bone invasion of a soft tissue tumor. Commonly performed MR imaging sequences for the brain include T1-weighted (T1), T2-weighted (T2), fluid-attenuated inversion recovery (FLAIR), diffusion-weighted imaging (DWI), and gradient echo (GRE). For spinal imaging, typical sequences are acquired in the sagittal plane and include T1, T2, and either T2 fat-saturated or short-tau inversion recovery (STIR) images, as well as GRE and postcontrast sequences. Axial image sequences for the spine are institution-dependent but typically include T1 and T2 images. If IV contrast is administered, postcontrast T1 images are obtained using fat-saturation techniques. Signal from fat is bright (hyperintense) on MRI. When background fat signal is suppressed, it appears dark (hypointense), increasing the conspicuity of contrast-enhanced malignant tissue. MRI imaging of the long bones often employs proton density (PD) sequences as an alternative to fat-saturated T2 images. Signal from blood is hypointense on GRE and demonstrates variable signal on T1 and T2 images depending on time course. As with CT angiography (CTA) or venography (CTV), MR angiography (MRA) and venography (MRV) can be used to assess for vascular pathology, although IV contrast is not always necessary.

Ultrasonography (US) Rapid, universally available, mobile, and accessible for clinician bedside usage. This soundwave-based modality is limited by image degradation that occurs at tissue interfaces with bone or air. Doppler US is ideally suited for the assessment of blood vessels and soft tissue vascularity and highly useful in procedural guidance owing to its portability and absence of radiation. US is a good tool for extremity soft tissue disease, ascites, pleural effusions, vessel patency, and biliary pathology. Some drawbacks of ultrasound include susceptibility to artifacts and dependence on operator technique and patient cooperation. (A separate chapter on emergency ultrasound follows.)

Nuclear Medicine In the emergent setting, ventilation-perfusion (V/Q) imaging may be used to evaluate for pulmonary embolism. V/Q studies are reserved for patients with contraindications to CT pulmonary angiogram (CTPA), such as a history of significant adverse reaction to iodinated IV contrast agents or renal insufficiency. A tagged red blood cell scan (erythrocytes labeled with technetium-99^{m}) may be used to localize the general area of gastrointestinal bleeding to guide subsequent treatment. Positron emission tomography (PET) has minimal value in the emergent oncologic patient due to increased patient preparation requirements, lengthy acquisition time, and limited availability. Other nuclear medicine exams have established utility in imaging oncologic patients (e.g., whole-body bone scintigraphy); however, these are infrequently used in the emergent setting.

Fluoroscopy Useful for esophagrams and to provide procedural guidance for lumbar puncture, myelogram injection, joint aspiration, and tube/drain placement.

Interventional Radiology Interventional procedures can provide further diagnostic information, as well as guide therapies in the acute setting, most commonly with the use of conventional catheter angiography, embolization for acute hemorrhage, and tube or drain placement for relieving obstruction or abscess drainage.

Radiologic Evaluation of Oncologic Emergencies

The following is a concise review of the imaging evaluation of oncologic emergencies, highlighting important imaging characteristics of key malignancy-related conditions across a range of organ systems to serve primarily as a resource for clinicians involved in cancer care and for radiology trainees, who will invariably encounter oncologic emergencies during training and beyond.

Neurologic Emergencies

Intracranial Mass Effect, Edema, and Hemorrhage Fundamentally, malignant tumors are space-occupying masses that compete with normal anatomical structures for limited space in the brain and spinal canal. Intracranial mass effect derives from a combination of tumor volume and peritumoral edema, which together are responsible for causing various cerebral herniation patterns and hydrocephalus. Effective tumor volume can change rapidly as a consequence of necrosis, hemorrhage, and cyst formation, which contribute to mass effect (Fig. 46.1).

On unenhanced head CT, the appearance of malignant tissue is variable, depending on its histological composition. Generally, malignant tumors are slightly hyperdense relative to white matter, and hemorrhagic or melanin-containing components are considerably denser (e.g., malignant melanoma). Cystic and necrotic components generally measure near-water attenuation depending on the presence of cellular debris or blood products. Perilesional edema results in relative hypodensity of the surrounding brain parenchyma. Especially on unenhanced CT, the presence of edema and associated mass effect may be the only indication of underlying malignancy, and further evaluation with a contrast-enhanced study, ideally MRI, is indicated. Edema from malignancy is a reactive process, and the amount of edema is proportional to tumor size and rate of growth. Accordingly, a small but rapidly growing mass may present as precipitously as a larger but more indolent mass. Tumor cell lysis and treatment-related neurotoxicity represent important additional sources of edema and mass effect, which can be antici-

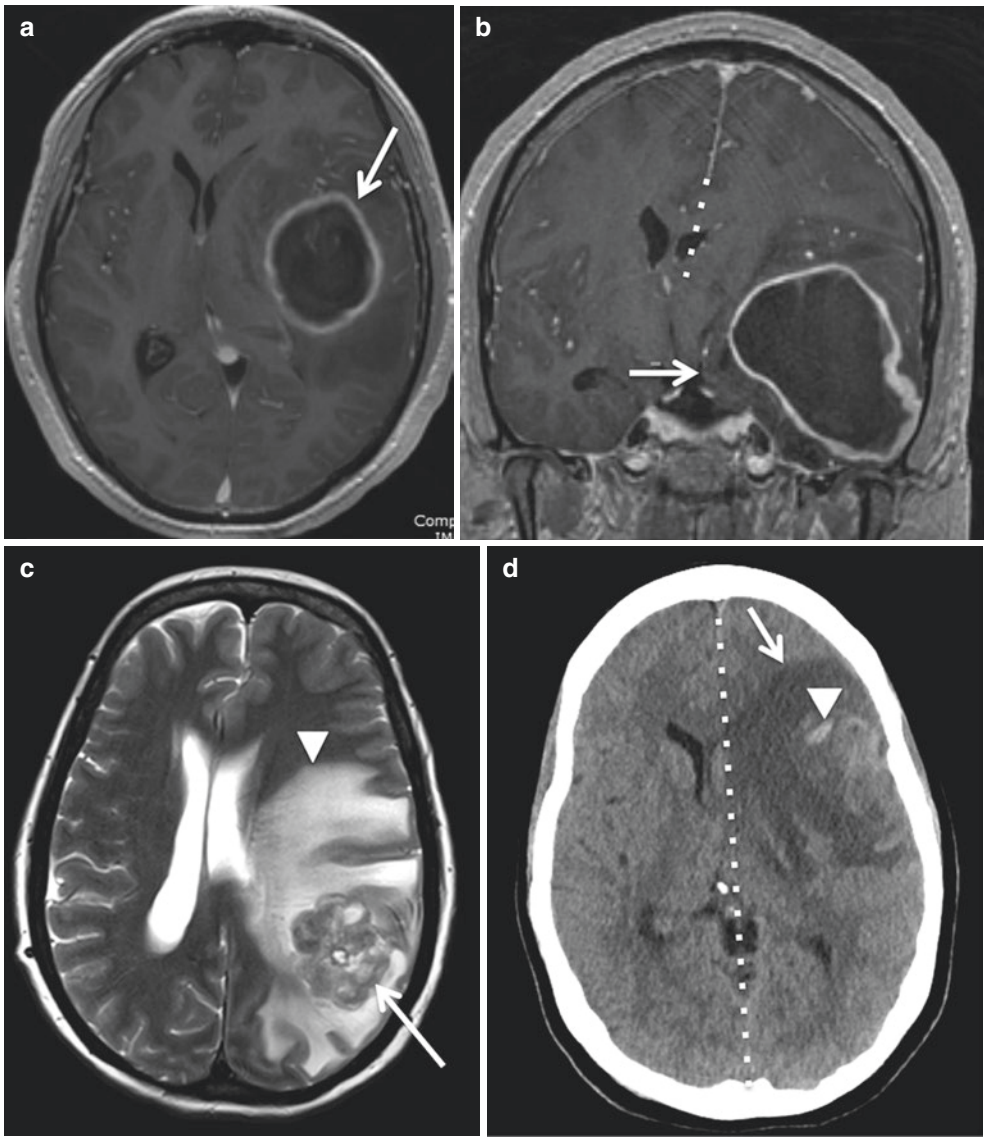

Fig. 46.1 Intracranial mass effect. (**a**) Axial postcontrast T1 brain MR image demonstrates a rim-enhancing intraparenchymal cavitary metastatic mass (*arrow*). (**b**) Coronal contrast-enhanced T1 MR image in the same patient demonstrates left-to-right midline shift (*dotted line*), compatible with subfalcine herniation. Uncal herniation is also shown by an arrow on image **b**. (**c**) T2 axial brain MR image depicts marked T2-hyperintense edema surrounding a cystic intraparenchymal metastatic lesion in the left parietal lobe (*arrow*). Note extent of edema beyond the actual mass (*arrowhead*). (**d**) Unenhanced head CT image demonstrates a left frontal lobe mass with marked surrounding hypodense edema (*arrow*) and local sulcal effacement and left-to-right midline shift (*dotted line*). There is small-volume intra-tumoral hemorrhage (*arrowhead*), which may have caused this patient's acute presentation

pated and prospectively managed with systemic corticosteroid administration.

Intracranial herniation resulting from mass effect can be classified as subfalcine, transtentorial, transalar, and tonsillar [7]. Transtentorial herniation can be further characterized as ascending (originating from the posterior fossa), descending (cerebral hemispheres), or uncal (temporal lobes), depending on the location of the tumor [1]. Ascending transalar herniation results from middle cranial fossa mass effect and causes superior and anterior temporal lobe displacement across the sphenoid ridge [7]. Descending transalar herniation results from frontal lobe mass effect and causes posterior and inferior displacement across the sphenoid wing [7]. Masses located in tightly confined structures, such as the posterior fossa, can result in the rapid development of clinically significant herniation.

Patients with hypervascular metastases, such as renal cell carcinoma, melanoma, thyroid cancer, and choriocarcinoma, are at highest risk for both intra-axial (within the brain substance) and extra-axial (within the epidural, subdural, or subarachnoid space) hemorrhage [8, 9]. Intracranial hemorrhage can also result from acute disseminated intravascular coagulation (DIC), to which patients with hematologic tumors are particularly predisposed [10]. Regardless of cause, intra-axial hemorrhage appears as a hyperdense mass with a variable degree of circumferential edema on unenhanced head CT. Hyperdensity in the subarachnoid, subdural, or epidural spaces indicates extra-axial hemorrhage. Contrast-enhanced brain MRI is essential for further characterizing the underlying malignancy.

Hydrocephalus Hydrocephalus is classified as noncommunicating (obstructive) and communicating (nonobstructive). Noncommunicating hydrocephalus results from obstruction of CSF flow, while communicating hydrocephalus is the result of excess CSF production or decreased resorption at the arachnoid villi. The foramen of Monro, aqueduct of Sylvius, and the fourth ventricle are anatomically prone to obstruction by the presence of an adjacent primary or metastatic mass [9]. Specifically, pineal metastases or primary pineal neoplasms have a particular association with hydrocephalus given the location of the gland within the narrow channel between the third ventricle and the superior cerebellar cistern [11]. The primary feature of communicating (nonobstructive) hydrocephalus on unenhanced CT is global ventricular enlargement. In noncommunicating (obstructive) hydrocephalus, there is disproportionate enlargement of the lateral ventricles; the third ventricle may also be disproportionately enlarged depending on the anatomic level of obstruction. In acute hydrocephalus, increased ventricular pressure can result in transependymal CSF accumulation, resulting in a low-density appearance to the immediate periventricular white matter.

Leptomeningeal Metastatic Disease The pia and arachnoid mater are interconnected, thin, weblike tissue that envelops the brain parenchyma and together comprise the leptomeninges; leptomeningeal metastatic disease (also referred to as leptomeningeal carcinomatosis) is characterized by the deposition of tumor along these membranes. These tumoral cells can subsequently impede CSF resorption by obstructing the arachnoid villi, leading to communicating hydrocephalus [9]. Leptomeningeal metastatic disease portends a dim prognosis, with median survival in the range of 2–3 months [12]. It is important to note that up to 40% of patients with leptomeningeal metastatic disease may have normal unenhanced CT, and in an additional 25% of cases, leptomeningeal metastatic disease is indistinguishable from intraparenchymal disease [13]. Unenhanced MRI findings include high FLAIR signal within the cerebral sulci, cerebellar folia, and cisterns and communicating hydrocephalus [14]. Contrast-enhanced MRI findings include linear or nodular enhancement within the sulci, cisterns, and ventricles and along the cranial nerves [1]. The most common primary solid malignancies associated with leptomeningeal metastatic disease are breast and lung [13].

Dural Venous Sinus Thrombosis There are many benign causes of dural venous sinus thrombosis (DVST), including oral contraceptive use, pregnancy, thrombophilic disorders (such as factor V Leiden, protein C/S deficiency), recent immobilization, and infection, such as meningitis or mastoiditis [15]; however, patients with malignancy have a particularly elevated risk for developing DVST related to dehydration, chemotherapy effects, and hypercoagulable state [16]. Tumor involvement of the cranium or skull base, dura, or leptomeninges may result in local venous stasis secondary to mass effect on a dural venous sinus, representing an additional mechanism for DVST formation. Specific cancer chemotherapeutic agents that have known association with the development of DVST include asparaginase, cisplatin, and thalidomide [17].

Unenhanced head CT is often the initial imaging modality used to evaluate patients suspected of having DVST, who may present with signs and symptoms of increased intracranial pressure [17]. The classic unenhanced head CT finding in uncomplicated DVST is hyperdensity within the affected dural venous sinus, although this is not invariably present (Fig. 46.2). The superior sagittal and transverse sinuses are most frequently affected in DSVT [16]. The diagnosis is confirmed with CTV or MRV, both of which will depict an intraluminal filling defect within the affected sinus. CTV is faster and usually more accessible after-hours, while MRV is performed alongside MRI of the brain, providing a more sensitive assessment for early venous ischemia or congestion resulting from DVST. In cases of venous infarct, edema or

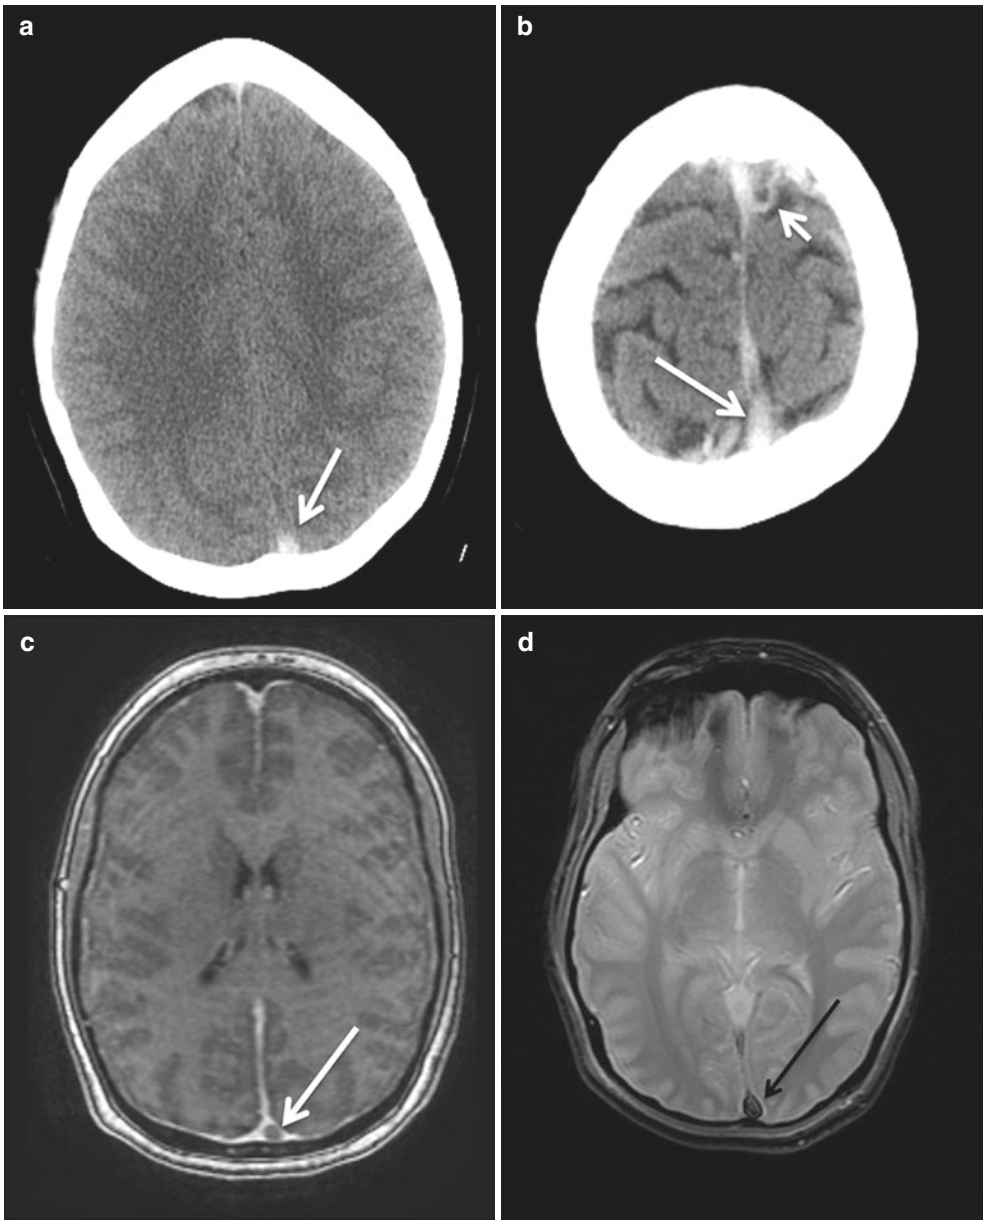

Fig. 46.2 Dural venous sinus thrombosis. (**a**) Axial unenhanced head CT image in a patient with lymphoma and headache demonstrates a hyperdense superior sagittal sinus (white *arrow*), suggesting superior sagittal sinus thrombosis. (**b**) A more superior unenhanced axial head CT image in the same patient near the vertex demonstrates continued superior sagittal sinus hyperdensity (*long arrow)* and multiple adjacent hyperdense cortical veins, suggesting thrombosis of these superficial veins as well (*short arrow*). (**c**) Postcontrast T1 axial brain MR image in the same patient illustrates a hypointense filling defect in the superior sagittal sinus, compatible with thrombus (*white arrow*). (**d**) Gradient echo axial brain MR image demonstrates "blooming" in the superior sagittal sinus, indicative of extracellular blood products (*black arrow*)

hemorrhage in a non-arterial distribution is common. Treatment of tumor-related DSVT is typically brain irradiation or chemotherapy, depending on tumor histology [10].

Stroke The hypercoagulable state of malignancy constitutes the primary risk factor for the development of cerebral vascular accidents (CVA) in oncologic patients [10]. As noted above, this population is at elevated risk for DVST, which can lead to ischemia and hemorrhagic infarction. Leptomeningeal infiltration of the Virchow-Robin perivascular spaces can result in arterial infarction secondary to thrombosis or vasospasm [10]. Additionally, arterial infarction can occur secondary to herniation as a consequence of compression of large arteries against rigid intracranial structures, such as the cerebral falx or tentorium. For instance, transfalcine herniation can result in anterior cerebral artery (ACA) compression and ipsilateral ACA-territory infarct [1, 8]. Similarly, transtentorial herniation can result in compression of the posterior cerebral artery (PCA) and therefore result in PCA-territory infarct [8]. Less commonly, transalar herniation can result in compression of the carotid terminus and lead to infarction in both the ACA and MCA territories.

Although the initial imaging evaluation of stroke patients regardless of cause is with unenhanced head CT, MRI provides optimal evaluation of tumor location and extent (including leptomeningeal metastatic disease) and is more sensitive in the identification of early ischemia as compared to CT. Areas of acute ischemia are markedly hyperintense on DWI and are typically associated with increased T2 signal.

Conventional MRI can provide an overall assessment of vessel caliber and enhancement, but dedicated MRA or MRV sequences provide better detail of arterial and venous pathology.

Spinal Pathology Spinal disease can be divided into pathology involving the osseous spine and that contained within the spinal canal (most commonly epidural or intramedullary involvement). Osseous spine disease is also addressed in the musculoskeletal subsection. Here, we focus primarily on epidural and intramedullary spinal disease, which can both present as oncologic emergencies. Metastatic disease of the spinal epidural space occurs in 5–10% of patients with cancer, most commonly from prostate, breast, and lung primaries [18]. When epidural tumor volume is advanced, it compresses the thecal sac and can result in malignant spinal cord compression (Fig. 46.3). In addition to metastatic disease, spinal cord compression can result from mass effect from primary bone tumors, osseous lymphoma, or multiple myeloma. Spinal epidural metastases localize to the thoracic region in 60% of cases and lumbosacral area in 30% of cases. Cervical spine involvement is less common [18].

Plain radiography is often the initial modality used in the evaluation of spinal cord compression, despite its poor predictive value in determining which patients will have spinal tumor involvement [19]. Vertebral body height loss secondary to pathologic compression is one of the most easily identifiable findings on plain radiography. Compression fractures resulting in loss of vertebral body height ≥50% is associated with spinal epidural disease in nearly 85% of cases [18]. Erosion of the osseous margins of the spine may be the earliest radiographic sign of intraspinal extension of disease, but this finding is not sensitive [20]. Vertebral pedicle erosion, in particular, may be the most specific finding of epidural disease [18]. CT is superior to plain radiography in accurately depicting bone erosion and assessing compression fractures. A further advantage of CT over plain radiography is that nonosseous disease can often be identified, although MRI is better suited for soft tissue pathology. CT can also be helpful in planning for interventional procedures or surgery.

MRI provides the most sensitive and specific evaluation of bone marrow pathology, epidural tumor and spinal cord compression, and intramedullary spinal disease. Spinal cord compression is discussed in detail in a separate chapter. Metastatic involvement of the spinal cord parenchyma is referred to as intramedullary spinal cord metastasis (ISCM) [18, 21]. Although ISCM has become much more frequently recognized in the era of MRI, spinal epidural disease is still nearly 20 times more common [18]. ISCM affects the cervical, thoracic, and lumbar cords equally and is most often solitary [18]. Bronchogenic carcinoma, particularly small cell carcinoma, accounts for the majority of cases (54%) [18]. MRI with IV contrast is necessary for the diagnosis of ISCM and can effectively discriminate spinal cord edema from enhancing tumor. Intravenous contrast also helps in differentiating tumor with surrounding edema from transverse myelitis.

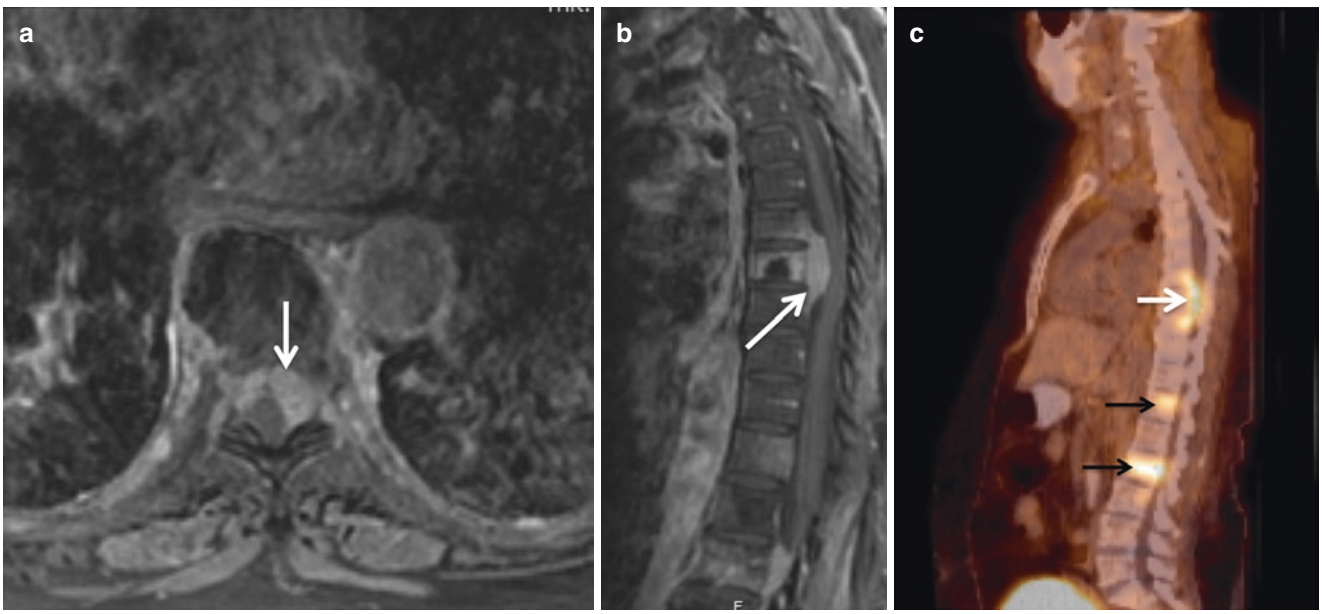

Fig. 46.3 Postcontrast axial T1 MR image (**a**) and sagittal postcontrast T1 MR image of the thoracic spine (**b**) depict an enhancing mass arising from the T7 vertebra and extending into the epidural space (*white arrows*). There is associated severe cord compression. A single fused sagittal FDG-PET/CT image of the entire spine (**c**) demonstrates robust metabolic activity in the tumor at the T7 vertebral level (*white arrow*) and at several other remote vertebral levels (*black arrows*)

Additional Acute Neurologic Complications of Malignancy Neurologic complications of cancer treatment include chemotherapy or brain irradiation-induced brain edema and attendant intracranial hypertension and opportunistic infection from systemic immunosuppression [8]. Infectious meningitis is often undetectable with unenhanced head CT; however, entities such as invasive fungal sinusitis or herpes encephalitis can be apparent on unenhanced head CT and be further characterized with brain MRI. Paraneoplastic limbic encephalitis, which can present with acute-onset confusion, short-term memory loss, hallucinations, and mood changes, is particularly difficult to diagnose clinically as it can be confused with primary psychiatric conditions. Furthermore, limbic encephalitis can have a similar imaging appearance to herpes encephalitis [8]. In 70–80% of patients with limbic encephalitis, MRI FLAIR or T2 sequences show hyperintense signal in one or both medial temporal lobes (Fig. 46.4) [22]. The tumors most frequently implicated are small cell lung cancer, testicular germ-cell neoplasms, thymoma, Hodgkin lymphoma, and teratoma [22].

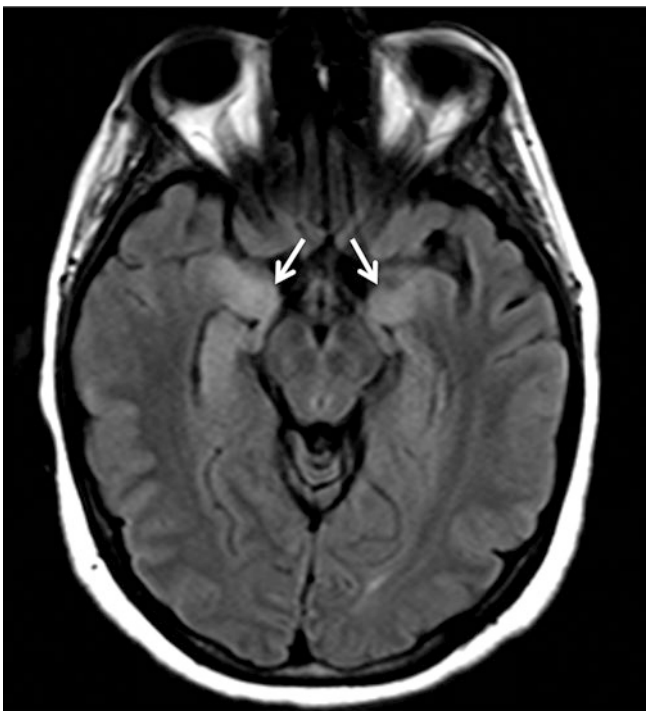

Fig. 46.4 Single FLAIR axial brain MR image in an emergency department patient with small cell lung cancer and altered mental status depicts bilateral medial temporal hyperintensity (*arrows*). Diagnosis of paraneoplastic limbic encephalitis was based on clinical and imaging characteristics

Chest Emergencies

Central Airway Obstruction Airway compromise necessitating palliative treatment occurs in 20–30% of patients with lung cancer over the course of their lifetime [23, 24]. Airway narrowing can result from intrinsic tracheobronchial disease, extraluminal compression by tumor, or a combination of both [2, 23]. Anatomical distortion of the airways as a result of surgery for lung cancer can also lead to airway compromise [23]. Chest radiography is often the initial imaging test in these patients and may reveal a mass involving the lung parenchyma, hilum, or mediastinum with associated post-obstructive atelectasis or pneumonia [2]. Tracheal deviation or airway narrowing may be present [25].

The imaging gold standard for the assessment of the central airway obstruction is contrast-enhanced CT chest and neck (above the thoracic inlet) (Fig. 46.5) [23]. CT accurately depicts the severity and extent of airway stenosis and helps differentiate intrinsic from extrinsic disease. CT also helps separate primary malignancy from metastases and distinguish tumor from atelectasis or post-obstructive pneumonia [2, 26]. Post-processed images, such as virtual bronchoscopy, can render the tracheobronchial tree in a visual format familiar to the clinician. This can assist in planning palliative interventions, such as stenting or ablative therapies, complementing conventional bronchoscopy to improve the technical success of airway recanalization (Fig. 46.6) [2]. FDG-PET will accurately discriminate a malignant hilar mass from adjacent post-obstructive atelectasis; however, patient preparation, imaging acquisition time, and availability limit its usefulness in the emergent setting [1].

Esophagorespiratory Fistula Esophagorespiratory fistula formation is a relatively rare but potentially devastating complication of esophageal and bronchogenic carcinoma, occurring in up to 22% of esophageal malignancy and around 1% of bronchogenic carcinoma [27, 28]. Nodal metastases and lymphoma can erode into the esophagus and airways and have also been implicated in esophagorespiratory fistula development [28, 29]. The risk of death is related to sepsis from repeated episodes of aspiration or from overwhelming lung infection [27]. Chest radiography findings are nonspecific and can include airspace consolidation, lung abscess, and pleural effusion resulting from aspiration of secretions and ingested material [29].

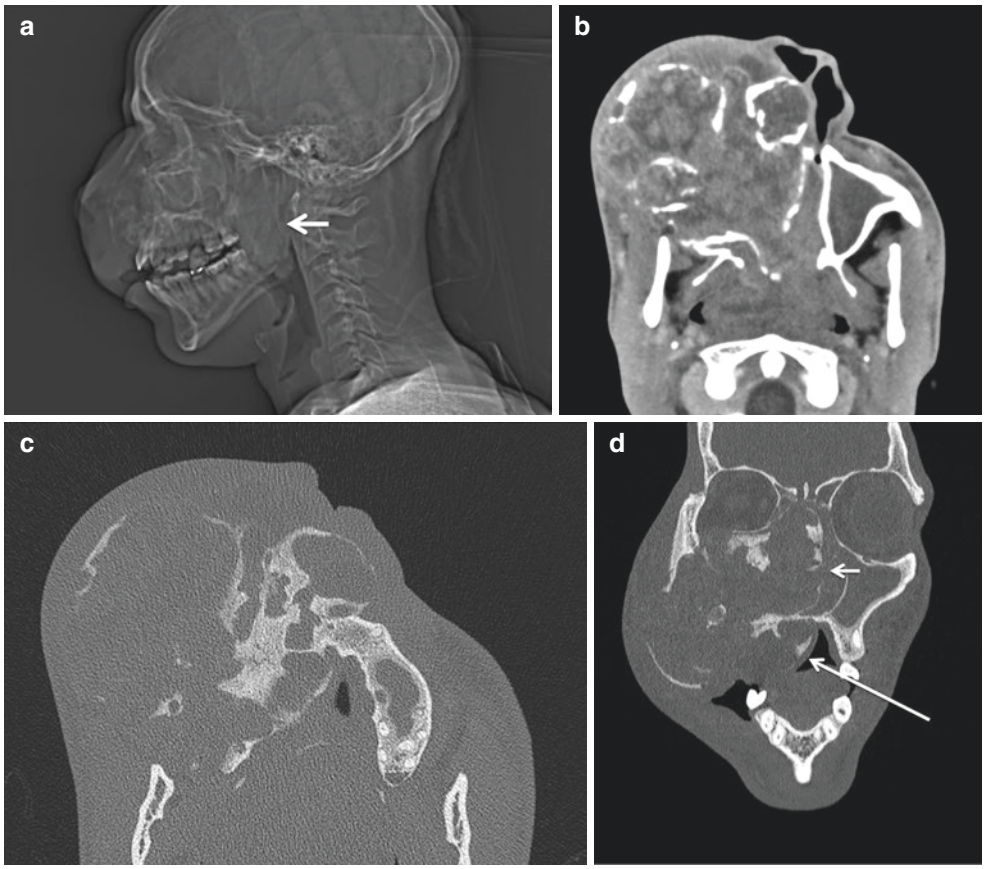

Fig. 46.5 Patient presenting to the emergency department with dyspnea. This case of advanced ameloblastoma of the right maxillary alveolar ridge in a young man demonstrates tumor mass effect involving the face and upper airway. The lateral scout image from head CT (**a**) depicts facial deformity as well as tumor replacing much of the nasopharynx (*white arrow*). Axial contrast-enhanced facial CT using soft tissue window (**b**) and bone window (**c**) depicts substantial mass effect in the right lower face and widespread local bone destruction. Coronal image (**d**) demonstrates the complete occlusion of the nasal cavity from tumor invasion and mass effect (*short arrow*) and substantial mass effect on the oral cavity (*long white arrow*)

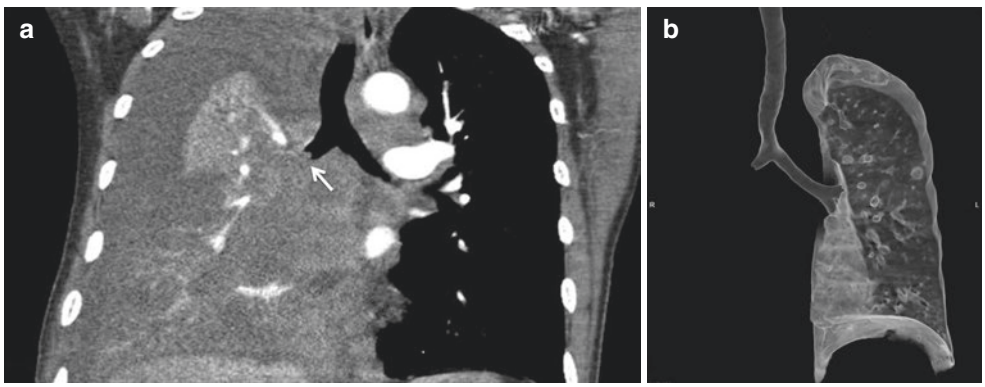

Fig. 46.6 Coronal contrast-enhanced chest CT (**a**) in a patient with squamous cell carcinoma demonstrates soft tissue occluding the right main bronchus *(arrow)* with total collapse of the right lung, inseparable from malignant tissue. Volume-rendered virtual bronchoscopy was created from the original contrast-enhanced chest CT dataset (**b**)

Fluoroscopic evaluation of the aerodigestive tract during the administration of an oral contrast agent will depict simultaneous opacification of the esophagus and tracheobronchial tree distal to the fistula. This procedure is best performed using a low-osmolar, water-soluble, iodinated contrast agent (iohexol), as large volumes of aspirated barium can compromise alveolar oxygen exchange and extravasated barium can incite an inflammatory response in the mediastinal soft tissues. Aspiration of high-osmolar, water-soluble contrast agents can lead to pulmonary edema and should likewise be avoided [30]. Chest CT performed after orally ingested contrast (CT esophagram) may demonstrate a direct communication between the respiratory tract and esophagus at the site of fistula formation with additional findings of ingested contrast agent within the respiratory tract distal to the fistula [29]. Abnormal soft tissue is often identified in the region of the fistula, indicating the site of malignancy [31]. CT is helpful in evaluating the extent and number of fistulas and the presence of a possible esophagorespiratory fistulous communication [29]. Virtual bronchoscopy or esophagography can enhance diagnostic confidence and serve as a component of treatment planning for emergent intervention [29].

Superior Vena Cava Syndrome Malignancy is responsible for 90% of cases of superior vena cava syndrome (SVCS) [32]. Benign causes of SVCS include thrombosis from

indwelling catheters, fibrosing mediastinitis due to immune response to *Histoplasma capsulatum* or tuberculosis, prior radiotherapy, cardiac pacer wires, and Behçet disease [27, 32, 33]. The clinical features of SVCS relate to venous congestion due to obstruction of the SVC from extrinsic compression by tumor or intraluminal occlusion from bland or tumor thrombus. Primary malignancy involving the superior vena cava resulting in SVCS is exceptionally rare [34]. Because bronchogenic carcinoma accounts for the majority of malignancy-related SVCS, chest radiography may reveal a lung mass with possible associated hilar or mediastinal involvement; however, cross-sectional imaging is necessary to confirm the diagnosis and identify the underlying etiology. Conventional venography was previously the imaging gold standard for diagnosing SVCS, but in contemporary practice, it is employed solely during endovascular intervention [34].

Contrast-enhanced chest CT is currently the preferred imaging modality for the assessment of SVCS. If this condition is suspected on the basis of clinical presentation, CT image acquisition following a 60-second delay optimally opacifies the systemic venous system and ideally characterizes the level (above or below the azygos arch) and extent of SVC obstruction [34]. Practically speaking, however, the diagnosis is often made on routine chest CT or CTPA protocol, which use shorter time delays [34]. Features of contrast-enhanced chest CT include complete occlusion of the SVC, an intraluminal filling defect within the SVC, marked narrowing of the SVC from surrounding soft tissue, and opacification of mediastinal or chest wall venous collateral vessels (Fig. 46.7) [34]. Included images of the upper abdomen may demonstrate intense enhancement of the medial segment of the left hepatic lobe ("quadrate lobe"), reflecting collateralization of the superficial epigastric veins and the left portal vein [34]. CT imaging findings of SVC obstruction may precede the development of the clinically apparent syndrome and present an opportunity for early intervention [32]. The underlying cause of the obstruction, most commonly bronchogenic carcinoma, lymphoma, or extrathoracic metastatic disease when considering malignant etiologies, will also be depicted at CT, representing a critical diagnostic advantage over catheter venography [31]. Although enhancement of soft tissue within the SVC represents intraluminal tumor, presumptive soft tissue enhancement without pre-contrast images for reference can be misleading. CT axial images and post-processed coronal and sagittal reformatted images also assist in planning for endovascular interventions. MRI approaches 100% sensitivity and specificity in the diagnosis of SVSC but is rarely used in the emergent setting due to limited scanner availability and patient factors [32].

Endovascular stenting has replaced chemotherapy and radiation therapy as the treatment of first resort in malignant SVCS, except in the case of chemotherapy-sensitive lymphoma, due to rapid clinical response and established long-term patency [32]. SVC stenting is carried out in the angiography suite. Under ultrasound guidance, the internal jugular, femoral, or subclavian vein is accessed, and superior vena cavography is performed to confirm the extent of disease and inform stent selection and placement. Using guidewires, the obstruction is traversed, and progressive dilatation of the obstructed lumen is optionally preformed prior to stent placement. In addition, local thrombolysis and mechanical thrombectomy may reduce the length of obstruction and risk of pulmonary emboli; however, thrombolysis has been associated with an increased risk of periprocedural bleeding [32]. A self-expanding endoprosthesis is deployed across the obstruction, taking care to not apply excessive pressure, which can result in SVC rupture and cardiac tamponade [32]. A chest radiograph is usually obtained following the procedure to confirm satisfactory stent placement and to serve as a baseline reference for future imaging. Reduction in symptoms is immediate, and clinical response to stenting is around 96% in bronchogenic carcinoma [35]. Recurrence

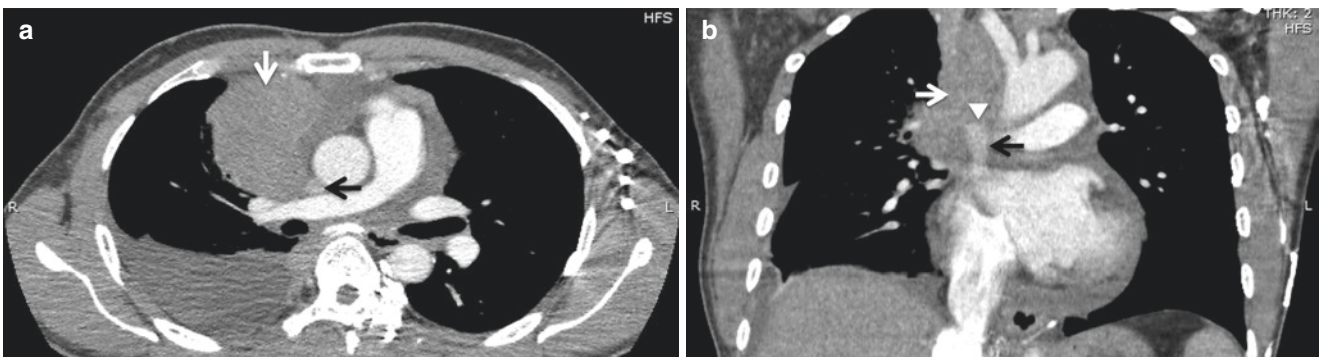

Fig. 46.7 Axial (**a**) and coronal (**b**) contrast-enhanced chest CT images demonstrate malignant SVC occlusion in this patient presenting with clinical SVC syndrome. Bulky enhancing soft tissue mass (*short arrows*) obliterates the expected location of the SVC. The inferior portion of the SVC is narrowed and displaced medially on the coronal image (**b**), superior to which SVC cutoff from tumor involvement is noted (*arrowhead*). Tissue sampling revealed bronchogenic carcinoma. A right pleural effusion is also present

of obstruction has been reported with an incidence of 0–40% [36]. Repeat stent placement is indicated in these cases and is associated with a high success rate [36].

Massive Hemoptysis Massive hemoptysis is generally defined as expectoration of ≥300–600 mL of blood within a 24-hour period and is associated with a 9–38% mortality rate [37, 38]. While pulmonary tuberculosis is the leading cause of hemoptysis worldwide, bronchogenic carcinoma is the most common malignant etiology [38]. Unstable patients presenting with massive hemoptysis are usually initially managed with bronchoscopy, which localizes the site of bleeding in the airways with a 73–93% diagnostic yield, and can be used for hemostasis [37]. Chest CTA performs equally well in determining the site of hemorrhage and is superior to bronchoscopy in identifying the underlying cause [37]. Chest radiography may reveal a lung mass, cavitary lesion, consolidation, or mediastinal mass, but up to 10% of patients with malignancy as the cause for hemoptysis may have a normal chest radiograph [39]. In most patients, chest CTA with post-processing is the diagnostic study of choice and can identify the site, underlying cause, and vascular origin of bleeding with a high degree of accuracy [38]. In 90% of patients with massive hemoptysis, a bronchial artery source is implicated [37]. On chest CTA, an abnormally dilated (≥2 mm diameter) or tortuous bronchial artery is suspicious for source of bleeding and targeted for embolization (Fig. 46.8) [38]. Active extravasation of contrast, while highly specific, is relatively rare and presents in only 3.6–10.9% of cases [38].

In addition to high diagnostic yield, chest CTA aids in planning the approach for catheter angiography and has been shown to decrease procedure time and technical success rate of subsequent embolotherapy [37, 38]. Bronchial artery embolization is an effective and safe treatment for massive hemoptysis with documented 73–99% success in effecting immediate control of bleeding [38]. Recurrence occurs in 10–29% in the first month and relates to incomplete embolization due to extensive disease or an occult non-bronchial source [38]. These patients are usually effectively retreated with embolization.

Pulmonary Embolism Acute pulmonary embolism (PE) is a leading diagnostic consideration in the oncologic patient presenting with acute chest pain. Left untreated, acute PE can be fatal [40]. Cancer patients are at particularly heightened risk for thromboembolic disease due to hypercoagulability. Used in conjunction with various clinical decision instruments to measure pretest probability, imaging plays an essential role in the diagnosis. As with any patient presenting with acute chest pain, chest radiography is used as an initial screening modality, although most patients with acute PE will have a normal chest radiograph [40]. The Westermark sign (geographic lucency related to regional oligemia from pulmonary arterial obstruction) and Hampton hump (wedge-shaped, peripheral consolidation representing infarcted lung tissue), though classically associated with acute PE, are rarely seen in practice. More commonly, atelectasis or airspace consolidation may be present in a minority of patients, but these findings are not specific [40]. The chief utility of chest radiography is to exclude other etiologies for chest pain, including pneumonia, pneumothorax, or pleural effusion [40]. In addition, chest radiography is helpful in interpreting ventilation-perfusion scintigraphy.

After excluding other causes of acute chest pain, CTPA is the imaging modality of first resort for diagnosis of acute PE. CTPA has well-established diagnostic accuracy, with 86% positive predictive value and 95% negative predictive value, having surpassed catheter pulmonary arteriography as the imaging gold standard [40, 41]. On CTPA, a centrally located hypodense intraluminal filling defect within the densely opacified pulmonary arterial system is seen in acute PE (Fig. 46.9) [40, 41]. Suboptimal vascular opacifi-

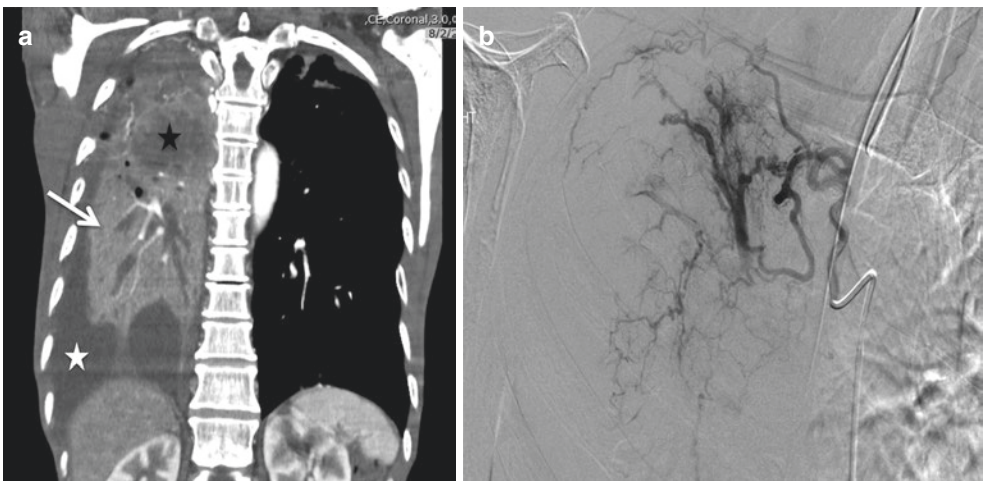

Fig. 46.8 (**a**) Coronal contrast-enhanced chest CT in a patient with massive hemoptysis depicts a hypodense right suprahilar mass (*black asterisk*) and subtotal right lung collapse (*arrow*). Pleural fluid is also seen adjacent to the collapsed lung (*white asterisk*). (**b**) Accompanying bronchial artery angiography with dilated and tortuous bronchial arteries, which were subsequently embolized, resulting in hemostasis

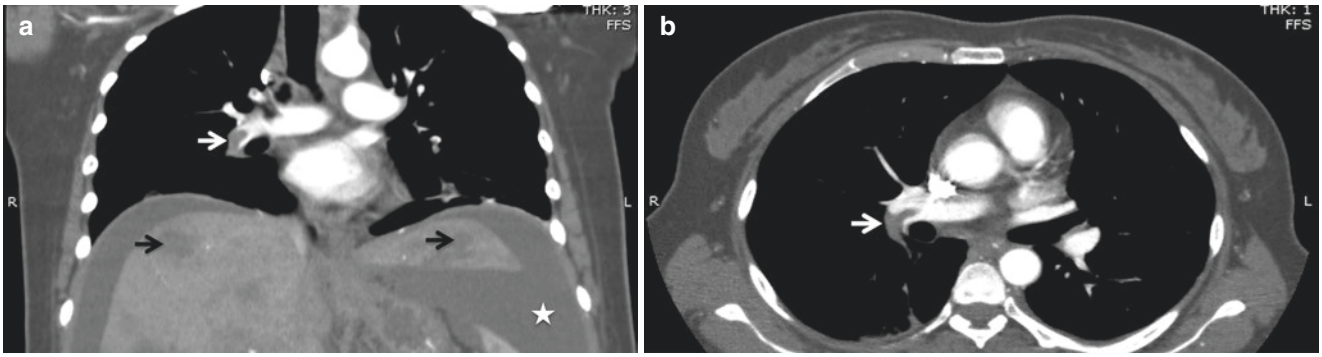

Fig. 46.9 Coronal (**a**) and axial (**b**) contrast-enhanced chest CT images demonstrate a hypodense filling defect in the contrast-opacified lumen of the right main pulmonary artery, with extension into the interlobar pulmonary artery, compatible with acute pulmonary embolism (*white arrows*). Also visible in the upper abdomen are multiple hepatic metastatic lesions (*black arrows*) and malignant ascites (*asterisk*)

cation and respiratory motion can reduce the diagnostic accuracy of CTPA, with a nondiagnostic rate of around 6%, whereas V/Q scintigraphy is inconclusive in over 25% of cases [40]. Incorporation of dual energy in CTPA has demonstrated improved sensitivity in detecting segmental and subsegmental pulmonary emboli [42]. Incidental but important additional findings can be detected with CTPA, such as pulmonary nodules and mediastinal lymphadenopathy [41].

Doppler and grayscale sonography of the deep venous system in the extremities is frequently employed as an adjunct to CTPA, since 36–45% of patients with acute PE have proximal deep venous thrombosis (DVT) [41]. Features of DVT on sonography include visualization of intraluminal thrombus, loss of venous compressibility, venous distention, and absence or diminution of Doppler color or spectral signal [40]. Serial negative extremity ultrasound examinations may obviate the need for additional investigative procedures or treatment in patients who are not candidates for CTPA related to renal insufficiency or adverse reaction to iodinated contrast or for whom CTPA or V/Q imaging is indeterminate [40]. By the same token, patients with evidence of extremity DVT by ultrasound and high pretest clinical suspicion for acute PE can be treated empirically without confirmatory imaging [41]. MR pulmonary angiography (MRPA) with and without gadolinium-based contrast agents has been studied in the evaluation of acute PE. Despite good documented diagnostic performance in technically adequate examinations, MRPA is currently not recommended for routine use due to limited availability and expertise in interpretation and suboptimal technical success [41].

Pericardial Effusion and Pericardial Tamponade Pericardial effusion and tamponade can be caused by primary malignancy in the chest, metastatic disease from a remote primary location, and following treatment for malignancy [43]. Common primary malignancies associated with pericardial effusion include bronchogenic carcinoma, breast carcinoma, lymphoma, and leukemia [43]. Lymphatic obstruction by tumor deposits is the predominant mechanism responsible for the development of malignant pericardial effusion, although direct contiguous extension (bronchogenic, esophageal, and breast) and hematogenous spread of tumor (lymphoma and leukemia) are other notable pathways for pericardial malignant disease [44]. Primary pericardial malignancies, such as mesothelioma or fibrosarcoma, are exceptionally rare etiologies for pericardial effusion [45, 46]. If accumulation of pericardial fluid is rapid, as little as 200–250 mL can result in tamponade physiology due to the relative inextensibility of the parietal pericardium [44].

A large pericardial effusion will result in an enlarged cardiac silhouette with a "water bottle" conformation on chest radiography [47]. On echocardiography, a pericardial effusion is readily apparent, and prolonged right atrial collapse during late diastole and right ventricular collapse in early diastole are characteristic for cardiac tamponade [47]. In the emergent setting, contrast-enhanced chest CT is ideally suited to establish the presence, extent, and possible cause of a pericardial effusion leading to tamponade. Fluid measuring near-water attenuation suggests a simple effusion, whereas higher-density fluid caused by hemorrhagic tumor deposits and cellular debris is often seen in malignant pericardial effusion [48]. An irregularly thickened (≥2 mm) pericardial lining with enhancing nodularity is highly suspicious for a malignant etiology in the appropriate setting, although mycobacterial infection can also have this appearance (Fig. 46.10) [48]. If a lung or chest wall mass and/or mediastinal adenopathy are present on CT, these findings would lend support to a malignant cause of a pericardial effusion. Definitive diagnosis is made by cytological examination of aspirated fluid. Treatment by pericardiocentesis with or without drain placement is performed with CT or echocardiography guidance [25, 31].

Fig. 46.10 Contrast-enhanced axial chest CT in a patient with metastatic melanoma depicts a large pericardial effusion (P). Findings are compatible with malignant effusion by CT given the effusion density and the nodular enhancing tumor foci (*long arrow*). Flattening of the right ventricular wall is suggestive of cardiac tamponade physiology (*short arrows*)

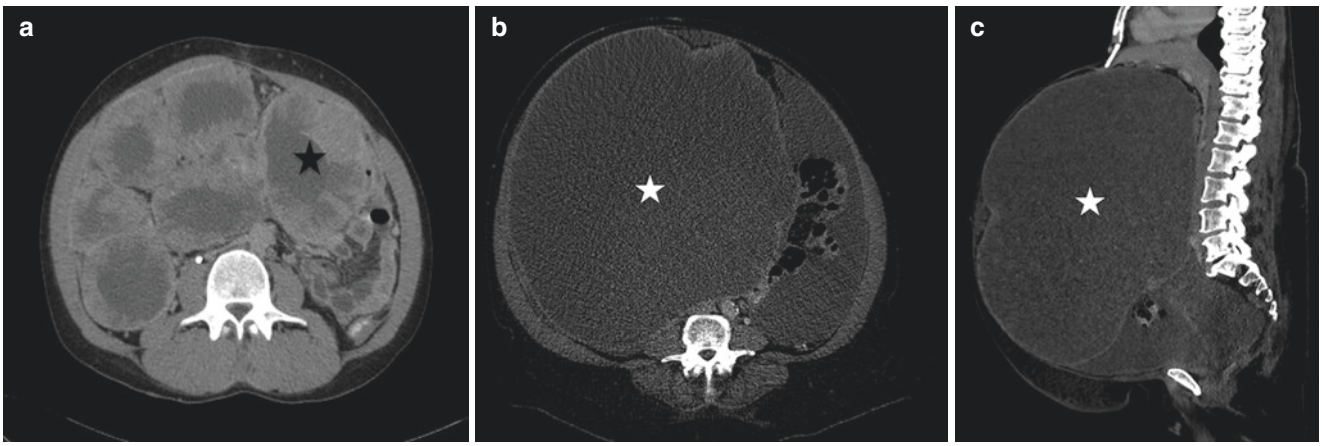

Fig. 46.11 Certain tumors, particularly late in a patient's disease course, can exert substantial mass effect in the peritoneal cavity. By virtue of this mass effect, they can compress the GI or GU tracts and result in early satiety, nausea, vomiting, and bowel or ureteral obstruction, respectively. A contrast-enhanced axial CT image of the abdomen and pelvis (**a**) demonstrates multiple large peripherally enhancing peritoneal implants from choriocarcinoma (representative lesion indicated by a black asterisk), which significantly displace normal structures. In a different patient, axial (**b**) and sagittal (**c**) contrast-enhanced CT images of the abdomen and pelvis demonstrate bulky multicystic masses (*white asterisks*) with very thin walls arising from a mucinous ovarian cystadenoma

Abdominopelvic Emergencies

Bowel Emergencies Bowel obstruction in patients with abdominal or pelvic malignancy results from impingent on the bowel lumen, either from intrinsic mural disease or from extramural compression usually from serosal implants (Fig. 46.11). In addition, many oncologic patients have undergone prior abdominal or pelvic surgery, which predisposes to bowel obstruction secondary to adhesions [49]. Bowel obstruction may also result from complication of treatment. For example, nivolumab, which is an immunotherapeutic agent for lung cancer, has been associated with increased risk of small bowel obstruction and perforation [50]. Colorectal carcinoma (10–30%) and ovarian malignancy (20–50%) are the most common cancers associated with bowel obstruction. Metastatic disease is more commonly implicated than primary malignancy in small bowel obstruction, as it is usually secondary to compressive effects from peritoneal metastases; however, primary gastrointestinal malignancy can rarely result in obstruction (Fig. 46.12). Additional primary cancers that can present with peritoneal metastases, and predispose to small bowel obstruction, include gastric, pancreatic, breast, and lung [49].

In the emergent setting, suspected bowel obstruction is often initially assessed with abdominal radiography. Supine abdominal radiographs may demonstrate abnormally dilated small bowel (≥2.5 cm in diameter) in small bowel obstruction and small bowel and colon in colonic obstruction [51]. Upright abdominal radiographs may show multiple air-fluid levels or, in the case of viscus perforation, free air accumulation under the diaphragms. Plain radiography is only around 50–60% accurate in the evaluation of small bowel obstruction and does not adequately predict the site of obstruction [51, 52]. Contrast-enhanced CT of the abdomen and pelvis is the imaging of choice when evaluating for bowel obstruc-

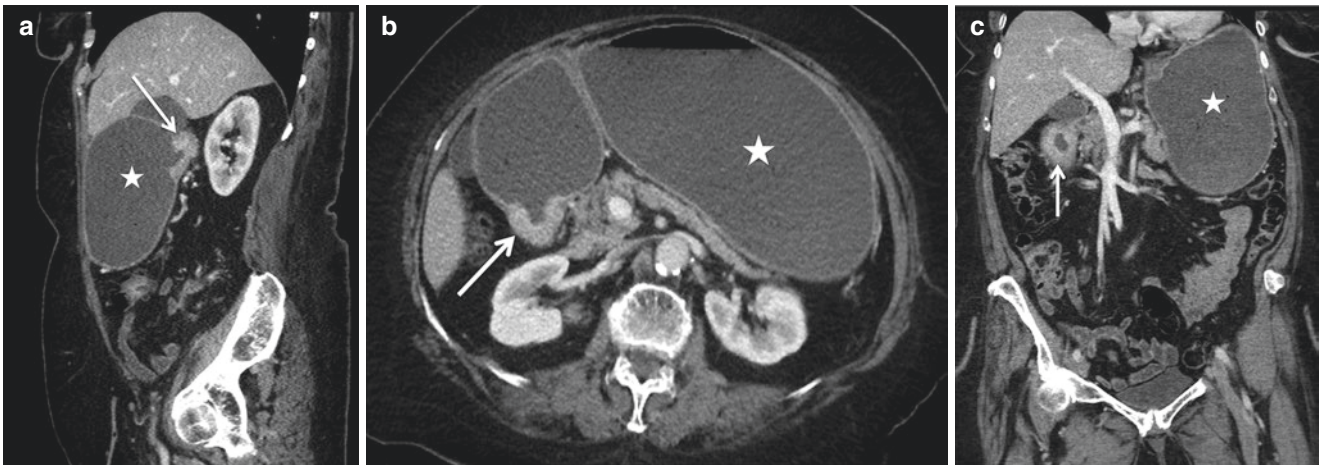

Fig. 46.12 A 57-year-old presented to the emergency department with nausea and vomiting. Sagittal (**a**), axial (**b**), and coronal (**c**) contrast-enhanced CT images of the abdomen and pelvis demonstrate a dilated fluid-filled stomach (*asterisk*). At the gastric antrum, there is irregular, enhancing wall thickening resulting in gastric outlet obstruction (*arrows*). Pathology revealed poorly differentiated gastric adenocarcinoma of the distal stomach and pylorus

tion, with far superior accuracy in securing the diagnosis (95%) and locating the site of obstruction [52]. On CT, dilated small bowel ≥2.5 cm (outer wall-to-outer wall) is seen proximal to a discrete transition point, distal to which the remainder of the small bowel and the colon are relatively decompressed (Fig. 46.13) [51]. Abnormal enhancing or necrotic soft tissue may be seen in the region of the transition point, representing peritoneal metastatic disease or, rarely, primary bowel malignancy. In contradistinction to small bowel obstruction, large bowel obstruction is most often caused by primary colorectal malignancy as opposed to metastatic disease [53]. Large bowel obstruction is diagnosed when both small bowel and colon (≥9 cm for cecum, otherwise ≥6 cm) are dilated proximal to a transition point within the colon [54]. Differentiating a transition point from a post-inflammatory or ischemic stricture in large bowel obstruction on CT can be difficult given similar imaging appearances. The presence of enlarged local lymph nodes may suggest a malignant etiology. Oral or rectal contrast is typically not administered except for suspected bowel complications, such as perforation or fistula or sinus tract formation [52, 55]. MRI is generally not used for evaluating bowel obstruction and is often reserved for pregnant or pediatric patients, in whom ionization radiation exposure is of particular concern.

Among patients with spontaneous pneumoperitoneum secondary to bowel perforation, 14% are attributable to malignancy [56]. Plain radiography is diagnostic in only 30–59% of cases of free intraperitoneal gas but approaches 100% accuracy in large-volume pneumoperitoneum [56]. Radiographic signs include free air under the diaphragms, increased bowel wall visualization from the presence of extraluminal and intraluminal gas (Rigler sign), lucency outlining the falciform ligament (falciform ligament sign), and air outlining the entire abdominal cavity (football sign) and a hyperlucent liver [56]. Abdominal radiography cannot pre-

Fig. 46.13 Single coronal contrast-enhanced CT image of the abdomen and pelvis in a patient presenting with nausea and vomiting demonstrates a heterogeneously enhancing cecal-region mass (*arrow*). There are dilated, fluid-filled segments of small bowel, compatible with small bowel obstruction. Pathology revealed appendiceal carcinoma. Note serosal metastatic implants (*arrowhead*)

dict the site of perforation. CT, however, is exceedingly sensitive for the detection of free intraperitoneal gas (96–100%) and can correctly identify the site of perforation with 80–90% accuracy [56]. CT features of bowel perforation include discrete bowel wall defect and extraluminal gas, oral or rectal contrast, or bowel contents [56]. Both colorectal carcinoma and gastrointestinal lymphoma are complicated by perforation with a prevalence of up to 9%, and systemic chemotherapy has been observed to further increase the risk of perforation in bowel lymphoma [57].

Ischemic colitis can coexist with colonic malignancy with an incidence of up to 7%, and 20% of patients with ischemic colitis have an underlying colorectal cancer [58, 59]. Ischemic colitis secondary to malignancy can result from increased intraluminal pressure and subsequent diminished blood flow in the dilated colon proximal to site of primary malignancy. In cases without mechanical obstruction, bacterial overgrowth in stagnant segments of colon has been implicated in ischemic colitis [60]. Pancreatic adenocarcinoma can compress the superior mesenteric artery and vein, resulting in critically diminished perfusion and subsequent bowel ischemia [60]. Metastases to the mesenteric root, including colon, breast, ovarian, and lung primaries, can similarly result in bowel obstruction by direct vascular impingement [1]. In ischemic bowel, contrast-enhanced CT of the abdomen and pelvis is the imaging modality of choice, and features include mural thickening, submucosal edema (low attenuation) or hemorrhage (high attenuation), engorgement of mesenteric vessels, mesenteric edema, altered or absent mucosal enhancement, and intramural gas or portal venous gas. Hypoenhancement of the bowel wall is considered the most specific sign for ischemic bowel, although these findings are often subtle. Dual-energy CT can increase the conspicuity of bowel wall hypoenhancement through the use of iodine maps or overlay images [61]. Permeation of intraluminal gas across damaged mucosa causes intramural gas and appears as focal or circumferential locules of air within the colonic wall (pneumatosis coli). Gas can then propagate into the mesenteric and portal veins, giving the appearance of air-attenuation filling defects within these vessels.

Intussusception is characterized by telescoping of a segment of bowel along with its corresponding mesentery into an adjacent segment of bowel. Whereas 95% of cases of intussusception are idiopathic in children, 80–90% of adult cases are associated with underlying mass lesions, referred to as "lead points," and are most commonly polypoid bowel neoplasms [62, 63]. In 30% of small bowel and 60% of colonic intussusceptions, an intramural or extrinsic lead point will be malignant [62]. With CT, intussusception is characterized by a "bowel-within-bowel" appearance with direct visualization of an inner bowel segment and surrounding fat (intussusceptum) enveloped by an adjacent outer segment of bowel (intussuscipiens), with or without accompanying vessels, rendering a targetoid or sausage-like appearance [53, 63]. Intussusception can be complicated by bowel obstruction or ischemia, the features of which are described above.

Spontaneous Intra-abdominal Hemorrhage Spontaneous hemorrhage from visceral organ malignancy is a rare, but potentially catastrophic, oncologic emergency. Around 10–15% of patients with hepatocellular carcinoma will present to the emergency department with tumor rupture leading to intraparenchymal hematoma, subcapsular hematoma, hemoperitoneum, or some combination. Risk factors for spontaneous hemorrhage of hepatocellular carcinoma include peripheral or subcapsular location and large tumor size [64]. Hypervascular metastases to the liver, such as melanoma and renal cell carcinoma, are at particularly heightened risk for spontaneous hemorrhage. Reports of spontaneous hemorrhage from primary angiosarcoma of the liver have been documented [3]. Although spontaneous splenic rupture is more commonly reported in infection, notably cytomegalovirus, Epstein-Barr virus, or malaria, lymphomatous or leukemic splenic involvement can also give rise to severe hemorrhage, necessitating immediate endovascular treatment or splenectomy [65].

Spontaneous tumor rupture is evaluated with contrast-enhanced CT of the abdomen and pelvis in order to confirm the presence of rupture, identify the site of involvement, and determine the extent of hemorrhage (Fig. 46.14). The appearance of extravascular blood on CT varies in a time-dependent manner. Acute blood products will demonstrate an attenuation in the range of 30–45 HU, whereas clotted blood has attenuation values from 45 to 70 HU [3]. When a focal area of high-density clotted blood is seen in the abdomen or pelvis on a background of lower-density unclotted blood, it is referred to as the "sentinel clot" and points to the site of primary source of bleeding [3, 53]. On occasion, ongoing bleeding can be seen during the acquisition of CT images as active extravasation of contrast, with focal areas of high-density (85–370 HU) extraluminal IV contrast material and surrounding clotted hematoma [66]. Ongoing bleeding requires emergent surgical or endovascular interventions to control blood loss. In this setting, particularly with unstable patients, catheter angiography and catheter-directed embolization can aid in management.

Urinary Obstruction Approximately one-quarter of patients with pelvic or retroperitoneal malignancy will develop life-threatening urinary obstruction [1]. Progressive urinary tract obstruction most often results from compression or invasion of the ureters, most commonly the distal one-third of the ureters below the level of the common iliac

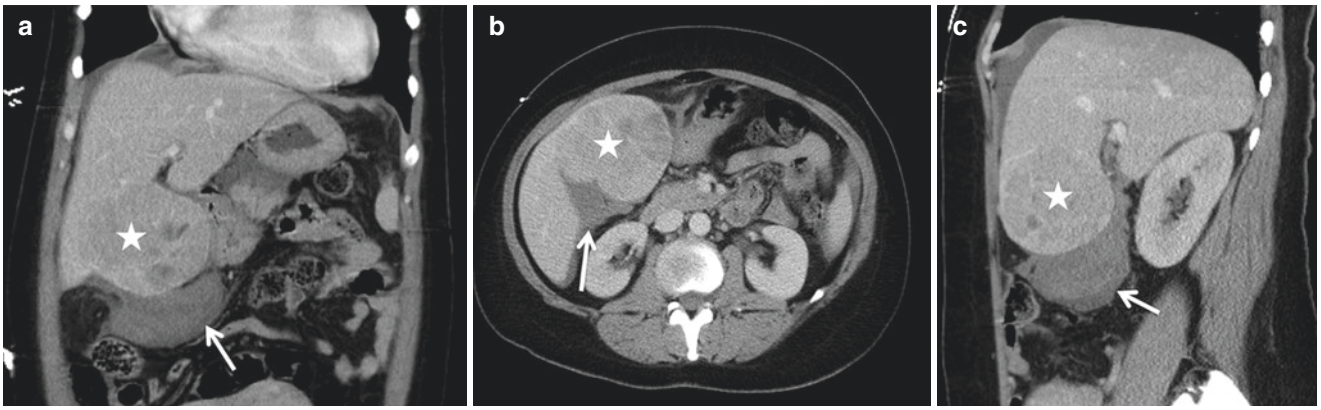

Fig. 46.14 A 47-year-old patient presented to the emergency department with acute-onset right upper quadrant pain. Coronal (**a**), axial (**b**), and sagittal (**c**) contrast-enhanced CT images of the abdomen reveal a heterogeneously enhancing exophytic hepatic mass (*asterisk*) arising from the right hepatic lobe. There is surrounding high-density fluid, compatible with blood products (*arrows*). Pathology revealed hemorrhagic hepatocellular carcinoma

arteries, by primary malignancies such as prostate, bladder, cervical, ovarian, or colorectal [1, 67]. Lymphoma and sarcoma, and less likely retroperitoneal metastatic disease from primary cancers such as cervix, urinary bladder, prostate, colorectal, ovary, and testes, can likewise result in ureteric obstruction by direct tumor invasion or compression [1, 67].

Hydronephrosis and hydroureter can be identified by ultrasound as expansion of the renal collecting systems and ureters with anechoic urine. The obstructing mass may not be evident on ultrasound, and advanced cross-sectional imaging is usually required to assess for the presence, size, and location of the malignancy. In the emergent setting, CT is often initially employed either as a standard single-phase postcontrast CT or formal CT urography. In single-phase CT, both the obstructed urinary tract and offending lesion are clearly depicted. A delayed enhancement pattern of the ipsilateral kidney may be present, reflecting compromised excretion of contrast due to downstream obstruction (Fig. 46.15). CT urography is not often employed in the acute setting but would consist of an unenhanced image set, followed by nephrogenic phase (100 seconds after IV contrast administration) and excretory phase (3 minutes after IV contrast administration) imaging [68]. The urographic component, however, may be limited in severe obstruction, which would inhibit excretion of contrast. Treatment of malignant urinary obstruction is palliative, as median survival is measured in months [67, 69]. Nephroureteral stent and percutaneous nephrostomy tube placement are the most common interventions for palliative urinary diversion [67].

Biliary Obstruction Obstruction of the biliary system from primary tumor invasion or compression of the bile ducts by hilar nodal metastases can result in significant morbidity and mortality [70]. Pancreatic adenocarcinoma, periampullary malignancy, and cholangiocarcinoma are most the most commonly implicated primary malignancies associated with biliary obstruction [70, 71]. In patients with known or suspecting malignancy presenting with jaundice, abdominal pain, and/or laboratory evidence of biliary obstruction, the obstructing mass and associated obstruction can be confirmed by abdominal ultrasound, CT, or MRI. CT and MRI offer the additional advantage of preprocedural planning and staging [72]. MR cholangiopancreatography (MRCP), which is always acquired in combination with conventional MRI of the abdomen, is a noninvasive imaging technique that provides exquisite anatomic detail of the dilated biliary tree and can often exclude choledocholithiasis as a cause of obstruction [73]. Endoscopic ultrasound can be complementary to CT and MRI/MRCP in difficult cases [72]. Pancreatic adenocarcinoma is typically characterized as an ill-defined and infiltrative mass, which is hypoattenuating with respect to normal pancreatic parenchyma on CT. In rare cases, pancreatic adenocarcinoma is indistinguishable from normal pancreatic tissue. When this occurs, the presence of malignancy in the pancreatic head can be inferred by the "double duct" sign, representing simultaneous common biliary and main pancreatic ductal dilatation [70]. Cholangiocarcinoma is classified as intrahepatic, hilar, or extrahepatic, and most occur at the bifurcation of the hepatic ducts (Klatskin tumor) [70]. At the time of presentation, the common imaging appearance of cholangiocarcinoma is biliary ductal dilatation, which can be focal or diffuse. On cross-sectional imaging, infiltrative hilar cholangiocarcinoma is further characterized by an ill-defined soft tissue mass with associated by bile wall thickening or complete duct luminal obliteration (Fig. 46.16). Intrahepatic (mass-forming) cholangiocarcinoma is hypovascular and demonstrates gradual centripetal enhancement in a time-dependent manner following IV contrast administration [70].

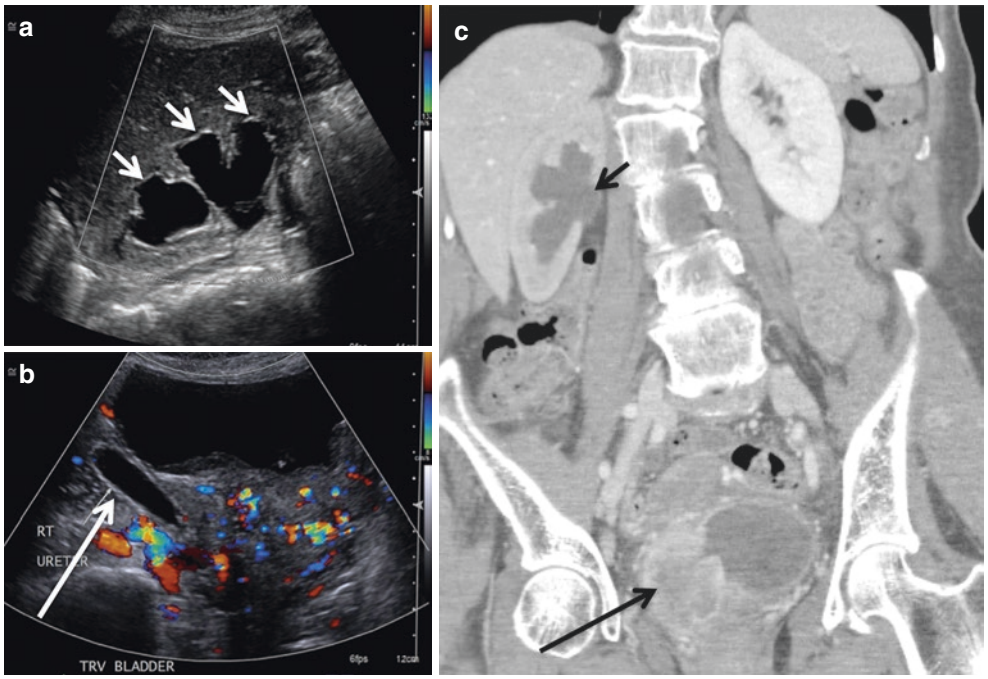

Fig. 46.15 A 70-year-old female with urinary bladder urothelial carcinoma. (**a**) Initial sonographic image shows dilation of the renal collecting system with calyceal blunting (*short white arrows).* Subsequent sonographic image of the pelvis (**b**) shows dilation of the distal ureter (long white arrow), with vascularized soft tissue mass in the urinary bladder. Coronal CT image (**c**) redemonstrates hydronephrosis (*short black arrow*) and confirms the enhancing mass in the right lateral aspect of the urinary bladder (*long black arrow*). Also present is relative hypoenhancement of the right kidney compared to the left kidney, termed a "delayed nephrogram," a finding often seen with higher-grade ureteral obstruction

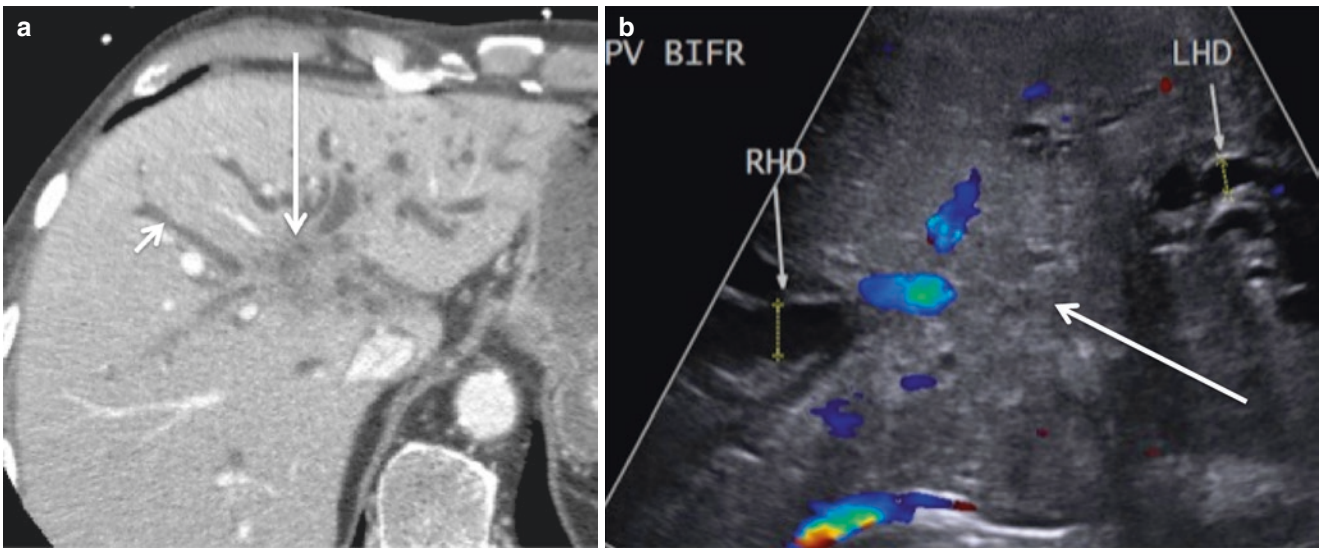

Fig. 46.16 Contrast-enhanced axial CT image of the abdomen (**a**) and transverse sonographic image centered at the hepatic hilum in a patient presenting to the ED with jaundice and right upper quadrant pain. The CT image depicts intrahepatic biliary ductal dilation (short arrow) and a hypoenhancing hepatic hilar mass, typical of cholangiocarcinoma (Klatskin tumor). Sonographic image of the right upper abdominal quadrant (**b**) demonstrates biliary ductal dilation and an ill-defined heterogeneous mass with Doppler signal, indicating vascularity. RHD, right hepatic duct; LHD, left hepatic duct

In patients with advanced malignant biliary obstruction, palliative biliary diversion can be performed surgically, endoscopically, or via a percutaneous approach. A surgical approach results in significant reduction in recurrent obstruction but is associated with a higher complication rate [71]. Endoscopic and percutaneous stenting using both plastic and metallic stents is associated with lower complication rates but higher reocclusion rates and need for repeat procedures [71, 74]. In general practice, bypassing distal biliary obstruction is usually initially attempted with ERCP, and percutaneous biliary drainage and stenting are reserved for endoscopic technical failure [74]. For proximal obstruction, both approaches can be taken, sometimes in combination; however, a percutaneous approach, which is usually carried out in the interventional radiology suite, may be more appropriate when drainage of segmentally dilated bile ducts is desired. This is because percutaneous ultrasound can first identify these structures, allowing for a more targeted subsequent intervention using fluoroscopic guidance [74].

Musculoskeletal Emergencies

Pathologic Fractures The musculoskeletal system is comprised of the axial and appendicular skeleton as well as the supporting muscles and soft tissues. Oncologic emergencies can affect both structural components, but skeletal complications are much more frequently encountered. Bone is the most common site for metastatic disease [75]. At postmortem examination, the incidence of metastatic bone disease was 73% in breast cancer, followed in frequency by prostate (68%), thyroid (42%), lung (36%), and renal (35%) [75]. The burden of osseous metastatic disease correlates to the frequency of skeletal-related events (SREs), which include fractures, surgical or therapeutic intervention for bone lesions, spinal cord compression, and hypercalcemia of malignancy [76].

The destruction of trabecular and cortical bone by primary or metastatic tumor degrades the intrinsic structural stability, and therefore the weight-bearing capabilities of bone, predisposing patients to pathologic fractures. These fractures occur in both the axial and appendicular skeleton but are more debilitating in the vertebra, pelvis, or lower extremities (Fig. 46.17).

Appendicular Skeleton Regarding the long bones, plain radiographs provide rapid initial screening. When fractured, subsequent orthopedic consultation and stabilization of a pathologic fracture restores functionality and decreases pain. If plain radiographs are not revealing, but there remains a high clinical concern for fracture, further imaging may be warranted. Specifically, in patients with low bone mineral density, nondisplaced fractures can be occult by plain radiography, and if the patient cannot bear weight or has unexplained pain, further evaluation with cross-sectional imaging may be warranted. Unenhanced MRI provides very sensitive evaluation for both metastatic involvement of bone and acute fracture; however, after-hours availability is not widespread. Normal bone marrow varies by location within bone and

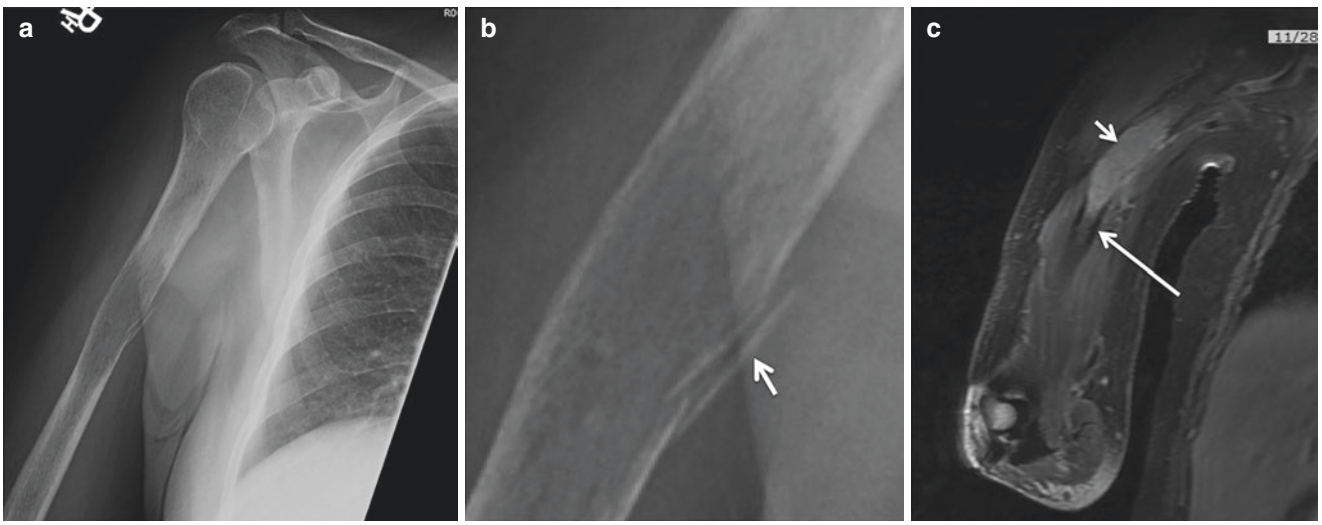

Fig. 46.17 AP radiograph of the humerus demonstrates a geographic, moth-eaten, lytic, destructive lesion, with cortical endosteal thinning and mild marrow cavity expansion (**a**). (**b**) Magnified image of the associated pathologic fracture with adjacent cortical fragments (*arrows*). Coronal T1 postcontrast fat-saturated MR image (**c**) demonstrates enhancing soft tissue mass replacing the normal fatty marrow cavity (*short arrow*) and obliterating the T1-hypointense cortex (normal cortex shown with *long arrow*). Diagnosis is plasmacytoma with pathologic fracture

patient age; however, in general normal marrow can be categorized as hematopoietic or fatty. Fatty marrow is T1-hyperintense and T2-hyperintense, while hematopoietic marrow is slightly hypointense on both sequences. The proportion of hematopoietic marrow decreases with patient age. Marrow can be replaced or infiltrated by metastases, leukemia, or lymphoma, resulting in T1 signal that is hypointense relative to skeletal muscle (which serves as an internal frame of reference) [77]. On fat-saturated T2 and STIR imaging, malignancy is usually hyperintense, resulting from intrinsically higher water content and reactive edema [77]. In the case of fracture, fluid-sensitive MRI sequences (T2 and T2 or PD with fat saturation) will demonstrate robust marrow edema, while T1 sequences are used to localize the site of cortical disruption. Unenhanced CT can be used in the emergent setting to identify and characterize fractures. The primary limitations of unenhanced CT in the evaluation of malignant involvement include diminished sensitivity for malignant soft tissue and early marrow metastatic disease.

Vertebral Fractures Metastatic disease to the spine is the most common form of skeletal malignancy, and osteolytic bone destruction may occur in up to two-thirds of patients [75]. As previously noted, plain radiography is widely available and rapid but relatively insensitive for pathologic vertebral body fractures. In the setting of trauma in cancer patients, if there is clinical concern for fracture, unenhanced CT is the imaging modality of choice for identification and characterization of fractures. With MRI, the presence of bone marrow edema (T2 or STIR hyperintensity) indicates an acute time course. The addition of IV contrast to an MR examination provides a more sensitive evaluation of epidural tumor extension but will not further characterize the underlying osseous malignancy and is not necessary in diagnosing fracture. This is because bone metastases do not always enhance after the administration of gadolinium. Sclerotic metastatic disease and treated or partially treated tumor foci, for example, typically do not enhance but will still be detected on MRI without IV contrast [77]. CT-guided vertebroplasty can help reduce pain in a wide variety of osteolytic vertebral lesions [78].

In the setting of vertebral fracture, spinal cord compression can result from retropulsion of bone fragments or soft tissue tumor into the spinal canal. Additionally, local hemorrhage resulting from the fracture can cause local mass effect and exacerbate spinal canal narrowing. MRI provides the optimal assessment of the spinal cord, including the degree and cause of narrowing and the presence or absence of spinal cord edema. For further information on this topic, please see the dedicated chapter on spinal cord compression. Image-guided treatment of this entity is discussed in the section on neuroradiologic emergencies.

Impending Fractures The Mirels classification system provides an overview of the risk of impending fracture in long bones, with a score ≥ 8 suggesting prophylactic surgical fixation [79–81]. The calculation of the Mirels score incorporates lesion site, nature of the osseous lesion, lesion size relative to cortical thickness, and pain, as follows:

- Location: upper limb (1 point), lower limb (2 points), and trochanteric region in the proximal femur (3 points).
- Lesion: blastic (1 point), mixed (2 points), and lytic (3 points).
- Size: the size of lesion expressed as a proportion of cortical involvement – less than 1/3 (1 point), 1/3 to 2/3 (2 points), and greater than 2/3 (3 points) [79, 81].
- Pain: subjectively classified as mild (1 point), moderate (2 points), or functional (3 points).

Imaging, usually consisting of both CT and plain radiography, is necessary in computing a Mirels score and can guide patient management by suggesting fixation prior to fracture.

Case Study

Introduction: A 67-year-old woman with 40-pack-year smoking history presents with a 1-month history of worsening lower back pain. She also reports that she has had 60-pound weight loss since the preceding year due to poor appetite and low energy from coughing all night. Physical exam is positive for diminished breath sounds over the right chest and tenderness to palpation over the mid-lower back. She undergoes chest radiography and CT of the abdomen and pelvis (Fig. 46.18)*. She returns to the emergency department 1 year later with acutely worsening low back pain and bilateral lower extremity hyperreflexia* (Figs. 46.19 and 46.20)**.**

Discussion: Findings are compatible with pathologic thoracic vertebral fracture secondary to metastatic disease from lung cancer. The spine is the most common location for skeletal metastasis and occurs in up to 10% of newly diagnosed cancers. Metastasis to the spine occurs due to hematogenous dissemination of malignant cells. On radiography and CT, metastases are classified as osteoblastic, mixed or osteolytic. Common primary malignancies that metastasize to the spine are lung (osteolytic), breast (mixed), and prostate (osteoblastic). In this case, the patient presented with osteolytic metastasis from metastatic lung cancer. In addition to metastasis, the differential diagnosis for lytic lesions in the spine includes primary bone tumors, multiple myeloma, lymphoma, discitis/osteomyelitis, and metabolic disorders.

Patients with metastatic disease to the spine present with spinal tenderness and, in more advanced cases, neurologic deficits. This may or may not be seen in setting of pathologic

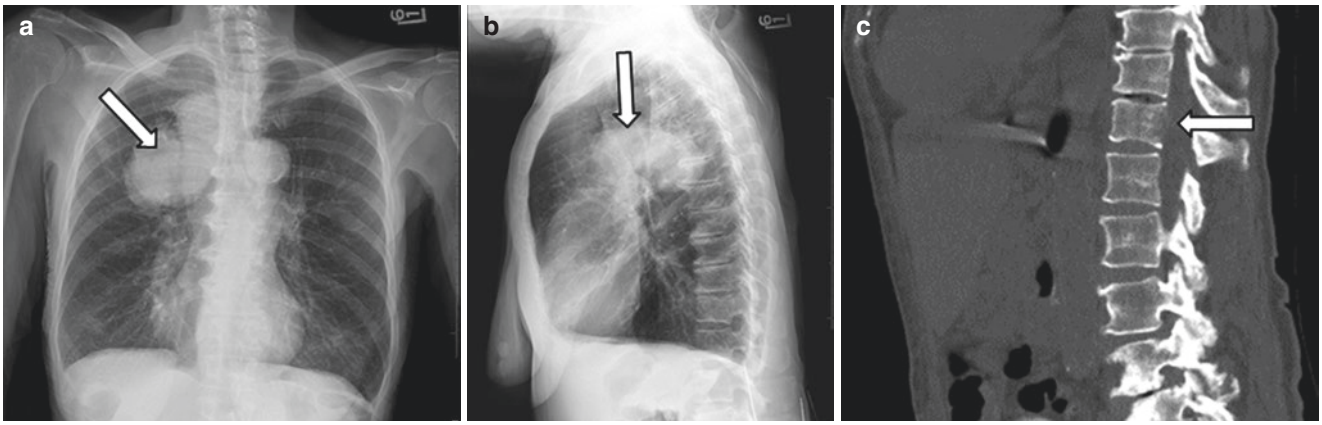

Fig. 46.18 *Case Study.* Imaging at initial patient encounter. Frontal (**a**) and lateral (**b**) chest radiographs demonstrate a lobulated right hilar/right upper lobe mass (*arrows* in images **a** and **b**) highly suggestive of malignancy. (**c**) Sagittal CT image of the abdomen demonstrates subtle erosion of the posterior vertebral body cortex of T12 (*arrow*)

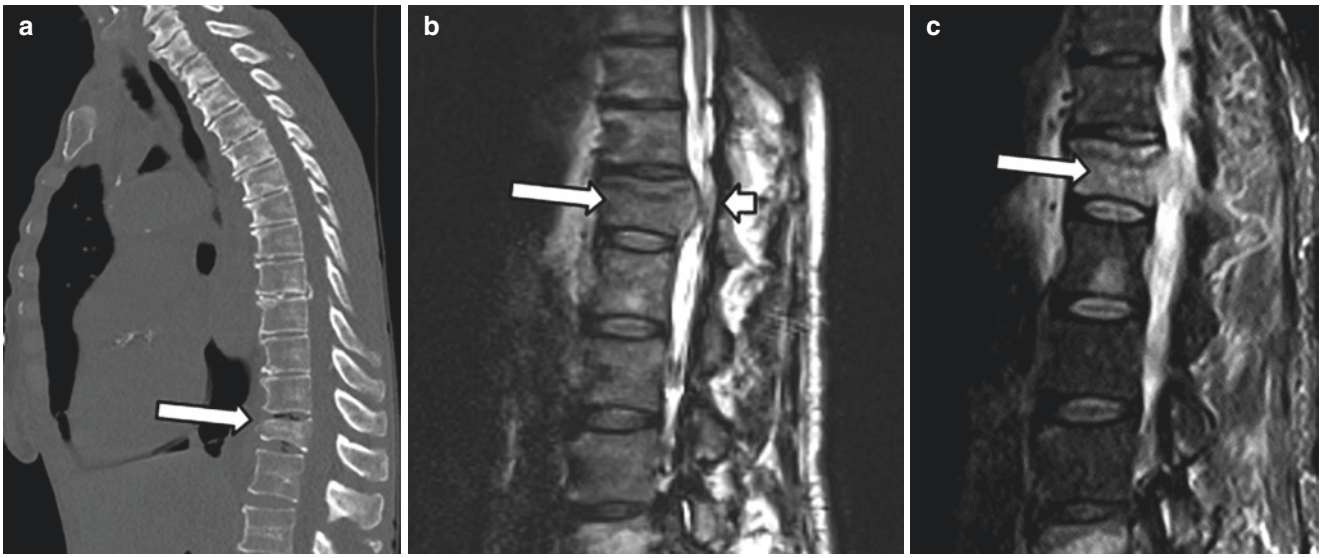

Fig. 46.19 *Case Study.* Imaging at follow-up patient encounter, 1 year later. Sagittal CT of the chest (**a**) demonstrates a wedging compression fracture of the T12 vertebral body with 50% anterior height loss (*arrow*); however, the age of this fracture is not definitively established by CT. T2-weighted MRI with fat saturation (**b**) demonstrates an acute pathologic compression fracture of T12 with bright marrow signal confirming the acute time course of this fracture

fracture and spinal cord compression. A Mirels score can be used to assess the risk of pathologic fracture, with a score greater or equal to 9 suggesting prophylactic fixation be performed. Treatment of pathologic fracture is multidisciplinary and involves a combination of chemotherapy, steroids, surgery, and radiation. There are three key factors involved in determining treatment: neurologic deficit, patient factors, and spinal stability. A spinal instability neoplastic score is often used evaluate for spinal stability, with a score of 7 to 18 warranting surgical consultation.

Pain Bone metastases are the most common cause of cancer-related pain, although the majority of individual metastatic bone lesions are not painful [75]. Radiographs can identify lytic bone lesions as an area of radiolucency but only after a loss of 30% or more of bone mineral density; radiographs can be used as a screening tool, but continued clinical concern for a metastatic lesion in the presence of normal radiographs may warrant cross-sectional imaging. Unenhanced CT provides detailed bone anatomy and can be useful in the assessment of impending fracture risk or in preoperative planning. MRI provides very sensitive evaluation, identifying smaller nondestructive regions of marrow infiltration or metastatic disease [77]. Image-guided percutaneous cryoablation has proven effective for bone pain management. Radiofrequency ablation is an additional treatment option but may cause a temporary pain exacerbation.

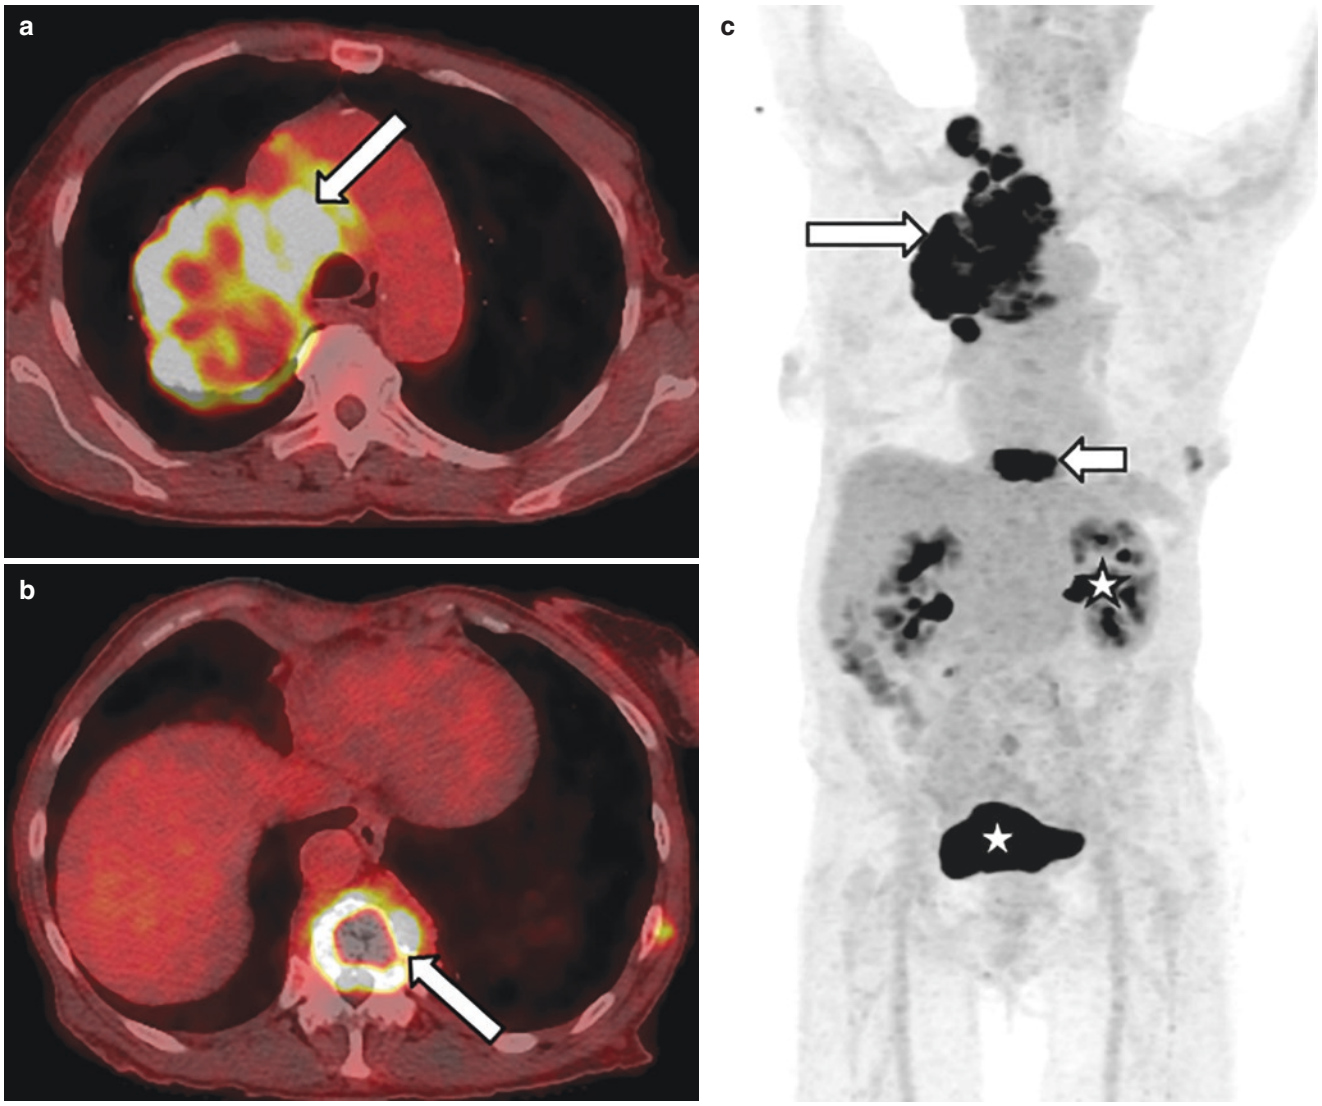

Fig. 46.20 *Case Study.* Imaging at follow-up patient encounter, 1 year later (**a**–**c**). Bright hot iron (*yellow/white*) color in axial fused FDG-PET/CT image indicates increased glucose (FDG) uptake in the highly metabolically active primary right hilar/right upper lobe malignancy. Bright hot iron color in (**b**) indicates metastatic lesion in the T12 vertebral body. Full-body three-dimensional FDG-PET projection in (**c**) demonstrates the primary tumor as a cluster of black masses (*long arrow*), vertebral metastasis (*short arrow*), and physiologic uptake in the renal collecting systems and urinary bladder due to excretion of FDG (*stars*). Metastatic right supraclavicular lymphadenopathy is demonstrated superior to the primary tumor

Hypercalcemia Hypercalcemia of malignancy comprises more than one-third of all cases of hypercalcemia presenting to the emergency department [47]. As many as one-third of cancer patients will experience hypercalcemia at some point in their disease course [25]. Hypercalcemia of malignancy can result from tumoral or systemic release of parathyroid hormone-related peptide (PTHrP), osseous metastases resulting in direct osteoclastic stimulation and osteolysis, and secretion of vitamin D analogues by the tumor [25, 47]. Radiologic manifestations of hypercalcemia of malignancy can include osteopenia and osteoporosis, resorption of bone at the distal clavicle and about the sacroiliac joints, and nephrocalcinosis and nephrolithiasis.

Ultrasound

47

Sherwin Soltani, Konrad Karasek, Lamees M. Alshaikh, Ideen Zeinali, and Jennifer Carnell

Introduction

The use of bedside ultrasound by trained physicians has advanced the practice of medicine. Over the past two decades, clinician-performed ultrasound has seen widespread adoption as a core skill in emergency medicine and critical care medicine [1, 2]. With appropriate training and a symptom-based approach, emergency ultrasound is field-tested in the rapid diagnosis and management of undifferentiated critically ill patients [3–5]. The numerous emergencies associated with cancer and its treatment, including septic shock, ascites, pleural and pericardial effusions, pulmonary embolism, deep venous thrombosis, and bowel obstruction, among others, can all be diagnosed with bedside ultrasound, helping the clinician focus their initial differential diagnosis, thus decreasing time to diagnosis and stabilization.

Bedside ultrasound, also known as point-of-care ultrasound (POCUS), emergency ultrasound, or clinical ultrasound, is an extremely broad topic, and the interested reader is encouraged to learn more about this topic through the many available resources in textbooks and free-and-open access medical education.

Basic Ultrasound Functionality

An ultrasound machine is always paired with a transducer that is applied to the patient's skin. The transducer contains piezoelectric crystals or a specialized transducer-on-chip that vibrates when electricity is applied to it, generating ultrasound waves typically in the range of 2–15 MHz that are conducted through the body through a coupling medium such as gel [6, 7]. Soft tissue, blood, simple fluid, fat, bone, and air all conduct these ultrasound waves with slightly different velocities and impedance, producing reflections that travel back to the transducer. These reflections are processed by the machine based on how long they take to return, where on the ultrasound array they are heard, how strong they are and their frequency, to produce a 2D representation called a B-mode image (Fig. 47.1a) [7, 8].

Bright or hyperechoic areas of B-mode images represent stronger reflectors of ultrasound waves such as bone. Dark or hypoechoic areas of the image are the result of weaker reflectors. Areas where there are no ultrasound wave reflections, as seen with fluid, are termed anechoic and appear black on the ultrasound screen. The resolution of an ultrasound image is a function of the machine's sensitivity and the frequency used to generate the image. Higher frequency ultrasound waves produce higher resolution images at the cost of decreased depth of penetration, while lower frequency ultrasound can image deeper structures but sacrifices resolution.

Modern ultrasound machines incorporate other functionality. M-mode images such as Fig. 47.1b are formed by taking a single "slice" of a B-mode image and graphing motion within that slice over time and are useful for imaging salient parts of rapidly moving structures, such as the heart [8]. Doppler imaging, so named for the physics concept behind the technology, measures the difference in returned ultrasound frequency to determine the velocity of fluid within the image. Color Doppler imaging (Fig. 47.1c) employs color over a grayscale image to indicate direction of flow within a structure, while spectral Doppler measures precise flow velocities and direction of flow within a structure.

Ultrasound Transducer Selection

Ultrasound transducers vary in their frequency range and the method they use to steer ultrasound waves. Usually, these transducers are marked on one side with a transducer marker, which may be a small notch or coloration. This corresponds to a dot or

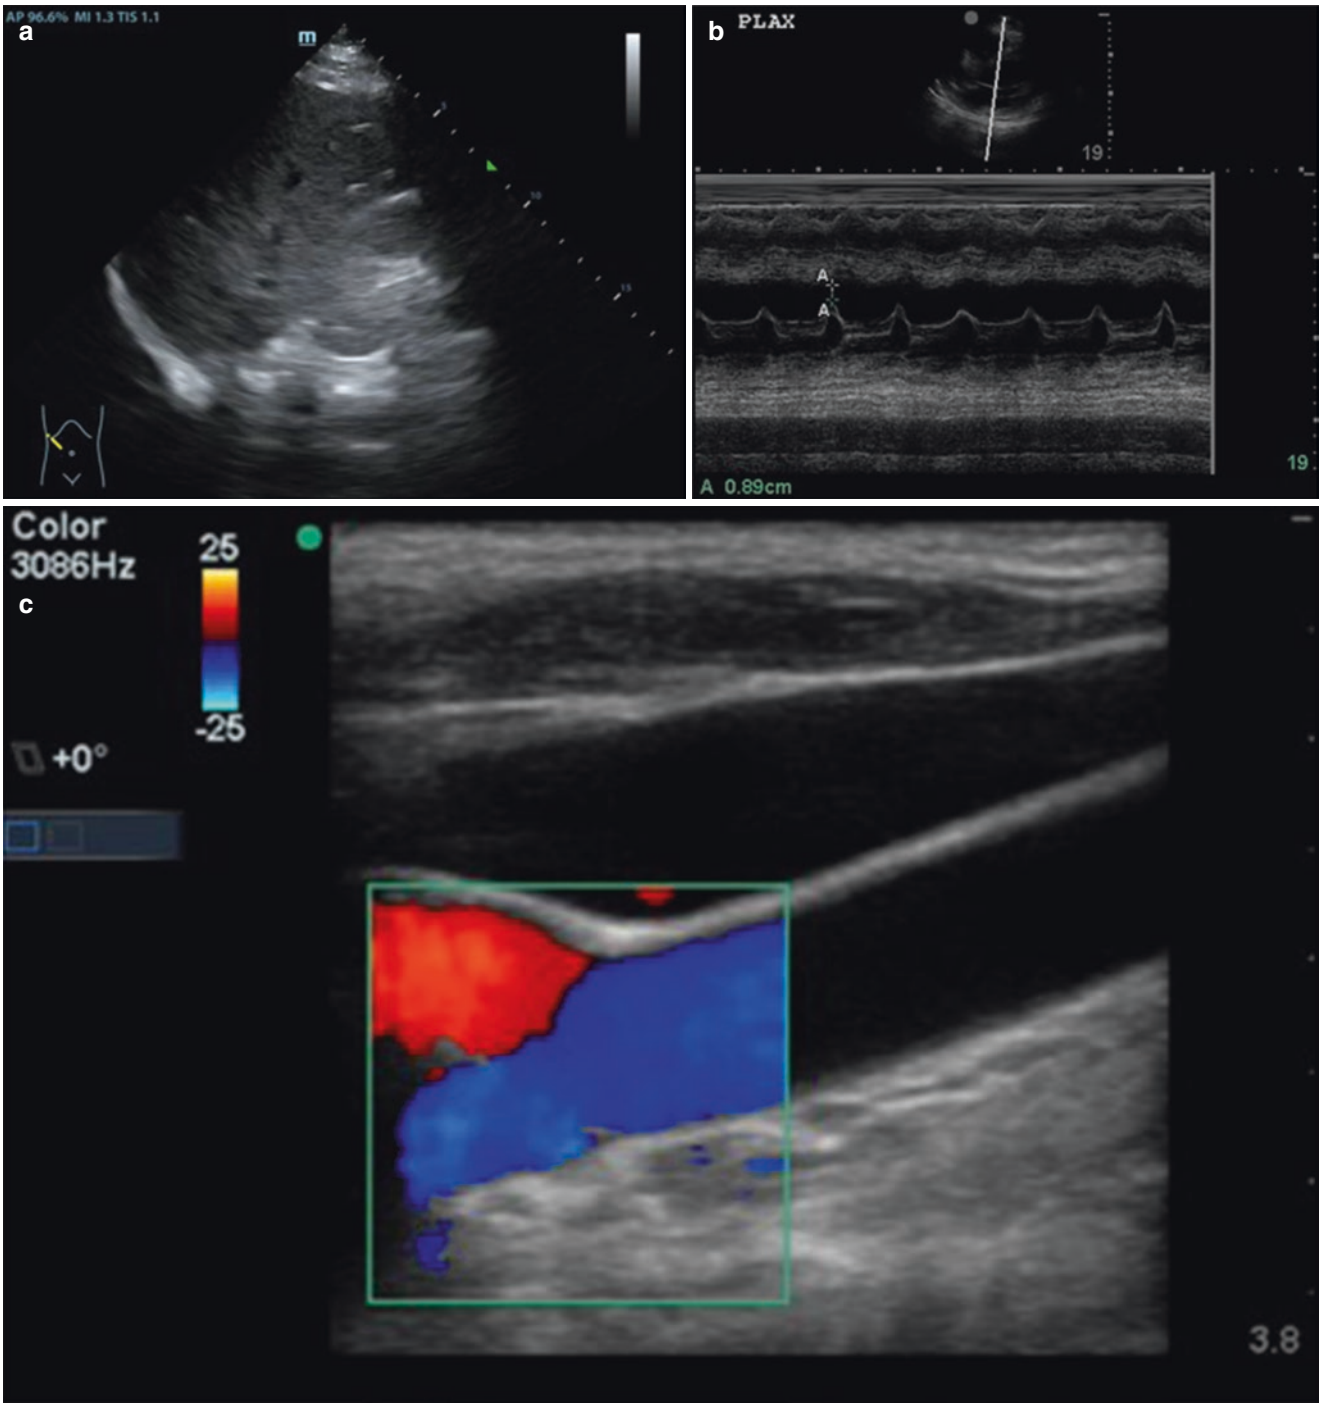

Fig. 47.1 Ultrasound imaging modes. (**a**) B-mode, also called 2D mode on some machines, produces 2D image of echo-producing interfaces of underlying objects. (**b**) M-mode, "motion mode," demonstrates movement of structures over time. All cardiac structures through which the solid white line passes in the top B-mode image are graphed over time in the bottom M-mode image. With this mode, precise measurements can also be made. (**c**) Color Doppler mode shows the direction of blood flow in a color map superimposed on this 2D image of the bifurcation of the common carotid artery

another marker on the ultrasound machine display, allowing the operator to anatomically orient their image on the screen.

Linear array transducers (Fig. 47.2a), as their name implies, use crystals arranged in a line, firing sequentially to produce an image which represents a slice of the overall area being imaged [6]. These high-frequency transducers produce images with excellent resolution but have limited depth of penetration. Consequently, they are primarily used for imaging superficial structures or masses, evaluating veins for thrombosis or for real-time procedural guidance.

Fig. 47.2 Commonly employed ultrasound transducers. (**a**) Linear array transducer (high frequency, 4–12 MHz), (**b**) curvilinear array transducer (low frequency, 1–5 MHz), and (**c**) phased-array transducer (low frequency, 1.5–4 MHz)

Curvilinear arrays are convex-shaped crystal arrays (Fig. 47.2b). Their larger footprint creates a wider field of view, allowing them to evaluate larger organs more easily. These transducers typically have lower frequency output and are suitable for imaging the abdomen, thorax, or deeper extremity structures.

Phased-array transducers (Fig. 47.2c) have a smaller footprint. Instead of using long arrays of crystals, a smaller number of crystals are instead pulsed in specific timing sequences that allow the beam to be steered electronically. These transducers produce pie-shaped images that are similar to curvilinear arrays. A significant advantage of their reduced footprint is that it allows imaging of areas of the body where acoustic windows are limited due to underlying air or bone, most notably in cardiac imaging. Phased-array transducers are also capable of general abdominal and thoracic imaging.

Endocavitary transducers commonly produce midrange ultrasound frequencies and are arranged as a highly convex curvilinear array. In combination with appropriate institutional protocols for high-level disinfection and sterile trans-

ducer covers, these transducers can be used for obtaining intraoral, transvaginal, or transrectal images that can aid in the visualization of certain organs or pathologies.

Adjusting the Ultrasound Image

On most machines, the operator has direct control over the depth, gain, and the imaging preset or resolution. Machines vary in their capabilities for more advanced functionality, such as Doppler imaging, M-mode imaging, zooming, frequency adjustment, or harmonic imaging. Depth has a dedicated control and is indicated to the side of the image by hash marks, and often the maximal depth is displayed numerically next to the image. Gain controls how bright or dark the image appears on the screen and can be adjusted for the entire image at once or can be adjusted at certain depths, depending on the machine's capabilities, a function called time gain compensation (TGC) [7].

Most ultrasound machines have imaging presets, for example, an abdominal, cardiac, or vascular mode. Presets may adjust frequency settings, output power, image post-processing, or the frame rate to help optimize the images displayed.

Safety of Bedside Ultrasound

The amount of ultrasound energy that is imparted during an exam should be minimized in accordance with the ALARA principle. Although ultrasound does not use ionizing radiation, ultrasound waves can induce effects such as cavitation, causing local tissue damage or thermal heating. These effects are displayed by the machine in terms of mechanical index (MI) and thermal index (TI), respectively, usually as unitless numbers. In general, the lowest numbers achievable with the shortest duration of imaging minimize the potential for adverse effects [8]. Tissue heating and mechanical disruption are of most concern for obstetric imaging and for imaging of the eye.

Other safety considerations include infection control, the need for sterile probe cover use during invasive procedures, and guidelines for disinfection of transducers, all of which are usually established by local institutional guidelines and protocols.

Emergency Cardiac Ultrasound

Basic Approach

There are four essential views for transthoracic cardiac ultrasound: the parasternal long axis, the parasternal short axis, the apical four chamber, and the subxiphoid. A small footprint phased-array transducer is used with the cardiac preset and a depth of 16–20 cm. A curvilinear array transducer may be used if the phased-array transducer is not available.

For the parasternal views, the transducer marker is aimed toward the right shoulder or the right hip for the long and short axis, respectively. In the apical four-chamber and the subxiphoid views, the transducer marker is aimed toward patient's right (Fig. 47.3). Cardiac visualization may be improved by placing the patient in the left lateral decubitus position and instructing the patient to hold their breath after exhaling. The subxiphoid view may be improved by having the patient flex their hips and knees and inhale slightly.

Pericardial Effusion and Cardiac Tamponade

Ultrasonography is the imaging modality of choice for detecting pericardial effusions and tamponade, common abnormalities found in oncologic patients, which may be a consequence of the underlying cancer diagnosis [9] or secondary to chemotherapy [10, 11]. In the normal heart, the pericardium appears as a hyperechoic outline of the more hypoechoic myocardium. A pericardial effusion appears between these two layers [12, 13]. An effusion with simple fluid typically appears as an anechoic stripe (Fig. 47.4; see Fig. 47.4b). However, complex malignant, exudative, or hemorrhagic effusions may have hyperechoic portions or contain septations.

The pericardial fat pad may mimic a small pericardial effusion. Frequently, this more solid component appears to contain internal echogenicity and moves with the epicardium to which it is attached in time with the cardiac cycle. Multiple cardiac views may be necessary to differentiate pericardial fat from an effusion [12].

Pericardial effusion is best detected in the subxiphoid and parasternal views by interrogating the most dependent potions of the pericardial sac where fluid is expected to collect first. The most dependent area in the subxiphoid view lies anterior and adjacent to the right ventricle and, in the parasternal views, lies along the posterior aspect of the pericardial sac, just anterior to the descending thoracic aorta (see Fig. 47.4b) [13]. In the apical view, fluid may appear anywhere circumferentially. While fluid in the pericardial sac preferentially collects in the most dependent area, in complex malignant, exudative, or hemorrhagic effusions, fluid may defy this rule and collect in nondependent areas.

Cardiac tamponade is a crucial diagnosis as it is a potentially reversible cause of shock. POCUS allows the real-time visualization of the effects of increased intrapericardial pressure on the heart. The right side of the heart typically

Fig. 47.3 Transducer placement for cardiac views. (**a**) Parasternal views, transducer normally placed in the fifth intercostal space to the left of the sternum. For the parasternal long-axis view, the transducer marker is oriented to the right shoulder, and for the short-axis view, it is rotated 90° to the right hip. (**b**) Apical view, with the transducer marker to the patient's right, typically placed at the midclavicular line at the level of the nipple line or at the mammary fold in female patients. (**c**) Subxiphoid view, with the transducer marker to the patient's right, transducer placed under the xiphoid process, aimed slightly to the left hemithorax

has the lowest intracardiac pressure and thus is affected first. The right ventricle (RV) and right atrium (RA) are best visualized in the apical four-chamber or subxiphoid views [12, 14]. Inversion of the RA occurring during systole (Fig. 47.5a), when atrial filling should occur, is the most sensitive, though least specific, sign of cardiac tamponade. As pericardial pressure increases, RV free wall inversion (RVI) can be noted during diastole (Fig. 47.5b) [12, 14]. M-mode imaging is of utility, as most patients with tamponade are tachycardic, making visual detection of signs of tamponade challenging. By positioning the cursor through the mitral valve (MV) leaflets and the RV free wall (Fig. 47.5c), diastole can be identified as the portion of the cardiac cycle when the MV leaflets are open and concurrent RVI may be detected (Fig. 47.5d).

In tamponade, elevated central venous pressure results in a dilated IVC that has minimal respirophasic variation.

In the rapidly deteriorating patient, derangement of vital signs may preclude in-depth cardiac examination, and a finding of pericardial effusion with clinical symptoms of tamponade should prompt emergent intervention by the clinician.

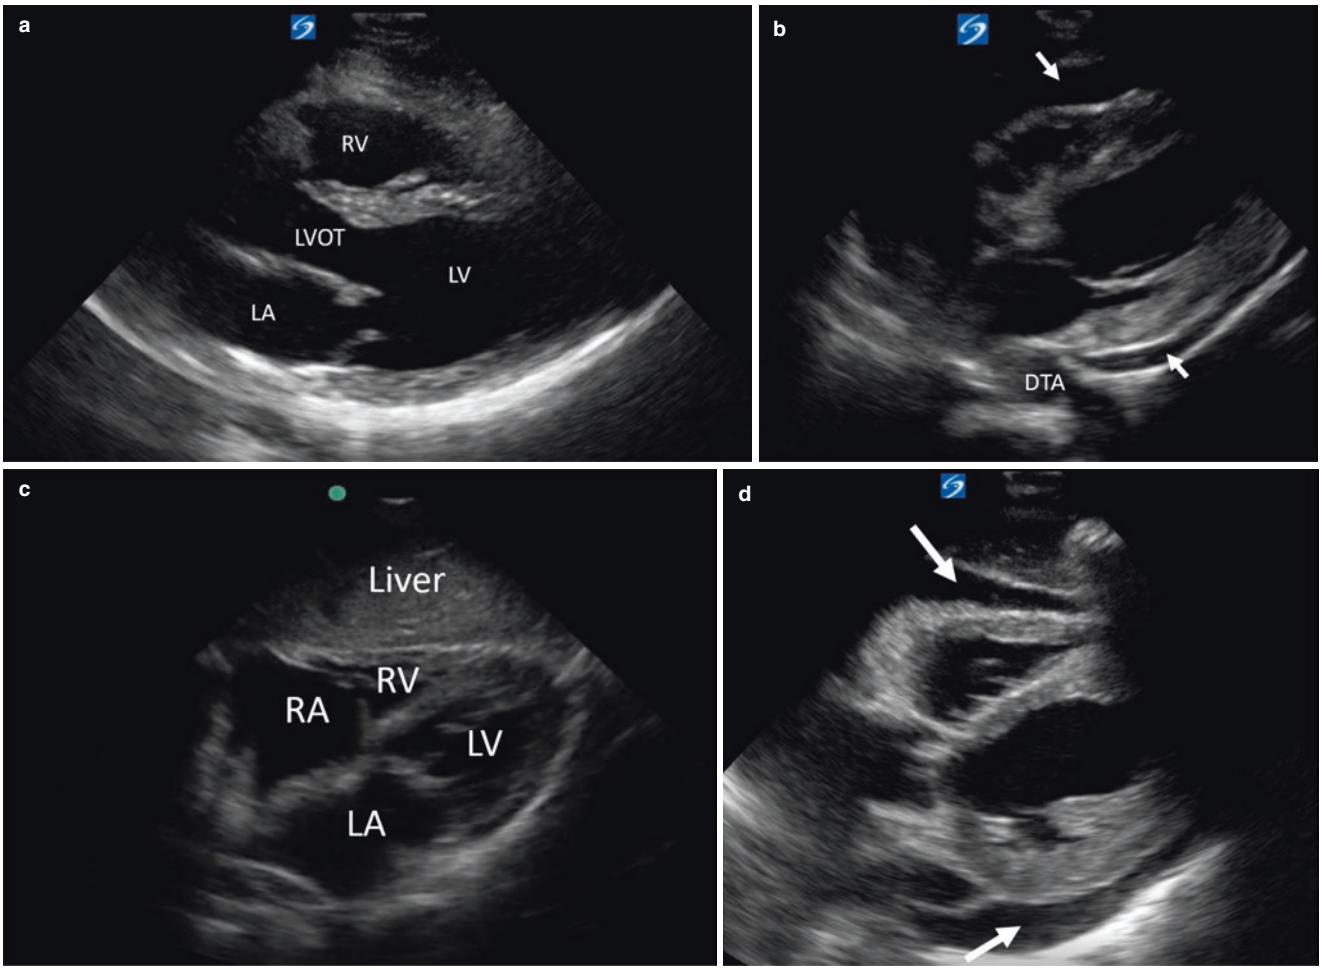

Fig. 47.4 Parasternal and subxiphoid views of the heart. (**a**) Normal parasternal long-axis view. (**b**) Parasternal long axis with circumferential pericardial effusion (*arrows*). (**c**) Normal subxiphoid view. (**d**) Subxiphoid view with effusion (*arrows*). LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; RA, right atrium; RV, right ventricle; DTA, descending thoracic aorta

Left Ventricular Function

Left ventricular systolic function can be rapidly estimated by a bedside echocardiogram. In the normal left ventricle (LV), there is simultaneous inward movement and thickening of the ventricular septal and free walls during systole (Fig. 47.6). Dilation, myocardial thinning, and poor contractility may all be observed in heart failure. Various methods of measuring the LV cavity size are known; however, visual estimation of the LV systolic function by emergency physicians skilled in bedside ultrasound has been shown to be comparable in performance to advanced measurements and estimation by cardiologists [15].

In patients without LV systolic impairment or MV disease, the MV opens briskly during early diastole, and the anterior leaflet, easily seen on the parasternal long-axis and apical views, moves toward the septal wall. The point at which the anterior MV leaflet is the closest to the septum is called the E-point, and the distance between the anterior MV leaflet and the septal wall is the E-point septal separation (EPSS). An EPSS of greater than 7 mm is highly sensitive for decreased LV systolic function, and in general the greater the EPSS, the worse the LV ejection fraction (LVEF) [16, 17]. The use of EPSS as an indicator of LV systolic function has not been validated in patients with valvular disease of the mitral or aortic valves, where impaired valve mobility may lower EPSS independent of LV function.

Right Ventricular Strain

Pulmonary embolus (PE) is one of the leading complications of malignancy and remains high on the differential of the cancer patient presenting with acute chest pain, shortness of breath, or hypotension. Massive or sub-massive PEs are a cause of obstructive shock and rapid decompensation [18].

With POCUS, the RV is best evaluated in the apical four-chamber view. RV dilation is variably defined; however, a

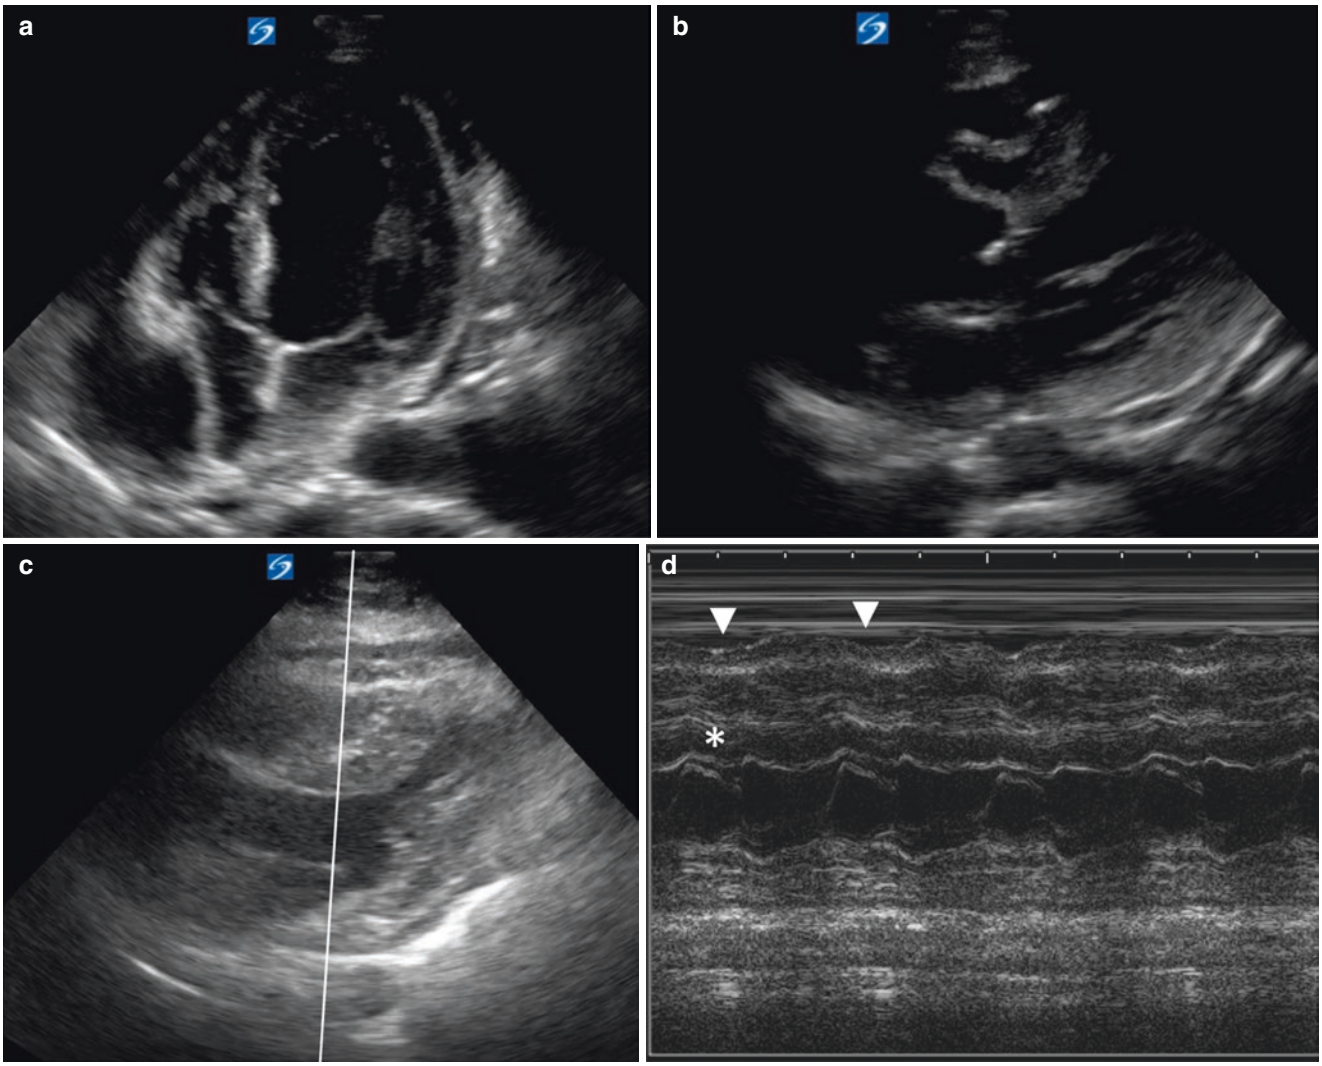

Fig. 47.5 Echocardiographic signs of tamponade. (**a**) Right atrial inversion (RAI) seen during systole (MV closed) in the apical four-chamber view, a more sensitive but less specific sign. (**b**) Diastolic right ventricular inversion (RVI), a more specific sign of cardiac tamponade. (**c**) M-mode through the anterior mitral valve leaflet and RV outflow tract in the parasternal long-axis view, with (**d**) showing the resulting M-mode tracing. When the MV is open (*) in diastole, there is inward movement of the RV free wall (*arrowhead*)

ratio of RV/LV >0.9 is considered abnormal [19, 20]. In the normal parasternal short-axis view, the LV has a uniform circular shape, with the septum pushed outward into the RV due to the higher chamber pressure within the LV relative to the RV.

In the setting of RV strain, there is dilation of the right ventricle. The increasing pressure within the RV can manifest as septal flattening, where the normal curvature of the septum into the RV is lost. This finding is known as the "D-sign" on the parasternal short-axis view and will initially be seen in diastole but progress to be present throughout the entire cardiac cycle (Fig. 47.7; see 47.7a). On the apical four-chamber view, RV free wall hypokinesis with relatively preserved apical motion, a finding known as McConnell's sign, may be seen [21]. Anterior movement of the tricuspid annulus during RV systole, a measurement known as tricuspid annular plane of systolic excursion (TAPSE), is a good surrogate for RV systolic function in the typical adult heart (Fig. 47.8) [22]. This can be measured using an M-mode cursor through the junction of the tricuspid annulus and the RV free wall. In general, an abnormal TAPSE is <17 mm [22], and in confirmed PE, TAPSE <15 mm confers increased risk of mortality or need for thrombolysis [19, 20]. Interrogation of the IVC may reveal dilation without respirophasic variation, suggestive of increased central venous pressure.

Measurement of the Inferior Vena Cava

The inferior vena cava (IVC) can be seen from a subcostal approach as it courses posterior to the liver before passing above the diaphragm. From a subxiphoid view of the heart,

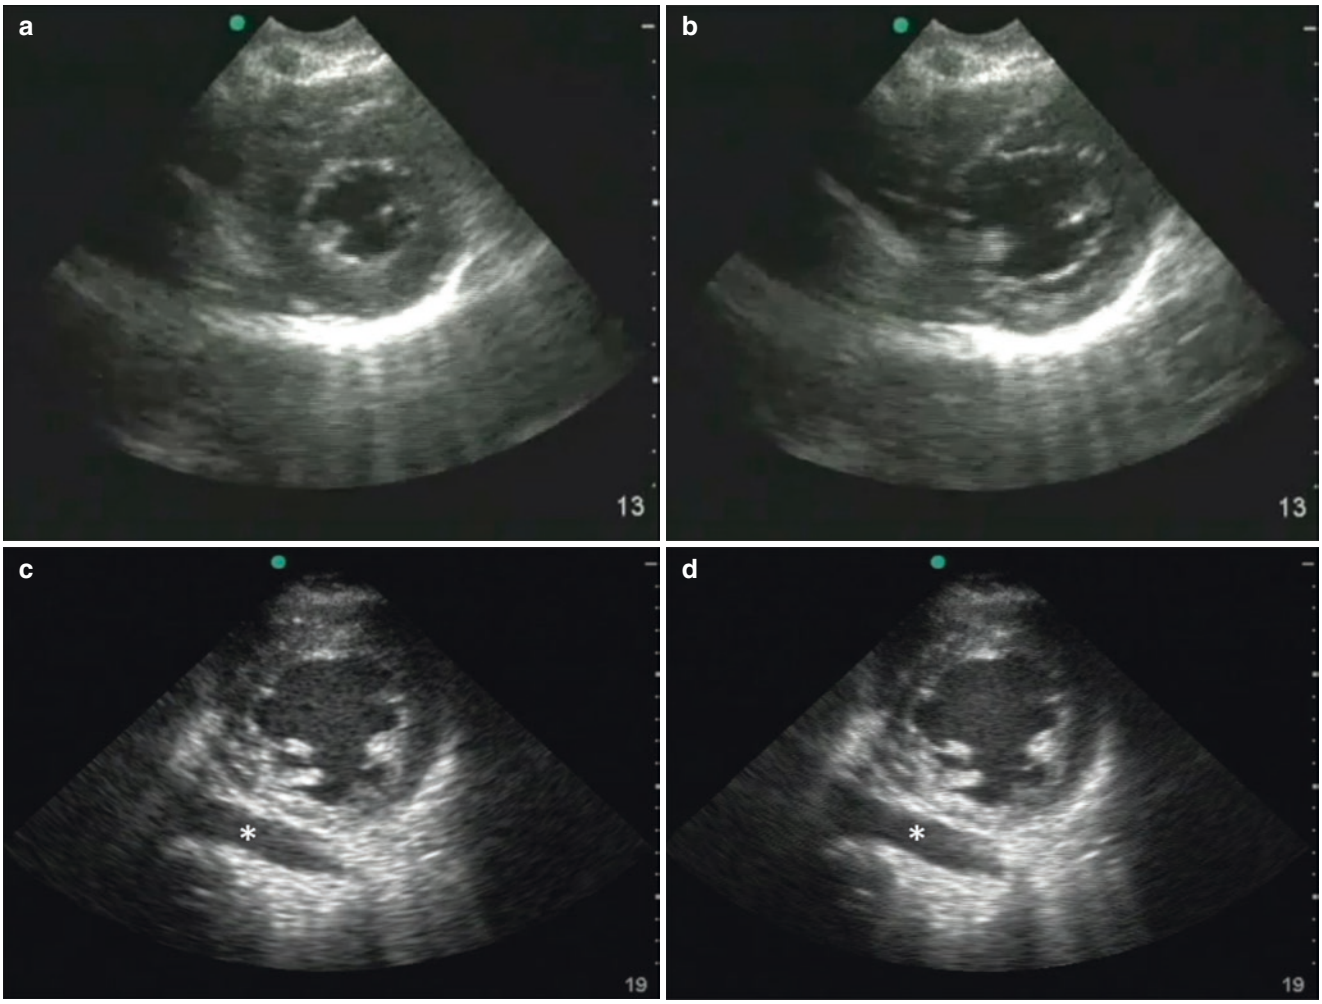

Fig. 47.6 Left ventricular ejection fraction evaluated in the parasternal short axis. (**a**, **b**) End systole and end diastole in a normal heart. (**c**, **d**) End systole and end diastole, with markedly reduced wall contraction resulting in little to no change in the left ventricular size. (*) Small left pleural effusion

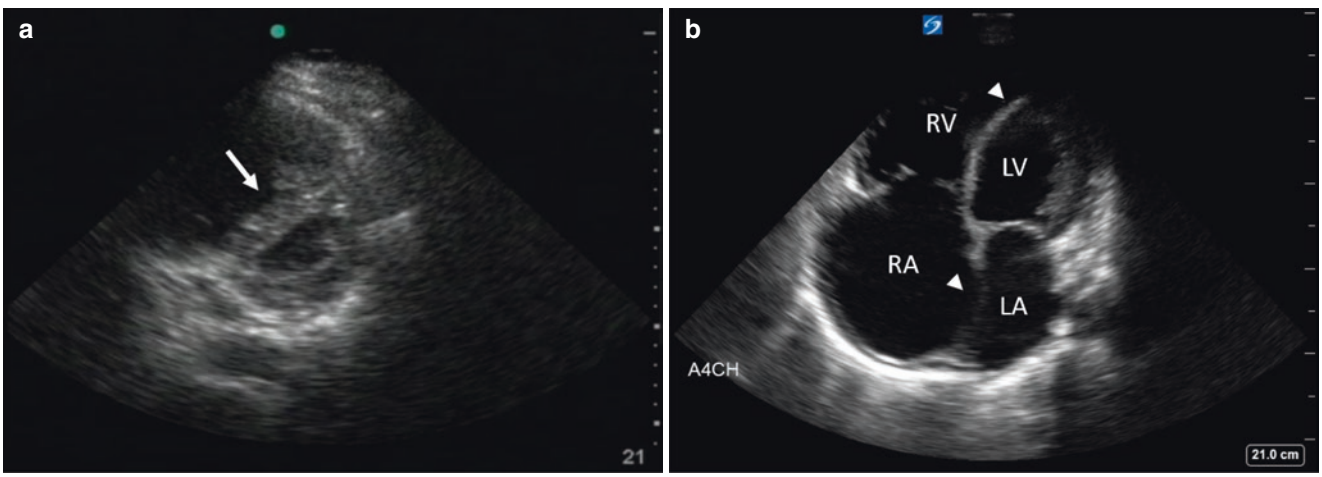

Fig. 47.7 Elevated RV pressure resulting in echocardiographic changes. (**a**) The "D-sign": RV strain produces septal flattening (*arrow*) on the parasternal short-axis view, which results in a loss of the typical cylindrical shape of the LV. (**b**) RV and RA dilation in the setting of elevated right heart pressures. In end diastole, the RV cavity size measured near the base is larger than the LV size, and the septum is pushed toward the left heart (*arrowheads*)

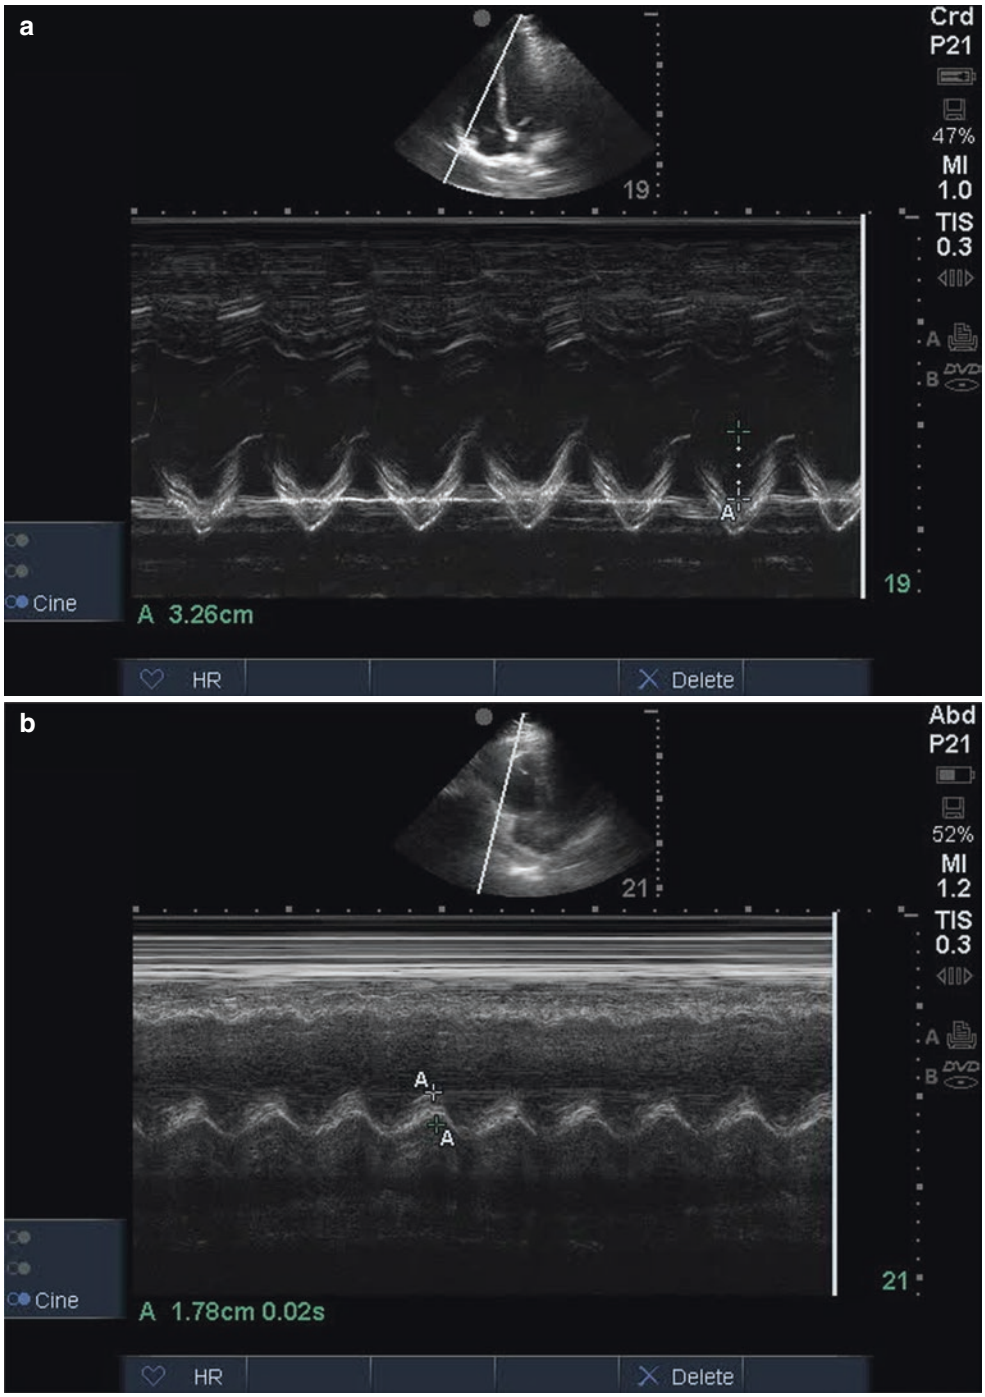

Fig. 47.8 Tricuspid annular plane systolic excursion (TAPSE) measurement. The M-mode cursor is positioned through the junction of the tricuspid annulus and RV free wall in the apical four-chamber view. The resulting M-mode tracing is measured peak to trough. (**a**) Normal TAPSE (32 mm). (**b**) Decreased TAPSE in a patient with acute right heart strain (17 mm)

the transducer should be fanned posteriorly until the IVC is identified near its junction with the right atrium. The transducer can then be turned to a long-axis view with the transducer marker cephalad. Direct visualization of the IVC in the supine, spontaneously breathing patient, assuming there is no IVC obstruction or altered anatomy, correlates to a limited extent with the central venous pressure (CVP) or right atrial pressure (RAP). Respirophasic variation in the IVC size is due to changes in intrathoracic pressure caused by the respiratory cycle.

CVP or RAP can be inferred either from the maximal IVC size (IVCmax; measured inferior to the hepatic vein) or from the percent change in size with inspiration $\left(\frac{IVCmax - IVCmin}{IVCmax}\right)$, also known as collapsibility index (CI). Significant heterogeneity in research methods used by studies to correlate CVP to IVCmax or CI exists, though guidelines suggest that IVCmax >2.1 cm with CI < 0.50 (with sniffing maneuver) suggests an approximate RAP of 15 mmHg [22, 23]. More qualitatively, a dilated IVC with

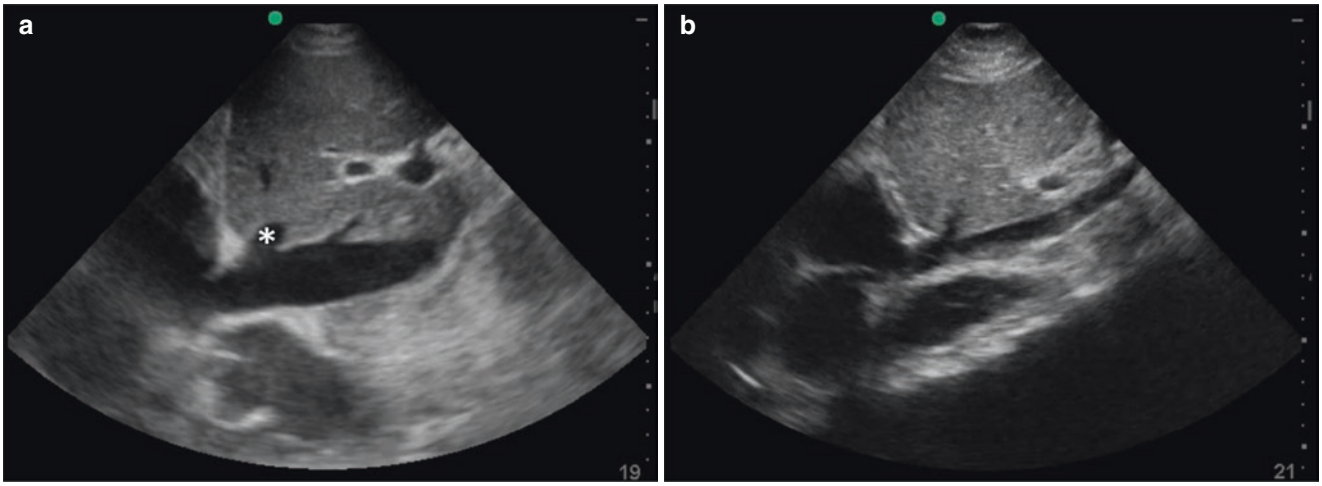

Fig. 47.9 Measurement of the inferior vena cava in the subcostal view. The liver overlies the IVC, and typically the hepatic vein can be seen emptying into the IVC (*). (**a**) Dilated IVC measuring greater than 2 cm, with low respiratory phasic variation (almost no collapse with inspiration) and thus a low collapsibility index (CI). The CVP in this patient is likely elevated. (**b**) Small IVC with CI of greater than 0.50, suggesting normal CVP

little respiratory variation may be seen in obstructive pathologies such as cardiac tamponade, pulmonary hypertension/PE, RV failure, or tension pneumothorax (Fig. 47.9).

Thoracic and Pulmonary Oncologic Emergencies

POCUS allows medical providers to perform real-time, bedside evaluation of undifferentiated oncologic patients with respiratory symptoms in the emergency department. It is rapid, reproducible, and often more sensitive and specific than a radiograph.

Lung ultrasound can be performed with any of the commonly accessible transducers – curvilinear, phased-array, or linear – and selection will depend on the specific application as well as provider preference. For most applications, a low-frequency curvilinear or phased-array transducer is best suited for detecting oncologic emergencies. Conventionally, the transducer marker is either oriented to the patient's right or toward their head. The exam mode should utilize the "pulmonary" or "lung" preset, and the depth of the image should be set to at least 18 cm. If a "lung" preset is not available, an "abdominal" preset is appropriate.

Zones of the Lung

Each hemithorax is divided into four distinct areas, for a combined eight zones on the anterolateral chest (Fig. 47.10). The lung assessment should be performed in a systematic and comprehensive manner. With the patient

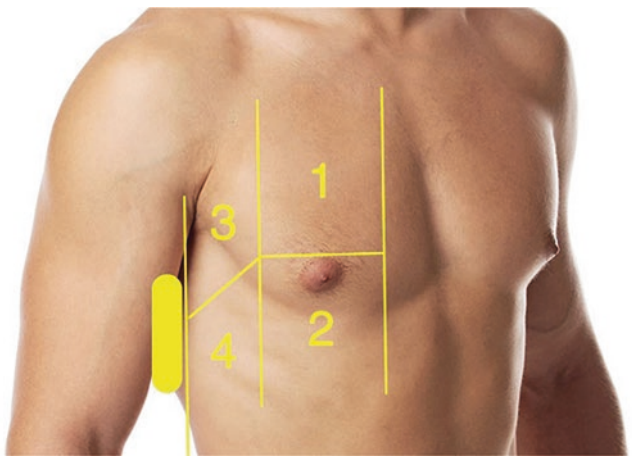

Fig. 47.10 Each hemithorax is divided into four distinct areas, for a combined eight zones on the anterolateral chest. Each field should be interrogated as part of the lung ultrasound exam. The PLAPS point (posterolateral alveolar and/or pleural syndrome) is the area where most pneumonias and consolidations will be visualized

supine or semi-recumbent, each hemithorax should be imaged in a sagittal orientation, with the transducer marker toward the patient's head. Landmarks include the pleural line (parietal and visceral pleura) and the lung parenchyma flanked by the ribs and their corresponding posterior acoustic shadowing. The angle of insonation should be manipulated to optimize the clarity of the pleural line (Fig. 47.11). Experts also recommend imaging the posterolateral alveolar and/or pleural syndrome (PLAPS) point, where most pneumonias and consolidations will be visualized [24, 25].

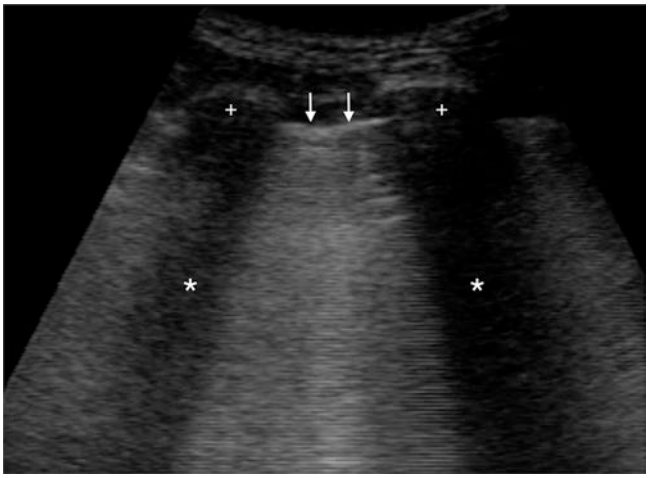

Fig. 47.11 The pleural line (*arrows*) appears as a bright hyperechoic line separating the superficial soft tissue from the lung parenchyma. The pleural line is flanked by hyperechoic ribs (+) with posterior acoustic shadowing (*). Utilizing an angle of insonation perpendicular to the pleural line will improve visualization of relevant findings. Lung sliding appears as a shimmering artifact at the pleural line and corresponds with the respiratory cycle

Lung Artifacts (A-Lines and B-Lines)

In normally aerated lung, there are linear, echogenic, horizontally oriented reverberations generated from the pleural line. These reverberation artifacts are called A-lines [26–28]. While A-lines are seen in normal lung, they are also seen in the setting of lung pathology such as chronic obstructive pulmonary disease (COPD), asthma, and pneumothorax. In contrast, B-lines are hyperechoic, discrete, vertical beams of artifact that generally obliterate A-lines, extend to the bottom of the screen, and move in synchrony with the patient's pleural line [26, 27]. B-lines represent increased density in the lung parenchyma and, depending on the clinical context, can be diagnostic of multiple pathologies relevant to malignancy, including tumor, pneumonia, pneumonitis, lung infarction, and fibrosis, among others (Fig. 47.12).

Diffuse Interstitial Syndrome

Looking in each of the eight scanning zones, a zone is positive if it has three or more B-lines at any point in a respiratory cycle. The presence of two or more positive zones, on both hemithoraces, is consistent with diffuse interstitial syndrome (DIS) [26, 27].

In general, DIS is most often due to cardiogenic pulmonary edema in the setting of heart failure (HF). One study showed that the combination of LVEF <45%, a distended non-collapsible IVC, and presence of DIS is 100% specific for the diagnosis of acute decompensated HF [29]. However, it is important to note that this is not always the case as DIS itself is nonspecific and may represent other causes of dyspnea. In cases of DIS where the triad above are not found, one should consider other causes such as HF with preserved LVEF, acute respiratory distress syndrome (ARDS), pulmonary fibrosis, diffuse parenchymal lung disease, pneumonitis secondary to chemotherapeutic agents, or multifocal pneumonia secondary to immunocompromised state. Additionally, the presence of unilateral or focal B-lines may also indicate any of the following: pneumonia, atelectasis, mass, or infarctions (mostly due to pulmonary embolism). As with all POCUS, integration of the entire clinical picture by the operator improves the accuracy of the diagnosis.

Consolidation

Patients with malignancy are often on chemotherapeutic agents and medications that cause immunocompromised state, putting them at higher risk for infection. Oncologic patients presenting with dyspnea are at high risk for pneumonia, which account for approximately 10% of their hospital admissions, with rates as high as 30% in patients with hematologic malignancies [30]. Additionally, prior surgeries, radiation, infections, or compressive masses can cause recurrent post-obstructive pneumonia due to the patient's inability to clear static secretions in bronchi and alveoli distal to the obstruction. This leads to atelectasis and subsequent microbial colonization, infection, and consolidation [30].

Pneumonia occurs on a spectrum, depending on how much of the aerated lung is replaced with fluid, pus, or increased density. This can progress between various degrees of focal B-lines, atelectasis, subpleural consolidation, and, ultimately, *hepatization* (lung taking on a tissue-like appearance of solid organs, Fig. 47.13). The presence of subpleural consolidation is demonstrated as an irregular pleural line with hypodensities adjacent and just deep to it and may indicate an infectious process (this finding is known as the *shred sign*, Fig. 47.14). The presence of *static* and/or *dynamic air bronchograms* can help distinguish between atelectasis and pneumonia. Static air bronchograms are caused by the air that remains within the bronchi in a consolidative process and appear as nonmobile hyperechoic lines extending out to the periphery of the lung signifying complete bronchial obstruction. Static air bronchograms may be seen in resorptive atelectasis and pneumonia and, therefore, cannot be used to differentiate these pathologies (see Fig. 47.13). Dynamic air bronchograms are caused by hyperechoic air moving toward the periphery of the lung with inspiration [31]. Dynamic air bronchograms have a 94% specificity and a 97% positive predictive value for diagnosing pneumonia and distinguishing it from resorptive atelectasis [31].

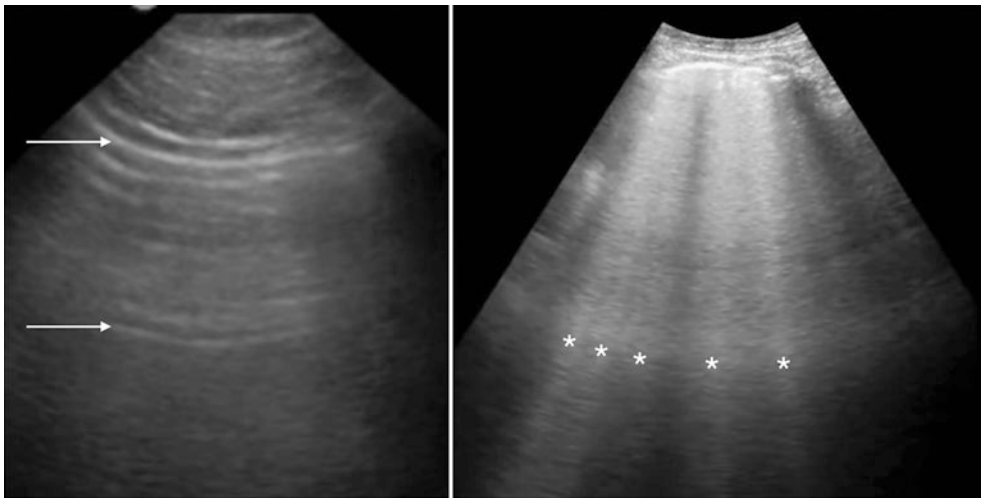

Fig. 47.12 A-lines are linear, equidistant, echogenic, horizontally oriented reverberation artifacts generated from the pleural line (*horizontal arrows*). B-lines result from increased density in the lung parenchyma and are hyperechoic, discrete, vertical beams that extend from and move with the pleural line, reaching a depth of 18 cm. B line artifacts (*) generally obliterate A-lines

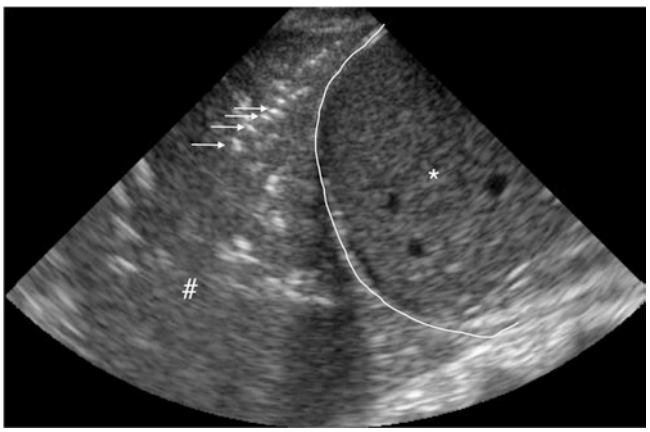

Fig. 47.13 Hepatization (#) represents highly consolidated lung parenchyma. It has similar echogenicity to the liver (*). The liver and consolidated lung are separated by the diaphragm (line). Within the consolidation, one can see static and/or dynamic air bronchograms (*arrows*)

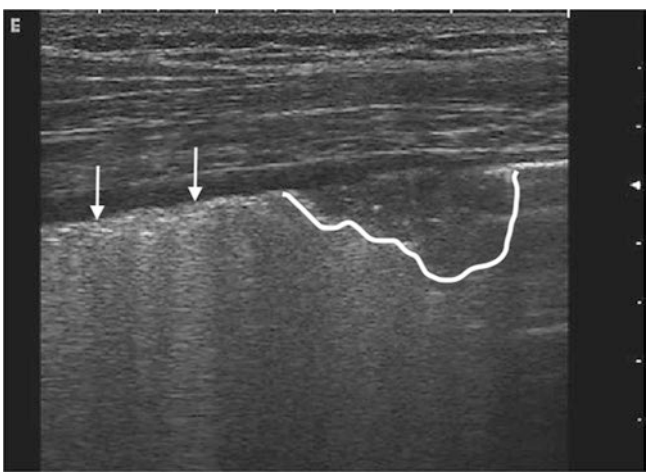

Fig. 47.14 Subpleural consolidation (*outlined*) is demonstrated as an irregular pleural line with subpleural hypodensities. It may indicate an infectious process. A normal pleural line (*arrows*) is also demonstrated here

Pleural Effusions

Pleural and parapneumonic effusions are common causes of dyspnea and chest pain in oncologic patients and have a significant effect on quality of life, often requiring frequent visits to the emergency department and procedures (i.e., thoracentesis) to help manage symptoms. While chest radiographs are traditionally used to diagnose effusion, POCUS is much more sensitive and specific, reliably identifying effusions as small as 20 mL, and is 100% sensitive for effusions >100 mL [32]. Pleural effusions are diagnosed by noting the absence of the mirror artifact (the echogenic reflection of the liver or spleen above the diaphragm) and by visualizing the spine sign (thoracic vertebral bodies extending cephalad past the diaphragm), which is approximately 93% sensitive and specific for detecting non-trace pleural effusions (Fig. 47.15) [33]. Effusions can be simple and anechoic, or complex and heterogeneous, sometimes mimicking consolidations or malignant effusions. POCUS can help distinguish whether the effusions are unilateral, bilateral, loculated, diffuse, simple, or complex. One study showed that ultrasonographic characteristics could help distinguish between transudative and exudative effusions. In this paper, they showed that transudates were *always* anechoic, whereas effusions with complex septated, complex non-septated, or homogeneously echogenic patterns were *always* exudative [34]. Additionally, POCUS can help identify relevant anatomy to help guide thoracentesis for recurrent malignant effusions and decreases the rate of pneumothorax from approximately 30% (landmark-based approach) to less than 3% [35].

Pleural Disease

The pleural line is best evaluated using the linear transducer, allowing for better resolution of the superficial structures.

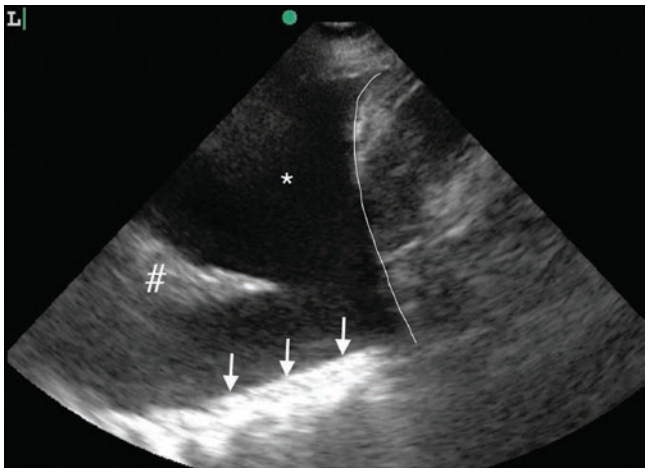

Fig. 47.15 This image shows an anechoic pleural effusion (*). Pleural effusions most commonly appear as anechoic collections above the diaphragm (line). Additional findings include absence of the mirror artifact (the echogenic reflection of the liver or spleen above the diaphragm) and the spine sign (visualization of thoracic vertebral bodies extending cephalad past the diaphragm) (*arrows*)

Normal pleura is smooth, hyperechoic, and thin (no more than 3 mm) [32]. The parietal and visceral pleura generally cannot be distinguished unless there is pathology present. Thickening can be caused by multiple etiologies, including infection and malignancy. Parietal pleura thickening >10 mm is predictive of malignancy [32]. Diffuse pleural irregularities are likely due to generalized processes like pulmonary fibrosis or pneumonitis, which may indicate an adverse reaction to chemotherapeutic agents in oncologic patients.

Pneumothorax

In patients with malignancy, iatrogenic causes (e.g., thoracentesis, biopsy, surgery) and the malignancy itself can cause pneumothorax. Approximately 10% of these patients will go on to have a malignancy-associated secondary spontaneous pneumothorax which is associated with increased morbidity and mortality [36].

POCUS is far superior to physical exam and chest radiograph for identifying pneumothoraces [37]. Pneumothoraces can be identified fairly quickly and easily with POCUS by placing a high-frequency linear transducer on the most superior portion of the anterior chest, with the transducer marker toward the head. Both sides of the chest should be evaluated. Start by looking for evidence of lung sliding between the parietal and visceral pleura. The appearance of lung sliding on ultrasound is best described as a "shimmering" of the pleural line or "ants crawling" along the pleural line and is produced by the apposed movement of the parietal and visceral pleura. Additionally, the presence of B-lines or comet tails at the pleural line is highly sensitive for ruling out pneumothorax [26, 27, 38]. The presence of lung point is the most specific (near 100%) for diagnosing pneumothorax [37].

Abdominal Oncologic Emergencies

Approximately 40% of cancer patients present to the emergency department with gastrointestinal symptoms [39]. POCUS can help evaluate for some of the more common pathologies.

Malignant Bowel Obstruction

Malignant bowel obstruction (MBO) usually results from mechanical obstruction caused by tumor burden, radiation-induced fibrosis, adhesive disease, or dysfunctional bowel motility. The incidence of MBO is approximately 3–15% of all patients with advanced cancer and occurs at all levels of the GI tract – gastric outlet, small bowel (most frequent), and large bowel [39].

In the supine position, a low-frequency curvilinear or phased-array transducer is used to scan the abdomen in both the transverse and sagittal planes, moving up and down the abdomen in the systematic lawn-mower pattern from one lower quadrant to another. The presence of a small bowel obstruction (SBO) is detected by identifying dilated (>2.5 cm, most sensitive), noncompressible, loops of bowel with the presence of back-and-forth movement of intraluminal contents (most specific, Fig. 47.16). Additional evidence of a bowel obstruction can be indicated by an increase in bowel wall thickness (>3 mm) or the presence of localized intraperitoneal free fluid tracking between the loops of bowel (*tanga sign*). POCUS is between 91–98% sensitive and 93–98% specific, for the diagnosis of SBO when performed by providers with minimal training [40, 41]. Large bowel obstruction has similar features but is generally dilated to >5.0 cm.

Ascites and Perforation

One of the most common complications that providers will encounter will be the presence of malignant ascites or free fluid in the abdomen – usually secondary to hepatobiliary, gynecologic, or metastatic malignancies. Specific views include the space between the liver and kidney (hepatorenal space or Morison's pouch), the area around the spleen (perisplenic space), and the area around and behind the bladder (retro-vesicular/rectovaginal space or pouch of Douglas) – these are components of the well-known FAST exam (focused assessment with sonography in trauma) [28]. A dark or anechoic area in any of these three potential spaces

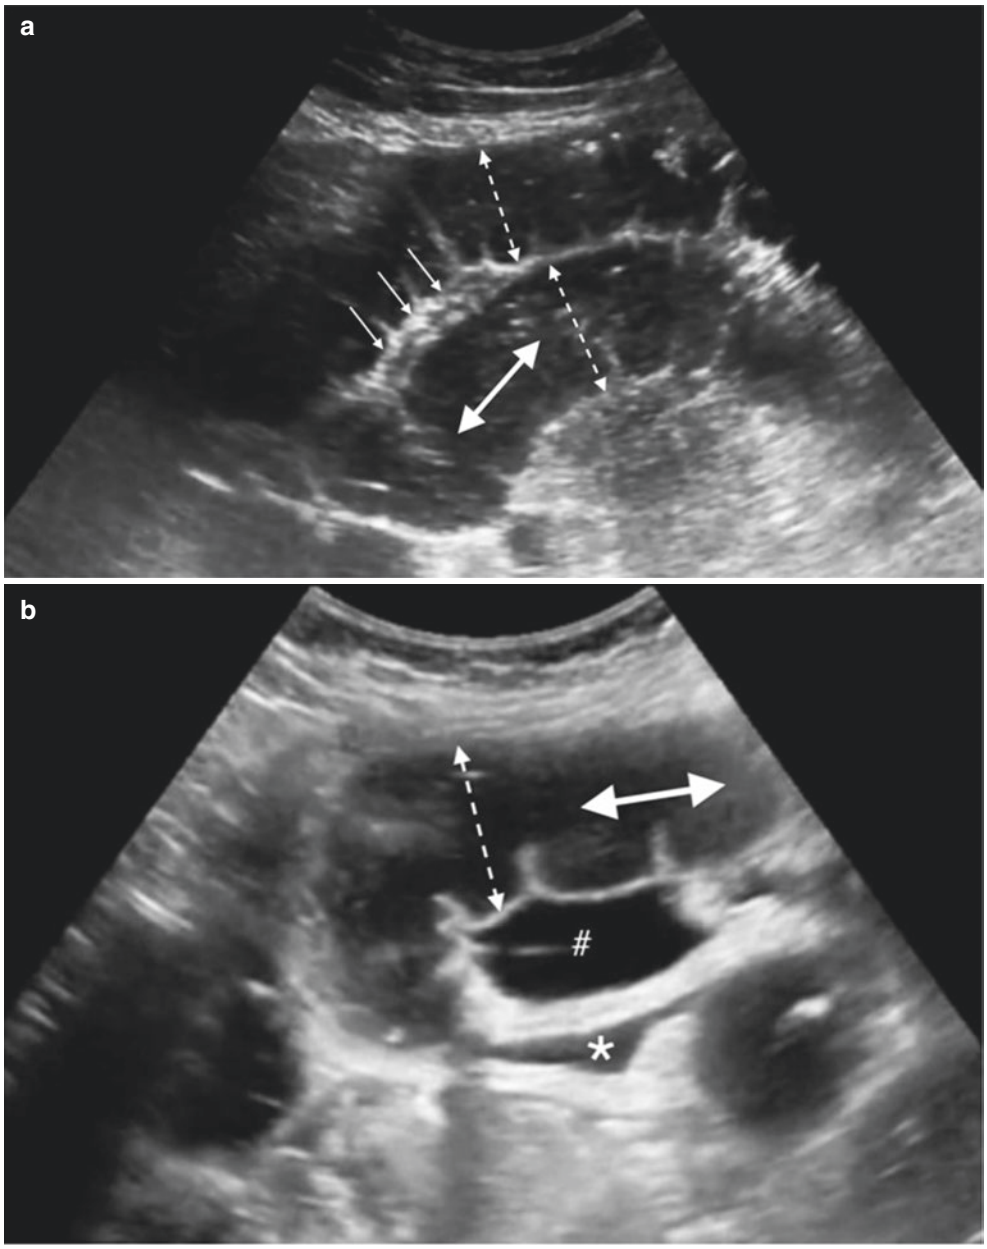

Fig. 47.16 Examples (**a**) and (**b**) of a small bowel obstruction (SBO). An SBO is detected by identifying dilated (>2.5 cm, most sensitive, double-headed dashed line), noncompressible loops of bowel with the presence of intraluminal contents without visible forward movement with peristalsis ("to-and-fro peristalsis," most specific, *solid double-headed arrow*). Additionally, increased bowel wall thickening, >3 mm (small *arrows*) (**a**), and localized free intraperitoneal fluid (#) or fluid tracking between the distended loops ("tanga sign") may also be seen (*) as in (**b**)

indicates free intraperitoneal fluid, which may represent ascites, blood, or bowel contents, depending on the clinical picture. Similar to thoracic pleural effusions, ascites fluid may be simple, complex, infectious, loculated, or debris filled. Again, a low-frequency curvilinear or phased-array transducer is generally used to interrogate for free fluid within the abdomen. With the patient supine, and with the transducer marker toward the head, the transducer is placed on the right and left flanks, approximately at the ninth/tenth intercostal space and angled in a slightly oblique angle to insonate between the rib spaces. This provides a view of the right and left hemi-abdominal potential spaces [28]. The final portion is the pelvic view, which is generally performed in both the transverse and sagittal planes, interrogating the retro-vesicular space in men and the rectovaginal space/pouch of Douglas in women [28]. The FAST exam has been reported to detect intraperitoneal fluid collections as small as 100 mL, with a median range of 250–620 mL commonly cited. The overall sensitivity and specificity of the FAST exam have been reported to be approximately 79% and 99%, respectively [42]. Similar to thoracentesis, ultrasound-guided paracentesis has been associated with a 68% decrease in bleeding complications when obtaining samples to better characterize the intra-abdominal fluid [35].

Immunocompromised oncologic patients are at increased risk for bowel perforation due to local infiltration, vascular

occlusion, or increased pressures from obstructive processes causing ischemia and necrosis of the intestinal wall [39]. Additionally, opportunistic infections such as cytomegalovirus, chemo-/radiotherapy, and steroids have been linked with spontaneous perforation [39]. In perforation, complex free fluid that is heterogeneous and echogenic may be visualized outside the luminal walls of the intestinal tract.

Colitis

Despite the benefits of new cancer treatments, many novel therapies including immune checkpoint inhibitors can lead to autoimmunity and immune-related adverse events resulting in significant morbidity [39]. Autoimmune processes, including graft-versus-host disease, and opportunistic gastrointestinal infections (e.g., cytomegalovirus or *Clostridium difficile*), can all lead to colitis. Neutropenic enterocolitis (NEC) is a common presentation of abdominal pain in oncologic patients, representing a spectrum of disease, which includes typhlitis, caused by inflammation of the gastrointestinal tract. Chemotherapy and neutropenia weaken the mucosal barrier allowing bacterial translocation across the intestinal wall, mucosal damage, intestinal hemorrhage, transmural necrosis, and local infiltration. NEC can mimic an acute surgical abdomen and is considered a diagnosis of exclusion. Ultrasound may help detect NEC by identifying bowel wall thickening (BWT). Clinically, the presence of BWT is associated with increased duration of symptoms and mortality [43]. Generally accepted criteria for diagnosis include BWT >4 mm (transverse scan) in any segment of the bowel for >3 cm in length (longitudinal scan) [44]. BWT >10 mm is associated with more severe disease and increased mortality [43]. The three mural layers of the gastrointestinal tract are often visualized as they become more edematous and generally have a distinct hyper-hypo-hyperechoic pattern [43]. Ultrasound imaging has also been found to be useful in monitoring the clinical response of patients with NEC by demonstrating measurable reductions in BWT. However, ultrasound does have some disadvantages compared to CT, including limited resolution in obese patients, operator dependency/training, lower sensitivity, and inability to completely evaluate or exclude other potential surgical causes of abdominal pain [44].

Genitourinary Oncologic Emergencies

Obstructive Urinary Pathologies

Patients with prostatic, vesicular, gynecologic, rectal, or intra-abdominal malignancies, metastases, or retroperitoneal lymphadenopathy/fibrosis are at risk for localized compression or obstruction of genitourinary structures which may, in turn, cause urinary retention, hydronephrosis, hematuria, anuria, and acute kidney injury or failure. The use of POCUS for the early identification of hydronephrosis or genitourinary lesions may guide management (e.g., radiation or decompression via nephrostomy, Foley catheter, or suprapubic aspiration) and help prevent these complications [39].

Similar to the abdominal evaluation as noted above, a low-frequency transducer is generally used for this view. With the patient supine, and with the transducer marker toward the head, the transducer is placed on the right and left flank approximately at the ninth/tenth intercostal space and angled in a slightly oblique angle to insonate between the rib spaces. The kidneys are identified on the right and left sides, caudal to the liver and spleen, respectively. To evaluate the bladder, place the transducer just superior to the pubic symphysis and aim the beam of the transducer inferiorly into the pelvis, scanning in two planes [28]. The presence of hydronephrosis is identified by a dilated collecting system at the center of the kidney, which is fluid filled and anechoic. Hydronephrosis is graded from mild to severe (Fig. 47.17). It is important to utilize the Doppler functionality to differentiate between a dilated collecting system and prominent renal vasculature, which normally produces a robust color Doppler signal.

Pelvic Pathologies

Patients with endometrial, ovarian, cervical, and metastatic cancer to the female pelvic organs may present to the emergency department with acute pelvic or abdominal pain. Adnexal masses greatly increase the risk of ovarian torsion, and POCUS may be useful in the initial screening.

The curvilinear, low-frequency transducer or endocavitary transducer is recommended for evaluating the pelvic organs. The endocavitary transducer provides better views and higher sensitivity in detecting subtle findings in early pregnancy and adnexal pathologies. B-mode is used for anatomic evaluation, and Doppler mode is necessary for assessing vascular supply and is particularly useful in cases of ovarian torsion. M-mode should be used to determine fetal heart rate as the use of Doppler carries a theoretical risk of thermal injury to a first trimester fetus and should be avoided.

Ovarian Torsion

Ovarian torsion is defined as an interruption to the ovarian vascular supply due to a rotation in the ovarian vascular ped-

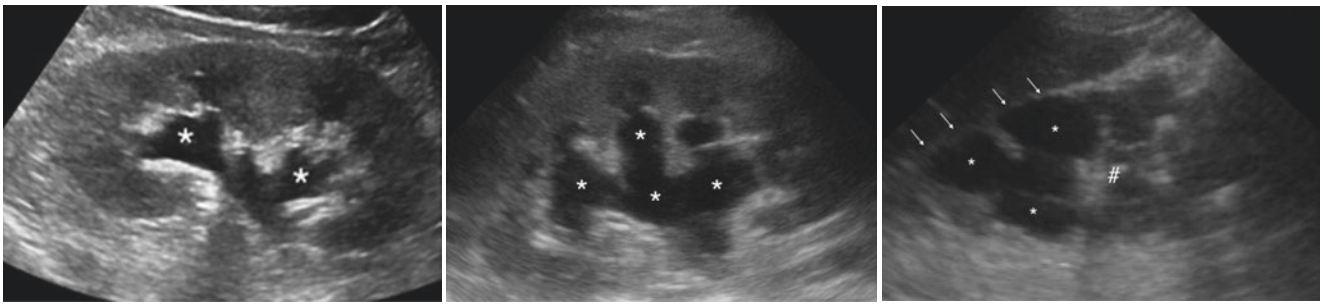

Fig. 47.17 Shown here is the spectrum of hydronephrosis including mild (*left*), moderate (*middle*), and severe (*right*). The presence of hydronephrosis (*) is identified by a dilated collecting system at the center of the kidney – it is fluid filled, and anechoic, and has absent color flow on color flow Doppler. Mild hydronephrosis has dilation of the renal pelvis only. Moderate hydronephrosis has dilation of both the renal pelvis and calyces. Severe hydronephrosis has ballooning of the renal pelvis and calyces with associated cortical thinning (*arrows*). In the image with severe hydronephrosis, there is an obstructing staghorn calculus (#)

icle which may result in ischemia and subsequent necrosis of the involved ovary [45]. Torsion begins with the twisting of the suspensory ligament which contains the ovarian artery, vein, and lymphatic vessel. Initially, the ovarian vein and lymphatic vessel are compromised which leads to ovarian edema. As the pressure increases within the ovarian capsule, arterial supply is ultimately compromised. Unfortunately, ovarian torsion is a difficult clinical entity to diagnose, as no one historical or exam feature or ultrasonographic finding can reliably exclude it [46]. As the number of sonographic signs suggestive of torsion increases, the likelihood of ovarian torsion increases [47].

Sonographic findings in ovarian torsion may include unilateral ovarian enlargement with diminished or absent Doppler flow. Other secondary signs include abnormal ovarian location, unilateral cyst or neoplasm, and free fluid in the pouch of Douglas.

The typical adult ovary measures 2 × 2 × 3 cm though in cases of unilateral edema it may be many times this size [8]. In ovarian torsion, stromal edema may also lead to displacement of visible follicles to the periphery of the ovary [47]. Color Doppler and spectral Doppler of the suspected ovary should be performed to confirm the presence of both arterial and venous flow. Absent Doppler flow greatly increases the likelihood of ovarian torsion, although the presence of flow does not rule out ovarian torsion [46]. Unilateral cysts or neoplasms may be visualized as anechoic or mixed-echogenicity lesions within the relatively homogenous hypoechoic echotexture of the ovary, although their presence or absence does not always predict or exclude torsion [46, 47].

Displacement of the ovary can sometimes be noted. For example, displacement of the ovary toward the midline and superior to the uterus, where it appears posterior to the bladder as another anechoic, fluid-filled structure, is known as the "double-bladder sign" [48]. Free fluid in the pelvis, either surrounding the affected ovary or in the pouch of Douglas, in combination with a suspicious exam, may also increase the likelihood of ovarian torsion [47].

Although POCUS is a feasible first-line modality in evaluating suspected cases of ovarian torsion, it may prove challenging to the inexperienced operator, and combination of this modality with CT, MRI, or radiology ultrasound, as well as early specialist consultation, should be considered.

Deep Venous Thrombosis

The hypercoagulable state of patients with malignancy makes them more susceptible to deep venous thrombosis (DVT). Only an estimated 50% of DVT cases present with the typical manifestations of unilateral upper or lower extremity edema, erythema, and pain [49]. In a study by Casella et al., the sensitivity of clinical examination in identifying bilateral DVT was 27.2%, and the estimated incidence of having bilateral DVT in patients presenting with unilateral signs was 32% [50]. Consequently, a high index of suspicion for DVT must be maintained.

With a sensitivity and specificity greater than 95%, the mainstay of bedside diagnosis of DVT is compression ultrasonography (CUS) [51]. CUS is considered the primary diagnostic test for those who have moderate to high pretest

probability based on the Wells score or physician gestalt. The combination of CUS plus D-dimer achieves a sensitivity of 100% for DVT [52]. The typical bedside CUS exam does not evaluate for a thrombus distal to the popliteal vein (PV). Therefore, in the setting of an initial negative bedside CUS but a positive D-dimer, a repeat CUS study 1 week later is recommended to evaluate for propagation of thrombus to the deep venous system at or proximal to the PV. However, if the initial D-dimer is negative, the diagnosis of DVT is ruled out and no additional CUS is needed [49].

The high-frequency linear transducer is used with the patient supine or in reverse Trendelenburg. The leg is externally rotated and abducted with the knee slightly flexed. The transducer is oriented transverse, inferior to the inguinal ligament with the indicator toward the patient's right. To exclude thrombus, compression with the ultrasound transducer should be applied until the lumen of the vein is completely flattened with the two walls touching each other (Fig. 47.18). If the lumen cannot be fully compressed, this is diagnostic of DVT. The common femoral vein (CFV) lies adjacent to the common femoral artery (CFA). Ideally, the transducer should initially be placed at the level where the greater saphenous vein (GSV) drains into the CFV. Although the GSV is considered superficial, a thrombus in the GSV has a higher probability of propagating into the CFV and becoming a DVT. Therefore, the GSV is evaluated for compressibility at the level of the CFV, as current guidelines recommend anticoagulation for thrombus within the proximal 5 cm of the GSV (Fig. 47.19). CUS is then performed distally in a continuous fashion by compressing at 1–2 cm intervals to the level of the adductor canal when the FV penetrates deeper and becomes difficult to assess [51]. To examine the popliteal vein (PV), the scan should be performed at the popliteal fossa with the knee slightly flexed. The vein is most often located superficial to or "on top of" the popliteal artery. Caution should be exercised as the popliteal vein is a relatively deep structure, and superficial vessels, depending on body habitus, may be mistaken for the PV.

Color and spectral Doppler may be used to help differentiate veins from other structures such as arteries, cysts, or lymph nodes, which may confuse inexperienced operators, such as in Fig. 47.19c.

US is not sufficiently sensitive in diagnosing more proximal VTE within the pelvic and abdominal veins. Additionally, an evaluation for VTE distal to the popliteal vein is not typically performed in bedside CUS exams as the sensitivity of CUS in diagnosing VTE in the calf is considered poor in symptomatic and asymptomatic VTE alike [49]. If the femoral and popliteal veins are not well visualized or their compressibility is questionable, additional diagnostic tests are needed, and the study should be deemed indeterminate due to insufficient data to make or exclude the diagnosis of DVT [52].

Fig. 47.18 The popliteal vein (V) seen here with an intramural thrombus (*) lies superficial to the artery (A) when examined at the popliteal fossa. The examiner is exerting pressure here to the extent that the artery is being partially compressed, but the vein (V) remains noncompressible which is consistent with DVT

Lymphadenopathy

Basic Approach

The linear transducer is used to image superficial lymph nodes. Color flow assessment adds critical information in the evaluation of lymph nodes.

Superficial Lymph Nodes: Benign Versus Malignant

POCUS can be used to evaluate superficial lymph nodes. Features such as size, shape, presence or absence of the hilum,

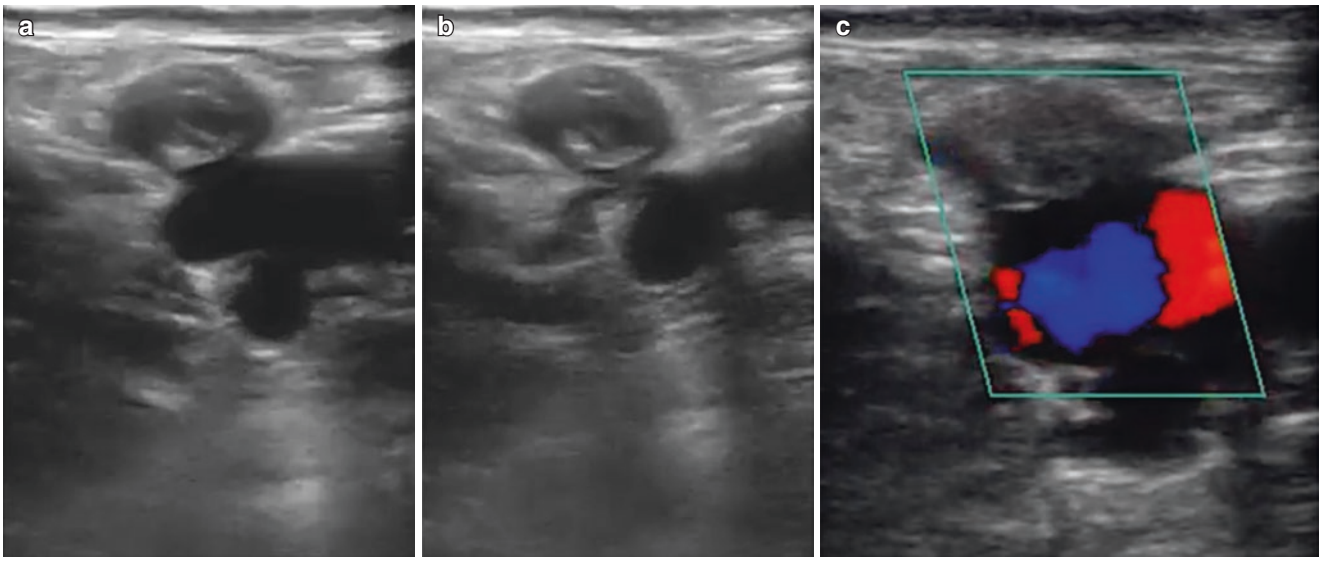

Fig. 47.19 A DVT involving the greater saphenous vein (GSV) at the junction with the common femoral vein (CFV). (**a**) An echogenic thrombus is seen in the lumen of the GSV with a patent anechoic CFV inferomedial to it. (**b**) With compression, the GSV does not compress, whereas the lumen of the CFV is completely obliterated with compression indicating the presence of a DVT in the GSV but not the CFV. (**c**) Applying color Doppler shows the presence of flow within the lumen of the CFV but not the GSV where the thrombus is present

echogenicity, margins, and structural changes may be useful in distinguishing benign from malignant lymph nodes [53]. Color flow evaluation of the presence, location, and pattern of flow within the lymph node aids in this differentiation.

Size and Shape

Size and shape are lymph node characteristics reflected in the ratio between the longitudinal and the transverse or short-axis nodal measurement, termed an L/S ratio. In general, benign lymph nodes are oval, and their longitudinal axis is at least twice the transverse/short-axis measurement. Malignant lymph nodes are more often round and their L/S ratio is less than 2 [53].

Hilar Appearance

Typically, benign nodes have a central, echogenic hilum, whereas malignant lymph nodes are more likely to have absence of the hilum.

Margins

Benign nodes will have a sharp, well-defined margin, while malignant nodes may demonstrate irregular, angular, or blurred margins.

Structural Characteristics

Structural changes such as intranodal necrosis, calcification, and matting are all suggestive of malignancy. Intranodal necrosis that appears as an anechoic area of fluid within the lymph node may indicate malignancy but can also be seen in intranodal abscess or tuberculosis. Intranodal calcifications may be seen in thyroid malignancies but are rarely seen in other malignancies. Matting of lymph nodes where multiple nodes are fused in a single, poorly defined mass is seen in malignancy when there is extracapsular invasion and in infections such as tuberculosis and mononucleosis. Matting is not typically seen in reactive lymph nodes and is, therefore, useful in differentiating malignant from reactive lymph nodes. Peripheral halo and perinodal edema may be seen in tuberculosis or malignancy but are not encountered in reactive nodes [53].

Color Flow

In benign lymph nodes, a single central, vascular pedicle entering the hilum may be visualized with color flow. In contrast, malignant lymph nodes may demonstrate multiple vascular pedicles, mixed peripheral and central color flow, or overall increased color flow due to increased vascularization.

POCUS Use in Pediatric Neck Masses

In one retrospective study of children presenting with neck masses to an ED, POCUS performed by pediatric EM physicians showed 100% agreement with final diagnosis by radiology department imaging for the category of "lymph node with malignant features" [54]. All four children whose neck mass was concerning for malignant lymphadenopathy subsequently received the diagnosis of Hodgkin lymphoma. If US evaluation of the neck mass revealed a lymph node with altered architecture, loss of the central hilum, a heterogeneous echo texture, and an abnormal blood supply, it was categorized as a "lymph node with malignant features."

A case series also demonstrated that POCUS evaluation of pediatric neck swelling can identify lymphadenopathy and further characterize the lymphadenopathy as reactive lymphadenitis, abscess collection secondary to suppurative lymphadenitis, disseminated tuberculosis, and concerning for malignancy (first case with lymphadenopathy with hyperechoic foci due to calcifications, second case with enlarged lymph nodes with loss of normal echotexture and destruction of the outer capsule) [55].

A prospective pilot study involving a convenience sample of pediatric patients also suggests that pediatric EM physicians are able to use POCUS to effectively evaluate undifferentiated soft tissue neck masses in the ED. POCUS was found to be 78% accurate in the sonographic assessment of soft tissue neck masses when compared to radiology department imaging and most often diagnosed infectious or inflammatory conditions [56].

Rapid Ultrasound in Shock and Hypotension (RUSH)

Case Study

A 55-year-old female with history of metastatic breast cancer presents with altered mental status. She last received her chemotherapy via *her port 5 days ago and has been ill for 1 day. Her partner reports that she awoke this morning confused and lethargic but is unable to provide further history.*

The patient is ill-appearing, pale, and diaphoretic on exam. Vital signs are as follows: temperature 99.2 °F, pulse 132, SpO2 96% on room air, respiratory rate 24, and blood pressure 86/50. Her right-sided chest port is palpable. Decreased breath sounds are noted bilaterally, and tachypnea is present without accessory muscle use. Heart rate is regular and there are no murmurs heard. Abdomen is mildly distended but non-tender to exam. No extremity edema is noted.

A RUSH protocol was initiated. On evaluation of the "pump," a large pericardial effusion was noted as well as diastolic compression of the right ventricle. The "tank" evaluation demonstrated a large IVC with minimal respiratory change. Suspecting tamponade physiology, the ED team performed an ultrasound-guided pericardiocentesis, with marked improvement in the patient's blood pressure and mental status.

The RUSH protocol is one of several systematic approaches to the undifferentiated hypotensive and hypoperfused medical patient. It allows the rapid identification of several pathologies which frequently afflict oncologic patients, including cardiac tamponade, septic shock, intra-abdominal hemorrhage, massive pulmonary embolism, and acute decompensated heart failure (Fig. 47.20) [3–5]. The RUSH exam integrates multiple applications as discussed above, including cardiac, thoracic, abdominal, and vascular ultrasound.

HI MAP ED Approach

The RUSH exam uses a phased-array or curvilinear transducer, and its components are captured in the "HI MAP ED" mnemonic (heart, IVC, Morison's pouch, aorta, pulmonary, ectopic, DVT). The *heart* is the first organ assessed in the RUSH exam using a phased-array transducer (or curvilinear transducer if this is not available), obtaining at least two of the four cardiac views, generally starting with the parasternal views. The heart is evaluated for the presence of pericardial effusion and, if one is present, whether there is associated tamponade (see Fig. 47.20). The LV ejection fraction is estimated or can be measured through M-mode measurement of EPSS. The right heart is assessed for signs of RV strain, including RV dilation, McConnell's sign, septal wall flattening, or decreased TAPSE, all of which raise suspicion for pulmonary embolism.

Next, the *IVC* is evaluated in the subcostal window. The presence of IVC dilation or decreased CI concurrent with pericardial effusion raises suspicion for tamponade, while its coexistence with right heart strain increases suspicion for acute obstructive shock.

The next areas to be evaluated are *Morison's* pouch in the right upper quadrant and the splenorenal space in the left upper quadrant. In oncologic patients, the frequent occurrence of ascites complicates this portion of the exam, as

ultrasound is insufficient to delineate the nature of the fluid in the abdominal cavity and cannot determine if it represents simple ascites or hemoperitoneum.

The next window of the RUSH exam is the *aortic* slide view, where the aorta is visualized in the transverse axis and assessed for evidence of aneurysm, defined as an anteroposterior diameter greater than 3 cm [57].

The *pulmonary* views are then evaluated, using the technique as described above, assessing the lungs for the presence or absence of the following pathologies: pneumothorax, pleural effusion, and B-lines or diffuse interstitial syndrome.

In female patients of child-bearing age, a pregnancy test should be checked, and the pelvic view examined for evidence of *ectopic* pregnancy. The presence of a positive pregnancy test plus free fluid in the right upper quadrant, especially in a patient without known ascites, increases the likelihood of the need for operative intervention [58, 59]. The uterus should be examined for the presence or absence of intrauterine pregnancy, which at a minimum requires the presence of a yolk sac or a fetal pole within a fluid-filled gestational sac in the uterus [8].

The presence or absence of *DVT* should be assessed with compression ultrasound of the bilateral legs. The finding of DVT plus evidence of right heart strain in a hypotensive patient may be considered diagnostic of a massive pulmonary embolus, and institutional protocols should be followed to consider the administration of thrombolytics, activation of interventional radiology, or activation of a specialized PE response team.

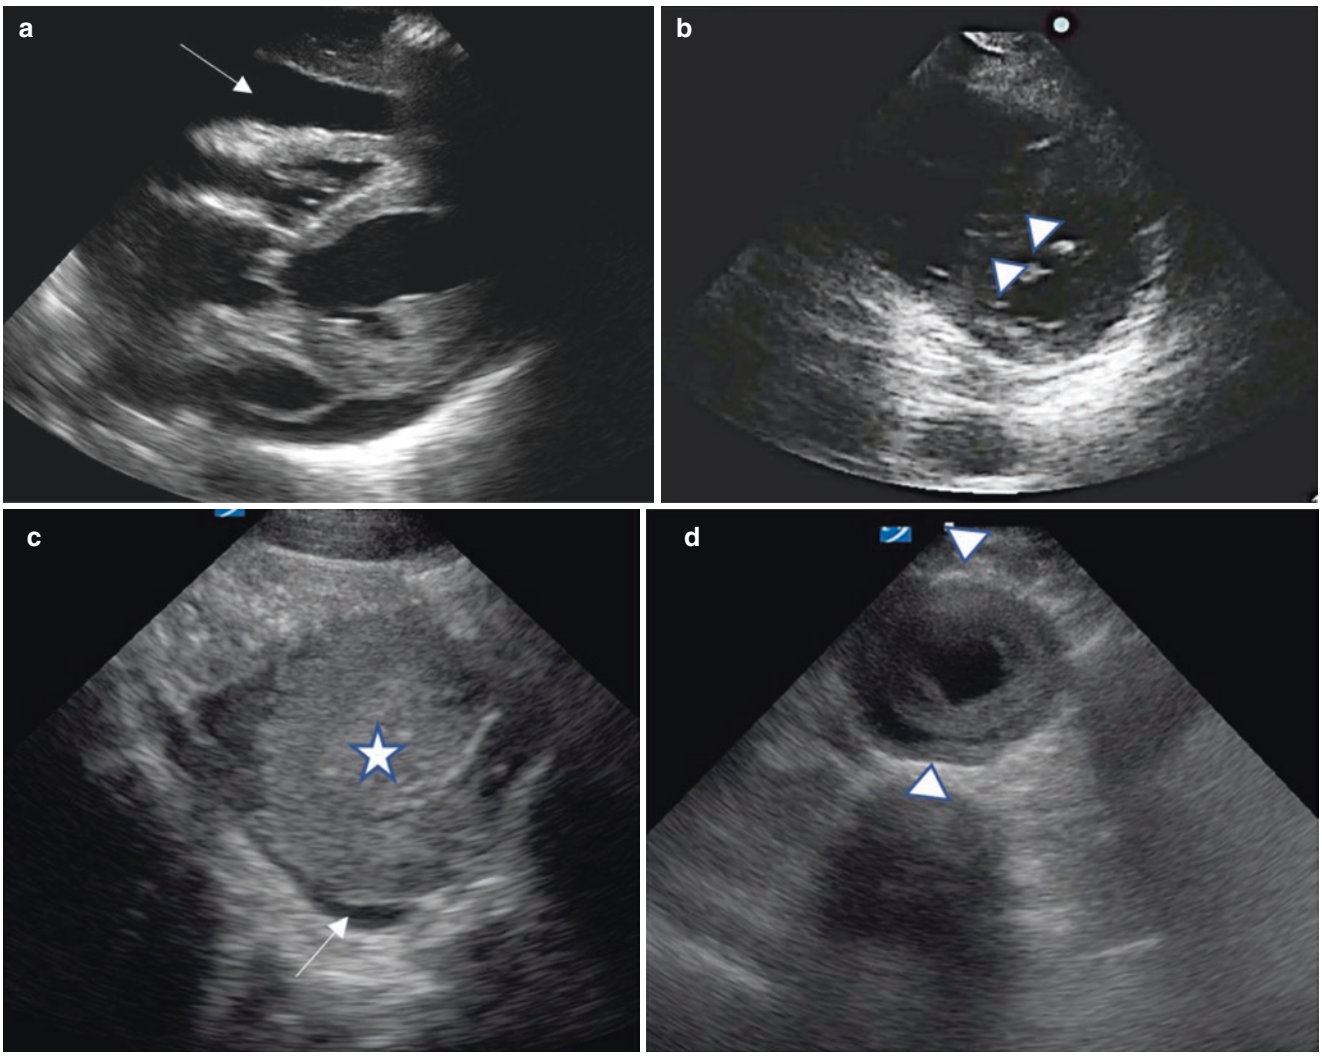

Fig. 47.20 Examples of pathological findings identified using the RUSH protocol. (**a**) Pericardial effusion seen on the subxiphoid view (*arrow*). (**b**) Interventricular septal deviation toward the, known as the D sign for the D shape of the LV. A sign of elevated RV pressure as may be seen in PE (*arrowheads*). (**c**) Minimal free fluid in the pelvic area (*arrow*) seen posterior to the uterus (*). (**d**) Abdominal aortic aneurysm (*arrowhead*) measuring 6 cm in diameter (<3 cm is normal). (**e**) Significant IVC respiratory variation with nearly complete IVC collapse as may be seen in hypovolemia (*arrows*). (**f**) Multiple B-lines extending from the pleura to a depth of 18 cm concerning for diffuse interstitial syndrome. (**g**) A significant pleural effusion (*) superior to the diaphragm and liver (L)

Part IV

Toxicities

Chemotherapy Toxicities

48

Katy M. Toale, Tami N. Johnson, Maggie Q. Ma, and Ngoc H. Vu

Introduction

There are many agents available to treat cancer. Chemotherapy, which includes but is not limited to alkylating agents, nitrosoureas, antimetabolites, antitumor antibiotics, topoisomerase inhibitors, and mitotic inhibitors, fights cancer through targeting cancer cells at different cell cycle phases. Other types of therapies used to treat cancer include targeted therapies, hormone therapy, and immunotherapy. Chemotherapy toxicity is a common and unfortunate consequence of therapy that can occur even at usual doses. Often these toxicities warrant emergency care. Timely recognition and appropriate management of chemotherapy toxicity in the emergency department (ED) is imperative.

While this chapter will not address all chemotherapy toxicities, we will discuss the most frequently encountered issues in the ED. Certain toxicities such as diarrhea, tumor lysis syndrome, myelosuppression, neutropenic fever, and mucositis are discussed in other chapters.

This chapter will include a review of the following chemotherapy toxicities: central nervous system toxicity, peripheral neuropathy, hypertensive crisis, nausea and vomiting, nephrotoxicity, electrolyte disorders, anaphylaxis, and extravasation.

It is important for clinicians working in the emergency setting to understand these chemotherapy toxicities and know how to manage them. Patient and caregiver education is also crucial because many of these serious side effects can occur while the patient is not hospitalized.

Case Study

BA is a 55-year-old male with bladder cancer being treated with cisplatin as part of his chemotherapy regimen. He presents to your ED complaining of weakness, fatigue, tinnitus, and paresthesias in his fingers and toes. He is able to answer questions, but his family states he has been having increasing confusion since yesterday. He has been experiencing severe nausea and vomiting and has been unable to keep any food or liquid down in the past 3 days. He is also unable to take his antiemetic medications. His vital signs are 84/65 with a heart rate of 120. His laboratory values are significant for a magnesium level of 1.1 mEq/L and sodium of 120 mEq/L and a serum creatinine of 3.5 mg/dL (baseline is 1.2 mg/dL). A computed tomography (CT) scan of the brain is unremarkable. Cisplatin is an alkylating agent with many toxicities. One of the major dose-related toxicities is nausea and vomiting which BA has been experiencing. This has caused severe dehydration and electrolyte abnormalities. In addition to nausea and vomiting, cisplatin can also cause nephrotoxicity, which manifests as hypomagnesemia and syndrome of inappropriate antidiuretic hormone (SIADH), causing hyponatremia. The tinnitus may be related to the ototoxicity of cisplatin, and the paresthesias could be related to the peripheral neuropathy associated with this chemotherapy agent. Management in the ED would include IV hydration, antiemetics, and electrolyte replacement, as well as initiation of an agent to improve the symptoms of neuropathy.

Central Nervous System (CNS) Toxicities

Chemotherapy drugs that readily cross the blood–brain barrier or administered via the intrathecal or intraventricular route can cause neurotoxicity [1]. CNS toxicity encompasses many different syndromes such as headache, somnolence, confusion, seizures, aseptic meningitis, cerebellar dysfunction, encephalopathy, intracranial hemorrhage, stroke, myelopathy, hearing loss, blindness, dementia, and coma.

Table 48.1 Central nervous system toxicities and associated chemotherapy agents [1–3]

CNS toxicity	Agent	
Intracranial hemorrhage	Antiangiogenic agents[a]	Asparaginase
Encephalopathy	Asparaginase Busulfan Carmustine Cisplatin Cytarabine Fluorouracil Ifosfamide	Lomustine Melphalan Methotrexate Paclitaxel Procarbazine Vincristine
Posterior reversible encephalopathy syndrome (PRES)	Antiangiogenic agents[a] Cisplatin Cytarabine Capecitabine	Gemcitabine Ifosfamide Fluorouracil Vincristine
Seizures	Busulfan Carmustine Cisplatin Cytarabine Fluorouracil Oxaliplatin	Ifosfamide Lomustine Methotrexate Paclitaxel Vincristine Any intrathecal chemotherapy agent
Cerebellar syndrome	Cytarabine	Fluorouracil
Stroke	Antiangiogenic agents[a] Cisplatin	Methotrexate
Aseptic meningitis	Cytarabine Thiotepa Topotecan	Methotrexate Any intrathecal chemotherapy agent
Myelopathy	Cytarabine	Methotrexate
Ototoxicity	Carboplatin	Cisplatin
Blindness	Carboplatin Cytarabine	Lomustine Vincristine
Dementia	Methotrexate	

[a]Antiangiogenic agents include bevacizumab, sorafenib, and sunitinib

Risk factors for developing CNS toxicity depend on the chemotherapy but may include high dosages, intrathecal or intraventricular administration, frequent administration, renal dysfunction, and hepatic dysfunction [2]. This section will focus on the more common acute neurotoxicities and their associated chemotherapy; a more extensive list of neurotoxicities caused by chemotherapy can be found in Table 48.1 [1–3].

Chemotherapy Agents Implicated

Methotrexate

Methotrexate does not easily cross the blood–brain barrier. Neurotoxicity is associated with intrathecal administration or high doses of intravenous methotrexate (>500 mg/m^2) [4]. Toxicity may be due to folate or homocysteine imbalance or direct neuronal injury [5, 6]. Neurotoxicity can present in many different forms. Intrathecal methotrexate causes aseptic meningitis in greater than 10% of patients [7]. Patients typically experience headache, nausea, vomiting, nuchal rigidity, and fever. This can occur 2–4 h after methotrexate administration and last up to 12–72 h. Although this toxicity is generally self-limiting, corticosteroids such as dexamethasone can be given to prevent or treat methotrexate-induced aseptic meningitis [7].

Methotrexate neurotoxicity can also present at different times. Acute reactions occur as soon as hours after drug administration and can include aseptic meningitis as mentioned above, somnolence, seizures, stroke-like symptoms, or mental status changes [8]. Subacute neurotoxicity may present as confusion, ataxia, hemiparesis, and seizures, generally occurring 5–10 days after therapy [2]. Subacute neurotoxicity typically resolves without intervention. Lastly, chronic or delayed neurotoxicity can present months to years later, with dementia, personality changes, leukoencephalopathy, gait disturbances, aphasia, coma, and death [2, 7, 8]. These toxicities may be related to concurrent or past radiation, concomitant chemotherapy, or larger cumulative doses greater than 140 mg via the intrathecal route [2, 8]. Radiation may cause vascular injury and alter the blood–brain barrier, allowing higher methotrexate concentrations to reach the CNS [9].

MRI imaging findings include white matter damage, diffuse white matter hyperintensity, ventricular enlargement, cortical calcifications, or cerebral atrophy [2, 8]. Leucovorin rescue therapy is usually given 24 h after methotrexate dose to decrease the toxicity associated with methotrexate folate imbalance [7]. Leucovorin 15 mg (~10–15 mg/m^2) is given every 6 h for approximately 72 h, and levels may vary based on renal function and methotrexate elimination [4].

Cytarabine

Cytarabine can be given via intravenous or intrathecal administration. It is known to cross the blood–brain barrier at high intravenous doses. The primary neurotoxicity caused by cytarabine is cerebellar dysfunction (dysarthria, ataxia, nystagmus), occurring in 10–20% of patients at doses greater than 27–36 g/m^2, and occasionally with encephalopathy and seizures [2, 7, 8]. Cytarabine is metabolized primarily by the liver and excreted in the urine. Hepatic or renal dysfunction can lead to decreased clearance and accumulation of cytarabine [10]. Neurotoxicity is commonly seen with higher doses, in elderly patients, or in patients with renal or hepatic dysfunction [8]. The onset is generally 3–8 days after drug administration and usually resolves upon drug discontinuation but can last for weeks or months. Cytarabine also can cause loss of Purkinje cells and permanent impairment [8, 11]. MRI imaging will depict cerebellar atrophy and reversible white matter changes [2]. Other CNS toxicities that can be seen with cytarabine include blurred vision, burning eye pain, blindness, confusion, somnolence, and myelopathy [2]. Although rare, intrathe-

cal cytarabine can cause aseptic meningitis, thought due to an immunologic response [1]. Steroid prophylaxis may prevent recurrence [10].

Ifosfamide

Up to 10–30% of patients receiving ifosfamide can experience some form of neurotoxicity, generally in the form of encephalopathy. Confusion is the most prevalent symptom, occurring in up to 80% of patients. Hallucination and psychosis can occur in up to 30% of patients, and other neurotoxicities such as lethargy, personality changes, extrapyramidal symptoms, hallucinations, seizures (including nonconvulsive seizures), and dysarthria are less common and can begin within 24 h of drug administration [2]. These toxicities are usually reversible within a few days of drug discontinuation, but cases of coma and death have occurred [12].

Risk factors for ifosfamide neurotoxicity include high doses, low albumin (potentially related to hepatic dysfunction), renal dysfunction, tumor in the lower abdomen/pelvis, pretreatment with cisplatin, oral administration, shorter intravenous (IV) infusion time, and prior CNS disease [7, 12, 13]. It is postulated that ifosfamide neurotoxicity is due to the ifosfamide metabolite, chloroacetaldehyde. Chloroacetaldehyde crosses the blood–brain barrier and can cause direct neurotoxic effects [12, 13]. Chloroacetaldehyde also depletes glutathione stores that are needed to protect against toxicity [14].

Brain imaging for ifosfamide neurotoxicity usually shows no abnormalities, and diagnosis is generally based on exclusion of other causes [12]. Although symptoms usually resolve spontaneously, methylene blue has been reported to shorten recovery time and prevent recurrence [12, 13, 15]. An electroencephalogram should be performed in patients presenting with altered mental status to rule out nonconvulsive seizures. Patients with seizures should be treated with a benzodiazepine.

Busulfan

Busulfan readily crosses the blood–brain barrier and is commonly used in high doses in conditioning regimens for patients undergoing hematopoietic stem cell transplantation [16]. The most common neurotoxicity in patients receiving high-dose busulfan is seizures, oftentimes warranting seizure prophylaxis prior to administration of busulfan. The incidence of seizures in patients who do not receive seizure prophylaxis ranges from 5% to 15% [7]. Risk factors for seizures include older age and higher doses of 600 mg/mg^2 or 16 mg/kg [17, 18]. Seizure onset typically occurs within hours of busulfan administration but may occur up to 24 h after the dose is complete [7, 16]. Busulfan-induced toxicity generally presents as tonic–clonic seizures, but electroencephalography (EEG) abnormalities can be present without apparent seizures. Historically, phenytoin has been used as seizure prophylaxis in patients receiving busulfan, but caution is warranted with this agent due to its effect on busulfan metabolism. Other agents that have been recommended include levetiracetam in combination with benzodiazepines [16].

Platinum-Based Compounds (Cisplatin, Carboplatin, Oxaliplatin)

The most common form of central neurotoxicity seen with platinum-based compounds is ototoxicity (presenting as tinnitus and hearing loss), occurring in up to 20–40% of patients [19]. Ototoxicity is more common with cisplatin compared to carboplatin and oxaliplatin. Platinum-based compounds accumulate in auditory sensory cells and lead to permanent hearing loss [20]. Ototoxicity is potentially related to high cumulative dose >400 mg/m^2, older age, renal dysfunction, and a longer duration of therapy [21, 22]. Other forms of CNS toxicity are rare. Cisplatin administration can cause direct neurovascular toxicity manifesting as encephalopathy, cortical blindness, stroke, seizures, and focal deficits [2, 20, 23]. Concomitant use of cisplatin with other chemotherapy agents or electrolyte abnormalities can increase the risk of neurotoxicity [1, 24].

Diagnosis and Treatment

Chemotherapy-induced neurotoxicity is a diagnosis of exclusion. Other causes for neurologic changes should be ruled out and treated. The treatment of chemotherapy-induced neurotoxicity generally involves prompt discontinuation of the offending agent. Depending on the agent, rechallenge with dose reductions and/or longer intervals between cycles may be considered [2]. In many cases, neurotoxicity is reversible upon discontinuation though it may take months for recovery; however, it can be irreversible and lead to permanent CNS damage.

Peripheral Neuropathy

Chemotherapy-induced peripheral neuropathy (CIPN) can significantly worsen quality of life and have an effect on cancer treatment due to dose reductions, treatment delays, and/or discontinuations [25]. In addition, this toxicity can also result in excessive healthcare costs and resources utilized [26]. Certain factors place patients at higher risk for nerve damage. These include the type of chemotherapy used, duration of treatment, cumulative dose, age, diabetes, African race, folate/vitamin B12 deficiency, smoking, impaired renal function, cancer-associated neuropathy, and prior or concomitant use of neurotoxic agents [25, 27].

Pathophysiology

The exact cause of CIPN differs between classes of chemotherapy agents. For platinum-based chemotherapy, it is thought the antitumor mechanism causes changes in the function of neuronal and glial cells. Mitochondria dysfunction can result in neuroinflammation, DNA damage, and axonal degeneration. Mechanisms for taxane-induced CIPN include axonal microtubule disruption, mitochondrial dysfunction, axon degeneration, altered calcium homeostasis, changes in peripheral nerve excitability, and activation of the immune system with development of neuroinflammation. Vinca alkaloids cause changes to large axons and dorsal root ganglion (DRG) neurons, leading to hyperexcitability of peripheral neurons and activation of immune cells, which leads to neuroinflammation. Bortezomib causes mitochondrial damage, increases in sphingolipid metabolism within astrocytes, and activation of immune cells, which results in neuroinflammation. Potential mechanisms for thalidomide-induced CIPN include an antiangiogenic effect, which may cause damage to sensory neurons and downregulation of tumor necrosis factor alpha (TNF-α) levels and inhibition of nuclear factor kappa B (NF-κB), which accelerates neuronal cell death. Ixabepilone-induced CIPN is postulated to cause microtubule disruption, damage of mitochondria, and activation of immune cells, resulting in neuroinflammation [27].

Epidemiology

Estimates vary but according to a recent review, 68% of patients develop CIPN after the first month of therapy, 60% at 3 months and 30% after 6 months [28]. There are many assessment methods for CIPN, but no single method is considered superior. This leads to a wide range in the reported prevalence of CIPN [29]. A detailed list of the most common agents implicated, incidence, and risk factors can be seen in Table 48.2 [25, 27, 30].

Presentation/Diagnosis

Peripheral neuropathy is clinically defined as any form of damage, inflammation, or degeneration of peripheral nerves. Patients may experience sensory nerve damage in addition to motor and autonomic nervous system damage. Symptoms usually present within the first 2 months of chemotherapy treatment and can progress until treatment is discontinued [27, 30]:

- Most often, symptoms are sensory, including paresthesias and pain.
- Symptoms may occur at any time during treatment, even after treatment is stopped.
- Symptoms are most often symmetrical.

Table 48.2 Characteristics of chemotherapy agents that cause chemotherapy-induced peripheral neuropathy [25, 27, 30]

Chemotherapy agent	Incidence	Additional risk factors	Others
Taxanes Paclitaxel Docetaxel	11–87% More common Less common	Cumulative dose Duration of infusion Simultaneous administration of platinum-based compounds History of peripheral neuropathy	Symptoms include paresthesia, numbness, or neuropathic pain in the hands and feet Symptoms usually improve after discontinuation but can continue indefinitely
Platinum-based compounds Cisplatin Oxaliplatin	70–100%	Cumulative dose Longer exposure times Oxaliplatin only: Cold temperatures Time of infusion Low body weight Preexisting peripheral neuropathy	Symptoms include numbness, tingling, and paresthesia in the hands and feet Symptoms usually improve or resolve within a year of completion of therapy; however, in some cases, the damage is not reversible "Coasting" phenomenon possible with worsening symptoms following discontinuation
Vincristine	60%	Cumulative dose	Symptoms include pain in hands and feet, muscle weakness, and cramping Symptoms are reversible upon discontinuation of therapy
Bortezomib	34%	Higher dosages Less toxicity with subcutaneous administration	Symptoms include chronic sensory peripheral neuropathy often with a neuropathic pain syndrome Occurs early in treatment and may last for weeks, months, or even years after discontinuation
Thalidomide	20–60%	Cumulative dose Advanced age Prior neuropathy	Symptoms include paresthesias, numbness and loss of dexterity on the toes and fingers
Ixabepilone	60–65%	Cumulative dose Prior doses of chemotherapy	Symptoms include paresthesia, numbness, or neuropathic pain in the hands and feet Symptoms usually improve after discontinuation

- Symptoms begin in the fingers and toes and spread proximally.
- In severe cases, loss of sensory perception can occur.

Prevention

Unfortunately, no agents have been proven beneficial for the prevention of CIPN [30]. Venlafaxine demonstrates some benefit for prevention of oxaliplatin CIPN; however, it is not routinely used due to concerns regarding its anticancer activity [31]. The clinician can consider dose reduction or discontinuation of the offending agent for patients unable to tolerate CIPN symptoms [25].

Management

Several agents have been tested for efficacy in treating CIPN. The most commonly used treatments for CIPN include topical amitriptyline/ketamine/baclofen, gabapentin, pregabalin, and duloxetine. Tricyclic antidepressants are commonly used in other neuropathic pain syndromes but have shown no benefit for CIPN, and adverse effects are a limitation. Characteristics of each medication can be seen in Table 48.3 [32]. Unfortunately, there is no gold standard for CIPN detection and grading, making clinical trials difficult to compare. Recently, guidelines on designing trials for prevention of CIPN have been published [33].

The agent with the highest level of recommendation for treatment of CIPN is duloxetine. Initial pilot studies utilizing duloxetine showed promise [34, 35]. Duloxetine was then evaluated in a randomized, double-blind, placebo-controlled crossover trial of 231 patients with CIPN from paclitaxel or oxaliplatin. Patients in the duloxetine group experienced less pain as well as a greater decrease in the pain that interfered with daily functions. The patients with oxaliplatin-induced peripheral neuropathy had better outcomes than patients on a taxane, and this may be explained by the different mechanisms causing CIPN [36]. Another ongoing trial should provide additional information to guide duloxetine use in CIPN [37].

In a study evaluating topical baclofen 10 mg, amitriptyline 40 mg, and ketamine 20 mg in pluronic lecithin organogel vs. placebo for CIPN, the topical compound showed a trend toward improved outcomes with no toxicities reported [38].

Gabapentin and pregabalin are used frequently for many types of neuropathic pain; however, current data does not support their use in CIPN. A trial of 115 patients who were randomly assigned to gabapentin or placebo showed no difference in outcomes [39]. Pregabalin was shown to improve outcomes in smaller trials [40]; however, a phase 4 study was terminated early when an interim analysis failed to detect a difference in outcomes [41].

Acupuncture has been studied for CIPN, and at this time there is not enough evidence to recommend it; however, it is considered safe and could potentially benefit patients suffering from CIPN [42]. Occupational and physical therapy trials are also limited but offer potential benefits to issues commonly faced by patients with CIPN, including gait issues, impaired postural control, and altered sensory organization [43].

Table 48.3 Characteristics of agents used in the treatment of chemotherapy-induced peripheral neuropathy (CIPN) [32]

Agent	Dose	MOA	Adverse effects	Comments
Duloxetine	30 mg PO daily for 1 week and then increase to 60 mg PO daily	Potent inhibitor of neuronal serotonin and norepinephrine reuptake and a weak inhibitor of dopamine reuptake	Fatigue Insomnia	Best evidence to support use in CIPN
Pregabalin	150 mg daily initially and then increase to 300–600 mg in two divided doses	Modulates calcium channel activity by binding to the α2δ receptor site	Somnolence Dizziness Peripheral edema Xerostomia Ataxia Weight gain	Schedule V controlled substance Do not discontinue abruptly
Gabapentin	300–900 mg daily initially and then increase to 1200–3600 mg in three divided doses	Modulates calcium channel activity by binding to the α2δ receptor site	Somnolence Dizziness Ataxia Confusion Disorientation	Do not discontinue abruptly
Topical amitriptyline/ketamine/baclofen	Apply two to three times daily	Amitriptyline: increases the synaptic concentration of serotonin and/or norepinephrine in the CNS by inhibition of their reuptake Ketamine: noncompetitive NMDA receptor antagonist that blocks glutamate	Anticholinergic effects Postural hypotension Sedation	Formulations vary and can include other agents such as lidocaine

CNS central nervous system, *MOA* mechanism of action, *NMDA* N-methyl-D-aspartate receptor, *PO* by mouth

Hypertensive Crisis

Hypertension is common in the general population and can lead to myocardial infarction, stroke, renal failure, and death if not detected early and treated appropriately [44]. Hypertension is a known long-term comorbidity of many patients with malignancy. The prevalence before treatment is similar to the community but increases after the initiation of chemotherapy and targeted agents [45]. The incidence of hypertension depends on age, cardiovascular comorbidities, type of malignancy, treatment regimen, and concomitant medications [46]. The estimated risk in patients with malignancy is as high as 36% [47].

Pathophysiology

The mechanisms underlying worsening hypertension in patients with malignancy are not well understood. It is hypothesized that certain chemotherapy and targeted or supportive agents associated with hypertension contribute to endothelial dysfunction with nitric oxide reduction, increase in vascular tone, decrease density of microvessels, renal thrombotic microangiopathy that leads to proteinuria, arterial vasoconstriction, sodium and fluid retention, and activation of the renin–angiotensin system [46].

Clinical Features

As in the general population, patients with malignancy are at risk for hypertensive crisis. For all levels of hypertension severity, including crisis level, Fraeman and colleagues reported that the incidence was considerably higher during periods of chemotherapy exposure versus without exposure. Patients experiencing crisis-level hypertension rates during exposure versus without, respectively, were 8.98 and 2.09 cases per 100 person-years [47]. Hypertensive emergencies are always associated with end-organ damage, such as hypertensive encephalopathy, cerebral infarction or hemorrhage, myocardial ischemia or infarction, heart failure, aortic dissection, and/or renal failure. Hypertensive emergency is not related to any specific blood pressure (BP) number but usually involves an acute elevation of the systolic BP (SBP) greater than 180 mm Hg or diastolic BP (DBP) above 120 mm Hg. The pace of the rise and percent increase in BP as well as the presence of end-organ damage is far more important than the actual number and demands immediate interventions to prevent further end-organ damage [48, 49].

Chemotherapy and Targeted Agents Implicated

The higher rate of hypertension in patients with malignancy can be contributed to the use of chemotherapy and targeted agents that can cause hypertension (angiogenesis inhibitors, 17–80%; alkylating agents, 36–39%; and immunosuppressants after stem cell transplantation, 30–80%) [45, 46]. Disruption of vascular endothelial growth factor (VEGF) signaling using antibody against VEGF-A (bevacizumab), antibody against receptor for VEGF (VEGFR2) (ramucirumab), and small molecule inhibitors of receptors for VEGF (sunitinib, sorafenib, etc.) is associated with hypertension, and its occurrence may be a useful marker of efficacy for these agents [50]. Some of the end-organ effects (e.g., heart failure, stroke, or renal failure) of these chemotherapy agents can compound hypertension or cause primary hypertensive crisis. Over 150 chemotherapy and targeted agents have been associated with hypertension, heart failure, stroke, and/or renal failure [32, 46].

Treatment

There is no specific guideline for treating hypertension or specifying which agents to use in patients with malignancy. Patients with hypertensive urgency should be treated, and this is usually achieved by administering oral agents followed by several hours of clinical observation [49, 51] (see Table 48.4 [32, 48, 52]).

Aggressive blood pressure control is mandatory for patients with hypertensive emergency in order to minimize the risk of end-organ damage. Patients with hypertensive emergency require admission to an intensive care unit (ICU), intravenous (IV) antihypertensive agents, and continuous BP monitoring. Based on the Seventh Report of the Joint National Committee (JNC-7) guidelines, the generalized BP goal is to lower the mean arterial pressure (MAP) by 20–25% within the first hour while avoiding excessive decreases in BP. When the patient is stable, the SBP can be lowered to 160 mm Hg, and DBP can be lowered to 100–110 mm Hg within the next 2–6 h. If this level of BP control is tolerated and the patient is stable, a gradual reduction to the patient's baseline BP can be achieved over the next 24–48 h [48, 49, 53]. There are exceptions to the generalized BP goal for patients who have hypertensive emergencies. This includes patients with certain complications such as acute aortic dissection, acute intracerebral hemorrhage, and acute ischemic stroke, with or without reperfusion therapy. The specific blood pressure goals are listed in Table 48.5 [48, 49, 52, 54, 55].

Table 48.4 Common antihypertensive agents used for hypertensive urgencies [32, 48, 52]

Agent	MOA	Dose	Onset	Duration	Common adverse effects[a]
Captopril	ACE inhibitor	12.5–50 mg PO every 1–2 h	15–30 min	4–6 h	Acute renal failure Angioedema Cough
Clonidine	Central α_2-agonist	0.1–0.2 mg PO every 1–2 h	30–60 min	6–8 h	Bradycardia Dry mouth Rebound hypertension after withdrawal Sedation
Furosemide	Loop diuretic	20–40 mg PO every 2–3 h	30–60 min	8–12 h	Hypokalemia Hyponatremia Volume depletion
Labetalol	A_1, β[beta]$_{1\&2}$-blocker	200–400 mg PO every 2–3 h	30–120 min	6–8 h	Bronchoconstriction Heart block Heart failure Hypotension Vomiting
Nitroglycerin 2%	Nitrate	1–2 inches topically every 6 h	20–60 min	4–8 h	Bradycardia Dizziness Headache Methemoglobinemia

ACE angiotensin-converting enzyme, *MOA* mechanism of action, *PO* per os, by mouth
[a]Hypotension can occur with all agents

Table 48.5 Agents for treating hypertensive emergencies with comorbidities and blood pressure goals [48, 49, 52, 54, 55]

Comorbidity	Preferred agent(s)[a]	Blood pressure goal
Acute aortic dissection	Esmolol[b]	SBP <120 mm Hg and heart rate <60 beats/minute within 20 min; lowest BP possible that maintains end-organ perfusion (SBP 70–90 mm Hg)
Acute heart failure (pulmonary edema)	Loop diuretics Nitroglycerin Nitroprusside	Generalized goal[c]
Acute ischemic stroke	Clevidipine Labetalol Nicardipine Nitroprusside	Ineligible for reperfusion therapy: <220/120 mm Hg, decrease no more than 15%
		Eligible for reperfusion therapy: <185/110 mm Hg
		During and post-reperfusion therapy for at least 24 h: <180/105 mm Hg
		Planned mechanical thrombectomy and have not received IV fibrinolytic therapy: <185/110
		During and post mechanical thrombectomy for 24 h: <180/105 mm Hg
Acute intracerebral hemorrhage	Clevidipine Labetalol Nicardipine Nitroprusside	SBP 150–220 mm Hg: Acute lowering of SBP to140 mm Hg is probably safe
		SBP >220 mm Hg: May be reasonable to consider aggressive reduction
Acute myocardial infarction	Clevidipine[d] Esmolol/labetalol Nicardipine[d] Nitroglycerin	Generalized goal[c]
Acute renal failure	Clevidipine Fenoldopam Nicardipine	Generalized goal[c]

BP blood pressure, *CPP* cerebral perfusion pressure, *ICP* intracranial pressure, *MAP* mean arterial pressure, *mm Hg* millimeters of mercury, *SBP* systolic blood pressure
[a]Agents are listed in alphabetical order, not in preference
[b]β[beta]-blockade must be used prior to other vasodilators
[c]Decrease MAP by 20–25% during first hour; if patient is stable, decrease SBP to 160 mm Hg and DBP to 100 mm Hg over next 2 to 6 h, then a gradual reduction to the patient's baseline BP over the next 24 to 48 h
[d]May be used in patients with heart rate <70 beats/min

Table 48.6 Common parenteral agents used for hypertensive emergencies [32, 48, 49]

Agent	MOA	Bolus dose	Continuous infusion dose	Dose titration	Onset	Duration	Adverse effects[a]
Clevidipine[b]	Calcium channel blocker	Not applicable	1–16 mg/h	1 mg/h every 2 min	2–4 min	5–15 min	Flushing Headache Heart failure Tachycardia
Esmolol	β[beta] $_1$-blocker	250–500 mcg over 1 min; may repeat after 5 min	25–300 mcg/kg/min	25 mcg/kg/min every 5 min	1–2 min	10–30 min	Bronchoconstriction Heart block Heart failure
Fenoldopam[c]	Dopamine-1 receptor agonist	Not applicable	0.1–1.6 mcg/kg/min	0.05–0.1 mcg/kg/min every 15 min	5–10 min	10–15 min	Flushing Headache Tachycardia
Labetalol	α[alpha]$_1$, β[beta]$_{1\&2}$-blocker	20–80 mg over 2 min every 10 min	2–8 mg/min; max dose for bolus and infusion is 300 mg/24 h	Titrate by 0.5 mg/min every 60 min	5–10 min	2–6 h	Bronchoconstriction Heart block Heart failure Vomiting
Nicardipine	Calcium channel blocker	Not applicable	5–15 mg/h	2.5 mg/h every 5 min	5–10 min	2–4 h	Flushing Headache Reflex tachycardia
Nitroglycerin	Converts to NO and increases cGMP	Not applicable	5–200 mcg/min	5–10 mcg/min every 5 min	1–3 min	5–15 min	Headache Methemoglobinemia Tachycardia Vomiting
Sodium nitroprusside[d]	Increase cGMP, blocks intracellular calcium	Not applicable	0.25–10 mcg/kg/min	Titrate by 0.5 mcg/kg/min every 5 min	Immediate	1–2 min	Cerebral auto regulation impairment Coronary steal Cyanate toxicity Nausea/vomiting

cGMP cyclic guanosine monophosphate, *h* hour, *kg* kilogram, *mcg* micrograms, *mg* milligrams, *min* minute, *MOA* mechanism of action, *NO* nitric oxide

[a]Hypotension may occur with all agents

[b]Caution with severe aortic stenosis and acute heart failure

[c]Caution with glaucoma and sulfite allergies

[d]Caution with high intracranial pressure, hepatic and renal failure

Treatment decisions with parental agents should focus on the end-organ system at risk and associated side effects caused by the specific agent used. See Table 48.5 [48, 49, 52, 54, 55] and Table 48.6 [32, 48, 49] for recommended intravenous agents per end-organ system.

Aortic Dissection Acute aortic dissection has a high mortality rate of 1% per hour over the first several hours [56]. Early diagnosis and treatment is crucial for survival. Intravenous, fast-acting β-blockers are the drug of choice due to their ability to lower the heart rate and reduce aortic stress [57].

Heart Failure Patients with heart failure, severe hypertension, and significant fluid overload should be treated initially with intravenous loop diuretics to reduce mortality [58]. Nitroglycerin and sodium nitroprusside are the most commonly used antihypertensive agents to help with filling pressures and left ventricular afterload [58].

Ischemic Stroke Appropriate management for ischemic stroke is very important. Studies have demonstrated a "U-shaped" relationship between BP and clinical outcome [59]. The concern with lowering the BP in patients with ischemic stroke is expansion of the central ischemic core. Cerebral autoregulation can be lost after a stroke, leaving the core, and the surrounding ischemic penumbra, prone to hypoperfusion and a potentially worse outcome [60]. There are limited studies evaluating the optimal BP goal and appropriate pharmacotherapy. Modest lowering of the BP is recommended and dependent on the patient's eligibility for reperfusion therapy [52].

Several small studies have compared labetalol to nicardipine for lowering BP. In a meta-analysis, these two agents had comparable side effects and efficacy for the treatment of hypertension in patients with several different types of strokes, including acute ischemic stroke, intracerebral hemorrhage, and subarachnoid hemorrhage [61]. In a more recent study, intravenous labetalol and nicardipine continuous infusions were comparable with no significant difference in time to BP goal, variability in BP, and use of rescue antihypertensive medications [62].

Hemorrhagic Stroke The most acute concern after hemorrhagic stroke is hematoma volume expansion [63]. Hematoma expansion occurs very early (first 3 h), with limited expansion beyond 24 h [59]. Two studies have confirmed the feasibility and safety of early rapid BP lowering in patients with intracerebral hemorrhage (Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial [INTERACT] pilot study and the Antihypertensive Treatment in Acute Cerebral Hemorrhage [ATACH] trial) [64, 65]. Labetalol and nicardipine are used to control BP in patients with hemorrhagic stroke as mentioned in the ischemic stroke section. Clevidipine is also used to lower BP in patients with a hemorrhagic stroke. No difference in safety and efficacy was found when compared to nicardipine [66–68].

Acute Coronary Syndromes The goal for patients experiencing acute coronary syndrome is to decrease myocardial oxygen demand and improve coronary perfusion. For patients experiencing hypertensive emergencies, both nitrates and β-blockers have been used to reach the above goal [69].

Renal Failure Fenoldopam has an indication for hypertensive emergencies and improves creatinine clearance, urine flow rates, and sodium excretion in severely hypertensive patients with both normal and impaired renal function [49, 66]. Therefore, it may be useful in patients with hypertensive emergencies and renal failure. Diuretic use in patients with severe hypertension and renal failure may be either beneficial or harmful and is completely dependent on the patient's volume status.

It is absolutely crucial to recognize hypertensive emergencies as soon as possible. End-organ damage can be minimized by early diagnosis and treatment. Treatment and the BP goal are dependent on the end-organ involved.

Nausea and Vomiting

Chemotherapy-induced nausea and/or vomiting (CINV) is a debilitating side effect of chemotherapy, potentially impacting fluid and electrolyte balance, nutrition status, future treatment courses, quality of life, and overall cost of healthcare. Direct healthcare costs of treating CINV per day can range from US$1300 to US$2400, not accounting for indirect costs associated with lost workdays or productivity losses [70]. After the introduction of serotonin (5-HT_3) receptor antagonists, prophylactic antiemetic regimens were able to reduce the incidence of CINV. Despite the improvement, CINV refractory to these prophylactic regimens occurs in up to 40% of patients receiving chemotherapy [71]. CINV can be characterized as acute, delayed, breakthrough, refractory, or anticipatory. This section will focus on management strategies for breakthrough CINV only.

Pathophysiology

CINV is initiated by the peripheral stimulation of enterochromaffin cells in the GI tract and the central stimulation of the chemoreceptor trigger zone by chemotherapeutic agents. Centrally, substance P release, which is triggered by chemotherapy, binds to NK-1 receptors and stimulates the chemotherapeutic trigger zone. Peripherally, stimulation of enterochromaffin cells causes a release of serotonin (5-HT), which sends information to the central nervous system [71, 72]. These signals are received and processed by the vomiting center in the medulla oblongata, which are then converted to signals promoting emesis [73, 74]. Serotonin is the predominant peripheral neurotransmitter involved in the first 24 h of CINV, while signals from dopamine and substance P (which corresponds with the primarily centrally located neurokinin-1 receptor) predominate after 24 h [75]. Other neurotransmitters and receptors involved include acetylcholine, corticosteroid, cannabinoid, histamine, neurokinin, and opioid [76].

Clinical Features

Nausea is an unpleasant sensation in the back of the throat or epigastrium that may or may not result in emesis. Vomiting is a motor reflex, which results in a forceful expulsion of GI contents [73, 74]. CINV can be categorized into acute and delayed phases. Acute CINV occurs within the first 24 h of chemotherapy, while delayed CINV occurs after 24 h and can last up to 7 days. Breakthrough CINV is any nausea or vomiting that occurs despite optimal prophylactic antiemetic regimens [76].

Chemotherapy Agents Implicated

Chemotherapeutic agents are classified into four different categories based on their emetogenicity risk. Highly emetogenic agents have a risk of greater than 90% (meaning 90% or more of patients receiving these agents will experience emesis without prophylactic antiemetics), moderately emetogenic agents have a risk of 30–90%, agents with low emetogenicity have a risk of 10–30%, and minimally emetogenic agents have a risk of less than 10% for emesis [77]. Other risk factors for CINV include female sex, younger age, history of little to no alcohol use, history of CINV or morning sickness during pregnancy, and susceptibility to motion

sickness. A chart grouping chemotherapy agents by emetogenicity risk can be found in the National Comprehensive Cancer Network (NCCN) guidelines [76].

Treatment

Treatment of breakthrough CINV is more challenging than preventing CINV. There are currently three published guidelines from three different cancer organizations—NCCN, American Society of Clinical Oncologic (ASCO), and Multinational Association of Supportive Care in Cancer/European Society for Medical Oncologic (MASCC/ESMO) [76, 78, 79]. NCCN provides the most comprehensive recommendations for breakthrough CINV. NCCN recommends using an agent different from those in the prophylactic regimen and suggested that multiple agents with different mechanisms of action may be needed. There is also a recommendation to utilize these agents on a scheduled, around-the-clock dosing strategy versus an as-needed basis. Therapeutic options include benzodiazepines, dopamine antagonists (including phenothiazines, olanzapine, haloperidol, and metoclopramide), cannabinoids, antihistamines/anticholinergics, corticosteroids, and serotonin receptor subtype 3 (5-HT_3) antagonists. Additionally, it may be beneficial to initiate an H_2 antagonist or proton pump inhibitor to treat concurrent dyspepsia, as well as maintain optimal hydration status and electrolyte balance [76]. See Table 48.7 [72, 73, 75, 76, 80–82] for details on pharmacotherapeutic treatment options for CINV. Beyond a small, phase 2 trial [83], neurokinin 1 (NK-1) receptor antagonists such as aprepitant have been studied primarily as part of prophylactic regimens and have not been recommended by any of the three main antiemesis guidelines from ASCO, NCCN, or MASCC/ESMO for the treatment of breakthrough CINV [76, 78, 79]. Aside from guideline recommendations, considerations such as previous success with certain antiemetic classes, drug–drug interactions, and patient-specific characteristics (e.g., allergies or QTc interval) should all be taken into account when selecting an antiemetic regimen for breakthrough CINV.

There is currently a paucity of literature to guide the practitioner in selecting antiemetics for breakthrough CINV. The majority of recent data highlights the antipsychotic, olanzapine. Likely due to its effect on multiple receptor sites involved in the pathophysiology of CINV, olanzapine has shown to be beneficial in treating breakthrough CINV [76].

One retrospective study observed 33 patients who experienced refractory CINV that failed to respond to both benzodiazepines and dopamine antagonists and received at least one dose of olanzapine. Of these patients, 65–70% had success with olanzapine. The typical dose given was 5–10 mg by mouth daily for a median of 4 days [75]. Another observational study evaluated medications received for breakthrough CINV. Of 39 patients who required rescue antiemetics, 88% received prochlorperazine, while 12% received a 5-HT_3 antagonist. Both groups reported a 75% reduction of nausea after 4 h. Both groups also noted significant symptom control within 30 min [84]. In one of the only randomized controlled trials evaluating treatment for CINV, Navari et al. studied 108 patients receiving either olanzapine or metoclopramide for breakthrough CINV. Patients were included if they received highly emetogenic chemotherapy with appropriate prophylactic antiemetic regimens. Olanzapine was given as a 10 mg dose orally every 24 h for 72 h, while metoclopramide was given as a 10 mg dose orally every 8 h for 72 h. Patients receiving olanzapine had a significantly lower incidence of both nausea and vomiting, and olanzapine was well tolerated [85]. In a retrospective study by Chiu et al., olanzapine was evaluated in 193 cases of breakthrough CINV and was found to improve nausea 88.1% of the time and vomiting 21.8% of the time. Several adverse effects were reported including sedation (42% of cases) and constipation (32% of cases). Of note, the majority of patients in this trial (94%) received a lower dose of olanzapine at 2.5 mg daily [86]. Lastly, Nakagaki et al. randomized 62 stem cell transplant patients (following chemotherapy) to ondansetron 32 mg infused over 24 h, olanzapine 10 mg daily + ondansetron IV three times daily, or a single dose of palonosetron 0.25 mg IV. The primary composite outcome of no emesis, no rescue medication use, and improvement in nausea by ≥50% was significantly higher in the olanzapine + ondansetron group at 24 h (45% versus 6% in the ondansetron infusion group and 18% in the palonosetron group) and at 48 h (64% versus 6% in the ondansetron infusion group and 18% in the palonosetron group) [87]. With growing evidence supporting olanzapine use in the treatment of breakthrough CINV, NCCN recommends treatment of CINV with olanzapine as a category 1 recommendation (unless olanzapine was used as part of the prophylactic regimen) [76].

CINV continues to be a significant adverse effect of chemotherapy that can impact the treatment of cancer. Utilizing the most effective prophylactic regimens based on the emetogenicity of the chemotherapy agent(s) is most important, but patients may still develop breakthrough CINV. In these cases, it is important to quickly control symptoms with scheduled antiemetics that have mechanisms differing from initial agents used for prophylaxis.

Nephrotoxicity

Chemotherapy-induced nephrotoxicity (CIN) is a significant complication of therapy, resulting in treatment delays, dosage reductions, and therapy discontinuation. In 2015, the International Serious Adverse Event Consortium report classified drug-induced kidney disease into four main

Table 48.7 Pharmacologic treatment options for breakthrough chemotherapy-induced nausea and vomiting (CINV) [72, 73, 75, 76, 80–82]

Agent	Dose	MOA	Adverse effects	Comments
5-HT_3 Receptor Antagonists				
Ondansetron	16–24 mg PO daily or 8–16 mg IV	Antagonistic effect at the 5-HT_3 receptor located in the GI tract, CTZ and vomiting center	QTc prolongation Headache Constipation	PO and IV are equally effective All are equally effective/safe when given in biologically equal doses If palonosetron was used in the prophylactic regimen, a different mechanism should be targeted for breakthrough CINV Most benefit seen when administered around-the-clock (scheduled) PO ondansetron has less QTc prolongation risk than IV
Dolasetron	100 mg PO daily			
Granisetron	1–2 mg PO daily or 1 mg PO twice daily or 0.01 mg/kg (maximum 1 mg) IV daily or 3.1 mg/24-h TD patch every 7 days			
Dopamine antagonists				
Haloperidol	0.5–2 mg PO/IV every 4–6 h	Butyrophenone, most potent dopamine antagonist; weak anticholinergic and alpha-1 adrenergic blocking effects	Sedation QT_c prolongation Dystonic reactions Extrapyramidal symptoms	Antiemetic properties seen at doses lower than antipsychotic doses
Metoclopramide	10–20 mg PO/IV every 4–6 h	Benzamide analog, peripheral dopamine antagonist; stimulates prokinesis via serotonin (5-HT_4) receptors	Dystonic reactions Tardive dyskinesia Akathisia Diarrhea Mild sedation Orthostatic hypotension	Increased efficacy at higher doses due to additional serotonin blockade Tardive dyskinesia risk is cumulative dose-dependent and more likely to occur with chronic use
Prochlorperazine	10 mg PO/IV every 6 h (max 40 mg/day) or 25 mg PR twice daily	Phenothiazine; dopamine antagonist; some anticholinergic and alpha-adrenergic blocking effects; prochlorperazine with more predominant dopamine antagonism; promethazine with more antihistamine properties	Sedation Dystonic reactions Extrapyramidal symptoms	Due to increased histamine receptor antagonism, promethazine causes more sedation than prochlorperazine
Promethazine	12.5–25 mg PO/IV every 4–6 h or 25 mg PR every 6 h			
Olanzapine	5–10 mg PO daily	Effects on multiple receptors (serotonin, dopamine, acetylcholine, muscarinic, histamine, alpha-1 adrenergic)	Sedation Orthostatic hypotension Increased appetite Dystonic reactions	Administer at bedtime to avoid daytime sedation Consider dose reduction (to 5 or 2.5 mg if higher dose causes excessive sedation) Sedation improves after day 2
Cannabinoids				
Dronabinol	5–10 mg capsule PO every 6–8 h	Effects on the cannabinoid receptors in the CNS and peripheral receptors	Sedation Dizziness Dysphoria Postural hypotension Hallucinations Appetite stimulation	Use is limited by side effects Titrate dose upward to minimize side effects Dronabinol oral solution has greater bioavailability than the capsule (2.1 mg oral solution = 2.5 mg capsule)
Nabilone	1–2 mg PO twice daily			
Benzodiazepines				
Lorazepam	0.5–2 mg PO/IV every 6 h	Binds to benzodiazepine receptors in the postsynaptic GABA receptors	Sedation Respiratory depression Hypnosis/amnesia	Added benefit of reducing anxiety Not recommended as monotherapy Caution when used with opioids

(continued)

Table 48.7 (continued)

Agent	Dose	MOA	Adverse effects	Comments
Corticosteroids				
Dexamethasone	12 mg PO/IV daily	Not fully understood	Insomnia Increased appetite Hyperglycemia GI distress	Is more commonly used in prophylactic regimens for CINV Administer in the morning to alleviate insomnia side effect
Other Agents				
Scopolamine patch	1.5 mg TD every 72 h	Antimuscarinic, anticholinergic	Sedation Fatigue Paradoxical CNS excitation Hallucinations Xerostomia	May benefit if CINV caused by excessive secretions or includes component of motion sickness

CNS central nervous system, *CTZ* chemotherapy trigger zone, *GABA* gamma-aminobutyric acid, *GI* gastrointestinal, *IV* intravenous, *kg* kilogram, *mg* milligrams, *MOA* mechanism of action, *PO* by mouth, *PR* per rectum or rectally, *TD* transdermal

types: acute kidney injury (AKI), glomerular disorder, tubular disorder, or nephrolithiasis/crystalluria. AKI is further broken down to acute tubular necrosis (ATN), acute interstitial nephritis (AIN), and osmotic nephrosis [88]. Chemotherapy can affect any area of the kidney including the glomerulus, tubules, interstitium, or microvasculature. Adverse effects may range from a simple rise in serum creatinine without other sequelae to acute kidney failure requiring dialysis [89].

Risk Factors

Several factors increase the risk of CIN including intravascular volume depletion due to fluid losses such as vomiting or diarrhea or fluid shifts as in ascites; urinary tract obstruction due to tumor involvement; and/or intrinsic renal disease related to diabetes, hypertension, or chronic heart failure [89]. Exposure to concomitant nephrotoxic agents (e.g., acyclovir, allopurinol, aminoglycosides, amphotericin B, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, contrast agents, diuretics, foscarnet, ganciclovir, lithium, nonsteroidal anti-inflammatory drugs, proton pump inhibitors, sulfonamides, tacrolimus, and vancomycin) also increases the risk of acute kidney injury [88]. The following section discusses chemotherapy agents most commonly associated with kidney injury.

Chemotherapy Agents Implicated

Platinum-Based Compounds

Nephrotoxicity is a major dose-limiting side effect of cisplatin occurring in about 30% of patients. Nephrotoxicity results from tubular epithelial cell toxicity, vasoconstriction, and proinflammatory effects. These effects are due to a chloride ion in the cis position. Carboplatin and oxaliplatin do not contain this chloride and consequently are less nephrotoxic. The renal dysfunction manifests as hypomagnesemia, salt wasting, a Fanconi-like syndrome, and anemia which can progress and potentially be irreversible [89]. To minimize CIN, intravenous hydration, mannitol, and amifostine can be used [90, 91].

Alkylating Agents

Hemorrhagic cystitis (HC) can result from administration of cyclophosphamide or ifosfamide. The toxic metabolite, acrolein, is filtered by the kidneys and then concentrates in the bladder, inducing an inflammatory response. In addition, chloroacetaldehyde, a major metabolite of ifosfamide, is toxic to tubular cells [89]. Forced saline diuresis and mesna can be used to prevent HC in patients receiving high-dose cyclophosphamide or ifosfamide. Patients should be instructed to drink fluids and void at first sensation as well as void at least once during the night [91]. Both agents can also cause syndrome of inappropriate antidiuretic hormone (SIADH) which results in hyponatremia. In addition, ifosfamide can cause Fanconi syndrome, characterized by a global transport defect in the proximal tubule of the kidney, and cause hypophosphatemia, polyuria, acidosis, hypokalemia, glycosuria, and proteinuria [90].

Antitumor Antibiotic

Renal toxicity with mitomycin can occur in up to 10% of patients and manifests as hemolytic uremic syndrome (HUS), resulting in thrombotic microangiopathy (TMA) from direct endothelial injury. The renal failure develops slowly and is usually associated with hypertension [89, 92].

Antimetabolites

High-dose methotrexate causes AKI in about 2% of patients secondary to ATN resulting from crystallization of the par-

ent drug and metabolites within the kidney. The AKI is usually reversible and can be minimized by ensuring appropriate hydration and high urine flow with urinary alkalinization (pH >7.0) [89]. Leucovorin is often given with high-dose methotrexate to reduce toxicities [90]. Pemetrexed has been associated with AKI, ATN, renal tubular acidosis, and diabetes insipidus. AKI is usually reversible upon drug discontinuation, but irreversible AKI and interstitial fibrosis have been reported [89, 93]. Gemcitabine may induce TMA through direct endothelial injury. It can also be caused by an immune-mediated mechanism, and if this is the case, the drug must be avoided for life [89, 93].

Targeted Therapy

Magnesium wasting is a major adverse effect of cetuximab therapy. Cetuximab is an antagonist of the epidermal growth factor receptor (EGFR). EGFR causes downregulation of the transient receptor potential cation channel, subfamily, member 6 (TRPM6), which results in magnesium wasting [94]. The hypomagnesemia usually resolves after drug discontinuation. To prevent adverse effects of hypomagnesemia, oral and/or intravenous replacement is necessary [89, 95].

Electrolyte Disorders

Electrolyte derangements are prevalent in cancer patients and can occur for a multitude of reasons. A common cause of fluid and electrolyte abnormalities in cancer patients is dehydration due to nausea, vomiting, diarrhea, or decreased appetite. Other reasons include tumor lysis syndrome, medication adverse effects, acute kidney injury, or complications of the cancer itself. Common electrolyte abnormalities in cancer patients are hyponatremia, hypomagnesemia, and hypo- or hyperkalemia [96]. Though many electrolyte abnormalities may not result from chemotherapeutic agents, many agents are well known to cause significant electrolyte disturbances, which will be the focus of this section. A detailed description of electrolyte disorders and chemotherapy agents implicated can be seen in Table 48.8 [97–100].

Pathophysiology

The mechanism by which chemotherapeutic agents cause electrolyte abnormality differs with each agent, ranging from renal wasting to direct tubular damage. Pathophysiologic details pertaining to each agent will be discussed within the sections below.

Chemotherapy Agents Implicated

Platinum-Based Chemotherapy

Platinum-based chemotherapeutic agents cause a wide variety of electrolyte abnormalities including hypomagnesemia, hypocalcemia, hypokalemia, and hyponatremia. Of all the platinum-based agents, cisplatin causes the most profound electrolyte disturbances, of which hypomagnesemia is most prevalent, occurring in up to 90% of patients [98]. The incidence appears to be dose-related and was found to reach 100% after the sixth cycle of chemotherapy in one study [101]. Hypomagnesemia occurs due to proximal tubular necrosis caused by cisplatin at the site of magnesium reabsorption, resulting in renal magnesium wasting [102]. Hypokalemia can also occur in the same manner [98].

Cisplatin-induced hypomagnesemia persists in many patients, up to years after cisplatin discontinuation [103]. Due to its high incidence of nephrotoxicity, cisplatin administration is usually preceded by judicious hydration with intravenous fluids. This induces an osmotic diuresis, which increases urinary magnesium excretion and can worsen hypomagnesemia [104]. Most patients are asymptomatic; however, muscle weakness and cramping, tetany, fatigue, seizures, arrhythmias, paralysis, and neurotoxicity can occur [98, 105]. Even if asymptomatic, it is important to correct because low serum magnesium can lead to refractory hypokalemia and hypocalcemia [98, 104, 106]. The persistence of hypomagnesemia has even been associated with decreased survival in ovarian cancer patients [95].

In addition to hypomagnesemia, hypokalemia, and hypocalcemia, platinum agents can also cause hyponatremia (in up to 43% treated with cisplatin) [98]. In a pharmacovigilance study where 19,901 adverse event reports were evaluated in non-small cell lung cancer patients, hyponatremia and hypokalemia were significantly associated with carboplatin exposure [107]. SIADH and renal salt wasting are likely the mechanisms by which platinum-based agents cause hyponatremia [98, 108]. Salt wasting can occur because of direct tubular damage from cisplatin, leading to a disruption in sodium and water reabsorption. This syndrome has been reported to occur in up to 10% of patients. One important consideration is to ensure an accurate diagnosis of hyponatremia, as treatment for SIADH and salt wasting syndrome differs significantly (free water restriction for the former and volume repletion for the latter) [108].

Cyclophosphamide

Hyponatremia resembling SIADH induced by cyclophosphamide was initially and is more commonly reported with high doses (30–50 mg/kg) [98]. However, this adverse effect has been reported with moderate doses and doses as low as 500 mg/m^2 and 10 mg/kg and even after a single dose of

Table 48.8 Electrolyte disorders and chemotherapy agents implicated [97–100]

Electrolyte disorder	Agents	Mechanism	Clinical presentation	Treatment[a]
Hyponatremia (serum sodium <135 mEq/L)	Carboplatin Cisplatin Ifosfamide	Renal salt wasting or SIADH	Headache Nausea/vomiting Confusion Seizures Hypovolemic if renal salt wasting Euvolemic if SIADH	Renal salt wasting: Volume repletion with PO/IV sodium chloride supplementation SIADH: Fluid restriction Can consider low-dose diuretics Can consider oral sodium chloride If severe or acute symptoms, consider initial management with hypertonic, 3% sodium chloride infusion at a rate of 15–80 mL/h, or up to 1–2 mL/kg/hour with frequent sodium monitoring
	Interferon Levamisole Melphalan Vinblastine Vincristine Vinorelbine	SIADH		
	Cyclophosphamide	SIADH or water intoxication		
	Methotrexate	Alteration in body fluid volumes		
Hypomagnesemia (serum magnesium <1.5 mg/dL)	Cetuximab Cisplatin Carboplatin Oxaliplatin Ifosfamide	Magnesium wasting (impaired reabsorption of magnesium in the kidneys)	Muscle cramps and weakness Paresthesias Tetany Tremulousness Arrhythmias Seizures	PO[b]/IV magnesium supplementation (e.g., magnesium oxide for PO, magnesium sulfate for IV) Mild to moderate hypomagnesium (1.0–1.5 mg/dL): 8–32 mEq Severe hypomagnesemia (<1.0 mg/dL): 32–64 mEq
Hypokalemia	Azacitidine Cisplatin Ifosfamide Streptozocin	Renal losses via renal tubular acidosis, Fanconi syndrome, or secondary to hypomagnesemia	Weakness Constipation EKG changes Arrhythmias	PO/IV potassium supplementation (e.g., potassium chloride) Mild to moderate hypokalemia (2.5–3.4 mEq/L): 20–40 mEq Severe hypokalemia (<2.5 mEq/L): 40–80 mEq Ensure adequate repletion of magnesium
	Abiraterone	Excessive mineralocorticoid activity		
Hypophosphatemia (serum phosphorus <2.7 mg/dL)	Azacitidine Ifosfamide Streptozocin	Proximal tubular damage impairing reabsorption of phosphorus, Fanconi syndrome	Respiratory distress Weakness Paresthesias Neurologic dysfunction Seizures	PO/IV phosphorus supplementation (i.e., sodium phosphate or potassium phosphate) Mild hypophosphatemia (2.3–2.7 mg/dL): 0.08–0.16 mmol/kg Moderate hypophosphatemia (1.5–2.2 mg/dL): 0.16–0.32 mmol/kg Severe hypophosphatemia (<1.5 mg/dL): 0.32–0.64 mmol/kg
Hypocalcemia (corrected serum calcium[c] <8.6 mg/dL)	Cetuximab Cisplatin	Potentially secondary to hypomagnesemia (causing impaired parathyroid function) or via renal losses	Tetany Seizures	PO/IV calcium supplementation (e.g., calcium carbonate for PO, calcium gluconate for IV) Mild to moderate/asymptomatic: Calcium gluconate 1–2 g IV or PO supplementation Severe/symptomatic: Calcium chloride[d] 1 g IV or calcium gluconate 3 g IV Ensure adequate repletion of magnesium

CrCl creatinine clearance, *DMSO* dimethyl sulfoxide, *IV* intravenous, *mg* milligrams, *SC* subcutaneous

[a]Treatment recommendations are for patients with normal renal function; for patients with impaired renal function, administer 50% or less of the recommended dose

[b]PO magnesium may cause diarrhea, especially in larger doses

[c]Corrected serum calcium = serum calcium + (0.8 × [4 − serum albumin])

[d]Requires administration via central IV access because extravasation may cause tissue necrosis

[a]Some literature suggests using cold compresses with taxanes

500 mg [83, 109]. Cyclophosphamide-associated SIADH is postulated to be caused by either an antidiuretic hormone (ADH)-like metabolite or a direct toxic effect on the renal distal tubule by cyclophosphamide or one of its metabolites [97, 110]. Hyponatremia presents variably depending on the acuity and severity, causing symptoms ranging from headache, nausea, and vomiting to altered mental status, seizures, and coma [99]. SIADH in this setting generally occurs 4–12 h after drug administration and usually resolves within 24 h of drug discontinuation [97]. Treatment for SIADH

centers on fluid restriction, but this may be challenging due to the recommendation for generous hydration to prevent cyclophosphamide-induced hemorrhagic cystitis [105].

Vinca Alkaloids

Of the vinca alkaloids, vincristine poses the highest risk of hyponatremia. This hyponatremia is thought to resemble SIADH and involves an inappropriate release of antidiuretic hormone in the setting of hypotonic hyponatremia [105]. The incidence is 1.3 in 100,000 treated patients and can be up to 44% of treated patients when given with azole antifungals due to a drug–drug interaction [98, 111]. The onset of hyponatremia occurs 1–2 weeks after administration and usually lasts for 2 weeks but can last up to 30 days. Hyponatremia induced by vinca alkaloids is usually reversible with proper treatment, but fatalities have been reported [97].

Ifosfamide

Fanconi syndrome is a well-known adverse effect of ifosfamide therapy as previously discussed [98, 112]. Fanconi syndrome involves damage to the proximal tubules resulting in impairment of electrolyte reabsorption, including phosphorus, bicarbonate, and glucose. The predominant concern is hypophosphatemia, which can be severe enough to cause rickets in the pediatric population [112]. Other signs and symptoms of hypophosphatemia include respiratory distress, neurologic dysfunction, and seizures [99]. Several risk factors for ifosfamide nephrotoxicity have been identified, including high cumulative doses of ifosfamide, concomitant cisplatin use, and nephrectomy [112]. Lastly, ifosfamide may also cause hypokalemia through renal wasting [98]. It is also important to note that manifestations of ifosfamide toxicities may not appear until years following therapy.

Cetuximab

Cetuximab was shown to cause hypomagnesemia in over 11% of patients in one retrospective study. Patients receiving a concomitant platinum-based agent had a more rapid and more significant decrease in magnesium levels at the end of 12 weeks [113]. The mechanism underlying cetuximab-induced hypomagnesemia appears to be impaired reabsorption of magnesium due to cetuximab's inhibition of epidermal growth factor receptor (EGFR), which aids in magnesium transport, thus resulting in magnesium wasting [114]. Although severe hypomagnesemia occurs in only 11% of patients, it has been shown that nearly half of patients who receive cetuximab develop some degree of hypomagnesemia [113]. Oftentimes, hypomagnesemia due to cetuximab use is refractory to oral magnesium replacement and requires intravenous replacement. Another study showed variable rates of hypomagnesemia based on cancer-type with non-small cell lung cancer at the highest risk and colorectal cancer at the lowest risk [115]. Interestingly, hypomagnesemia was shown to be predictive for delayed disease progression and improved survival in colorectal cancer patients [114].

Treatment

It is important to be cognizant of the common electrolyte disorders that can occur with chemotherapy in order to monitor serum electrolytes accordingly. Treatment of chemotherapy-induced electrolyte disorders requires vigilant monitoring and judicious replacement or correction when warranted. Oftentimes, the culprit for the electrolyte disorder is difficult to pinpoint due to confounders such as concomitant medications and disease processes, GI losses from vomiting or diarrhea, dehydration, and poor nutrition status. When identified, treatment of these electrolyte disorders usually requires only replacement or correction of balance of water and electrolytes (e.g., fluid restriction for SIADH hyponatremia) but may require alterations in therapy such as chemotherapy dose reductions, transitioning to alternative agents within the same class, changing the administration schedule, or even discontinuing the agent. When replacing electrolytes such as magnesium, potassium, phosphorus, and calcium, the clinician should be mindful of the patient's renal function and adjust replacement accordingly for impaired function. Electrolytes should be replaced orally if the patient is able to tolerate oral intake and if the patient is asymptomatic or mildly symptomatic. For acute, severe, or symptomatic electrolyte disturbances, electrolyte replacement should be given intravenously. The reader is advised to refer to other references for a more detailed discussion of the treatment of electrolyte disorders [99, 116, 117].

Anaphylaxis

Patients with cancer are increasingly exposed to a wider range of chemotherapy and targeted agents. Increased exposure leads to a higher opportunity to develop severe hypersensitivity reactions such as anaphylaxis.

Pathophysiology

The exact mechanism by which hypersensitivity reactions occur is often unclear and may vary among agent [118]. Most reactions to chemotherapy and targeted agents are consistent with type I hypersensitivity based on the Gell and Coombs immunopathologic mechanism [118, 119] (see Table 48.9 [119, 120]).

Table 48.9 Types of hypersensitivity reactions [119, 120]

	Type I	Type II	Type III	Type IV
Mediated	IgE	IgG or IgM Destruction of cells	Antigen–antibody complexes	T-cell ($CD4^+$ or $CD8^+$)
Timing	Seconds to minutes Can be delayed (1–72 h)	Days	Hours to days	Delayed (2–3 days)
Reactions	Anaphylaxis Laryngeal edema Bronchospasms Cutaneous reactions Nausea Vomiting	Hemolytic anemia Thrombocytopenia	Inflammation Serum sickness Vasculitis	Dermatologic
Causes	Hay fever Food IV contrast dye Latex Vaccines Insect bites/stings Medications such as chemotherapy and targeted agents	Transfusion reactions Methylene blue Heparin	Beta-lactams Quinidine Minocycline	Organ transplant rejection Poison ivy

Clinical Features

Anaphylaxis is an allergic reaction characterized by multisystem involvement and is considered a type I mediated reaction that is seen with certain chemotherapy and targeted agents listed below. The initial symptoms of anaphylaxis are often nonspecific and include tachycardia, faintness, cutaneous flushing, urticaria, diffuse or localized pruritus, and a sensation of impending doom. These symptoms usually occur within minutes of administering the offending agent, but reactions may develop later. Biphasic or late-phase reactions that occur 1–72 h after the initial attack have been reported [121, 122].

Chemotherapy and Targeted Agents Implicated

Hypersensitivity reactions are more commonly associated with certain chemotherapeutic and targeted agents such as taxanes, platinum-containing compounds, epipodophyllotoxins, asparaginase, procarbazine, monoclonal antibodies, and, occasionally, doxorubicin and 6-mercaptopurine [120, 123]. Immediate, acute reactions from monoclonal antibodies have been reported in 5–10% of patients for rituximab, 2–3% for infliximab, and 0.6–5% for trastuzumab and have also been reported with omalizumab, natalizumab, basiliximab, abciximab, and cetuximab [123]. Hypersensitivity symptoms to taxanes usually develop in the first few minutes of the infusion and mostly occur on the first or second exposure. Platinum-containing compound reactions usually occur at the time of cancer reoccurrence or after the patient has been exposed for at least six cycles [123].

Treatment

Early and rapid assessment is crucial and every minute counts. If a patient is unresponsive and pulseless, cardiopulmonary resuscitation should begin, and the appropriate advanced cardiovascular life support (ACLS) algorithm should be used. Advanced airway management with oxygen should be established and maintained without any delay. Circulation should be supported initially with a rapid fluid challenge of 500–2000 mL of 0.9% sodium chloride [122, 124].

Epinephrine treatment is also used to help maintain circulation in patients experiencing anaphylaxis. In a Cochrane systematic review, no randomized controlled trials using epinephrine were identified. The widespread use of epinephrine in anaphylaxis is based on non-randomized studies and expert opinion and is recommended in all anaphylaxis guidelines published to date [122]. Other types of studies include fatality studies; most people who died from anaphylaxis did not receive an epinephrine injection before cardiac arrest [125].

The adult dose of epinephrine for weight-based dosing is 0.01 mg/kg, to a maximum dose of 0.5 mg intramuscularly (IM) repeated every 5–15 min, as needed for unresolved anaphylaxis symptoms [122]. Epinephrine IM injections into the lateral aspect of the thigh have been reported to provide more rapid absorption and higher plasma epinephrine levels than IM or SC administration in the arm [126]. When anaphylaxis is not responding to repeated epinephrine IM or SC doses, intravenous (IV) epinephrine should be considered [122, 127]. However, caution should be taken when using this route. In an observational study by Campbell and colleagues, they noted that all epinephrine overdoses occurred in patients receiving IV bolus, with more arrhythmia and ischemic events than with IM and SC injections [128].

Adjunctive therapy includes H_1-antihistamines, H_2-antihistamines, and glucocorticoids. None of these therapeutic modalities have rigorous evidence to support their use, and they are second-line or adjuvant therapies in most guidelines. The first-generation, H_1-antihistamine, diphenhydramine, has been used because of its availability in IV formulation and its efficacy in relieving urticaria and itching within minutes after oral or IV administration. Due to its ability to cross the blood–brain barrier readily, diphenhydramine causes drowsiness and impaired cognitive function. Diphenhydramine given orally, IM, or slow IV in a dose of 25–50 mg has been suggested [129]. There are no studies supporting administration of H_2-antihistamines or recommending one over another; however, this class of drugs has a low potential to harm and may be helpful in the management of anaphylaxis. Giving an H_2- with a H_1-antihistamine may decrease urticaria, flushing, headache, hypotension, and rhinorrhea [125].

Glucocorticoids are traditionally administered to help reduce symptoms and to prevent biphasic anaphylactic reactions that may occur. The onset of the glucocorticoid action can be anywhere from 4 to 6 h. They are not the drug of choice for the initial phase of anaphylaxis and due to low evidence are not recommended for use in the 2020 anaphylaxis practice parameter publication [122]. Figure 48.1 is an algorithm detailing steps for treating patients with signs and symptoms of anaphylaxis.

Early recognition and treatment of anaphylaxis saves lives. There is little to no supporting evidence for the treatment of anaphylaxis, but epinephrine has shown to be beneficial, and death has been associated with failure to use epinephrine before cardiac arrest.

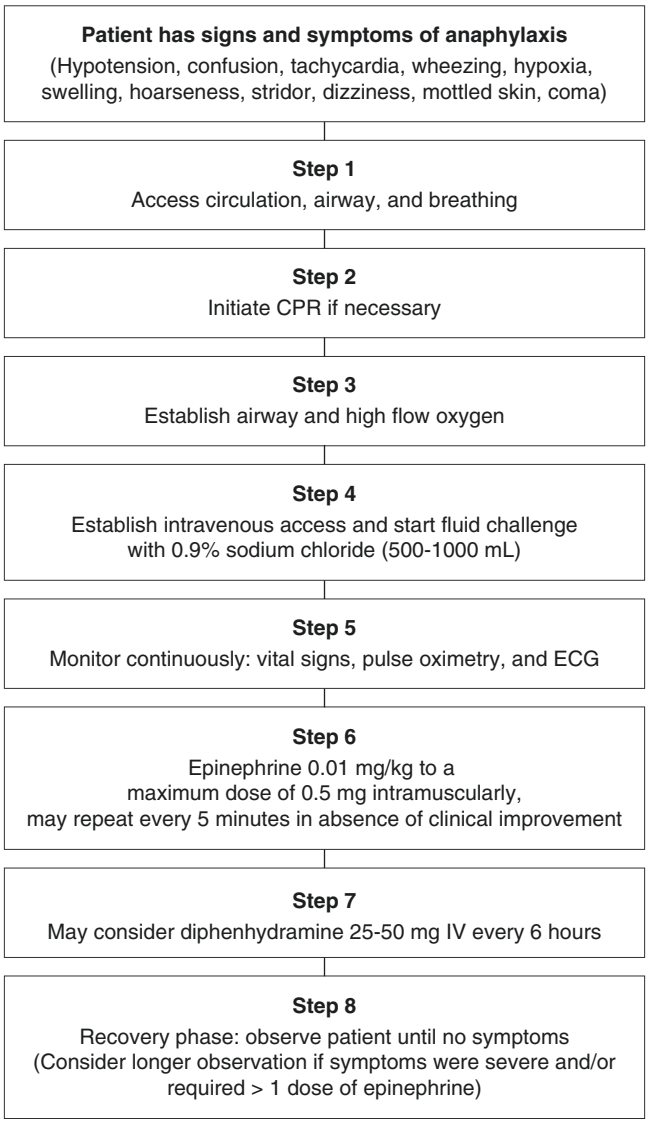

Fig. 48.1 Algorithm detailing steps for treating patients with signs and symptoms of anaphylaxis

Extravasation

Extravasation is a well-recognized complication of intravenous chemotherapy [130]. The incidence of accidental extravasation of intravenous drugs into the tissue can be anywhere from 0.1% to 6.5% [130, 131].

Clinical Features

Extravasation is the unintentional instillation, leakage, passage, or escape of fluid or drug from a blood vessel into surrounding tissue. This may result in varying degrees pain, necrosis, and tissue sloughing. The degree of tissue damage is related to the properties of the drug extravasated, the duration of tissue exposure, and the amount of drug that infiltrated [132]. Chemotherapy drugs are classified into three categories according to their potential cause of tissue damage: vesicant, irritant, and non-vesicant. A vesicant is any agent with potential to cause tissue destruction, blistering, severe injury, or tissue necrosis, when extravasated [132, 133]. An irritant is any agent that can cause inflammation or irritation characterized by aching, tightness, and phlebitis but without necrosis. Non-vesicants are drugs that rarely produce acute reactions or destroy tissue when they infiltrate.

Chemotherapy Agents Implicated

Chemotherapy agents are often classified into the above three categories (Table 48.10 [130, 131, 133–135]). Every attempt

Table 48.10 Classification of chemotherapy agents according to their vascular damage potential [130, 131, 133–135]

Vesicants	Irritants	Non-vesicants
Cisplatin[a] (if >20 mL of 0.5 mg/mL)	Arsenic trioxide[b]	Arsenic trioxide[b]
Docetaxel[a]	Bleomycin[b]	Asparaginase
Dactinomycin	Bortezomib[b]	Bleomycin[b]
Daunorubicin	Busulfan	Bortezomib[b]
Doxorubicin	Carmustine	Cladribine[b]
Epirubicin	Carboplatin	Cyclophosphamide
Idarubicin	Cladribine[b]	Cytarabine
Mechlorethamine	Cisplatin[a] (if concentration less than 0.5 mg/mL)	Fludarabine
Mitomycin C		Gemcitabine[b]
Mitoxantrone	Dacarbazine	Ifosfamide[b]
Oxaliplatin[a]	Docetaxel[a]	Interferons
Paclitaxel[a]	Etoposide	Interleukin-2
Vinblastine	Fluorouracil	Melphalan[b]
Vincristine	Gemcitabine[b]	Methotrexate
Vindesine	Ifosfamide[b]	Monoclonal antibodies
Vinorelbine	Irinotecan	Pemetrexed
	Ixabepilone	Pentostatin
	Liposomal cytarabine	Raltitrexed
	Liposomal daunorubicin	Temsirolimus
	Liposomal doxorubicin	Thiotepa[b]
	Liposomal vincristine	
	Melphalan[b]	
	Mitoxantrone[a]	
	Oxaliplatin[a]	
	Paclitaxel[a]	
	Paclitaxel, nanoparticle albumin bound	
	Plicamycin	
	Streptozocin[a]	
	Teniposide	
	Thiotepa[b]	
	Topotecan	

[a]Has been described as both an irritant and vesicant in the literature
[b]Has been described as both irritant and non-vesicant in the literature

should be made to minimize the risk of extravasation. This is a collaborative practice involving physicians, nurses, pharmacists, patients, and patients' caregivers. All healthcare professionals should adhere to institutional policies and procedures to prevent extravasation. Unfortunately, not all extravasations are preventable; however, individualized risk factors for extravasation are recognized (Table 48.11 [134, 136, 137]). All parties involved should be cognizant of the signs and symptoms of chemotherapy extravasation. These may include stinging or burning pain, as well as erythema, induration, blister, or vesicle formation. Around the injection site, there may be venous discoloration, swelling, or leakage of fluid. The flow rate of the infusion may change with increased resistance that cannot be explained. Blood return from the infusion line may be impaired or impossible [132, 134]. Chemotherapy extravasation reactions may not manifest until hours, days, or even months after the infusion has been stopped or completed [138].

Table 48.11 Patient risk factors for extravasation [134, 136, 137]

Patient associated	Others
Small and fragile veins	Insufficient training of staff, poor technique
Vascular disease, Raynaud's disease; peripheral neuropathies; peripheral vascular disease such as diabetes	Butterfly, metal, or large-gauged needles
Impaired lymph flow and venous circulation	Inadequate secured needle
Superior vena cava syndrome	Veins used adjacent to tendons, nerves, or arteries
Locally infiltrating tumors	Needle location (e.g., antecubital fossa, wrist or dorsum of hand)
Age—elderly and young at the highest risk	Inappropriate needle length
Restlessness, agitation, altered mental status, or confusion	Catheter failure
Cerebral vascular accident	Multiple attempts at cannulation
Coagulation abnormalities	Irritant and vesicant drugs
Obesity	Prolonged infusions
Prior extravasation injury	Infiltration volume
	Multiple treatments of chemotherapy agents
	Previous vinca alkaloids administration
	Radiation therapy—current or past

Treatment: Pharmacologic and Non-pharmacologic

Extravasation of chemotherapy requires prompt management. Delays in vesicant extravasation treatment can cause further tissue damage, necrosis, and pain that require surgical intervention. The type of chemotherapy, drug concentration, amount of drug extravasated, pH, and osmolarity play a role in severity of tissue injury [132]. The general approach to extravasation management is early recognition and treatment to minimize the extent of extravasation and prevent further tissue damage. For patients reporting burning, pain, or any other infusion-related issue, such as swelling, increased resistance, or leakage of fluid around the site, the chemotherapy infusion stopped immediately. The infusion site should be inspected for extravasation. Patients with extravasation due to a vesicant and any large-volume extravasation or those having worsening pain at extravasation site or evidence of ulceration or tissue necrosis should present to the ED for evaluation and consideration of plastic surgery consultation.

Institutions administering chemotherapy infusions should have policies and procedures in place to ensure early intervention for extravasations. An extravasation kit should be available in the chemotherapy infusion areas. These contain both non-pharmacologic and pharmacologic treatment supplies, including disposable syringes, small-gauged needles, cold–hot packs, gauze pads, adhesive plaster, sterile and protective gloves, and medications (e.g., dexrazoxane, dimethyl sulfoxide [DMSO] 50–99%, and hyaluronidase). Pre-prepared kits allow providers to initiate treatment in the infusion areas and minimize any delay in care.

Step 1	Stop chemotherapy infusion immediately. Leave needle in place. Identify chemotherapy agent.
Step 2	Aspirate any additional drug out of catheter with syringe. Record volume aspirated.
Step 3	Remove needle.
Step 4	Mark the area and take photo of extravasation; notify physician.
Step 5	Administer non-pharmacologic and pharmacologic treatment based on chemotherapy (see **Table 48.13**).
Step 6	Elevate limb; administer additional medications as needed for pain. Assess area for necrotic tissue; consider surgical management.

Fig. 48.2 Treatment steps that should be completed when patients present with signs and symptoms of chemotherapy extravasation [130, 134]

Figure 48.2 [130, 134] denotes all treatment steps that should be completed when patients present with signs and symptoms of chemotherapy extravasation. The infusion should be discontinued as soon as extravasation is suspected. The infusion line should be disconnected, and the needle should be left in place to allow for aspiration of residual chemotherapy. Extensive or large-volume extravasation of irritants and non-vesicants should be evaluated by a plastic surgeon for further intervention and management. Small extravasation of irritants and non-vesicants should be monitored over several days to ensure that the skin is viable and pain resolves. A plastic surgery consult is recommended if the extravasation site develops full-thickness necrosis and chronic nonhealing ulceration or if the patient experiences persistent or worsening pain [139]. Vesicants should be treated with both non-pharmacologic and pharmacologic approaches. Physicians should be notified immediately with information regarding the chemotherapy agent to ensure appropriate and prompt treatment initiation. The extravasation area should be marked with a pen to monitor for extravasation spread. If the first four steps have not been completed prior to ED presentation, it is crucial that they be completed as soon as possible.

Various non-pharmacologic and pharmacologic treatments have been utilized in the past to help minimize the damage of chemotherapy agent extravasations. Available studies report varying degrees of success in managing extravasations. It should be noted that only a handful of treatment options or "antidotes" exist that can be injected or topically applied to the affected area. Vesicant chemotherapy agents can be divided into two categories: DNA binding versus non-DNA binding (Table 48.12), and treatment options for these categories differ [130].

DNA binding vesicants, such as anthracyclines, bind to the DNA in the cells of healthy tissue and promote cell death. DNA-chemotherapy complexes are released from the dead cells in the tissue and are taken up by adjacent healthy cells via endocytosis. This process is cyclic and can continue for

Table 48.12 Classification of vesicant chemotherapy agents [130]

Classification	Examples	Pharmacologic treatment
DNA binding		
Alkylating agents	Mechlorethamine	Sodium thiosulfate
Anthracyclines	Daunorubicin, doxorubicin, epirubicin, idarubicin	DMSO or dexrazoxane
Others	Mitoxantrone, mitomycin dactinomycin	DMSO
Non-DNA binding		
Vinca alkaloids	Vinblastine, vincristine, vindesine, vinorelbine	Hyaluronidase
Taxanes	Docetaxel, paclitaxel	Hyaluronidase

weeks to months after the incident [130]. If left untreated, the cell damage spreads larger and deeper, becoming more painful with time. Debridement may be required if severe injury results in tissue necrosis. Localizing the offending agent can be achieved by cooling the area with a dry cool compress or cold gel pack. This procedure may lessen the pain by constricting vessels and preventing the offending agent from spreading to surrounding healthy tissue. There is insufficient published evidence to support the efficacy of this treatment, but it may be beneficial in reducing discomfort, burning sensation, and tenderness [136]. The next step is to neutralize the offending agent, and this will depend on the extravasated chemotherapy agent (Table 48.13 for dosing) [130, 140–144].

Non-binding DNA vesicants, such as vinca alkaloids, have an indirect effect on healthy tissue. Non-DNA-binding chemotherapy agents are metabolized in the tissue and are more easily neutralized [130]. The injury caused by these agents is localized, is mildly to moderately painful, and improves over time [145]. Local warming is preferred with this group of agents to increase blood flow to the area. Warm compresses distribute the chemotherapy agent and promotes its absorption [131]. However, some controversies have arisen regarding this technique. Some literature reports wors-

Table 48.13 Treatment after extravasation [130, 140–144]

Drug	Non-pharmacologic treatment	Pharmacologic treatment dosing
Anthracyclines	Dry cold compress (3-day course)	*Dexrazoxane* (3-day course)
Daunorubicin Doxorubicin Epirubicin Idarubicin	Immediately for 20 min and four times daily—do not apply 15 min prior to or during dexrazoxane infusion	Within 6 h: 1000 mg/m^2 (max 2000 mg) IV Day 2: 1000 mg/m^2 (max 2000 mg) IV Day 3: 500 mg/m^2 (max 1000 mg) IV Maximum dose of 2000 mg per day. Doses are 24 h apart and infused over 1–2 h in opposite arm If CrCl is less than 40 mL/min—decrease dose by 50% or *DMSO 50–99%*
		Immediately apply topically 1–2 mL with cotton swab over area twice the size of that affected and allow to air dry every 6–8 h for 7–14 days; do not apply if using dexrazoxane
Cisplatin	Dry cold compress	*Sodium thiosulfate* 1/6 M
		1/6 M = 4 mL 10% sodium thiosulfate + 6 mL water
		Inject 2 mL for each 100 mg of extravasated cisplatin through existing needle; if needle has been removed, inject 1 mL SC (0.1 mL doses clockwise around extravasation using small-gauged [25 or less] needle); may repeat SC dose several times over the next 3–4 h
Mechlorethamine	Dry cold compress	*Sodium thiosulfate* 1/6 M
		1/6 M = 4 mL 10% sodium thiosulfate + 6 mL water
		Inject 2 mL for each 1 mL of extravasated mechlorethamine into existing needle; if needle has been removed, inject 1 mL SC (0.1 mL doses clockwise around extravasation using small-gauged [25 or less] needle); may repeat SC dose several times over the next 3–4 h
Mitomycin C *Mitoxantrone*	Dry cold compress (3-day course)	*Topical DMSO 50–99%*
	Immediately for 20 min and four times daily	Immediately apply topically 1–2 mL with cotton swab over area twice the size of that affected and allow to air dry every 6–8 h for 7–14 days
Taxanes	Dry warm[a] compress (3-day course)	*Hyaluronidase*
Docetaxel Paclitaxel	Immediately for 20 min and four times daily	Inject 1–6 mL of 150 units/mL solution through the existing needle; if needle has been removed, inject 1 mL of solution per 1 mL of extravasated chemotherapy agent SC in a clockwise manner into multiple sites of the extravasation area using small-gauged (25 or less) needle; may repeat SC dose several times over the next 3–4 h
Vinca alkaloids		
Vincristine Vinblastine Vindesine Vinorelbine		

CrCl creatinine clearance, *DMSO* dimethyl sulfoxide, *IV* intravenous, *mg* milligrams, *SC* subcutaneous
[a]Some literature suggests using cold compresses with taxanes

ening injury at the extravasation site with warm compresses and rather recommends cold therapy to limit the diffusion of chemotherapy [135, 146, 147]. Pharmacologic treatment used for these agents helps dilute the offending agent (see Table 48.13 for dosing) [130, 140–144].

DNA-Binding Agents

Dexrazoxane

Dexrazoxane is approved for anthracycline extravasations. Dexrazoxane inhibits DNA topoisomerase II—the target of anthracyclines—minimizing pain and oxidative damage in the tissue by chelating metal ions from anthracycline [148]. Dexrazoxane is well tolerated and highly effective in avoiding surgical resection after anthracycline extravasation [140, 141]. Patients receiving dexrazoxane may experience bone marrow suppression (underlying disease and chemotherapy), mild transient elevation of liver enzymes (occurs in ~25% of patients), nausea (20%), and local infusion site pain [140]. Concomitant use with dimethyl sulfoxide may reduce the efficacy of dexrazoxane [149].

DMSO

Dimethyl sulfoxide (DMSO) is a topically applied solvent that increases skin permeability, promotes absorption of extravasated vesicants, and scavenges free radicals. DMSO has been studied in various amounts and concentrations (50–100%), application frequencies (every 2–8 h), durations of treatment (2–14 days), and for several different types of chemotherapy extravasations [137]. DMSO should be applied immediately and reapplied every 6–8 h for 7–14 days to decrease risk of ulceration and need for surgical debridement. Pain and erythema usually resolved in the first 1–2 weeks, and DMSO

may be used for up to 6 weeks. Reported side effects include mild pigmentation in the area, mild discomfort at the injection site, and a characteristic garlic breath odor [142]. Local DMSO in combination with dexrazoxane should be avoided. DMSO in combination may lessen the effects of dexrazoxane [135, 149]. Toxicity associated with mitomycin C may also be prevented by DMSO used topically [143, 150].

Sodium Thiosulfate

Mechlorethamine can cause severe ulceration and tissue damage. Sodium thiosulfate 1/6 M (0.17 M) solution is the only antidote currently available and recommended for extravasation of mechlorethamine or concentrated cisplatin (>20 mL of greater than 0.5 mg/mL) (see Table 48.13). When given subcutaneously into the extravasation area, sodium thiosulfate binds and neutralizes the extravasated vesicant and reduces production of hydroxyl radicals [151].

Non-DNA-Binding Agents

Hyaluronidase

Hyaluronidase can be used to treat vinca alkaloids or taxane extravasation [135, 144, 152]. Hyaluronidase is a protein enzyme that helps degrade hyaluronic acid that holds tissue planes together, rapidly dilutes the offending agent, and enhances drug absorption. Hyaluronidase doses range from 150 to 200 units, administered into the indwelling catheter or subcutaneously around the extravasation site [144, 149]. It has been shown to decrease pain and the amount of tissue injury over several days [144].

Surgical Intervention

The optimal timing of surgical intervention is unknown. Only one-third of vesicant extravasation in the extremities actually results in ulceration. Therefore, routine surgical intervention should not be the initial treatment [153]. Ulceration can progress to necrosis and infection. A plastic surgical consultation is recommended if the patient experiences a large-volume vesicant extravasation (not defined) and severe pain, if healing has not occurred 1–3 weeks after extravasation, or if there is early necrosis present [132, 135]. Surgical interventions may include debridement, fasciotomy, reconstruction, and grafting.

Saline flushing or washout/flush-out techniques have been described in the literature. There is some evidence that this may be beneficial. Several techniques have been used alone and in combination with other treatments [136]. The flush-out technique is usually performed by plastic surgeons, and the most recent described technique involves making several small-stab incisions and administering large volumes of 0.9% sodium chloride to dilute and flush out the extravasated drug [154, 155]. Saline washouts completed within 24 h of extravasation have been shown more effective than those completed more than 24 h post extravasation.

Treatment Toxicity: Radiation

49

Thomas J. FitzGerald, Maryann Bishop-Jodoin, Fran Laurie, Eric C. Ko, Allison Sacher, Gregory A. Volturo, Daniel C. Han, Paul S. Rava, and Eric W. Dickson

Introduction

Exposure to radiation can result from diagnosis and primary management of a malignancy, or it can be an unintended consequence of nuclear accidents or an intentional act of terrorism. More than 60% of cancer patients will have radiation therapy as part of their primary treatment, and the accelerated risk of nuclear events increases our collective need for education of health-care providers in the knowledge and evaluation of radiation exposure and injury [1–8]. Although effects on tissue may not be visible or clinically apparent during an emergency evaluation, exposure is an important aspect to the medical history of the patient as it leaves an invisible clinical footprint which may be relevant to medical situations at a later time point, even decades after exposure. Intentional exposure is usually well documented with dose-volume precision in the radiation oncologic treatment record. However, at the time of an unanticipated emergency department visit, hospital record documentation is often limited to a few words describing treatment total dose and volume in a brief qualitative manner as the shadow radiation therapy record or radiation digital health record is often not directly linked to the hospital informatics systems. Therefore, information valuable to the emergency health-care team may be cursory, incomplete, or even inaccurate if obtained from a service unfamiliar with radiation treatment and exposure to normal tissue.

Unintentional exposure is more challenging to document and often limited to mathematical models of duration and distance from the primary incident, as victims are often unmonitored. While the models may be helpful, they often can be less accurate, especially in computation of the integral or total body dose [1, 6, 8]. Fluoroscopy during interventional radiology/cardiology procedures can lead to a surprisingly high-radiation dose to underlying structures that is often poorly documented, again comprising a relatively hidden risk in patient care [2–4].

With an increasing number of cancer survivors, including transition of survivors from pediatric to adult physicians, there is a developing knowledge gap at the primary care and emergency medicine levels concerning both acute and late effects of radiation exposure and how these interrelate with patient health care in the acute care setting. It is incumbent on the radiation oncologic community and radiation exposure experts to improve documentation and communication to health-care staff in order to better prepare patients and physicians for identifying contributing factors and strategies of short- and long-term normal tissue-driven processes that affect patients after radiation treatment and exposure.

Acute Radiation Toxicity: Unintended Exposure

Normal Tissue Toxicity

Acute toxicity from radiation exposure can be divided into acute (up to 90 days from exposure), subacute (from 90 days to 2 years from exposure), and chronic or late (>2 years from exposure) phases of injury. Although acute intentional injuries are traditionally managed by the responsible treating physicians during primary management of a malignancy, accelerated normal tissue damage that affects hydration balance and nutrition can often require evaluation by emergency services for triage and disposition. Unintentional exposure uniformly requires evaluation by emergency services with

appropriate support from experts trained in managing acute radiation effects and radiation safety officers trained in assessing the nature of the exposure and possible radiation dose received by the victims. This would also include the evaluation of risk to personnel caring for the victim. The acute phase of injury can affect many cell systems, including toxicity to tissues of both limited and rapid self-renewal potential. These include, but are not limited to, the central nervous system, bone marrow, skin, and mucosal surfaces lining the head/neck and gastrointestinal system.

Knowledge of the effects of radiation damage to the body has been acquired through animal models as well as events in history documenting human exposure. These events include atomic bomb survivors and people affected through unintended nuclear fallout and nuclear accidents. Symptoms associated with unintended radiation exposure vary with the severity of the exposure. At very high single-fraction total body doses (>10 Gy), death will occur through cerebrovascular syndrome in spite of support within 24–48 h. The syndrome is due to uncontrollable swelling within the central nervous system associated with compromise of all neuromuscular processes. At total body doses of 5–12 Gy, death without support will occur in 1–2 weeks due to denudation and destruction of the gastrointestinal system associated with profound fluid loss and diarrhea. These cells have a self-renewal capacity measured within a few days; thus, a single total body dose of 10 Gy will eliminate a large portion of the stem cells within the gastrointestinal crypts. Although this dose does not affect differentiated adult cells, the exposure eliminates the self-renewal potential of the stem cell; therefore, the mucosal surface of the gastrointestinal tract becomes denuded with no barrier for fluid and blood loss within a short period of time, measured in days. At total body exposure doses of 2–5 Gy, death will occur from damage to the hematopoietic system with primary damage to progenitor cells inhibiting self-renewal. Lymphocytes may die an intermitotic death, and this finding may be a surrogate biomarker for acute exposure within the first few hours to days of an incident [1, 5–8]. However, by day 30, most circulating blood elements are depleted with death often attributed to infection. The term, LD (lethal dose) 50/30, is borrowed from our pharmacology colleagues and reflects the LD of an agent that will cause 50% mortality in 30 days. Although radiation is not a drug, the LD 50/30 is now generally thought to be 5 Gy with modern hospital support [1].

After exposure, victims will develop symptoms consistent with a radiation syndrome that can be visible as early as 15 minutes from the time of exposure [1, 6, 8]. The reaction may last several days until symptoms merge with other events associated with the exposure. Symptoms are generally gastrointestinal and neuromuscular. At lower doses, victims experience anorexia, nausea, and vomiting associated with lassitude. The degree of symptoms is commensurate with dose. At higher doses, patients can experience severe diarrhea, fever, and hypotension suggesting more immediate toxicity including more pronounced neural damage. Usually at low doses, the prodromal phase is followed by a latent period where the victim may appear and feel well for a period of days to weeks. At that point gastrointestinal and hematopoietic damage becomes more evident and requires intervention [1, 5, 6, 8].

If the total body exposure is less than 4–5 Gy, the majority of experts recommend no immediate intervention other than symptomatic treatment as needed. This would include hydration and antiemetic therapy for nausea/vomiting. Antibiotics can be given for infection as needed. If the exposure is greater than 5 Gy, then death associated with the hematopoietic syndrome becomes a real concern. Intervention with isolation and barrier nursing with appropriate blood product support may improve survival. Experience from Chernobyl suggests that efforts to limit infection, bleeding, and physical trauma during the time of blood count nadir may improve the LD 50/30 to and possibly beyond 7 Gy. To the best of current knowledge, no human being has survived a single total body exposure beyond 10 Gy. The use of bone marrow transplant in this setting remains controversial with strong advocates on both sides of the question [7].

Injuries to the gastrointestinal system and hematopoietic systems may be accompanied by dermal injury. Often in particle exposure including low-energy photons, there is significant asymmetry in dose as often the event is triggered by an accident involving the hands. Dermal injuries can be primitive biomarkers for dose with epilation/erythema at doses of 3–6 Gy and wet desquamation, bullae, ulceration, and necrosis seen at higher doses [1, 9]. These injuries can be life-threatening due in part to concomitant infection and should be managed with the same support offered to burn victims.

In the triage of victims with unintended exposure, it is most important to develop as accurate an assessment of dose as possible. Health-care workers will likely be monitored; however, the general public will not, and therefore experts trained in radiation exposure and dose assessment are crucial in the early phase of the evaluation. There are several basic tools to use as part of the initial evaluation. The time to emesis decreases with increasing radiation dose. The rapid onset of nausea and vomiting suggests a higher exposure. A decline in lymphocyte count can be associated with an exposure dose of best relative estimate occurring within 48 h of exposure. This is often hampered because the preexposure lymphocyte count is unknown. If a laboratory for cytogenetic evaluation is available, another surrogate evaluation is to assess the number of chromosomal aberrations in peripheral lymphocytes when they are stimulated to divide. This technique has more value at lower doses as lymphocytes die quickly at high doses [1, 7, 8].

There have been numerous nuclear accidents over the past 50 years with people exposed to total body or partial body radiation. These include nuclear events as well as unintentional exposure to victims unaware of the immediate risk [6, 8]. The Medical Sciences Division of the Oak Ridge Institute for Science and Education operates a Radiation Emergency Assistance Center for the US Department of Energy. The center is a 24-h consultation service with medical and health physics support for issues associated with radiation events and exposure. Resources include expertise for radiation dose assessment, computation of dose from radionucleotides, and laboratory facilities for dose assessment. The 24-h emergency telephone number is 865.576.3131, and the website is http://www.orau.gov/reacts.

Since the development of nuclear weapons, there has been a keen scientific interest in identifying chemical compounds that can protect normal tissues from the effects of radiation exposure. Radiation protectors are elements that are given prior to exposure or in some cases, shortly thereafter, to limit the effect of exposure on normal tissue. Radiation mitigators are compounds that have the potential of influencing the effect and impact of the exposure. Therapeutic compounds are applied once the injury has occurred. There have been more than 4000 compounds synthesized to address this point. Sulfhydryl compounds (SHs) have been shown to be effective radioprotectors with the simplest compound being cysteine, which contains a natural amino acid. It was shown in 1949 that this compound could protect animals from lethal doses of total body radiation if injected or injected in large amounts (equivalent of 150 mg/kg) [10, 11]. The toxicity of sulfhydryl compounds can be limited by the addition of a phosphate group [10]. Once the compound becomes intracellular, it loses the phosphate group, and the compound is thought to serve as a free radical scavenger limiting intracellular damage. The only compound approved by the US Food and Drug Administration (FDA) is amifostine (WR-2721). It is sold as Ethyol and has been used to prevent xerostomia in patients undergoing radiation therapy for head/neck carcinoma [12]. Amifostine has been used in several clinical trials evaluating effectiveness in protecting multiple mucosal surfaces as well as a protectant for pulmonary injury in patients undergoing total body radiation therapy as part of bone marrow transplant [12]. In a Radiation Therapy Oncologic Group (RTOG) clinical trial, amifostine was associated with an improvement in patient assessment of mouth dryness and swallowing [12, 13]. In this trial, there was no difference in tumor control between patients receiving amifostine or placebo. Citrin and colleagues [10] have identified nitroxides as agents for radioprotection in clinical development. Stable nitroxide free radicals and their specific electron reduction products, hydroxylamines, protect cells when exposed to oxidative stress; therefore, compounds such as these are under evaluation. Other antioxidants, including alpha-tocopherol and beta-carotene, have not yet been shown to be of clinical benefit [14, 15]. Simultaneous tumor protection has been a concern in the clinical use of radioprotectors and is the reason these compounds have not been easily integrated into clinical management. Investigators have explored the use of intracellular superoxide dismutase (SOD) using gene therapy vectors to enhance the intracellular component of SOD to limit damage caused by superoxide radicals [16, 17].

Mitigators are compounds that can limit damage associated with radiation exposure prior to the clinical manifestation of both acute and late toxicities of radiation exposure and treatment. These compounds are generally thought to influence the metabolic cascade of events that occur after exposure and in turn limit radiation-associated damage. To date, most of the compounds are cytokines and growth factors directed to stimulate stem cell proliferation and balance the inhibition of stem cell growth induced by radiation to the hematopoietic and GI systems. These include granulocyte colony-stimulating factor (G-CSF) and keratinocyte growth factor (KGF) [18]. These factors contribute to many aspects of cell recovery. KGF has a positive influence in the recovery of mucosal surfaces during the acute phase of toxicity as well as limits the late effects of radiotherapy, including xerostomia [10]. Mitigators of late toxicity are largely directed to limit fibrosis, which is thought to be a primary factor in late pulmonary injury and other tissues of more limited self-renewal potential [10, 14–17, 19–23]. The primary target for this strategy is thought to be transforming growth factor beta (TGF B), which appears to play an important role in the development of fibrosis associated with radiation [24–26]. Accordingly, many compounds in development to prevent late effects either directly or indirectly target the TGF B signaling pathway including receptor inhibition [24–26]. Tumor protection is also a concern in the evaluation of treatments associated with this parallel pathway.

Investigators at the University of Massachusetts Medical School have evaluated the use of interleukin-1 alpha (IL-1α) as a mitigator to dermal damage associated with radiation exposure. Interleukin-1 (IL-1) inhibits neutrophil infiltration into the initial inflammatory response to radiation damage. Dermal injury was induced with electron particle therapy. Knockout mice deficient in IL-1α or the IL-1 receptor demonstrated both decreased dermal injury and more rapid healing suggesting the importance of this cytokine in the generation of radiation-associated skin damage. Neutrophil inhibition generated subsequent to radiation-induced tissue injury influences the pathogenesis of radiodermatitis. In a separate group of experiments, investigators from the same institution demonstrated that hyperspectral optical imaging (HSI) can demonstrate both acute and late oxygenation and perfusion changes in dermal tissue with changes occurring as early as 12 h after radiation exposure using a strontium-90

applicator [27, 28]. Imaging changes in oxygenation and perfusion predated clinical visible skin change by 14 days [28]. Unpublished data sets from this group as part of a human IRB clinical trial in breast cancer patients undergoing radiation therapy have shown that changes in imaging correlate very well with radiation dose and dose asymmetry in the treated volume.

In summary, with the increased risk of nuclear radioterrorism and increased radiation exposure identified during air and space travel, there is a renewed sense of urgency to better define and refine our response to a nuclear event. It is important to acknowledge that dose and particle contamination become essential points during the initial triage of the patient. Potential exposure to first responders must be assessed. The best supportive care has the potential of improving patient survival, which may include hydration and blood product support. There is renewed interest in developing a targeted pharmacologic response to both protect and mitigate issues surrounding radiation exposure [29].

Normal Tissue Effects of Radiation Therapy

Often oncologic patients under active treatment are seen in evaluation by emergency physicians, particularly during non-primary clinic times including evenings and weekends. In large academic centers, this practice is under change as outpatient weekend service is becoming more important to clinical oncologic as more primary patient care management, including bone marrow transplantation, moves to the outpatient setting. Nevertheless, often emergency personnel are involved with patient care matters that are directly or indirectly associated with the management of the malignancy or the sequelae of management including triage of acute care problems that may be related in part to previous therapy delivered years and decades in the past. In the following sections, we will address sequelae of management and how this influences patient care for modern emergency medicine [30].

Management of Acute Effects of Radiation Therapy

Sequelae to normal tissue are mostly attributed to cell death from radiation therapy. The balance between stem cell development and cell death is driven in a large part by tissue organization, stem cell proliferation, stem cell number, and cytokine response for growth stimulus. Acute effects from therapeutic radiation therapy are associated with cell systems that have rapid self-renewal potential including bone marrow progenitors and mucosal surfaces. These sequelae are driven by several factors including the concomitant use of cytotoxic chemotherapy and the volume of mucosal tissue in the radiation therapy treatment field. Acute effects generally occur during the course of radiation therapy and can affect multiple organ systems largely associated with mucosal surfaces including the skin, head/neck, gastrointestinal tract, and bone marrow. Acute effects are exacerbated by the use of chemotherapeutic and/or molecularly targeted small molecule agents delivered both before and during radiation therapy. Although not well validated through mechanism, patients can experience dramatic acute effects from low-dose radiation therapy to the skin and mucosa if they have received prior sensitizing medications including low-dose chemotherapy for autoimmune disease (methotrexate for rheumatoid arthritis) and selected antibiotics (tetracycline) [9]. The phenomenon, referred to as radiation recall, can even be seen in patients who received medications years in the past [9]. Although acute effects mostly impact tissues of rapid self-renewal potential, there can be selected circumstances where near-immediate changes occur that are often not anticipated by the primary providers of care. Patients treated in the head and neck region can experience swelling of the parotid glands with 24 h of exposure of 200 cGy. The adventitia of the parotid gland is tight with limited capacity for expansion from swelling; therefore, rare patients can experience severe pain and discomfort from low-dose therapy. There is often a need to urgently treat patients with significant tumor burdens, particularly in the mediastinum. Radiation to tumors of the mediastinum particularly sensitive to treatment (lymphoma, small cell lung cancer, or germ cell neoplasm) can trigger both nausea and metabolic crisis (hyperkalemia, hypercalcemia, etc.) from rapid tumor lysis. Symptomatic treatment including fluids and medication to counter metabolic by-products is essential for a good outcome.

Acute effects to tissues of rapid self-renewal potential are influenced by total radiation dose, daily treatment dose (fractionation), and volume of tissue treated. This information is often not immediately available to emergency departments when patients present for evaluation as specific treatment documentation is often in the department shadow record and not directly integrated into electronic health-care records. The volume of the treatment target influences the number of stem cells directly affected from daily treatment. Daily treatment dose also influences injury to stem cells. Hence, total and daily doses as well as target volume are all directly related to the development of sequelae from the treatment. Specific acute injuries to organ systems are discussed in the following section.

Skin

The epidermis is the site of many acute reactions to radiation exposure. The dermal stem cells abut the basement membrane and are the active proliferating cell component covered by lay-

ers of keratinized cells, which are desquamated. The stem cells are the target for injury. The time for dermal cell division and migration is between 14 and 21 days depending on the area of the body under evaluation. Single doses of 5 Gy will generate early erythema followed by vasodilation, fluid exudation, cellular migration, and loss of proteins and other constituents of plasma products [9, 31, 32]. Investigators have shown that this process can be identified on hyperspectral imaging within 12 h of exposure with evidence that the evaluation on imaging can be dose specific in spite of the fact that clinical expression of change may not become apparent for 2–3 weeks [27, 28]. Fluoroscopy procedures use orthovoltage (low-energy) X-rays that deliver higher percentages of radiation dose to the skin surface [2, 3]. Complicated procedures in interventional radiology requiring significant fluoroscopy time can create acute dermal injury even in the modern era as acute injuries are influenced by fractionation (daily dose) and total dose. With hypofractionation protocols using high daily dose with compressed treatment schedules including stereotactic therapy for the lung and liver, we are again witnessing injuries to the skin and soft tissue that were traditionally seen in a historical context [33]. The treatment for acute injury is driven in a large part by radiation dose and treatment volume. Modern accelerators deliver the majority of the radiation dose below the skin surface; therefore, with traditional fractionation, it is unusual to have patients demonstrate significant dermal sequela with conservative measures, including various skin creams and ointments. Radiation beams resonate on skin surfaces within dermal folds; therefore, these intertriginous areas are more vulnerable to injury during treatment. Hypofractionation protocols may deliver a higher-dose fractionation to dermal surfaces if treatment planning is not optimal. There are reported soft tissue injuries to the skin during stereotactic body radiosurgery when immobilization devices unintentionally functioned as bolus devices augmenting radiation dose to skin surfaces [33]. As information matures on molecularly targeted therapies, there is increasing evidence of skin toxicity to multiple new agents including EGFR inhibitors (rash 2–4 weeks into therapy), BRAF inhibitors (rash/photosensitivity), BCR-ABL inhibitors (keratosis pilaris/maculopapular rash), and m-TOR inhibitors (rash/pruritus) [10].

Hematopoietic System

The effects on the hematopoietic system are driven by the volume of the bone marrow and lymphoid system treated, previous chemotherapy and radiation treatment, as well as radiation dose. Age of the patient also influences bone marrow injury as there is asymmetry of location in marrow locations between children and adults. Total body exposure will result in a near-immediate decrease in circulating B and T lymphocytes, and a total body dose of 3.0–4.0 Gy likely inhibits the ability to respond to new antigen stimuli. Most patients receive radiation treatment to a partial body, and usually partial organ volume that would have a limited effect on the immune response unless the patient is neutropenic from concurrent chemotherapy [34]. This permits migration of stem cells from outside of the therapy field to stabilize bone marrow function.

Gastrointestinal Tract

The mucosa of the tract has similar organization to skin tissues as stem cells reside at the basal layer and migrate to the surface at varied time points during their life cycle. In general, the cells that line segments of the gastrointestinal (GI) tract possess a shorter life span than their counterparts in the skin. The mucosa of the head and neck and large bowel self-renew every 2 weeks, the mucosa of the gastric region renews nearly every day, and the small intestine renews every 3 days. This explains, in part, why nausea from therapy directed to the gastric region and small bowel can be apparent very early postexposure.

Because the mucosal systems have rapid self-renewal potential, acute sequela from management can be substantial and is driven by radiation dose, daily treatment fraction, and volume of mucosa in the treatment field. By the second week of treatment, the mucosa of the head and neck becomes denuded with increasing pain. Secondary tissues including salivary glands and taste buds also display limited function driven in a large part by the volume of mucosa in the treatment field. By week 4, the mucosa will slough and be replaced by confluence of white cells and fibrin exudate. The impact on secondary tissues becomes more pronounced with severe xerostomia and loss of taste. This creates challenges with maintaining adequate dental hygiene and nutrition. Often patients treated to substantial mucosal volumes require supplemental nutrition for extended periods of time during and beyond treatment completion. These patients can be cured of their primary malignancy; therefore, adopting an aggressive approach to the management of the acute effects from the treatment is reasonable and medically appropriate. Symptomatic pain management with topical and enteral medications is an important management vehicle for care during this period of time [34].

The epidemiology of carcinoma of the esophagus has changed during the past 30 years in North America. Squamous cell carcinomas associated with alcohol and tobacco use have been replaced by primary adenocarcinomas, largely of the distal esophagus associated with gastric surface gland migration (Barrett's esophagus). This has been seen in multiple countries and is now the great majority of esophageal cancers. The mucosa of the esophagus will self-renew in a time frame similar to head and neck mucosa; therefore, 2 weeks into a treatment course, the patient will

begin to develop swallowing discomfort related to treatment. Often these patients initially feel improved due to tumor response; however, mucosal denudation from treatment also becomes apparent during this time, and symptoms associated with dehydration and nutritional imbalance become more visible. Symptomatic management with pain medication and fluid support is an important adjunct during this period.

Treatment of the gastric mucosa can cause near-immediate nausea/vomiting due in a large part to the rapid self-renewal capacity of gastric stem cells. During a treatment course of radiation therapy, delayed gastric emptying can be observed due to edema in the bowel wall as well as the development of ulceration due to limited stem cell renewal capacity.

Early complications of the small and large bowel are similarly driven by radiation dose, treatment fractionation, volumes of bowel in the radiation therapy treatment field, and previous abdominal surgery. Previous abdominal surgery can result in adhesions which can fix segments of the bowel into a specific location, potentially exacerbating acute injury due to limitation of blood supply and repeated high-dose treatment [15, 35]. The small bowel absorbs protein, carbohydrate, fat, and water. If the mucosal surface is denuded, foodstuffs cannot be absorbed. Carbohydrate and fat function as a micelle and draw more water into the gastrointestinal tract resulting in increased bowel movement frequency and symptoms consistent with malabsorption. The large bowel mainly absorbs water; therefore, if generous segments of the large bowel are included in the therapy field, increased bowel frequency may occur with risk of dehydration and electrolyte loss often exacerbated with the concurrent chemotherapy. Although some of these issues can be anticipated and addressed through daily clinical care with fluid and electrolytes, often, these patients present for emergency department evaluation during evenings and weekends for symptom management. Therefore, up-to-date clinical information can often facilitate and support emergency services when needed including the risk of secondary infections associated with therapy. From a clinical perspective, patients being treated for recurrent disease often have more acute and potentially more serious sequela than patients being treated on an adjuvant basis. The root cause for this phenomenon is multifactorial, likely driven in part by tumor compromise of normal tissue function and vasculature prior to the initiation of therapy [34].

Subacute and Late (Delayed) Effects of Treatment

For both primary and emergency health-care providers, the late effects of cancer management can be less visible to casual observation but become a highly visible component to patient care years and decades after primary management. As patients are cured of their primary malignancy, secondary effects of therapy on normal tissue structure and function are now important for follow-up and preventative care as needed. As children treated for malignancy grow and become adults, adult physicians will need to embrace previous therapy as a significant component to their past medical history and treat accordingly. Acute effects of treatment are not always a predictive indicator of late effects, specifically patients without acute effects during the primary management phase of treatment remain at identifiable risk for late effects.

Usually acute effects of radiation management affect cells that have a rapid self-renewal capacity. Nearly every cell system in both adults and children is at risk for late effects driven in a large part by the total radiation dose and volume of normal tissue treated. Late effects are also influenced by daily treatment dose. Children remain at significant lifetime risk as growth and development of all cell systems is directly affected by therapy [15].

The relationship of chemotherapy to delayed effects from radiation therapy to normal tissue is less well described [15]. Although it is recognized in a qualitative manner that chemotherapy exacerbates acute effects of radiation therapy to tissues of rapid self-renewal potential, the impact of chemotherapy on late effects of treatment is not understood. To date, most radiation oncologists have not made adjustments in dose to normal tissue targets; however, our volumetric dose volume tools are now providing metrics through histogram analysis. The quantitative analysis of normal tissue effects in the clinic (QUANTEC) is a significant effort by radiation oncologists to define dose volumetrics for thresholds for normal tissue injury [36]. This effort reviewed most of the available and relevant published data to date and provides guidelines for physicians to follow for prevention of injury [36]. Because of modern computer metrics, the guidelines are driven by radiation dose and volume exposed to treatment. When treatment is developed through three-dimensional planning and executed through conformal delivery systems, including intensity modulation, normal tissue volumetrics are available for analysis through dose-volume histogram tools.

In this section, the late effects of radiotherapy will be described. This is important for emergency physicians as often this information is not available as part of the past medical history of the patient during an acute care evaluation and triage for advanced medical care. Improved knowledge of late effects will influence management and evaluation including the evaluation strategy in the acute care setting. Understanding these effects will improve patient care and evaluation moving forward.

Skin

Acute effects (described previously) of radiation injury to the skin generally resolve within 1 month of completion of

therapy. With traditional fractionation to radiation doses of 7000 cGy, there can be thinning of the epidermis with deceptive prominence of the vascular pattern (telangiectasia) in the dermis. The degree of vascularity is decreased; however, thinning of the epidermis can make the vessels in the dermis appear more prominent [9]. With hypofractionation protocols now in clinical use, there can be more visible injury associated with varying degrees of fibrosis [33]. Hyperspectral imaging demonstrates that oxygenation is decreased, providing an explanation to limitations in wound healing when there are secondary injury and infection [10, 27]. Local immunity and moisture glands significantly diminish; therefore, injury to irradiated tissue can result in significant delay in healing with persistent ulceration and damage possibly requiring aggressive surgical care including hyperbaric oxygen therapy in extreme situations [9]. To date there has been little progress on specific therapies that can be applied to radiation injury once it is clinically apparent. The current standard of care is to follow optimal wound care strategies.

Skin tissue can also demonstrate a phenomenon termed *recall*. Chemotherapy agents and antibiotic agents can cause acute erythema and skin breakdown in areas that were previously irradiated. This can occur years after primary radiation therapy management.

Patients with autoimmune disorders including lupus and scleroderma may be vulnerable to accelerated fibrosis from traditional radiation therapy. This creates wound healing issues for secondary injury as well as limitations in function of organs requiring coordinated muscle function including the esophagus [9].

The mechanism of visible injury is due to damage to stem cells and the reticulum support elements of the skin. The repair becomes disorganized, and the injury to the dermis does not support the development of the epidermis as in an untreated skin. Secondary infections are more difficult to heal when identified in treated areas.

Bone Marrow

Although the primary focus of attention is with acute effects, the bone marrow can remain fragile years after therapy and vulnerable to various medications and external agents after radiation therapy. This is especially true for white cell elements and platelets. If there is a diminution in red cell count, this is usually not associated directly with radiation therapy and will require more extended evaluation for blood loss and anemia. Pancytopenia and bone marrow aplasia are becoming more common consequences of cancer therapy and often first identified in an acute care environment. This often influences choice and duration of treatment of infections and other late sequelae of management. Secondary blood dyscrasias including secondary blood malignancies are associated with primary management and are often first identified in the acute care setting [15, 34]. The role of transplant of both primary and support cell marrow elements to repopulate bone marrow remains under study.

Gastrointestinal Tract

There are substantial late effects of management to be considered in the acute care environment. These are issues that can significantly complicate patient management and often require adjustments in management.

The mucosa of the oral cavity recovers in a manner similar to the skin; however, there is residual compromise of the oral cavity environment, which is long-standing in nature. The floor of the mouth is taut and lacks mucosal redundancy; therefore, it is susceptible to injury and heals less well than other structures in the oral cavity. If ulceration occurs, debris and particles can sequester in the open space and cause necrosis of underlying structures including the mandible. This requires careful management including hyperbaric therapy and surgery. These issues are challenging and may become more frequent as radiation therapy moves to more hypofractionation protocols for head and neck cancer. Patients have dry mouth due to radiation dose to the parotid glands, the submandibular glands, and the often overlooked submucosal gland structures that provide moisture to the mucosal surface. These microscopic glands are ubiquitous in distribution throughout the mucosal surface and create secondary issues for dentition in adults and children. Although teeth do not self-renew and by default are not directly affected by radiation, treatment affects the oral cavity environment and both the growth and development of teeth in children and the oral cavity environment for adults. The saliva becomes more acidic and prone to fungal overgrowth. The gingival mucosa becomes thin and denuded. These changes can lead to chronic decay and demineralization of teeth. Fluoride mouthwash with periodic use of baking soda/water rinses helps deacidify the oral cavity and promotes more optimal oral hygiene; however, these changes are often unrelenting and difficult to control. Optimal radiation planning strategies with intensity modulation may help mitigate these changes moving forward. Building a strong relationship with dental medicine helps facilitate optimal patient care [15, 34].

Motility of the gastrointestinal tract is not a well-described side effect of radiation management; however, this is becoming a more visible issue in the management of head and neck malignancies and esophageal cancers [37]. Contractility of the medial constrictor muscles of the hypopharynx is now described and appears to mimic swallowing issues often seen in patients with neurodegenerative disorders [37]. At times these changes are related to treatment-associated dermal and

interstitial edema, and addressing the edema through lymphedema clinics can be very helpful. As more patients survive their primary malignancy, these issues are becoming more frequent and impose significant restrictions on patient recovery from treatment. Delayed gastrointestinal emptying associated with antral fibrosis and denudement of the mucosa of the gastric lining cells can be seen in patients treated to the gastric region, usually at doses of greater than 45 Gy to the gastric region or the gastric resection site.

Late effects to both small and large bowel include every tissue component. There is atrophy of the mucosa resulting in limited absorption of protein, carbohydrate, and fat. This contributes to various degrees of malabsorption syndromes and inconsistent bowel function. If there is previous abdominal surgery, the bowel may be fixed in position resulting in stenosis and ulceration requiring surgery. Relatively little is known about effects to the exocrine and endocrine pancreas although atrophy of the pancreas can be seen on imaging years after treatment of an upper abdominal malignancy [15, 34].

Liver

There is renewed interest in defining radiation dose effects to the liver as stereotactic body radiosurgery techniques have been effective in the treatment of both metastatic disease to the liver and primary hepatocellular carcinoma. Sequela to the liver, known as radiation-induced liver disease (RILD), is driven by the volume of the liver treated and the functional status of the liver at the time of therapy. Both primary and metastatic diseases can impose varying degrees of veno-occlusive changes in the parenchyma, and treatment can induce scar tissue that can limit the functional status of the remaining liver. Magnetic resonance imaging has become a valuable tool in validating the degree of veno-occlusive changes and has evolved into a quantitative metric in predicting possible radiation-associated liver injury prior to the administration of radiation therapy [38]. Investigators are using metrics identified on dynamic contrast imaging to establish the appropriate radiation dose to target. The threshold of injury to the liver is significantly decreased when the entire organ volume is treated. Sioshansi et al. have demonstrated injury to the diaphragm without changes in the chest wall resulting in chronic pleuritic pain among patients undergoing stereotactic body radiosurgery [39]. The liver is sensitive to interactions with chemotherapy perhaps best demonstrated in the pediatric population when radiation therapy is delivered with actinomycin D chemotherapy for Wilms' tumor. Sequela can include a dramatic decrease in blood counts as well as changes consistent with liver failure including coagulation disorders [34].

The mechanism associated with therapy-associated hepatic injury is related to direct injury to hepatocytes and the structural integrity of their organization. The injury is expressed through the associated disorderly repair of hepatocytes coupled with nodular regeneration limiting normal function of the liver. Investigators are currently describing two forms of radiation-induced liver disease. The traditional form of injury (classical) is imposed on pre-injury normal hepatic parenchyma. In these patients, abdominal pain, hepatomegaly, anicteric ascites, and elevation of alkaline phosphatase are seen as the clinical manifestation of injury. In nontraditional (nonclassical) injury, patients often present with jaundice and elevation in transaminase enzymes. Biopsy of the liver will demonstrate edema of the endothelium and narrowing of hepatic venules creating retrograde congestion and veno-occlusive changes. Microthrombi can develop which further exacerbates congestion. Models have demonstrated that an increase in transforming growth factor beta is associated with increasing degree of injury. Hepatic stellate cells are responsible for regeneration of hepatocytes as well as secretion of various growth factors supporting development and regeneration. However, if the reticulum architecture is damaged, the hepatocytes do not have an infrastructure platform to repair in an orderly manner. Disorganized repair is nodule regeneration. Because of a larger separation between hepatic parenchyma and the blood supply, the liver has less meaningful function. This is reflected in the fact that radiation-induced liver disease has a lower threshold for injury when therapy is applied to the liver with pre-existing injury prior to radiation therapy. It is thought that the mean dose threshold for injury in the otherwise healthy liver is 30 Gy while the mean dose threshold for patients with pre-existing injury or lower based on the degree of pre-existing comorbidity.

Because there are no identified therapies to mitigate or treat injury, prevention of injury is essential for current cancer management. Modern radiation therapy techniques including image guidance and motion management have significantly improved patient care and limited the impact of therapy on normal tissue function. Modern imaging techniques including indocyanine retention and magnetic resonance imaging have served as excellent surrogates for liver function which have supported appropriate targeting and radiation target dose and dose fractionation [38, 40–42].

Kidney

The kidney, similar to the liver, is a relatively late-responding radiosensitive critical organ. Radiation doses of greater than 20 Gy in 2 Gy fractions can result in renal damage with anemia and hypertension. Although not yet validated through clinical trials, the threshold for injury is thought to be lower when nephrotoxic chemotherapy is used with radiation therapy. Using intensity modulation and image guidance, radiation

oncologists can be creative with partial volume therapy and spare as much renal parenchyma as possible. Nevertheless, in comparison with siblings, there is an increased risk of renal failure in the cancer survivor; therefore, investigators should attempt to limit renal dose to as little as possible during treatment planning. To date this issue has not yet been defined as a point of interest for imaging and avoiding delivery of contrast agents; however, this may become an important issue in the clinic moving forward [15, 34, 36].

The mechanism of injury is multifactorial as radiation therapy likely has impact in all compartments of the kidney including the glomeruli, mesangium, and endothelium. Often injury from therapy is challenging to distinguish from more typical forms of injury including hypertensive renal disease. Oxygen-related species generated as secondary byproducts of therapy are thought to directly impact glomeruli with denuded tubules permitting entry of toxins into interstitial tissues. The development of scar within the kidney and subsequent decrease in size of the affected area are thought to be driven in part by transforming growth factor beta. The sequelae of injury include hypertension which needs to be managed aggressively and followed with rigor. Often the use of angiotensin-converting enzyme inhibitors (ACE inhibitors) and angiotensin receptor blockers is helpful in management. As per other sites of normal tissue injury as noted, the best therapy is prevention. Care and attention to radiation therapy treatment planning with intentional conformal avoidance of renal parenchyma during therapy is essential for the modern cancer patient [43–45].

Lung

As with the liver and kidney, the lung is a very sensitive intermediate to a late-responding tissue. In extreme situations, injury to the therapeutic lung can be life-threatening. There are generally two periods of damage that can be identified. Pneumonitis (period of active inflammation) can occur 2–6 months after completion of radiation therapy, and fibrosis can occur years after treatment delivery. During the pneumonitis phase of injury, there is active inflammation often visible on thoracic imaging. If the patient is asymptomatic, observation is a reasonable approach. Symptoms including cough and shortness of breath associated with these imaged changes are often managed by corticosteroids and antibiotics as appropriate [46]. There are reports of radiation injury to the lung tissue outside of the radiation treatment field. Although felt to be spurious at initial review, investigators have suggested that production of nitric oxide gas as a byproduct of radiation-induced injury may play a role in generating injury in other parts of pulmonary parenchyma not directly in the radiation therapy treatment region [47]. Fibrosis as a late change can result in parenchymal scar as well as pleural and pericardial effusions resulting in limitation of pulmonary reserve and chronic need for supplemental oxygen. Modern radiation techniques including the use of motion management and intensity modulation may limit the risk of injury by limiting the volume of parenchyma receiving higher doses. Dose-volume histogram analysis also suggests that it is likewise important to limit the volume of normal lung parenchyma receiving 20 Gy. Modern radiation therapy techniques seek to limit the volume of lung receiving both high and low doses. Interactions with other pulmonary toxic agents such as bleomycin play a key role in evaluating the dose-volume effect of radiation therapy. This is especially important in patients treated for Hodgkin lymphoma. Recent studies do reveal an increased risk of chronic pulmonary disease in cancer survivors in comparison with siblings [15, 24, 25, 48].

The mechanism of pulmonary injury is directly related to damage to lung parenchyma. Radiation both primarily generates injury and secondarily creates reactive oxygen and nitrogen species that produce oxidative injury to cell structures leading to cell death. Predominantly, type 1 pneumocytes are directly injured by radiation. Type 2 pneumocytes are less common. Although they can de-differentiate into type 1 pneumocytes, they are conversely stimulated by radiation and exhibit hyperplasia and growth following exposure. Hyperplasia is associated with growth factor production including removal of debris. Inflammatory cells migrate into the region which leads to fibroblast production and fibrosis. Initially the injury is related to cell death and damage to alveolar/capillary structures which ultimately lead to disorganized repair and fibrotic lung tissue.

The degree and severity of injury are often driven in large part by the volume of parenchyma treated. Other variables influencing outcome include baseline pulmonary function and medical comorbidities. Chemotherapy including immunotherapy can have a significant influence on outcome including patients who have favorable metrics with respect to radiation therapy treatment volumes. Radiation metrics including volumes of regions receiving high, moderate (V20, volume receiving 20 Gy), and low (V50, volume receiving 5 Gy) dose each contribute to a normal tissue outcome with varying degrees of influence, often in a patient-specific manner. Further research is needed to see how these variables relate to each other as predictive indicators of function and outcome [49–51].

Case Study

Two patients in Figs. 49.1 *and* 49.2 *represent therapy-driven pneumonitis outlining the radiation therapy field while on immune checkpoint inhibition with improvement after withdrawal of the drug.*

Heart and Peripheral Vessel

Historically the heart was considered to be a late-responding tissue with exception of pericarditis, which could occur during or shortly following radiation therapy, especially in patients with generous cardiac volumes in the treatment field. Patients typically present with sharp, anterior chest pain and pericardial fluid causing shortness of breath and a low-grade fever. Anti-inflammatory medication and treatment interruption alleviate symptoms. With modern cardiology evaluation techniques including magnetic resonance and nuclear medicine studies, we can now identify previously unforeseen cardiac events. This is important as studies are suggesting an association between radiation therapy and the development of cardiovascular disease when the heart is an unintended target of treatment. Tangential irradiation to the left breast as treatment for breast cancer can deliver a measureable mean dose to the heart even with intensity modulation techniques [52].

Anterior-posterior treatment techniques used to treat Hodgkin lymphoma with historical non-image-guided techniques resulted in full-dose radiation therapy to multiple critical cardiac structures. In reviewing the anterior-posterior cardiac anatomy using traditional radiation therapy

treatment fields for Hodgkin lymphoma, multiple critical structures reside in the parallax of the vertebral body including the primary cardiac vessels, the electrical conduction nodes, and the aortic valve. The mitral valve resides generally 2 cm lateral to the left edge of the vertebral body in patients without chronic lung disease. Therefore, traditional radiation treatment for Hodgkin lymphoma included many cardiac structures treated at high dose, placing these tissues at risk for the lifetime of the patient. Modern cardiac imaging using multiple platforms reveals segments of the myocardium, which can demonstrate dyskinesis in small segments of the cardiac myocardium (apex) after tangential radiation therapy for breast cancer. The clinical importance of these findings is uncertain. Intensity modulation decreases radiation dose to the heart; however, there is a population treated with radiation therapy in the pre-intensity modulation era that will be at risk for the next several decades for heart disease. Recent studies demonstrate a significant risk of heart disease in the cancer survivor compared to their siblings [31, 39, 48, 52–65].

Large peripheral vessels were historically viewed as resistant to radiation therapy; however, as we begin to move forward with hypofractionation protocols, reports of injury are being reported. During historical times when treatment was delivered with orthovoltage therapy, carotid injury was described recognizing that dose to carotid was likely much higher than the reported tumor dose. Pathologies of injury include intimal hyperplasia and weakening of the carotid muscle. There are reports of fistula formation and sudden death due to rupture of the carotid vessels [31, 62]. Reports of injury to other large vessels (subclavian, femoral, etc.) were reported when there was overlap with radiation therapy treatment fields necessitating large radiation dose to a tubular structure [62]. With modern radiation therapy and traditional fractionation strategies, radiation injury to large vessels is uncommon. However, with higher daily doses to tubular structures, late injury can result and become clinically important. Symptomatic injury to veins is less common, and injury to capillaries can be visible at radiation doses of 50 Gy. This is an area, however, where retreatment of second cancers may predispose to injury in future patients.

The mechanism associated with the impact of radiation therapy on the heart and blood vessels is driven by inflammation related to the trauma of injury coupled with late fibrosis and functional instability. Intimal damage to cardiac vessels followed by cell proliferation in a disorganized manner can lead to premature coronary artery disease and atherosclerosis. Damage to cardiac valves can lead to late fibrosis and calcification which are able to cause both stenosis and insufficiency. Myocardial and pericardial inflammation can lead to muscle dysfunction, cardiomyopathy, and congestive heart failure. Pericarditis can be seen in situations where a large volume of heart receives radiation therapy and acute inflammation can lead to constriction of function. Electrical conduction deficits are seen and thought to be related to fibrosis in conduction pathways. Multiple chemotherapy agents influence cardiac health, and their relationship to injury imposed by radiation therapy remains under evaluation.

To date there is no mitigation management and therapeutic intervention available to manage cardiovascular disease driven by radiation therapy. Surgical teams need to be seasoned and expert in managing these patients. Often these experts need to both review and understand the nature of treatment and how it was applied to optimize outcome for each patient. The most optimal treatment is prevention by a seasoned radiation oncologic team with advanced knowledge of cardiac anatomy and how it can be applied to therapy with conformal avoidance and image guidance with breath-hold techniques to decrease cardiac dose. With modern radiation therapy, therapy targets are designed in four dimensions, and conformal avoidance can be applied as best as possible. Cancers are not convenient, and often cardiac structures receive both high- and low-dose radiation and cannot be avoided. In this cohort of patients, it is best to involve onco-cardiology early in the survivorship process to best ascertain imaging and functional analysis to optimize post-therapy care and identify issues in their early development when intervention may be best utilized and optimized [66].

Central and Peripheral Nervous System

The brain has several categories of cells susceptible to injury including the glia (support cells), primary neurons, and blood vessels. All of these tissues are generally considered as late-responding tissues; therefore, most sequelae occur as late events. The most important sequela is necrosis, which can occur within 6 months of radiation therapy; however, reports of late injury indicate that events can occur several years after treatment. Necrosis is seen more often now that radiosurgery techniques are used more commonly in patient care. Rarely, demyelinating syndromes can occur in the central nervous system. These syndromes can also occur in the spinal cord. Reversible syndromes can occur in the spinal cord in doses as low as 35 Gy; however, irreversible changes including myelitis begin to occur at doses of 45–50 Gy with traditional fractionation and appear to incrementally increase with larger radiation dose and larger volume of the spinal cord included in the treatment field. Toxicity may be increased with the addition of neurotoxic chemotherapy including *cis*-platinum, vinblastine, Ara-C, gemcitabine, and methotrexate. Peripheral nerves can likely tolerate a higher dose of radiation therapy as the cauda equina, and larger nerves appear to tolerate radiation doses in excess of 55 Gy without evidence of injury [67]. Visual field changes are seen in radiation doses higher than 5400 cGy to the optic nerve

and chiasm [68]. It is thought that the chiasm is sensitive to radiation therapy as it has an end-arterial blood supply. This was first described in patients treated to the pituitary gland for pituitary adenomas using daily treatment fractions of greater than 200 cGy/day [69]. Therefore, with modern-day image guidance and partial volume therapy, some investigators believe that tolerance of these structures may be higher than described in the historical literature. The cochlea can be affected by radiation, and this effect can be more pronounced at lower doses with the use of chemotherapy including *cis*-platinum. Historically the lens is very sensitive to radiation therapy with cataract formation identified at very low dose (500 cGy) [9, 70].

Brachial plexopathy has been described in breast cancer patients treated to peripheral lymph nodes. Although the radiation dose threshold for injury is thought to be 5400 cGy, this is an uncommon side effect for patients treated with higher doses of radiation for head and neck cancer. The prevailing thought is that the more sensitive part of the plexus is the region where the nerve bundles coalesce immediately inferior to the lateral third of the clavicle. In the early days of radiation therapy, this area was calculated using an anterior field to a depth of 5 cm. The nerves can be as superficial as 1 cm below the skin surface; therefore, the nerve region received a higher percent dose and in some case would have received the equivalent of a high daily fraction (>120% of the prescribed dose). This is compounded further by the use of posterior axillary boosts, which were often viewed and calculated as separate fields with exit overlap at the egress points of the brachial plexus into the upper extremity. Therefore, it is entirely possible that the threshold dose for brachial plexus injury may be higher than described in historical literature due to unintentional overlap of radiation field volumes and unspecified increases in daily fraction size to a critical target. Today, using three-dimensional volumetrics, the axilla is a volume and modern planning permits more uniform radiation dose distribution through a volume than two-dimensional treatment planning constructs [71].

The mechanism of damage to the central nervous system and peripheral nerves is multifactorial in origin. All forms of irradiation including application of orthovoltage and electrons are associated with injury. Acute changes from therapy generally affect cells with rapid self-renewal potential, relatively few cell systems in the central nervous system divide frequently, and therefore injury is generated through multiple pathways. Although damage is generated to DNA through traditional mechanisms, oxidative species generates injury to lipid bilayers, cell adhesion molecules, blood vessels, and mitochondria. The coupled imprint of primary and subcellular damage alters cell architecture and structure, thus impacting the cellular microenvironment. Vascular permeability is increased which promotes penetration of drugs into the central nervous system. Repair can be generated by stem cells residing in multiple sites of the central nervous system. If the cellular architecture and infrastructure are damaged, repair including remyelination becomes fragmented and disorganized. Irregular and disorganized regeneration of lipid bilayers is seen as leukoencephalopathy. Often injury and tumor recurrence have identical features on MR sequences and can be indistinguishable. Demyelination is frequently seen in peripheral nerves as the primary manifestation of injury as neural stem cells are sparse in peripheral locations.

Injury is often superimposed on previous changes in the central nervous system including vascular and degenerative changes, and it is often difficult to accurately assess the role of therapy on both imaging and neurocognitive testing. Medication interventions are under evaluation at this time to decrease neurocognitive changes associated with therapy. As with most organ systems, the most optimal strategy to prevent injury is to apply radiation therapy to titrated volumes when appropriate and to choose fractionation schemes to optimize repair [72, 73].

Reproductive Organs, Genitalia, and Endocrine

Spermatogonia are among the few cell systems that can die an intermitotic death; therefore, the absolute number of sperm cells markedly decreases with modest doses of radiation. The development period of stem cell to spermatozoa is 75 days; therefore, exposure to radiation can induce damage to mature sperm. In regions of nuclear events such as Chernobyl, there are reports of increased neurocognitive and developmental abnormalities in children born to survivors of these events [6]. Most oncologists offer sperm banking to patients with a known direct exposure to radiation therapy. Indirect exposure with scatter radiation dose will often require the use of birth control for two cycles of sperm development (6 months) to lessen risk of damaged sperm in the ejaculate. Leydig cells secrete testosterone, and their specific function is regulated by pituitary gonadotropins, prolactin, and luteinizing hormone. Treatment to the pituitary gland may impose secondary events to gonadal function. Although Leydig cells are more resistant to radiation exposure, there is an incremental decrease of testosterone in doses exceeding 20 Gy. Various chemotherapy agents including vincristine and mechlorethamine (Mustargen) influence sterility. Oocytes are very sensitive to radiation and, as sperm, die an intermitotic death. Because hormonal secretion is associated with follicular maturation, unlike the testicle, treatment of the ovaries results in more immediate suppression of hormonal function. Female genitalia can demonstrate mucosal atrophy and loss of moisture [15, 34, 74]. Radiation therapy to children for pelvic malignancies including rhabdomyosarcoma can result in significant atrophy and maldevelopment of gonadal organs and pelvic anatomy. Cardiovascular health

as well as other medical comorbidities including problems associated with growth can be significantly influenced by diminution of hormonal function at a young age.

Hypothyroidism is a common sequela associated with both surgery and radiation therapy to the low neck. This is quite prevalent in patients treated for head/neck cancer and Hodgkin lymphoma. Neck dissection and primary surgery also influence the incidence of hypothyroidism in patients treated for head and neck cancer. Pituitary therapy creates panhypopituitary syndrome with a need for replacement therapies as appropriate. This can have significant health issues in multiple endocrine organs. Interestingly, there is little data for adrenal function; however, there are reported cases of adrenal malfunction and decreased cortisol with high-dose radiation therapy. More often, adrenal malfunction occurs in patients as a secondary bystander effect to pituitary therapy [15, 34, 75].

Pediatrics

Treatment of children is unique as every cell system has self-renewal potential; therefore, unlike adults, sequelae are visible and identified in all tissues due to growth and development. The bone and cartilage are key areas that distinguish adults from children. In general terms, with radiation doses of 20 Gy, growth deficits in the bone may be irreversible as stem cells depopulate [34, 76]. The deficits in bone and cartilage development are more visible with higher radiation doses and younger age. In adults, the threshold dose for bone necrosis may be 55 Gy with traditional fractionation strategies; however, there are interesting reports of the use of advanced technology imaging including MR demonstrating sacral fractures in gynecological patients receiving less than 50 Gy to the bone [76]. Radiosurgery techniques, particularly to targets in close approximation to the chest wall, are reinviting injury to the rib and chest wall that is often non-healing. Treatment techniques including volume-modulated arc therapy [77] appear to play an essential role in decreasing this risk.

Recent studies have demonstrated that long-term survivors of cancer therapy, including radiation, are frailer than their counterparts and acquire chronic diseases at a higher rate. They may also be susceptible to premature death than their sibling counterparts [48].

Conclusion

Intentional and unintentional radiation exposures have a powerful impact on normal tissue function and can induce both short-term and long-term injuries to all cell systems. In the evaluation of acute phase management, assessing radiation dose and exposure is essential to management strategy. Appropriate support can be given to those at risk for serious acute injury. The effects of radiation treatment and exposure, however, last for the lifetime of the patient and can have implications for all organ systems. A broad understanding of these effects is essential for today's acute health-care provider in the emergency department setting.

Mucositis

50

Jennifer A. Novak and Arya Amini

Introduction

Mucositis is a known potential toxicity associated with several systemic chemotherapies [1], targeted therapies [2], immunotherapies [3], radiation treatments [4], and hematopoietic stem cell transplants (HSCT) [5]. Mucositis is subdivided into two main categories: oral mucositis and gastrointestinal mucositis.

Oral mucositis refers to inflammation and ulcerative injury within the oral cavity. Oral mucositis is one of the most common toxicities among patients receiving chemotherapy or targeted therapy for a variety of cancers. Oral mucositis is also commonly caused by radiation therapy or chemoradiation therapy for cancers involving the head and neck. Additionally, oral mucositis is a known adverse effect of myeloablative therapies preceding HSCT. The most common symptoms of oral mucositis are burning discomfort and pain, which often result in a difficulty eating, drinking, swallowing, and talking. These symptoms lead to decreased oral intake and, in some cases, the inability to meet nutritional and hydration needs. Patients with oral mucositis often have difficulty maintaining good oral hygiene, thereby increasing the risk of severe infection from an odontogenic source.

Gastrointestinal mucositis can occur anywhere along the gastrointestinal tract distal to the oral cavity. Injury to the gastrointestinal mucosa results in ulcerative changes similar to those seen in cases of oral mucositis. However, differences in anatomy, microbial environment, and physiology underlying the development of gastrointestinal mucositis are key reasons for this subclassification. Gastrointestinal mucositis may result in any of the following symptoms, depending on anatomic location: nausea, vomiting, abdominal cramping, diarrhea, rectal pain, or rectal bleeding. Decreased oral intake is a common downstream effect of gastrointestinal mucositis.

Department of Radiation Oncology, City of Hope National Medical Center, Duarte, CA, USA
e-mail: aamini@coh.org

Mucositis is a dose-limiting toxicity and may result in premature discontinuation of anti-neoplastic therapies. Further, severe cases of mucositis may require hospitalization. Treatment interruptions due to premature discontinuation of therapy or hospitalization are linked to poor oncologic outcomes such as increased risk of disease recurrence and decreased overall survival.

Case Study

A 65-year-old male with a 35-pack-year smoking history presented to his dentist with a nonhealing oral ulcer. Physical exam revealed a large ulcerative lesion over the left tongue with associated induration of the surrounding tissue. A biopsy of the lesion demonstrated P16-negative squamous cell carcinoma. A CT of the head and neck revealed asymmetric thickening of the left tongue as well as an enlarged left level 2 lymph node. An FDG-PET CT demonstrated FDG avidity associated with the left tongue as well as the left level 2 lymph node, but no evidence of distant metastasis. The patient underwent a hemiglossectomy and bilateral neck dissection demonstrating SCC measuring 3.0 cm in the left tongue with a depth of invasion of 10 mm and multiple positive lymph nodes in the left neck. Margins were focally positive. The patient was recommended to undergo postoperative chemoradiation treatment to the oral cavity and bilateral neck to a maximum dose of 66 Gy in 33 fractions with concurrent weekly cisplatin. During the third week of chemoradiation, the patient complained of discomfort in his oral cavity when eating. Physical exam revealed grade 1 oral mucositis. Over the following 2 weeks, the patient experienced progressive pain in his oral cavity, decreased oral intake, and weight loss exceeding 10% of his total body weight. Physical exam during the fifth week of chemoradiation revealed grade 3 oral mucositis. During the patient's sixth week of treatment, the patient was hospitalized for sepsis and failure to thrive, requiring discontinuation of chemoradiation.

History/Background

Over the past several decades, there have been a few improvements to anti-mucositis agents [6]. While some agents have been shown to decrease the severity and duration of mucositis, there are no known curative agents. Despite the number of randomized studies suggesting a benefit to anti-mucositis agents, the results often lack reproducibility, making development of treatment guidelines a challenge. Thus, mucositis remains a significant problem both for cancer patients and their physicians.

Anatomy

The oral and gastrointestinal mucosae arise from the endoderm and consist of a continuous membrane lining the entirety of the alimentary tract from the oral cavity through the anal canal. There are several layers that comprise the mucosa including most superficially (interiorly) the epithelium, followed by a layer of connective tissue, followed by a muscular layer (muscularis mucosa). The mucosae overlie a layer of dense connective tissue known as the submucosa. The purpose of the mucous membrane is to secrete mucous, providing a barrier to pathogens.

Pathophysiology

The pathogenesis of injury to the oral and gastrointestinal mucosa is characterized by five key phases: initiation, upregulation, signal amplification, ulceration, and healing [7]. Anti-neoplastic therapies, such as chemotherapy and radiation, are known to cause both direct and indirect injuries to the oral and gastrointestinal mucosa. Direct tissue injury occurs when double-stranded DNA breaks induce apoptotic signaling and the production of reactive oxidative species. In turn, pro-inflammatory cytokines are released, such as TNF-α and IL-1β, and NF-κB signaling pathways are activated, which play a key role in the pathogenesis of mucositis [8, 9] (Fig. 50.1). Indirect tissue injury occurs when anti-neoplastic therapies reduce the mucosal barrier through villus blunting and crypt ablation. The combination of direct and indirect tissue injury leads to signal amplification and exacerbated tissue injury.

Several studies have demonstrated the impact of the local tissue microbiome on the pathogenesis of mucositis. Differences in the microbiome in the oral cavity compared to that of the gastrointestinal tract help to explain some of the site-specific reactions to therapeutic agents. Bacterial ligands of resident gastrointestinal flora not only regulate the mucosal immune response to anti-neoplastic agents but also play an important role in mucosal regeneration [10].

The physiologic mechanisms underlying the symptoms caused by mucositis also vary depending on anatomic location. In the small bowel, mucosal injury to enteric cells results in the release of 5-hydroxytryptamine (5-HT), serotonin, and substance P. These chemicals act as neurotransmitters and stimulate the dorsal brainstem, leading to symptoms such as nausea and vomiting [6, 11]. In the colon, mucosal injury results in the release of pro-inflammatory cytokines, which stimulate a neuronal feedback signal resulting in diarrhea.

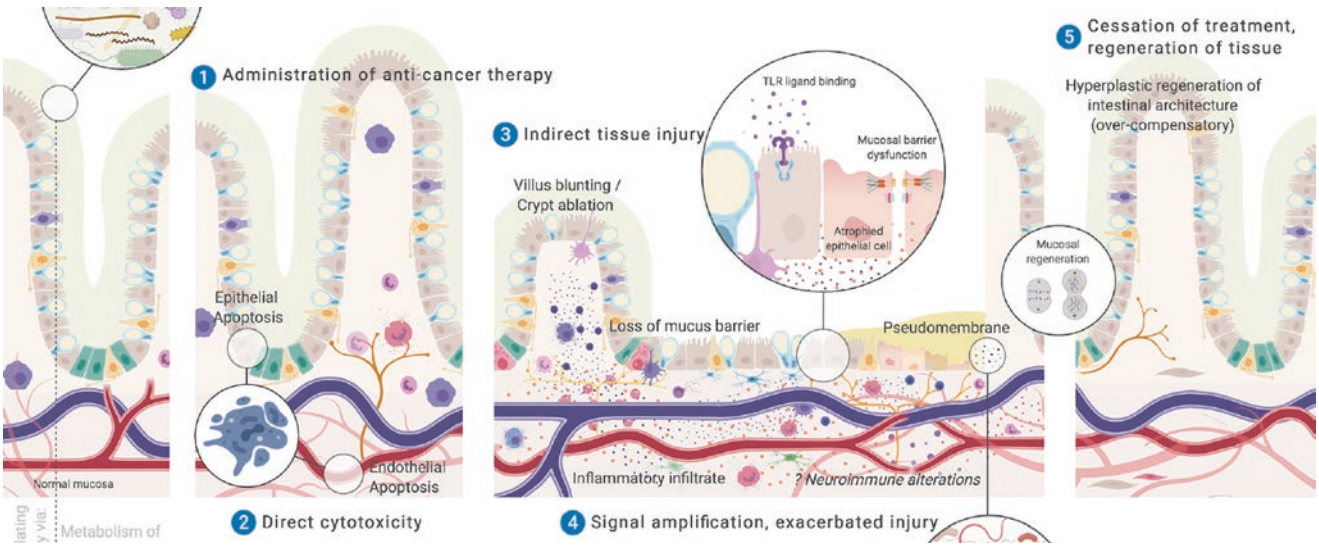

Fig. 50.1 The pathogenesis of mucosal injury. Anti-neoplastic therapies (1) cause both direct (2) and indirect (3) mucosal injuries, which result in activation of TNF-α and IL-1β, and NF-κB signaling pathways (4). The local tissue microbiome exerts immunomodulatory effects and plays a role both in mucosal damage and regeneration (5). (Adapted from Bowen et al. with permission [8] Springer Nature)

Epidemiology

Approximately one fifth of advanced cancer patients will experience mucositis [12]. Of those, 60% will experience a decrease in oral intake, 40% will experience severe impairment of nutrition or hydration, and 6% will experience complete prevention of nutrition or hydration due to mucositis. Of the approximate 440,000 patients receiving chemotherapy annually in the USA, more than one third will experience mucositis [13]. Of the 20,000 hematopoietic stem cell transplants in the USA annually, at least 87% of patients will experience mucositis [14].

Patients with cancer arising from the head or neck are at particularly high risk of developing oral mucositis, with an odds ratio of 6.31 [6]. In 2020, there will be an estimated 65,630 new cases of head and neck cancer diagnosed in the USA [15] and 650,000 new cases worldwide [16], and at least 80% undergoing radiation for head and neck cancer will experience mucositis [17].

Individuals at the greatest risk for the development of mucositis include the pediatric and geriatric populations. 80% of pediatric patients receiving chemotherapy experience oral mucositis [18] and 99% of pediatric patients undergoing hematopoietic stem cell transplant [19] experience either oral or gastrointestinal mucositis. Geriatric patients comprise a majority of new cancer cases and tend to have poor tolerance of oncologic therapies. Further, geriatric patients often recover more slowly from anti-neoplastic toxicities than do younger patients.

Health Economics

Cases of oral and gastrointestinal mucositis have a significant economic impact. A study published in 2008 reported that the total median medical costs of patients with mucositis or pharyngitis related to anti-neoplastic therapy were $39,313 [20]. These costs were approximately double that of the total median medical costs of $20,798 for patients without therapy-induced mucositis. The largest contributor to increased medical costs for patients with mucositis is extended inpatient hospitalizations, which can occur as a result of the potential sequelae of mucositis, such as infection or nutritional deficiency. A report based on data from 2012 estimated a combined cost of $15,500 for every inpatient hospitalization due to severe mucositis [21].

Toxic mucositis results in annual costs of $13.23 billion in the USA [6]. Cases of grades 1–2 mucositis account for roughly 60% of the total cost burden, and cases of grades 3–4 mucositis account for the remaining 40%.

Indirect costs of mucositis relate to the amount of time spent by physicians and clinical staff managing patient's symptoms of mucositis. Nurses and physicians spend an additional 9.0 and 5.7 hours, respectively, per head/neck cancer patient managing mucositis during their treatment course [22].

Presentation

The symptoms associated with mucositis vary depending on the anatomic location of the mucosal injury. Patients with oral mucositis initially present with a burning sensation in the oral cavity or oropharynx, which progresses to pain. Pain associated with oral mucositis can range from mild to severe and may result in difficulty chewing or swallowing, unintentional weight loss, or the inability to maintain oral hygiene. Oral mucositis increases the risk of infection and, in some cases, can result in hospitalization or premature discontinuation of anti-neoplastic therapy. Based on patient-reported data, the approximate duration of oral mucositis in patients undergoing radiation treatment is 70–84 days and 68–102 days in those undergoing chemotherapy (4–6 cycles) [17, 23].

Patients with gastrointestinal mucositis present with inflammatory symptoms and, depending on the anatomic location of mucosal injury, can be characterized as pharyngitis, esophagitis, gastritis, colitis, or proctitis. Patients with mucositis-related pharyngitis or esophagitis may experience odynophagia, dysphagia, or retrosternal pain. Patients with mucositis-related gastritis or colitis may experience nausea, vomiting, abdominal cramping, or diarrhea. Patients experiencing mucositis-related proctitis may experience pain with bowel movements or rectal bleeding.

Diagnosis

Oral mucositis can be diagnosed by inspection of the oral cavity for erythema, edema, and ulceration of the oral mucosa. Detection of mucosal injury distal to the oral cavity is more challenging. Endoscopy allows for the visualization of mucosal changes; however, endoscopy is not recommended in patients with suspected or presumed mucositis, as it may lead to further tissue injury. There are ongoing studies of non-invasive methods to aid in the diagnosis of mucositis, though these methods have not been adopted as common practice. For example, esophageal mucositis is associated with mucosal thickening identified on CT-based imaging [24]. Similarly, bowel wall thickening visualized on ultrasound may indicate inflammation related to gastrointestinal mucositis [25]. Additional studies are aimed at identifying one or more biomarkers associated with mucositis. At this time, gastrointestinal mucositis largely remains a clinical diagnosis made based on the presence of patient-reported symptoms.

Table 50.1 Comparison of mucositis assessment tools

	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
RTOG/EORTC [27]	Irritation or erythema of the mucosa; may experience mild pain; may require topical analgesic; may require soft diet; <5% weight loss from pretreatment baseline; nausea, abdominal discomfort, and increased frequency of bowel habits not requiring intervention	Patchy mucositis that may produce an inflammatory serosanguinous discharge; may experience moderate pain; may require narcotic analgesics; may require puree or liquid diet; <15% weight loss from pretreatment baseline; may experience nausea, vomiting, abdominal pain, or diarrhea requiring intervention	Confluent fibrinous mucositis; may include severe pain requiring narcotic; >15% weight loss from pretreatment baseline requiring feeding tube, IV fluids or hyperalimentation; nausea, vomiting, abdominal pain/distention despite medication	Ulceration, hemorrhage, or necrosis; perforation or fistula; ileus; obstruction; GI bleeding requiring transfusion; abdominal pain requiring tube decompression or bowel diversion	N/A
WHO [26]	Mild symptoms; oral soreness, erythema	Moderate symptoms; oral erythema or ulcers, solid diet tolerated	Severe symptoms; oral ulcers with extensive erythema, requiring liquid diet only	Life-threatening symptoms; requirement for parenteral or enteral support	N/A
NCI CTCAE [28]	Erythema of the mucosa; minimal discomfort; normal diet; not interfering with function; intervention not indicated	Patchy ulcerations or pseudomembranes; symptomatic but can eat and swallow; modified diet; no interference with activities of daily living; medical intervention indicated	Confluent ulcerations or pseudomembranes; bleeding with minor trauma; symptomatic and unable to adequately aliment or hydrate orally; stool incontinence or other symptoms interfering with activities of daily living	Tissue necrosis; significant spontaneous bleeding; life-threatening consequences	Death

RTOG Radiation Therapy Oncologic Group, *EORTC* European Organisation for Research and Treatment of Cancer, *WHO* World Health Organization, *NCI CTCAE* National Cancer Institute Common Terminology Criteria for Adverse Events

There are several criteria by which the severity of mucositis can be classified. Grading systems include the World Health Organization (WHO) scale for mucositis [26], the Radiation Therapy Oncologic Group (RTOG) and European Organisation for Research and Treatment of Cancer (EORTC) toxicity criteria [27], and the National Cancer Institute Common Terminology Criteria for Adverse Events (NCI CTCAE) [28] (see Table 50.1). Examples of oral mucositis grades 1–4 based on the WHO grading scale can be seen in Fig. 50.2. Other assessment tools include the Oral Mucositis Assessment Scale (OMAS) [29] and the patient-reported outcome measure (PROM) scale [30].

Prophylaxis and Management of Oral Mucositis

Anti-inflammatory Agents

Benzydamine is an anti-inflammatory agent used for the prevention and treatment of oral mucositis. Benzydamine inhibits prostaglandin synthetase, thereby blocking the production of pro-inflammatory cytokines such as TNF-α and IL-1β. Benzydamine is currently the only agent for which there is level 1 evidence supporting its use in the management of mucositis. Benzydamine mouthwash can be used both for the prophylaxis and treatment of oral mucositis in patients receiving chemotherapy alone, radiation treatment alone, or concurrent chemoradiation to the head/neck [31, 32]. Randomized studies have demonstrated that benzydamine improves pain [33] as well as severity of oral mucositis [34]. However, benzydamine may not control radiation-induced oral mucositis at radiation doses greater than 50 Gy [35–37].

Irsogladine maleate is an anti-inflammatory agent that inhibits the production of reactive oxidative species. There are data demonstrating a benefit of systemic irsogladine maleate for the prevention of chemotherapy-induced oral mucositis [38].

Rebamipide is an anti-inflammatory agent with several mechanisms of action that ultimately promote mucosal protection. One randomized study demonstrated a decrease in the severity of oral mucositis in patients receiving chemoradiation treatment in patients using rebamipide mouthwash compared to placebo [39].

Oral Cryotherapy

Oral cryotherapy is the method of cooling the oral cavity either by ice or cold liquids. Oral cryotherapy results in local vasoconstriction, reducing the exposure of mucous membranes in the oral cavity to cytotoxic agents present in systemic therapies. Evidence supports its use in the prevention of chemotherapy-induced mucositis, especially in patients receiving fluorouracil-based chemotherapy or high-dose melphalan-based therapy preceding HSCT [40, 41].

Fig. 50.2 Examples of oral mucositis on physical exam according to the WHO [26]. Panel (**a**) is an example of WHO grade 1 mucositis, characterized by erythema of mucous membranes. Panel (**b**) is an example of WHO grade 2 mucositis, characterized by the presence of oral ulcers. Panel (**c**) is an example of WHO grade 3 mucositis, characterized by the presence of extensive ulcers causing a need for liquid diet. Panel (**d**) is an example of WHO grade 4 mucositis, characterized by the presence of severe mouth sores inhibiting oral intake

Ease of administration and cost-effectiveness are additional benefits of oral cryotherapy. In comparing anti-mucositis agents, oral cryotherapy is suggested to be the best intervention to reduce the incidence of oral mucositis with a few side effects [42].

Palifermin

Palifermin is a keratinocyte growth factor that induces the epithelial cell proliferation in the oral and gastrointestinal mucosa. Palifermin results in cytoprotective effects, decreases the production of pro-inflammatory cytokines, and promotes mucosal regeneration. Palifermin is recommended for the prevention of oral mucositis in patients undergoing high-dose chemotherapy and total body irradiation prior to HSCT. Data have suggested that palifermin reduces both the severity and duration of oral mucositis in patients undergoing HSCT [43]. The recommended dose of palifermin for the prevention of oral mucositis is 60 ug/day for 3 days prior to conditioning treatment and 3 days following stem cell transplant [5, 44]. A common side effect of palifermin is taste disturbance [42].

Photobiomodulation

Photobiomodulation (PBM), also referred to as low-level light therapy or low-level laser therapy, consists of nonionizing light sources. PBM has been shown to promote wound healing and decrease inflammation following mucosal injury. Several randomized studies have demonstrated the benefit of intraoral PBM for the prevention of oral mucositis in patients undergoing HSCT [45]. Studies have also demonstrated a benefit of intraoral PBM for the prevention of radiation-induced oral mucositis. PBM used for the prevention of oral

mucositis should be delivered at a wavelength of 650 nm, power of 40 mW, and tissue energy dose of 2 J/cm^2 [5, 44].

Opioid Analgesics

Patient-controlled morphine has been recommended for the management of severe oral mucositis in patients undergoing HSCT [5]. There is no evidence to demonstrate the superiority of continuous infusion morphine over patient-controlled morphine; however, patient-controlled morphine is associated with less total consumption [46]. Topical morphine, in the form of mouthwash, has been shown to reduce the severity of oral mucositis in patients undergoing radiation, chemotherapy, or chemoradiation therapy for cancer of the head/neck [47, 48]. Transdermal fentanyl has been shown to be both safe and effective in managing pain due to chemoradiotherapy-related oral mucositis [49].

Gabapentin

Gabapentin is a structural analog of gamma-aminobutyric acid (GABA), an amino acid that acts as an inhibitory neurotransmitter. Gabapentin is known for its effectiveness as an antiepileptic, though it is also commonly used in the treatment of neuropathic pain. There are data supporting the use of gabapentin for reduction of pain associated with radiotherapy-induced oral mucositis [50, 51]. Gabapentin can reduce or completely eliminate the need for opioid pain medications. The recommended dose of gabapentin for oral mucositis is 2700 mg daily.

Doxepin

Doxepin hydrochloride is a tricyclic antidepressant shown to have analgesic and anesthetic effects when used topically. Studies have demonstrated a statistically significant reduction in pain related to oral mucositis among patients undergoing radiotherapy for head and neck cancer using doxepin oral rinse [52, 53].

Nutritional Supplements

Glutamine is an amino acid that promotes cellular proliferation and survival. Oral glutamine has been shown to delay the onset, and reduce the severity of, oral mucositis in patients receiving chemoradiotherapy to the head and neck [54, 55]. The recommended dosage is 10−30 mg per day, and it is available in various formulations including a mouth rinse as well as oral forms.

Zinc is an electrolyte that promotes homeostasis, wound healing, and immune responses. Several randomized studies have demonstrated the benefit of zinc in the prevention of oral mucositis among patients receiving radiation or chemoradiation treatment to the head/neck [56, 57].

Elemental diet formulations are nutrient-rich liquids and may be beneficial in preventing oral mucositis in patients undergoing radiation treatment to the head/neck [58].

Vitamin E is an antioxidant with anti-inflammatory properties. Studies have shown a benefit of vitamin E for the treatment of chemotherapy-induced oral mucositis [59, 60]. Topical vitamin E, available in a mouth rinse, appears to be more effective than in pill form [61]. There are data suggesting a benefit to vitamin E in preventing radiation-induced oral mucositis as well [62].

Natural Agents

Honey has been shown to reduce the severity of radiation-induced oral mucositis [63]. Honey functions both as an antimicrobial and also to maintain the integrity of the mucosal epithelium. The high sugar content of honey increases the risk of dental caries; therefore good dental hygiene practices are crucial for patients using honey.

Aloe vera has both anti-inflammatory and antimicrobial properties, and it has been shown to modulate the immune system when delivered orally [64]. There are data to suggest that aloe vera reduces both the incidence and the severity of oral mucositis in patients undergoing radiation to the head/neck [65, 66]. Additional studies are needed to identify the optimal dose of aloe vera, as high concentrations can result in diarrhea and drug interactions [67].

Curcumin is a compound found in turmeric with anti-inflammatory, antioxidant, and antitumor properties [68]. Turmeric mouthwash has been shown to delay the onset of mucositis and decrease the severity of mucositis in patients undergoing radiation therapy for cancer of the head/neck [69, 70].

Oral Care

Professional oral care and routine oral hygiene practices performed at home by patients may reduce the severity of oral mucositis and the risk of infection from odontogenic sources. Studies have shown that professional dental evaluation and treatment reduces the severity of oral mucositis and improves pain associated with oral mucositis [71]. Patient education is recommended to improve patient compliance with oral hygiene practices at home. Patients should also be instructed to drink plenty of water and avoid painful stimuli such as hot or spicy foods or liquids, smoking, alcohol, and objects that

may cause trauma to the oral cavity (e.g., ill-fitting dentures). There have been studies demonstrating a benefit to saline or sodium bicarbonate mouth rinses in reducing the severity of oral mucositis. A multi-agent regimen is recommended to optimize oral care in patients undergoing chemotherapy, HSCT, or radiation to the head/neck.

Prophylaxis and Management of Gastrointestinal Mucositis

Amifostine

Amifostine is a prodrug with several mechanisms of action related to the scavenging of free radicals and DNA repair. A recommended dose of 340 mg/m^2 of intravenous amifostine can be administered for prevention of radiation-induced proctitis [29]. There are also data suggesting a benefit for amifostine to reduce esophageal mucositis in patients undergoing radiation treatment for non-small cell lung cancer [72].

Octreotide

Octreotide is a somatostatin analog that causes arterial vasoconstriction. Octreotide is best known for its use in the management of acute gastrointestinal bleeding. There are data to suggest the use of intramuscular octreotide in the treatment of diarrhea associated with HSCT, but only following a failed trial of loperamide [44].

Sucralfate

Sucralfate is an agent best known for its use in peptic ulcer disease. Sucralfate functions both as an acid buffer and a protective barrier for gastrointestinal mucosa. Prior studies have suggested its benefit for radiation-induced proctitis [73, 74].

Antimicrobials

The use of oral antibiotics ciprofloxacin and metronidazole was studied in a randomized trial for the treatment of chronic radiation-related proctitis and demonstrated a benefit [75, 76].

Antihistamines

Histamine receptor antagonists, such as famotidine, may be useful for the prevention of gastrointestinal mucositis in patients undergoing radiation treatment for prostate cancer, though additional studies are needed [77].

Nutritional Supplements and Dietary Modifications

Numerous modified diets have been studied for efficacy in the prevention and management of gastrointestinal mucositis. There is no clear benefit of fat-modified diets, fiber supplementation, or prebiotic supplementation. However, there are data to support the use of oral glutamine to reduce the severity of radiation-induced esophagitis [78–80] and to decrease the duration of diarrhea in patients undergoing HSCT [81]. Probiotics, or oral formulations of live bacterial species found in normal gut flora, may be useful in the prevention of chemotherapy or radiation-induced diarrhea [82, 83].

Formalin

Topical formalin reduces superficial mucosal blood flow [84], and data suggest a benefit in cases of hemorrhagic radiation-related proctitis [85].

Palifermin

In addition to using palifermin for the prevention of oral mucositis, it has been shown to decrease the severity of chemotherapy-induced and HSCT-related gastrointestinal toxicity [86, 87].

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy (HBO) is a treatment modality by which 100% oxygen is delivered in a pressurized chamber. HBO results in the production of reactive oxygen and nitrogen species, which promote tissue healing via several molecular pathways. HBO has been studied in the context of late radiation toxicity, and data support the use of HBO for treatment of late radiation-related proctitis [88].

Disposition/Follow-Up

Patients with a history of therapy-induced mucositis should receive regular oncologic follow-up, at which time they can be evaluated for long-term effects of mucosal injury. Patients recovering from mucositis may benefit from follow-up with a dietician. There are several screening tools to

evaluate patients for chronic nutritional deficiency, such as the malnutrition universal screening tool (MUST) and the NUTRISCORE tool [89, 90].

Prognosis/Treatment Complications

Most cases of acute therapy-related mucositis will resolve with time. Significant risks associated with mucositis include severe infections, dehydration, and weight loss. Such infections and severe malnutrition result in unexpected treatment breaks or premature discontinuation of anti-neoplastic therapies and are associated with increased rates of recurrence and worse survival. Patients should be monitored closely with additional nutritional support including a feeding tube if needed and routine IV hydration.

Common Pitfalls

Patients at high risk of oral and gastrointestinal mucositis should be identified prior to initiating therapy. Education regarding the symptoms of mucositis and the importance of oral hygiene and nutrition should precede initiation of therapy. Patients at risk for developing mucositis should undergo thorough evaluation by both a dental health professional and a dietician. Throughout the course of therapy, patients should be screened weekly for weight loss and for symptoms of mucositis. Early intervention with intravenous fluid hydration and/or enteral feeding tube placement is critical in patients experiencing rapid, continuous weight loss and can reduce the risk of hospitalization or treatment break.

Future Needs/Vision

Despite the growth of literature pertaining to anti-mucositis agents, guidelines continue to lack specific recommendations for many agents studied in the prevention and management of oral and gastrointestinal mucositis. The range of anatomic sites of mucositis development, as well as the numerous therapies known to cause mucositis, results in highly specific studies. Furthermore, the distinction between prevention of mucositis and treatment of mucositis is important due to differences in the mechanisms of early compared to chronic mucosal injury. Ongoing studies should further elucidate the pathogenesis of mucositis, and their results may be valuable in identifying potential targets for anti-mucositis agents.

Residency and fellowship training should include formal didactics pertaining to the diagnosis, documentation, and management of oral and gastrointestinal mucositis.

Health Services/Resource Use

Educational resources for patients and physicians can be found via the Multinational Association of Supportive Care in Cancer (MASCC) [5], an organization that has published its recommendations for the management of mucositis. The European Society for Medical Oncologic (ESMO) and the National Comprehensive Cancer Network (NCCN) have published their own sets of clinical guidelines [44, 91].

Documentation

Mucositis is often underreported by physicians. Patient-reported duration and severity of mucositis are typically longer and worse compared to that reported by physicians [92]. The cause of underreporting is multifactorial. However, the attitude among health professionals that toxicities related to therapy are "normal" and fear among physicians that adverse events will reflect poorly on their practice may be contributing factors [93, 94].

Key Points/Pearls

- Pathogenesis of mucositis is mediated by pro-inflammatory cytokines released as a result of both direct and indirect mucosal injuries. Ongoing studies are aimed at elucidating the role of the microbiome in the pathogenesis of mucositis, as well as the process of mucosal regeneration/healing.
- Diagnosis of oral mucositis is based upon physical exam; however, the diagnosis of gastrointestinal mucositis is based on patient symptoms aided by the use of patient-reported assessment tools.
- Early nutritional intervention and counseling are recommended for patients at risk of developing mucositis. Nutritional counseling by a dietician specializing in oncologic, dental evaluation by a dental health professional, and education regarding the importance of routine oral hygiene practices are recommended for those patients identified as high risk.
- Evaluation of patients early in the course of therapy for symptoms of mucositis is critical to reduce the likelihood of hospitalization or treatment interruptions, which are associated with worse oncologic outcomes.

Stoma Complications

51

Patricia A. Brock and Kumar Alagappan

Introduction

Creation of a stoma in the course of cancer treatment is common and may lead to complications seen in the emergency department (ED). The United Ostomy Association estimates that slightly more than 500,000 Americans now have some type of stoma. Annually in the USA, roughly 100,000 people undergo the creation of either a colostomy or ileostomy. The incidence is increasing due to the rising prevalence of colorectal cancer and diverticular disease in this country [1]. More than 75% of stomas are placed as part of the management of colorectal cancer [2]. This surgically created opening placed in the abdomen is felt to be a simple procedure; however, consequences can be complex, serious, and costly to the healthcare system. Data regarding complication rates is lacking but is thought to range from 21 to 70% in one review [3], while another study reports morbidity ranging between 31 and 60% [1]. Stomas are formed in both the gastrointestinal and urogenital tracts as a means of redirecting stool and urine content, respectively. They can be permanent or temporary. Some are placed after a planned surgical procedure, while others follow an emergency operation. Surgical advancements improving ostomy care include enhanced recovery after surgery as well as new robotic and laparoscopic techniques. Additionally, ostomy equipment enhancements provide better appliance options for patients [4].

Case Study

A 49-year-old female underwent a subtotal colectomy and proctectomy with end ileostomy formation. She had initial difficulties with leakage, but follow-up with the stomal therapist led to a proper pouching system and she remained leak-free. Three weeks postoperatively, she presented to the ED with high stomal output (4–5 L/day) and an elevated creatinine. Her abdomen was nontender. She received IV fluids in the ED and was admitted to the hospital. Stool studies were negative, and her diarrhea was controlled through dietary manipulation and addition of antidiarrheal medication.

Classification

Intestinal ostomies are classified according to the segment of the bowel brought to the surface. Ileostomies or small-bowel ostomies are often located on the left side of the abdomen. In the USA, an estimated 165,000–265,00 individuals live with this type of ostomy at the rate of 40,000 new ostomies annually [5]. This is distinguished from colostomies, which originate from the large bowel and are most often on the left side of the abdomen. Ostomies can either be a terminal or end ostomy with the bowel divided and the proximal stump brought to the surface. Alternatively, a loop ostomy is created when the anterior wall of the bowel is brought to the surface and is not transected.

A urostomy is made in cases where drainage of urine through the bladder and urethra is not possible, as in the case of a cystectomy following the diagnosis of invasive bladder cancer, the sixth most common cause of cancer in the USA.

Factors such as body habitus and pre-existing conditions contribute to poor outcomes. Although most issues arise in the first 5 years postoperatively, the risk of complications from stoma formation can last throughout one's life and can affect daily activities for the patient [4]. Early complications include inappropriate placement, skin irritation, soilage, stoma retraction, dehydration, and stoma necrosis. Late complications include stomal prolapse, peristomal hernia, chronic dermatitis, and orifice narrowing. Compounding ostomy complications in cancer patients are issues related to ongoing treatments with chemotherapy, immunotherapy, and radiation, as well as the increased prevalence of malnutrition and weight loss.

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_51

When evaluating the ostomy/stoma, physicians should be familiar with common complications and be ready to call for a surgical consult, if needed, especially if unfamiliar with the device.

Health Economics

A 2017 study by Taneja et al. estimated the cost of peristomal skin complications in the USA. In their retrospective cohort of 128 patients undergoing colostomy, ileostomy or urostomy (cancer and non-cancer related), they found that one-third experienced peristomal skin complications within 90 days and that total healthcare costs were almost $80,000 higher for these patients in comparison with those without such complications [6]. In addition to economic costs, cancer survivors with ostomies face a number of challenges related to self-care. Bulkley et al. surveyed 177 long-term rectal cancer survivors with ostomies, finding that the majority reported ongoing challenges, most commonly leakage around the pouching system and peristomal skin problems [7]. In a more recent study, Sun et al. found that the greatest challenges posed by ostomies were associated with the use of ostomy appliances and time requirements for ostomy care [8]. Additionally, they noted bleeding, pain, leakage, skin problems, and ostomy cleaning as challenges. Patients reported anxiety related to leakage, odor, and skin irritation as barriers to social activity and self-confidence. To prevent ostomy-related ED visits, enhancements in community-based, ostomy self-management initiatives may hold promise. In 2018, Hornbrook et al. estimated the cost of an ostomy nurse-led, small-group program, and concluded that a five-session training course conducted over 8 weeks would cost $1812 per patient [9]. Given the high cost of stoma complications, this expense would appear to provide a cost benefit.

Diarrhea

Daily volumes exceeding one liter above baseline generally define the presence of ileostomy-associated diarrhea. When portions of the ileum and the colon are not available for normal fluid absorption, excess liquid and the accompanying electrolytes are eliminated through the ileostomy. Adaptive changes occur after the initial postoperative period in many patients, but in some, this condition, also referred to as high-output stoma, is troublesome and can be dangerous [5]. High-output stomas occur in 16% of stomas created [10]. In the early postoperative period, 16–50% of patients report high-output diarrhea, and nearly 20% require readmission as a consequence [5].

When presenting to the ED, this complaint is often associated with dehydration and electrolyte imbalances. Close attention to renal function is necessary as having an ileostomy is a risk factor for kidney failure [5]. Large sodium losses with high volumes of fecal waste may occur, leading to hyponatremia. Poor absorption of magnesium also occurs. Evaluation for an obstruction or an infectious etiology, most commonly, *Clostridium difficile*, is important. Risk factors for high stomal output include the use of diuretics, coexisting diabetes mellitus, and having undergone a total proctectomy [10].

Diarrhea associated with a colostomy is described as having loose or watery bowel movements more than four times in 1 day. Although benign causes such as a change in diet may be the culprit, more severe etiologies include infection or an intestinal blockage.

After a thorough medical history, noting prior surgeries and oncologic interventions, the emergency evaluation of a patient presenting with diarrhea will include laboratory analysis of the electrolytes and renal function, as well as close attention to the volume status of the patient, which may be manifested by a low blood pressure or an elevated heart rate. Skin turgor and mucus membranes should be noted, and palpation and auscultation of the abdomen may detect tenderness or signs of obstruction. The clinician should directly examine the stoma and its contents. Stool analysis for an infectious process, most commonly, *C. difficile*, is important. A review of all medications for prokinetic properties, including metoclopramide, laxatives, erythromycin, etc., is imperative. Metformin may provoke increased stomal output, as can an abrupt discontinuation of steroids. Review of dietary changes may be informative. Imaging should be ordered only if an obstructive etiology is considered or pain is a prominent feature of the presentation.

Initial management should focus on fluid management, electrolyte replacement, and control of the diarrhea. If tolerated, fluid resuscitation may be provided via the oral route, with isotonic drinks the best option. Avoid intake of hypotonic drinks, tea, coffee, alcohol, and fruit juices. In most cases, however, adequate venous access will be important. IV supplementation of electrolytes will be guided by laboratory results. Cardiac monitoring may be necessary in the setting of severe electrolyte derangements. Most commonly used antimotility agents include diphenoxylate/atropine and loperamide. In several randomized studies of established ostomies, loperamide reduced output by 22–30% [5]. The typical dose is 4 mg four times per day before meals and at bedtime.

In severe cases where outputs are over 3–4 L per day, octreotide can be used [5]. However, if considering octreotide, the patient will likely require a general surgery consultation and admission.

If available, consultation with an experienced enterostomal therapist could provide assurance of a good device fit and reinforce the patient's knowledge of daily maintenance.

Decisions for inpatient admission or observation are made based on labs, volume status, and whether the patient tolerates fluids orally.

Skin Irritation

Despite the improvement of ostomy systems and study of the creation and care of the stoma, skin complications remain a common occurrence following colostomy, ileostomy, or urostomy surgery. Its occurrence is reported to be 43%, most commonly after an ileostomy [11]. Skin irritation is related to the caustic, watery content of the frequent movements, which contain proteolytic enzymes and a high pH [12]. Ill-fitting appliances leading to areas of the skin exposed to erosive content may be a consequence of normal ostomy maturation, and the remedy may be as easy as proper adjustment of wafer size [13]. However, prevention of this complication should begin in the operating room with creation of a quality stoma protruding 2–3 cm above the skin surface [4]. Additionally, poor placement of the ostomy in relation to body folds makes secure application of the appliance difficult. Regular assessment of the pouching system may avert the skin irritations that can become cyclic if left unchecked. Infectious causes, mainly fungal, also result in skin irritation and are seen in immunocompromised and diabetic patients (Fig. 51.1) [14].

Visual inspection of the intact ostomy bag is key, noting whether the selected wafer size matches the ostomy. Examination of the skin may reveal an erythematous papular rash consistent with candidiasis. This rash may be present under the wafer as well as in the skin surrounding the stoma. An allergic contact dermatitis, often due to an ostomy care product, may produce papules, vesicles, and redness. The patient will complain of itching and burning.

Ensuring proper wafer placement is often aided by a referral to an ostomy specialist. To manage suspected contact dermatitis, change the product currently being used, add a skin sealant to the local area, and make an outpatient referral to a stomal specialist or a dermatologist. Irritant dermatitis responds well to topical corticosteroid lotions [13]. Nystatin powder is the optimal treatment when candidiasis is suspected.

Hernia

A parastomal hernia (PSH) can occur with either an ileostomy or colostomy [15] and is variably reported to have a

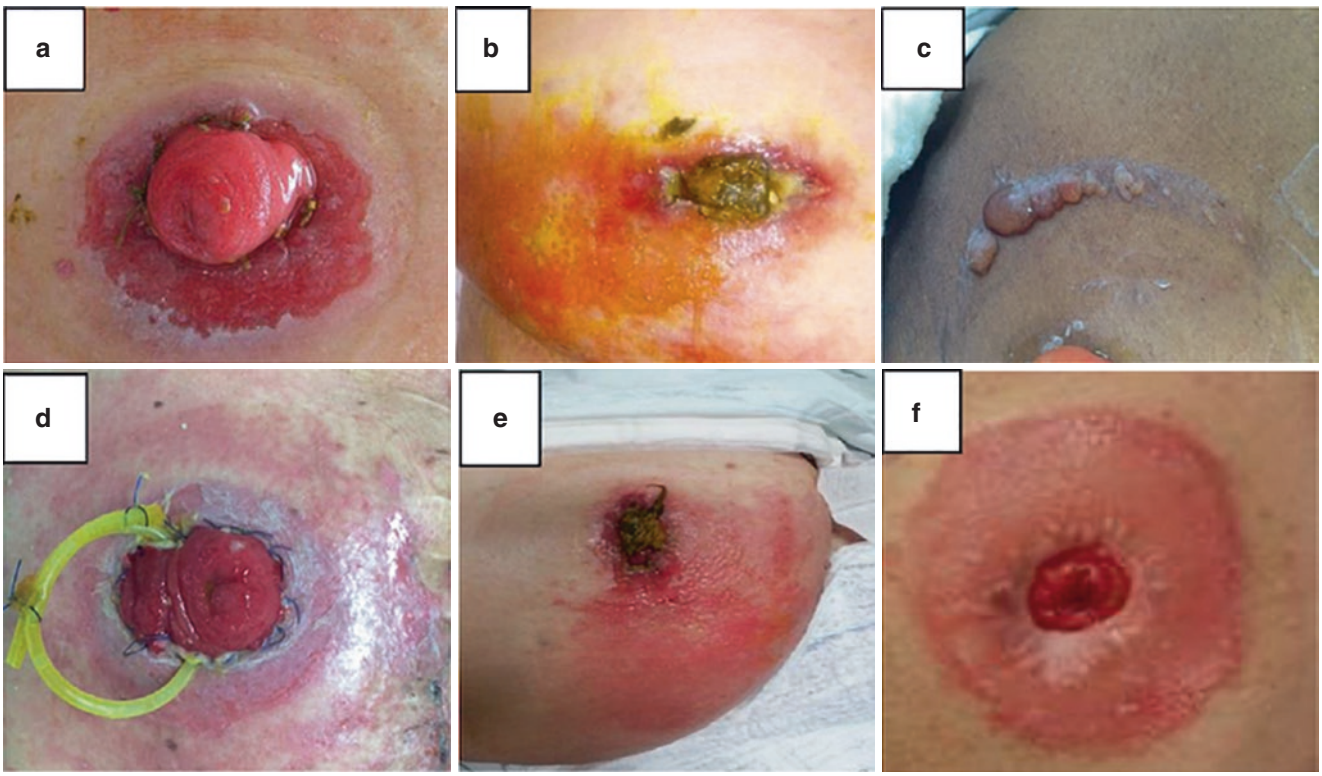

Fig. 51.1 Peristomal dermatitis. Irritation caused by the effluent in an inadequate pouch adaptation to the skin allowing the prolonged feces/skin contact (**a**) and an early pouch detachment (**b**). Blister at the adhesive area in the periphery of pouch resin itself (**c**). Dermatitis caused by both pouch resin and peripheral adhesive (**d**). Dermatitis due to contact of feces with the skin (**e**). Fungal dermatitis (**f**). (From Rodrigues et al. [14] with permission CC by 3.0)

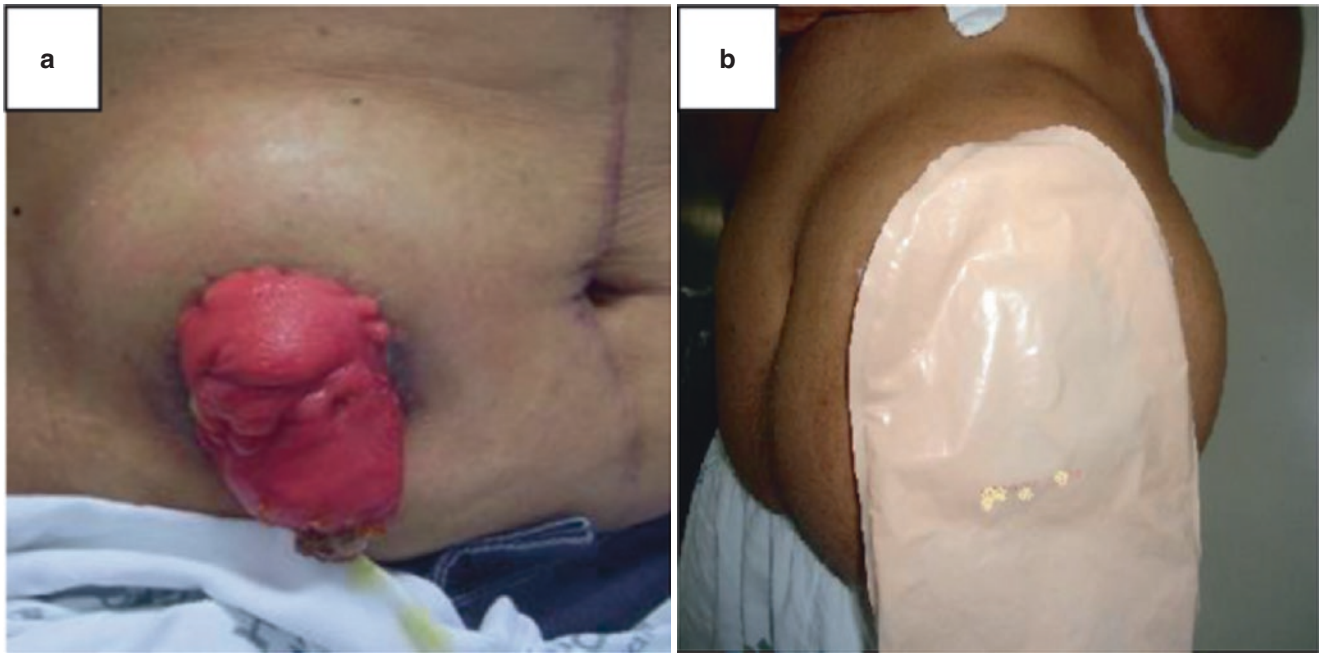

Fig. 51.2 Parastomal hernia in a prolapsed stoma (**a**) and a huge parastomal hernia (**b**). (From Rodrigues et al. [14] with permission CC by 3.0)

3–50% incidence due to a wide range of definitions [10]. Most are asymptomatic, but as they grow these hernias can cause problems. End colostomy has a higher rate of parastomal hernias. A late complication of ostomy surgery, PSH is symptomatic in 75% of patients but can lead to a reduced quality of life. Symptoms range from esthetic complaints, discomfort, local pain, leakage, and poor appliance application to emergent presentations with strangulation and obstruction. Risk factors for the development of a hernia are either patient-related or attributed to a technical problem. Perioperative steroid use has also been cited as a factor [16] (Fig. 51.2).

Clinical examination is necessary for the diagnosis of parastomal hernia. Direct inspection can be challenging, as detection of a bulge and cough impulse is a subjective finding. Details of the fascial defect and concomitant incisional hernias, as well as other occult pathologies, may obscure the diagnosis. In addition, clinical detection of PSH can be challenging in the obese patient. When diagnostic uncertainty exists, computed tomography and ultrasonography may be useful adjuncts. Nonurgent surgical evaluation is advised, unless a surgical emergency is suspected.

The majority of peristomal hernias are managed conservatively with the aid of a stoma care nurse advising the patient on proper appliance placement and improved adhesive adjuncts, as well as supportive garments. Outpatient referral for elective surgical intervention should be considered for those with high symptom burden. However, the patient presenting with a picture of bowel obstruction and/or signs of intestinal ischemia requires expeditious surgical consultation and resuscitation while preparing for a possible eminent operative procedure.

Retraction

Although usually seen acutely in the immediate postoperative period due to ischemic changes, retraction can be a late stoma complication. Retraction is the inversion of the mucocutaneous junction toward the abdominal wall. Poor fitting of the stoma appliance results in spillage of stool contents and skin irritation/inflammation. The latter is likely the reason for ED presentation (Fig. 51.3). In mildly symptomatic patients, a change in the stomal appliance may be useful to decrease bowel leakage. In severely symptomatic patients, a surgical referral for revision is necessary.

Stenosis

A stenosis or stricture of an ostomy can cause a mechanical obstruction to the passage of bowel contents. The patient presents with symptoms ranging from constipation to crampy abdominal pain. Ischemia of the bowel at the level of stoma may be causative; in patients with a prior history of Crohn's or malignancy, this may represent a recurrence. A narrowing of a colostomy may result from local infection or inadequate skin opening. Strictures associated with ileostomies most often require definitive surgical treatment. Those associated

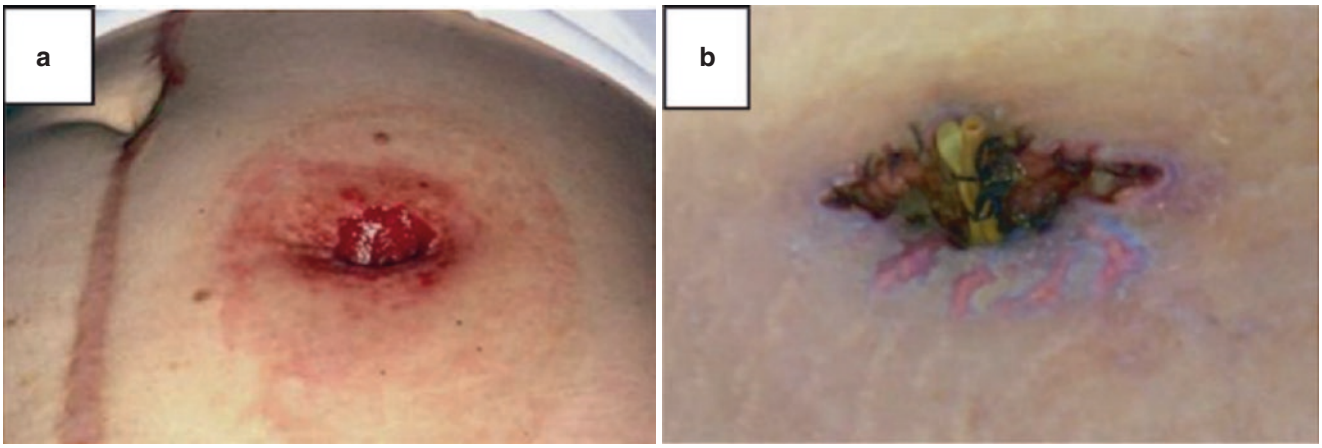

Fig. 51.3 Ostomy retraction with light (**a**) and severe (**b**) inflammatory reaction. (From Rodrigues et al. [14] with permission CC by 3.0)

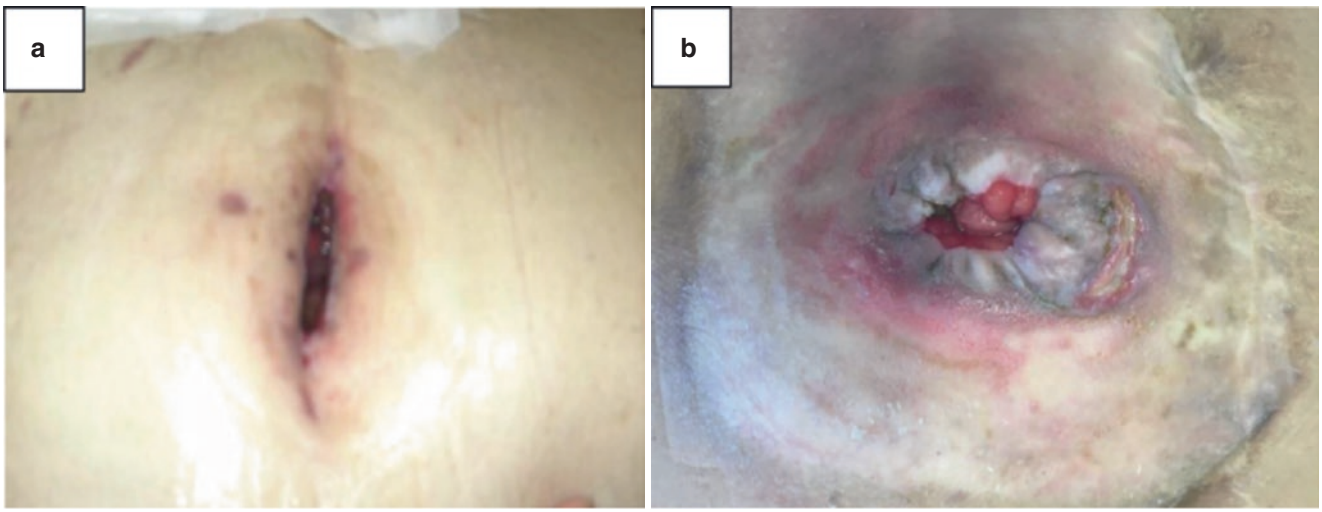

Fig. 51.4 Stoma stenosis. Note the retraction of the skin (**a**) and the scar tissue around the stoma opening in a chronic stoma stenosis (**b**). (From Rodrigues et al. [14] with permission CC by 3.0)

with colostomies may respond to dietary modifications and expectant management (Fig. 51.4).

In addition to a thorough abdominal assessment, examination of the stoma is critical. Digital inspection to the level of the fascia will yield important information regarding the degree of stenosis. Imaging will be required if obstruction is suspected.

Minor stenosis can be managed by changes in diet. However, symptomatic patients with obstructive symptoms require a surgical consultation and management. Management may include dilatation of the stoma with a 36 Fr Foley as a temporizing maneuver.

Prolapse

Stomal prolapse occurs as a late complication with the patient presenting to the ED with a segment of bowel protruding through the stomal opening. Occurring more often in the transverse loop colostomies [10], a prolapse can occur with any stoma and has a reported incidence between 2–26% [16]. This complication is found more often in obese patients and may be due to the original surgical technique. Although this is an unsightly and distressing complication, it is usually of little clinical significance. However, left untreated it can result in incarceration and strangulation from edematous bowel (Fig. 51.5).

Symptoms include skin irritation, difficulty with appliance application, and bleeding from the mucosa secondary to exposure. There is a low risk of bowel obstruction, incarceration, and strangulation associated with stomal prolapse.

The patient's history of an acute onset versus intermittent prolapse will supplement the necessary digital inspection of the ostomy for bowel viability. Further workup for bowel strangulation or obstruction should be conducted as indicated.

Some prolapses are amenable to bedside reduction. With significant bowel edema, however, osmotic therapy with

Fig. 51.5 Stoma prolapse. Note the abnormal length of the stoma. If left untreated the ostomate is more susceptible to abrasions or infection. (From Rodrigues et al. [14] with permission CC by 3.0)

simple table sugar applied to the prolapsed stoma and allowed to sit for 30 minutes may allow for a reduction [10]. Outpatient referral can be considered for further evaluation along with adjustment in pouch size. If viability of the bowel is in question, a surgical evaluation is necessary in the ED.

Bleeding

Local stomal bleeding is a rare occurrence. Local trauma can cause visible blood related to improper pouching technique or a rigid appliance encroaching on the mucosa. Recurrent trauma can lead to exuberant granulation tissue that is friable and bleeds frequently. A more consequential reason for profuse bleeding may be stomal or parastomal varices. Although usually appearing in the presence of portal hypertension, blockage of vessels within the mesentery can result in mucosal venous congestion and bleeding. In patients with a diagnosis of cirrhosis, this is a recognized ectopic site for variceal development. In some cases, these varices can be singular causes for focal bleeding. Variceal bleeding is usually painless, profound, and recurrent [17].

While digital examination of the stoma is of prime importance for local bleeding, consideration of a source anywhere along the gastrointestinal tract should be entertained and dealt with in a similar manner as in any patient with a GI bleed. Most bleeding from a stoma will have a visible site of injury or a bleeding vessel. If this is not evident, treat the patient as if they were having a GI bleed. The majority of cases of peristomal varices can be easily identified on physical exam by a bluish hue in the peristomal skin and presence of caput medusae in the peristomal area [16].

Local manual pressure is the first therapeutic maneuver with acute stomal bleeding. A useful adjunct is an epinephrine-soaked gauze. Isolated minor trauma-related bleeding will stop with local pressure and time. Granulation tissue associated with chronic local trauma is treated with local destruction by silver nitrate or judicious electrocautery. Suturing of a visible vessel can be considered, but ligation of a bleeding varix is often futile and long-term success unlikely. Mortality is high due to underlying severe liver disease. Medical and/or surgical consultation should be obtained which will focus on reduction of portal pressure.

Urostomy Complications

Urinary diversion following cystectomy for bladder cancer management is increasing in prevalence [18]. When a urostomy is created, it is either incontinent or continent, and the patient will be familiar with the type constructed. The incontinent urostomy drains into a stoma bag attached via an appliance. The continent urostomy requires intermittent catheterization in order to drain the urine.

The ileal conduit, an incontinent urostomy, is the most common type of urinary diversion following cystectomy, accounting for 85% [19]. Typically created from the terminal ileum, these stomas have a lower risk of electrolyte imbalance.

The continent urostomy uses either the ileum or colon, or a combination of both, as a reservoir. Patients are instructed to routinely self-catheterize to avoid complications such as urinary tract infections, hydronephrosis leading to upper pole injury, stone formation, and perforation.

Metabolic derangements commonly occur in patients with intestinal urinary diversions due to the absorptive surface of the bowel.

Future Needs

The creation of a stoma represents a major life event that will affect a rising number of individuals, especially as the rate of colorectal cancer accelerates. The healthcare system will be impacted, and the ostomate will continue to face the potential of complications throughout their life.

Several innovative strategies to mitigate these effects might include:

1. *Prehabilitation* is a preoperative tactic to identify and address the malnutrition and physical deconditioning present in cancer patients as well as identify psychological needs of those requiring an ostomy [20]. Adding a

robust and comprehensive discharge plan with patient education material [21] combined with referral to a support group and a connection to a stomal expert would be part of this process.

2. *Centralizing information* regarding optimal practice patterns, including knowledge about basic ostomy care, ostomy product availability, and standardized care plans, has been advocated to improve clinical outcomes [22].
3. Proactive monitoring of *patient-reported outcome measures* (PROMs) has been utilized, leading to improved adaptation to life after ostomy surgery. PROMs may play a role in physical and psychological adaptation [23].
4. Adding *ostomy telehealth* services for cancer survivors could expand the options for meaningful follow-up for ostomates, especially new ones, whose use of resources outstrips other colorectal patients [24, 25].

Hematopoietic Cell Transplant

52

Sherilyn A. Tuazon, Victor A. Chow, Phuong T. Vo, and Masumi Ueda

Introduction

Hematopoietic cell transplantation (HCT) has the potential to cure both malignant and nonmalignant hematologic diseases that may not be possible with conventional therapy. HCT allows for the administration of high-dose chemotherapy and radiotherapy while providing an opportunity for hematologic recovery with stem cell reinfusion. In the context of allogeneic HCT, an immunologic attack against the tumor cells is also conferred, termed graft-versus-tumor (GVT) effect.

Broadly, HCT consists of three phases: conditioning, stem cell infusion; and, for allogeneic HCT, graft-versus-host disease (GVHD) prophylaxis. The choice of conditioning regimen, stem cell source, and GVHD prophylaxis depends on patient and disease characteristics, as well as donor availability. The purpose of conditioning regimen is to eliminate tumor cells resistant to conventional doses of chemotherapy and, in the case of allogeneic HCT, produce sufficient immunosuppression to prevent graft rejection. Conditioning regimens used prior to autologous HCT are myeloablative, characterized by irreversible marrow aplasia requiring stem cell rescue. For allogeneic HCT, conditioning regimens can be classified as myeloablative; nonmyeloablative, which cause minimal cytopenias and can be given without stem cell support; and reduced-intensity, which result in intermediate degrees and duration of marrow suppression [1]. The source of stem cells can be from bone marrow, peripheral blood, or umbilical cord blood. HCT can also be categorized according to the relationship between the donor and recipient [autologous, syngeneic, or allogeneic (matched related, matched unrelated, or haploidentical)].

In 2018, approximately 23,000 HCTs were performed in the Unites States; of these, over 60% were autologous and the remainder were allogeneic. The most common indication for autologous HCT is multiple myeloma followed by lymphoma (non-Hodgkin and Hodgkin). Acute leukemias (acute myeloid leukemia, acute lymphocytic leukemia) and myelodysplastic syndrome (MDS) are the most common indications for allogeneic transplants, accounting for 75% of allogeneic HCTs [2]. Nonmalignant conditions that can be treated with HCT include, but not limited to, aplastic anemia, thalassemia, and autoimmune disorders (e.g., systemic sclerosis).

Complications of High-Dose G-CSF Administration

The most commonly used agent for hematopoietic cell mobilization and collection is granulocyte colony-stimulating factor (G-CSF), which triggers neutrophil elastase and cathepsin G to cleave bone marrow adhesion molecules, such as vascular cell adhesion molecule-1, stromal cell-derived factor, and CXCR4 [3, 4]. It is administered generally for 4 days before apheresis, with the goal of mobilization and increasing the total white blood cell (WBC) in the peripheral blood, of which a fraction is CD34+ stem cells. The majority of adverse events (AEs) associated with G-CSF are minor and not life-threatening, including bone pain, particularly along the back, pelvis, and/or ribs (82–94%); headache (34–70%); body aches; fatigue; and nausea/vomiting; however, serious and life-threatening AEs have been reported, including splenic rupture and ischemic complications, which constitute oncologic emergencies [4].

Splenic Rupture

The Research on Adverse Drug Events and Reports (RADAR) project reviewed AEs associated with G-CSF administration [5]. In addition to the common toxicities mentioned above, they also reported rare instances of

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_52

splenic rupture, allergic reactions, flares of underlying autoimmune disorders, lung injury, and vascular events [5]. Several studies have evaluated short-term administration of G-CSF on spleen size, with an average increase of 10% in volume and 11 mm in length occurring in 95% of subjects [6]. Although spleen size returned to baseline ~10 days after completion of G-CSF, instances of splenic rupture have been reported in the literature. While rare, a small number of case reports note a timing of rupture between day 3 and day 10 after the first G-CSF administration with outcomes ranging from those requiring conservative measures or splenectomy and even death [5]. An open-label study evaluating splenic changes in normal donors found that a predicted twofold change in spleen volume occurred in donors 60 years of age or older, although the physiological changes accounting for this phenomenon are unknown [6]. The leading hypothesis comes from pathologic evaluation of ruptured spleens requiring splenectomy, with histology indicating extramedullary myelopoiesis possibly leading to expansion of the hematopoietic tissue in the spleen.

Ischemic Complications

Ischemic complications have also been reported after G-CSF administration, especially in individuals with known coronary artery disease (CAD). In a study by the American College of Cardiology aiming to mobilize progenitor cells from the bone marrow to promote myocardial neovascularization and relief of ischemia, no objective evidence of cardiac benefit was found; rather, there were concerns for potential adverse outcomes. Their study of 16 patients reported 2 patients with serious AEs:

1. A 52-year-old diabetic man with a history of 2 myocardial infarctions (MIs) and class III angina, despite prior percutaneous coronary intervention (PCI), who developed severe chest pain, nausea, and diaphoresis with electrocardiogram (ECG) showing new ST-segment depression and mild ST-segment elevation treated with enoxaparin and nitroglycerin paste.
2. A 69-year-old man with class IV angina, history of MIs and 16 PCIs, coronary artery bypass, transmyocardial laser revascularization, and enhanced external counterpulsation, who experienced 3 episodes of angina without ECG changes, was ultimately hospitalized 2 weeks later for severe chest pain, and developed electrical-mechanical dissociation followed by asystole and death [7]

These individuals are extreme examples of baseline cardiovascular disease and would unlikely meet criteria for an ASCT; however, even rigorous testing with echocardiograms and ejection fraction cutoffs with input from cardiology consultation may not always identify patients at high risk for cardiovascular complications during the transplant process. Hence, it is standard practice at the Fred Hutchinson Cancer Research Center (FHCRC) to admit patients for G-CSF mobilization on telemetry if they have known CAD and a history of cardiac disease and, particularly, AL amyloidosis patients who may or may not have cardiac involvement. The pathophysiology behind exacerbations of underlying CAD by G-CSF is unclear, but in vitro experiments have shown that pro-inflammatory markers such as C-reactive protein (CRP) may play a role in promoting plaque destabilization and rupture.

Complications of Apheresis

Once the level of CD34+ cells is adequate in the peripheral blood, the process of apheresis is initiated for collection and storage of these progenitor cells. In general, apheresis is relatively safe but can also lead to serious, albeit manageable, complications. One of the most commonly encountered complications is citrate-induced hypocalcemia, as it is used as an anticoagulant throughout the apheresis procedure. Citrate will complex calcium, resulting in hypocalcemia in upward of 9% of treatments and leading to symptoms of perioral or distal extremity paresthesias [8]. If not reversed, severe citrate-induced hypocalcemia may prolong the QTc and lead to cardiac arrhythmias, in addition to muscle spasm, chest pain, and hypotension. Infusion providers are aware of this common complication and readily supply calcium tablets or intravenous calcium to mitigate hypocalcemia. Other commonly encountered phenomena after apheresis are thrombocytopenia and anemia, which may be further pronounced in a patient who recently received cytotoxic therapy or with bone marrow infiltration from their underlying disease. Various mechanisms for thrombocytopenia may contribute, and decreases of platelet count up to 50% have been reported, especially with older apheresis devices. Coupled with anemia and a hematocrit drop of up to 10%, hemorrhage may occur after an apheresis procedure [8]. Providers should be aware of these transient decreases in blood counts, monitor levels accordingly, and have a low threshold to work up any evidence for vital sign changes and signs or symptoms reminiscent of hemorrhage. Patients should be counseled on the potential need for transfusions even without bleeding events.

DMSO Toxicity

Dimethyl sulfoxide (DMSO) is the most commonly used cryopreservation agent for autologous stem cells collected via apheresis, protecting cells from the injurious effects of

freezing and crystal formation prior to storage. While relatively nontoxic to patients in small amounts, reinfusion of DMSO with the thawed autologous stem cells may trigger complications as much as 20–50% of the time in the acute setting, ranging from uncomplicated to serious toxicities [9]. Manageable or expectant side effects can be seen such as skin flushing, nausea, vomiting, diarrhea, and abdominal cramping brought about by a vagal response upon intravenous infusion of the cold product; however, sudden and severe toxicities have also been reported [9, 10]. These include cardiovascular or respiratory complications such as sudden and severe hypotension, bradycardia, fatal arrhythmias, dyspnea, respiratory arrest, and diffuse alveolar hemorrhage [9, 10]. Serious neurologic complications such as reversible leukoencephalopathy, strokes, and epileptic seizures have also been reported [11]. These serious toxicities are presumably from histamine-induced vasodilation and release; therefore, DMSO toxicity may result in increased morbidity and prolonged hospital admissions and incur additional treatment-related costs. In a survey from 444 European Bone Marrow Transplantation (EBMT) centers to assess DMSO-related complications, 95 centers completed the questionnaire for a 22% response rate. Of the 95 responding centers, 57 reported at least 1 DMSO toxicity (60%). Approximately 34,000 transplants were carried out by the 95 centers, giving an overall incidence of 1.4%, or approximately 1 in every 70 transplants [12].

Case Study

A 64-year-old male with IgG kappa multiple myeloma ultimately receives his cryopreserved autologous peripheral blood stem cells and experienced no major complications; however, he now presents with vomiting, debilitating oropharyngeal pain, and diarrhea 6 days after stem cell infusion with a conditioning regimen consisting of melphalan 200 mg/m^2. The patient was treated supportively with antiemetics, loperamide (after a negative stool Clostridium difficile test), intravenous fluids, patient-controlled analgesia, and total parenteral nutrition.

By day + 14, the patient noted improvement in symptoms with supportive management. However, on day + 16, the patient developed new-onset generalized erythematous rash, fever, and 3-kg weight gain. CBC with differential count showed a hemoglobin of 8.6 g/dL, white blood cell count of 1.5 K/uL, absolute neutrophil count (ANC) of 540/uL, and platelets of 19 K/uL. Comprehensive metabolic panel is remarkable only for hypokalemia at 3.6 mEq/L and slightly elevated creatinine at 1.3 mg/dL (baseline 0.8 mg/dL). Blood and urine cultures were negative. Chest X-ray showed slightly increased interstitial markings but no consolidation.

Oral Complications of HCT

Oropharyngeal mucositis (OM) is a common complication that typically peaks 6–11 days following high-dose conditioning regimens and then eventually heals over 1–2 weeks [13]. Recombinant keratinocyte growth factor (palifermin) is occasionally given with conditioning regimens, particularly those that include total body irradiation (TBI), to reduce the incidence of severe OM [14, 15]. Adverse reactions with palifermin include rash, oral dysesthesia, tongue thickening and discoloration, as well as taste alteration. With high-dose melphalan conditioning, oral cryotherapy (use of ice chips) is instituted to reduce the severity and duration of OM [16].

The development of OM may predispose patients to systemic bacterial infections originating from the mouth flora (e.g., *Streptococcus viridans* or *S. mutans*). In addition, when severe, OM may increase the risk for aspiration and airway compromise [13]. Bleeding may occur with OM, but is often minimal given platelet-support protocols and routine herpes simplex virus (HSV) prophylaxis [13]. Treatment is supportive with regular oral hygiene, saline rinses, mucosal coating agents (e.g., antacids), and topical anesthetics. Caution is advised when recommending topical anesthetics due to the risk of inadvertent mucosal injury while eating or performing oral care while the mouth is temporarily anesthetized. Oral anesthetics may also impair the gag reflex, increasing the risk of aspiration. When local measures are inadequate in providing relief, systemic pain management with opioid patient-controlled analgesia is usually effective.

Concurrent infection can accentuate the severity of OM. Candidiasis and HSV are common oral infections after HCT. However, the routine use of antifungal and antiviral prophylaxis has dramatically reduced the incidence and extent of these infections. When suspected, swabbing of the oral ulcers or lesions for histopathologic examination and culture should be performed.

Parotiditis is another oral complication typically seen among patients who are receiving total body irradiation and high-dose chemotherapy [17, 18]. Treatment is supportive with analgesics, warm compresses, and stimulation of salivation (i.e., lemon drops).

Gastrointestinal Complications of HCT

Following most conditioning regimens, nausea, vomiting, and diarrhea are common. Adequate control of nausea and vomiting is important not only for patient comfort but also to prevent complications such as dehydration, malnutrition, electrolyte or metabolic derangements, aspiration, erosive esophagitis, and esophageal tears.

Although chemotherapy-induced diarrhea is common after conditioning, patients should be ruled out for *C. difficile*, which is the most common cause of diarrhea in healthcare settings [19]. Because *C. difficile* colonization occurs in approximately 10–15% of HCT patients [20] and current testing is not capable of differentiating true disease from colonization, it is important to carefully select patients appropriate for testing. *C. difficile* testing is indicated in patients with new-onset diarrhea defined as three or more loose stools in 24 hours [19]. The preferred drug for treating an initial episode of *C. difficile*-associated diarrhea is vancomycin (125 mg PO QID × 10 days) because it has been shown to result in superior clinical cure compared to metronidazole [19]. However, metronidazole (500 mg PO TID × 10 days) is an acceptable alternative if oral vancomycin is not available. In patients with significant diarrhea despite active *C. difficile* treatment, loperamide may be considered as an adjunct, but should be approached with caution because there have been no prospective or randomized studies supporting its safety in the context of active *C. difficile* infection [19, 21, 22].

During the expected period of profound neutropenia following HCT, patients can develop neutropenic enterocolitis (NEC) (also termed typhlitis, ileocecal syndrome, or necrotizing enterocolitis). It is manifested as fever, nausea, vomiting, diarrhea, and abdominal pain [23]. The pathogenesis likely involves chemotherapy-induced disruption of the gastrointestinal mucosa and transmural translocation of pathogens [24]. Polymicrobial infection is frequent with gram-negative bacilli, gram-positive cocci, anaerobes (*C. septicum*), and even fungal infection, most commonly by *Candida* spp. The diagnosis is based on clinical presentation and radiologic findings. Contrast CT can demonstrate bowel thickening or dilation, mesenteric stranding, and pneumatosis [25]. Management includes supportive therapy with bowel rest, intravenous fluids or parenteral nutrition (if indicated), and antimicrobial therapy. Empiric antibiotics should cover enteric gram-negative and anaerobic pathogens. Piperacillin-tazobactam (Zosyn) or dual therapy with cefepime plus metronidazole is preferred. The carbapenems (imipenem-cilastatin and meropenem) are alternative agents for patients allergic to the recommended antibiotics or suspected to have resistant gram-negative bacteria, such as an extended-spectrum beta-lactamase (ESBL)-producing organisms [26].

Engraftment Syndrome

Neutrophil engraftment is defined as an ANC ≥500/uL for three consecutive days, whereas platelet engraftment is defined as an unsupported platelet count ≥20,000/uL. The timing for neutrophil engraftment typically occurs 2–3 weeks after stem cell reinfusion, but largely varies on patient and disease characteristics, stem cell source, and dose and conditioning regimen.

Engraftment syndrome (ES) can occur as a complication of autologous HCT, approximately 4–5 days before and after neutrophil recovery [27, 28]. ES is likely mediated by the release of pro-inflammatory cytokines. It encompasses a range of clinical manifestations such as noninfectious fever, rash, diarrhea, organ dysfunction, and features of capillary leak (noncardiogenic pulmonary edema, weight gain) with no alternative etiology other than engraftment [28]. Although no definitive biomarkers of ES have been identified, elevated levels of C-reactive protein have been associated with ES [29, 30]. The diagnosis of ES is clinical, and a standard diagnostic criterion has not been established. The Spitzer [27] and Maiolino [31] diagnostic criteria for ES have been proposed (Table 52.1).

Differences in diagnostic criteria used likely account for the wide range (7–90%) of reported incidence [32]. Because the clinical presentation of ES can be seen with infection, a comprehensive workup for infectious sources should be performed. If infection is ruled out, systemic corticosteroids can be used for treatment with favorable responses, although the majority of ES cases are mild and self-limited.

Peri-engraftment respiratory distress syndrome (PERDS) likely represents a pulmonary-predominant presentation of ES. PERDS can be defined by the presence of fever, hypoxia, and diffuse lung infiltrates on radiographs in the absence of infection, cardiac dysfunction, or fluid overload, within 5 days of neutrophil recovery [33]. Bronchoalveolar lavage

Table 52.1 Proposed diagnostic criteria of engraftment syndrome

	Spitzer criteria [27]	Maiolino criteria [31]
Requirements	3 major *or* 2 major +1 minor	Major +1 minor
Major criteria	Noninfectious fever (≥101 °F) Erythrodermatous rash over >25% of the body not linked to medication Noncardiogenic pulmonary edema	Noninfectious fever
Minor criteria	Weight gain (2.5% increase) Hepatic dysfunction (bilirubin ≥2 mg/dL or a twofold increase in transaminase over baseline) Renal dysfunction (twofold increase in serum creatinine over baseline) Transient encephalopathy	Skin rash Pulmonary infiltrates Diarrhea
Timing of symptoms relative to engraftment	96 hours within ANC 500/uL	Commencing 24 hours before or at any time after the appearance of neutrophils

ANC absolute neutrophil count

(BAL) can assist in ruling out infection and assessing for diffuse alveolar hemorrhage (DAH). DAH is characterized by the return from BAL becoming progressively bloodier or demonstrating ≥20% iron-laden macrophages on staining [34]. When no infectious etiology is identified, the primary therapy for both PERDS and DAH is with systemic corticosteroids. However, a higher dose of steroids is recommended for DAH, given as pulse doses of methylprednisolone 1 g daily, whereas in ES or PERDS, the dose of steroids is 0.5–1 mg/kg prednisone equivalent daily.

Autologous GVHD

A GVHD-like syndrome may occur in patients following autologous HCT, termed autologous GVHD. Although there may be overlapping clinical manifestations observed in ES and autologous GVHD, both are generally considered as distinct syndromes. Autologous GVHD is supported by histologic findings of classic GVHD (apoptosis with or without lymphoid infiltrate). The pathogenesis of autologous GVHD is not well understood, but is hypothesized to be related to immune dysregulation and inappropriate recognition of self-antigens [35]. Autologous GVHD is clinically and histologically similar to traditional acute GVHD, and can involve the skin, liver, and, most commonly, the GI tract [36]. Systemic corticosteroid is the mainstay of therapy and generally effective. Mild cases of autologous GVHD involving the skin can be treated with topical steroids only.

Transfusion-Associated GVHD

Transfusion-associated GVHD (TA-GVHD) is a rare but usually fatal complication of blood-component transfusion therapy. TA-GVHD occurs when viable donor lymphocytes proliferate in susceptible patients after transfusion. Patients with primary immunodeficiency syndromes, hematologic malignancies, and following HCT are at risk for TA-GVHD. The clinical features of TA-GVHD are similar to those of traditional GVHD but with an earlier onset, generally occurring 7–10 days after transfusion [35]. Patients may present with rash, fever, transaminitis, diarrhea, or abdominal pain [37]. One distinguishing clinical feature of TA-GVHD is profound pancytopenia; this increases the risk of infections, the most common cause of death in TA-GVHD, often occurring 3–4 weeks after the diagnosis [35]. Given the lack of effective therapy for TA-GVHD and its high fatality rate (80–90%), prevention of TA-GVHD is critical [38]. Irradiation of whole blood and cellular components is the only widely adopted technique to prevent TA-GVHD. Irradiation inactivates donor T lymphocytes, thereby abrogating the potential for GVHD. The US Food and Drug Administration recommends irradiation at a dose of 2500 cGy [38]. In addition to using irradiated blood products, patients with hematologic malignancy and following HCT should also only receive blood products that are leukoreduced to avoid alloimmunization and cytomegalovirus (CMV) transmission.

Acute Complications After Allogeneic HCT

Acute toxicities related to high-dose chemotherapy used as part of conditioning prior to autologous or allogeneic HCT are similar. However, allogeneic HCT is associated with distinct acute complications not present after autologous HCT due to the presence of donor cell alloreactivity (graft-versus-host disease (GVHD)), immunosuppressive medications used to prevent or treat GVHD and prevent graft rejection, and the resulting greater degree of host immunosuppression. Here we discuss acute complications unique to allogeneic HCT recipients.

Acute Infectious Complications After Allogeneic HCT

In recipients of HCT, the risk of infection is greatest during the period of pancytopenia following conditioning chemotherapy and/or radiation, but persists for 6–12 months after autologous HCT and up to 24 months following allogeneic HCT, due to the need for B- and T-cell immune reconstitution. In the allogeneic transplant recipient, this may be exacerbated by ongoing need for immunosuppression for prevention or treatment of graft-versus-host disease (GVHD). Prior to engraftment after HCT, mucosal and cutaneous damage from the conditioning regimen presents the main risk for infection. Neutropenic fever is common during this period and occurs in most patients. In the early period (<100 days after HCT), a variety of infections can occur, as summarized in Table 52.2. Specific pathogens which are important to consider in the HCT recipient are also outlined in Table 52.2.

Veno-Occlusive Disease (VOD) (Previously Termed Sinusoidal Obstruction Syndrome)

Liver complications after allogeneic HCT have become less frequent over time due to better understanding regarding the prevention and treatment of serious hepatobiliary problems. The use of ursodeoxycholic acid, a hydrophilic bile acid, during the peri-transplant period has significantly contributed to improved outcomes after HCT by reducing hepatic complications and severe acute GVHD, thus improving survival [39]. VOD is a clinical syndrome characterized by ten-

Table 52.2 Acute infections in the early post-HCT patient

Sign/symptom	Pathogens	Differential diagnosis
Diarrhea	CMV colitis *Clostridium difficile* Adenovirus Enteric organisms (coxsackie A, rotavirus, norovirus, echovirus) *Cryptosporidium parvum* (rare)	Acute GVHD Medication side effect Mucosal injury due to conditioning chemotherapy/radiation
Pneumonia	Invasive aspergillosis Mucormycosis *Fusarium* species CMV Respiratory viruses Pneumocystis pneumonia Disseminated strongyloidiasis (rare) Disseminated toxoplasmosis (rare)	Pulmonary edema Engraftment syndrome Diffuse alveolar hemorrhage IPS Drug-/radiation-induced pneumonitis Aspiration
Hepatitis	Hepatitis viruses (HBV, HCV most common) CMV EBV HHV-6 Adenovirus Hepatosplenic candidiasis	Medication toxicity Acute GVHD Iron overload Sinusoidal obstruction syndrome
Encephalitis	HHV-6 HSV VZV CMV EBV JC polyomavirus West Nile virus Adenovirus Toxoplasmosis	Medications PRES
Hemorrhagic cystitis	BK polyomavirus (common) Adenovirus (less frequent) CMV, JC polyomavirus (rare)	Drug-induced cystitis (cyclophosphamide)

HCT hematopoietic cell transplantation, *CMV* cytomegalovirus, *GVHD* graft-versus-host disease, *IPS* idiopathic pneumonia syndrome, *EBV* Epstein-Barr virus, *HHV* human herpesvirus, *HSV* herpes simplex virus, *VZV*, varicella-zoster virus, *JC*, John Cunningham virus

der hepatomegaly, fluid retention/weight gain, and elevated serum bilirubin in patients who receive high-dose myeloablative conditioning chemotherapy and/or radiation. Patients receiving high-dose cyclophosphamide (120 mg/kg) and total body irradiation (TBI) over 14 Gy are at greatest risk. In addition, pre-existing liver disease poses a significant increased hazard of VOD. The clinical presentation includes enlarged liver size, right upper quadrant tenderness, weight gain, and renal sodium retention occurring 10–20 days after the start of a myeloablative conditioning regimen. Elevated bilirubin occurs 4–10 days after these preceding signs, and concurrent portal hypertension, thrombocytopenia, and renal and lung dysfunction usually accompany the overall presentation. Diagnosis is based on clinical presentation, although liver imaging and transvenous liver biopsy and/or measurement of hepatic venous pressure may provide additional guidance [40]. Treatment of VOD is largely supportive, including management of fluid and sodium balance and maximizing renal blood flow. Patients with multi-organ failure may require hemodialysis or mechanical ventilation. A phase III trial of defibrotide for treatment of severe VOD with multi-organ failure showed improvement in day 100 survival and response; however, outcomes in patients given defibrotide were compared to historical controls. The day 100 survival was 38% with defibrotide vs. 25% in controls ($p = 0.01$) [41].

Acute Pulmonary Complications After Allogeneic HCT

Respiratory failure is the most common reason for intensive care unit (ICU) admissions among HCT recipients, affecting approximately 60% of HCT recipients requiring ICU care [42]. Differential diagnoses of hypercapnic and hypoxemic respiratory failure in the HCT recipient are outlined in Table 52.3.

Idiopathic pneumonia syndrome (IPS) is a term used to describe a clinical syndrome including a spectrum of non-infectious diffuse lung injuries following HCT. Diagnosis requires evidence of widespread alveolar injury, absence of active lower respiratory tract infection, and absence of a cardiac, renal, or iatrogenic etiology [43, 44]. The incidence of IPS is reported to be 4–12% associated with high case fatality rates (60–86%) in the first 100–120 days fol-

Table 52.3 Differential diagnoses for acute respiratory failure in the HCT recipient

Hypercapneic respiratory failure	Hypoxemic respiratory failure
Neurologic causes Opiates and sedative medications Intracranial hemorrhage PRES (see below) Airway obstruction Underlying conditions (COPD, asthma) Laryngeal edema due to mucositis Early-onset acute bronchiolitis obliterans syndrome (BOS)	Infectious pneumonia Pulmonary edema from volume overload Congestive heart failure Pneumonitis caused by aspiration, infection, chemotherapy, or other medications Idiopathic pneumonia syndrome (includes peri-engraftment respiratory distress syndrome, acute fibrinous organizing pneumonia, delayed pulmonary toxicity syndrome, diffuse alveolar hemorrhage) Pulmonary embolism Pneumothorax Cryptogenic organizing pneumonia

PRES posterior reversible encephalopathy syndrome

lowing HCT [43, 45]. Pathological specimens will show diffuse alveolar damage and interstitial pneumonitis. Treatment includes high-dose steroids and use of TNF-alpha inhibitors such as etanercept. IPS is thought to be triggered by damage due to conditioning chemotherapy and radiation leading to endothelial injury and oxidative stress, propagated by host innate and donor T-cell immune reactions [46].

In a subset of patients with IPS, pulmonary hemorrhage or hemorrhagic alveolitis occurs. Diffuse alveolar hemorrhage (DAH) occurs in 5–12% of HCT recipients at a median time to onset of 12–19 days following both autologous and allogeneic HCTs [44]. This develops secondary due to diffuse alveolar damage from high-dose conditioning chemotherapy and/or radiation, exacerbated by thrombocytopenia. Infection may trigger this presentation as well. While radiographic features are often telling, the diagnosis is confirmed by bronchoalveolar lavage showing increasingly bloody return of lavage fluid. Treatment involves high-dose steroids (up to 2 mg/kg/day), platelet transfusions (to keep a threshold of at least 50,000), and supportive care. DAH is associated with high mortality rates, up to 60–100% [44]. A slow and prolonged steroid taper is advised following initial response to therapy.

Acute Renal Complications After Allogeneic HCT

Evaluation of the post-HCT patient with acute elevation in serum creatinine level requires a vigilant search for the underlying cause. Workup should include complete urinalysis and urine albumin/creatinine ratio, as well as workup for hemolysis, including complete blood count with blood smear, lactate dehydrogenase, haptoglobin, and serum level of calcineurin inhibitor (if applicable). Opportunistic viral infections such as BK virus and adenovirus may impact renal function or cause viral nephropathy and should be tested in the serum. Kidney ultrasound should also be considered where clinically indicated.

Transplantation-Associated Thrombotic Microangiopathy (TMA)

The presence of renal dysfunction, microangiopathic hemolytic anemia, elevated lactate dehydrogenase, and negative workup for immune-mediated hemolysis (negative direct and indirect Coombs tests), associated with neurologic dysfunction points toward a clinical diagnosis of TMA [47]. Guidelines propose that concurrent renal and neurologic dysfunction and defined schistocyte count are not required for TMA diagnosis [48]. There is no defined or effective treatment. Discontinuation of the use of calcineurin inhibitors and replacement with other methods of GVHD prophylaxis, such as sirolimus or mycophenolate mofetil, can be considered but are not proven strategies. Posttransplant considerations such as graft-versus-host disease (described below) may limit options for a switch in immunosuppressive treatment. Other therapies that have been investigated include plasma exchange with or without rituximab. Patients with elevation in plasma levels of C5b-9 may benefit from therapy with eculizumab, although clinical trials have shown mixed results [49, 50].

Acute Neurologic Complications After Allogeneic HCT

Chemotherapy used as part of the conditioning regimen prior to infusion of donor stem cells, as well as the immunosuppressive medications used for prevention of GVHD, is associated with a variety of neurologic complications. Among these, calcineurin inhibitors (cyclosporine and tacrolimus) are most commonly used and are associated with tremors, seizures, and posterior reversible encephalopathy syndrome (PRES). PRES is characterized by rapidly evolving (over hours to days) symptoms, including headache, altered consciousness, visual disturbances, and seizures [51]. Elevated serum levels of immunosuppressive medications are not related to the onset of neurologic symptoms [52]. Less common side effects of tacrolimus include brachial plexopathy, optic neuropathy, and hearing loss; cyclosporine has been associated with pseudotumor cerebri [53]. Other possible neurologic complications of chemotherapy agents commonly used in conditioning for allogeneic HCT are summarized in Table 52.4. In addition, prophylactic antiviral medications (e.g., acyclovir) and antibiotics frequently used in this population (e.g., cefepime, imipenem) are associated with risk of seizure. Cefepime and acyclovir may cause encephalopathy as well. Voriconazole commonly causes visual hallucinations in patients who take this for prophylaxis or treatment of invasive fungal infection in the peritransplant period.

Table 52.4 Neurologic complications of drugs commonly used in allogeneic HCT conditioning regimens

Drug	Neurologic complication
Busulfan Melphalan Cytarabine	Seizure
Cyclophosphamide Fludarabine Melphalan	Posterior reversible encephalopathy syndrome
Cytarabine	Cerebellar dysfunction
Cytarabine Thiotepa	Lymphocytic meningitis
Alemtuzumab Rituximab Fludarabine	PML (progressive multifocal leukoencephalopathy)

In addition to drug-induced neurologic complications, pancytopenia following conditioning chemotherapy increases the risk of intracranial bleeding, such as subdural hematoma and intraparenchymal hemorrhage. Neutropenia and immune compromise lead to increased risk of opportunistic CNS infections, including viral encephalitis from herpes simplex, Epstein-Barr virus, varicella-zoster virus, CMV, and HHV-6. Other etiologies may include fungal (*Aspergillus*, *Rhizopus*, *Candida* spp.) and parasitic organisms (*Toxoplasma gondii*).

Acute GVHD

Acute graft-versus-host disease (aGVHD) is a frequent and potentially life-threatening complication that occurs within the first 3–4 months following allogeneic HCT. It is an inflammatory process mediated by immune-competent T cells contained in the donor graft that recognize tissues of the recipient as "foreign." The GI tract, liver, and skin are the primary organs involved. Despite prophylaxis with immunosuppressive agents, aGVHD requiring treatment occurs in approximately 50% of patients after an HLA-matched related donor HCT. The incidence and severity of aGVHD increase with a higher degree of HLA disparity between the donor and recipient. Manifestations of aGVHD are outlined in Table 52.5.

The diagnosis of acute GVHD is made clinically based on classic signs and symptoms occurring within the first several weeks to months of allogeneic HCT. However, the diagnosis is not always straightforward, and alternative diagnoses (e.g., drugs, infection, residual toxicities from preparative regimen, VOD) must be ruled out. Biopsy of the involved tissues (i.e., skin and/or GI mucosa) helps corroborate the diagnosis of GVHD. Due to the increase risk of bleeding, especially in the setting of expected posttransplant thrombocytopenia, liver biopsy is reserved for patients in whom the results would unequivocally affect clinical decision-making. The severity of aGVHD is determined by an assessment of the degree of involvement of the skin, liver, and GI tract (Table 52.6). This grading system should not be confused with histological grades sometimes noted in pathology reports from skin and GI mucosal biopsies.

Table 52.5 Clinical manifestations of acute graft-versus-host disease (GVHD)

Organ involvement	Clinical manifestation
Skin	Erythematous maculopapular rash, often initially involving the palms and soles. May progress to involve the entire body surface and may be pruritic and painful in severe cases. Bullae may form leading to desquamation
Liver	Cholestasis with or without frank jaundice. Cholestasis enzymes are comparatively more elevated than transaminases
Gastrointestinal	Upper tract: anorexia, nausea, and vomiting Lower tract: diarrhea. In severe cases, may contain blood and mucosa and may be accompanied by abdominal cramping and paralytic ileus Endoscopy: in mild cases, may only show edema and erythema. In more severe cases, may show hemorrhage and ulcerations

Table 52.6 Clinical organ staging and grading of acute graft-versus-host disease (GVHD)

Stage	Skin	Liver	Gastrointestinal (quantity of diarrhea)
1	Maculopapular rash <25% of body area	Bilirubin 2.0–3.0 mg/dL	500–1000 mL
2	Maculopapular rash 25–50% of body area	Bilirubin 3.1–6.0 mg/dL	1001–1500 mL
3	Generalized erythroderma	Bilirubin 6.1–15.0 mg/dL	>1500 mL
4	Generalized erythroderma with bullae and desquamation	Bilirubin >15.0 mg/dL	Severe abdominal pain with and without ileus
Grade	*Organ involvement*		
I	Stage 1 or 2 skin involvement; no liver or gut involvement		
II	Stage 1 to 3 skin involvement; grade 1 liver or gut involvement		
III	Stage 2 or 3 liver or gut involvement		
IV	Stage 4 skin liver or gut involvement		

aGVHD limited to the skin and involving less than 50% of body surface area can be easily managed with topical glucocorticoids alone. In more advanced cases, first-line treatment consists of systemic glucocorticoids while continuing the original immunosuppressive prophylaxis regimen. While a prednisone-equivalent dose of 2 mg/kg/day used to be the conventional starting dose for patients requiring systemic immunosuppressive therapy, a randomized trial has shown that lower initial doses (0.5–1.0 mg/kg/day) are safe and effective for patients who present with mild-to-moderate aGVHD [54]. Minimally absorbed oral glucocorticoids (beclomethasone dipropionate and budesonide) are typically used concurrently for GI aGVHD. There is no general consensus on treatment duration and taper rates once symptoms have resolved. We typically treat with systemic glucocorticoids for 7–10 days and then attempt a taper over 1–2 months, as tolerated.

Only ~50% of patients will have a long-term response to systemic glucocorticoids. Secondary immunosuppressive therapy should be considered for patients receiving systemic glucocorticoids who have *(i)* progressive symptoms in any organ after 3 days of treatment, *(ii)* persistent grade III symptoms after 1 week of treatment, or *(iii)* persistent grade II symptoms after 2 weeks of treatment [55]. Patients with

aGVHD resistant to treatment with glucocorticoids have a dismal long-term prognosis, with an overall survival likelihood of approximately 50% at 6 months. The oral Janus-activated kinase (JAK) 1/2 inhibitor, ruxolitinib, is only one FDA-approved agent for treatment of steroid-refractory aGVHD [56].

Patients receiving prolonged systemic immunosuppressive therapy are at an increased risk for infections; therefore, prophylaxis against fungal infections, HSV/VZV reactivation, and PJP should be instituted concurrently. In addition, weekly screening for CMV should be performed to detect early reactivation necessitating preemptive therapy. Patients with acute gut GVHD are at high risk for malnutrition. Maintaining even minimal oral caloric intake appears to have GI-protective effects and should be encouraged. If parenteral nutritional is needed, feeding solutions should be low in fiber, fat, and lactose. Complete bowel rest and TPN may be indicated, at least temporarily, in severe cases of gut GVHD. Supportive measures with antidiarrheal agents, including loperamide or octreotide, may be considered.

Graft Failure

Graft failure (GF) is defined as the lack of engraftment following autologous or allogeneic HCT. GF is classified as primary when there is no evidence of engraftment within the first month after transplant, or secondary when there is a loss of a previously functioning graft. The incidence of GF is less than 3–5% in the autologous and matched allogeneic HCT but up to 10% in haploidentical or cord blood recipients. GF is associated with a dismal prognosis with an overall survival of only 20% at 3–5 years following its diagnosis [57]. Infections and bleeding are the primary causes of mortality. Table 52.7 lists risk factors for GF.

There is currently no standard approach to the management of GF. Common management strategies include ensuring therapeutic doses of immunosuppression, discontinuation of myelosuppressive drugs, administration of growth factors and thrombopoietin analogues (eltrombopag, romiplostim), donor lymphocyte infusion, and CD34+ cell boost. A second HCT is the only potential curative option for patients with GF [58, 59]. There is no definitive data guiding the choice of conditioning regimen and donor type. A nonmyeloablative or reduced-intensity conditioning regimen is typically used with the second HCT to avoid unacceptable cumulative toxicities. In patients with an immune-mediated graft rejection, the use of an alternative donor, whenever possible, is recommended [59].

Table 52.7 Risk factors of graft failure

Pretransplant	Peri-transplant	Posttransplant
HLA mismatch HLA antibodies ABO mismatch Iron overload Transfusion history Underlying diseases (nonmalignant disease, myelofibrosis, advanced disease) Splenomegaly	Graft sources (cord blood/bone marrow stem cell source, and haploidentical donor) T-cell depletion graft manipulation Reduced-intensity conditioning Low CD34+ cell count	Viral infections GVHD Drug toxicity

HLA human leukocyte antigen, *GVHD* graft-versus-host disease

Toxicities of Novel Antineoplastic Therapies

53

Eva Rajha and Sai-Ching Jim Yeung

Introduction

Many novel cancer therapy agents, altogether about a hundred, have been approved by the US Food and Drug Administration (FDA) between 2011 and 2020 for hematologic malignancies (Table 53.1) and solid tumors (Table 53.2). These new treatments offer improved clinical outcomes and survival of cancer patients at the price of treatment-related adverse events. Thus, the emergence of new treatment-related adverse events and syndromes will present diagnostic and management challenges to emergency physicians when they provide care for the cancer patient.

Case Study

A 65-year-old man with metastatic melanoma presents to the emergency department (ED) with the chief complaints of general weakness and confusion. He is not known to have brain metastasis, and his magnetic resonance imaging (MRI) of the brain did not show any metastatic disease 1 month prior to ED presentation. For his melanoma, he is not on cytotoxic chemotherapy and received his fourth dose of immunotherapy with ipilimumab 1 week ago. He complains of progressive general weakness, and he felt too weak to get out of bed without assistance for the past 2 days. He has lost his appetite and has nausea for about 3 days, resulting in decreased oral intake. He is lethargic and disoriented but without focal neurological complaints. His review of systems reveals symptoms of mild headache and constipation.

His vital signs are normal except for orthostatic hypotension. His physician examination is within normal limits except for disorientation to time, lack of concentration, inability to perform serial-7 subtraction, and lethargy. Laboratory testing reveals the following: serum sodium 128 mEq/L, blood urea nitrogen 35 mg/dL, creatinine 1.1 mg/dL, and glucose 68 mg/dL. The rest of the comprehensive metabolic panel and complete blood count with differential are normal.

Further testing in the ED shows that cortisol level is 2.7 μg/dL, thyrotropin 0.06 mIU/L, and free thyroxine 0.6 ng/dL. MRI of the sella reveals a slightly enlarged pituitary gland (1.2 cm in height, 1.1 cm in anterior-posterior dimension, and 1 cm in width). The dome of the mass is slightly indenting the inferior aspect of the optic chiasm.

The patient is diagnosed with adrenal insufficiency and central hypothyroidism due to ipilimumab-induced hypophysitis. The patient is hospitalized for further evaluation and management of this immune-related adverse effect (irAE). Endocrinology service is consulted; dynamic testing with low-dose cosyntropin stimulation test and measurements of adrenotropin corroborates central hypoadrenalism. Testing of other pituitary axes reveals panhypopituitarism.

General Approach

To appropriately and promptly diagnose and manage these toxicities, emergency physicians should be familiar with the array of adverse effect of these cancer therapies. This chapter will summarize the recent therapeutic advances in the field of oncologic and provide a reference for emergency physicians dealing with adverse events that are caused by these new agents and may present as oncologic emergencies. Some of these presentations can mimic sepsis, and we propose an algorithm to guide emergency providers in their approach to these complications (Fig. 53.1), linking to existing diagnostic guidelines.

Table 53.1 Novel drugs approved after 2010 for hematologic malignancies and their associated adverse events

Generic name	Brand name	FDA approval date	Mechanism of action	Indication	Comments	Adverse events
Chimeric antigen receptor-T-cells						
Tisagenlecleucel	KYMRIAH	08/30/17	CD19-directed genetically modified autologous T-cell immunotherapy	ALL	Patients with ALL up to 25 years	CNS events Cytokine release syndrome Hypogammaglobulinemia Infections, pancytopenia
				LBCL	Relapsed or refractory LBCL	CNS events Cytokine release syndrome Hypogammaglobulinemia Infections, cytopenias
Axicabtagene ciloleucel	YESCARTA	10/18/17	CD19-directed genetically modified autologous T-cell immunotherapy	LBCL	Relapsed or refractory LBCL	CNS events Cytokine release syndrome Infections, cytopenias
Monoclonal antibodies against programmed cell death protein-1 (PD-1), an immune checkpoint molecule						
Pembrolizumab	KEYTRUDA	06/13/18	PD-1 humanized mouse mAb	PMBCL, cHL	Mediastinal LBCL	Immune-mediated adverse events (most common, musculoskeletal pain, infection, fatigue, cough, dyspnea, diarrhea, abdominal pain, nausea, headache; most serious, arrhythmia, myocardial infarction, pericardial effusion) Infusion-related reactions
Nivolumab	OPDIVO	05/17/16	PD-1 human IgG4 mAb	cHL		Immune-mediated adverse events (most common, rash, diarrhea, cough; most serious, pneumonia, pneumonitis, pyrexia, infusion reaction) Transplantation-related complications (GVHD) Hepatic veno-occlusive disease
Small molecule inhibitors						
Enasidenib	IDHIFA	08/01/17	IDH2 inhibitor	AML	Relapsed or refractory acute myeloid leukemia	Indirect hyperbilirubinemia Differentiation syndrome
Ivosidenib	TIBSOVO	07/20/18	IDH1 inhibitor	AML	Relapsed or refractory AML	QT prolongation Leukocytosis Differentiation syndrome
Midostaurin	RYDAPT	04/28/17	FLT3 inhibitor	AML	AML *FLT3* mutation-positive (*FLT3*+), advanced mastocytosis	Febrile neutropenia Mucositis, nausea, vomiting Headache Petechiae, epistaxis Upper respiratory tract infection
Ponatinib	ICLUSIG	12/17/12	BCR-ABL inhibitor	CML, ALL	CML, Philadelphia chromosome-positive ALL	Cardiac and arterial vascular occlusive events Arrhythmias, HF Pancreatitis, hepatotoxicity Reversible posterior leukoencephalopathy
Nilotinib	TASIGNA	03/22/18	BCR-ABL inhibitor	CML	Philadelphia chromosome-positive CML	QT prolongation, sudden death Myelosuppression Cardiac and arterial vascular occlusive events Pancreatitis and hepatotoxicity

Bosutinib	BOSULIF	09/04/12	BCR-ABL inhibitor	CML	Philadelphia chromosome-positive CML	Myelosuppression Diarrhea, pancreatitis, hepatotoxicity Cardiovascular events
Zanubrutinib	BRUKINSA	11/14/2019	BCR inhibitor	MCL		Myelosuppression Arrhythmias
Ibrutinib	IMBRUVICA	11/13/13	Irreversible inhibitor of Bruton tyrosine kinase (BTK)	MCL, CLL, WM		Cytopenias Hypertension
Acalabrutinib	CALQUENCE	10/31/17	Second-generation BTK inhibitor	MCL		Headache, diarrhea, fatigue, myalgia Neutropenia, anemia, pneumonia Cardiac adverse events
Idelalisib	ZYDELIG	07/23/14	Phosphatidylinositol 3-kinase δ inhibitor	CLL, NHL, SLL	Relapsed CLL	Serious hepatotoxicity Diarrhea, colitis, perforation Pneumonitis Myelosuppression, infections
Duvelisib	COPIKTRA	24/09/18	Phosphatidylinositol 3-kinase δ and γ (PI3K-δ, γ) inhibitor	CLL, SLL, FL	Refractory CLL, SLL, or FL	Nausea, diarrhea Pyrexia Cytopenias
Copanlisib	ALIQOPA	09/14/17	Pan-class I phosphoinositide 3-kinase (PI3K) inhibitor	FL	Relapsed FL	Hyperglycemia, hypertension, infections, neutropenia Noninfectious pneumonitis Severe cutaneous reactions
Belinostat	BELEODAQ	07/03/14	Deacetylase I and II inhibitor	PTCL	Relapsed/refractory PTCL	Myelosuppression, infections Thrombotic microangiopathy Thromboembolic events Renal and hepatic toxicity Pneumonitis Tumor lysis syndrome QT prolongation Reversible posterior leukoencephalopathy
Panobinostat lactate	FARYDAK	02/23/15	Pan-deacetylase inhibitor	MM		Cytopenias, peripheral neuropathy Cardiac ischemia, arrhythmias Severe diarrhea
Carfilzomib	KYPROLIS	07/20/12	Proteasome inhibitor	MM		Myelosuppression, infections Hepatic toxicity Tumor lysis syndrome HF, QT prolongation
Ixazomib citrate	NINLARO	11/20/15	Proteasome inhibitor	MM		Cytopenias, vomiting, diarrhea, constipation, neuropathy, peripheral edema, back pain
Venetoclax	VENCLEXTA	4/11/2016	BCL2 inhibitor	CLL, SLL		Tumor lysis syndrome Myelosuppression Autoimmune hemolytic anemia
Ruxolitinib	JAKAFI	11/16/11	JAK inhibitor	Myelofibrosis, PV		Myelosuppression, sepsis HF Herpes zoster infection

(continued)

Table 53.1 (continued)

Generic name	Brand name	FDA approval date	Mechanism of action	Indication	Comments	Adverse events
Fedratinib hydrochloride	INREBIC	8/16/2019	JAK2 inhibitor	Myelofibrosis		Serious and fatal encephalopathy, thiamine deficiency Anemia, thrombocytopenia Gastrointestinal, hepatic toxicity Amylase, lipase elevation
Omacetaxine mepesuccinate	SYNRIBO	10/26/12	BCR-ABL1 and Mcl-1 synthesis inhibitor	CML	CML after failure of two or more TKIs	Myelosuppression Glucose intolerance
Monoclonal antibodies against cell surface antigens						
Ofatumumab	ARZERRA	04/17/14	CD20 human mAb	CLL	Recurrent or progressive CLL	Reactivation of hepatitis B virus infection Progressive multifocal leukoencephalopathy Tumor lysis syndrome Infusion reaction Cytopenias
Obinutuzumab	GAZYVA	11/01/13	CD20 humanized mAb	CLL, FL		Febrile neutropenia, thrombocytopenia Infusion reactions
Daratumumab	DARZALEX	11/21/16	CD38 human IgG1k mAb	MM		Cytopenias, diarrhea, pneumonia
Elotuzumab	EMPLICITI	11/30/15	Signaling lymphocyte activation molecule family 7 (SLAMF7) humanized mAb	MM		Pyrexia, anemia, pneumonia, pulmonary embolism, acute renal failure, hepatotoxicity Infusion reactions Second primary malignancies
Mogamulizumab-kpkc	POTELIGEO	08/08/18	CC chemokine receptor 4 (CCR4) humanized mAb defucosylated at the Fc region to enhance antibody-mediated cellular cytotoxicity	MF		Rash, infusion reactions GVHD if allogenic transplantation within 50 days of treatment
Antibody-drug conjugates						
Inotuzumab ozogamicin	BESPONSA	08/17/17	CD22 humanized mAb covalently conjugated to N-acetyl-γ-calicheamicin dimethylhydrazide	ALL	Relapsed or refractory B-cell precursor ALL	Veno-occlusive disease (sinusoidal occlusion syndrome) Infusion reactions Thrombocytopenia, neutropenia QT prolongation
Gemtuzumab ozogamicin	MYLOTARG	09/01/17	CD33 humanized mAb covalently conjugated to N-acetyl-γ-calicheamicin dimethylhydrazide	AML	CD33-positive AML	Infection, bleeding, prolonged thrombocytopenia Veno-occlusive disease, transaminitis
Brentuximab vedotin	ADCETRIS	09/19/11	CD30 chimeric mAb covalently linked with cleavable linkers to 3–5 units of monomethyl auristatin E	T-cell lymphoma, cHL	Anaplastic large cell or other CD30-expressing T-cell lymphomas, relapsed or refractory Hodgkin lymphoma	Progressive multifocal leukoencephalopathy Peripheral neuropathy Myelosuppression

Immunotoxin						
Moxetumomab pasudotox-tdfk	LUMOXITI	09/13/18	CD22-directed cytotoxin	HCL	Relapsed or refractory HCL	Hemolytic uremic syndrome Capillary leak syndrome
Bi-specific T-cell engager						
Blinatumomab	BLINCYTO	13/3/14	CD19-/CD3-bi-specific mAb	ALL	B-cell precursor ALL	CNS events Cytokine release syndrome
Protein-based therapy						
Asparaginase *Erwinia chrysanthemi*	ERWINAZE	11/18/11	Cytotoxicity by catalyzing deamidation of asparagine	ALL	ALL with hypersensitivity to *E. coli*-derived asparaginase	Serious hypersensitivity Bleeding or thrombosis Hypertriglyceridemia, pancreatitis Hyperammonemia
Immunomodulatory agent with antineoplastic activity						
Pomalidomide	POMALYST	02/08/13	Angiogenesis inhibitor, TNF-α inhibitor	MM		Myelosuppression Tumor lysis syndrome Severe cutaneous reactions Birth defects, fetal death Thromboembolic events ILD, pneumonitis

FDA US Food and Drug Administration, *ALL* acute lymphoblastic leukemia, *LBCL* large B-cell lymphoma, *PMBCL* primary mediastinal large B-cell lymphoma, *cHL* classic Hodgkin lymphoma, *GVHD* graft-versus-host disease, *AML* acute myeloid leukemia, *CNS* central nervous system, *CML* chronic myeloid leukemia, *HF* heart failure, *MCL* mantle cell lymphoma, *CLL* chronic lymphocytic leukemia, *WM* Waldenstrom's macroglobulinemia, *NHL* non-Hodgkin lymphoma, *SLL* small lymphocytic lymphoma, *FL* follicular lymphoma, *PTCL* relapsed/refractory peripheral T-cell lymphoma, *MM* multiple myeloma, *MF* mycosis fungoides, *HCL* hairy cell lymphoma, *PV* polycythemia vera, *ILD* interstitial lung disease

Table 53.2 Novel drugs approved after 2010 for solid tumors and their associated adverse events

Generic name	Brand name	FDA approval date	Mechanism of action	Indication	Comments	Adverse events
Monoclonal antibodies against programmed cell death protein-1 (PD-1), an immune checkpoint molecule						
Pembrolizumab	KEYTRUDA	09/04/14	PD-1 humanized mouse mAb	Melanoma		Immune-mediated adverse events (most common, musculoskeletal pain, infection, fatigue, cough, dyspnea, diarrhea, abdominal pain, nausea, headache; most serious, arrhythmia, myocardial infarction, pericardial effusion) Infusion-related reactions
		10/02/15		NSCLC		
		11/23/15		Renal cell cancer		
		08/05/16		Head & neck cancer		
		05/18/17		Urothelial cancer		
		09/22/17		Gastric cancer		
		06/12/18		Cervical cancer	HCC	
		11/09/18		Liver cancer		
		12/19/18		Merkel cell cancer		
		06/18/19		SCLC		
		07/30/19		Esophageal cancer		
		09/17/19		Endometrial cancer		
Nivolumab	OPDIVO	12/22/14	PD-1 human IgG4 mAb	Melanoma		Immune-mediated adverse events (most common, rash, diarrhea, cough; most serious, pneumonia, pneumonitis, pyrexia, infusion reaction) Transplantation-related complications (GVHD) Hepatic veno-occlusive disease
		03/04/15		Lung cancer	NSCLC, SCLC	
		11/23/15		Renal cell cancer		
		11/10/16		Head & neck cancer		
		02/02/17		Urothelial cancer		
		08/01/17		Colorectal cancer		
		09/22/17		Liver cancer	HCC	
Atezolizumab	TECENTRIQ	05/18/16	PD-1 humanized IgG1 mAb	Urothelial cancer		Immune-mediated adverse events (most common, fatigue, rash, diarrhea, transaminitis, infection, renal dysfunction; most serious, myositis, colitis, adrenal insufficiency, pneumonitis, myocarditis) Infusion-related reactions
		10/18/16		Lung cancer	NSCLC	
		03/08/19		Breast cancer		
		03/18/19		Lung cancer	SCLC	
Cemiplimab-rwlc	LIBTAYO	09/28/18	PD-1 recombinant human IgG4 mAb	Cutaneous squamous cell carcinoma		Immune-mediated adverse events (most common, fatigue, rash, nausea; most serious, cellulitis, pneumonitis, pleural effusion, duodenal ulcer, colitis, hypercalcemia, hypophysitis) Infusion-related reactions
Monoclonal antibodies against programmed cell death ligand 1 (PD-L1), an immune checkpoint molecule						
Avelumab	BAVENCIO	03/23/17	PD-L1 human IgG1 mAb	Merkel cell carcinoma		Immune-mediated adverse events (most common, fatigue, rash, emesis, elevated lipase; most serious, pneumonitis, hepatotoxicity, adrenal insufficiency) Infusion-related reactions
		05/09/17		Urothelial cancer		
		05/14/19		Renal cell cancer		
Durvalumab	IMFINZI	05/01/17	PD-L1 human IgG1κ mAb	Urothelial cancer		Immune-mediated adverse events (most common, fatigue, pruritus; most serious, hepatotoxicity) Infusion-related reactions
		02/16/18		NSCLC		
Monoclonal antibodies against cytotoxic T lymphocyte-associated antigen 4 (CTLA4), an immune checkpoint molecule						
Ipilimumab	YERVOY	03/25/11	CTLA4 human mAb	Melanoma		Immune-mediated adverse events (most common, fatigue, rash; most serious, colitis, HLH) Infusion-related reactions
		16/4/18		Renal cell cancer		
		11/6/18		Colorectal cancer		

Small molecule inhibitors						
Vandetanib	VANDETANIB	04/06/11	VEGFR inhibitor	Thyroid cancer		QT prolongation Hypertension, HF Dermatologic toxicity Interstitial lung disease
Regorafenib	STIVARGA	10/27/12	VEGFR inhibitor	Colorectal cancer Advanced GIST tumor Liver cancer		Hypertension Serious hepatotoxicity Dermatologic toxicity Reversible posterior leukoencephalopathy
Axitinib	INLYTA	01/27/12	VEGFR inhibitor	Renal cell cancer		Hypertension, HF Dermatologic toxicity Thrombotic events
Erdafitinib	BALVERSA	04/12/19	Pan FGFR kinase inhibitor	Bladder cancer	Locally advanced or metastatic urothelial carcinoma with abnormal FGFR gene	Hyperphosphatemia, nausea, stomatitis, dry mouth Central serous retinopathy/retinal pigment epithelial detachment
Neratinib maleate	NERLYNX	07/17/17	Irreversible HER2 and EGFR inhibitor	Breast cancer		Gastrointestinal toxicity, diarrhea
Lenvatinib mesylate	LENVIMA	02/13/15	VEGFR inhibitor	Endometrial cancer Renal cell cancer Liver cancer Thyroid cancer	HCC	Hypertension, cardiac dysfunction, QT prolongation, arterial thromboembolic events Renal and liver toxicity Hemorrhagic events Reversible posterior leukoencephalopathy Palmoplantar erythrodysesthesia
Cabozantinib-s-malate	COMETRIQ CABOMETYX	11/29/12 04/25/16	RTK inhibitor	Thyroid cancer Renal cell cancer Liver cancer		Hypertensive crisis Hemorrhage, perforations, fistulas, wound complications Thrombotic events Diarrhea Osteonecrosis of the jaw Reversible posterior leukoencephalopathy Palmoplantar erythrodysesthesia
Alectinib	ALECENSA	12/11/15	ALK inhibitor	NSCLC	ALK-positive NSCLC	Hepatic and renal toxicity ILD/pneumonitis Bradycardia Myalgia and CPK elevation
Crizotinib	XALKORI	11/20/13	ALK inhibitor	NSCLC	ALK-positive or ROS1-positive NSCLC	Myelosuppression QT prolongation, bradycardia Liver and lung toxicity Ocular toxicity
Ceritinib	ZYKADIA	04/29/14	ALK inhibitor	NSCLC	ALK-positive NSCLC	QT prolongation, bradycardia Gastrointestinal, liver, lung, and ocular toxicity Pancreatitis

(continued)

Table 53.2 (continued)

Generic name	Brand name	FDA approval date	Mechanism of action	Indication	Comments	Adverse events
Brigatinib	ALUNBRIG	04/28/17	ALK inhibitor	NSCLC	ALK-positive NSCLC	ILD/pneumonitis Hypertension, bradycardia Myalgia and CPK elevation Visual disturbance Pancreatic enzymes elevation Hyperglycemia
Lorlatinib	LORBRENA	11/02/18	RTK, ALK, ROS1 inhibitor	NSCLC	ALK-positive or ROS1-positive NSCLC	Serious hepatotoxicity ILD/pneumonitis Atrioventricular block CNS disturbance Hyperlipidemia
Entrectinib	ROZLYTREK	08/15/19	Pan-TRK ROS1, ALK inhibitor	NSCLC Solid tumors with NTRK gene fusion	ROS1-positive NSCLC Solid tumors with NTRK gene fusion	Liver and renal toxicity CHF CNS and visual disturbance Skeletal fractures QT prolongation Hyperuricemia
Osimertinib mesylate	TAGRISSO	11/13/15	Mutant selective EGFR inhibitor	NSCLC	EGFR T790M mutation-positive NSCLC	ILD/pneumonitis QT prolongation Cardiomyopathy Diarrhea, rash
Dacomitinib	VIZIMPRO	09/27/18	Second-generation pan EGFR inhibitor	NSCLC	NSCLC with EGFR exon 19 del or exon 21 L858R substitution mutations	ILD/pneumonitis Diarrhea, rash
Afatinib	GILOTRIF	06/12/13	Pan-HER and EGFR inhibitor	NSCLC	NSCLC with EGFR exon 19 del or exon 21 L858R substitution mutations	ILD/pneumonitis Cardiovascular toxicity Gastrointestinal and liver toxicity Severe cutaneous reaction
Vemurafenib	ZELBORAF	08/17/11	BRAF inhibitor	Melanoma	Melanoma with BRAF V600E mutation	Liver and renal toxicity Pancreatitis QT prolongation Severe cutaneous reactions Cutaneous malignancies Radiation sensitization Severe hypersensitivity Dupuytren contracture, plantar fascial fibromatosis
Dabrafenib	TAFINLAR	05/29/13	BRAF inhibitor	Melanoma	Melanoma with BRAF V600E mutation	Severe cutaneous reactions New cutaneous malignancy Hemorrhage, febrile reaction Cardiomyopathy, QT prolongation ILD/pneumonitis Ocular toxicity Venous thromboembolism

Encorafenib	BRAFTOVI	06/27/18	RAF kinase inhibitor	Melanoma	Melanoma with BRAF V600E or V600K mutation	New primary malignancies Hemorrhage QT prolongation Gastrointestinal toxicity Uveitis, rash
Trametinib	MEKINIST	05/29/13	MEK1/2 inhibitor	Melanoma	Melanoma with BRAF V600E or V600K mutation	Severe cutaneous reactions New cutaneous malignancy Hemorrhage, febrile reaction Cardiomyopathy, QT prolongation ILD/pneumonitis Ocular toxicity Venous thromboembolism
Cobimetinib	COTELLIC	11/10/15	MEK1 inhibitor	Melanoma	Melanoma with BRAF V600E or V600K mutation	New primary malignancies Hemorrhage Cardiomyopathy Photosensitivity, serous retinopathy, retinal vein occlusion Hepatotoxicity Severe dermatologic reaction Rhabdomyolysis
Binimetinib	MEKTOVI	06/27/18	MEK1/2 inhibitor	Melanoma	Melanoma with BRAF V600E or V600K mutation	Cardiomyopathy Venous thromboembolism Serous retinopathy, retinal vein occlusion, uveitis ILD/pneumonitis Hepatotoxicity Rhabdomyolysis Hemorrhage
Pexidartinib	TULARIO	08/02/19	KIT, CSF1R, FLT3 inhibitor	Tenosynovial giant cell tumor		Serious and potentially fatal hepatotoxicity
Larotrectinib sulfate	VITRAKVI	11/26/18	TRK inhibitor	Solid tumors with NTRK gene fusion		Neurotoxicity Hepatotoxicity
Palbociclib	IBRANCE	02/03/15	CDK inhibitor	Breast cancer	HR-positive, HER2-negative breast cancer	Neutropenia Gastrointestinal toxicity
Ribociclib	KISQALI	03/13/17	CDK inhibitor	Breast cancer	HR-positive, HER2-negative breast cancer	QT prolongation Hepatobiliary toxicity Neutropenia
Abemaciclib	VERZENIO	09/28/17	CDK inhibitor	Breast cancer	HR-positive, HER2-negative breast cancer	Diarrhea, Hepatotoxicity Neutropenia Venous thromboembolism
Olaparib	LYNPARZA	12/19/14	PARP inhibitor	Breast cancer Ovarian cancer	BRCA-mutated ovarian and breast cancer	Myelosuppression Secondary MDS/AML Pneumonitis
Rucaparib camsylate	RUBRACA	12/19/16	PARP inhibitor	Ovarian, fallopian tube, or primary peritoneal cancer		Secondary MDS/AML

(continued)

Table 53.2 (continued)

Generic name	Brand name	FDA approval date	Mechanism of action	Indication	Comments	Adverse events
Niraparib tosylate monohydrate	ZEJULA	03/27/17	PARP inhibitor	Ovarian, fallopian tube, or primary peritoneal cancer		Secondary MDS/AML Myelosuppression Hypertensive crisis
Talazoparib tosylate	TALZENNA	10/16/18	PARP inhibitor	Breast cancer	BRCA-mutated, HER2-negative breast cancer	Secondary MDS/AML Myelosuppression
Alpelisib	PIQRAY	05/24/19	Phosphoinositide 3-kinase (PI3K) inhibitor	Breast cancer	HR-positive, HER2-negative, PIK3CA-mutated breast cancer	Severe hypersensitivity Severe cutaneous reactions Hyperglycemia, DKA Pneumonitis Severe diarrhea
Trifluridine and tipiracil hydrochloride	LONSURF	09/22/15	TFT and TPI inhibitor	Esophageal cancer Gastric cancer Colorectal cancer		Severe myelosuppression Gastrointestinal toxicity
Enzalutamide	XTANDI	08/31/12	Androgen receptor antagonist	Prostate cancer	CRPC	Ischemic cardiovascular events, hypertension Fractures and falls Posterior reversible encephalopathy, seizure
Apalutamide	ERLEADA	02/14/18	Androgen receptor antagonist	Prostate cancer	mCSPC, nmCRPC	Ischemic cardiovascular events Fractures and falls Seizure
Darolutamide	NUBEQA	07/30/19	Androgen receptor antagonist	Prostate cancer	nmCRPC	Fatigue, pain in extremity, rash
Vismodegib	ERIVEDGE	01/30/12	SMO antagonist	Basal cell carcinoma		Embryo-fetal death, severe birth defects Muscles spasms Gastrointestinal toxicity
Sonidegib	ODOMZO	07/24/15	SMO antagonist	Basal cell carcinoma		Embryo-fetal death, severe birth defects CPK elevation
Cytotoxic agents						
Irinotecan hydrochloride liposome	ONIVYDE	10/22/15	Liposomal formulation of irinotecan	Pancreatic cancer		Fatal neutropenic sepsis Severe diarrhea ILD Severe hypersensitivity
Trabectedin	YONDELIS	10/23/15	DNA binding and cross-linking	Soft tissue sarcoma		Neutropenic sepsis Rhabdomyolysis Hepatotoxicity Cardiomyopathy Extravasation with tissue necrosis

Monoclonal antibodies against cell surface antigens						
Pertuzumab	PERJETA	06/08/12	HER2 recombinant humanized IgG1 mAb	Breast cancer	HER2-positive breast cancer	Cardiotoxicity Infusion reaction Hypersensitivity Gastrointestinal toxicity
Ado-trastuzumab emtansine	KADCYLA	02/22/13	HER2 recombinant humanized IgG1 mAb	Breast cancer	HER2-positive breast cancer	Cardiotoxicity Hepatotoxicity Gastrointestinal toxicity Infusion reaction Hypersensitivity
Ramucirumab	CYRAMZA	12/12/14	VEGFR2 recombinant IgG1 mAb	NSCLC Gastric cancer Colorectal cancer Liver cancer		Infusion-related reaction Hypertension Hemorrhage Arterial thrombotic events Reversible posterior leukoencephalopathy Wound healing complications
Dinutuximab	UNITUXIN	03/10/15	GD2 mouse/human IgG1 mAb	Neuroblastoma		Infusion reactions, capillary leak syndrome, hypotension Neuropathic pain Ocular neuropathy Myelosuppression Electrolyte abnormalities Hemolytic uremic syndrome

"Familiar Scenes with New Actors"

Differentiation Syndrome

Differentiation syndrome (DS), also called the retinoic acid syndrome, was first recognized as a complication of treatment with all-*trans* retinoic acid and/or arsenic trioxide for acute promyelocytic leukemia. This life-threatening emergency is characterized by fever, hemodynamic instability, pulmonary infiltrates or effusions, edema, and renal failure within the first month of induction therapy in 25% (range: 2–48%) of acute promyelocytic leukemia cases [1–3]. In addition, DS can occur in a different clinical context: patients with relapsed or refractory acute myeloid leukemia who are receiving isocitrate dehydrogenase inhibitors (IDH inhibitors) [1]. Ivosidenib (IDH1 inhibitor) causes DS in 10.6% of patients [1] and enasidenib (IDH2 inhibitor) in 11.7% [1, 4]. These are lower rates than in acute promyelocytic leukemia. Classic DS has a bimodal distribution with peak incidence in the first and third weeks after initiation of induction therapy for acute promyelocytic leukemia, but IDH inhibitor-induced DS has a median onset time of 48 days (range 10–340 days) for enasidenib and 29 days (range 5–59 days) for ivosidenib [1, 5]. Thus, IDH inhibitor-induced DS may occur 1 week to 5 months after treatment initiation. Furthermore, IDH inhibitor-induced DS can recur after therapy interruption or dose escalation [4].

DS involves migration and infiltration of differentiated white blood cells into various organs, leading to endothelial activation and release of cytokines and vascular factors [1]. DS is a challenging clinical diagnosis because there are no specific laboratory tests or imaging modalities. Classic signs are dyspnea, unexplained fever, >5-kg weight gain (from fluid retention), unexplained hypotension, acute renal failure, pulmonary infiltrates, and pleural and/or pericardial effusion on imaging [2, 3]. DS grading is based on the number of classic signs and symptoms (Table 53.3). Because DS can mimic decompensated heart failure, pneumonia, and sepsis, emergency physicians should be aware of the clinical settings that raise suspicion of DS in order to promptly diagnose and manage DS. Early intervention and treatment with corticosteroids can reduce mortality from 30% to <1% [2, 3].

Table 53.3 Differentiation syndrome signs, symptoms, and grading [2, 4]

Signs and symptoms	Grading	
Bone pain	≤2 signs or symptoms	Mild
Dyspnea		
Fever		
Headache		
Hepatotoxicity	3 signs or symptoms	Moderate
Hypotension		
Leukocytosis		
Peripheral edema		
Pleuropericardial effusion	≥4 signs or symptoms	Severe
Pulmonary infiltrates		
Renal failure		
Weight gain >5 kg		

Elevated white blood cell count >5 × 10^9/L and serum creatinine level are associated with an increased risk of severe DS and mortality [2]. In the right clinical settings, DS should be treated as soon as suspected because delayed workup and management increases morbidity [1, 6]. The role of the emergency physician is critical for early diagnosis and timely management (including a timely hematology/oncologic consultation). The mainstay treatment is high-dose glucocorticoids (dexamethasone 10 mg/day) until symptom resolution [1, 3, 4]. The addition of broad-spectrum antibiotics is appropriate when sepsis is suspected because of the overlap with the signs and symptoms of DS. Uric acid must be checked, and hyperuricemia management is important [1, 2, 4]. For patients with renal failure, hemodialysis may be required, and for those without renal failure, fluid overload can be treated with diuretics [4]. In severe cases, oxygen supplementation, ventilatory and hemodynamic support, and admission to the intensive care unit may be required.

Infusion-Related Reactions

An infusion-related reaction is an adverse reaction to the infusion of a pharmacologic or biologic substance as defined in the National Cancer Institute's Common Terminology Criteria for Adverse Events (CTCAE, version 5.0) [7], and it occurs upon infusion or within a few hours after infusion of a drug (commonly a monoclonal antibody (mAb) and a biological) [8]. CTCAE provides a severity grading scale [9]. Many chemotherapy agents administered intravenously are associated with infusion-related reactions. Infusion reactions can be allergic (IgE-mediated) or anaphylactoid in nature (i.e., not truly allergic and non-IgE-mediated). Both types of reactions involve the immune system and can have a similar clinical presentation: rash, urticaria, pruritus, bronchospasm, nausea, vomiting, abdominal pain, dizziness, headache, throat irritation, oropharyngeal pain, dyspnea, pharyngeal or laryngeal edema, flushing, fever, hypotension, and tachycardia [10]. This combination of signs and symptoms is related to cytokine release within the first few hours after administration. Infusion-related reactions can manifest hours after the patient has left the outpatient infusion facility, requiring presentation to an ED for acute management [11]. Severe reactions require prompt evaluation and management to avoid severe morbidity and mortality [10]. Unlike hypersensitivity reactions, symptoms of these reactions seem to become less intense with subsequent doses.

For the new biologic drugs (see Tables 53.1 and 53.2), infusion-related reactions are usually mild to moderate

(grade ≤2). The incidence rates of infusion-related reactions appear to vary among these agents. Blinatumomab is a bispecific T-cell engaging molecule that is administered as a continuous infusion for several weeks for patients with acute lymphoblastic leukemia. Infusion-related reactions occur in about half of these patients, but only 0.5% are serious reactions [11, 12]. Ofatumumab and obinutuzumab are associated with around 60% incidence [11, 13]; daratumumab and elotuzumab, 40–50% [11, 14]; mogamulizumab, 34% [15]; brentuximab, 11–15%; inotuzumab ozogamicin, 10% [16]; and pembrolizumab and nivolumab, 1–5% [11].

Management depends on the severity. In the emergency setting, infusion of the triggering agent should be stopped if not already completed. Treatment includes corticosteroids, antihistamines (both H1 and H2 receptor antagonists), and epinephrine (subcutaneous or intramuscular anaphylaxis doses). Stabilize the respiratory status and support hemodynamics according to resuscitation guidelines [11, 17].

QT Prolongation

Acquired QT prolongation on an electrocardiogram is a potentially serious adverse effect of medication. A long QT interval increases the risk for polymorphic ventricular tachycardia (*torsade de pointes*) and sudden death. The FDA recommends to correct the QT interval using the Fridericia formula (QTc), and cautions against a QTc >450 ms, and especially if >500 ms [18]. QT prolongation is most commonly associated with electrolyte derangements (especially hypomagnesemia and hypokalemia in cancer patients), heart disease, certain antiarrhythmic agents, antiemetic drugs (e.g., ondansetron), antibiotics (e.g., ciprofloxacin), antipsychotics, and antidepressants [19]. It is also associated with multiple drugs used for treatment of malignancies and cancer-associated symptoms and complications [20]. Several new drugs (ivosidenib, nilotinib, belinostat, carfilzomib, and inotuzumab ozogamicin) for hematologic malignancies have QT-prolonging side effects (see Table 53.1) and quite a number (vandetanib, lenvatinib, crizotinib, ceritinib, entrectinib, osimertinib, vemurafenib, dabrafenib, encorafenib, trametinib, and ribociclib) for solid tumors (see Table 53.2).

In general, a thorough medical history (including current use of QT-prolonging medications), physical examination, and electrocardiogram should be obtained for ED patients taking these novel agents who have significant electrolyte abnormalities or symptoms of palpitations, dizziness, or syncope. In many electronic medical record systems or medication prescribing systems, concurrent use of QT-prolonging drugs will trigger warning messages. Caution is advised when QT-prolonging drugs are used together. Vigilance should be maintained to avoid co-administration of QT-prolonging drugs in the ED. Management of significant QT prolongation starts with discontinuation of QT-prolonging agents, correction of electrolyte abnormalities, assessment of patient stability, and cardiologist consultation when deemed necessary. In the setting of cardiac arrest, resuscitation and treatment of arrhythmias are guided by the advanced cardiac life support (ACLS) protocols [9], keeping in mind that intravenous magnesium sulfate would be indicated for *torsade de pointes*.

Sinusoidal Occlusion Syndrome

Sinusoidal occlusion syndrome (SOS), also called hepatic veno-occlusive disease (HVOD), is caused by a prothrombotic hypofibrinolytic state causing obliterative terminal venulitis in the liver. SOS is a serious emergency that happens in 8–14% of patients during the first month after hematopoietic stem cell transplantation. Antibody-drug conjugates, gemtuzumab ozogamicin and inotuzumab ozogamicin (see Table 53.1) are humanized anti-CD33 and anti-CD22 mAb, respectively, conjugated to a potent DNA-binding cytotoxic antibiotic ozogamicin (a derivative of calicheamicin) [21]. With these new drugs, SOS occurs in about 9% of patients with acute myeloid leukemia who receive gemtuzumab ozogamicin [22–24], around 1% in patients with relapsed or refractory B-cell non-Hodgkin lymphoma who receive inotuzumab ozogamicin, and as high as 13% in patients with relapsed or refractory acute lymphoblastic leukemia who receive inotuzumab ozogamicin [25, 26]. The triad of jaundice, hepatomegaly, and ascites should raise suspicion of SOS in these clinical settings.

The clinical presentation typically includes hyperbilirubinemia, elevated liver enzyme level, weight gain, ascites, and tender hepatomegaly. The differential diagnosis includes graft-versus-host disease, Budd-Chiari syndrome, congestive heart failure, medication toxicity, viral hepatitis, and sepsis. Grading is based on clinical findings, such as bilirubin level, liver enzyme levels, weight gain due to fluid retention, increased serum creatinine, and rate of progression (Table 53.4) [27]. With multi-organ failure, 80% of patients may die.

Table 53.4 Clinical grading of sinusoidal obstruction syndrome [27]

Grading criteria	Mild	Moderate	Severe
Total bilirubin, mg/dL	<5	5–8	>8
Liver enzymes (AST, ALT)	<3× ULN	3–8× ULN	>8× ULN
Serum creatinine	Normal	<2× ULN	>2× ULN
Weight above baseline	<2%	2–5%	>5%
Rate of clinical progression	Slow (6–7 days)	Moderate (4–5 days)	Fast (2–3 days)

AST aspartate transferase, *ALT* alanine transferase, *ULN* upper limit of normal

Treatment of SOS is mainly supportive. The main challenge for emergency physicians is fluid management, because intravascular volume needs to be optimized with crystalloids or colloid (e.g., albumin) solutions without overload to avoid hepatorenal syndrome. Colloid solutions may be indicated in the presence of hypoalbuminemia. Adequate oxygenation and maintenance of oxygen-carrying capacity by transfusion would help to minimize hepatic ischemic injury. Nephrotoxic and hepatotoxic drugs should be avoided. In moderate to severe cases, high-dose glucocorticoids (methylprednisolone 1 mg/kg/day intravenously) are indicated [28].

Emergency physicians must be aware of the potential for SOS after treatment with these antibody-drug conjugates or in patients who have recently undergone hematopoietic stem cell transplantation. Early suspicion of SOS is vital given the triad of jaundice, hepatomegaly, and ascites in the above clinical settings. The primary role of the emergency physician is to recognize and diagnose this syndrome and initiate glucocorticoid therapy along with a hematologist/oncologist consultation.

Tumor Lysis Syndrome from Venetoclax-Based Therapy

Tumor lysis syndrome is a well-known oncologic emergency, especially when the tumor/malignancy burden is high. Venetoclax, a BCL2 inhibitor used as a single agent or in combination with other targeted therapies (see Table 53.1), has shown an increase risk of tumor lysis syndrome [29].

Novel Adverse Effects of New Immunotherapy for Cancer

Immune-Related Adverse Events (irAEs)

Immunotherapy has emerged as an effective cancer treatment by enhancing the ability of immune cells to kill cancer cells [30]. Malignant cells can evade host immune surveillance by usurping immune checkpoint pathways. Immune checkpoints regulate the immune response to prevent hyperinflammation or autoimmunity [31–35]. mAbs that bind and block cytotoxic T lymphocyte-associated protein 4 (CTLA4), programmed cell death protein-1 (PD-1), and programmed cell death ligand 1 (PD-L1) are approved to treat many different cancers by "releasing the brakes" on T-cell activation. Immune checkpoint inhibitors are now used for many solid tumors and hematologic malignancies (see Tables 53.1 and 53.2).

Stimulating the immune system to fight cancer is a double-edged sword; it can cause autoimmunity, leading to many irAEs. The estimated incidence of irAEs of any severity/grade was about 30% for anti-PD-L1 and anti-PD-1 therapies, and 75% for anti-CTLA4 therapy [36]. Most irAEs affect the integumental, gastrointestinal, endocrine, pulmonary, and musculoskeletal systems. Serious renal, neurologic, and cardiac irAEs may also occur. Prompt investigation of symptoms is vital for timely diagnosis and management.

Emergency physicians are at the front line to deal with acute presentation of irAEs. Existing guidelines from various professional organizations (National Comprehensive Cancer Network [NCCN] [37], American Society of Clinical Oncologic [ASCO] [38], Society for Immunotherapy of Cancer [SITC] [39], and European Society for Medical Oncologic [ESMO] [40]) can provide a framework for management of irAEs.

In the ED setting, the medical history about ICI therapy and onset of symptoms may cue the investigation of potential irAEs, since the incidence of irAEs usually peaks around the fourth dose (12–16 weeks after initiation) [41]. However, irAEs can occur any time during treatment (from after a single dose [42] to a prolonged period [40] and even after treatment discontinuation [43–46]). Grading of the severity of irAEs is based on CTCAE, version 5.0 [7]. Table 53.5 compiles grading and grade-based treatment considerations in the ED for common irAEs.

Immunosuppression with a glucocorticoid is the primary treatment for clinically significant irAEs. Escalation to other immunosuppressants (e.g., infliximab for colitis [47] or mycophenolate mofetil for hepatitis [48]) may be required in steroid-refractory cases or when significant steroid-induced side effects occur. Emergency physicians will primarily be dealing with the decision to initiate first-line therapy with glucocorticoids, in collaboration with the primary oncologists [37–39]. The occurrence of irAEs and subsequent use of immunosuppressive therapy do not seem to affect cancer response rates or antitumor therapeutic activity [49, 50].

Cardiac irAEs Cardiac dysfunction induced by ICI results from damage by lymphocytic infiltration [51–55]; immune-mediated myocarditis may present in EDs as acute life-threatening events. The onset may be rapid and can lead to cardiac failure or dysrhythmias (including ventricular tachycardia or complete atrioventricular heart blocks) that are potentially fatal [51, 56, 57] (see Fig. 53.1). The incidence of cardiac dysfunction is not clear but is perhaps ≤1% [51, 52]. The acute management of cardiac irAEs basically follows the ACLS algorithms along with consideration for initiation of glucocorticoid therapy emergently and other considerations mentioned in Fig. 53.1. These patients will often need to be admitted for cardiac monitoring, and intensive care needs to be considered.

Endocrine irAEs Endocrine toxicities of ICIs manifest hormone deficiency or excess. The spectrum of clinical ill-

Table 53.5 Management of common irAEs based on grades in the emergency department* [37]

	Grade	1 (mild)	2 (moderate)	3 (severe)	4 (life-threatening)
	General guidance for grading	Mild or no symptoms	Limiting age-appropriate ADL	Medically significant; limiting self-care; need hospitalization	Urgent intervention needed to prevent death
General management[a]					
	Systemic corticosteroid		Prednisone equivalent (0.5–1 mg/kg/day)	Prednisone equivalent (1–2 mg/kg/day)	Prednisone equivalent (1–2 mg/kg/day)
	ED disposition	Discharge	Consider hospitalization	Hospitalize	Hospitalize; ICU if indicated
Specific considerations					
Maculopapular rash	Grading	<10% BSA	10–30% BSA	>30%BSA	
	Management	Antihistamine Emollient Topical corticosteroid (moderate potency)	Antihistamine; emollient; topical corticosteroid (high potency)	Urgent dermatology consult; topical corticosteroid (high potency)	
Pruritus	Grading	Mild and/or localized	Widespread and intermittent; skin changes from scratching	Widespread and constant; limiting self-care or sleep	
	Management	Topical corticosteroid (high potency)	Dermatology consult; antihistamine; topical corticosteroid (high potency); systemic corticosteroid not needed	Urgent dermatology consult; prednisone (0.5−1 mg/kg/day); GABA agonist (gabapentin/ pregabalin); measure serum IgE and histamine; if high, treat with omalizumab and antihistamine, respectively	
Blistering dermatological disorders (bullae)[b]	Grading			Skin sloughing <10% BSA in SJS	Skin sloughing 10–30% BSA in SJS or ≥30% BSA in TEN
	Management	Urgent dermatology consult; skin biopsy; topical corticosteroid (high potency)	Urgent dermatology consult; skin biopsy	Urgent dermatology & ophthalmology consults; skin biopsy	Urgent dermatology & ophthalmology consults; skin biopsy
Diarrhea/colitis	Grading	<4 BM/day above baseline & no symptoms of colitis	4–6 BM/day above baseline & colitis symptoms; no interference of ADL	>6 BM/day above baseline & colitis symptoms interference of ADL	>6 BM/day above baseline & colitis symptoms; interference of ADL
	Management	Hydration Antidiarrheals	Gastroenterology consult; CT scan of the abdomen/pelvis; r/o infection; inpatient supportive care; methylprednisolone (1 mg/kg/day IV)	Gastroenterology consult; CT scan of the abdomen/ pelvis; r/o infection; inpatient supportive care; methylprednisolone (2 mg/ kg/day IV)	Gastroenterology consult; CT scan of the abdomen/ pelvis; r/o infection; inpatient supportive care; methylprednisolone (2 mg/ kg/day IV)
Transaminitis (hepatic)	Grading	<3× ULN	35× ULN	>5−20× ULN	>20× ULN
	Management	Consider gastroenterology consult; r/o other causes (e.g., viral infection); discontinue hepatotoxic drugs	Consider gastroenterology consult; r/o other causes; discontinue hepatotoxic drugs; if bilirubin >1.5× ULN, hepatology consult, inpatient care, and prednisone equivalent (2 mg/kg/day)	Hepatology consult; r/o other causes; discontinue hepatotoxic drugs; prednisone equivalent (1−2 mg/kg/day); if bilirubin >1.5× ULN, prednisone equivalent (2 mg/kg/day)	Hepatology consult; r/o other causes; discontinue hepatotoxic drugs; methylprednisolone (2 mg/ kg/day IV)

(continued)

Table 53.5 (continued)

	Grade	1 (mild)	2 (moderate)	3 (severe)	4 (life-threatening)
Pneumonitis	Grading	No symptoms; confined to one lobe or <25% lung tissue	New and worsening symptoms	Involving all lobes or >50% lung tissue; limited self-care ADL	Life-threatening respiratory compromise
	Management	Pulse oximetry; chest imaging	Chest imaging; infection workup; consider bronchoscopy; supplemental oxygen; prednisone equivalent 1–2 mg/kg/day; empiric antibiotics	Chest imaging; infection workup; consider bronchoscopy; supplemental oxygen; prednisone equivalent 1–2 mg/kg/day; empiric antibiotics; pulmonary and infectious disease consults	Chest imaging; infection workup; consider bronchoscopy; supplemental oxygen/mechanical ventilation; fluid management; prednisone equivalent 1–2 mg/kg/day; empiric antibiotics; pulmonary and infectious disease consults

ADL activity of daily living, *BSA* body surface area, *ICU* intensive care unit, *SJS* Steven-Johnson syndrome, *TEN* toxic epidermal necrolysis, *ULN* upper limit of normal

[a]Generally applicable unless otherwise stated in special considerations below

[b]Steven-Johnson syndrome and toxic epidermal necrolysis are considered grade 3–4 bullous dermatitis

[*]The specific considerations shown in this table only cover some common irAEs. Please see the NCCN guidelines for more details

ness ranges from no symptoms to life-threatening endocrine emergencies [58–63] (e.g., thyroid storm [64], myxedema coma [65], diabetes ketoacidosis [66]) (see Fig. 53.1). ED visits for endocrine irAEs are often related to the thyroid, adrenal, and pituitary glands [67].

Hypophysitis often presents with nonspecific symptoms (headache, fatigue, and general weakness) that are often misattributed to malignancy, but failure to recognize and diagnose hypophysitis can lead to adrenal crisis [68–70]. Anorexia, nausea, weight loss, altered mental status, heat intolerance, and arthralgia are less common symptoms (10.5–21.1%) [68, 70, 71]. Visual defects, typically bitemporal hemianopsia, are rare because pituitary enlargement is mild [72]. Hyponatremia is a major electrolyte disorder associated with hypophysitis (47–56% of patients) [70, 71, 73]. Morbidity is predominantly related to central adrenal insufficiency [74], and can be fatal if undiagnosed and untreated. Initial treatment includes high-dose glucocorticoids (1 mg/kg methylprednisolone or equivalent) along with management of hyponatremia and hypotension. Without significant hyponatremia, intense headaches, or optic chiasm compression, physiologic replacement of glucocorticoids may be considered [75].

Primary adrenal insufficiency associated with ICIs is uncommon but may be underreported due to concurrent treatment with glucocorticoids for various reasons (including oncologic indications) or coexistence of central adrenal insufficiency [76]. Symptoms of adrenal crisis include hypotension, dehydration, and electrolyte abnormalities (especially hyponatremia), which require immediate intervention [74]. These symptoms can improve rapidly after starting corticosteroids [70]. Hydrocortisone and fludrocortisone are the mainstay treatments [77].

Most cases of primary thyroid irAE are related to thyroiditis [78]. Thyroiditis can manifest as subclinical or overt hyper- or hypothyroidism with a typical clinical course of transient hyperthyroidism (due to thyroid hormones released by gland destruction) followed by prolonged or permanent hypothyroidism [78, 79]. Graves' disease is an autoimmune hyperthyroidism in which autoantibodies stimulate the thyroid-stimulating hormone receptor. Thyrotoxic cancer patient may present to the ED for arrhythmia (e.g., atrial fibrillation, atrial flutter, and supraventricular tachycardia), but these patients with arrhythmia will also need to be evaluated to rule out myocarditis and pericarditis as concurrent irAEs contributing to arrhythmia. Thyrotoxicosis in thyroiditis is usually mild and manageable with β-blockers. However, in patients with Graves' disease, life-threatening thyroid storms can occur. Serum thyroid-stimulating antibodies and radionuclide thyroid scans can distinguish Graves' disease from thyroiditis. Graves' disease can be managed with β-blockers, antithyroid agents, and glucocorticoids [80] and, if needed, additional agents that block thyroid hormone release (e.g., potassium iodide, iopanoic acid, etc.) [81].

Immune thyroiditis may destroy enough thyroid tissue to cause primary hypothyroidism. Hypothyroid symptoms are often nonspecific [82]. Typical complaints include fatigue, lethargy, constipation, and cold intolerance. Unrecognized severe hypothyroidism may progress to myxedema coma. If a cancer patient with a history of immune checkpoint inhibitor therapy is in the ED with confusion, lethargy, bradycardia, hyponatremia, hypothermia, or constipation, severe hypothyroidism should be included in the differential diagnosis. Primary hypothyroidism is primarily managed with thyroid hormone replacement (e.g., levothyroxine) and supportive care [83].

New-onset type 1 diabetes mellitus may present with diabetic ketoacidosis in patients receiving ICI therapy [84–86],

and can occur even after one dose [42]. Although rare, diabetic ketoacidosis is potentially life-threatening and requires early recognition to initiate timely management including intravenous insulin infusion. Once stabilized, the patient requires long-term, if not lifelong, insulin therapy [87].

Gastrointestinal irAEs Patients treated with combination ICI therapy had incidence rates of 13.6%, 9.4%, and 9.2% for all-grade colitis, severe colitis, and severe diarrhea, respectively [88], which are higher rates than in monotherapy. Symptoms typically start 6–8 weeks after beginning ICI therapy [89, 90]. Corticosteroids are the primary treatment for gastrointestinal toxicities, with escalation to infliximab (mAb against tumor necrosis factor-alpha) for severe steroid-refractory colitis [37, 91–93]. Vedolizumab (mAb against α4β7 integrin) can be effective in steroid-refractory and infliximab-resistant enterocolitis [94, 95]. Immune-related hepatotoxicity is usually mild, presenting with no or a few nonspecific symptoms, but can be severe or even fatal in some cases [96]. Median time to hepatitis is typically 5–6 weeks after starting therapy but can occur months later. The differential diagnosis should be broad, and infectious hepatitis must be ruled out, especially when the patient also has fever. Autoimmune and drug-induced hepatitis can have similar presentations and may require further imaging studies and/or biopsy.

Hemophagocytic lymphohistiocytosis (HLH) HLH is also called macrophage activation syndrome (MAS) and is a life-threatening syndrome of hyperinflammation and progressive immune-mediated organ damage. ICI-induced HLH is rare. HLH is diagnosed by having ≥5 of the following criteria: (1) fever; (2) splenomegaly; (3) cytopenias (at least two lineages in complete blood counts); (4) hypertriglyceridemia or hypofibrinogenemia; (5) hemophagocytosis; (6) low natural killer cell function; (7) high serum ferritin; and (8) high-soluble IL-2 [97, 98]. Some of the diagnostic criteria will not be able to be assessed in the emergency center, but HLH should be considered in the differential diagnosis for cancer patients treated with ICIs presenting with fever, cytopenias, and signs of hyperinflammation [99] (see Fig. 53.1). Optimal treatment for HLH caused by immunotherapy is not known. In two case reports of HLH, one patient was treated with etoposide and dexamethasone [100], and the other was treated with prednisone and mycophenolate mofetil [101]. Morbidity and mortality due to HLH are partially attributed to delayed diagnosis, hence the vitally important role of the emergency physician in achieving early diagnosis and intervention with high-dose glucocorticoids.

Integumental irAEs IrAE involving the subcutaneous tissue is relatively rare, manifesting as varying forms of panniculitis [102–104]. In contrast, cutaneous irAEs are the most common irAEs, occurring in almost half of the patients receiving ICI therapy (Table 53.2). The majority are low grade, presenting within the first two cycles of therapy [105–109] with itching, erythema, rash, vesicles, or blisters [105, 108, 110, 111]. High-grade cutaneous irAEs occur in about 1–3% of patients, and require ICI therapy discontinuation and treatment with high-dose corticosteroids; GABA agonists (e.g., pregabalin or gabapentin) can be used for severe pruritus [38, 106, 110, 112]. Serious irAEs such as toxic epidermal necrolysis (TEN), drug rash with eosinophilia and systemic symptoms (DRESS), and Steven-Johnson syndrome (SJS) can be fatal if not recognized and treated with high-dose corticosteroids as inpatient [37, 113–115].

Neurologic irAEs Low-grade and nonspecific neurologic symptoms, such as headache, dizziness, and sensory impairment, occur in 6–12% of patients receiving ICI combination or monotherapy [45, 116]. About 0.4–0.2% of patients treated with nivolumab and pembrolizumab have grade ≥3 irAEs [116, 117]; 0.3–0.8%, with ipilimumab [118, 119]; and up to 0.7%, with combination nivolumab and ipilimumab [120]. Overall, severe neurologic irAEs is rare (<1% of patients) [45], and usually happens within 1–7 weeks of therapy [121–123]. Seizures, confusion, ataxia, abnormal behavior, and altered consciousness warrant evaluation for encephalitis which occurs in 0.1–0.2% of patients [116, 124–127] (see Fig. 53.1). Emergent brain imaging with CT or MRI with and without contrast if available in the ED is indicated. Brain MRI is the imaging modality of choice for evaluation of neurologic irAEs. Non-enhanced MRI shows T2 hyperintensity in a quarter of cases [124, 125]. Dural thickening and meningeal enhancement may also be present [127]. If fever is present together with headache and/or meningeal signs, lumbar puncture with analysis of cerebrospinal fluid (CSF) in the ED is indicated to rule out meningitis. In neurologic irAEs, CSF analyses are consistent with lymphocytic meningitis (with mild to high pleocytosis, negative cultures, elevated protein, and cytopathology negative for malignancy).

Pulmonary irAEs The most frequently reported pulmonary symptoms are dyspnea (see Fig. 53.1) and nonproductive cough, with fever and chest pain reported less commonly [113, 128]. The presence of extrapulmonary irAEs is relatively common and should raise suspicion for coexisting pneumonitis [129] (see Table 53.2). Generally, new persistent cough or shortness of breath in patients receiving immune checkpoint inhibitors should prompt evaluation for pneumonitis. The incidence of pneumonitis is <1% but varied across trials of immune checkpoint inhibitors, perhaps because of underreporting of low-grade irAEs [130]. Nevertheless, pneumonitis is one of the most serious irAEs and can be fatal [74, 128, 131–133]. In patients with acute

pulmonary symptoms, infectious pneumonia is in the differential diagnosis, and empiric antibiotics coverage is indicated. Evaluation of suspected pneumonitis should include a CT scan of the chest and possibly, after admission from the ED, a bronchoalveolar lavage and lung biopsy [134]. Patients with grade ≥2 pneumonitis should start glucocorticoids, and be closely monitored [38]. Grade ≥3 pneumonitis requires inpatient care, evaluation to exclude infections, and probably consultation with pulmonary and infectious disease experts. Treatment with high-dose glucocorticoids (methylprednisolone, 1–2 mg/kg per day) should be initiated after discussion between the emergency physician and the oncologist, aiming to improve symptoms down to grade ≤1. Other immunosuppressant agents (e.g., infliximab, mycophenolate mofetil) or intravenous immunoglobulins are generally not used in the ED but may be used after admission if not improved after 48 hours.

Rheumatologic irAEs Rheumatic manifestations in cancer patients receiving immune checkpoint inhibitors are primarily arthritis, sicca symptoms (dry eyes, dry mouth, and parotid gland enlargement), and a polymyalgia-like syndrome [44, 135]. Among irAEs involving the musculoskeletal system, myositis can be serious. Myositis presents as proximal muscle weakness with an increase in serum muscle enzymes, with or without respiratory complaints [56, 136–148]. De novo cases have been reported [136, 149]. Necrotizing myositis is an emerging irAE [136, 146, 147, 150–152]. Several cases of concomitant myositis and myasthenia-like manifestations have been documented [136, 145]. Patients often present with "dropped heads," bilateral proximal limb muscle weakness, muscle pain, dyspnea, and, occasionally, fever. Of note, myositis can also be associated with unilateral or bilateral ptosis, ophthalmoparesis, and bulbar weakness. Creatine phosphokinase and aldolase levels—and sometimes cardiac troponins—are elevated. Further diagnostic evaluation may involve acetylcholine receptor antibody and myositis serum antibodies and electromyography, which usually occur after admission from the ED. The time from initiation of immunotherapy to development of myositis is variable, but in most cases, myositis occurs after a few infusions. Myositis can be life-threatening because of CO_2 retention and respiratory failure, and severe rhabdomyolysis may cause renal failure, electrolyte imbalance, and fatal arrhythmia; both requiring prompt diagnosis and management. When respiratory compromise is suspected (as prompted by shallow rapid breathing, dyspnea, low oxygen saturation, etc.), ventilatory status should be evaluated with arterial blood gas measurement, peak flows, and/or bedside pulmonary function tests (negative inspiratory force and vital capacity). If patient has respiratory failure, support with positive pressure ventilation or intubate for mechanical ventilation.

Chimeric Antigen Receptor (CAR)-T-Cell Therapy

Genetically engineered T-cells constitute a new class of therapeutic agents that offer hope for cure of malignancies. CD19-CAR-T-cell therapy was recently approved for the treatment of hematologic malignancies (see Table 53.1). CAR-T-cell therapy causes a new spectrum of acute toxic effects, which differ from those typically organ-specific irAEs associated with ICIs [30, 41, 153]. CAR-T-cell therapy-related toxicities are related to markedly increased circulating cytokines and manifest as two syndromes: cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS) [12, 154, 155]. Occasionally, CRS can progress into HLH [12, 156, 157]. Glucocorticoids are immunosuppressive and effective in cellular therapy-induced CRS, ICANS, and HLH. Even though ED visits for these adverse events are rare as these patients are typically hospitalized during treatment, this landscape is likely to change as clinical experience with CAR-T-cell therapies increases and the duration of hospitalization will shorten.

Cytokine release syndrome Symptoms of CRS range from mild "flu-like" to life-threatening inflammatory responses (Table 53.6) [158]. Symptoms include high-grade fever, hypotension, hypoxia, fatigue, arthralgia, myalgia, rash, and/or multi-organ toxicity, which can also be symptoms of infection or sepsis (see Fig. 53.1). Serious CRS is characterized by hypotension and hyperpyrexia that can progress to an uninhibited systemic inflammatory response syndrome with circulatory shock requiring vasopressors, vascular leak, disseminated intravascular coagulation, and multi-organ system failure. Laboratory abnormalities include cytopenias, elevated creatinine, elevated liver enzymes, impaired coagulation, and elevated C-reactive protein level. The primary differential diagnosis is sepsis and septic shock, and empiric antibiotic coverage is recommended.

Respiratory involvement is common with CRS. Mild cases may involve tachypnea and cough but may progress to hypoxemia with bilateral pulmonary infiltrates on chest radiography. Some cases can progress to acute respiratory distress syndrome requiring mechanical ventilation. Moreover, patients with serious CRS often display vascular leak with peripheral and pulmonary edema and may have signs of cardiac dysfunction with reduced left ventricular contractility.

Management of CRS varies by grade [155, 159] (Fig. 53.2). For grade 1, supportive care should keep the patient well-hydrated using intravenous fluids with special attention to fluid balance to avoid pulmonary vascular congestion. For grade 2, hypotension should be treated promptly with intravenous crystalloid fluid. In patients who

Table 53.6 American Society for Blood and Marrow Transplantation cytokine release syndrome consensus grading[a]

Parameter	Grade 1	Grade 2	Grade 3	Grade 4
Fever[b]	Present	Present	Present	Present
		Accompanied by		
Hypotension	None	Vasopressors not required *And/or*[c]	Vasopressor with/without vasopressin	Hypotension requiring multiple vasopressors any except vasopressin
Hypoxia	None	Hypoxia requiring low-flow nasal cannula[d] or blowby	Hypoxia requiring high-flow nasal cannula, face mask, non-rebreather mask, or Venturi mask	Hypoxia requiring positive pressure[e]

Adapted from Lee et al. [158], with permission from Elsevier
[a]Organ toxicities associated with CRS may be graded according to CTCAE v5.0, but they do not influence this CRS grading
[b]Fever as temperature ≥38 °C not attributable to other case
[c]CRS grade determined by the more severe event
[d]Low-flow nasal cannula as oxygen ≤6 L/min. High-flow nasal cannula is defined as oxygen >6 L/min
[e]CPAP, BiPAP, intubation, and mechanical ventilation

are refractory to fluid boluses, management should include therapies that block IL-6 signaling (i.e., anti-IL-6 receptor antibody tocilizumab or anti-IL-6 antibody siltuximab) and glucocorticoids. For grade 3 or 4, emergently manage arrhythmias, hemodynamic shock, and respiratory compromise with antiarrhythmics, vasopressors, oxygen, and ventilation support, therapies that block IL-6 signaling and high-dose glucocorticoids. If possible, the emergency

team should be aware of all patients treated with CAR-T-cell therapy in the affiliated hospitals to facilitate prompt awareness of their CAR-T-cell therapy status when these patients present to the ED.

Immune effector cell-associated neurotoxicity syndrome Neurotoxicity is the second most serious adverse event following CAR-T-cell therapy [160]. Patients may develop a toxic encephalopathy (immune effector cell-associated encephalopathy [ICE]) with symptoms of confusion/delirium, problems with word retrieval, headache, somnolence, hallucinations, aphasia, hemiparesis, cranial nerve palsies, tremors, and, occasionally, seizures [77, 155–157, 161–166]. The pathophysiology of neurotoxicity is poorly understood, and is not strictly associated with the timing of CRS [155]. ICANS often starts shortly after CAR-T-cell infusion while the patients are still hospitalized, but some are delayed, and these patients may present to EDs with only neurologic symptoms.

The earliest signs of ICANS are decreased attention span, loss of language coherence, and impaired handwriting (Table 53.7). In severe cases (grade ≥3), seizures, motor weakness, incontinence, increased intracranial pressure, obtundation, papilledema, and cerebral edema may occur (see Fig. 53.1). The diagnosis of ICANS and evaluation may be guided by the need to obtain the information to use Table 53.7 to obtain the Immune Effector Cell-Associated Encephalopathy (ICE) score for the American Society for Blood and Marrow Transplantation Consensus Grading Scale. Emergent imaging study of the brain using CT or MRI is necessary. Emergent lumbar puncture for cerebrospinal fluid analysis would be indicated in the presence of mental status change and fever (e.g., concurrent CRS) to examine the differential diagnoses of meningitis and encephalitis.

Similar to CRS, the management of ICANS is also based on the toxicity grade (Table 53.8). For grade 1, supportive care is provided. Increasing the angle of the head of the bed to >30° may minimize the risk of aspiration and improve cerebral venous blood flow. Neurology consultation should be expeditiously requested to facilitate evaluation, including electroencephalogram, evaluation of intracranial pressure, and brain imaging studies. For grade 2, give high doses of glucocorticoids (dexamethasone 40 mg/day or methylprednisolone 1 g/day) until neurologic recovery [167]. For grades 3 and 4, in addition to high-dose glucocorticoids, control seizures and treat status epilepticus. Cerebral edema and increased intracranial pressure may require intensive care [168], and management with mechanical hyperventilation, acetazolamide, and/or mannitol [167]. In patients with concurrent neurotoxicity and CRS, treatment should include tocilizumab (8 mg/kg) and glucocorticoids until resolution of symptoms [167].

Table 53.7 Assessment of immune effector cell-associated neurotoxicity syndrome (ICANS)

Signs and symptoms	Grade 1 (mild)	Grade 2 (moderate)	Grade 3 (severe)	Grade 4 (critical)
ICE[a]: orientation to year, month, city, hospital, 4 points; able to name three objects, 3 points; following simple commands, 1 point; able to write a sentence,1 point; or able to count backwards from 100 in 10s, 1 point	Able to perform 7–9 tasks	Able to perform 3–6 tasks	Able to perform 0–2 tasks	Obtunded and cannot perform tasks
Depressed level of consciousness	Spontaneous awakening	Awakening to voice	Awakening limited to tactile stimulus	Unarousable/requiring repeated or vigorous tactile stimuli for arousal Stupor/coma
Seizures	NA	NA	Clinical seizure focal or generalized resolving rapidly or nonconvulsive seizures on EEG responding to intervention	Life-threatening extended seizure (greater than 5 mins); or repeated clinical or electrical seizures with no return to baseline
Motor findings	NA	NA	NA	Deep focal weakness, e.g., hemiparesis/paraparesis
Increased intracranial pressure/cerebral edema	NA	NA	Focal/local edema on brain imaging	Diffuse cerebral edema on brain imaging; decerebrate or decorticate posturing; or abducens nerve palsy; papilledema; or Cushing triad

Adapted from Lee et al. [158], with permission from Elsevier
NA not applicable, *CRS* cytokine release syndrome, *EEG* electroencephalogram
[a]For Immune Effector Cell-Associated Encephalopathy (ICE) score, naming one object counts as one task, so the patient has the opportunity to perform three tasks

Table 53.8 Management of immune effector cell-associated neurotoxicity syndrome [167, 168]

Grade	Grade 1 (mild)	Grade 2 (moderate)	Grade 3 (severe)	Grade 4 (critical)
Supportive care[a]	+	+	+	+
Neurology consult	+	+	+	+
Glucocorticoids	NA	Dexamethasone (40 mg/day) or methylprednisolone (1 g/day)	Dexamethasone (40 mg/day) or methylprednisolone (1 g/day)	Dexamethasone (40 mg/day) or methylprednisolone (1 g/day)
Tocilizumab	NA	NA	If concurrent with CRS, tocilizumab (8 mg/kg)	If concurrent with CRS, tocilizumab (8 mg/kg)
Seizure management	NA	NA	+	+
Cerebral edema and ICP management	NA	NA	Acetazolamide and/or mannitol	Mechanical hyperventilation, acetazolamide and/or mannitol
Critical care	NA	NA	+	+

CRS cytokine release syndrome, *ICP* increased intracranial pressure, *NA* not applicable
[a]Supportive care may include elevating the head of the bed to >30° to minimize the risk of aspiration and improve cerebral venous blood flow

Conclusion

Maintaining a fund of knowledge with updated information about the adverse effects of new cancer therapeutics is important. Knowing the timing, risk, and type of cancer treatment-induced toxicity will arm emergency physicians with the appropriate level of suspicion not to miss the correct diagnosis such that prompt management can improve patient outcomes. Rapid recognition and prompt initiation of appropriate evaluations and treatments are critical actions in the care of these oncologic emergencies.

Fluorouracil or Capecitabine Overdose

54

Natalie R. Neumann and Christopher O. Hoyte

Case Study

A 62-year-old female recently diagnosed with metastatic colon cancer is brought to the emergency department (ED) by family members after revealing to them that she ingested her chemotherapeutic medication in a self-harm attempt. She reports to ED staff that she took several weeks' worth of her prescribed capecitabine. The ingestion was 8 hours ago, and the patient is currently asymptomatic. Her physical exam, EKG, and laboratory tests including a complete metabolic panel, complete blood count, and troponin are all reassuring. After discussing the case with the patient's oncologist and a toxicologist through the local poison center, the patient is administered uridine triacetate and admitted to the hospital for further observation and serial laboratory assessment.

History and Epidemiology

5-Fluorouracil (5-FU) is a mainstay of oncologic therapy. Its development is a classic example of rational drug design; it was created in the 1950s when researchers discovered that malignant cells utilized exogenous uracil, a pyrimidine base, more rapidly than nonmalignant cells to sustain ribonucleic acid (RNA) synthesis and thus tumor growth [1–4]. It is classified as a fluoropyrimidine derivative, its structure consisting of a pyrimidine bonded to a fluorine atom. 5-FU is, as the name suggests, a uracil analogue bonded to a fluorine atom in place of a hydrogen atom [3]. Other subsequently developed fluoropyrimidine derivatives that are used in oncologic therapy include capecitabine, doxifluridine, floxuridine, carmofur, and tegafur [5–9]. Fluoropyrimidines are themselves classified as antimetabolic agents. Antimetabolites are compounds that are similar enough to natural chemicals that they participate in physiologic biosynthetic pathways, but different enough that they also disrupt normal cell functions [5]. For the sake of simplicity, this chapter will focus largely on 5-FU and its prodrug, capecitabine. Cytotoxicity from these two fluoropyrimidines is attributed to their deleterious incorporation into RNA and deoxyribonucleic acid (DNA), and to their inhibition of thymidylate synthetase [1, 3, 4, 10] (Fig. 54.1).

Fluoropyrimidines may be administered as monotherapy or in combination with other chemotherapeutic agents. They are predominantly used for the treatment of gastrointestinal, breast, and head and neck cancers [1, 11, 12]. As of 2008, several hundred thousand patients in the United States received either 5-FU or capecitabine annually [13]. 5-FU is an intra-

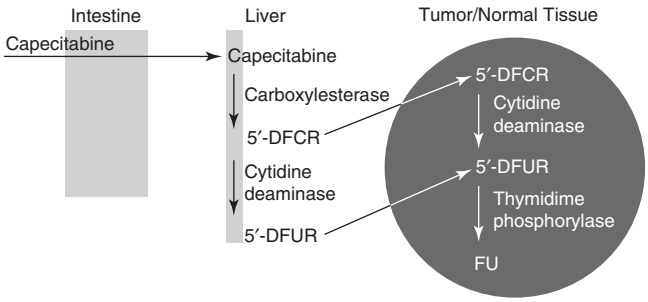

Fig. 54.2 Diagram of the conversion of the prodrug, capecitabine, to the active drug, 5-fluorouracil (5-FU). Capecitabine is first absorbed through the gastrointestinal tract and then converted by carboxylesterase in the liver to 5′-deoxy-5-fluorocytidine (5′-DFCR). Cytidine deaminase, present in both normal (e.g., liver) and malignant tissues, subsequently metabolizes 5′-DFCR to 5′-deoxy-5-fluorouridine (5′-DFUR). Thymidine phosphorylase, generally found in higher concentrations in tumor tissue compared to normal tissue, will finally convert 5′-DFUR to 5-FU. (Adapted from Walko et al. [10], with permission Elsevier)

venous (IV) formulation approved by the Food and Drug Administration (FDA) for the treatment of adenocarcinoma of the colon and rectum, breast, stomach, and pancreas [12]. It may be administered as a bolus or infusion [12]. Capecitabine is an oral prodrug which is metabolized intracellularly to 5-FU (Fig. 54.2) [10]. It was designed with the goal of creating a medication that delivered not only higher intra-tumor concentrations but greater convenience and tolerability for patients (i.e., fewer adverse effects) [10, 11, 14, 15]. According to the FDA, capecitabine is indicated for the treatment of metastatic colorectal cancer and metastatic breast cancer, and as an adjuvant treatment for colon cancer [11]. Survival and tumor response rates for both medications vary depending on the type of cancer being treated. Similarly, while adverse reactions to therapeutic administration of 5-FU and capecitabine are quite common, the exact rates vary depending on patient age, cancer type, means of administration, and whether the agents are used as monotherapy [11, 14, 16]. Studies differ, but it is estimated that between 10% and 40% of patients on 5-FU and capecitabine develop some form of severe or life-threatening toxicity, including mucositis, myelosuppression, neurotoxicity, cardiotoxicity, and hand-and-foot syndrome [16–25]. Mortality from 5-FU and capecitabine-induced toxicity is estimated at approximately 0.4–2% [16, 24, 26, 27]. A significant proportion of fatalities are thought to occur in the setting of therapeutic administration rather than acute overdose, and they are often attributed to genetic polymorphisms [18, 22, 28–31].

Pharmacodynamics

5-FU, as noted previously, is an analogue of uracil and an antimetabolite chemotherapeutic agent. It is hypothesized that 5-FU is taken up into cells via the same active transport system used to take up uracil [32]. Capecitabine, once ingested orally, is metabolized to 5-FU in liver and tumor cells. One enzyme critical to this conversion is cytidine deaminase (CDA) which is present in both normal and malignant tissues [11, 33, 34]. The third and final enzyme responsible for converting capecitabine to 5-FU is thymidine phosphorylase. Thymidine phosphorylase is thought to be found in much higher concentrations in tumor cells compared to normal tissues. Capecitabine's ability to localize to tumor cells and its improved side effect profile compared to 5-FU are attributed to this disparity in distribution [11, 34, 35].

Once 5-FU is present within the cell (after either direct uptake or metabolism of capecitabine), it is converted to three principal active metabolites which induce cytotoxicity by interfering with the function of thymidylate synthase (TS) and with the synthesis of RNA and DNA [1, 3]. These metabolites are fluorodeoxyuridine monophosphate (FdUMP), fluorouridine triphosphate (FUTP), and fluorodeoxyuridine triphosphate (FdUTP). Conversion of 5-FU to these active metabolites is accomplished in several steps and by multiple enzymes, including orotate phosphoribosyltransferase (OPRT) [1, 36]. Most administered 5-FU is not anabolized to an active metabolite, however. The enzyme dihydropyrimidine dehydrogenase (DPD) catabolizes approximately 80% to an inactive component which is largely excreted in urine [4, 37]. The aforementioned enzymes – CDA, TS, OPRT, and DPD – are relevant to understanding the toxicity of 5-FU as their genetic polymorphisms are associated with variable risk of developing clinical toxicity at therapeutic fluoropyrimidine dosing (Fig. 54.3) [1, 18, 30].

Thymidylate synthase is an enzyme that catalyzes the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), a nucleotide needed to synthesize DNA. Under physiologic conditions, thymidylate synthase uses 5,10-methylene tetrahydrofolate as a methyl donor to convert dUMP to dTMP. FdUMP, however, binds to TS with higher affinity than endogenous dUMP [38]. When present in the cell, FdUMP will form a stable but reversible ternary complex with thymidylate synthase (a dimer) and 5,10-methylene tetrahydrofolate [38–41]. Formation of this complex prevents binding of dUMP and so inhibits de novo dTMP production [1, 3]. This process is depicted in Fig. 54.4.

The exact means by which dTMP depletion leads to inhibition of DNA synthesis is not entirely known. Inadequate conversion of dUMP to dTMP is thought to create to a relative overabundance of dUTP. dUTP may then be incorporated inappropriately into DNA, resulting in strand damage and cell death [42–47]. FdUTP, another metabolite of 5-FU, can also be misincorporated into DNA, causing similar downstream effects [48–51]. In addition, decreased production of dTMP ultimately results in decreased dTTP availability which is thought to alter the concentrations of other

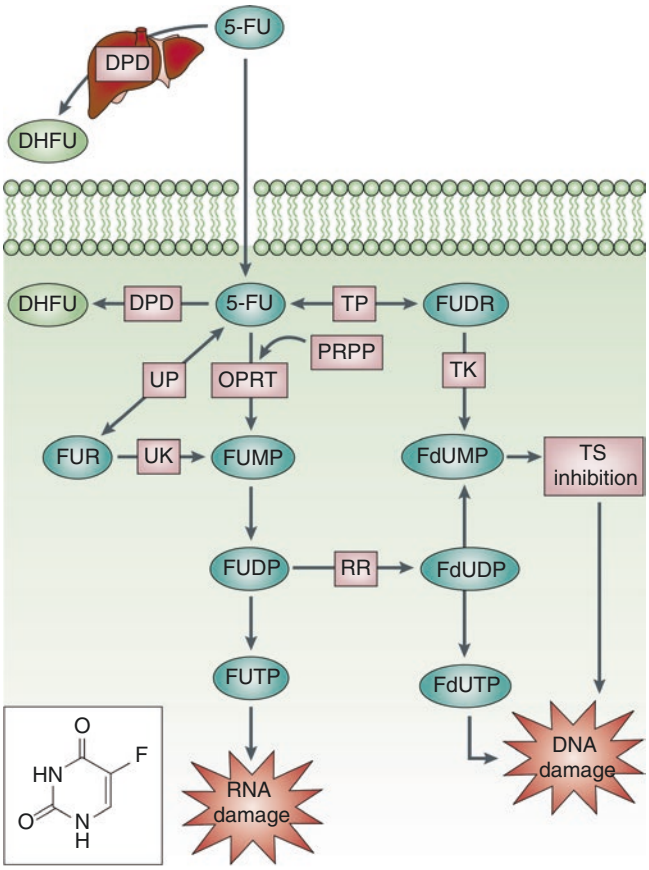

Fig. 54.3 A more detailed overview of the metabolism and mechanism of action of 5-FU. 5-FU is mostly catabolized by dihydropyrimidine dehydrogenase (DPD) to the inactive compound dihydrofluorouracil (DHFU). Much of this conversion takes place in the liver, but catabolism may also take place in other normal tissues and in tumor tissue. 5-FU may alternatively be metabolized to one of the three active metabolites: fluorodeoxyuridine monophosphate (FdUMP), fluorodeoxyuridine triphosphate (FdUTP), and fluorouridine triphosphate (FUTP). FUTP is formed in one of the two ways: 5-FU may be metabolized to fluorouridine monophosphate (FUMP) by orotate phosphoribosyltransferase (OPRT) with phosphoribosyl pyrophosphate (PRPP) acting as a cofactor. Alternatively, 5-FU may be metabolized by uridine phosphorylase (UP) to fluorouridine (FUR) and then to FUMP by uridine kinase (UK). FUMP, once formed, is phosphorylated to make fluorouridine diphosphate (FUDP) which may be subsequently phosphorylated to form FUTP. FUDP, rather than being converted to FUTP, can alternatively be metabolized to fluorodeoxyuridine diphosphate (FdUDP) by ribonucleotide reductase (RR). FdUDP may then be phosphorylated or dephosphorylated to form FdUTP or FdUMP, respectively. FdUMP is also formed if 5-FU, rather than being metabolized by UP or OPRT, is converted by thymidine phosphorylase (TP) to fluorodeoxyuridine (FUDR) and then to FdUMP by thymidylate kinase (TK). (From Longley et al. [1], with permission Springer Nature. © 2003 Nature Publishing Group)

deoxynucleotides. This imbalance is itself thought to damage DNA synthesis and repair [52, 53]. Finally, the abnormal ratio of dUTP to dTTP inhibits the action of uracil-DNA glycosylase, which as a nucleotide excision repair enzyme would normally remove inappropriate, uracil-based nucleotides from DNA strands [1, 48, 54]. Of note, thymidylate can be salvaged by thymidine kinase (TK). Increased intra-tumor thymidine kinase activity is a proposed mechanism of resistance to therapy (Fig. 54.4) [1, 55].

RNA disruption is achieved through multiple mechanisms as well, and is increasingly thought to be a significant contributor to cytotoxicity [47]. When present in the cell, FUTP, a 5-FU metabolite, may replace uridine triphosphate (UTP) and be incorporated into all forms of RNA [56, 57]. In this way it can disrupt the function of ribosomal RNA (rRNA), messenger RNA (mRNA), translational RNA (tRNA), and small nuclear RNA (snRNA) [3, 58–62]. Specifically, FUTP prevents the formation of mature rRNA by inhibiting pre-rRNA processing, disrupts the posttranslational modification of tRNA, inhibits polyadenylation of mRNA, and prevents snRNA-protein complex assembly [63–68]. Together these actions inhibit cellular function and may lead to cell death.

Pharmacokinetics

5-FU is administered intravenously. When given as a bolus, 5–20% is excreted unchanged in the urine over 6 hours. What remains is largely metabolized in normal and malignant tissues to active and inactive metabolites. The majority of 5-FU is catabolized (i.e., degraded to inactive compounds) by DPD in the liver and other tissues [3, 4, 12, 47, 69]. The degree to which 5-FU undergoes anabolism to metabolically active metabolites is thought to depend on the extent of catabolism [4, 37]. In other words, the more 5-FU is catabolized by DPD, the less is available to be converted to active metabolites. In general, less than 5% of 5-FU is anabolized [4].

Variable elimination half-lives and volumes of distribution have been reported for 5-FU; these range from 8 to 22 minutes and 14 to 54 liters, respectively [3, 12, 69–71]. The vast majority of 5-FU metabolites are excreted in the urine within 24 hours; approximately 2–3% undergo biliary excretion [37]. The half-lives of 5-FU's catabolites vary depending on the compound from 1 to 33 hours [3, 37]. Pharmacokinetic data regarding 5-FU continuous infusions is limited [3]. There are no specific recommendations for adjusting the dose of 5-FU in the setting of renal or hepatic dysfunction [3, 12, 72].

The bioavailability of IV 5-FU is by definition 100%. Tissue concentrations, however, vary significantly (up to a thousandfold difference) depending not only on the degree of hepatic metabolism but on whether or not the medication is administered as a bolus or as a slow infusion [71]. The oral bioavailability of 5-FU is highly variable and generally considered to be quite low given first-pass metabolism (one study reported a mean bioavailability of 28% with a range of 0–74%) [71, 73, 74]. Capecitabine also has rela-

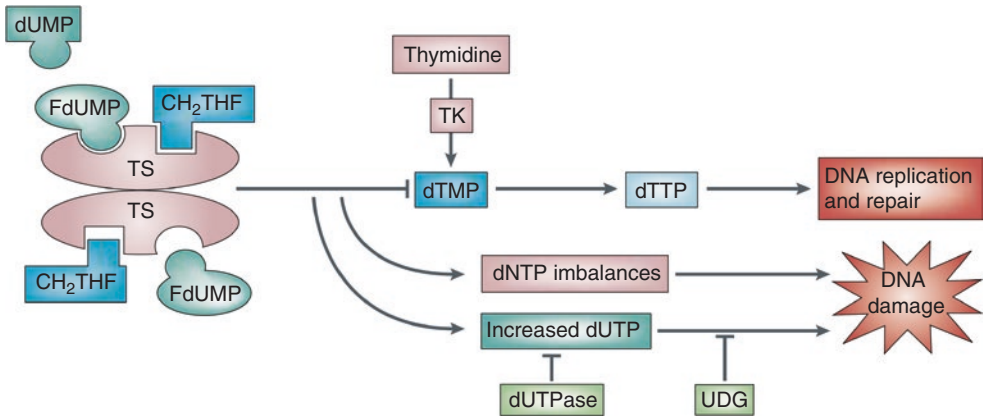

Fig. 54.4 Diagram of 5-FU's inhibition of thymidylate synthase (TS). TS uses 5,10-methylene tetrahydrofolate (CH_2THF) to catalyze the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). Fluorodeoxyuridine monophosphate (FdUMP), a 5-FU metabolite, interferes in this process by binding at the nucleotide-binding site of TS to form a stable ternary complex with TS and CH_2THF. When this complex forms, dUMP is unable to access the nucleotide-binding site, and dTMP synthesis is inhibited. This inhibition leads to deoxynucleotide (dNTP) pool imbalances and increased concentrations of dUTP, and DNA damage ensues. The degree of DNA damage caused by dUTP depends on pyrophosphatase dUTPase (dUTPase) and uracil-DNA glycosylase (UDG) concentrations. Thymidine kinase (TK) may salvage dTMP from thymidine. (From Longley et al. [1], with permission Springer Nature. © 2003 Nature Publishing Group)

tively low bioavailability. A study measuring the serum presence of 5′-deoxy-5-fluorouridine (the immediate precursor to 5-FU in the metabolism of capecitabine) determined that capecitabine had a mean oral bioavailability of 42% in cancer patients with normal hepatic function and 62% in those with hepatic dysfunction [75].

After oral dosing, capecitabine reaches peak serum concentrations at 1.5 hours; peak 5-FU concentrations occur at 2 hours [11]. Food consumption decreases both the rate and absolute amount of capecitabine absorption and delays by 1.5 hours the time to peak serum concentrations of both capecitabine and 5-FU. Less than 60% of capecitabine and its metabolites are protein bound, and this percentage is not dependent on drug concentrations [11, 76]. As noted previously, capecitabine undergoes three enzymatic steps to produce 5-FU; subsequent metabolism is identical to that of 5-FU [10, 11]. Mild to moderate hepatic dysfunction is not shown to have a clinically significant impact on the pharmacokinetics of capecitabine and its metabolites, but the FDA recommends that patients with hepatic dysfunction be monitored carefully on the medication [11, 75]. Similarly, no dose adjustment is initially required in the setting of mild renal dysfunction, but capecitabine is contraindicated in the setting of renal failure as defined by a creatinine clearance of less than 30 mL/min. The FDA also recommends that the dose be decreased in the setting of moderate renal impairment as defined by a creatinine clearance of 30–50 mL/min [11].

Of note, both 5-FU and capecitabine are found to decrease warfarin clearance, leading to an increase in INR [11, 77]. They are also known to increase phenytoin concentrations [11, 78]. Both warfarin and phenytoin are metabolized by CYP2C9 in the liver, suggesting that other drugs metabolized by this pathway should be closely monitored [10].

Toxicokinetics

Toxicity from 5-FU and capecitabine can result from intentional overdose, iatrogenic overdose, and therapeutic dosing [79–81]. Ma and colleagues, in one of the first studies exploring the use of uridine triacetate, noted that toxicity due to overdose was both rate and dose dependent. When three times the appropriate dose was administered, the observed outcome was death [28].

Toxicity in the setting of therapeutic drug administration is often associated with genetic variations that lead to abnormal enzyme activity [80, 81]. Genetic polymorphisms can lead to either excessive or deficient enzymatic activity. Polymorphisms associated with increased fluoropyrimidine toxicity are found in genes that code for the previously mentioned enzymes: DPD, CDA, and TS [18, 25, 29–31, 36, 82–86]. Other enzymes that are suspected of causing increased toxicity due to genetic polymorphisms include methylene tetrahydrofolate reductase (MTHFR) and orotate phosphoribosyltransferase (OPRT) [25, 30, 36].

Of these polymorphisms, DPD is the best studied. It is generally accepted that a significant proportion of patients who present with severe 5-FU- or capecitabine-induced toxicity (defined previously in studies as symptoms consistent with grade 3 or 4 toxicity) have a partial or complete DPD deficiency. Approximately 25–60% of patients with severe toxicity have a DPD deficiency, and such findings have led to recommendations that genetic testing be performed prior

to initiating fluoropyrimidine therapy [21, 30, 87–93]. Of note, it is estimated that only 2.7–5% of the general population (including those with cancer) has a partial DPD deficiency [93, 94]. Reduced DPD activity is not associated with increased age or abnormal liver function, but its relationship to gender is unclear, and rates of deficiency vary greatly between ethnicities [25, 93–95].

Risk factors that have been associated with higher rates of severe toxicity at therapeutic capecitabine dosing include increased age, pre-treatment with uracil, decreased renal function, decreased body surface area, female sex, and the use of capecitabine in combination therapy [24]. Abnormal hepatic function has not been clearly associated with increased risk of toxicity [33, 72, 75].

Data characterizing acute, one-time lethal doses of capecitabine and 5-FU in patients or subjects not undergoing treatment for malignancy is scarce. According to Burns and colleagues, Hoffmann-La Roche reported an LD50 in male Swiss mice of 365 mg/kg [96]. Johnson et al. reported a murine LD90 of 458 mg/kg [97]. A third study found that 50 mg/kg of 5-FU given once daily for 3 days resulted in 40% mortality in a mouse model while 60 mg/kg resulted in 100% [98]. Interestingly, the lethal dose is thought to vary based on circadian rhythms [96]. With respect to capecitabine specifically, the FDA reports that doses up to 2000 mg/kg are not lethal in mice, rats, or monkeys [11]. There is no data available regarding changes to bioavailability in the overdose setting for either medication.

Pathophysiology

The pathophysiology of toxic effects and the pharmacology of therapeutic effects are largely the same. Fluoropyrimidines are designed to kill cells; they preferentially destroy malignant cells, but in killing tumors, they may also damage normal tissue. There are, however, two unique toxicities that bear mentioning: hand-and-foot syndrome and fluoropyrimidine-induced cardiotoxicity.

Hand-and-foot syndrome, also known as palmar-plantar erythrodysesthesia and chemotherapy-induced acral erythema, is one of the few side effects seen more commonly in patients on capecitabine rather than 5-FU [11, 15, 99]. The mechanism is not entirely clear, but one popular theory suggests that higher concentrations of thymidylate phosphorylase in the palms as well as increased basal cell proliferation may be responsible [99–101]. Another study found a significant correlation between the presence of a particular methylene tetrahydrofolate reductase genotype and the development of hand-and-foot syndrome [30].

Reports describing the epidemiology of fluoropyrimidine-induced cardiotoxicity vary in their assessments. Most reports suggest a prevalence of around 4% [102–107]. In a review of 1350 patients without pre-existing cardiac disease, however, only 1.2% of patients were found to have cardiac complications [108]. Symptoms can range from asymptomatic EKG changes to myocardial infarction (MI), heart failure, and cardiogenic shock [104, 109]. Patients may also develop cardiomyopathy with left ventricular systolic dysfunction, ventricular dysrhythmia, arterial vasospasm, and direct endothelial damage. The pathogeneses of these phenomena are not entirely known [103, 108, 110–112]. Coronary vasospasm has historically been considered the most significant contributor to cardiotoxicity [108]. More recently, researchers have suggested that endothelial dysfunction, thrombus formation, direct myocardial damage, and accumulation of cytotoxic 5-FU metabolites may also play a role [108, 111]. The majority of case reports and review articles describing 5-FU- and capecitabine-induced toxicity describe symptoms occurring while patients are actively undergoing therapy [104, 105, 108–111, 113, 114]. Its occurrence appears to be dependent on the dose and means of administration; its relationship to pre-existing cardiovascular disease is unclear [102, 103, 107, 114].

Clinical Presentation

Toxicity from fluoropyrimidines may be considered as being on the spectrum of adverse effects due to chemotherapy. The Common Toxicity Score (CTS) developed by the National Cancer Institute (NCI) characterizes all symptoms of toxicity from mild adverse effects to death according to a five-point scale. Grade 0 describes absent symptoms, grade 1 mild, grade 2 moderate, grade 3 severe and undesirable, grade 4 life-threatening or disabling, and grade 5 death. The definition of mild, moderate, severe, etc. depends on the particular toxicity in question (e.g., neurologic versus hematologic) [115]. To the emergency physician, symptoms consistent with grades 3, 4, and 5 are the most concerning.

Common adverse effects from 5-FU and capecitabine include fatigue, nausea, vomiting, stomatitis, abdominal pain, hyperbilirubinemia, anemia, leukopenia, and neutropenia (neutropenia being the most common hematologic toxicity) [11, 26]. Peripheral sensory neuropathies may also occur, as well as nonspecific neurologic findings including headache, dizziness, and insomnia. Alopecia, venous thrombosis, and predisposition to infection are among other complications. The frequency of each adverse event and the proportion of patients who develop severe or life-threatening signs and symptoms depend on patient characteristics, the type of malignancy being treated, and the treatment protocol being used. (5-FU demonstrates different rates of adverse events when it is delivered as a bolus versus as a continuous infusion; rates also vary when fluoropyrimidines are administered as monotherapy versus combination therapy.) As discussed, capecitabine is generally better tolerated than

5-FU although it is associated with higher rates of hand-and-foot syndrome. Cassidy et al. reported stomatitis in 61.6% of patients with metastatic colon cancer on 5-FU with leucovorin while 24.3% developed stomatitis on capecitabine. In the same study, 10.3% of patients developed neutropenia on 5-FU versus 1.2% of those on capecitabine [1, 10–12, 14–16, 24, 26, 35, 72, 116].

Death and life-threatening toxicity are generally associated with neutropenia, leukopenia, severe diarrhea, and mucositis. A combination of these effects, especially neutropenic fever and mucositis or diarrhea, can lead to sepsis, shock, and multi-organ dysfunction [19, 24, 26, 80]. Death from therapy occurs in about 0.4–2% of patients, and severe toxicity frequently presents during the first treatment cycle [16, 24, 26, 27, 80]. Other rare but potentially fatal complications include central neurologic dysfunction and 5-FU-induced cardiotoxicity. Neurotoxicity may vary in presentation: ranging from confusion and altered mentation to frank encephalopathy and coma [80, 117–121].

The clinical manifestations of cardiovascular toxicity are described in the section on toxicokinetics. They range from asymptomatic EKG changes to cardiovascular collapse. The more dramatic presentations, including myocardial infarction, coronary dissection, ventricular dysrhythmias, cardiogenic shock, and heart failure, are likely to be obvious to the emergency physician. Death from cardiotoxicity results most frequently from heart failure and sudden cardiac death. Patients can also present, however, with anginal symptoms, asymptomatic ST segment changes, and QT interval prolongation [103, 106, 108, 112, 114, 122–124]. Rezkalla et al., in a prospective study, found that 68% of patients receiving 5-FU infusion had asymptomatic ST segment changes (versus 24% who had asymptomatic abnormalities prior to treatment). The study reported that while CK-MB concentrations generally increased during treatment, ST segments all returned to baseline by the end of the study and no patients developed myocardial infarction. Of note, however, two of the patients who developed ST segment changes and ventricular ectopy during therapy died within hours of completing the study; new infarctions were not noted on patient autopsies [109]. In another study, De Forni et al. found that 62.5% of patients who developed anginal symptoms during treatment demonstrated myocardial dysfunction on echocardiogram (ECHO). All ECHOs returned to normal within 2–6 days [123].

Hand-and-foot syndrome, a characteristic adverse effect of fluoropyrimidines, is generally graded according to a three-point severity score [11]. Symptoms range from paresthesias or painless swelling of the palms and soles (grade 1), to painful erythema and edema which do not interfere greatly with activities of daily living (grade 2), to obvious desquamation, blistering, ulceration, and pain which interfere with daily activities (grade 3) [11, 100, 101].

Evaluation and Diagnostic Testing

A diagnosis of fluoropyrimidine-induced toxicity is made by history, physical exam, and laboratory assessment. Laboratory tests may include a complete blood cell count and complete metabolic panel, including liver enzymes. If a patient complains of anginal symptoms, an EKG and troponin should be obtained, and an echocardiogram should be considered. Given the frequency with which patients develop silent ischemia (including ST segment changes without chest pain), physicians may consider performing an EKG on even those patients who do not present with anginal symptoms. If an EKG is performed and is found to be abnormal, consideration should be given to performing cardiac enzymes [109]. Other testing should be directed toward the patient's chief complaint (e.g., blood cultures for infection, lumbar puncture in the setting of acute altered mentation, etc.). There are no specialized laboratory tests that are required emergently, and there is no need to obtain plasma 5-FU concentrations. This test will not change management and it may take days to weeks to result.

Management

Management of patients presenting with fluoropyrimidine-induced toxicity consists first and foremost of stabilization, resuscitation, and supportive care. Consultation with the treating oncologist, if possible, is recommended. In many cases, toxicity can be managed with simple dose reduction [10, 11, 15, 30, 72, 88, 100, 113]. Uridine triacetate is the well-publicized and expensive antidote for fluoropyrimidine-induced toxicity. Its indications are limited, however, and ideally an emergency physician would discuss giving this medication with an oncologist and/or toxicologist prior to its administration. Uridine triacetate will be discussed in the section that follows.

With respect to cardiotoxicity specifically, stabilization and supportive care take priority. Given that most patients who develop cardiotoxicity are actively undergoing treatment with a fluoropyrimidine, one of the first steps consists of discontinuing therapy (i.e., turn off the infusion pump). Prophylaxis and treatment with calcium channel blockers and nitroglycerin have been studied, with incon-

sistent results [103, 106, 112, 125]. Given the conflicting data, it seems appropriate to consider these medications in consultation with a cardiologist, oncologist, or toxicologist, and, more importantly, to use conventional therapies (e.g., follow standard ACLS guidelines) in patients who are unstable [106, 108, 112]. There is insufficient evidence to recommend the use of steroids in the setting of cardiotoxicity [110]. Patients with anginal symptoms and elevated cardiac enzymes should be admitted to the hospital, their cardiac enzymes trended and consideration be given to performing an ECHO [108, 123]. The treating oncologist or cardiologist should be consulted regarding the management of patients undergoing therapy who present with asymptomatic EKG changes and without laboratory evidence of ischemia.

Neurotoxicity appears to respond to aggressive supportive care and to withholding chemotherapy [118–121]. Uridine triacetate should be considered if the patient otherwise meets established criteria.

Treatment for hand-and-foot syndrome is similarly supportive (pain control and wound care as needed). Immersing hands and feet in cold water and applying topical emollients may be beneficial [101]. It is also generally recommended that treatment be discontinued, or the dose be reduced, until symptoms resolve [11, 15, 100]. Dose adjustments should be made in consultation with the treating oncologist. Steroids are not recommended due to insufficient evidence of benefit [100].

Toxicity related to 5-FU's interaction with CYP2C9 should be managed supportively, and any long-term dose adjustments to medications such as warfarin or phenytoin should be made in consultation with the treating oncologist and/or the patient's prescribing physician [10, 77, 78, 126].

Granulocyte colony-stimulating factor (G-CSF) may be considered to treat myelosuppression, even in addition to uridine triacetate [26, 79, 90, 127, 128]. Recommendations on the administration of G-CSF are available from an article by Smith et al. on behalf of the American Society of Clinical Oncologic [128]. The decision to administer G-CSF should be made in conjunction with the treating oncologist.

Extracorporeal elimination has not been studied in the setting of overdose or early-onset severe toxicity. The FDA suggests that dialysis may reduce the plasma concentration of cytotoxic 5-FU metabolites [11]. Given these compounds' large volumes of distribution and rapid elimination in urine, and the lack of data to support this intervention, renal replacement therapy for fluoropyrimidines is only recommended for those patients who already require the therapy (e.g., end-stage renal disease, profound acidemia, etc.) [37, 69, 129].

Antidotal Therapy: Uridine Triacetate

Uridine triacetate (UTA) is the acetylated oral prodrug of uridine, a pyrimidine analogue consisting of uracil bound to a ribose ring. Once absorbed in the gut, it is deacetylated to form uridine. Uridine is subsequently converted to uridine triphosphate (UTP) which competes with FUTP for incorporation into RNA [80, 81, 126]. It has a time to peak serum concentration of 2–3 hours and is absorbed into cells via nonspecific nucleoside transporters [126]. It is metabolized via typical pyrimidine catabolic pathways and also excreted renally [126]. Uridine triacetate is dosed in adults as 10 grams every 6 hours for a total of 20 doses. In pediatric patients it is dosed at 6.2 grams/m^2/dose, up to 10 grams, for a total of 20 doses [126]. It is typically well tolerated; adverse effects include vomiting, nausea, and diarrhea [80, 126].

According to the FDA, uridine triacetate is indicated in two settings. The first is after overdose of 5-FU or capecitabine, defined on the package insert as "the administration of fluorouracil at a dose, or infusion rate, greater than the intended dose or maximum tolerated dose for the patient's intended regimen of fluorouracil." Uridine triacetate is indicated in this setting regardless of the presence of symptoms. No distinction is made between intentional, unintentional, and iatrogenic overdoses. Its second indication is in the setting of "early-onset, severe or life-threatening toxicities affecting the cardiac or central nervous system, and/or early-onset, unusually severe adverse reactions (e.g., gastrointestinal toxicity and/or neutropenia)" that occur within 96 hours of the patient completing a 5-FU infusion or capecitabine administration [126].

The evidence for the use of uridine triacetate in humans comes largely from studies by Ison et al. in 2016 and Ma et al. in 2017, which compared the outcomes of patients in two open-label, single-arm trials to historical case controls. The studies demonstrate a difference in survival at 30 days of 96% in those who received uridine triacetate (97% in those with overdose and 86% in those with early-onset symptoms) versus 16% in those who did not. Of those patients who developed early-onset symptoms but started uridine triacetate over 96 hours after last dose administration, only 38% survived. All deaths among patients with early-onset symptoms occurred in this cohort. Of note, this study included both pediatric and adult patients, and several patients received UTA via nasogastric, orogastric, and gastrostomy tubes [80, 81]. Since these studies were published, multiple other authors have reported success in reversing toxicity with uridine triacetate [79, 130–132].

Ma et al. defined severe or life-threatening signs and symptoms as "severe cytotoxic mucosal and/or hematologic toxicities as well as acute encephalopathy and/or cardiomy-

opathy" [80]. The FDA's indications for uridine triacetate are broader. If possible, it is recommended to consult with the treating oncologist when deciding to administer UTA as this medication not only may undermine 5-FU's therapeutic effects but is expensive and potentially difficult to obtain [133, 134]. In situations where the degree of toxicity is unclear, or where it is unclear if toxicity requires therapy, it is recommended to consult with an oncologist and/or a toxicologist.

Part V

Palliative Care

Emergency Department Use at End of Life

55

Hsien Seow and Kayla McMillan

Introduction

As cancer treatments advance and patients with cancer are living longer, there is also a growing potential for increased visits to the emergency department (ED) at end of life. End-of-life (EOL) care specifically refers to the final weeks of a patient's life, when symptoms commonly increase in intensity and death approaches [1]. EOL care is related to palliative care, which is a holistic approach to care, with emphasis on preventing or relieving suffering and improving quality of life [2]. Stakeholders have been advocating for improved EOL care and earlier integration of palliative care into the cancer trajectory for over two decades (Fig. 55.1) [3]. The American Society of Clinical Oncologic endorsed a clinical practice guideline supporting the provision of early palliative care concurrently with standard oncologic care in 2017 [4]. Without effective EOL or palliative care, many dying cancer patients have unmet clinical needs, uncontrolled symptoms, and poor quality of life, as well as fear, anxiety, and depression, which may cause them to visit the ED [5]. Avoiding unnecessary ED visits may lead to economic benefits (ED visits and the ensuing hospital care are costly), improve patient experience (many patients do not want to be cared for in a hospital or ED at the EOL), and improve quality of care (some causes of ED visits are avoidable with proper planning).

The ED is a setting of care focused on the management of acutely presenting medical problems. It is a fast-paced work environment with an emphasis on identifying the problem and instituting a solution over a very short interval of time. In contrast, dying cancer patients typically have complex medical histories, multiple symptoms, and difficult psychosocial circumstances. Therefore, optimal EOL care requires a great deal of time to honestly discuss prognostic information, make clear recommendations, facilitate patient-family discussions, affirm patient choices, address holistic/psychosocial aspects of well-being, and plan for unexpected changes in a patient's condition. This is the antithesis of care typically provided in the ED. EOL trajectories in the ED have been characterized as being either "spectacular" (e.g., sudden, traumatic death) or "subtacular" (e.g., slow process of dying or a nonemergency death) [6]. ED staff are well trained to deal with "spectacular" deaths but often distance themselves from patients dying "subtacular" deaths. As a result, EOL

care in ED is typically far from ideal. Hence, ED visits at the EOL are a widely used indicator of poor-quality care [7, 8].

There have been a few literature reviews on EOL care in the ED that were not cancer-specific. One review focused on the evidence for managing dying patients in the ED and identifying areas for improvement [9]. The authors observed that of the 160 papers included in the overview, the 6 main themes that arose were (1) the uncertainty of treatment in ED for patients at EOL; (2) quality of life issues; (3) costs; (4) ethical and social issues; (5) interaction between ED and other services; and (6) strategies for out-of-hospital care. Another similar review focused on barriers to providing optimal care in the ED. Of the 27 studies included, they identified minimal resources, lack of staff education, and outdated models of care as the main challenges [10]. A third review focused on older adults at EOL in the ED and identified 14 articles [11]. The review noted there was limited evidence regarding the definition, clinical profile, care delivery, and outcomes for older people requiring EOL care in the ED, though they did note that there were multiple tools available for dealing with EOL care, including predicting mortality and assessing functional status, comorbidities, symptom distress, palliative care needs, quality of life, and caregiver's stress. Nonetheless, the growing numbers of older adults, the increased pressures of access to high-quality care in a timely manner, and the escalating costs of healthcare delivery are bringing more attention to appropriate use of ED services, especially for cancer patients at the EOL with well-documented symptom needs.

This chapter will review the topic of ED use at the EOL with a specific focus on cancer patients. It will review:

1. The rationale for investigating ED use at EOL
2. The frequency with which ED visits occur
3. Common reasons for ED visits at the EOL
4. Factors associated with ED visits at the EOL
5. Evidence for strategies to mitigate ED use at the EOL

Case Study

Mr. X, a 75-year-old white male, presents to the ED at 11:00 pm with increasing abdominal pain and worsening fatigue over the past several days. He is accompanied with his wife, who is his primary caregiver at home. Mr. X has been a patient of your hospital for many years, and as such you look up his records in the hospital EMR. From the EMR you learn that Mr. X was diagnosed with squamous cell carcinoma of the lung approximately 7 years ago and underwent a wedge resection 5 years ago. Since his lung resection, he has also had chemotherapy. He and his wife live in a suburb outside of town, which is where his primary care doctor is located. Also from the EMR, you learn that approximately 5 months ago, Mr. X. was diagnosed with a metastasis in his brain. He has been followed by his oncologist in the outpatient setting. You can also see that he has not met with the palliative care service which is available at your hospital.

After you have read about his history in the EMR report, you decide to ask Mr. X and his wife some questions to gain his understanding about his illness and his current symptoms. After discussing his abdominal pain, you rule out any other contributing factors, and provide symptom management for him, as well as you provide a prescription to last him until he is scheduled to see his family doctor in the community next.

After assessing for any other contributing factors, it is likely that his fatigue is related to his decline in overall functioning. After speaking with him and his wife, you understand that he is unable to get out of bed most days, and he is having trouble walking without assistance. You ask Mr. X about his outpatient follow-up, in order to ascertain whether he has been seen by a palliative care specialist in the community. His wife lets you know that he has not; no one has suggested this to them. You take a few minutes to explain why a palliative care service is appropriate for him, and after letting him discuss it with his wife, they agree to be referred to the service at your hospital so they can see someone quickly. You refer him to your inhospital palliative care team, and request an urgent consult, given his advanced illness and his steady decline. Once the palliative care team member arrives, you give handover to ensure seamless transition and that no details are missed, including letting them know you gave him a prescription for pain medicine.

Rationale for Investigating ED Use at EOL

Indicator of Poor-Quality Care

In 2003, Earle et al. published a landmark paper describing quality indicators of EOL cancer care that could be measured with administrative healthcare data [7]. The impact of this publication was significant because (1) stakeholders began to discuss the merits of the quality indicators, selected through literature review, focus groups with patients and family members, and an expert panel, and (2) researchers began measuring them using readily available administrative healthcare data. One of the key indicators of poor-quality care identified was frequent ED visits near the EOL. It became operationalized as more than one ED visit in the last 30 days of life [8]. The rationale for this indicator is because high rates of unplanned medical encounters at EOL, exemplified by ED visits, may indicate overuse of aggressive care, inattention to symptom issues, poor planning by providers to anticipate patient needs, insufficient support or education for the caregivers, lack of advance directives, or inadequate availability of palliative care resources, such as hospice ser-

vices; when these elements are provided or addressed, they can help avoid unnecessary ED visits at EOL. Examples of other poor-quality care measures that emerged from this publication include a short interval of time between chemotherapy and death, ICU admissions near EOL, and a short time interval between hospice enrollment and death.

Patients and Families' Perspective on ED Visits at EOL

Cancer patients will frequently visit the ED when symptoms are uncontrolled and they find themselves with unmet needs [12]. Many would prefer care by their usual provider or someone from the cancer center where they typically receive care. However, when the need arises and patients present at their local ED, it presents a challenge to the emergency physician [13].

Most reports indicate that patients prefer to be at home at the EOL [14–17]. Earle et al.'s original indicator [7] was developed by including perspectives from 12 patients with incurable cancer and 4 family members: they associated ED visits primarily with toxicity management of aggressive chemotherapy. Early in the trajectory, this was expected and described as a necessary part of receiving therapy. Later in the trajectory of care, patients' willingness to tolerate toxicity for non-curative therapy diminished. In turn, their willingness to endure ED visits or accept them as a necessary component of care also diminished. Interestingly, in a study of Japanese bereaved family members, only 14% endorsed the appropriateness of frequency of ED visits as an indicator of poor-quality care. This suggests that this particular measure may be perceived differently in different cultures where the perspective on a "good death" may be different [18].

In a study of stakeholder perspective of quality indicators for EOL care, 16 women with metastatic breast cancer and 8 bereaved family caregivers participated in focus groups to provide their perspectives on quality indicators at EOL [19]. The dominant themes that emerged were support for, access to, and early enrollment for palliative care services, continuity of care, and multidisciplinary care. The authors do not describe a dominant theme related to ED visits, though ED visits clearly disrupt continuity of care in the ambulatory setting and lack of adequate access to palliative care may lead to ED visits.

Healthcare Provider Perspective on ED Visits at EOL

Healthcare providers strongly endorsed ED visits as a quality indicator. In a Delphi process conducted in Canada with healthcare professionals evaluating the acceptability of frequency of ED visits near the EOL, more than 80% of participants agreed the indicator was meaningful and important [19]. An American qualitative study of perspectives of care providers in the ED, including physicians, nurses, and other providers, revealed several emerging themes. These include conflict among providers about the feasibility and desirability of providing palliative care in the ED, not seeing a difference between palliative care and EOL care, poor communication between providers in the inpatient and outpatient setting, conflicts about withholding life-prolonging treatment, and inadequate training in pain management. A similar study from Germany describes ED physicians as having difficulty dealing with palliative patients because of uncertainty regarding aspects of psychosocial care and EOL decision-making [20]. Relatedly, a survey from Australia indicates that ED physicians feel that the care they provide to EOL cancer patients is futile [21]. These sentiments conceptually endorse the notion that, from a provider perspective, the ED may not be the best place to care for this patient population.

System Perspective on ED Visits at the EOL

In some jurisdictions, ED use at EOL is being measured at a population level and has even become a system-wide metric in some countries. In Australia, routine data from the Department of Veterans Affairs showed that cancer decedents averaged one ED visit in the last 6 months of life [22]. Another study in Australia examined the ED use in the last year of life among cancer and non-cancer patients revealing that 70% had at least one ED visit [23].

In the UK, the National EOL Care Intelligence Network, now a part of Public Health England, is measuring ED use for quality improvement. In 2018, a study by Henson et al. discovered that as many as 30.7% of patients in the UK who died of any cancer had at least one ED visit [24]. In another UK study for urological cancer patients in the last year of life, they found that emergency admissions tended to be significantly longer and more costly than planned admissions to hospital. As well, emergency admissions were far more common than planned admissions to hospital in the three largest urological cancer groups [25].

In the USA, the Veterans Health Affairs Department has reported data on ED visits at end of life [26]. At a national level, the American Society for Clinical Oncologic has included the "percentage of patients who died from cancer with more than one emergency department visit in the last 30 days of life" as a measure for voluntary reporting for their end-of-life module in the Quality Oncologic Practice Initiatives (QOPI) [27]. For instance, one cancer center reported their ED visit admission rate as 68% in their last month of life, compared to peer healthcare institutions

reporting an average of 32% [28]. Nonetheless, the difficulty of risk stratification to separate those for whom the ED visit was appropriate versus avoidable continues to be a challenge for its use as a national quality indicator for accreditation [29].

In Canada, the cancer agency for Ontario has created the "Cancer System Quality Index" which for many years included ED visits in the last 14 days of life as a quality indicator (www.csqi.on.ca). The index, published annually on the Internet, includes a plethora of quality indicators for cancer across the care trajectory. For instance, in their 2016 report, they noted that 40% of cancer patients visited the ED in the last 2 weeks of life [30]. Nationally, the Canadian Partnership Against Cancer has begun measuring this quality indicator in their annual system performance reports. For instance, in their 2017 report, they noted that 49% of cancer patients who died in hospital visited the ED once, 25% twice or more, and 27% no times in their final 28 days of life [31].

Frequency of ED Visits at EOL

The frequency of ED visits depends on several definitional and contextual factors. Table 55.1 [7, 23, 31–51] lists a review of publications describing the frequency of ED visits at the EOL. These publications typically used population-based retrospective cohort studies linking large administrative data. They were conducted in Canada, the USA, Australia, Egypt, England, Mexico, and Taiwan, ranging in cohort sizes from 154 to 272,832, where years of study periods spanned 1991–2018. The prevalence of ED visits ranged from 1.5% having two or more ED visits in the last 30 days of life [32] to 85% having an ED visit in the last 6 months of life [33]. The duration of the observation window from death varies from 2 weeks to 1 year, with 30 days being most common. The patients in the numerator may be counted with any ED visits, but in several papers, more than one visit is required. Many studies are population based, but some are institutional. Some include all cancer types, where others include only specific cancers. These differences in study design, definitions, and inclusion/exclusion criteria should be considered when making comparisons.

The majority of studies used an observation window looking backwards from the date of death to create a decedent cohort (i.e., people who have died) rather than a prospective cohort that followed patients until they all died. This approach has been criticized since people who have died may not be the same people one would identify as actively dying [53]. However, when used with administrative data, this approach allows for easy identification of relevant cohorts, efficient study of all patients who died (rather than a nonrandom subset), and timely evaluations for quality improvement [54].

Contextual factors must also be considered. Specifically, what are the palliative care supports available for study participants, and more generally, how is care structured? For example, in Warren et al., ED use was compared in Ontario, Canada, and the National Cancer Institute Surveillance, Epidemiology, and End Results Program (SEER) regions in the USA. The methods of the study explicitly harmonized all definitions in both jurisdictions to ensure a fair comparison. ED rates differed by about 10%, which is likely a reflection of differences in health policies, structures, and process of care in the two settings, such as access to home care, medications, and hospice services [43].

Despite these differences, most authors conclude that ED use in cancer patients at EOL is too high and that this population-based metric should be driven down as low as possible. Studies examining regional variation have attempted to define a benchmark rate. Earle et al. in 2005 described the regional variation in ED visit rates at the EOL among Medicare beneficiaries with cancer; they found almost threefold variation among 11 different regions in the USA [55]. They defined an empiric benchmark as the top decile of performers to derive a benchmark of <4% with more than one ED visit in the last 30 days. This benchmark was achieved in only one other study in a community setting [56]. In fact, the majority of the studies with a similar definition exceed this proposed benchmark. For instance, Barbera et al. examined 33 health regions in 3 provinces in Canada, and the top decile had a 34% ED visit rate [57]. While negative publication bias may partially explain this, the existing data support the impression that improvements in care are required. It is important to remember that this measure is meant to be considered at a population level. It would be impossible to have a system where the value of this measure is zero. ED care may be entirely appropriate for a particular individual. But when population values are in excess of 30%, one ought to further examine the health policies and systems of care. This was reinforced by a Canadian study of cancer decedents by Seow et al. which showed ED visit rates at EOL varied more greatly by provinces than by community population size [58].

Reasons for ED Visits at the EOL

There have been several studies examining why cancer patients go to the ED, though most do not restrict their evaluation to the EOL period. Mayer et al. conducted a study identifying over four million ED visits in North Carolina, USA [59]. The top three complaints were related to pain, respiratory distress, and gastrointestinal issues. Beyond treatment, in a Korean study of over 5500 cancer-specific ED visits, 55% of visits were related in some way to disease progression [60]. This disease progression often leads to worsening

Table 55.1 Frequency of ED visits at end of life

First author	Year of publication	Country	Jurisdiction	Cancer type	Cohort size	Time window prior to death	Patients to ED (%)
Allende-Pérez et al. [34]	2020	Mexico	Mexico City	Any cancer	426	30 d	8.9% >= 3 ED admissions

symptoms. Indeed, one study showed that physical symptom burden in the ambulatory cancer setting was strongly associated with the likelihood of an ED visit [61].

A systematic review of reasons for ED use by all cancer patients revealed that many visits are likely chemotherapy-related toxicity as demonstrated by frequent visits for fever, neutropenia, and gastrointestinal complaints [62]. Another review also identified fever, urinary complaints, malnutrition, neutropenia, and gastrointestinal complaints as main reasons [63]. Similarly, a third study examined 18 EDs in the USA and found that three-quarters of cancer patients presenting to ED had undergone cancer treatment in the past 30 days and over 60% had advanced or metastatic cancer [64]. The five most common ED diagnoses were abdominal pain, fever, shortness of breath, nausea/vomiting, and throat/chest pain [64].

A few studies focused on cancer ED visits at end of life. In one Canadian study of over 91,000 cancer patients, they identified 36,600 ED visits in the last 2 weeks of life. The main reasons for visits to ED in the last 2 weeks are listed in

Table 55.2 Top ten reasons for ED visits in the last 2 weeks of life [48]

Rank	Reasons	Frequency	
		(no.)	(%)
1	Lung cancer	3242	8.9
2	Dyspnea	1844	5.0
3	Pneumonia	1832	5.0
4	Abdominal pain	1126	3.1
5	Malaise and fatigue	1084	3.0
6	Palliative care	1042	2.9
7	Dehydration	944	2.6
8	Pleural effusion	717	2.0
9	Altered consciousness	689	1.9
10	Pancreatic cancer	585	1.6

Table 55.2 [48]. Pain was responsible for about 5% of visits. As well, dyspnea, pneumonia, and pleural effusion were also very common. This study used administrative sources of data and was limited by the coding system for the diagnoses associated with each visit. As such, lung cancer was the most common "reason," although this does not actually reveal the cause of the visit. This likely reflects the impact of progression of disease in a common cancer type and is consistent with other works specific to lung cancer [51]. In a US study of cancer patients who died in the ED in the state of North Carolina, over one-third of those deaths had a cause of death due to lung cancer. Across all cancer deaths, the most common chief complaints were respiratory, gastrointestinal, and neurological [65]. Similarly, a Turkish study examining ED visits within a month of death identified dyspnea as the main complaint, with lung cancer as the most common cancer [66]. In the Netherlands, a study of advanced cancer patients visiting the ED within 3 months of death found that pain and dyspnea were the main reported symptoms [67]. A nationwide population-based study of Taiwanese cancer patients at end of life also identified "symptoms, signs, and ill defined conditions" as the main cause of admission for a third of cases, using ICD-9-CM diagnosis codes [37]. A study in Singapore looking at reasons for ED visits among cancer patients in the last week of life identified breathlessness as the cause for nearly 60% of patients, followed by pain (35%), general weakness or lethargy (27%), and decreased appetite (24%) [68].

Pain management warrants specific attention because it is commonly experienced by ambulatory cancer patients at the EOL [1] and often leads cancer patients to visit the ED [48, 59–62]. Two studies, one with Canadian patients and another from the USA, indicate that about a third of cancer patients have inadequately managed pain [69, 70]. In a study from Mexico, uncontrolled pain was also one of the principal reasons for ED visits [34]. This observation is essentially unchanged over the past two decades [71]. Meanwhile, emergency physicians have indicated they are not comfortable managing pain in this population [50]. Furthermore, overcrowding, a common ED problem, is associated with worse pain management [72]. Cancer patients deserve meticulous management of their pain by those best trained to do so.

When considering why patients visit the ED, a natural follow-up question is whether the visit was possibly avoidable or was the ED the best and only place for the patient to receive care? In a Canadian study, potentially avoidable visits were defined as ED visits related to a technical issue, such as catheter issues or prescription refills, and occurred about 1% of the time in the last 2 weeks of life. 8.4% of visits were for reasons such as malaise, fatigue, or need for palliative care, which likely represent some version of the patient "not coping" at home [48]. Arguably, these visits are also avoidable. In one small Irish study that prospectively documented reasons for ED visits in cancer patients who were under the care of a specialist palliative care program, about half of the visits were felt to be avoidable [73]. To a certain extent, the concept of avoidable ED visits is highly dependent on the alternative places available for care delivery. In the absence of readily available access to care elsewhere, ED visits may not be avoidable at all.

In summary, cancer patients at the EOL visit the ED because of symptoms related to their malignancy. Pain and respiratory issues are common, as are difficulties coping at home. Chemotherapy toxicity is a problem for all patients, regardless of their trajectory, and contributes significantly to ED visits.

Factors Associated with Increased Risk of ED Visits

ED visits at EOL have been shown to be associated with several different patient, tumor, treatment, and health system factors. However, the differences in definitions and populations studied lead to inconsistent results in the literature.

Among patient factors, sex has been most consistently demonstrated as an important factor with men more likely to visit the ED than women [8, 39, 41, 49, 52, 74–77]. Age is also important with older patients less likely to make visits [8, 39–41, 45, 49, 52, 75, 77–79]. Those with more significant comorbidity are also more likely to visit the ED [8, 41, 63, 74, 75, 80]. This is due to the complications related to chronic comorbidities, such as an exacerbation of COPD symptoms [81]. With one exception [40], those living in rural regions are also more likely to visit the ED [41, 52, 74–76, 78, 82]. ED visits are also more likely for patients who live in lower-income neighborhoods [52, 74, 76], with some exceptions [75]. Race has also been shown to play a factor [63].

Some tumor and treatment factors have been examined. Hematologic patients are more likely to make ED visits than

patients with solid tumors [41, 79]. Among solid tumors, those with lung cancer are at the highest risk [74, 76, 77]. Patients with higher symptom burden are more likely to visit the ED [61]. Treatment factors are also important. Patients with metastatic cancer receiving chemotherapy are more likely to visit the ED [83]. As will be reviewed in the next section, palliative care interventions may decrease the likelihood of ED visits.

The influence of healthcare system factors has also been demonstrated. For example, as previously mentioned, harmonized comparisons between countries give some insight into the possible effects of different systems, such as the US hospice system versus more generalized access to palliative care [43]. Similarly, within the USA, those within the Department of Veterans Affairs (VA) system were less likely to have ED visits than those enrolled in Medicare [46].

Evidence for Strategies to Mitigate ED Use at EOL

It is unrealistic to expect that all ED visits at the EOL can be avoided. An ED visit can be a very taxing ordeal for patients at this point in their cancer journey, and most agree it happens more often than is desirable. This section will review the evidence for interventions that mitigate and reduce visits to the ED for patients at the EOL. A number of different studies have found that having access to palliative care programs can reduce ED visits for patients with advanced cancer at the end of life. For example, Temel et al.'s study in a comprehensive cancer care, where patients with advanced non-small cell lung cancer were randomized to early palliative care versus usual care, showed that early referral could reduce ED visits. Those randomized to the intervention arm experienced fewer ED visits in the last 30 days of life (22% versus 30%) [84]. Evidence also exists for community-based palliative care interventions to reduce ED visits. A randomized controlled trial of home-based palliative care versus usual care also demonstrated a decrease in ED visits for those in the intervention arm, from 33% to 20% [85]. In addition, a pooled matched analysis of a retrospective cohort that was exposed to a specialized palliative home care team or usual home care demonstrated that the risk of having an ED visit at the EOL was 32% less for those who received care from the specialized palliative care teams [86]. The impact of early palliative care referral has also been demonstrated in observational datasets. For example, an Australian cohort of 28,331 decedents residing in an area with community-based palliative care program found that those who had the program initiated (58% of cohort) had less unplanned ED visits in the last 6 months of life [87].

Another study that showed access to palliative care services reduced ED visits was conducted as part of the Cancer Care Outcomes Research and Surveillance Consortium. This was a prospective cohort study of 1231 patients with stage IV lung or colorectal cancer, which demonstrated that patients who had an EOL discussion more than 30 days prior to their death were much less likely to use acute care services (ED and hospitalization) in the last 30 days [88]. A single-institution retrospective chart review of 220 women who died of ovarian cancer found that when an EOL discussion occurred more than 30 days prior to death, visits to the ED decreased [89].

Palliative care programs work because they can address many different factors of serious illnesses. Some of these include improved symptom control, decreased chemotherapy use, and improved knowledge of expectations. This was shown by Temel et al. in that patients in an intervention arm had better quality of life as well as less depression and anxiety [84]. Temel's study also revealed longer survival for those receiving palliative care. Palliative care is often provided by specialized care teams that are interdisciplinary, providing more opportunity for education and symptom management. They also tend to provide home-based services and are available 24/7. Nonetheless, some of the challenges to integrating palliative care into oncologic ED are the delays in palliative care consultations, patient and family expectations, and the fast-paced ED culture with limited resources [81].

While palliative care programs are important to reduce and avoid unnecessary ED visits, what can be done for those patients who do visit the ED? One intervention used a brief negotiated interview which allowed ED clinicians to motivate patients to have their needs met [90]. Another option for managing palliative care patients in the ED is to implement a screener questionnaire to identify patient needs, including cancer patients. In one study, a screener was integrated in the hospital's electronic health record system, which ultimately triggered referrals to consultants based on the results of the questions, e.g., pharmacy consult for medication reconciliation or social work consult for unmet needs at home [91]. This study showed that novel pathways and integrated communication led to many of the patients having their needs met quickly and efficiently. Another example of an intervention used in the ED is the Choosing Wisely campaign, which urged ED physicians to proactively engage with palliative care and hospice care services. One study used the Choosing Wisely campaign to create a pathway from ED to more appropriate services [92]. The ED physicians in the study would contact the palliative care team directly during regular office hours and allow them to decide next steps or, if during weekends or evenings, patients would be referred to a "hot clinic." The "hot clinic" saw patients in a timely manner, usually within a week of the ED visit. Another study in South Korea developed a dedicated ED cancer unit to specifically manage oncologic emergencies [60].

However, not all palliative care intervention studies in the ED have been positive [93–95]. Some studies have been positive for other outcomes, such as satisfaction, cost, or hospitalization, but not for ED visits [93, 96, 97]. For example, Bakitas et al. published a palliative care randomized trial using a nursing-led, multicomponent, psychoeducational intervention in a comprehensive cancer center [93]. This trial showed improvements to quality of life and mood, but did not reduce ED visits at the end of life. In a systematic review of the literature, DiMartino et al. could not substantiate whether palliative care interventions were more effective than usual care at reducing ED visits [98]. The nature of interventions and the different ways of reporting outcomes are perhaps a few reasons for the differing results.

It is important to recognize some of the factors that may explain varying outcomes in studies of ED visit mitigation. Intensity of care is important to note as a possible factor. In a study of patients receiving palliative home nursing, Seow et al. demonstrated a dose response such that patients receiving more nursing hours of care at home were less likely to visit the ED [75]. Studies conducted in two different provinces in Canada have demonstrated that increased continuity of physician care in the outpatient setting also decreased ED visits [52, 76]. Another factor may be a patient's access to hospice services. In one study, patients using hospice services were compared to matched cases who did not [36]. Patients enrolled in hospice services had less ED visits than their matched controls.

Structural aspects, for example, of a palliative care team, the health system, or the care setting itself, are also important. A case series of four regions with either high or low ED visit rates demonstrated that regions with lower ED rates have specific features of their palliative care systems that were absent in the other regions [99]. These included overall palliative care needs planning, a common chart, standardized patient assessments, 24/7 palliative care team access, advance practice nursing expertise available, and designated roles for the provision of palliative care services. Related to the physical structure of care settings, some jurisdictions have restructured the ED to create cancer-specific ED programs as an alternative place for assessment [60]. This particular structural change would facilitate easier access with short waits for cancer patients. It would also potentially hone the expertise of the ED staff working there and improve communication with the ambulatory team. Such an approach, however, seems to result from failure to optimize care upstream in the trajectory.

Future Directions

The literature provides some opportunities for better providing EOL care in the ED, when these unavoidable visits happen. These include providing education to ED clinicians on the holistic nature of end-of-life care and educating staff on enhancing their communication techniques [10]. There is also opportunity for future research in this area. There has been little to no research evaluating the impact of psychoeducational interventions for informal caregivers on ED visits at EOL. A systematic review of informal caregivers' needs identified a lack of practical support for nursing skills [100]. The clinical approach taken for patients at EOL may be quite different [101] and may require additional training and skills. A systematic review of qualitative and quantitative studies of unmet needs for patients and carers identified that the most frequently unmet need was effective communication with healthcare professionals [102]. Another future opportunity is further exploration of hospital integration of palliative care divisions within EDs, which could lead to better coordination with existing services such as social workers, psychologists, or caseworkers [81].

Conclusion

Most practitioners are familiar with the aphorism, "To cure sometimes, to relieve often, to comfort always." The field of medicine has excelled in technical aspects of providing care, and we cure much more often than we did in the past. As a result, the importance of offering relief and comfort is sometimes forgotten. Population-based measures of ED visits in cancer patients at the EOL are a meaningful indicator of quality of care. With administrative healthcare data, this measure is easy to follow. Currently, ED visits are happening more often than is desirable. Increased efforts are needed to minimize the use of toxic therapies at the EOL and to create effective palliative care structures and processes which are readily accessible.

Pain Management

56

Danielle M. McCarthy and Laurie M. Aluce

Case Study

A 56-year-old man with a history of metastatic pancreatic cancer receiving gemcitabine chemotherapy presents to the ED with 2 days of worsening abdominal pain. He describes the pain as sharp, constant, located throughout his entire abdomen, and ranks it an 8/10 on the numerical pain rating scale. He also feels nauseated and has not had a bowel movement in 2 days. He denies fever or urinary symptoms.

He states that his cancer-related chronic pain is usually well controlled with his fentanyl patch and extended release morphine, so he usually only needs a couple doses of his PRN immediate-release morphine per day. In the last 24 hours, however, he has taken the immediate-release morphine exactly every 4 hours due to pain.

The nurse asks the physician, "What would you like to give for pain?" The physician is torn. The etiology of the pain remains unclear, and he does not want to make any potential opioid-induced constipation worse. The patient is in a severe pain crisis, however, so the physician decides to treat with IV opioids while awaiting imaging results. He orders 6 mg IV morphine.

After 15 minutes, the patient remains in severe, 8/10 pain despite the morphine. He is not exhibiting any adverse side effects from the opioids. The physician wonders if he should order a higher dose of morphine. After consulting his equianalgesic table and converting the patient's home pain medication requirements into IV morphine equivalents, the physician realizes he severely under-dosed the first round of morphine. The physician orders a second, more appropriate dose of IV morphine, which provides adequate relief to the patient.

Introduction

Pain is one of the most common symptoms experienced by patients with cancer. Prevalence estimates (pooling patients with multiple types of cancer and in various stages of treatment) suggest that >50% of cancer patients experience pain [1]. The prevalence of pain is higher for patients who have metastatic or advanced stage disease, and greater than a third of cancer patients rate their pain as moderate or severe [1]. The prevalence of pain in the subset of cancer patients visiting the emergency department is less well defined. It is estimated that approximately 10–41% of all ED visits made by cancer patients involve pain as the primary complaint [2, 3]. Regardless of the chief complaint that prompted the ED visit (e.g., presenting primarily for pain crisis or presenting for infectious symptoms), giving analgesics is among the most frequent treatments provided to cancer patients in the ED. The severity of patient self-reported symptoms, including pain, is a reliable predictor of emergency department visits [4, 5].

Classification of Pain

The National Comprehensive Cancer Network states that a "pain crisis" is an occasion on which a patient is experiencing severe pain (at least a numerical rating of 8 on a 10-point scale) [6]. Such a pain crisis may arise from inadequate control of a patient's baseline persistent pain or may be a more acute pain crisis superimposed on a well-established history of chronic pain. Such pain is commonly referred to as "breakthrough pain." While breakthrough pain may result from cancer progression, it may also result from increased analgesic tolerance or end-of-dose failure. Similar to the more general pain prevalence estimates detailed above, nearly two-thirds of patients with chronic cancer pain syndromes experience breakthrough pain episodes [7]. In general, it is accepted that a patient's baseline persistent pain must be well

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_56

controlled before attributing the pain episode to "breakthrough pain" [8].

Such pain crises require a rapid response from emergency physicians to achieve adequate analgesia. The approach to a pain crisis should be similar to the emergency physician's approach to any other emergency and include an assessment of the history, severity, timing, and location of the pain, in addition to a thorough physical exam. In addition to classifying pain in cancer patients as baseline pain or breakthrough pain, other important considerations when assessing pain in cancer patients include the following: awareness of the pain mechanism or pathophysiology, consideration of the triggers of the pain crisis, and discussion of the goals of care.

Pain Severity

Many tools are available to assess pain severity and thereby quantify pain. Examples of such pain severity assessment tools include numerical rating scales (NRS), visual analogue scales (VAS), and picture scales (e.g., Faces Pain Scale). More in-depth assessments, which often incorporate numerical or visual analogue rating scales, are also available and include the Brief Pain Inventory, the McGill Pain Questionnaire, and the Memorial Pain Assessment Card. Pain is subjective, and at times in the ED, high pain scores are greeted with skepticism; therefore, it is important to use one of these validated measures to assess patients' pain. This is particularly important for patients with chronic pain who may not exhibit more objective signs (e.g., grimacing) or vital sign changes such as tachycardia [9]. Using a pain score measure, and applying it consistently, will help to add a more objective means of reproducibly tracking patients' pain and response to treatment over time. Although any of the abovementioned measures are validated and can be useful if applied consistently, for purposes of ED evaluation of cancer pain, a numerical rating scale (NRS) is preferred [10, 11]. Specifically, in cancer patients, a NRS has better capability to distinguish between a patient's background or chronic pain and breakthrough pain [11]. The NRS is an 11-point scale ranging from 0 to 10. When asking patients to rate their pain on this scale, it is important to provide consistent verbal anchors to the scale [12]. Most commonly, the anchors are "0 = no pain" and "10 = worst pain possible" or "10 = pain as intense as you can imagine" [10].

In addition to pain ratings, it is important to ask patients their expectations regarding pain relief. Asking "At what level of pain do you feel comfortable?" recognizes that patients with chronic pain, including those with chronic cancer pain, do not necessarily expect pain intensity scores to reach zero [13]. Use of such personalized pain goals may allow adequate analgesia while avoiding the overtreatment of pain and resultant adverse effects.

Pain Mechanisms

In addition to assessing pain intensity, the pathophysiology and trigger of the pain should be considered. No universally accepted system for classifying cancer pain exists [14]. Nonetheless, cancer pain is often described in terms of the pathophysiology of the pain and is broadly divided into nociceptive or neuropathic pain. Nociceptive pain is caused by tissue injury and can be further subdivided into visceral pain (from organs) or somatic pain (related to bones, joints, soft tissue). Visceral pain (e.g., peritoneal carcinomatosis) is more poorly localized than somatic pain (e.g., bone metastases). Neuropathic pain is related to dysfunction of nerves; this dysfunction may be central or peripheral and has many possible etiologies, including direct compression of a nerve or related to treatment (e.g., inflammation post-radiation). Often, those with cancer suffer from complex pain states combining both nociceptive and neuropathic mechanisms. Chronic pain in cancer survivors may have a unique etiology and symptomatology [6]. Studies have shown that chronic pain affects approximately one-third of cancer survivors and that, even among survivors who are disease free, approximately one-third continue to use opioids long term [15, 16]. Considering the pathophysiology of the pain is important because different types of pain may respond to treatments differently. Additionally, patients with cancer may suffer from non-cancer-related pain syndromes such as pre-existing diabetic neuropathy or arthritis pain. Although these pain syndromes are not directly related to the cancer, they can nonetheless contribute to patients' psychological distress and suffering.

Other historical factors, such as recent treatments and the stage of the cancer, can also aid the emergency physician in defining a trigger for the pain. This information can help the physician determine if the pain represents a reversible pain crisis, an anticipated worsening related to recent treatment, or a worsening related to progression of disease. A new pain or pain in a new location may represent disease progression and as such may require more extensive diagnostic evaluation than an increase in intensity of a known chronic pain.

Before beginning an extensive diagnostic search for the cause of a new pain and before starting a patient on a new analgesic, it is important to discuss the goals of care with the patient as part of a shared decision approach to care. These conversations can be difficult because of the lack of a pre-existing relationship, but are nonetheless important. The extent of the patient's diagnostic evaluation will depend on their goals of care and should take into consideration the risk or discomfort of diagnostic tests and what action would be taken with different results of those tests.

Oligoanalgesia

Any discussion of pain control in emergency medicine should include a discussion of oligoanalgesia – the underuse of analgesics. Oligoanalgesia has been a problem for cancer patients but is perhaps improving in recent years. A recent review found that the percentage of cancer patients with undertreated pain decreased from 43% to 32% over the course of 6 years [17]. This estimate implies that, while there has been an improvement in the treatment of pain in cancer patients, many patients seeking care in the ED for breakthrough pain may still have had inadequate baseline pain control. In fact, one recent study found that opioid-tolerant cancer patients were less likely to receive an adequate initial pain medication dose in the ED if they had higher home opioid doses [18]. Psychosocial factors such as depression, spiritual concerns, or misconceptions regarding prescribed medications may also contribute to oligoanalgesia in cancer patients [19]. The problem of oligoanalgesia for these patients is then compounded by a well-established history of oligoanalgesia in the ED itself. Specifically, recent studies have found that pain is undertreated in the ED and that disparities in pain treatment exist related to age and race [20–23]. Many factors likely contribute to oligoanalgesia in the ED. One concern in particular relates to significant tension between providing adequate analgesia and ongoing concerns relating to drug misuse, addiction, and deaths from prescription opioids in the USA [24]. According to the Centers for Disease Control and Prevention, the overall opioid prescribing rate decreased 19.2% between 2006 and 2017, with the largest annual reductions occurring in the most recent 4 years [25]. A study regarding opioid prescribing practices between 2007 and 2013 showed that opioid prescribing stayed relatively constant for cancer patients while it increased by approximately 2% for non-cancer patients [26]. Further research will need to be conducted to monitor these trends and watch for possible decreases in opioid prescriptions to cancer patients as the opioid epidemic continues and overall opioid prescribing declines. In the context of the cancer patient in the ED, the immediate focus should be on controlling the breakthrough pain during the ED visit. Decisions about new prescription analgesics from the ED can be made in conjunction with the treating oncologist or palliative care physician.

Treatment Options

Treatment of cancer pain should be individualized. There are many treatment modalities available to the cancer patient, including pharmacologic, interventional (e.g., injection therapies, neural blockade), rehabilitative (e.g., therapy for lymphedema), psychological (e.g., cognitive behavioral therapy), neurostimulation, or integrative (e.g., massage) [27, 28]. Those modalities may be applied singularly or in a combined modality fashion. Most of these therapies are not immediately accessible to the emergency physician; thus, while an awareness of these therapies is important, the primary tools at the emergency physician's disposal to improve pain are pharmacologic.

WHO Analgesic Ladder

Over 30 years ago, in 1986, the World Health Organization published recommendations for the management of cancer pain. These recommendations included a three-step analgesic "ladder" intended to guide the selection and escalation of analgesics [29] (Fig. 56.1). This model has been frequently used for not only cancer pain but other painful syndromes. Over the intervening 30 years, modifications to the existing ladder have been suggested, including eliminating the second step of the ladder, adding a fourth step, or "fast tracking" patients to the top of the ladder [30, 31]. When considering the individual patient, it is important to reconcile evidence-based clinical guidelines and new information (e.g., new medications, importance of risk assessment) with the original WHO consensus-based guidelines [27]. However, the WHO analgesic ladder provides a good framework for the

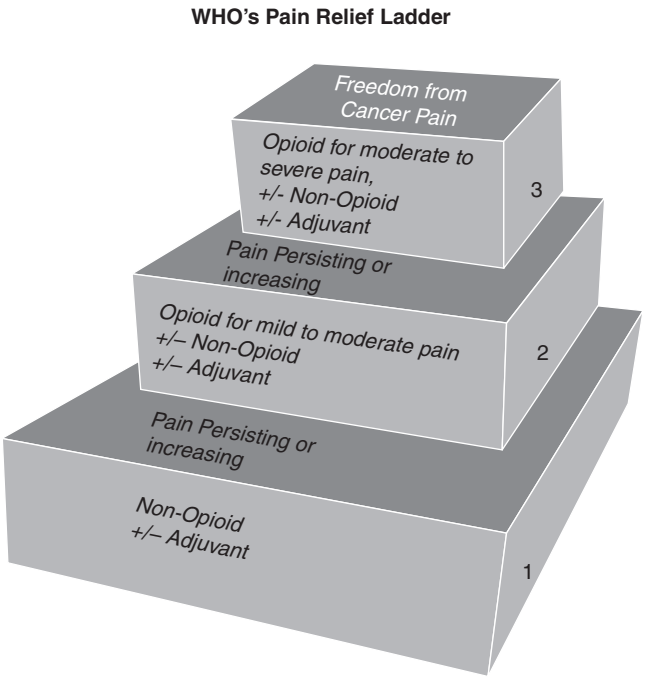

Fig. 56.1 WHO analgesic ladder. (Reprinted with permission of The World Health Organization: http://www.who.int/cancer/palliative/pain-ladder/en/. Accessed 18 Mar 2020)

discussion of the different types of analgesics and the rationale that analgesic choice should be given commensurate to the patients' pain intensity, as measured by a pain scale.

Non-opioid Analgesics

Non-opioid analgesics include nonsteroidal anti-inflammatory medications (NSAIDs) and acetaminophen. These medications are useful in the management of acute and chronic pain. One limitation of both NSAIDs and acetaminophen is a "ceiling effect" wherein increasing the dose above a certain level does not provide any additional pain relief. The ceiling effect therefore limits the ability of these medications to be titrated for severe pain; however, even when NSAIDs and acetaminophen alone are insufficient for pain control, they should be considered as a co-analgesic to opioid treatment because they may reduce the dose of opioid needed to achieve pain control.

Acetaminophen is a non-salicylate analgesic that does not have any antiplatelet activity. It does not have clinically detectable anti-inflammatory effects; however, it may be a useful analgesic for some conditions. One concern with acetaminophen is potential hepatotoxicity. The FDA advises that doses in patients with normal liver function should not exceed 4000 mg/day, and the National Comprehensive Cancer Network (NCCN) panel suggests that providers consider limiting chronic administration of acetaminophen to 3000 mg or less per day [6].

NSAID medications possess both anti-inflammatory and analgesic properties. These medications act by inhibiting isoforms of an enzyme called cyclooxygenase (COX); inhibition of this enzyme results in decreased synthesis of prostaglandins. Different classes of NSAIDs have varying selectivity for the isoforms of the COX enzyme (COX-1 and COX-2). Depending on the source of the patient's pain and comorbidities, a choice of a nonselective or selective NSAID can be made. Patients who respond to one of the NSAIDs may not respond as well to others. NSAID medications also have significant side effects that should be considered prior to administration. All NSAIDs cause a reversible decreased platelet aggregation (while the drug is at therapeutic serum concentrations). If patients already have a high risk of bleeding, the use of NSAIDs should be carefully considered. All NSAIDs can cause gastrointestinal (GI) adverse effects, ranging from dyspepsia to bleeding gastric ulcers. Medications to protect the gastric mucosa, such as a proton pump inhibitor (PPI), should be considered to minimize the risk. NSAIDs can also lead to renal insufficiency through multiple mechanisms, and caution should be used when patients have risk factors for renal impairment, including advanced age, dehydration, diuretic use or multiple myeloma.

Opioid Analgesics

When a patient's pain is not adequately controlled by non-opioid analgesics, opioid analgesics represent the next step on the WHO analgesic ladder. Opioid medications can be classified as naturally occurring opioids (e.g., morphine, codeine) and semisynthetic (e.g., dihydromorphone, oxycodone) or synthetic compounds (e.g., fentanyl, methadone). Opioids can further be classified by their action at the opioid receptor (agonist, partial agonist, or antagonist) and by the receptor where they primarily function (mu, delta, or kappa). Opioid receptors exist in both the central nervous system and the peripheral tissues; however, the clinical effects of opioids are thought to be related primarily to the opioid action on central rather than peripheral receptors [32].

Tramadol is a mixed-mechanism drug that acts as a weak mu opioid receptor agonist but also demonstrates some norepinephrine and serotonin reuptake inhibition. A recent Cochrane review concluded that there is little evidence to support the use of tramadol for cancer pain and that it is less effective than morphine [33].

Opioids can be administered by multiple means, including oral, transmucosal, rectal, transdermal, intranasal, subcutaneous, or intravenous routes. The intramuscular route is generally not recommended as it provides no pharmacologic advantage over subcutaneous administration and has the disadvantage of causing additional pain. If time permits, the oral route of administration is preferred [29]; however, for patients in a severe pain crisis, more rapid pain control may necessitate the use of intravenous opioids. Opioids, with the exception of methadone, follow first-order kinetics and achieve their peak plasma concentration (and maximal analgesic effect) along a similar timeline: 60–90 min for oral/rectal administration, 30 min for subcutaneous/intramuscular administration, and 6–10 min for intravenous administration [19, 34].

If time permits the administration of an oral opioid, it is also important to remember that many oral opioids are combination pills with a non-opioid analgesic (e.g., acetaminophen). The presence of the non-opioid limits titration of the medication orally to avoid toxicity from the co-analgesic (e.g., maximum of 4000 mg/day of acetaminophen).

For those patients in more severe pain, or requiring intravenous dosing for other reasons (difficulty swallowing), there are many available intravenous opioids. For the opioid-naïve patient, morphine is a safe, standard drug to start therapy [6, 35]. However, morphine should be used with caution in patients with renal impairment because one of the active metabolites (morphine-6-glucoronide) can accumulate with renal dysfunction. For intravenous dosing of the opioid-naïve patient, a starting dose of 2–5 mg of morphine (or equivalent) is recommended. This dose should be followed by a reassessment at 15 min, and if the pain score remains

Table 56.1 Equianalgesic dosing[a]

Opioid	Oral dose	Parenteral dose	Duration of action (h)
Morphine	30 mg	10 mg	3–4
Hydrocodone	30 mg	–	4–8
Hydromorphone	7.5 mg	1.5 mg	3–4
Oxycodone	15–20 mg	–	3–6
Fentanyl[b]	–	50–100 μg	1–2

[a]This table is a guide only. Equianalgesic dosing tables vary subtly and this table should not replace more in-depth review of dosing
[b]Applies to IV conversion only. For transdermal fentanyl conversion, see package insert

unchanged or increased, the initial dose given should be increased by 50–100%. If the pain score is decreased but still moderate (e.g., 4–7), the same initial dose should be repeated, and if the pain level is low (e.g., 0–3), then the initial dose can be used as needed [6].

For the opioid-tolerant patient (a patient that takes at least 60 mg/day oral morphine, 25 mcg/hr transdermal fentanyl, 30 mg/day oral oxycodone, 8 mg/day oral hydromorphone, 25 mg/day oral oxymorphone, or an equianalgesic dose of another opioid for 1 week or longer), the drug choice will likely be informed by their home medications and prior opioid use [6]. Patients may be on a combination of opioid medications at home (e.g., transdermal and oral preparations or long-acting and immediate-release preparations). In order to identify the approximate opioid use of a patient at home, and thereby to more accurately estimate their pain control needs in the ED, equianalgesic dosing tables can be used (Table 56.1).

Equianalgesic dosing tables were first constructed in the 1960s and 1970s to codify the relative potency of different opioid formulations. These tables can be used to calculate patients' baseline outpatient opioid use. Recently, experts have expressed concerns over the limitations of the data used to construct the dosing tables and their applicability in the clinical realm [36, 37]. Specifically, the studies used to construct these tables were primarily acute rather than chronic pain. Research also suggests that there is significant variability in the dose needed to achieve pain relief between individuals which may be influenced not only by prior exposure to opioids but also by age, gender, and genetic polymorphisms that affect opioid binding [9]. Given this potential for wide variability in dose response, the equianalgesic dosing recommendations as well as the starting doses noted above should be considered a guideline, to be individualized by the practicing physician.

When using the equianalgesic dosing tables, the first step is to calculate the patient's "equianalgesic dose equivalent" based on the analgesic use over the previous 24 h. After choosing the opioid to administer, the initial IV dose will be determined by converting the previous 24-h requirement to a total IV equivalent. Once a 24-h IV equivalent has been calculated, the first dose should be 10–20% of that total dose [6]. After the first dose is given, a reassessment should occur within 15 min, and, similar to opioid-naïve patients, if the pain level remains ≥8, the dose should be escalated by 50–100%. If the pain is moderate (e.g., 4–7), the same initial dose should be repeated, and if the pain level is low (e.g., 0–3), then the initial dose can be used as needed [6].

Another reason to exercise caution when switching opioids is because of opioid cross-tolerance. Patients on opioids will develop tolerance; this is expected. One of the signs of tolerance is achieving less pain relief from the same dose of the medication. One approach to optimize pain control when tolerance is present is to switch (or rotate) the opioid being used. In other clinical situations, opioid rotation may be useful to minimize adverse effects. Although there is some cross-tolerance between opioids, it is not complete. This incomplete cross-tolerance is due to many factors, including individual variations in metabolism, concurrent medications that impact metabolisms, and individual variations in opioid receptors. Due to this variability in individual response when switching opioids, it is recommended to first calculate the equianalgesic dose and then to decrease the calculated dose by 25–50% [9, 36]. Ultimately, the clinical situation should be considered when choosing a 25% reduction vs. a 50% reduction, including factors such as the patient's pain control and individual adverse effect profile. Two medications with exceptions to the 25–50% automatic reduction are methadone and fentanyl. Methadone has a nonlinear relationship to other opioids [19]. When switching to methadone, larger automatic dose reductions are recommended (75–90%) [27]. Converting to transdermal fentanyl should follow the calculated equianalgesic dose in the package insert and does not require an automatic dose reduction [28]. Initiation and titration of methadone and fentanyl are complex and should only be done by emergency physicians in consultation with the treating oncologist, pain specialist, or palliative care team.

Opioid Side Effects

Opioid analgesics have many potential side effects that may make patients or prescribers reluctant to use the medications or use them in adequate doses to achieve pain control. Patients can develop a tolerance to certain side effects (e.g., nausea or respiratory depression); however, other side effects (e.g., constipation) are not decreased with chronic use (Table 56.2). Several symptoms including pruritus and rash may result from either allergy or direct opioid effects from mast cell degeneration and histamine release. True anaphylaxis to opioids is rare, but can occur. Care must also be taken to distinguish between opioid side effects and the underlying clinical manifestations of comorbidities such as dehydration or drug interactions [38].

Table 56.2 Adverse effects of opioids

Adverse effect	Develop tolerance	Treatment
Constipation	No	Use laxative prophylactically
Pruritus	No	Opioid rotation
Nausea	Often	Opioid rotation Anti-nausea medications
Sedation	Yes	Decrease or rotate opioid Discontinue other medications that can cause sedation
Respiratory depression	Yes	Decrease or rotate opioid Discontinue other medications that can cause sedation Sedation will precede respiratory depression
Delirium	No	Decrease or rotate opioid Discontinue other medications that can cause delirium Avoid sedating medications unless necessary and consider the use of antipsychotic medications
Hyperalgesia	No	Rotate opioid Use non-opioid medication/strategy

Respiratory depression is one of the most feared side effects of opioids; however, tolerance can develop in a period of days to weeks of being on opioids, and it is rare in patients taking opioids chronically. Respiratory depression occurs in a dose-dependent fashion due to opioid action at the brain stem respiratory centers. Concomitant use with other sedating medications, such as benzodiazepines, may increase the risk for respiratory depression. Sedation precedes respiratory depression. If there is a concern for respiratory depression (from either home medications or medications administered in the ED), naloxone can be administered. Naloxone is an opioid receptor antagonist which will reverse the effects of the opioid; however, the half-life of naloxone is shorter than the half-lives of many opioids, so patients need continued observation if there was a concern for respiratory depression. Naloxone can precipitate acute and severe withdrawal symptoms in the patient taking chronic opioids and should be administered cautiously. Diluting 1 mL of the standard 0.4 mg/mL concentration of naloxone in 9 mL of normal saline (for a total of 10 mL) and administering 1–2 mL (0.04–0.08 mg) approximately every minute until respiratory rate improves will allow reversal of respiratory depression while minimizing withdrawal symptoms.

Nausea is one of the most common side effects of opioids with estimates ranging from 10% to 40% of patients experiencing nausea [39]. Opioid causes nausea through several mechanisms including stimulation of the chemoreceptor trigger zone, slowed gastric emptying, and effects on the vestibular system. Depending on the source of the nausea, different antiemetics will have variable efficacy. Dopamine receptor antagonists (e.g., prochlorperazine or haloperidol) or serotonin antagonists (e.g., ondansetron) will be the most useful for nausea related to the chemoreceptor trigger zone, whereas promotility agents (e.g., metoclopramide) may have more impact when gastric stasis is causing the nausea.

Constipation is another common side effect that emergency physicians should anticipate in patients for whom they prescribe opioids. Among cancer patients on chronic opioids, the prevalence of constipation is as high as 90% [40]. Opioids slow bowel transit time and peristalsis, and tolerance to constipation does not develop over time. When a cancer patient presents with symptoms of constipation, it is important to rule out bowel obstruction/impaction before starting medications to treat constipation.

Pharmacologic agents to ease constipation are typically divided into five categories: bulk-forming agents, softeners, stimulants, osmotic agents, and peripheral mu opioid receptor antagonists. Bulk-forming agents increase fecal mass to stimulate peristalsis. Stimulants act by increasing intestinal motility, whereas osmotic agents (e.g., polyethylene glycol, lactulose) act by increasing water content in the large bowel. The NCCN recommends prophylaxis with both a stimulant (or pro-kinetic) agent and the osmotic agent polyethylene glycol [6]. Bulk-forming agents and stool softeners are unlikely to be effective in isolation. A 2010 Cochrane review recommended the use of polyethylene glycol over lactulose for chronic constipation because of better outcomes related to stool frequency, form, associated abdominal pain, and use of additional products [41]. If constipation persists despite the above medications, the provider can titrate the existing regimen or add an additional agent, such as magnesium hydroxide [6]. Two peripherally acting mu opioid receptor antagonists may be considered if laxative therapy has failed. Both methylnaltrexone, administered subcutaneously or orally, and naloxegol, an orally active agent, have demonstrated efficacy in reversing opioid-induced constipation [42, 43].

Adjuvants (Co-analgesics)

Adjuvant medications, also known as co-analgesics, are a diverse group of drugs that may have a primary indication other than pain; however, they work to enhance the effects of traditional analgesics, "have independent analgesic activity in certain painful conditions, or counteract the adverse effects of analgesics" [9, 44]. The emergency physician may not be starting these medications in the ED to achieve pain relief in the acute setting; however, it is important to have a familiarity with these medications both when taking the patient's history and when discussing future treatment options with their outpatient oncologist or palliative care team.

Adjuvant medications are on every step of the WHO pain ladder, and they encompass many drug classes, including

Table 56.3 Adjuvant drugs for use during ED cancer pain crisis[a]

Category	Example	Indication	Comments
Corticosteroids	Dexamethasone Methylprednisolone	Spinal cord compression Bone metastases Neuropathic pain	Often used to treat emergencies associated with cancer progression (e.g., spinal cord compression) but also have utility for other painful conditions including bone metastases and neuropathic pain The use of corticosteroids should be discussed with the oncologist given possibility of affecting treatment course
Benzodiazepines	Lorazepam Diazepam	Anxiety Muscle spasm	Use with opioids can be limited because of sedation
Anticonvulsants	Gabapentin Pregabalin	Neuropathic pain	Dose adjustment for renal insufficiency is required. Initiation requires close follow-up for titration
Anesthetics			
Local	Topical lidocaine 5% patch	Neuropathic pain	FDA approved to be worn for 12 h and then removed for 12 h
Systemic	Ketamine	Intractable pain	Dissociative anesthetic without significant respiratory depression Use of low-dose (sub-anesthetic) ketamine + opioids for treatment of acute cancer pain is an area of ongoing research
Intraoral	Magic/miracle mouthwash Lidocaine gel	Mucositis	Used in conjunction with parenteral opioids and good oral care regimens

[a]Other adjuvant drugs include antidepressants, stimulants, bisphosphonates, and cannabinoids; these drugs are not included in the table because they are less likely to be used in the acute pain setting in the ED

antidepressants, corticosteroids, anticonvulsants, local anesthetics, muscle relaxants, and benzodiazepines. The addition of some of these medications may result in a better balance of patient safety and efficacy of pain relief. However, caution must be used to avoid oversedation or other side effects related to polypharmacy as many co-analgesics are potentially sedating.

Specific adjuvant medications that may be useful to emergency physicians for use in patients with pain crises are outlined in Table 56.3.

Psychosocial Support

There are many non-pharmacologic interventions that have been shown to be helpful for cancer pain, including physical interventions (e.g., massage, physical therapy), cognitive-behavioral interventions (e.g., breathing exercises, music), and spiritual interventions (e.g., chaplain support) [6]. While emergency physicians likely won't have access to all of these modalities when treating acute pain, it is important for them to provide psychosocial support and perform a focused assessment of the patient's support system, cognitive status, and level of psychological or spiritual stress as this will likely affect therapeutic outcomes [19, 45].

Opioid Safety

As referenced earlier, providers may feel tension when attempting to balance the use of opioids to achieve adequate analgesia with the current public health crisis of addiction, misuse, abuse, overdose, and death related to opioids. Cancer patients are also at risk for these same adverse outcomes associated with opioids. Using validated screening tools, one ED-based study found that one-third of cancer patients on opioids presenting to the ED were at high risk for opioid misuse and suggest screening for opioid misuse in the ED [46]. In addition, the majority of cancer patients (and parents of pediatric cancer patients) do not store opioids safely, save unused opioids, and are unaware of how to safely dispose of opioids [47, 48]. Finally, a recent study found that the incidence of ED visits for opioid overdose in patients with cancer doubled between 2006 and 2015 [49]. Despite the fact that cancer patients are at risk for adverse outcomes associated with opioids, emergency providers must still strive to effectively control pain. The principles listed below can help emergency providers treat cancer patients with uncontrolled pain in the ED while also maximizing safe opioid use [6, 34, 50].

- Use as low of a dose as possible to achieve adequate analgesia and minimize side effects
- Avoid combining opioids with other potentially sedating medications, particularly benzodiazepines
- Titrate doses carefully, particularly in patients at high risk of adverse effects (patients with decreased renal/hepatic function, lung disease, upper airway compromise, sleep apnea, and/or poor functional status)
- Review prescription drug monitoring program databases if available and monitor patients for signs of misuse/abuse of opioids.
- Work closely with primary care doctors, oncologists, and palliative care teams, relay any concerns regarding misuse/abuse of opioids, discuss any new/updated prescriptions, and ensure close follow-up
- Educate patients and caregivers about safe use, storage, and disposal of opioids

EPEC-EM

The Education for Physicians on End-of-Life Care (EPEC™) curriculum is intended to teach the core competencies of palliative care and is a useful resource for physicians wanting to learn more about this topic [51]. Supported by the National Institutes of Health, the EPEC-Emergency Medicine curriculum is an adaptation of the original EPEC curriculum designed for those who work in the emergency department. One of the tenets of care advocated by EPEC™-EM curriculum and others is the rapid titration of opioids to achieve pain control.

Rapid Titration

Rapid titration of opioids has been advocated to achieve adequate pain control for patients presenting to the ED rather than traditional outpatient oral medication titration which can require several days to achieve analgesia [52]. Several different protocols, utilizing various opioids, have been evaluated in the literature and found to be safe [53–55]. The commonalities between the recommended protocols include having a formal numerical assessment of pain followed by administration of medications based on severity of pain and a formal reassessment of pain at a scheduled interval (ranging from 5 to 30 min). These cycle or reassessment and medication administration continue until either pain control is achieved or unwanted side effects limit further opioid use.

EPEC-EM advocates the following approach to the rapid assessment of cancer pain [19, 34]:

Step 1: Assess the patient and history This assessment should include discussion of the home medication use and dosing of both opioids and adjuvants. Additionally, the responsiveness of the pain to opioids should be estimated.

Step 2: Administer treatment For patients with severe pain (>7/10), IV medications should be given. For those with mild to moderate pain, the best route and choice of medication can be individualized based on the assessment and goals of care.

- For opioid-naïve patients: 0.1 mg/kg of IV morphine equivalent (less if patient is elderly or high risk).
- For opioid-tolerant patients: 10% of the previous 24-h IV morphine equivalents.

These recommend starting doses are guidelines and should be customized to the clinical scenario and take into account the patients' presentation, polypharmacy, and goals of care.

Step 3: Reassess the patient's pain, and reassess for unwanted side effects (somnolence or confusion) when Cmax has been achieved

The timing of the reassessment can vary based on when the maximum concentration (C_{max}) of the medication is reached (calculated by route of administration, e.g., approximately 15 min for IV administration). This timing is chosen because the maximum side effects will be experienced at the time of C_{max} [19]. Although parental agents will reach C_{max} faster than orally or subcutaneously dosed opioids, there is some variation within parental agents as to the speed of achieving peak plasma concentrations. Fentanyl, which is more lipophilic than morphine, can achieve peak plasma concentrations within 5 min and therefore may be particularly useful for rapid titration [52, 55].

Step 4: Achieve adequate pain control by redosing the medication if necessary For patients with persistent severe pain (>7/10) in whom no unwanted side effects have been noted, the initial opioid dose can be doubled. For those in whom there has been an improvement in pain control, but an unacceptable level of pain persists, the initial dose can be repeated. Both of these strategies will increase the effective C_{max} and thereby decrease pain.

Steps 3 and 4 should be repeated until pain control is achieved or side effects limit further administration of opioids. Additionally, adjuvant medications should be considered.

Step 5: Determine the plan for disposition, discharge instructions, and follow-up Patients whose pain cannot be adequately controlled in the ED should be considered for admission. Similarly, patients may have other medical conditions aside from pain that prompted their ED visit and should be admitted if further evaluation or treatment is needed. In the case that a patient presented solely for pain and the rapid titration of pain medication in the ED has controlled their pain, discharge can be considered. Adjustments to the patients' long-acting and breakthrough opioids can be determined based on patients' previous medication use, allergies, and tolerance of medications in the past. Methadone should not be started or titrated in the ED without consultation because of its complicated dosing. Communication with the patients' treating primary care physician, oncologist, or palliative care specialist is important, as is ensuring follow-up for the discharged patient.

Palliative Sedation

Distinct from the rapid titration of medications, another strategy that can be considered in the ED for pain control in cancer patients with intractable pain is "palliative sedation." A commonly accepted definition for palliative sedation ther-

apy is "the use of specific medications to relieve intolerable suffering from refractory symptoms by a reduction in patient consciousness" [56]. The goal of palliative sedation is to relieve distress and not to speed the dying process and therefore is distinct from euthanasia or physician-assisted suicide. Morphine has been used for the relief of dyspnea but is not effective at achieving sedation. Ketamine, a short-acting NMDA receptor antagonist, preserves respiration but can effectively achieve sedation and be used for intractable pain or agitation [57]. Emergency physicians will likely have some familiarity with ketamine from procedural sedations and use for acute, opioid-refractory pain, but when initiating it for palliative sedation, consultation with the palliative care team may be useful.

Consultation

Once the emergency physician has assessed the etiology of the cancer patient's pain, he or she may consider consulting specific services for assistance. Specific consulting services are outlined in Table 56.4.

Palliative Care in the Emergency Department

Consultation with the cancer patients' treating physicians, including their palliative care doctor, is useful not only in coordinating discharge but also in determining their treatment in the ED [58]. Some patients presenting to the ED may not have previously interacted with a palliative care physician; the emergency physician can and should consider consulting with palliative care if deemed necessary after an evaluation of the patient and discussion of wishes, regardless of patients' prior engagement with palliative care. The "Improving Palliative Care in Emergency Medicine" project has recommended the use of a screening tool to assist in the decision to consult palliative care from the ED [59]. If the patient has a serious, life-threatening illness (in the case of cancer, this includes patients with metastatic or locally advanced incurable disease) and any one of the following conditions, palliative care consultation should be considered:

- Not surprised: You would not be surprised if the patient died in the next 12 months.
- Bounce backs: The patient has had >1 ED visit or hospital admission for the same condition within several months.
- Uncontrolled symptoms: The current ED visit is prompted by difficult-to-control physical or psychological symptoms.
- Functional decline: Their presentation reveals a decline in function, feeding intolerance, unintentional weight loss, or caregiver distress.
- Increasingly complicated: There exist complex long-term care needs that require more support.

The ED is an important point of contact for patients with palliative care needs, and, more recently, there has been growing interest in studying the effects of palliative care in the ED [60]. A recent study found that greater than 50% of patients with active cancer presenting to the ED had at least one unmet palliative care need (e.g., uncontrolled pain, feeling overwhelmed, difficulty with getting care/medications) [61]. Despite this apparent need, few palliative care consults are placed from the ED; one study showed that only 5% of consults to palliative care occurred in the ED [62]. While the ED is a fast-paced environment and there are perceived barriers to consultation, research shows that screening and referral for palliative care consultation *are* feasible in the ED [63, 64]. One study even found that they were able to effectively screen for unmet palliative care needs in the ED and then offer services to address those needs using existing ED resources (e.g., pharmacist and social worker) without increasing ED length of stay [61]. A 2020 systematic review of the existing literature found that palliative care in the ED is feasible, may improve quality of life, and does not appear to decrease survival; the authors, however, were unable to determine its effects on healthcare utilization [60]. Further research is needed to determine the most efficient and effective method of linking palliative care with emergency medicine.

Table 56.4 Consulting services

Service	Indication
Oncologist	Discuss therapeutic plan, disposition
Palliative care	Symptom control, provide support
Pain specialists	Refractory symptoms, consideration for interventional strategies (e.g., nerve block, regional infusion)
Physical therapy, occupational therapy	Other modalities for pain control, improving pain related to movements
Psychiatry Social work Spiritual care	Relief of psychological pain Psychosocial support, relief of psychological pain Relief of suffering from unmet spiritual, existential needs

Summary

Patients with cancer often seek care in the emergency department, for both pain related to their condition and for other symptoms. Regardless of the symptom prompting the visit, it is important to assess and manage pain in this population. Multiple classes of medication to acutely control pain are

available to the emergency physician. It is important to assess the pain formally, using pain scales, and to discern if the pain crisis is related to progression of disease, expected breakthrough pain, or if a search for a new pain precipitant is needed. Regardless of the cause, pain should be managed quickly, and the patients' pain score should be frequently reassessed. The exact choice of medications will vary depending on the clinical situation and should be determined after reviewing the patients' home medications, comorbidities, and goals of care.

Dyspnea in the Dying Patient

57

Ashley Shreves

Case Study

A 65-year-old female presents with severe shortness of breath. On review of the medical record, this patient has widely metastatic lung cancer, diagnosed 3 years prior, and recent imaging studies have shown progression of disease, despite chemotherapy and radiation. In the past 2 weeks, she has become weaker and has lost all interest in food. On review of the oncologic clinic notes, there has been discussion about enrolling the patient in a clinical trial, but her oncologist also suggested that she consider enrolling in hospice. In the ED, the patient's triage VS are abnormal: HR 120, RR 35, O2 sat 80%, BP 110/60, and temp 100. The patient is too ill to engage in discussions about goals of care, and her husband, who is her healthcare power of attorney, has not arrived to the hospital yet. The nurse asks: "Should we get everything ready for you to intubate the patient?" As there are no documented advance directives in the patient's electronic medical record and no surrogate decision-maker available for discussion, you decide to give patient a trial of noninvasive ventilation, while ordering labs and a chest X-ray, with the hopes of identifying the underlying etiology of her dyspnea. The patient initially tolerates the BIPAP well, with her RR improving from 35 to 25 and her oxygenation improving from 80 to 95%. She also appears more comfortable. Her labs show multiple abnormalities, including acute renal failure, an elevated troponin, a lactate of 5, and a WBC count of 20. Chest X-ray shows a small effusion and diffuse pulmonary metastatic disease, increased from the prior imaging study. When the patient's husband arrives, he tells you that his wife had actually decided to enroll in hospice but they hadn't had a chance yet and they panicked this morning when she became short of breath. He's certain that she would want to go home today, if hospice care could be arranged. You administer 2 mg morphine intravenously and this further improves her dyspnea. Thirty minutes later, she needs an additional dose: this time 4 mg is given. She is then weaned from the BIPAP and is comfortable on 4 L of oxygen, delivered via nasal cannula. Hospice is called and says they can manage the patient's dyspnea at home and can have all of the necessary equipment available, including oxygen, by the afternoon. Both the patient and her husband are comfortable with this plan, and the patient is discharged home with hospice care from the ED.

Introduction

Dyspnea is a broad, general term used to characterize any sensation of respiratory discomfort. In a statement by the American Thoracic Society from 2012, dyspnea was appropriately defined as "a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity" [1]. It is important to emphasize that dyspnea is indeed subjective and thus a *symptom*; this contrasts to classic *signs* of respiratory distress including tachypnea, nasal flaring, and accessory muscle activation. As such, a variety of language may be used to describe the sensation: terms such as breathlessness, shortness of breath, tightness, air hunger, difficulty breathing, labored breathing, and heavy breathing. All of these descriptors relate to an increased awareness of the breathing process—normally an unconscious physiologic activity—caused by any number of insults to be described later in this chapter.

As a common endpoint for multiple disease processes, dyspnea is remarkably prevalent in the advanced cancer population at the end of life. Some degree of dyspnea has been reported in up to one-third of all older adults living at home, approximately half of all patients admitted to tertiary care hospitals, 70–80% of patients with terminal cancer in the last 6 weeks of life, and up to 94% of patients with chronic lung disease at some point in the last year of life [2–6]. It is both debilitating for patients and emotionally upsetting for their families and caregivers. It also ranks among the most

distressing symptoms at the end of life, leading to a marked reduction in the quality of life and a source of both fear and anxiety for all parties involved [7].

Derangements of the pulmonary/respiratory system have long been recognized by emergency providers as an indicator of serious illness and of the potential need for prompt intervention. Patients who present to the emergency department (ED) in respiratory distress appear extremely ill and receive rapid attention, in many cases leading to intubation and the use of mechanical ventilation. When caring for a patient with end-of-life/terminal dyspnea, however, for whom these aggressive interventions may be misaligned with patient's goals of care, the necessity for rapid treatment is no less imperative. In these situations, a focused and patient-centric plan coupled with an empiric approach to symptom management is necessary. This chapter will present a structured approach to the management of dyspneic patient at the end of life whose goals are not purely curative and for whom comfort and quality of life are of primary importance. As emergency providers are well aware, responding to acute symptomatology often requires treatment prior to definitive diagnosis, and the management of terminal dyspnea is no different. In some instances, however—namely, those with reversible causes—diagnosis is worth pursuing, and those instances will be discussed herein.

Neurophysiology

The pathophysiology of dyspnea is complex and remains poorly understood compared to other common clinical phenomena such as pain or nausea. The best current evidence counters the traditional model of dyspnea as a singular entity, instead suggesting multiple neurophysiologically distinct afferent pathways each replete with a unique subjective experience and a different set of predisposing stimuli [8, 9]. To illustrate, one such multifaceted model subdivides dyspnea into (1) air hunger, which is the urge to breathe characterized by an increased ventilatory drive secondary to hypercapnia; (2) increased work of breathing, associated with exhaustion due to effortful breathing; and (3) tightness, a sensation most associated with bronchoconstriction and asthma [10]. While the details of this particular multidimensional model of dyspnea are beyond the necessary scope of knowledge for the emergency provider, it is worth noting that data will continue to emerge on these discrete neurologic pathways, with potential implications for specifically targeted therapeutic options in the future. It also highlights the need for careful appraisal of the literature concerning dyspnea and potential for conflicting study outcomes, as the majority of evidence to date is based on the assumption of a single unified perception of dyspnea.

A more practical understanding of dyspnea as it relates to oncologic etiologies focuses primarily on the brainstem respiratory complex and its relation to the most common variant of dyspnea, air hunger [11]. Through direct action on medullary chemoreceptors, $PaCO_2$, PaO_2, and pH act to regulate respiratory drive by modulating both rate and effort [12]. When an insult causes disruption in homeostasis of any of these variables, an appropriate motor response is elicited to correct this imbalance. The end result of these physiologic insults, whether they be mechanical, metabolic, or neuromuscular, is often a failure to match ventilation with brainstem-mediated respiratory drive. Once this mismatch occurs, the patient develops a sensation of breathlessness and air hunger, which may then exacerbate the predisposing condition through increased metabolic demand. Anxiety and fear, sensations which both precipitate *and* are exacerbated by dyspnea, are cortically mediated (primarily limbic and paralimbic) and are distinct from those initial sensations mediated by the brainstem respiratory motor drive [13]. This neurologic distinction allows for multiple therapeutic approaches to be discussed.

Etiology and Prevalence

Dyspnea is widely prevalent in advanced cancer, with a marked increase in symptoms as patients near the end of life [4]. Furthermore, dyspnea is both commonly present in advanced cancer patients presenting to the ED and a predictor of death in this population [14]. While primary lung cancer conveys the highest risk of all malignancies for developing shortness of breath—affecting up to 84% in one large cross-sectional study—all primary cancers are associated with some increased incidence of dyspnea [3, 15]. There are many specific conditions associated with respiratory compromise which disproportionately affect patients with active malignancies. Below is a partial list of these diagnoses with particular emphasis on cancer-related etiologies and common comorbid conditions. Many are reversible, and these will be explored individually later in this chapter [16].

- Airway obstruction: foreign body/aspiration and tumor burden
- Anaphylaxis and angioedema
- Asthma/reactive airway disease
- Anemia: blood loss, nutritional deficiency, and chemotherapy-induced
- Behavioral/emotional: anxiety and panic attack
- Chronic obstructive pulmonary disease/emphysema
- Deconditioning/cachexia/muscle weakness
- Decreased cardiac output: myocardial ischemia, arrhythmia, tamponade, and hypovolemia

- Decreased chest wall compliance: hepatosplenomegaly, ascites, obesity, and tumor burden
- Diaphragmatic/respiratory muscle weakness: neuromuscular disorders and fatigue
- Metabolic acidosis: renal failure, sepsis, and toxic ingestions
- Pneumonia
- Pneumothorax
- Pulmonary edema/congestive heart failure
- Pulmonary effusion: malignant and infectious
- Pulmonary embolism
- Pulmonary hypertension
- Pulmonary fibrosis/interstitial lung disease: autoimmune, environmental, and secondary to radiation or chemotherapy
- Pulmonary receptor stimulation: environmental irritants
- Ventilation/perfusion mismatch

Complicating diagnosis and treatment, most patients will present with multiple, coexisting etiologies of dyspnea; a study of 100 advanced cancer patients revealed a median of 5 different abnormalities that could have contributed to their shortness of breath [17]. The most frequent cause for symptoms in this cohort was a direct pulmonary pathology related to disease progression; this was followed by treatment-related pathologies secondary to chemotherapy or radiation and then by nonmalignant etiologies such as underlying chronic lung disease. There were, in up to 30% of patients with dyspnea and advanced cancer, no clear identifiable causes for their dyspnea [17].

Evaluation

Arrival in ED/History

Evaluation of the undifferentiated patient with respiratory distress may be challenging in the emergency setting. Frequently, providers face an acutely unstable patient with limited access to complete medical history. Patients may arrive initially unaccompanied by family or caregivers to provide historical context to the hospital visit. In these situations, management should proceed as with any other emergency patient: with focus on stabilization of the airway, breathing, and circulation, as represented through legal advance directives. In many states, the increasingly utilized POLST (Physician Orders for Life-Sustaining Interventions) advanced directive contains the only legally recognized out-of-hospital Do Not Intubate (DNI) order and can provide critical guidance in the early management of unstable patients with advanced cancer. If the situation arises in which an intervention was made—such as endotracheal intubation—and it later becomes clear that this was misaligned with the patient's stated goals of care, there is no legal or ethical barrier to withdrawing these life-sustaining treatments in the ED [18].

Physical Exam

There are many elements of the physical exam in the dyspneic cancer patient which can aid in both prognostication and diagnosis. As patients may be unable to communicate either secondary to their chronic disease process or from their dyspnea, exam findings must be used to guide acute medical management. Classic signs associated with respiratory distress include gasping, accessory muscle activation, tachypnea, shallow respirations, and poor air movement on lung auscultation. Facial expressions should also be noted, as grimacing may suggest pain or discomfort from dyspnea [16]. Family members or caregivers may be especially helpful in this regard, as they may be more skilled at distinguishing specific nonverbal cues or changes from baseline appearance [19]. Chest auscultation for abnormal breath sounds may also guide management—diffuse wheezing may suggest an obstructive process such as asthma/COPD, while bibasilar or focal rales may be more indicative of pulmonary edema or pneumonia. Stridor is concerning for upper airway obstruction or allergic reaction. A focal or asymmetric decrease in breath sounds could indicate pulmonary effusion, pneumothorax, or hemothorax. Distant cardiac sounds or a cardiac rub is concerning for pericardial effusion. In patients with notable skin pallor, anemia may be contributing to dyspnea, while peripheral cyanosis would suggest a more significant hypoxic state. Abdominal distention may represent underlying malignant ascites, which may cause restriction in lung expansion and subsequent respiratory distress. Peripheral edema, especially a change from baseline, may indicate worsening heart or renal failure, while asymmetric extremity edema may be concerning for deep vein thrombosis and pulmonary embolism.

There is prognostic value in certain physical exam findings at the end of life. For example, the inability to clear oral secretions, colloquially known as a "death rattle," has been associated with a median time from onset to death of 23 h [20]. Other physical exam findings to guide expectations include respirations with mandibular movements (median time 2.5 h), extremity cyanosis (1 h), and inability to palpate radial pulse (1 h) [20]. A retrospective chart review of advanced cancer patients revealed the following historical and vital sign abnormalities as predictors of death within 2 weeks: triage respirations >28 (RR 12.7), pulse >110 (RR 4.9), history of uncontrolled progressive disease despite treatment (RR 21.9), and history of metastatic disease (RR 3.9) [21].

Laboratory Studies

There is no strong evidence to guide the decision to send laboratory studies in the acute emergency setting for the terminal cancer population. Consider sending labs if they could provide diagnostic clues which will lead to action consistent with the patient's stated goals. In some patients, the placement of an intravenous line alone is an unwelcome burden.

If mechanical ventilation is an option, assessment of $PaCO_2$ may be of clinical utility. If the patient wishes to receive blood transfusions, a complete blood count should be checked, along with a type and screen. While lactate levels have been shown to correlate with mortality and thus could theoretically be used as a prognostic tool, a study on patients with advanced cancer found that arterial blood gas could not help differentiate between patients who died imminently and those who did not [21, 22].

EKG

An electrocardiogram is a noninvasive intervention which provides rich diagnostic information and minimal patient burden. An EKG can provide diagnostic clues to indicate myocardial infarction, dysrhythmia, pericarditis/myocarditis, pericardial effusion, pulmonary embolism/heart strain, electrolyte abnormalities, or digoxin effect. In the absence of any compelling reason not to, or if refused by the patient, obtaining a 12-lead EKG should be part of the ED evaluation of the dying patient with dyspnea.

Imaging

Chest X-ray is similar to the electrocardiogram in terms of great diagnostic value compared to minimal burden. Common etiologies of dyspnea may be diagnosed rapidly in the emergency setting with chest radiography: pleural effusions, pneumothoraces, and pulmonary infiltrates/edema are all easily identifiable and may allow for target therapies to relieve symptoms. For patients with limited functional status, portable films may be shot at the bedside. As an adjunct, or even a potential replacement, for chest radiography is bedside ultrasound. Emergency physicians are becoming more adept at using ultrasound as a diagnostic tool and as a procedural aide, and the noninvasive nature of the modality allows for high-quality images to be collected with a minimum burden to the patient. Recent studies have shown that thoracic ultrasound can differentiate between cardiac and pulmonary causes of dyspnea and accurately diagnose free or loculated pleural effusions, pneumothoraces, and lung consolidations [23, 24].

Generally, there is limited value in computed tomography (CT) for the diagnosis and treatment of dyspnea in terminal cancer patients. While CT represents the gold standard for detection of pulmonary embolus (PE) and therefore should be used if the patient's goals of care and functional status align with PE treatment protocols, this test requires that the patient briefly leave their monitored bed and move to a radiology suite where close symptom management is challenging and onto a flat exam table which may exacerbate dyspnea [25]. Also, since it is reasonable to discontinue or hold anticoagulation for treatment of venous thromboembolism when advanced cancer patients enter the dying phase, it extends that withholding anticoagulation for acute PE is also reasonable; these patients are unlikely to see significant long-term benefit from anticoagulation and are at higher risk for complications [26]. Symptomatic management can and should continue despite the lack of a concrete diagnosis, so if PE is suspected, the decision to pursue advanced imaging should come only after a frank discussion with patient and family about the risks of harm and benefit of the proposed treatment course.

Cardiac Monitoring/Telemetry/Vital Signs

Cardiac monitoring provides real-time information to providers and can also help to identify transient dysrhythmias. However, it also provides a noisy and oftentimes fear-producing distraction for patients and their families. Unless there is a clear and convincing reason to keep patients on cardiac monitoring, consider changing alarm limits, turning off in-room monitor screens, or removing the patient entirely to minimize physical barriers between patient and family. Vital sign abnormalities should be expected in the dying patient, and unless the rapid identification of these vital signs will make a meaningful impact in patient care, it may be best to keep them off. This will allow the family to focus on their loved one without distractions and remind providers that treatment of the patient should come before treatment of vital sign abnormalities in this population.

General Management

There exist two approaches to the alleviation of dyspnea, as there are with most acute symptoms: One approach is to correct the underlying disorder responsible for the insult in physiologic hemostasis. For example, this may include the drainage of a symptomatic pleural effusion or pericardial effusion. It may involve provision of supplemental inhaled oxygen to a hypoxic patient or bronchodilators to an asthmatic. In the acute setting, however, diagnostic uncertainty exists, and a direct approach is not always possible. And in some scenarios, the medical treatment necessary for correction of a primary insult may come with an unacceptable side

effect profile or burden to the patient being treated. In these situations, a second approach is necessary to alleviate dyspnea by interfering with the downstream cortical pathway. This is not a departure from standard emergency practice—many patients present to the ED with undifferentiated pain or nausea, which requires prompt symptomatic treatment prior to availability of diagnostic testing.

Opioids

The general approach to nonspecific, terminal dyspnea primarily consists of systemic opioid administration. Opioids are safe, effective, and largely predictable and fall well within the comfort zone of the emergency provider. The majority of laboratory and clinical trials to date suggest a benefit of opioids for the treatment of symptomatic breathlessness in advanced illness [11, 27]. But similar to the pathophysiology of dyspnea itself, the exact mechanisms by which opioids exert their influence and alleviate dyspnea are not entirely understood. Leading theories based on current experimental evidence indicate that opioids likely function to modulate the effect of chemoreceptor-activated central respiratory drive on actual ventilation rate and effort [28]. By reducing this reaction to insult and the subsequent compensatory physiologic changes, an increased subjective tolerance may be reached. In addition, the established presence of opioid receptors in bronchial epithelial cells indicates a potential function in both central feedback and local inflammatory response [29, 30]. Finally, there exists a strong emotional component of anxiety which is commonly reported alongside dyspnea and acts to exacerbate the subjective experience. Though it is unclear whether there exists a direct or indirect effect, opioid administration has been shown to measurably decrease reported anxiety in dyspneic patients [30].

In 2011, Banzett and colleagues performed a well-controlled randomized trial using morphine for the relief of dyspnea [31]. This study artificially stimulated air hunger by limiting minute ventilation in healthy patients while inducing hypercapnia. Using patient-reported dyspnea scores on the validated VAS as their primary outcome, IV morphine was compared to IV saline with a significant benefit in both dyspnea scores and anxiety in the morphine study arm. While this study was performed on young and healthy subjects and therefore is less representative of the typical cancer patient, it provides insight into the mechanics of dyspnea and offers valuable data from a controlled environment.

Larger analyses of clinical data have also revealed similar findings. In a 2015 systematic review, opioids demonstrated modest effectiveness for dyspnea in cancer patients. Most of the included studies evaluated morphine. The quality of the included studies varied, with only 4 of the 14 including a placebo arm [32].

The choice of opioid medication for the relief of breathlessness is based on provider preference and departmental availability, similar to the treatment of pain. The literature bears this to be true, as dyspnea studies often use different, but generally equivalent, opioid regimens. There have been clinically significant results shown in trials with oral dihydrocodeine [33], oral hydromorphone [34], IV morphine [35], and oral morphine [36] and multiple studies on subcutaneous morphine [37]. Renal dysfunction has been cited as a justification for caution in morphine administration secondary to the theoretical risk of limited renal clearance of toxic metabolites, although the data for this is not robust [38]. Fentanyl has no clinically significant active toxic metabolites and may be effectively used if there is provider concern [39].

Route of administration should be based on patient-specific parameters; in patients with intravenous access, for whom peripheral IV placement is within their established goals of care and does not represent and unwelcome burden, IV administration is straightforward and rapid. These medications can also be delivered subcutaneously in patients without IV access with minimal discomfort and may also be given orally for those patients able to safely swallow. As was described earlier, there is no strong data to support the use of nebulized opioid formulations, despite the potential for benefit given the known presence of local opioid receptors within lung epithelial cells [30]. However, it has been suggested that many of these nebulized trials have failed to show a difference against placebo due to the fact that nebulized saline could also be an effective treatment modality [27]. Finally, there have been no randomized controlled trials on formulations other than morphine for nebulized delivery, so additional investigation must be performed prior to ruling out nebulized opioids altogether [37].

In terms of dosing and escalation, providers should treat opioid administration for dyspnea similar to pain, by giving a reasonable starting dose and reassessing symptom progression in 10–15-min intervals, up-titrating as needed [16]. Recent prospective trials have used mean doses of 2.5 mg of PO hydromorphone (equivalent to 0.4 mg IV) and 9.4 ± 8.8 mg of PO morphine (equivalent to 0.8 mg IV) to achieve a desired level of patient comfort. Reasonable starting doses for opioid-naïve patients, therefore, should be approximately 1–2 mg IV morphine equivalent or 0.2–0.4 mg IV hydromorphone. If symptoms are unchanged after 10–15 min, consider re-dosing an equivalent or increased amount. If symptoms are improved, but not fully controlled, consider giving another 50% of the starting dose, and continue to reassess. Be aware that higher doses may be necessary in patients who are opioid tolerant; many advanced cancer patients will be on chronic standing and/or breakthrough opioids for chronic pain. In these situations, start by administering approximately 10% of the patient's total daily

opioid dose. For example, if a patient takes 15 mg of oral morphine every 4 h around the clock, their total daily dose equals 90 mg. An appropriate initial dose would be 9 mg PO morphine (equivalent to 3 mg IV). If the patient is taking multiple formulations of opioids, a conversion table should be employed to ensure safe dosing practices. Complicated dosing or high-dose opioid regimens should warrant a consultation with the palliative care service, if available.

Measure improvement in dyspnea through direct patient report, if possible. Again, similar to pain management, the patient's subjective experience of their symptoms is the best indicator of improvement. A visual analog scale (VAS) is usually used for these purposes in both research and clinical use. However, as patients near the end of life are oftentimes unable to effectively communicate, providers will often be forced to rely on elements of the physical exam and family gestalt to gauge response to treatment. It has been suggested to use simple "yes/no" questioning for symptom relief in patients struggling to communicate, as many patients who are unable to provide a scaled response to symptom improvement are still able to indicate yes/no responses [19]. There has also been a respiratory distress observation scale developed for these clinical scenarios, which involves heart rate, respiratory rate, degree of restlessness, accessory muscle use, end-expiratory grunting, nasal flaring, and a "look of fear" [40]. These tools are necessary to prevent undertreatment of a patient's symptoms due to communication challenges.

It is important to consider the potential side effects associated with opioid administration, chief among them being constipation. For this reason, any patient placed on scheduled opioid treatment should be managed expectantly with a bowel regimen. Common prophylactic regimens include a stool softener (e.g., docusate, polyethylene glycol, magnesium) with a stimulant laxative (e.g., senna, bisacodyl) [41]. Other side effects to consider include nausea, vomiting, sedation, pruritus, and allergy/anaphylaxis. These can be managed supportively.

There is understandable hesitation on the part of emergency physicians when considering the use of opioids in patients with dyspnea. In sufficient doses, opioids can lead to respiratory depression and even apnea, so administering these medications to a patient with respiratory compromise can seem dangerous. Fortunately, there is evidence to support the safety of these agents in cancer populations suffering from dyspnea, particularly those patients at the EOL. In several small prospective observational studies, mostly comprised of patients with advanced cancers, carefully administered opioids, even when given to opioid-naïve patients, did not result in clinically important respiratory depression or hypercapnia [42–44]. Furthermore, two large observational studies of hospice patients found minimal to no association with opioid usage, dosage, and life expectancy [45]. The key to safe, effective opioid administration, as stated earlier, is to "start low, go slow" carefully targeting symptomatic relief, titrating up doses in appropriate intervals and with appropriate clinical monitoring.

Benzodiazepines

In select clinical scenarios, administration of benzodiazepines may be considered as a second- or third-line pharmacologic agent. The primary indication for this medication is when anxiety appears to be playing a significant role in the patient's discomfort and when other interventions have failed to alleviate symptoms. As briefly stated earlier, there is a physiologic justification for benzodiazepines despite the current lack of strong supporting clinical evidence. In current neurophysiologic models of dyspnea, there appears to be a distinct emotional component of dyspnea, which may be modulated by opioids but may theoretically benefit more from the anxiolysis associated with benzodiazepine administration [10].

There is, however, a very weak clinical evidence base for this intervention with few studies indicating effectiveness. The largest review to date published in 2016 examined 8 independent trials composed of 214 subjects and found no benefit to these agents when compared to placebo or opioids [46]. Compared to placebo, somnolence and drowsiness were observed more frequently in patients receiving benzodiazepines. Surprisingly, when midazolam and morphine were directly compared, morphine was associated with more adverse events.

Given limited evidence for efficacy but without evidence for serious harm when used in small doses, benzodiazepines should be considered as an adjunct to opioids in situations where anxiety appears to be playing a role in symptomatology [47]. A starting dose of lorazepam 1 mg (PO or parenteral) or diazepam 5 mg (PO or parenteral) would be appropriate in most patients.

Corticosteroids

Corticosteroids represent a treatment for certain conditions associated with advanced cancers and should not be applied generally in the same fashion as opioids and benzodiazepines. There is limited data on their use, but case studies report temporary symptomatic improvement for specific conditions such as lymphangitic malignant spread and chemotherapy-/radiation-induced pneumonitis [48]. Corticosteroids are the mainstay of treatment for radiation-induced lung injury, typically treated with a taper starting with 60–100 mg of daily oral prednisone [49]. There are also case reports of rapid improvement in dyspnea associated with upper airway tumor

obstruction after administration of steroids, likely secondary to reduction in airway edema [50]. Reported doses include 10 mg IV dexamethasone and 125 mg IV methylprednisolone, administered every 6 h. A recent systematic review found no benefit to steroids in cancer patients with dyspnea, though the quality of the included studies was low, limiting the ability to draw firm conclusions [51]. Significant side effects exist and must be considered. These include hyperglycemia, infection risk, fluid retention, and potential psychomotor agitation [52]. In patients with life expectancies of days to weeks, however, long-term side effects are less concerning and therefore should be balanced against potential benefit.

Supplemental Oxygen

Supplemental oxygen is often reflexively administered to patients presenting to the ED with dyspnea, particularly those patients suffering from hypoxia. While oxygen has been demonstrated to improve the QOL and longevity of patients with severe COPD, its use in patients with dyspnea at the EOL is more controversial [53, 54]. In one large randomized trial of patients with advanced illnesses and dyspnea, about 15% of whom had cancer, home oxygen resulted in no symptomatic improvements when compared to room air [55]. Surprisingly, in a prospective cohort study of patients admitted to a palliative care unit with advanced cancers, hypoxia and dyspnea showed little correlation. Furthermore, patients in this study had more dyspnea relief with opioid rather than oxygen administration [42]. As hypoxia is likely just one of the many factors contributing to dyspnea at the EOL, these results are somewhat predictable. Regardless, certain oxygen delivery devices like nasal cannula are minimally burdensome, so a time-limited trial in hypoxic, dyspneic patients can be considered, even those endorsing comfort-oriented goals. More caution should be used, however, when applying more burdensome devices like a non-rebreather mask, if the goals are comfort-oriented, as this may actually contribute to discomfort without clear evidence of efficacy.

Noninvasive Ventilation (NIV)/Mechanical Ventilation

NIV has been well studied and its efficacy well demonstrated in patients with CHF and COPD [56]. In recent years, this tool has been applied to a broader range of patients, even those with advanced cancers. A randomized trial evaluated the use of NIV when compared to oxygen (via venture or non-rebreather mask) for patients with advanced cancers presenting with acute respiratory failure. Patients receiving NIV had greater improvements in dyspnea scores and needed less opioids; however, about 10% of patients randomized to NIV discontinued therapy secondary to issues like mask intolerance (compared to none in the oxygen group). Mean survival was the same in both groups, 4–5 days; however, seemed to favor the use of NIV in those patients with concomitant hypercapnia [57]. In an observational study of patients with advanced cancer and respiratory failure, over half of patients treated with NIV actually survived their acute illness and were discharged alive from the hospital [58]. In a cohort of lung cancer patients receiving NIV, predictors of mortality included a new lung cancer diagnosis or progressive disease, multiorgan failure, and need of NIV as the first-line therapy for respiratory failure. The 1-month mortality for this small cohort was approximately 40% [59]. These studies suggest that for select patients with advanced cancer and a potentially reversible cause of acute dyspnea/respiratory failure, NIV can be a useful tool that improves symptoms and meaningfully prolongs life. In other patients, however, particularly those with respiratory failure secondary to progression of underlying disease, NIV may artificially prolong dying and worsen suffering at the EOL [60]. Prior to initiation of this therapy, it is recommended that clear, time-specific goals be established with the patient and/or key decision-makers. For example, if there is no marked improvement in the patient's mental status and/or the mask seems to be causing discomfort in the next 24 h, NIV should be transitioned off, and opioids used exclusively to alleviate dyspnea.

Intubation is often considered, particularly in the ED, in advanced cancer patients with dyspnea and respiratory failure. Counseling patients and their families about the risks and benefits of this invasive intervention is critical. A recent study of cancer patients admitted to the ICU requiring ventilatory support demonstrated the importance of contextualizing the respiratory failure within a broader understanding of the overall illness. In the subgroup of patients with relapsed cancer and poor performance status (poor baseline function), hospital mortality was high, approaching 90% [61]. Trends over the last 10 years suggest more patients with metastatic cancer receiving mechanical ventilation, despite no changes in outcomes over this time frame [62]. Patients and families should be counseled that the use of mechanical ventilation is very unlikely to meaningfully prolong life in patients dying from an advanced cancer and is likely to lead to a burdensome death within the ICU setting.

High-Flow Nasal Cannula

High-flow nasal cannula (HFNC) has emerged a useful tool in managing hypoxemic respiratory failure in select patients. Heated and humidified oxygen is delivered at higher rates

than would be possible via a traditional nasal cannula system. Unlike other advanced modalities like NIV and a non-rebreather mask, HFNC theoretically leads to improved comfort as patients can still communicate and eat and drink while wearing the device. In patients with respiratory failure and electing DNR/DNI status, HFNC seems to improve oxygenation and decrease the respiratory rate. When compared to other oxygen delivery modalities, however, there is no difference in dyspnea scores or morphine usage [63]. Similar to studies of NIV in patients with advanced cancer, mortality rates in these studies are high, ranging from 40 to 87%. In awake patients still able to engage with loved ones and/or interested in eating and drinking, this tool can be considered.

Management of Specific Conditions

Pleural Effusion

Malignant pleural effusion is a challenging entity in the emergency setting, particularly in symptomatic patients with guarded prognoses. It is a common condition, with an estimated 150,000 cases in the USA annually and a prevalence in advanced cancer of approximately 15% [64, 65]. Most pleural effusions will not become symptomatic until they reach over 500 cc in volume, and they can expand to over 2000 cc in volume. Practice guidelines for malignant effusions have traditionally recommended drainage with bedside thoracentesis, with consideration of pleurodesis—typically with talc—for prevention of recurrence and re-accumulation [66]. Talc pleurodesis, however, requires inpatient hospitalization and surgery, may be distressing and painful, and may lead to further complications including pneumothorax or empyema. Increasingly, indwelling pleural catheter drainage is being employed for either permanent or temporary management of re-accumulation, thus diverting patients away from the traditional and burdensome pleurodesis [64]. Compared to pleurodesis, patients with malignant effusions receiving an indwelling catheter spend fewer days in the hospital near the end of life [67]. Of note, palliative chemotherapy may actually benefit patients with recurrent effusions who have chemotherapeutic-responsive tumors [65]. This does not represent an emergency intervention but should be known when discussing the full range of therapeutic options with a family.

Functional status and patient prognosis should guide treatment, along with patient and family values and goals of care. In general, therapeutic thoracentesis alone is typically recommended in patients with a short expected prognosis or poor functional status, which allows for temporary evacuation of pleural fluid without necessitating hospital admission. Effusions may re-accumulate rapidly within days or slowly, on the order of months. There are no good predictors to help determine which patients are at a higher risk for rapid re-accumulation [64]. The potential for rapid recurrence is an important detail to share with patients' families who may have very different expectations of this procedure. Most, but not all, patients will experience relief in dyspnea following a thoracentesis, but given that dyspnea is multifactorial in advanced cancer, families should also understand that thoracentesis is not necessarily a definitive treatment for an individual patient's symptoms. For those patients with frequent recurrent pleural effusions or for those with predicted longer life expectancies, it may be more appropriate to refer for pleurodesis or tunneled catheter placement.

If performed in the emergency setting, thoracentesis should be done by an experienced provider utilizing ultrasound guidance. A retrospective study on 445 patients undergoing thoracentesis for malignant pleural effusion revealed a 0.97% pneumothorax rate with ultrasound guidance and 8.89% without [68]. Re-expansion pulmonary edema is a known potential complication and may occur if greater than 1.5 L are removed at once, although the incidence of this is uncommon, around 0.5% in a series of 185 cases [69, 70].

Anemia

Advanced cancer patients have a high prevalence of anemia, with studies suggesting up to 70% of these patients live with a hemoglobin concentration below 12 g/dL. While the majority of anemia in this population is of unclear etiology, many are thought to have anemia of chronic disease or nutritional deficiencies, notably of folic acid [71]. In a study aimed at establishing the cause of dyspnea in advanced cancer patients, up to 20% of enrollees were found to have a hemoglobin level which was low enough to have affected tissue perfusion [17]. In these situations, transfusion should be considered. Major elements impacting this decision include prognosis, functional status, and goals of care. There are risks and burden associated with transfusion, including additional time spent in the hospital, necessarily placement of intravenous access, and the risks of transfusion reaction, infection, or fluid overload. A prospective study of outpatient palliative care patients with cancer found that by using a transfusion cutoff of 8 g/dL, patients had a significant improvement in both self-reported dyspnea and fatigue, but these effects began to decrease approximately 2 weeks after transfusion [72]. The decision to transfuse should be left up to the treatment team in conjunction with the patient and family, though they should be aware that the subjective benefit in dyspnea relief is likely temporary and does carry some limited risk.

Oral Secretions

As death approaches, secretions pool in the posterior oropharynx, and patients become too weak to swallow or clear them. Anticholinergic agents are commonly used to address the noisy breathing that many patients experience as a result. Most patients are unconscious at this point and thus unlikely to be bothered by what is known as the "death rattle" [20]. Family members, however, can find the noise distressing, so treatment is often considered. Unfortunately, there is a lack of high-quality evidence on this topic to guide management. In a 2014 systematic review of interventions for noisy breathing near the end of life, only one small study was placebo-controlled, and the authors could find with no clear benefit found to any treatments evaluated [73].

For patients with intravenous access, glycopyrrolate 0.2 mg IV or atropine 0.1 mg IV can be administered. For those without IV access, drops of atropine 1% ophthalmic solution can be given by mouth [74]. More important than medication choice, however, is educating family and caregivers that this is a normal part of the dying process unlikely to be distressing to the patient. It is also an established prognostic sign that life expectancy is likely hours to days.

Tumor Burden

Lymphangitic carcinomatosis (LC), a condition involving hilar/mediastinal lymphatic inflammation secondary to malignant spread, affects between 6% and 8% of patients with intrathoracic metastases with the most common underlying primary tumors being breast, stomach, and lung [75]. LC manifests as nonspecific, nonproductive cough with associated dyspnea and may be definitively diagnosed by CT scan or bronchoscopy/biopsy [76]. As a late finding in advanced cancer, it carries a poor prognosis, with 50% survival at 3 months after first respiratory symptom. Corticosteroids have a palliative role by decreasing inflammation and should be considered in patients who carry this diagnosis [48]. In certain cases, palliative chemotherapy may also be offered and may give temporary improvement in symptoms over time.

Palliative Extubation

Establishing goals of care can be a time-intensive and arduous process. Oftentimes, a patient presents profoundly dyspneic to the ED alone or with EMS and with no ability to communicate their wishes about the use of life-sustaining treatments (LST). In these situations, unless emergent airway management appears futile, patients will be intubated and placed on mechanical ventilation. After medical stabilization, when it is possible to clarify a patient's wishes with family or supporting documentation, it may become clear that the patient's goals are inconsistent with mechanical ventilation. Appropriate management in these situations will vary—some families prefer to wait until they leave the ED into a more controlled environment (a hospital room or on a palliative care floor) prior to withdrawal of mechanical ventilation. In other situations, the emergency provider may withdraw support in the ED.

There may be hesitation on the part of the healthcare provider regarding the ramifications of withdrawal of LST in the ED. A public health survey of medical attending physicians in 1993 revealed that only 43% agreed that "there is no ethical difference between forgoing a life support measure and stopping it once it has been started" [77]. But from both an ethical and legal standpoint, there is no difference between these two actions [78]. The ethical principle of *autonomy*, which dictates that a patient has the right to make his or her own decisions, must be honored. Providers should seek documentation of the patient's wishes in the form of advance directives like a living will or POLST. When written directives are not present, surrogate decision-makers can use the principle of substituted judgment to make decisions that they feel would be in the best interest of the patient [79].

Prior to withdrawal of mechanical ventilation, family should be informed about the prognosis and potential outcomes following withdrawal. There is a common expectation that death is imminent after endotracheal tube removal, so appropriate counseling on the range of outcomes should be given. In a small cohort of patients terminally extubated in the ICU, mean time to death was 2–3 hours [80]. In another study of mechanically ventilated ICU patients who were terminally extubated, half died within 1 h of withdrawal, with the majority dying within 10 h [81]. Factors that were predictive of an earlier time to death included a high oxygen requirement ($FIO_2 > 70\%$) and the use of vasopressors. Note that over half of this study group had been mechanically ventilated for over 10 days, and therefore these results may not be entirely reflective of the acute/emergency population. While most patients will live minutes to hours, families should be counseled that some can live for days.

Families should be allowed to make any necessary spiritual arrangement. Monitors and unnecessary equipment including blood pressure cuffs and pulse oximeters should be turned off and/or removed. It is best to keep IV access in place for rapid administration of sedatives if necessary.

There is debate about whether patients being extubated should be weaned from mechanical ventilation gradually, allowing the careful matching of opioids to symptoms, or extubated abruptly. In an uncontrolled study, when compared to immediate extubation, weaning seemed to lead to improved patient comfort [82]. If weaning is selected, the amount of pressure support and oxygen should be gradu-

ally decreased over 30 minutes prior to extubation. At the time of extubation, the tube cuff is deflated, and then the tube is removed, followed by cleaning and suctioning of oral secretions.

A dose of glycopyrrolate 0.2 mg IV can be given to minimize respiratory secretions, prior to extubation. As dyspnea is the primary symptom post-extubation, opioids are the first-line agents used during this procedure. Prior to extubation, an opioid should be given. Typical doses of morphine used are 4–6 mg. The goal of palliative medications is to minimize tachypnea and prevent agitation [79]. Families may be concerned with sedative administration, but similar to the management of undifferentiated dyspnea without airway management, provision of opioids after palliative extubation does not appear to have any effect on hastening death [83, 84]. Be available to the family, as they will often have questions during the dying process and may ask for frequent reexaminations of their loved one.

After the patient dies, ensure that the family is able to spend time around the bedside and provide bereavement support as needed.

Summary

Dyspnea in advanced cancer is distressing, complex, and often multifactorial. As patients approach the end of life, dyspnea becomes a common endpoint for multiple disease processes, with many factors simultaneously contributing to a patient's underlying shortness of breath. Many of these patients will seek care in the ED, necessitating emergency providers to have a strong understanding of the pathophysiology and management of terminal dyspnea. Above all, clear and open communication will help guide the diagnostic workup and treatment course for a patient with dyspnea near the end of life. Patient's goals may range from purely symptomatic treatment to aggressive extension of life, and therefore each patient will need to receive truly customized care from the onset of their ED visit.

Fortunately, while the neurophysiology of dyspnea is complex, the treatments are not. Opioids are the clear mainstay of symptomatic management. The proper titration of opioids will often be sufficient to adequately treat dyspnea at the end of life, but in certain situations a patient may require or request more intensive treatment. These interventions range from blood transfusions to noninvasive ventilation to bedside thoracentesis. By developing a keen understanding of the risks, benefits, and long-term outcomes of these interventions, the emergency provider is better able to equip the patient and family with the information they require to decide whether the intervention aligns with their goals and values.

Acknowledgments The author wishes to acknowledge the contribution made by Dr. Trevor Pour, author of this chapter in the first edition upon which this revision is based.

Cardiopulmonary Resuscitation

58

Mohammad Adrian Hasdianda and Kei Ouchi

Introduction

Cardiopulmonary resuscitation (CPR) can be a lifesaving intervention; however, the indiscriminate use of CPR among unselected populations, and particularly among those with cancer, confers beneficial outcomes (e.g., survival to hospital discharge) on only a small proportion of patients [1–12]. In the USA, CPR is routinely provided to those suffering cardiac arrest without their consent. Only when patients give caregivers explicit instructions to withhold CPR is it not performed [1, 13, 14].

In 1960, Kouwenhoven et al. [14, 15] first described closed-chest massage, intended for administration to otherwise "healthy patients" with reversible conditions who experienced sudden and unexpected cardiorespiratory arrest. Today, despite the near universal application of CPR, in most cases and particularly among cancer patients, CPR merely prolongs the dying process [2, 12, 16–22]. During the last 15 years, researchers have determined that cancer patients have a particularly low rate of return of spontaneous circulation (ROSC) and survival to hospital discharge (SHD) after CPR [1–11]. SHD rates are substantially better for in-hospital CPR compared to out-of-hospital CPR among all comers. SHD rates for out-of-hospital CPR and in-hospital CPR in an unselected population undergoing CPR are 1–10% and 15%, respectively [2, 16–22], but for cancer populations it is <6% [9, 10]. Even among patients with stage IV cancers who survive in-hospital CPR, the median survival after discharge is only 22 days [23]. Cardiopulmonary arrest is the common final pathway for most terminal diseases, including cancer [9, 10]. Despite the low rates of SHD and short survival after discharge, CPR may be aligned to patient's goals of care. More information is needed to better understand the quality of life for survivors and under what conditions CPR is appropriate.

An increased emphasis on palliative and supportive care for cancer patients improves quality of life [24–26]. Palliative services incorporated in planning and executing therapeutic interventions hold the promise that CPR might be used more selectively. A more selective approach to initiating CPR, incorporating the patient's goals of care, should lead to increases in goal-concordant care.

In this chapter, we discuss how to determine whether CPR is aligned with goals of care among patients with cancer, explore palliative and supportive care resources, and describe CPR outcomes in tertiary cancer centers. We will also examine the issue of family-witnessed resuscitation.

What Outcomes After CPR Are Acceptable to Patients?

Emergency physicians understand that when patients with cancer arrive in the emergency department (ED), many have an inaccurate understanding of their illness and prognosis. Studies show that 69% of patients with stage IV lung cancer and 81% of those with colorectal cancer did not report understanding that chemotherapy was not at all likely to cure their cancer [27]. When asked about CPR, only 2.7% of hospitalized older patients with end-stage cancer or other advanced diseases understood that actual CPR success rates were <10%. Only 11% of these patients could describe more than two components involved in CPR [28].

To determine whether CPR is indicated for ED cancer patients with limited understanding of both their prognosis and CPR, emergency physicians should focus on a patient-centered prognosis (i.e., what patients with serious, life-limiting illnesses would consider good outcomes). In a national survey study of physicians and seriously ill patients, a number of end-of-life items were rated as significantly more important to patients than physicians, including being mentally aware, having made funeral arrangements, feeling that one's life was complete, not being a burden, being able to help others, coming to peace with God, and praying [29]. Furthermore, ≥60% of seriously ill older adults consider inability to "get out of bed" or "rely on a breathing machine

to live" as equal to or "worse than death" [30]. The vast majority (87%) of seriously ill, hospitalized, older adults express that they would even trade 1 year of a 5-year lifespan to avoid dying in an ICU on life support [31]. Considering prognosis and likely functional outcomes, emergency physicians must determine what patients would consider an acceptable quality of life should they survive CPR.

How Should Emergency Physicians Make Recommendations Regarding CPR?

To make an empathic and goal-concordant recommendation around CPR, integrate the patient's baseline function and values with knowledge of the patient's prognosis. Ask yourself, "In the best-case scenario, would this patient be able to achieve the minimal quality of life worth living for after CPR?" If this answer is a clear "no" or likely outcome would be considered "worse than death" for the patient [30], emergency physicians can confidently make a recommendation against CPR. If the answer is unclear (e.g., the surrogate may not know the minimal quality of life that patient would consider acceptable to live) or likely outcome would be an acceptable quality of life worth living for, emergency physicians can make a recommendation for CPR (Fig. 58.1). The language used to make the recommendation should reflect how the recommendation was made (e.g., "based on what I heard about you, I would recommend CPR"). Emphasize what you will do (e.g., "focus on ensuring comfort"). Consider explaining why you would not recommend certain therapies in the context of the baseline function and values [32].

Palliative and Supportive Care Interventions

The goal of palliative and supportive care is to prevent or treat, as early as possible, the symptoms of the disease, side effects caused by treatment, and psychological, social, and spiritual problems related to the disease or its treatment. Palliative care focuses on the assessment and management of physical and psychosocial distress of patients with advanced cancer as well as family support and advance care planning [24, 25]. Patients make better-informed decisions with less distress when physical and emotional symptoms are controlled [26]. Furthermore, the manner in which physicians communicate about CPR is important. Of patients with advanced cancer randomly assigned to learn about CPR by either viewing a video decision support tool or listening to a verbal narrative, 79% of those viewing the video opted out of CPR, while only 51% receiving a verbal description decided against CPR [34].

Palliative care is not only pertinent to the end of life; rather, it can and should be provided early in the cancer journey. When engaged early, these services improve quantity and quality of life concurrently with the oncologic care model [26]. This model enables supportive/palliative care to be integrated into the collaborative model that exists among surgical, radiation, and medical oncologists as the fourth pillar of comprehensive cancer care. This multidisciplinary approach allows additional consultants the opportunity to participate in care including, but not limited to, pain specialists; psychiatrists for emotional distress, depression, and anxiety; pulmonologists for relief of bronchial obstruction; and psychosocial interventionists for end-of-life issues [9–11, 24–26]. Incorporating end-of-life education into the day-to-day management of these patients is essential.

Comprehensive Cancer Centers

In one comprehensive cancer center, between the periods 2002–2007 and 2008–2012, rates of ROSC after CPR showed small and statistically insignificant improvements, while SHD outcomes did not change [35] (Fig. 58.2). Any trend toward improved ROSC outcomes that may exist could result from improvements in CPR quality [36, 37].

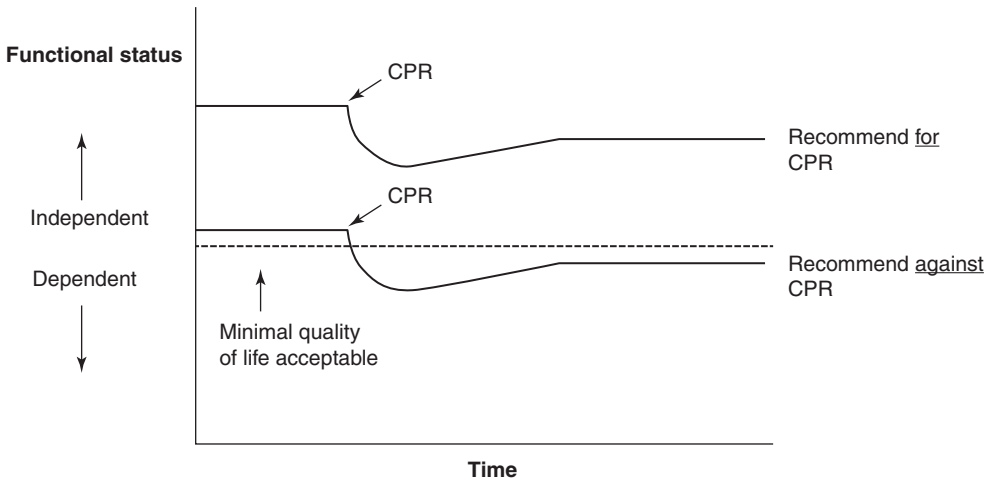

Fig. 58.1 CPR recommendation based on quality of life acceptable to patients. (From Ouchi et al. [33], with permission Elsevier)

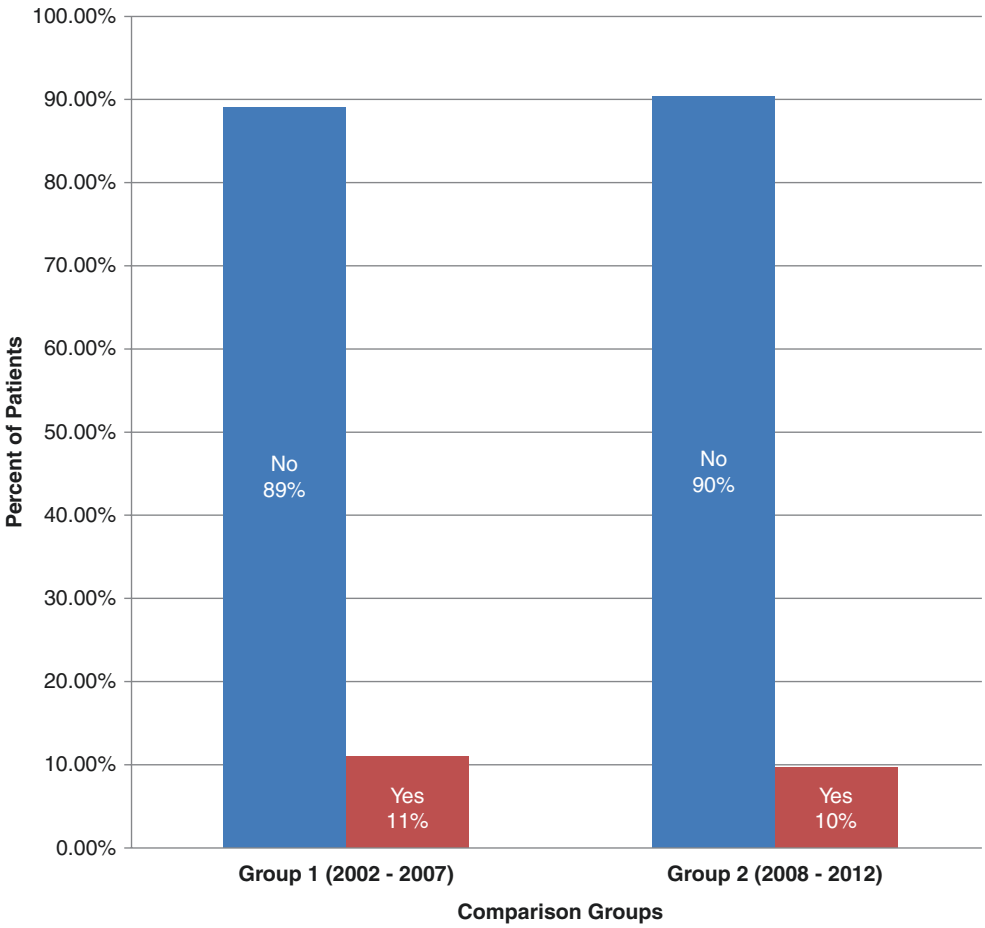

Fig. 58.2 Survival to discharge among 126 cancer patients undergoing cardiopulmonary resuscitation (CPR) in a comprehensive cancer center comparing group 1 (2002–2007) and group 2 (2008–2012). (From Miller et al. [35] with permission SpringerPlus [CC by 4.0])

The lack of improvement in SHD may suggest that CPR in cancer patients continues to be performed on an unselected cancer population, rather than being targeting toward subsets of cancer patients who are more likely to receive benefit.

Reisfield et al. [11] reported in a 2006 meta-analysis that among 1118 patients with cancer receiving CPR, the rate of SHD was 7.1% among those with solid tumor vs. 2% for those with hematologic cancer. Consistent with these data, Hwang et al. [10] reported that during 2000–2002, of 41 cancer patients receiving CPR in their ED, only 6 of 33 patients (18%) with solid tumors and 1 of 8 (13%) with hematologic malignancies were ultimately discharged alive to another facility.

Future research could identify the specific type(s) of cancer that could benefit from CPR. End-of-life and advanced care planning may contribute to improved outcomes of CPR by allowing those terminally ill to avoid ineffective terminal interventions [38]. Improved advance care planning communication and/or documentation and family education can be exploited to improve CPR outcomes in both cancer and noncancer populations. These interventions allow patients and loved ones to avoid transportation to the hospital and CPR [1, 39–41]. As cancer populations increase in the USA, discussions about end-of-life issues will become particularly relevant with regard to economic impact [12].

Family-Witnessed Resuscitation

As noted, survival outcomes measured by improved quality of life are particularly dismal after CPR for cancer patients. Even though the statistics are unfavorable, the decision to resuscitate is often multifactorial. Ideally, end-of-life planning should occur early in the course of treatment so that patient wishes will be clear and based on an adequate consideration of alternate treatment plans. Indeed, planning should occur at all stages of disease.

An important topic particularly relevant to emergency care is that of family-witnessed resuscitation (FWR). According to Boyd, FWR is "the process of active 'medical' resuscitation in the presence of family members [42]. The concept of having family members present during resuscitative efforts was introduced in the 1980s when Foote Hospital in Michigan began promoting FWR [43]. In 1992, Hanson and Strawser presented initial research data on this topic [44]. Twenty years later, in 2000, the American Heart

Association published guidelines recommending that family members be allowed to witness CPR. At the time, there was a lack of research to provide quantitative proof that FWR was beneficial. Another 20 years later, FWR remains the exception in EDs internationally [45].

The question of whether family members or loved ones desire to be present during resuscitation, or whether the emergency physician should consider offering this choice, remains an important policy issue for the ED. Planning and establishing procedures for FWR should occur well before the need to make such decisions arise [46]. We will discuss the pros and cons based on perspectives of all parties that may be present during resuscitation and ethical contexts regarding this issue. We suggest conditions under which FWR should be considered based on a review of existing research.

Perspectives of Family Members

Family members of both pediatric and adult patients play an increasingly larger role as caregivers given the shift in emphasis of care from the hospital to outpatient setting. Oftentimes, they initiate an emergency response in the prehospital setting if their loved one is in distress. Given that family members often participate in treatment planning and day-to-day care, it is not uncommon for them to wish to be present with their loved one during the final moments of life, including resuscitation attempts.

Multiple studies focusing on the attitudes of family members reveal that most prefer to be present during resuscitation when given the opportunity. One 1982 survey assessing bereaved family members in Michigan found that 72% preferred to be present during resuscitation attempts. Other studies confirm the strong desire of family members to be present and that those participating in FWR would recommend the same to other families [47–52].

Despite the strong preference of family members to participate in FWR, the practice remains uncommon. Hospital staff have traditionally excluded nonmedical personnel because witnessing the resuscitation was thought to cause emotional distress. Multiple studies counter this belief and indicate that family members do not suffer negative psychological consequences after witnessing resuscitation. In 2013, Jabre et al. [53] performed a 1-year post-resuscitation study of 408 family members measuring symptoms of posttraumatic stress disorder (PTSD), anxiety, depression, and complications of grief. Family members witnessing resuscitation appeared to suffer less PTSD-related symptoms [53, 54]. A common belief is that participating in FWR allows for a sense of closure after family members witness that everything possible had been done to increase the chance of survival [49, 52, 55, 56].

Perspectives of Healthcare Workers

With endorsement by the Resuscitation Council UK, the European Resuscitation Council, and the American Heart Association, FWR is more frequently performed in the ED. In a survey of 162 UK EDs with a mean patient volume of 47,000 patients per year, 79% (128 EDs) reported allowing adult patients to have FWR [57]. However, FWR is not universally supported by healthcare workers despite studies suggesting that it is beneficial to family members. A survey of 132 ED staff members at a hospital in Singapore found that 80% of doctors and 78% of nurses actually disapproved FWR. Of those surveyed, 32% of doctors and 24% of nurses had received requests from relatives to be present during resuscitation within the past 6 months [58]. Another survey of 100 healthcare professionals at an academic medical center in the USA showed a contrasting result, in that the majority of staff members (77%) were in favor of allowing FWR [59].

Attitudes of healthcare workers toward FWR differ by discipline, patient age, and practice environment. Nurses are more open to FWR than doctors, and family members tend to approach a nurse rather than physician asking permission to witness resuscitation of their loved one [60, 61]. Those caring for younger patients and their families are generally more positive toward FWR. One-third of pediatricians surveyed would allow family presence during CPR, and almost two-thirds with FWR experience would allow this to happen again. In a study comparing pediatric vs. adult pulmonologists, pediatric pulmonologists were far more accepting of FWR [62]. The nature of pediatric care may allow staff to be more accepting of FWR as a right for parents who are legal guardians for their children [63]. A small South African qualitative study revealed that ED staff disliked FWR as they believed it to be harmful for the witnesses as well as a threat to the staff [45].

Practice environment also influences the attitudes of healthcare workers. Staff at urban hospitals are less supportive of FWR than staff at suburban hospitals [64]. Macy suggests that logistics may play a role given that urban hospitals may have inadequate resuscitation space per patient volume. Urban hospitals have smaller staff/patient ratios which may cause staff to feel that family members' presence is a distraction. This study found that patient/personnel ethnicity had no significant effect on overall attitudes toward FWR by medical staff [64]. A cross-sectional study conducted at an American community hospital suggested that critical care nurses who had experience FWR had a trend toward more positive attitudes about the benefits and outcomes of FWR, though the findings were not statistically significant [65].

In general, healthcare professionals opposing FWR express a common concern that witnessing a loved one

undergoing aggressive resuscitation predisposes family members to additional psychological burden [63]. Staff report that witnessing resuscitation may cause family members to suffer flashbacks and other signs of posttraumatic psychological trauma. The reality of what may occur during resuscitation differs than what is usually depicted in movies or on television, and nonmedical personnel may not be mentally prepared to witness a real resuscitation.

A second concern expressed by many healthcare workers is that FWR negatively impacts staff performance. The presence of family members may cause additional stress to healthcare workers, especially those less experienced with code blue situations [66]. Resuscitation is a stressful event, and coping mechanisms, such as humor or detachment from a patient, may certainly be deemed inappropriate by family members. Unrealistic expectations may also exist as family members are not expected to understand resuscitation procedures and may interfere or interrupt resuscitation efforts. Resuscitation may also be inappropriately extended beyond usual time limits based on family presence. An increase in potential for litigation is also cited as an issue given that relatives in the room may be at risk for needle sticks or being injured by a piece of equipment [67, 68]. These findings contrast with the result of several other studies [54, 65].

Given these concerns, most healthcare workers recommend FWR in a controlled setting with protocols in place and specifically trained personnel to accompany family members. Hospital staff would also require additional training which would add to hospital expenses [69, 70]. After receiving education, it is interesting to note that in some studies, staff felt that witnessed resuscitation may indeed lessen the risk of lawsuits and complaints given that family members witnessed firsthand that everything was done for their loved one. Communication about the death of the relative was also found to be easier [58, 63, 71, 72].

Perspectives of Patients

Only 10–15% of patients receiving CPR following cardiac arrest in the hospital survive to be discharged. Therefore, fewer studies exist which examine FWR from a patient perspective. Albarran performed face-to-face interviews with 21 resuscitation survivors, and although the study was statistically insignificant, it suggests that patients who survive resuscitation favor having family members present [73]. Patients would like the opportunity to be asked to approve FWR and were not as concerned about confidentiality issues. Another pilot study by Robinson et al. consisting of three patients surviving resuscitation reported that their confidentiality and dignity were not compromised by FWR [71].

Ethical Considerations

Patients are rarely asked about their preference for family-witnessed resuscitation when preparing advanced directives. The lack of documented consent creates medicolegal implications for FWR because of the potential for breaching patient confidentiality. Acceptable guidelines for pediatric patients do not transfer to adults, given that family members have no legal rights to care for their adult relatives. For adults, permission must be granted from the patient before discussing medical care with relatives. Even if a patient is unconscious, these rights are still present; thus, an assumption cannot be made that all patients would give automatic consent for FWR [63]. Consequences must be considered if a patient survives the resuscitation and is not happy with the decision, though concerns regarding litigations from FWR have not been demonstrated [74].

Guidelines

When considering FWR, the interests of patients, family members, and staff must be taken into consideration, and this is difficult during an emergency situation. Optimally, FWR should be discussed with patients prior to potential resuscitations, e.g., during advance directive planning. If a hospital decides to incorporate FWR, it is recommended that an ED-specific protocol be established. Training of specific ancillary staff should occur so that a qualified staff member can accompany the relative at all times during the resuscitation. The role of this staff member will be to debrief the loved ones prior to entering the resuscitation room, to answer questions during the resuscitation, to escort the relative out of the room if necessary, and to help debrief the relative after resuscitation. Education is desired for the multidisciplinary resuscitation team on what to expect with FWR so that any fear or apprehension can be addressed. If a protocol for FWR is in place and staff are educated, they will less likely deny family member requests to be with their loved one during resuscitation, and family members can be allowed near or even touch their loved one during the process with less concern interfering with resuscitation procedures [69, 75].

Conclusions

In this chapter, we have reviewed the literature pertaining to CPR on patients with cancer. To improve the current status, more teaching of palliative and supportive care to maximize quality of life concurrently with disease-oriented therapies is needed. Despite well-intentioned resuscitation efforts over the last 40 years, the survival outcomes for those with cancer particularly metastatic cancer have not improved [11, 38,

41]. FWR should be considered in the ED; however, the ultimate impact of FWR on family members and loved ones remains uncertain.

Palliative Surgery

59

Caitlin Hodge and Brian Badgwell

Case Study

A 68-year-old woman presents to the emergency department with progressive nausea, vomiting, vague abdominal pain, and weight loss. She reports that her last bowel movement was 2 days ago and that she has lost 20 pounds in the past few months. On exam, she appears cachectic and jaundiced. Her vital signs are stable. Her abdomen is distended and tympanic. X-rays show dilated loops of bowel with air-fluid levels. A CT scan reveals a 5 cm pancreatic head mass and concern for liver metastases. Labs reveal a total bilirubin of 14 and a normal white count and lactate. She can climb two flights of stairs without difficulty.

IVs are placed and fluids are started. An NG tube is placed, which returns bilious output. Her abdominal discomfort improves after NG placement. She is admitted to the hospital for further work-up and resuscitation. An endoscopic ultrasound and ERCP are performed. Biopsies are taken, which confirm the diagnosis of pancreatic adenocarcinoma. Management options for her symptoms resulting from gastric outlet and biliary obstruction are discussed. After thorough discussion of risks and benefits, it is determined that her primary goals are to return home and to start chemotherapy. She then undergoes successful biliary stent placement followed by laparoscopic gastrojejunostomy. She recovers from these procedures and is discharged home.

Introduction

Palliative care, defined by the World Health Organization, is care to improve the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering [1]. Palliative care involves the assessment and treatment of pain and other physical, psychosocial, and spiritual problems. The first distinction that must be made in addressing palliative surgery is differentiating surgical palliative care from medical palliative care. Medical palliative care is the management of symptoms such as pain, nausea, cachexia, delirium, and fatigue. Surgical palliative care can broadly be separated into two main categories. The first is operative palliative surgical care in which surgical interventions are the treatment modality utilized to palliate patients with advanced or incurable illness. Palliative surgery is defined as surgery performed with the purpose of alleviating symptoms and improving quality of life [2]. This form of palliative surgical care is often encountered during surgical consultation or in the emergency department. The second form of palliative surgical care involves nonoperative care and decisions about the appropriate level of care in postoperative or trauma patients with life-threatening conditions or postoperative complications. This form of palliative surgical care is most often encountered in the intensive care unit or postoperative inpatient unit.

The focus of this chapter on palliative surgery will be clinical diagnoses evaluated for potential surgical intervention. Palliative surgical consultation is a frequent occurrence in hospitals that treat cancer patients. Approximately half of all inpatients undergoing surgical consultation at major cancer centers meet the criteria for palliative care. In a study at MD Anderson of over 1000 inpatient surgical consultations, 40% met the criteria for surgical palliative evaluation [3]. The low overall median survival of all patients (2.9 months) highlights the need for a selective approach to patients undergoing palliative surgical consultation. Attempts to identify variables associated with poor survival, and perhaps identify

patients that should be managed without surgery, were largely unsuccessful in this study although patients with two or more radiologic sites of disease and carcinomatosis had poorer survival. The risks of palliative surgery are significant as palliative surgical procedures have reported morbidity and mortality rates of 20–40% and 4–7%, respectively [3, 4]. In appropriately selected patients, palliative surgery can achieve up to 90% symptom resolution [4] and mean duration of symptom control of 135 days [5].

The most important factor in decision-making for surgical palliation is patient selection. While no single instrument has been defined as the best metric, several criteria have been proposed including symptom control, prognosis, preoperative performance, quality of life, tumor burden amenable to palliation, procedure-related morbidity and mortality, feasibility of nonsurgical options, anticipated duration of hospitalization, requirement for additional palliation, and cost [6]. Risk-benefit discussions during the consent process for palliative surgery are difficult owing to several limitations in existing data and research. First, the benefits of palliative surgery are largely unknown due to a paucity of high-quality, prospective, patient-reported outcome studies. Second, prognostication is difficult for advanced cancer patients, and the risks of surgery must be balanced against the estimated remaining length of life for patients undergoing palliative surgical consultation. There is no tool that specifically predicts complications for palliative intent surgical procedures. For example, the proportion of patients undergoing palliative surgical intervention for cancer within the American College of Surgeons National Surgical Quality Improvement (ACS-NSQIP) calculator pool is small, which limits the calculator's predictive ability for this population [7]. This calculator has been shown to significantly overestimate mortality but underestimate length of stay for palliative procedures [8]. Lastly, randomized clinical trials are difficult to perform in palliative populations and particularly in the palliative surgical population [9].

Despite a selective practice of surgical intervention, palliative surgery can still account for approximately 20% of a surgical oncologist's practice and over 1000 procedures per year at cancer centers [5, 10]. The frequency of palliative surgical consultation and intervention aids in the identification of common diagnoses and treatment patterns. Gastrointestinal obstruction is the most common indication for palliative surgical consultation at approximately 40% [3]. Gastrointestinal bleeding and wound complications/infections each account for 10% of palliative surgical consultations. Abdominal pain of unclear etiology is also common and often includes patients with constipation, ileus, carcinomatosis with resultant gastrointestinal dysfunction, and medication- or treatment-related side effects. The common theme throughout many of these palliative surgical consultations is the acute presentation of symptoms as these patients are often evaluated in the hospital or emergency department. Although acute in nature, palliative surgical consultations rarely require urgent surgical intervention and allow for time to engage in multidisciplinary care discussions and a thorough evaluation of the associated risks and benefits.

Gastrointestinal Obstruction

Gastrointestinal obstruction is one of the most common indications for surgical consultation, even in patients without cancer. The standard approach by general surgeons in the evaluation of patients with obstruction includes a history to identify the anatomic site and degree of obstruction. The approach to assessment of gastrointestinal obstruction proceeds similarly in patients with and without cancer. Past surgical history is an important component of the subjective assessment for patients with obstruction as adhesions and hernias are the two most common causes of obstruction. Cancer is notably the third most common cause in the bowel obstruction differential diagnosis in patients undergoing general surgery evaluation. The objective assessment should first focus on vital signs to evaluate for hemodynamic instability. Fever and tachycardia are findings worrisome for ischemia. A complete physical examination should be performed. A focused assessment of the abdomen is necessary to evaluate for strangulated incisional or inguinal hernias, the degree of abdominal distention, and peritoneal signs. Laboratory analysis is necessary to manage electrolyte abnormalities and evaluate for leukocytosis, which could also indicate ischemia. Imaging is frequently obtained, first with plain films, but computed tomography imaging is often required in cancer patients not only to determine the site of obstruction but also to evaluate for sites of metastases within the abdomen, multifocal obstruction, and ascites. Treatment should begin during the evaluation of patients with bowel obstruction and may include nasogastric tube decompression, intravenous fluid resuscitation, and Foley catheter placement.

There are various definitions for gastrointestinal obstruction in cancer patients. Definitions include malignant bowel obstruction, patients with bowel obstruction secondary to recurrent cancer, patients with stage IV cancer and obstruction, and definitions based on anatomic site of obstruction [11–13]. A definition formulated during an international multi-institutional and multidisciplinary conference tasked with creating a definition for subsequent palliative trials defined malignant bowel obstruction as (1) clinical evidence of a bowel obstruction via history, physical exam, or radiographic examination, (2) bowel obstruction beyond the ligament of Treitz, (3) intra-abdominal primary cancer with incurable disease, or (4) non-intra-abdominal primary cancer with clear intraperitoneal disease [14]. A simplified defini-

tion for malignant bowel obstruction is blockage of the small or large intestine in a patient with advanced cancer [15]. As treatment varies depending on the anatomic site of obstruction, defining the obstruction as gastric outlet, small bowel, or large bowel can help identify differences in the utilization of endoscopic or surgical procedures and also identify differences in outcomes such as survival or symptom improvement [9, 13]. Regardless of the definition, bowel obstruction in patients with advanced cancer is common with reported rates of up to 42% of patients with advanced ovarian cancer and up to 24% of patients with advanced colorectal cancer developing obstruction during their lifetime [16]. Adding to the complexity of defining bowel obstruction in cancer patients is that somewhere between 3% and 40% of obstructions may have a benign etiology and are caused by adhesions or strictures not associated with malignancy [17].

Emesis and abdominal distention in patients with incurable cancer can be due to a myriad of factors other than mechanical obstruction. Patients with advanced cancer can suffer from electrolyte abnormalities, cachexia with metabolic derangements, pain medication side effects, constipation, autonomic dysfunction due to plexus involvement from malignancies with a tendency for perineural invasion, and chemotherapy/radiotherapy side effects. There are many surgical consultations for bowel obstruction that are ultimately found to have gastroparesis, ileus, or constipation.

Bowel obstruction in patients with advanced cancer is rarely a surgical emergency and typically allows time to consider multidisciplinary aspects of the patient's condition. Previous treatment, cancer stage, and prognosis are unique variables to consider in cancer patients with gastrointestinal obstruction. Although accurate prognostication is difficult, it is helpful to attempt to determine if a patient can recover from abdominal surgery and obtain a meaningful quality of life prior to death from their malignancy. The next aspect of surgical decision-making to consider is morbidity and mortality rates, which are considerable in patients undergoing palliative surgery. Morbidity and mortality rates are widely variable in the literature with a range of morbidity from 9% to 90% and a range of mortality from 9% to 40% [16]. A recent series from our institution demonstrated morbidity and mortality rates for surgical intervention of 44% and 5%, respectively [13].

Recognizing the lack of randomized trials and limited data from observational and retrospective studies of patients with advanced malignancy and bowel obstruction, various groups have attempted to provide consensus statements and treatment algorithms for these difficult clinical scenarios. The working group of the European Association for Palliative Care has provided clinical practice recommendations that state surgery should not be routinely undertaken and will only benefit selected patients with end-stage cancer and mechanical obstruction [16]. The working group went on to recommend absolute contraindications to surgery, such as previous abdominal surgery that showed diffuse metastatic cancer, involvement of the proximal stomach, and ascites that recurs rapidly after drainage. Relative contraindications include poor general performance status, poor nutritional status, and extra-abdominal metastases producing symptoms that are difficult to control. Many investigators have sought to identify variables associated with adverse outcomes. A systematic review of surgery for malignant bowel obstruction reported that poor performance status, diffuse carcinomatosis, previous radiotherapy, and small bowel site of obstruction were associated with failure of surgery [18]. Additionally, ascites and carcinomatosis are frequently reported as independent indicators of poor survival and also diminished ability to tolerate oral intake after palliative surgical intervention [19–21]. The combination of ascites and carcinomatosis creates a situation that is rarely palliated with surgery, other than venting gastrostomy tube placement.

Gastric Outlet Obstruction

Gastric outlet obstruction is defined as obstruction of the distal stomach or proximal duodenum and is most often associated with gastric, duodenal, or pancreatic malignancy. Figure 59.1 demonstrates a CT image of a patient with gastric outlet obstruction secondary to gastric cancer involving the pylorus. Gastric outlet obstruction accounts for only approximately 20% of palliative surgical consultations for gastrointestinal obstruction but has a low median survival of 3 months, highlighting the need for selective surgical intervention [9]. Management options include surgical loop gastrojejunostomy or endoscopic stenting. As the majority of

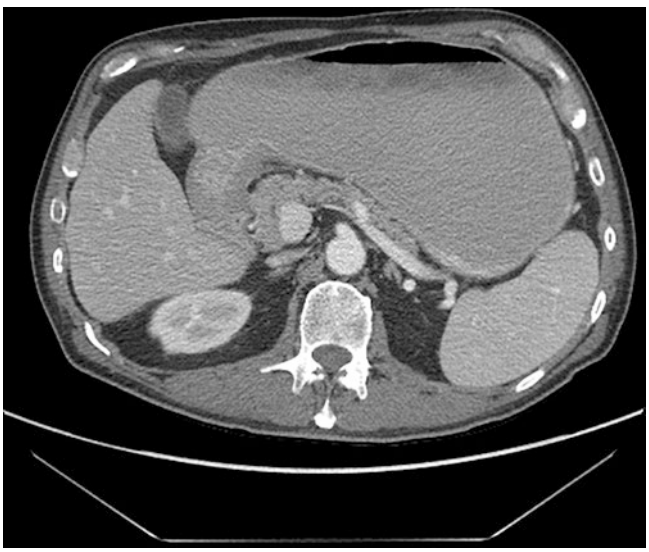

Fig. 59.1 CT image demonstrating gastric outlet obstruction

cancers that cause gastric outlet obstruction are associated with limited survival, prognostication plays an important role in treatment selection.

Although technically simple, morbidity and mortality rates after loop gastrojejunostomy are significant, and temporary delayed gastric emptying can occur [17]. Laparoscopic gastrojejunostomy may carry less morbidity and is associated with a lower incidence of delayed gastric emptying and faster resumption of oral intake [22]. Endoscopic stents, on the other hand, have less risk of morbidity and mortality but lack the durability of a surgical bypass [18, 19]. Stents can be complicated by occlusion or migration and are more likely to require re-intervention [23, 24]. A Cochrane review found that despite similar rates of technical success, stents were associated with a slightly shorter time to oral intake and a shorter length of stay [24]. This allows for earlier resumption of chemotherapy, although a survival difference has not been demonstrated [25]. Furthermore, stents are associated with a lower overall cost for index hospitalization and lower rates of 90-day readmission [23]. However, given the rates of recurrent obstructive symptoms and re-interventions in patients undergoing endoscopic stent placement, several authors have proposed surgery should be considered in patients with a life expectancy of 2 months or longer [21, 22]. A new technique for treatment of gastric outlet obstruction is endoscopic ultrasound-guided gastroenterostomy, which has shown similar technical and clinical success with less need for re-intervention impaired to endoscopic stenting [26], but long-term follow-up studies are needed [27].

Venting gastrostomy tubes are another option for patients with symptoms of nausea and emesis who have contraindications to surgical or endoscopic palliation. Gastrostomy tube placement may be performed through open surgery, laparoscopic surgery, endoscopy, or interventional radiology, although preference is given to the least invasive procedure possible as median post procedure survival rates are reported as only a few weeks [28–30]. Both endoscopic and interventional radiologic placement can be complicated by tube migration, leakage, and infections of the tube site, but literature reviews suggest endoscopic placement has fewer complications [24]. A retrospective review found that for patients who received a decompressing gastrostomy tube, a longer interval to placement was not associated with a change in overall survival, which suggests that venting gastrostomy tubes are often placed late in the course of disease [30].

Small Bowel Obstruction

Small bowel obstruction is defined as obstruction from the terminal portion of the duodenum to the ileocecal valve. Small bowel obstruction represents the most common indication for palliative surgical consultation in patients with gastrointestinal obstruction (64%) but has a similar median survival (3.5 months) to gastric outlet obstruction [13]. Only 25% of patients with small bowel obstruction undergo surgical intervention with the majority (52%) undergoing non-operative/nonprocedural management and 24% undergoing endoscopic/interventional procedures. The majority of endoscopic or interventional radiologic procedures in this population are venting gastrostomy tubes, as stents are typically not an option for small bowel obstructions. Many patients with advanced cancer and bowel obstruction have had previous surgery, adding difficulty in the differentiation of an obstruction due to malignancy from an obstruction due to benign adhesive disease. The surgical procedure is often not decided upon until completing exploration of the abdomen, and the two most common approaches are either bowel resection or intestinal bypass. A venting gastrostomy tube can be placed at surgery for patients with disease prohibiting resection or bypass, and conditions felt to be at high risk for early re-obstruction.

Large Bowel Obstruction

As many as 8–29% of patients with primary colorectal cancer present with malignant colonic obstruction [31]. Management options include surgical options of bypass, bowel resection or diverting ostomy placement, endoscopic stenting, or supportive care. Stents can be used as a palliative therapy in patients who are not good operative candidates or can be used as a bridge to surgery in patients presenting with an obstruction. A retrospective review found that stenting was clinically successful in 86% of patients undergoing palliative stenting and 89% of patients undergoing stenting as a bridge to surgery [32]. Stents are associated with a low risk of perforation [32] but can migrate or obstruct and thus require re-intervention [33] or urgent surgery in up to one third of patients [34]. Peritoneal carcinomatosis is associated with decreased technical and clinical success in stent placement [35], although a lower likelihood of delayed perforation [36]. The advantages of stent placement include shorter length of stay, avoidance of a stoma, and allowance for a better oncologic resection in patients who are later amenable to curative surgery [31, 33, 34]. Patients with inoperable malignant bowel obstruction can be treated with medical therapy including antiemetics, steroids, anti-secretory agents, octreotide, and hyoscine butylbromide [37]. One retrospective study found that 49% of these obstructions resolved with medical management, with functional mechanisms of obstruction more likely to resolve [37].

Gastrointestinal Bleeding

Similar to bowel obstruction, gastrointestinal bleeding in patients with cancer can be due to benign or malignant causes. The initial evaluation focuses on determining the severity of bleeding and assessing for hemodynamic instability. Utilizing the same initial approach taught through advanced trauma and life support training, surgeons assess the airway, breathing, and circulation of patients with gastrointestinal bleeding while ensuring adequate intravenous access. During this time, laboratory analysis should begin to include a complete blood count, blood typing and cross-matching, coagulation factors, and electrolytes with BUN and creatinine. A nasogastric tube and Foley catheter are often required for patients with active bleeding. Most patients are hemodynamically stable which allows time for medical management and diagnostic workup. Endoscopy is the primary modality utilized in gastrointestinal bleeding for diagnosis and therapy. Other less commonly required tests include tagged red blood cell scans, arteriography, and capsule endoscopy. As patients with advanced cancer are often best treated without surgical intervention, therapeutic options frequently involve embolization performed by interventional radiologists.

Bleeding secondary to tumor or treatment-related complications can involve many site-specific diagnostic and treatment issues. Tumors of the gastroesophageal junction and stomach often account for anemia through a slow rate of gastrointestinal hemorrhage and rarely require urgent surgery. In a recent review of 289 patients with advanced gastric cancer from Massachusetts General Hospital, only 3.5% required emergent surgery at presentation, of which none were performed for bleeding [38]. In addition, 233 patients in this series were managed without resection of the primary tumor, of which only 6 patients required subsequent emergency surgery for obstruction or perforation and no patient required surgery for bleeding. The low rate of surgical intervention for gastric hemorrhage is likely due to the many options available for bleeding secondary to tumor involvement such as endoscopic interventions, chemotherapy, and radiotherapy. For patients with gastric cancer, palliative radiotherapy can control bleeding in 70% of patients with a low rate of requirement for additional interventions during the patient's remaining life [39] and a duration of symptom control of 15 weeks [40].

Bleeding from small bowel tumors can be secondary to primary or metastatic malignancy. The small intestine can be a difficult diagnostic challenge as endoscopy will typically only assess to the level of the duodenum from above and terminal ileum from below. The remainder of the small bowel may involve arteriography or capsule endoscopy to accurately localize the site of bleeding. Bleeding from the large intestine and rectum can often be localized with colonoscopy, with the majority of cases attributable to primary colon and rectal cancer. Primary tumor response rates to palliative chemotherapy and radiation (for rectal cancer) are good and infrequently require emergent surgery.

Wound Problems and Infections

Palliative wound care can be a challenging clinical scenario that is of extreme importance to the patient. Problems related to wounds include bleeding, exudate, odor, pain, and limitations in function. Wound complications and infections are a frequent indication for palliative surgical consultation, representing 10% of palliative surgical inpatient consults at comprehensive cancer centers [3]. Treatment approaches include local wound care, excision, amputation, systemic therapy, and radiation. Traditional wound care management strategies are limited by the impaired healing of patients with advanced malignancy or patients that have received recent immunosuppressive therapy. Malignant fungating wounds are a unique challenge due to malodor and discharge that can affect up to 5% of people with cancer [41]. Figure 59.2 demonstrates a malignant fungating squamous cell cancer of the posterior scalp. Systematic reviews have identified few high-quality studies or effective therapies to guide the topical treatment of malodor and discharge in fungating wounds. However, a Cochrane review found one study showing that foam castings containing silver provided improved control of malodor, and another study showed similar results with regard to exudate, malodor, and pain with manuka honey and nanocrystalline silver dressings [42]. Although typically

Fig. 59.2 Fungating malignant wound of the posterior scalp

used for more short-term wound care, one small study found that the use of negative pressure wound therapy for malignant wounds led to decreased pain, fewer dressing changes, and increased resumption of social interactions, with an average duration of 49 days [43]. Surgery is rarely an option but may be a last resort in patients that have wounds refractory to other therapy and are appropriate surgical candidates. Involvement of plastic surgery for advanced wound closure techniques is frequently required in patients undergoing surgery for wound problems.

Obstructive Jaundice

Options for treating biliary obstruction in patients with cancer include endoscopic stent placement, percutaneous catheter placement, or surgical bypass. Prognostication, although difficult and often inaccurate, can help identify the optimal treatment method. Endoscopic stent placement via endoscopic retrograde cholangiopancreatography (ERCP) is now the gold standard for biliary drainage as it is safe and effective [44]. Recurrent obstruction can occur but may be decreased with the use of self-expanding metallic stents. A systematic review and meta-analysis showed lower occlusion rates but increased rates of migration and pancreatitis for covered stents compared to uncovered stents, with no significant difference in survival or overall complication rates [45]. Percutaneous catheter placement by interventional radiology is often reserved for patients that fail endoscopic stent placement, as percutaneous procedures are more invasive. A systematic review and meta-analysis found that percutaneous transhepatic biliary drainage has a higher incidence of bleeding and dislocation but lower incidence of cholangitis and pancreatitis compared to endoscopic stenting. Yet, they found no difference in therapeutic success rate, overall complication rate, or 30-day mortality [46]. Endoscopic ultrasound-guided biliary drainage is a more recent procedure that can be used if ERCP stent placement is not feasible [47]. Several randomized controlled trials have found similar stent patency, adverse events, and re-interventions in centers where this technique is available [48].

Surgery is required in a fraction of patients but should be considered in patients that fail endoscopic attempts, live far away from referral centers with endoscopic expertise, or have other indications for surgical intervention such as concomitant gastric outlet obstruction. Even in the setting of gastric outlet obstruction, a gastric bypass and biliary stent may be preferred to a double bypass, as a double bypass procedure is associated with a higher rate of both biliary and non-biliary complications [49]. Figure 59.3 shows a CT image of a patient with concomitant bile duct obstruction and duodenal narrowing secondary to a locally invasive pancreatic neuroendocrine tumor. *Roux-en-Y* hepaticojejunostomy/choledochojejunostomy is the most frequently performed method of palliation and involves anastomosis of a 40–60 cm Roux limb to the bile duct in an end-to-side or side-to-side fashion. Anastomosis of the bowel to the gallbladder (cholecystojejunostomy) is a simpler method of biliary bypass that may be conducive to a laparoscopic approach, with acceptable results in small series [50]. However, a large population-based analysis of the SEER-Medicare data found a biliary intervention rate of 7.5% for patients undergoing cholecystojejunostomy and only 2.9% for patients undergoing bile duct bypass [51].

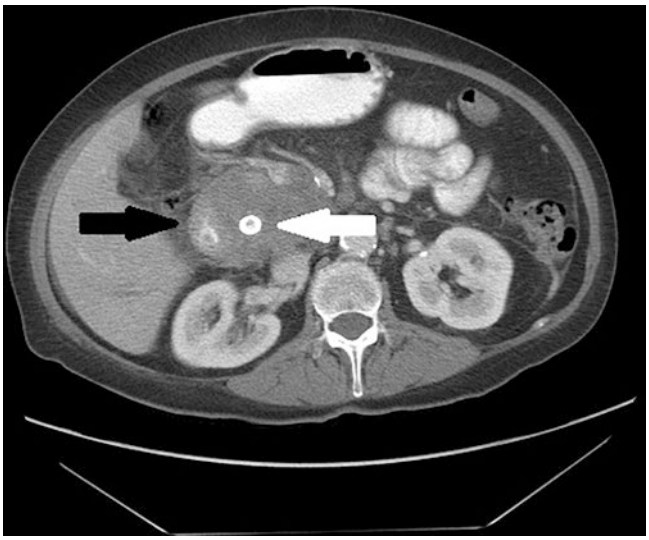

Fig. 59.3 CT image demonstrating a locally invasive pancreatic cancer causing narrowing of the duodenum (*black arrow*) and bile duct obstruction requiring metallic stent placement (*white arrow*)

Bowel Perforation

As with gastrointestinal bleeding and obstruction, there are benign and tumor-related causes of bowel perforation. Common benign causes of perforation include peptic ulcer disease and diverticulitis. Tumor-related causes include direct tumor invasion with perforation but also the side effects of cancer treatment such as immunosuppression, radiation effects, steroid administration, and the direct effects of chemotherapy that may render cancer patients more prone to bowel perforation. Cancer patients may also be more prone to iatrogenic bowel perforation due to the need for frequent endoscopic and interventional radiology procedures. As many cancer patients with bowel perforation have advanced or incurable disease, the optimal treatment is often based on a balance between the clinical presentation and oncologic prognosis. The majority of cancer patients with bowel perforation are treated with surgery with a 30-day mortality rate of 15% and morbidity rate of 46% [52].

Nonoperative care is another option, particularly in patients with incurable disease, and may have similar outcomes in select patients without abdominal tenderness, limited extent of perforation or contained free air, and aggressive treatment with antibiotics and drain placement [52]. One retrospective review found better outcomes after palliative surgery for intestinal perforation in patients who had higher albumin, low ECOG performance status, and absence of dyspnea and thus recommended consideration of nonoperative management for patients with unfavorable prognostic factors [53].

A unique and complex clinical situation is bowel perforation or fistula formation during treatment with bevacizumab. Bevacizumab is a humanized monoclonal antibody to vascular endothelial growth factor that has been proven efficacious in a number of disease sites, including several phase III randomized trials of patients with metastatic colon cancer [54]. Although generally well tolerated, bevacizumab has been associated with gastrointestinal perforation in 1–3.5% of patients [55, 56]. In a large retrospective review, risk factors for perforation included poorly differentiated signet ring cell carcinoma, stent use, and rectal location of primary and intact primary, although complications requiring surgery did not change survival [56]. Wound healing complications are increased in patients that undergo surgery during treatment, and most surgeons exercise caution in performing a gastrointestinal anastomosis in patients with bevacizumab-associated perforation [55].

Anorectal Infections

Anorectal infections and abscesses in noncancer patients are typically straightforward in management consisting of incision and drainage with complex treatment required in only a minority of patients. Anorectal infections in patients with immunosuppression, neutropenia, recent chemotherapy, or stem cell transplant and advanced hematologic disease can be a difficult palliative situation with considerable treatment and quality of life implications. Older reports of anorectal disease in neutropenic patients detailed associated mortality rates of up to 50%, while more recent reports suggest improvements in survival [57]. Anorectal infections in cancer patients are classified as either an abscess or perianal infectious process (pain or erythema without abscess/fluid). Necrotizing soft tissue infections are rare (~2%) but associated with significant mortality [57]. Patients often need imaging to evaluate for abscess or fluid formation, as physical exam findings can be misleading. Patients with fluid typically undergo an exam under anesthesia with drainage and seton placement or catheter placement via interventional radiology. Patients with a perianal infectious process without documentation of fluid are managed with antibiotics and close monitoring.

Ascites

Malignant ascites has a detrimental effect on quality of life with associated symptoms of abdominal pain, dyspnea, nausea, vomiting, anorexia, impaired movement, and fatigue [58, 59]. It is associated with limited survival, on the order of 1–6 months [58, 60–63], with only 11% of patients surviving greater than 6 months after the development of malignant ascites [64]. However, ovarian cancer has a more favorable prognosis than other primaries in the setting of ascites with reported survival rates of 24 months [64]. There are a wide variety of treatment options including diuretic administration, fluid restriction, systemic chemotherapy, intermittent paracentesis, peritoneal drainage catheters, and hyperthermic intraperitoneal chemotherapy.

Paracentesis is the most common treatment modality. In a physician practice survey, 98% of practitioners reported using paracentesis, and 89% reported it to be effective [65]. While paracentesis provides temporary relief for 90% of patients [66], repeat large-volume paracentesis is associated with decreased quality of life as paracentesis is only performed once symptoms recur [67]. Tunneled peritoneal catheters, such as the PleurX system, can provide a more durable option by allowing more frequent and smaller-volume drainage that can be performed outside of the hospital [68–71]. Tunneled catheters can be placed under fluoroscopic, ultrasound, or CT guidance and have reported technical success rates of close to a hundred percent in several retrospective and nonrandomized prospective studies [68–73]. The majority of patients with the PleurX catheter report good control of their symptoms, and the need for further interventions to restore catheter function is infrequent [71]. Surgeons infrequently perform peritoneal venous shunt placement due to its less effective control of ascites as well as higher complication rates, including sepsis, heart failure, disseminated intravascular coagulation, and shunt malfunction or infection [67].

Hyperthermic intraperitoneal chemotherapy (HIPEC) is combined with cytoreductive surgery in the treatment of peritoneal surface malignancy, appendiceal mucinous neoplasms, and colorectal/ovarian carcinomatosis. However, cytoreduction combined with HIPEC is a morbid procedure with an established mortality rate and lengthy post procedure hospitalization that is not generally appropriate for palliative surgical scenarios. Laparoscopic HIPEC, without cytoreduction, has been performed in patients with malignant ascites with excellent results in small series (Fig. 59.4). The laparoscopic approach appears to alleviate much of the morbidity – a multi-institutional analysis of 52 patients undergoing laparoscopic HIPEC reported a complication rate of only 6% with no postoperative mortalities [74]. Remarkably, the laparoscopic HIPEC procedure prevented re-accumulation of ascites in all but one patient [74]. Furthermore, small studies have found an average increase in Karnofsky performance scores of 20 points after treatment [74, 75].

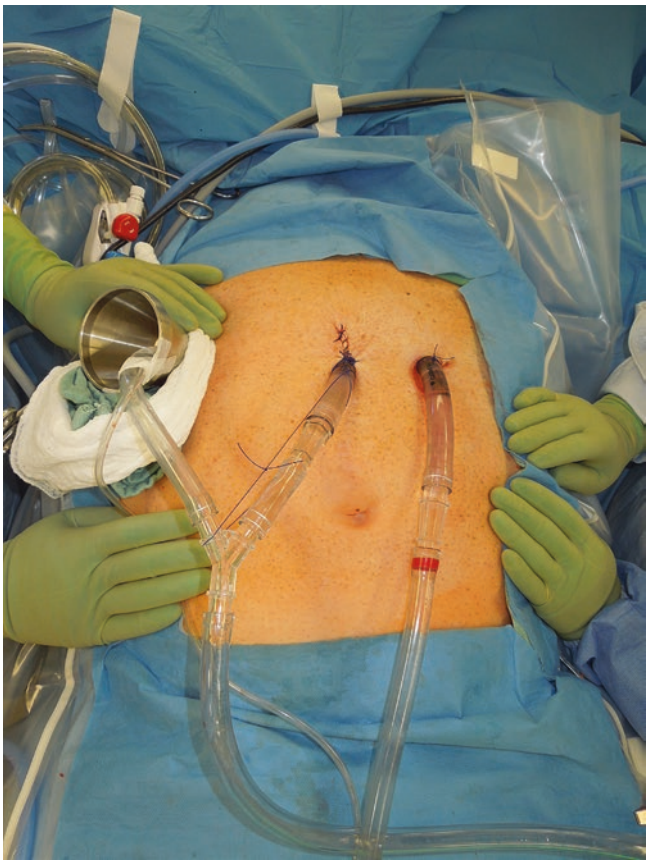

Fig. 59.4 Intraoperative cannula placement for laparoscopic hyperthermic intraperitoneal chemotherapy administration

Abdominal Pain in Unique Patient Populations

Celiac Plexus Involvement

Tumors with a propensity for perineural invasion, such as pancreatic cancer, can cause debilitating abdominal pain that radiates to the back. Pain in cancer patients, however, is infrequently attributable to a single cause but is more often a multi-factorial syndrome of tumor-related causes, treatment-related causes, and chronic pre-existing pain unrelated to cancer or its treatment. Opioids are the first line of treatment and often the only treatment that is needed. Palliative radiation is another treatment option for patients with pain secondary to celiac plexus involvement [76]. Celiac plexus neurolysis is a good local treatment option that can be performed through a percutaneous or endoscopic approach. Recent systematic reviews of plexus block procedures demonstrate improvements in pain with side effects usually limited to diarrhea, hypotension, and temporary increased levels of pain [77]. With multiple nonoperative options to alleviate celiac plexus-associated pain, surgical chemical blocks are relegated to the intraoperative scenario of finding unresectable disease during attempted pancreaticoduodenectomy. In such a situation, there is evidence from a randomized clinical trial that an intraoperative celiac block can lower pain in patients with preoperative pain and also prevent pain in patients without preoperative pain [78]. In situations where unresectable pancreatic cancer is detected during diagnostic laparoscopy, a laparoscopic celiac block has similarly been proven efficacious in reducing pain scores [79].

Neutropenia

Abdominal pain in neutropenic cancer patients presents a palliative clinical challenge as 90-day mortality rates are approximately 50%. The differential diagnosis includes causes of abdominal pain common in general surgery consultation such as bowel obstruction, diverticulitis, and appendicitis but also cancer treatment-related causes such as neutropenic enterocolitis and *Clostridium difficile* colitis [80]. Mortality associated with surgical intervention in the presence of neutropenia has been reported as high as 57% [81]. Surgeons will often deliberately delay treatment to allow for resolution of neutropenia, if possible [80].

Multiple Myeloma

Multiple myeloma is a plasma cell malignancy with systemic overproduction of antibodies resulting in bone pain, anemia, and renal insufficiency, with progressive tumor formation resulting in bone marrow failure. Surgical interventions are primarily palliative for long bone compression fractures or spinal cord compression. Abdominal pain requiring surgical consultation in myeloma patients is a serious condition with an associated 90-day mortality rate of 43% [82]. The differential diagnosis in this unique patient population is notable for the frequency of neutropenic enterocolitis (22%) and bowel perforation (13%) [82]. Prompt attention should be given to new complaints of abdominal pain in patients with myeloma as surgery may be required, although consideration should be given to the frequent comorbid conditions, severe sepsis, and recent administration of chemotherapy in the setting of a disease with often limited survival.

Outcome Measures

The palliative surgical literature is difficult to interpret due to the lack of commonly accepted outcome measures. In a review of studies from the palliative surgical literature, quality of life measurements were only included in 17% of stud-

ies, while morbidity and mortality were reported in 61% [83]. Morbidity and mortality, although important outcome measures in the risk analysis of surgery, must be balanced against patient-reported benefits of palliative surgery. Adding to the complexity of palliative surgical studies are the high attrition rate and difficulty in administering burdensome general quality of life instruments [84]. Observational outcome measures may provide some improvement in rates of postoperative symptom evaluation [85]. Future studies of easily administered, quick, patient-reported outcomes will be needed to identify the optimal outcome measure and then identify variables associated with outcome to select patients appropriately for surgery [86].

Conclusion

In summary, palliative surgical care is becoming increasingly recognized as critical in the multidisciplinary treatment of cancer patients. Traditional literature has focused on outcomes of morbidity and mortality with recent efforts to identify optimal patient-reported outcomes. There are few standardized guidelines for surgical intervention, and the decision to proceed with surgery is based on patient, family, and provider discussions incorporating a risk versus benefit model. Careful consideration is given to prognosis, although difficult and sometimes inaccurate, as well as future oncologic treatment options. As patients undergoing palliative surgical consultation are often dealing with severe symptoms, these discussions should be started as soon as possible, and attempts to anticipate future palliative clinical scenarios are helpful.

Palliative Care

60

Sangeeta Lamba and Rebecca Goett

Integrating Emergency Palliative Care for Patients with Advanced Cancer

Seriously ill patients (with malignant and nonmalignant chronic illnesses) who suffer from a high disease and symptom burden often visit the emergency department (ED) for acute crisis events related to their illness [1–13]. Though the ED is primarily designed to resuscitate and stabilize the acutely ill and injured, increasingly those with chronic serious underlying disease processes such as malignancy seek care in this setting [1–5, 7, 10–18]. Malignancy-related symptoms and oncologic emergencies therefore often lead to ED visits, and these visits tend to increase as the patient's clinical status deteriorates and as they approach the end of life [1, 3, 4, 11]. Most hospitalizations in patients with underlying malignancy are initiated from the ED, and these early hours of care often include life-sustaining decisions such as ventilator support and symptom control that establishes, for better or for worse, the trajectory of future in-hospital care [15–20]. When a patient with a life-threatening oncologic emergency presents to the ED, these rapid decisions often occur in the context of uncertain prognosis and rapidly evolving clinical status, especially if the event was unexpected [17–20]. Determining goals of care rapidly so that initial treatment pathways align with patient values (thus avoiding future conflict) is challenging in most circumstances, but perhaps even more so in the ED setting [17–20]. At times, ED providers may need to change gears and shift their focus to comfort and quality of life goals for the patient (palliative care) as opposed to the traditional focus on cure or disease-centered treatment. Strategies to provide optimal care to the seriously ill patient with cancer include (1) use of best practice based clinical decision-making models [21, 22] and (2) incorporation of patients' values and goals in plans of care [15–19].

S. Lamba (✉) · R. Goett

The World Health Organization defines palliative care as an approach that "improves the quality of life of patients and their families when facing the problems associated with life-threatening illness, through the prevention and relief of suffering by early identification, impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" [23]. Palliative care applies to *all phases* of a life-limiting condition and is not just for dying patients (Fig. 60.1) [11, 16, 17, 23–25]. In fact, maximal benefit is likely when there is early integration of palliative care into management plans as opposed to only considering such care as a last resort measure when "no more can be done" for the patient [1, 7, 16, 17, 23–31]. The early integration of palliative care is associated with a higher quality of life, including better understanding and communication, access to home care, emotional and spiritual support, well-being and dignity, care at time of death, and lighter symptom burden. In fact, some evidence suggests that, on average, palliative care and hospice patients may live longer than similarly ill patients who do not receive such care [6, 17, 32]. Palliative care also has the ability to simultaneously improve quality and control the cost of care for the most seriously ill patients [25, 28, 30–38].

The Institute of Medicine (IOM) report "Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life" highlights the current disconnect between how most Americans wish to be cared for at the end of their lives and the care that is actually pro-

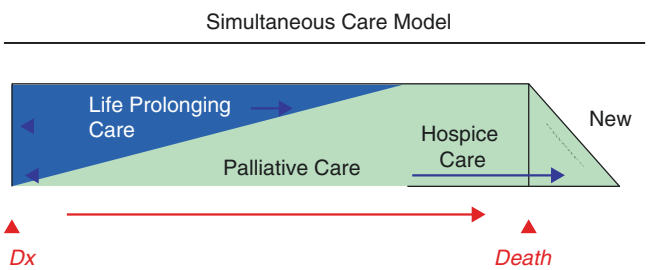

Fig. 60.1 Simultaneous care model of palliative care

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_60

vided to them [32]. The report lists a similar disconnect between the services that seriously ill patients and families need and the services they currently receive [32]. People nearing the end of life often experience multiple transitions between healthcare settings (the ED being a major setting for end of life crises) and high rates of apparently preventable hospitalizations—which can further fragment the delivery of care and create an added burden for patients and families [32].

The IOM report also makes a recommendation that "All people with advanced serious illness should have access to skilled palliative care or, when appropriate, hospice care in all settings where they receive care (i.e., health care facilities including the ED, the home, and the community)" [32]. This report also proposes that comprehensive care for individuals with advanced serious illness who are nearing the end of life should:

- Be seamless, integrated, patient-centered, family- oriented, and consistently accessible
- Consider the physical, emotional, social, and spiritual needs of individuals and family
- Include coordinated, efficient information transfer across all providers and all settings
- Be consistent with individuals' values, goals, and informed preferences [32].

These proposed goals are consistent with palliative care principles and are integral components of both palliative care and hospice care (Table 60.1) [23, 26, 32]. However, it is important to note that hospice care services in the United States are primarily based on prognosis (as reimbursed by Medicare) and considered when a patient has a terminal prognosis with 6 months or less of predicted survival [16, 17, 20].

Palliative care is "whole person care" or patient-centered care and involves an interdisciplinary team, including board-certified or trained hospice and palliative medicine physicians, nurses, social workers, and chaplains, together with other healthcare professionals as needed [16, 17, 20]. Depending on local resources, access to this team may be on site, via virtual (phone) consultation, or by transfer to a setting with these resources and this expertise level, such as an in-hospital palliative care unit [16, 17, 20]. Although most now recognize the importance of the ED setting in caring for the seriously ill, many barriers and competing priorities for both ED and palliative care providers jeopardize more widespread integration of these two disciplines [16, 17, 39]. The term "integration" is used to indicate the incorporation of palliative care principles (outlined in Table 60.1) [23, 26, 32] into daily ED practice with or without the involvement of a dedicated palliative care team or inpatient palliative care unit.

Table 60.1 Principles and elements of palliative care[a]

Patient and family centered care Care plan is aligned with preferences and determined by goals of patient and family and there is a support system to help family cope with the patient's illness and with bereavement
Timing Support starts early in the course of illness and may exist along with therapies that are intended to prolong life (such as chemotherapy) Support continues until disease cure or patient death
Interdisciplinary team approach to care A team meets the needs of patients and families (may include nurses, social workers, clergy, nursing assistants, pharmacists, and volunteers)
Comprehensive care Multidimensional assessment to treat physical, psychological, social, and spiritual distress
Relief of suffering Prevent and relieve suffering from pain and other distressing symptoms
Skills in the care of the dying and bereaved Prognostication Offers a support system to help patients live as actively as possible until death
Quality of life Focus on enhanced quality of life (may also positively influence the course of illness) Regards dying as a normal process while affirms life
Continuity of care Ensure communication and coordination of care in transitions across settings Prevent crises and unnecessary transfers are important outcomes
Quality assessment and performance improvement[b] Address safety and incorporate the systems of care that reduce error Use validated instruments for data to measure outcomes, when feasible

[a]Patient population: patients of all ages experiencing a serious chronic or life-threatening illness or injury

[b]Crucial emergency department (ED) and hospital metrics may include ED visits, ED length of stay, time of arrival to time of disposition, hospital and intensive care unit (ICU) length of stay, hospital readmissions, ICU admissions, documenting advance directives, and pain/symptom control *Adapted from the National Consensus Project for Quality Palliative Care: Clinical Practice Guidelines for Quality Palliative Care and the World Health Organization palliative care Definition* [23, 26, 32]

Generalist Versus Specialist Emergency Palliative Care [17, 40, 41]

Many palliative care-related skills such as management of pain and other distressing symptoms as well as aligning management with a patient's goals of care are expected to be delivered by all emergency practitioners, so-called generalist practitioner level skills [7, 17, 22, 40, 41]. However, more complex palliative skills such as negotiating a difficult family meeting and managing advanced or refractory symptoms may require a "specialist level" of expertise [7, 17, 22, 40, 41]. Though it may be ideal to have a specialist manage all elements of palliative care, the reality is such that there are

Table 60.2 Generalist versus specialist levels of palliative care [40, 41]

Generalist-level palliative care	*Examples of tasks*
Provided by healthcare professionals who manage seriously ill patients, but palliative care is not the main focus of their daily work Includes care in settings not specialized in palliative care such as the emergency department	Basic management of pain and other distressing symptoms Basic discussions about prognosis, goals of treatment, and advance directives
Specialist-level palliative care	
Provided by healthcare professionals where main activity is the provision of palliative care Includes care in settings specialized in palliative care such as inpatient palliative care unit or hospice	Management of refractory pain or other difficult-to-treat complex symptoms Conflict resolution regarding goals of care (between family members and between family and healthcare team) Futility of care conversations

not enough specialists in the workforce, to do so. As people live longer with a higher burden of chronic illness, the demand for both generalist and specialist palliative care will rise [40]. Palliative care training programs have expanded nationwide, but the current levels of new trainees in palliative medicine will not meet the needs for all patients who may benefit from such "specialist" care [40, 42]. An optimal care model includes both generalist emergency palliative care (skills that all emergency clinicians should have) and specialist emergency palliative care (skills for managing more complex cases) (Table 60.2) [17, 40, 41]. The Education on Palliative and End-of-life Care (EPEC), EPEC-EM, and End-of-Life Nursing Education Consortium courses are examples of training that seek to build the generalist level of skills for emergency practitioners [43, 44]. Workshops and guides available from multiple resources also target further specific palliative skill development for interested practitioners [45, 46]. Due to the palliative care workforce gap, there is a growing need to develop generalist palliative care skills during emergency medicine resident training and also to provide continuing medical education to practicing clinicians [17, 40]. In addition, some state licensing boards require completion of pain and palliative care education credits prior to license renewal [47]. Performance and quality measure metrics can be used to reinforce the ongoing emphasis on generalist emergency palliative care as an integral component of high-quality patient care [27, 48].

Integrated Emergency Medicine-Palliative Care Initiatives

The Improving Palliative Care in EM (IPAL-EM) project is a resource development and dissemination initiative begun in 2010 by the Center to Advance Palliative Care (CAPC) with funding provided by the Olive Branch Foundation [7, 49, 50]. The goal of this initiative was to accelerate the integration of palliative care services into ED settings. It brought together an advisory panel of nationally recognized leaders in the disciplines of emergency medicine and palliative care [7, 22, 49, 50]. IPAL-EM offers an online portal for sharing essential expertise and available best evidence, tools, and practical resources to assist emergency clinicians and ED administrators in the successful integration of palliative care and EM [22, 49]. Currently, an institutional subscription to CAPC provides access to all the resources gathered as part of the IPAL-EM project, including clinical practice guidelines, needs assessment tools, and ED-specific quality metrics with a relevant library of peer-reviewed consensus/policy statements [49]. Finally, the American College of Emergency Physicians (ACEP) Palliative Care Section provides a variety of online resources to support ED-based palliative care [51].

Demonstration Models of Integrated Emergency Palliative Care

In the last decade, several programs have established ED palliative care initiatives to identify patients that may benefit from early palliative care interventions [22]. The IPAL-EM initiative collected information on existing models or demonstrations of ED and palliative care service integration. Eleven US hospital-based clinical integration programs were interviewed after they were identified from a review of literature, national presentations, and feedback from peer emergency palliative care experts [22]. These programs had varying levels of collaboration between their institutional palliative care program and the ED. Four themes emerged regarding ED palliative care programmatic development including (1) traditional consultation, (2) basic integration, (3) advanced integration, and (4) ED-focused advanced integration models (Fig. 60.2) [22].

Traditional Consultation Programs Similar to other consultation services that interact with the ED, a palliative care expert or consultant is contacted by the ED provider to help answer questions or issues in patient care and to help manage difficult-to-control symptoms [24, 40]. In this model there are no common programmatic goals or process steps to improve overall care delivery [22].

Basic Integration Programs In these models there exists a somewhat more formal relationship between the palliative care program and the ED, and they may work together to achieve some common programmatic goals and objectives. For example, there may be defined protocols for improved patient workflow such as expedited admission to a palliative care unit or targeted generalist-level palliative care education for the ED staff [22].

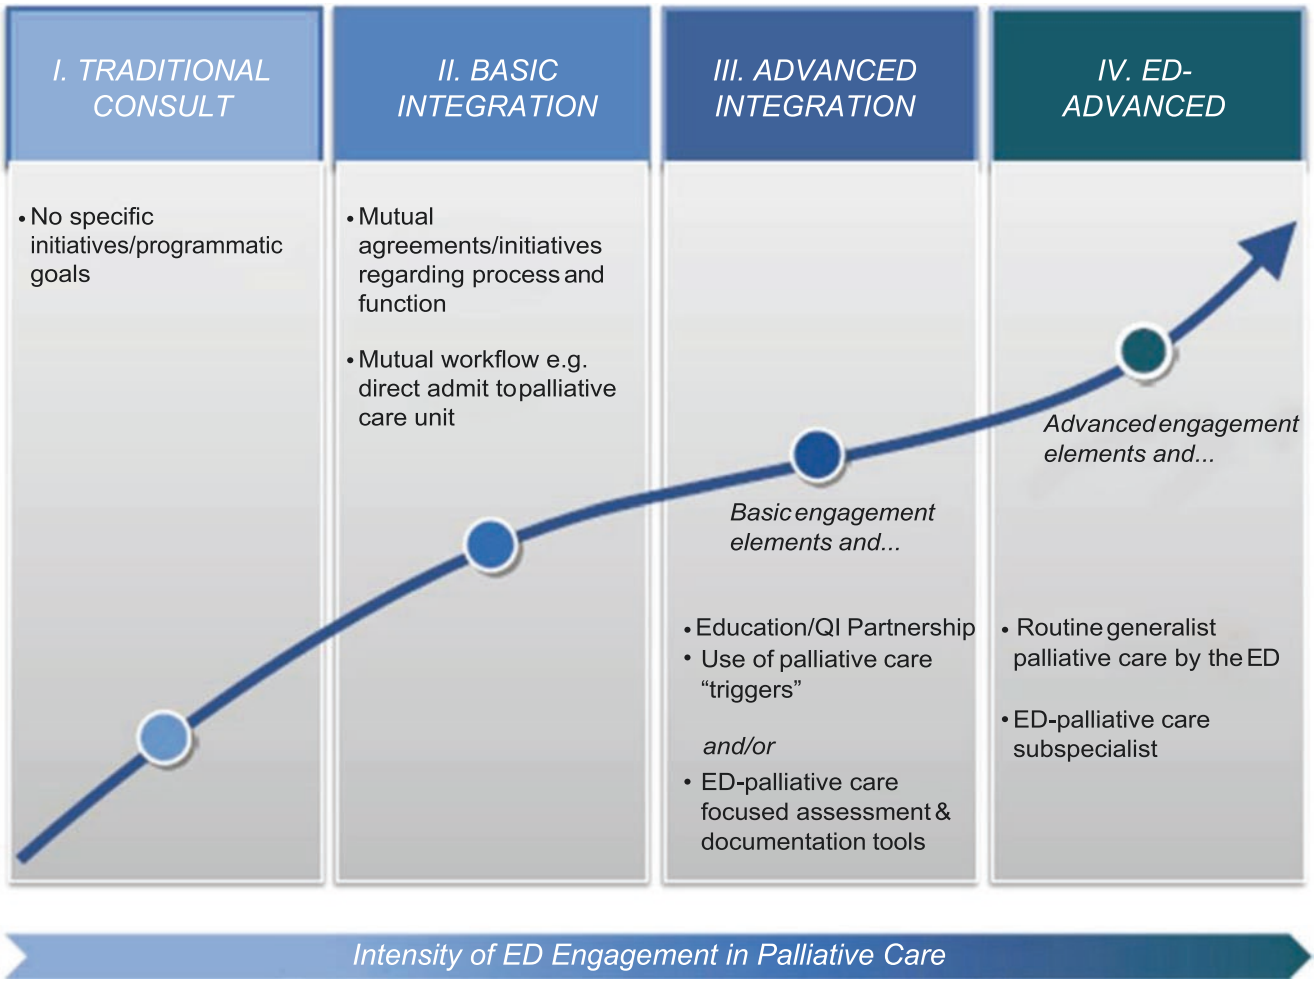

Fig. 60.2 Observed models of ED and palliative care integration [22]

Advanced Integration Programs These programs build on the basic integration models to set up common programmatic processes and protocols with the ED increasingly taking on a more active role, while an enhanced level of ED generalist-level palliative care is provided [22, 52].

ED-Focused Advanced Integration Programs In these programs, the ED is very engaged and focused on palliative care-related processes. In some cases the ED may lead the integration and the palliative care services in the institution. Common themes in these programs include case management for high-risk palliative care patients and existence of dual EM and palliative medicine-certified physicians who are passionate about the integration initiatives. Additionally, these programs often have increased numbers of personnel resources to support palliative care, including ED social workers or bereavement supporters for families. They may also implement reorganization and structural changes to improve patient care at the end of life, such as a designated private room or space for imminently dying patients and their families [22, 53].

Jump-Starting an ED Palliative Care Integration Initiative

Researchers have identified a number of important barriers to emergency medicine and palliative care integration. Surveys of physicians, nurses, and administrators list barriers such as (1) the ED culture of life-prolonging care and resuscitation that places a lower emphasis on nontechnical skills, (2) palliative care staffing and availability for the 24-hour, seven days a week, needs of the ED, (3) logistical issues including lack of access to patient medical records, and (4) medicolegal concerns particularly if life-prolonging therapy is not offered [10, 15, 39, 54]. One manuscript describes the ED as being "caught in the middle" when caring for such patients. It lists the challenging physical environment (privacy, noise, lack of information and delay, and lack of defined pathways), with limited resources (overcrowding, time pressures, competition with other emergencies) and variable roles and expectations of the staff providing care (comfort with dying, views of dying in the ED, expertise

and comfort in caring for those with serious and advanced illnesses) [10]. On the other hand, the emergency medicine resident and attending physician surveys report that they believe that palliative care skills are important for EM practice but that they are not yet adequately educated and trained in providing such care [15, 55]. Domains of particular interest identified for emergency physician training include management of patients under hospice care, withdrawal of life-prolonging measures, prognostication, and pain management [15, 17, 55]. Recently, hospice and palliative medicine educational milestones were developed for emergency medicine resident training [56].

It is important to begin an ED-PC initiative with identified ED "champions" who can effectively build upon lessons learned from other prior successes and failures so that the initiative is tailored to fit the unique ED setting [7, 50]. The design of the initiative should recognize the preexisting hospital and community resources, availability and hours of access to palliative care consultation services to the ED, and key institutional deficiencies in ED palliative care [7, 50]. Some common examples of initial targets for integration may include:

- Setting up an ED bereavement program
- Defining screening criteria to identify high-risk patients for early palliative care team interventions
- Educating ED staff on pain and palliative care protocols
- Embedding palliative care staff in ED rounds
- Improving throughput to the inpatient palliative care unit, when available

These initiatives have a higher chance of success if aligned with the key metrics important to the institution, such as ED length of stay, hospital readmission rates, and utilization metrics related to observation and intensive care units [7, 17, 48, 50]. Described below are four steps that may help jump-start such an integration initiative [7, 50].

1. *Put Together a Team: Palliative Care "Champions" in the ED*

Recruiting work group or team members who are interested and committed to the integration of palliative care in the ED is important. For example, identify those individuals who have previously expressed concern, frustration, or sensitivity to a patient's unmet palliative care needs. The interdisciplinary collaborative nature of palliative care allows for engagement of varied professional disciplines based in the ED such as social workers and case managers, as well as other providers throughout the institution who interact with the ED, such as chaplains. Since the integration initiative has the potential to impact other hospital services and processes, a wider range of administrative and clinical personnel should also be considered for inclusion. Table 60.3 lists some of the members to consider when setting up an initial work group. Though the type of members engaged in such an initiative will likely vary from one ED to another, it is vital to include key ED administrators such as the ED medical director and nurse manager(s) in the work group. They not only know their own ED's needs but can also provide valuable perspectives, taking into account resources (staffing, training needs) that may be critical for designing and implementing feasible integration efforts [7, 50]. The ED administrators may also be best equipped to engage support among both ED colleagues and at a broader institutional level.

Table 60.3 Suggested members for the emergency department (ED) palliative care integration initiative [7]

ED medical director
ED physician(s)
ED nurse manager and ED nurse(s)
Director or designee of the palliative care program
Nursing educator
Social workers
Case managers
Chaplain
Representatives of key hospital services (e.g., hospitalists, ICU, surgery, oncologic) that may be affected by this initiative in the ED
Hospital leadership: administration and finance
Others relevant to the success of a specific part of the initiative (e.g., ethics consultant, mental health professional, pharmacist)

2. *Explore the Resources Available: Existing Literature and Resources*

The literature in emergency palliative care is increasing rapidly. Consensus statements on the role of palliative care and ED such as the policy statements and the Choosing Wisely campaign from the American College of Emergency Physicians and Emergency Nurses Association on roles of the ED and ethical issues at end of life are important to note [57–59]. Specific guidance from the Choosing Wisely campaign states: "Don't delay engaging available palliative and hospice care services in the emergency department for patients likely to benefit" [57]. While there is no identified optimal model of ED integration of palliative care, there are a growing number of examples in the literature of specific strategies and programs that have proven to be successful [21, 22, 30, 31, 60]. Other topics relevant to emergency palliative care include:

- Palliative and end-of-life care in the ED [1, 2, 4, 5, 7, 16–20]
- Communication skills [5, 15]
- Family experience and surrogate decision-making [5]
- Palliative care specialists in the ED [19, 40]
- Ethical issues [5, 15]
- Quality improvement/practice change [48]

- Protocols and screening criteria [30, 31, 60]
- Family presence during resuscitation [17]
- Bereavement care [17, 25]
- Education and training [55, 61]

An open-access educational online resource published by the Palliative Care Network of Wisconsin, *Fast Facts and Concepts*, is worth noting since it provides concise, practical, peer-reviewed, and evidence-based summaries on key topics important to clinicians and trainees caring for patients facing life-limiting illnesses [62]. *Fast Facts* are free, easily accessible, and clinically relevant monographs on palliative care topics. They are intended as quick teaching tools for bedside rounds, as well as self-study material for trainees and clinicians who work with patients with life-limiting illnesses. For example, separate *Fast Fact* monographs review protocols for ventilator withdrawal protocol, guidance for calculating opioid dose conversions, and practical aspects of initiating a hospice referral from the ED [62, 63]. In addition, there are several formal educational opportunities in palliative care targeted to ED clinicians. Some programs address overall palliative care skills for many types of providers, while others target profession-specific skill development, for example, those for social work and chaplains. Sponsoring some or all of the identified "champions" at such a conference may help build an institutional pool of qualified candidates who can not only train others but could then be targeted for future career development. Some opportunities include:

(a) EPEC-EM (Education in Palliative and End-of-life Care for Emergency Medicine): EPEC-EM is a 2-day conference designed to teach clinical competencies in palliative care to ED healthcare professionals in a train-the-trainer format. The conference covers topics specific to ED practice including rapid palliative assessment, disease trajectories and prognosis, care of the hospice patient, chronic and malignant pain management, family-witnessed resuscitation, communication, and more. There is also a focus on techniques for teaching the curriculum to other emergency practitioners [43].
(b) ELNEC (End-of-Life Nursing Education Consortium): ELNEC offers a modular train-the-trainer end-of-life training program for nurses [44].
(c) Communication skills building workshops such as Vital Talk [45, 46] that have now developed ED-specific workshops.
(d) Hospice and palliative medicine fellowship.

The American Board of Emergency Medicine is one of ten sponsoring boards for the hospice and palliative medicine subspecialty. The ACGME provides a program listing and additional information about individual pro- grams that can be accessed online [64].

3. *Identify and Ease Access to Local Hospice and Palliative Care Resources*

Identify palliative care resources (both personnel and services) that are available: (1) within the ED, such as case managers; (2) in the institution, such as a chaplain, social worker, or bereavement counselor; and (3) in the community such as collaborative arrangements with hospice agencies [30, 31]. These resources are often available, but remain unfamiliar to the ED staff and even if known are not easily identifiable by ED staff at the time of critical need. Collating information and making it easy to access are therefore valuable. Other steps to ease access to palliative resources may include: (1) Identifying and listing various hospital and community resources (Table 60.4); (2) cataloguing their roles, responsibilities, and contact numbers; (3) posting call schedules for personnel in a visible, high traffic area of the ED for ease of access; and (4) identifying clearly the hours of availability of support personnel and whether they are available in person or by phone. Additionally, consider explaining roles and responsibilities of personnel. For example, social work and case managers may be essential partners when navigating disposition issues and maximizing community resource utilization [7].

Palliative Care Consults If the institution has a specialty-level palliative care team, it may be important to collaborate with them to create screening criteria that assist ED staff in identifying appropriate reasons for consultation (Table 60.5) [7, 60]. Since many such palliative care consultation teams offer in-person services during regular working weekday hours and phone support during off-hours and weekends, it may be useful to create collaborative guidelines to determine what will constitute a non-urgent versus urgent/emergent level of consultation [7, 40, 59].

Inpatient Palliative Care Units Similarly, if the institution has a specialized inpatient palliative care unit, it may be useful to not only establish formal guidelines and processes for admissions from the ED but also educate ED staff on the scope and capabilities of care in this setting. This collaboration

Table 60.4 Potential list of institutional and community resources [7, 50]

Palliative care team call schedules
Palliative care team hours of in-person availability
Outpatient palliative care clinic availability and practice hours
Community hospice: home and residential hospice
Chaplaincy support and availability
Social work support and availability
Bereavement support and availability
Ethics consultant
Child life specialist support and availability (for pediatric patients or children of adult patients)

Table 60.5 Screening criteria for a palliative care assessment at the time of admission [60]

A potentially life-limiting or life-threatening condition (such as malignancy)[a] *and*
Primary criteria:
Global indicators that represent the minimum that hospitals should use to screen patients at risk for unmet palliative care needs
The "surprise question": Would you be surprised if the patient died during this admission?
Frequent admissions (admissions for same condition within several months)
Difficult-to-control (moderate-severe) physical or psychological symptoms
Complex care requirements (functional dependency; home support for ventilator or tube feedings)
Decline in function or overall failure to thrive
Secondary criteria:
Specific indicators that may suggest a high likelihood of unmet palliative care needs
Admission from a long-term care facility
Metastatic or locally advanced incurable cancer
Chronic home oxygen use
Out-of-hospital cardiac arrest
Current or past hospice program enrollee
Limited social support (family stress, chronic mental illness, etc.)
No history of completing an advance care planning discussion/ document

[a]Life-limiting or life-threatening condition is defined as any disease known to be life-limiting (e.g., chronic obstructive pulmonary disease, metastatic cancer) or that has a high chance of leading to death (e.g., multi-organ failure, sepsis). Serious medical conditions for which recovery to baseline function is routine (e.g., community-acquired pneumonia in a healthy adult) are not included in definition

with the palliative team and ED may be able to prevent some unwanted ED visits, for example, by referrals to an outpatient palliative care clinic.

Hospice Collaborations In addition, appropriate referrals to hospice from the ED are feasible and may facilitate early dispositions [20, 63]. Since these decisions are based on patient-determined goals of care with engagement of loved ones, they have the potential to increase patient and family satisfaction with ED care [20]. Fostering collaborative relationships with local hospice agencies and engaging them in a timely manner for appropriate patients may help clinicians initiate hospice referrals directly from the ED [20]. These relationships also have the potential to improve dialogue when managing patients under hospice care who arrive to the ED with a crisis event related to control of distressing symptoms [20].

4. *Complete a Needs Assessment for ED Palliative Care*

An assessment of needs helps identify opportunities for improvement in ED palliative care. This may help with targeting of areas where simple interventions can lead to early success that in turn provides momentum to the integration initiative. The needs assessment can outline barriers to the integration initiative and specific institutional strengths and weaknesses and finally identify adherence gaps between best practice guidelines and local practice. This information can focus initial attention and aid decisions on assigning resources [7].

Table 60.6 Sample section of the needs assessment tool [26, 65]

Domain 2: Physical aspects of care				
Guideline 2.1: ED clinicians use a multidisciplinary approach to pain and symptom control				
Indicator		*Present*	*Absent*	*Comment*
2.1	ED clinicians collaborate with specialists from different disciplines to create a comprehensive pain/ symptom control plan of care	☐	☐	
Guideline 2.2: ED clinicians assess symptoms using validated assessment tools appropriate for patients across the life span				
Indicator		*Present*	*Absent*	*Comment*
2.2.1	Standardized pain assessment tools are used	☐	☐	
2.2.2	Standardized symptom distress assessment tools are used	☐	☐	
Guideline 2.3: Emergency nurses use nurse-initiated protocols to relieve the symptom burden of patients				
Indicator		*Present*	*Absent*	*Comment*
2.3	The ED uses nurse-initiated analgesic protocols	☐	☐	

Core guidelines for effective palliative care are outlined by the National Consensus Project for Quality Palliative Care (NCP) and address eight palliative care domains, including physical aspects of care and social aspects of care [26]. These guidelines represent goals and ideal practices that enable programs to define their own palliative program organization, resource requirements, and performance measures. These guidelines have been adapted to develop ED-specific clinical practice guidelines and translated into a "needs assessment tool" that programs may find useful to identify areas for improvement (Table 60.6) [65].

Monitoring Integrated Palliative Care Initiatives

The Agency for Healthcare Research and Quality (AHRQ)/ American College of Emergency Physicians conference on "Improving the Quality and Efficiency of Emergency Care Across the Continuum: A Systems Approach" identified four key topics or questions for emergency medicine and palliative care: (1) Which patients are in greatest need of palliative care services in the ED (identifying the target population in

Table 60.7 Potential measurable quality metrics and outcomes for an emergency department (ED) palliative care integration initiative

Operational
Mean/median ED length of stay (hours)
Discharge disposition status
ED arrival to time of disposition (to palliative care unit)
% With repeat ED visits within 30 days (within 60, 90 days)
% With repeat hospital admits within 30 days (within 60, 90 days)
Number of hospice referrals from the ED
Number of palliative care referrals from the ED (if available)
Clinical
% Charts with documentation of the healthcare decision-maker/ advance care directives
% Of patients prescribed opioids with bowel regimen on discharge
% Of patients with documented pain assessment on presentation and % reassessed
% Of families with documented offer of spiritual support after ED death
% Of patients in target populations who have a documented palliative care assessment
% Of caregivers in target patient populations screened for caregiver strain
Patient satisfaction
% Of ED patients who report being adequately informed about their condition or treatment plans and options
% Of families who report excellent overall end-of-life care after patient's ED death
% Of patients reporting satisfaction with communication regarding discharge instructions

need)? (2) What is the optimal role of emergency clinicians in caring for patients along a chronic trajectory of illness (what skills are necessary)? (3) What is the effect on healthcare utilization after the integration and initiation of palliative care training and services in the ED? and (4) What are the educational priorities for emergency clinicians in the domain of palliative care? The conference proposed that future emergency palliative care research gathers evidence in these domains using six categories of inquiry: descriptive; attitudinal; screening; outcomes; resource allocation; and education of clinicians [48, 66]. Examples of some relevant quality indicators to measure progress toward ED-palliative care integration are listed in Table 60.7. Emerging work is exploring the efficacy of decision support tools and accuracy of screening triggers and tracking outcomes of the initiatives described above [67, 68].

Health Economics

Building palliative care capacity or launching new integrated palliative care initiatives in the ED may have costs that can range from minimal to substantial. For example, if the goal is to identify patients with palliative care needs early in the ED, an approach that uses preexisting resources such as the ED triage nurse to screen will have nominal costs, whereas if a dedicated staff such as a social worker will perform initial screening, the cost will be substantial. Therefore, leveraging preexisting resources such as nurse and faculty educators for educational initiatives and sharing interdisciplinary team members such as social work across units may allow for significant success without a large financial impact. Use of qualitative assessment (QA) EMR consult triggers, documentation templates, or order sets are also relatively inexpensive to place but need promotion and education around implementation.

For major and advanced palliative care integration initiatives, the main cost is personnel related, and buy-in from the administration would be needed. Highlighting elements that are important to the institution such as the fact that palliative care has been shown to increase patient satisfaction, improve quality of life, and decrease number of ICU days (and therefore related costs) may be useful to make the case and the value proposition for funding palliative care [6, 17, 25, 28, 30–38]. Leveraging philanthropy may offer ways to get smaller seed funds to jump-start an initiative as well. Education of clinicians around existing re-imbursement pathways may also incentivize good practices. For example, in 2018, Centers for Medicare & Medicaid Services updated their policy for providers to code for reimbursement when they provide advanced care planning and goals of care discussions with patients.

Case Studies

Case 1 Communication Skills: Delivery of Difficult or Serious News

A 67-year-old woman with hypertension and a history of ovarian cancer with surgical resection 7 years ago presents to the ED with moderate shortness of breath. Since the patient is afebrile and has unexplained tachycardia, she has a CT scan of the chest performed to rule out a pulmonary embolism. Multiple large pulmonary nodules suspicious of metastatic disease are seen. This disease progression is new based on patient's records.

ED Tasks Communication of serious or difficult news, advance care planning, aligning goals of care, symptom control, psycho-social and emotional support, and disposition to hospital or palliative care unit.

Case 2: Rapid Goals of Care Discussion

A 68-year-old woman with diabetes and breast cancer with metastatic bone disease is undergoing palliative radiation for pain management. She has severe fatigue, fever, and short-

ness of breath with oxygen saturation of 87% on 15-liter non-rebreather mask and high flow nasal cannula. Her chest X-ray shows diffuse bilateral ground glass infiltrates consistent with coronavirus infectious disease 2019. She is awake, anxious, and struggling to speak more than two to three words. She wants her live-in boyfriend of 10 years to make decisions regarding intubation but does not want her only daughter engaged. She also says that if she stops breathing, "that's God's will."

ED Task Effective communication of serious news, rapid goals of care, identifying healthcare proxy, managing possible family conflict, ethical issues, symptom management.

Case 3: Symptom Management: Actively Dying Patient

Patient is an 83-year-old man with congestive heart failure NYHA Class 4 and prostate cancer with bony metastases and presents to the ED for acute respiratory failure and hypotension with septic shock. He is enrolled in hospice at home, but his wife got anxious because he was struggling to breathe and she says, "please help him." Patient has a do-not-resuscitate and do-not intubate order on file.

ED Tasks Symptom management, aligning goals of care, coordinating disposition, transitioning care to in-patient hospice and/or palliative care unit, bereavement, and spiritual and psychosocial support of caregiver.

Summary

Optimal care for the seriously ill patient with cancer in the emergency department includes an early integration of palliative care for eligible patients. This capacity for palliative care is built by fostering the skills and competencies for the generalist ED clinician who will provide much of this care to meet patient needs such as effective communication of serious news, aligning treatment with patient's goals of care and wishes, and managing distressing symptoms. Capacity is further built using an integrated approach with early identification of patients with complex palliative care needs who would benefit from specialist-level consultation in the ED and navigating patient and family to appropriate palliative care and hospice resources. Integration initiatives in the ED may have a higher chance of success when ED champions are fully engaged with palliative care experts to collaboratively define not only resources and processes but also appropriate metrics to track outcomes and measure impact of the integrated initiative.

Hospice

61

Bonnie K. Marr and Danielle J. Doberman

Why This Chapter Is Important

Most emergency physicians can recall a patient presenting to the emergency department (ED) with severe pain, dyspnea, or other symptoms and having to give the gut-wrenching news of a new cancer diagnosis or significant disease progression [1, 2]. With sensitive discussion, the patient may reveal they were referred to hospice services by their outpatient specialist for management of their symptom burden or extensive disease progression and ultimately declined to follow these recommendations. Even more memorable is the patient who is currently receiving hospice services yet presents to the ED actively dying. These scenarios are common and stand out due to the complexity of untangling the patient and family's true goals when presenting to the ED. As a clinician new to a patient's journey with serious illness, negotiating the intricacies of "breaking bad news" or navigating goals of care—especially for a patient who may be actively dying—in a time-constrained environment with limited information available is unlike other areas of medicine. However, emergency providers are in a unique and important position to make an impact on the patient's overall illness trajectory and care plan. This chapter will provide additional tools for navigating these circumstances and highlight the progress that can be made despite the challenges of the ED.

Cancer continues to be the leading diagnosis for those enrolled in hospice according to the National Hospice and Palliative Care Organization, with 30.1% of hospice decedents having a principal diagnosis of cancer in 2017 [3]. Therefore, within this text, it is important to emphasize that emergency physicians should be facile in communicating the differences between hospice and non-hospice palliative care (PC), evaluating the reasons a patient may present to the ED while enrolled in hospice services, confirming patient and family goals of care, and utilizing available resources to insure a smooth transition across settings.

Background

The Center to Advance Palliative Care (CAPC) defines palliative care as "… specialized medical care for people with serious illnesses... Palliative care is appropriate at any age and at any stage in a serious illness and can be provided together with curative treatment" [4]. Serious illness may include diagnoses, such as cancer, cardiac disease, respiratory disease, kidney failure, dementia, HIV/AIDS, amyotrophic lateral sclerosis (ALS), and many other serious and progressive illnesses. CAPC emphasizes that palliative care should not be initiated based on a patient's prognosis alone, but rather on the need for specialized, coordinated medical care for patients living with any stage of a serious illness from diagnosis onward, and can be provided along with curative treatments. CAPC further defines the overall goals of palliative care to be improved quality of life for the patient and family through assisting with management of symptoms and enhanced coping, which often can include clarification of goals of care [4, 5].

Emergency physicians who engage in reviewing goals of care with a patient and/or family can find it challenging to describe hospice and compare and contrast its services to those offered by palliative care. Both fields share a common philosophy of care that prioritizes patient-centered goals, focuses on the patient and family adaptation to illness and coping, and offers proactive symptom management. Hospice, however, is a program of services for patients who have a prognosis of 6 months or less and is provided to those who forgo further curative or life-prolonging care to focus on dignity and comfort at the end of life [6].

Under hospice care, a physician-signed "Certification of Terminal Illness" (CTI) is required, whereby that physician attests that the patient's prognosis is anticipated to be less than 6 months if the terminal illness were to continue on the anticipated trajectory. Emergency physicians may be asked to sign this form when making referrals to hospice from the ED. At the time of hospice enrollment, the patient designates their Medicare or other insurance benefits to hospice care rather than ongoing curative treatment for the terminal illness and/or related conditions [7]. A helpful resource to review when exploring hospice designation for providers and patients can be found at https://www.medicare.gov/coverage/hospice-care. In addition, the assessment may be complex in supporting the CTI, and your ED case manager or hospice medical director may have special expertise in reviewing this documentation.

When a Patient Enrolled in Hospice Presents to the Emergency Department

Patients presenting from a hospice model of care to the ED are often experiencing a crisis, such as uncontrolled or poorly controlled symptoms, new symptoms such as a seizure or bleeding, or caregiver exhaustion due to the demands of care for someone with a progressive disease [1, 8, 9]. Symptom control needs may simply outpace the capacity of the home environment. On arrival to the ED, patients and their family and support systems do not necessarily wish to revoke hospice. Rather, they seek the rapid assessment and provision of symptom control EDs are known to routinely offer. In the setting of duress, a loved one may call for emergency medical services because this is a familiar way to seek urgent medical care. This type of presentation represents a critical juncture to confirm goals of care and an opportunity to coordinate treatment with the hospice of the patient's choice and align care with the patient's wishes. Counseling the family regarding the patient's current clinical status or recent decline and evaluation for potential refractory symptoms is often required. In addition, as outlined in Table 61.1, coordination of care with the hospice of their choice to ensure needs are being met, expectations are managed, and clear communication provided may prevent hospital admission or a return to the ED.

Given the variety of life-prolonging treatments available in the ED setting, and procedures such as thoracentesis or addressing an unstable fracture, which can dramatically improve comfort for patients even in their last days, yet can carry iatrogenic risks, conversations to urgently confirm and clarify goals of care and discuss alternatives provided by the hospice should take place whenever possible before a plan of care is finalized. Patient-defined goals of care should dictate any testing and treatment and take precedence over ED protocols as these may no longer be appropriate in the context of the patient's wishes. The hospice where the patient is enrolled likely has information regarding advance directives, previous intended plan of care, and prior wishes of the patient. They may even be able to send personnel to the ED who can be helpful in further exploration of the patient's goals as well.

Table 61.1 Reasons hospice patients present to the emergency department [1, 9]

Patient and support system reasons	Hospice care coordination reasons
Symptom control not optimized and felt to be intolerable (e.g., pain regimen felt to be ineffective despite titration by hospice)	Inability to address patient needs in a timely manner to improve comfort/lessen suffering
Urgent new symptom (e.g., seizure, hemoptysis, urinary retention, impaction, epistaxis, fall with fracture, or need for suture/cast)	Poor communication and/or anticipatory guidance and education with the patient and family
Medical equipment or supportive device malfunction (e.g., gastrostomy tube dislodgement, oxygen supply running out)	Hospice arranged for ED presentation to assist with supportive device/medical equipment restoration in keeping with patient's advance directives
Patient and caregiver(s) have differing/conflicting philosophies of care	Equipment malfunction/failure without timely repair or replacement to maintain patient's comfort (e.g., nebulizer, suction device, home oxygen, BiPAP)
Caregiver fatigue or challenge meeting the demands of maintaining the patient's comfort/needs	Family new to hospice/hospice experience and unaware to telephone hospice for their needs
Conflict about life-prolonging treatments. These may be treatments that were discontinued (e.g., chemotherapy) or interventions that were never initiated (e.g., hemodialysis)	Patient traveling between hospice catchment areas with unanticipated symptoms and not sure how to obtain hospice assistance
Automatic response to patient distress, a loved one may call EMS because this is a familiar way to seek urgent medical care	Presenting from a skilled nursing facility where staff is to be directed by hospice team to provide care and staff unfamiliar with hospice procedures/policies without proper training and require urgent assistance
Patient has enrolled in hospice requesting full resuscitation and EMS activated in keeping with their advance directives	

Time for the Talk: Introducing Hospice

As outlined earlier in this chapter, patients presenting to the ED with an oncologic diagnosis may qualify for hospice services, including with discovery of disease progression or functional decline; however, clinicians may be hesitant to

broach the topic given the constraints of a time-limited interaction and perceived difficulty in coordinating this transition in care [10]. Emergency providers should feel empowered to assess a patient's hospice eligibility and review this with the patient's primary physician, often an oncologist, cardiologist, or other specialist. In introducing hospice, it is necessary to review a patient's understanding of their clinical situation, sometimes called their "prognostic understanding" [11]. Having a shared understanding of prognosis between all providers, patient, and family is key to a successful hospice referral. Next, a provider would review goals of care and ascertain if the patient's wishes are aligned with hospice philosophy of care. Many of the steps in determining the appropriate level of hospice care and reviewing what services can be provided through the hospice are nuanced and based on the patient's clinical status and wishes. Table 61.2 provides a quick reference for overview of the hospice referral process, and Table 61.3 reviews the levels of hospice care.

It is often helpful to include ED social work and case management as early as possible in the care of a patient for whom hospice is being entertained to help in exploring possible options. It may also be useful to discuss the patient directly with the medical director of the hospice of the patient's/family's choice for further coordination of care. While it may seem there are a lot of moving parts to coordinate transition to hospice from an ED visit, this may be an ideal opportunity to facilitate the patient's goals and help the patient and family negotiate a crossroads in their healthcare journey. When there is a pre-existing relationship with the local hospices within the hospital's catchment area and the ED and hospital, the process of direct admission into hospice care from the ED can work smoothly. In these circumstances, social work and case management teams likely have experience offering the patient and family choices of hospice vendors with varying capacities and then facilitating assessment by the hospice(s) of their choice. The ideal scenario is a transfer to either a hospice inpatient unit (IPU) directly from the ED or the arrangement of a hospice intake visit (initial visit by a nurse at the patient's home or place of residence who will admit the patient to hospice and review policies/procedures and medications for symptom control) on the same day as discharge from the ED.

However, despite these efforts, some patients and family may decline to enroll in hospice from the ED, preferring a discharge home without services. Hitting the proverbial pause button on a disease-modifying plan of care that may not be in alignment with the patient's values and wishes for the future they envision can be an important first step in developing a treatment plan which supports their wishes. Due to the time-compressed environment of the ED, connecting with the patient's primary care physician or primary physician of record (cardiologist, oncologist, etc.) to convey the need for further goals of care discussions and plan for further in-depth discussions in the outpatient setting can facilitate a smooth transition of care. The primary physician may wish to hold these discussions themselves or may request an outpatient palliative clinic consultation be arranged from the ED. If the patient/family are strongly considering hospice and have not yet confirmed this choice, another option is to arrange a hospice informational visit, during which a representative from the local hospice of the patient's choice visits the patient at bedside or in their home to explain the program and its services. This is an ideal opportunity to assist the patient and their family in the information-gathering stages.

Review of Emergency Department and Palliative Care Collaborations: Toward Developing Pathways for Efficient Transfer to Hospice Care

For ED patients who are eligible for hospice, collaboration between ED providers and the hospital's palliative care service may be useful to identify patients who would benefit from a palliative care consult, provide over-arching support for seeking out goal-concordant care, and assist with care coordination with local hospices as appropriate. Quest and colleagues developed the Improving Palliative Care in Emergency Medicine (IPAL-EM) curriculum and not only identified an algorithm for considering palliative care involvement but also review a stepwise process to promote emergency medicine and palliative care collaboration, including the use of a needs analysis [12, 13]. Each institution may differ in the results of the analysis, especially as the viewpoints of various stakeholders are considered; however, through CAPC, this tool kit is available to tailor collaboration based on the needs identified. In terms of hospice, there are opportunities to streamline communication between ED staff and local hospices as well as utilize the local strengths of the ED interdisciplinary team, including social work and case management, to make direct hospice referrals. Patients and families must have the freedom of choice regarding which hospice they choose, and staff should be educated to provide these options and assist with coordination of care. An ED with an established PC partnership may use standard mutually agreeable screening tools to identify patients with unmet palliative care needs for PC consultation and hospice eligibility. A number of screening tools exist to identify these patients [14–16].

Early PC involvement in the ED presents the possibility for increased efficiency in the form of decreased length of hospital stay, improved patient/family satisfaction, decreased ICU utilization, and increased direct hospice referrals [16–20]. Further, PC programs often have relationships with hospices within a hospital's catchment area and can build

Table 61.2 Coordinating transition to hospice from the emergency department [1]

Steps to consider	Why this is important	Potential resources to assist	Nota bene
Determine hospice eligibility	Patients must qualify for hospice based on general Medicare guidelines used in conjunction with disease-specific considerations	Remember "Certification of Terminal Illness" is required where the patient's prognosis is anticipated to be less than 6 months if the terminal illness were to continue on the anticipated trajectory with specific criteria required [6]. The criteria can be complex and generally provide evidence for the clinical judgment above with factors related to demonstrating overall decline in clinical status versus non-disease-specific and disease-specific guidelines. It is recommended to review if a patient is eligible for hospice with their provider of record and the hospice of choice [11]	Hospice and palliative care teams are great resources for information
Discuss with provider of record	Can confirm hospice eligibility, review remaining treatment options and current treatment regimen, coordinate care, and engage provider with trusted rapport with the patient	Oncologist or primary care doctor may be the point of contact. They also may wish to be the provider of record for the hospice	This provider may also want to speak to the patient/family directly, and therefore it is important to include this person in the beginning for care coordination
Elicit patient information preferences, understanding, and goals of care	Prior to introducing hospice, it is important to find out what information the patient and/or family wants to receive (e.g., some may not want to know specific prognosis), assess understanding of their status to better manage expectations and elucidate gaps in communication/knowledge, and *further establish specific patient-centered goals of care*	Please see earlier chapter on communication for specific strategies and resources	Consider palliative care consult
Review philosophy of hospice if compatible with goals of care	Review that hospice is not a specific "place," but a philosophy of care focused on comfort and dignity at the EOL. May be helpful to ask the patient's understanding of hospice or prior experiences to help directly address concerns	Helpful to have social work and case management involved in discussions and to assist in reviewing available care in the home if this is the patient's preference and clinically appropriate	Work with your department to have a ready list of local hospices for ease of providing written materials to patients/families
Hospice choices/facilitate coordination of care	SW/CM may be helpful in reviewing local hospice resources to provide patients and families with choices available. Once this is done, hospice liaisons may be involved to evaluate the case	It can be helpful to review the case with the medical director of the hospice of the patient's choice as hospices have varying policies/procedures regarding certain interventions, such as IVF, TPN, antibiotics, etc. This is also a chance to review level of care needs—patients must meet certain criteria to be admitted to inpatient units (IPUs)	May be helpful to have list of contact information for liaisons/medical directors for local hospices available for providers
Disposition preparation	What you will need to do: Generally, hospices will require a "Certification of Terminal Illness" and decisions regarding hospice provider of record (of note, this can be the hospice medical director). A finalized MOLST/POLST dependent on the state laws may be needed	What needs to be arranged with the hospice: Arrangement with the hospice for delivery of DME, hospice intake visit, and review of prescriptions that may be needed until a patient's enrollment in hospice is complete	Care coordination with the patient's primary provider, especially if transition to hospice is not possible at time of determination of disposition
Clear sign out!	All the time invested in discussions with the patient, family, hospice, and primary provider should be thoroughly discussed at sign out and carefully documented. Discussions and family meetings are important and like a procedure should be recorded	Given the intense nature of these discussions and the shift nature of most ED provider's schedules, consider introducing the new provider coming on shift to the patient and their family, if possible, to establish continuity and provide clear communication	As in any other discharge, a patient should be assessed for stability for transport and anticipatory guidance given to families as appropriate if there is concern for potential death during transport

Table 61.3 Descriptions and considerations for levels of hospice care

Level of care	Description	Considerations	Helpful facts
Routine	*Routine care* is hospice care that patients have caregivers who can provide around the clock care if needed, have stable symptoms or symptoms anticipated to be controlled utilizing measures accessible *within the home, or home-like settings*, such as an assisted living, group home, or long-term care environment [12]	Hospices can have different policies regarding caregiver availability (most—but not all—require someone available 24/7). Some may also allow a trial at home in the setting of a recent symptom exacerbation if the patient's primary wish is to be in the home, or a home-like setting, and there is a plan in place to address this symptom across care settings	Home hospice includes visits from the IDT and can include nurses, social workers, chaplains, home health aide, and trained volunteers, with the physician of record overseeing care
Continuous	*Continuous care* can be provided in times of crisis (must be 8 out of 24 h), and 50% of this time must be provided by a nurse [12]	It is important to discuss with the hospice if a patient transferring from an acute care setting into continuous care may be better served by GIP level of care	It is helpful to review with the hospice of their choice what their policies are surrounding providing continuous care
General inpatient (GIP)	*GIP* level of care typically requires pain or symptom management in an inpatient facility that cannot be provided in another setting [12, 13]	Hospices will evaluate the symptom burden being considered, what has been done to address it, and potential for future exacerbations and complications	Generally, this is not meant to be the final disposition for the patient as they will be transferred to a less intense level of care once symptoms are stabilized. However, the facility may allow the patient to remain if death is considered imminent
Respite	*Respite care* is meant to provide temporary relief of caregiver responsibilities and has specific parameters surrounding this benefit [12]	Consider respite care for patients whose caregivers require a temporary "respite" from caregiving responsibilities, or if there are temporary reasons why the patient cannot stay in a particular routine LOC setting, but otherwise does not qualify for GIP level of care and is considered routine. Examples include the caregiver themselves falls ill, or a protracted power outage in the home of an oxygen-dependent patient makes return for a few days impossible	Collaboration with social work and other members of the ED IDT may be helpful. Remember: patients may present from hospice to the ED with goals of care unchanged related to social reasons and respite care may provide a solution

working relationships for protocols between the hospital and the hospice of a patient's choice when the need for hospice is identified by an emergency provider, and communication is required to jump-start the transition from the ED to hospice placement. In these cases, a PC consult may not always be required, but through a pre-existing collaboration, the process can be developed to make a referral seamless and routine, rather than requiring admission for disposition determination, especially if not desired by the patient and family.

Case Studies

Case Study 1

Mr. M is a 73-year-old man with past medical history significant for hypertension, coronary artery disease, and stage IV non-small cell lung cancer (NSLC) diagnosed 7 months ago and known metastases to the bone and liver. He has recently developed recurrent malignant pleural effusions, and due to his worsening dyspnea, pleurodesis has been discussed versus *a tunneled indwelling pigtail drainage catheter. He presents to the ED today complaining of profound dyspnea, especially with mild exertion such as trying to cross a room from bedroom to bathroom, and he had a small amount of hemoptysis earlier, of about a teaspoon in volume, 4 or 5 times. His last available documentation in your healthcare system's medical record reveals initial discussions were held about hospice with decision to maintain code status as a "full code." He had been awaiting review of potential clinical trials at a nearby academic center before electing to enroll in hospice care. You note that he has been to the ED once already this month and received an emergent thoracentesis and was evaluated by radiation oncologic without plans for further radiation at this time. He also describes worsening tolerance to activities of daily living (ADLs), requiring his wife's help to bathe and dress, and that he is spending more than half the day laying down or sitting in a chair.*

Question: Does Mr. M Meet Criteria for Hospice Enrollment?

Gather Information Patients may be referred for hospice services if their illness physiologically meets criteria of a prognosis of 6 months of less, should the illness run its usual course, and, after counseling regarding the implications of this prognosis and available options, have accepted this prognosis and elect a treatment regimen and plan of care which focuses only on comfort-based treatments and services. In this case, documentation by the oncologist supports the introduction of hospice due to the extent of progression of Mr. M's NSLC and specifically mentions that no further disease-modifying treatments are available outside of a clinical trial.

In addition, his worsening performance status also supports this assessment. The use of the Palliative Performance Scale (PPS) may support the evaluation as well. A recent systematic review by Baik et al. *assessed the capacity for the PPS—a prognostic index independent of a specific disease, which is based on functional status variables—to estimate survival at the end of life found: "All nine studies reported a significant association between PPS scores and survival among palliative care patients with advanced cancer"* [21].

Pause and Consider: How Would You Explore Goals of Care with Mr. M?

Gather Information If needed, consider accessing free resources to guide goals of care discussions, including those available through VitalTalk.org and resources from CAPC (if available at your institution).

Back to the Case Mr. M tells you he has been giving thought to hospice and asks if he will "go there to die." You review that hospice is a Medicare benefit based upon a philosophy of care rather than being in a specific place and that care and services can be provided in many settings, including the patient's home. You review that benefits include careful attention to symptom management with the ideals of maintaining comfort and dignity at the end of life. You also mention that the patient can choose to leave hospice at any time and re-enter hospice care at a later date [5, 10]. *He states he is tired of repeated visits to the hospital and worries about the stress on his wife. He also notes the clinical trial "doesn't seem like it would help me much anyway." You provide reflective listening and inquire how best to preserve his quality of life for as long as possible. He identifies goals of maintaining independence and being home with family. You echo how his goals can be incorporated into the plan of care and review how hospice can insure these remain cornerstones of his care plan. He and his wife agree with referral to social work and case management to evaluate which hospice would best meet their needs and arrange next steps. You also offer to call his oncologist and provide the update about the hospice referral, and he appreciates this coordination.*

Pause and Consider: What Further Information Would Be Helpful to Know for His Disposition and Management?

Gather Information Please reference Tables 61.2 and 61.3 *for guidance on what information would be helpful in assessing hospice level of care (LOC) and arranging the enrollment process. A detailed outline of this process is also presented in the article by Drs. Quest and Lamba: Hospice Care and the Emergency Department: Rules, Regulations, and Referrals* [1].

Additional Interventions During your phone call with the oncologist, they agree with the hospice plan and elect to be the physician of record for Mr. M's hospice care. You share this news with Mr. M who is appreciative of this continuity of care and notes he has provided the choice of hospice to the social worker on the case. After making the referral, the social worker asks you to report the symptoms Mr. M is experiencing and his current management for the hospice to review. After reviewing his vital signs, you note that he is mildly hypoxic at 93% on RA at time of arrival and has improved to 97–100% on oxygen via *nasal cannula. He is otherwise hemodynamically stable, and his chest X-ray reveals adequate placement of the pigtail catheter; however he has had worsening evidence of possible lymphangitic spread from imaging done on his last visit to the ED and continues to complain of significant subjective dyspnea, despite improvement in his oxygen saturations. Based on his volume status (which you assess as likely hypovolemic), you opt to avoid diuresis at this time and instead implement low-dose oral morphine, as opioids can alleviate the sensation of subjective dyspnea* [22]. *Mr. M does not identify symptoms aside from dyspnea and reviews his priority of returning home again on reassessment. You broach code status with him, and after careful counseling, he elects to remain full code as he is looking forward to seeing his grandson graduate from college in 2 weeks and demonstrates in his responses that his code status is emotionally tied to this milestone event.*

Consider: What Might Be Important to Sign Out to the Hospice of His Choice?

Gather Information Review what you would typically sign out for ongoing care for a patient, and consider how this care should be transitioned across settings.

In your review of his overall clinical status, including hemodynamic stability and improvements in subjective dyspnea with low-dose opioids, your assessment concludes that his comfort can be maintained at home with routine hospice care as his symptoms likely do not require rapid medication titration. If Mr. M did require more aggressive control of his symptoms, and more frequent reassessment and titration, these could be available in an IPU or via *short-term, continuous care services in the community. Returning to his own home is consistent with his goals of care, and social work reveals that he has 24/7 caretaker support in the home. Further, the hospice is able to arrange for a nurse liaison who can do an intake visit tonight, with DME equipment delivery tomorrow morning, which is acceptable to the patient. You confirm this with the hospice, review his decision to remain full code at this time, and also discuss that he has a pigtail catheter that he has previously been given education on utilizing and that he will require ongoing nursing care to maintain. You also request oxygen for symptomatic control of dyspnea, with the standard hospice parameters of "titrate for comfort." After summarizing his case, the hospice provides instruction and requests prescriptions for medications to address symptoms that may evolve in the coming days.*

Case Study 2

Ms. H is a 90-year-old woman with history of Alzheimer's dementia presenting from home hospice to the ED via *EMS. Her vital signs are unremarkable, and her daughter reports that she is concerned hospice is not providing the care that her mom requires. After further discussion, you learn the patient's daughter was recently diagnosed with breast cancer and requires surgical intervention with a lumpectomy and lacks other social supports to continue caring for her mother at home. The patient's physical exam is benign overall, and the daughter denies changes in behavior or new symptoms. Your exam is consistent with an alert, non-verbal patient who does not follow commands or provide responses to questions but does not appear to be in any acute distress. You do not observe signs of neglect. Your colleague inquires if you're planning to admit the patient given limited resources at home for social reasons?*

Question: What Next Steps Should Be Considered?

Gather Information

- *Confirm goals of care based on substituted judgment.*
- *Evaluate the family's concerns and underlying reasons for presentation.*
- *Consider how collaboration with the patient's hospice can be utilized.*

You call the patient's hospice and learn that the hospice interdisciplinary team (IDT) was unaware of the daughter's diagnosis and impending surgery. They report the patient has only been on service for 5 weeks, and the IDT has found the daughter to be very private about sharing personal information and is unmarried with no children to offer additional support. In addition, the IDT shares that she has appeared reluctant to accept assistance at times, including declining the use of care aides and volunteers. After learning this information, the hospice offers to send a social worker to the ED to discuss care plan options and goals of care directly with the daughter. Via *the social worker, the hospice offers to provide 5 days of respite care at a local skilled nursing facility, and after further discussion with the patient's daughter, she agrees to this plan and is appreciative. The hospice social worker also shares with you that the daughter is the youngest of the patient's five children and the only daughter. She has voiced her fear that her brothers (all out of state) will feel she is not taking "good enough care of mom" if she allows others to help or to allow a respite. The social worker and the patient's daughter telephoned two siblings from the ED who both confirm that all the siblings consider the daughter to be the spokesperson for the family with plans to inform the remaining brothers of the plan. They provide reassurance to the patient's daughter and endorsed the need for the daughter to take care of herself and for the respite to proceed.*

This case underlines the importance of collaboration with the hospice agency when a patient presents to the ED while enrolled in hospice services. It is necessary to have careful discussions with the patient's surrogate decision-maker for healthcare to uncover the reason behind the presentation and confirm goals of care. At times, addressing communication challenges between the patient-family unit and the hospice is essential to providing the care the patient needs and can avoid unnecessary admissions.

Case Study 3

Mr. R is a 68-year-old man with history of COPD on 2L of oxygen via *nasal cannula at home and long-term steroid*

dependency. He presents with a femoral neck fracture acutely after tripping over his oxygen tubing. After initial stabilization and consult to orthopedics, you note that he has recently had repeated exacerbations requiring frequent hospitalization (three times in the last 2 months) and his FEV1 is less than 35% of predicted with weight loss of over 15% in the last year as noted by his pulmonologist. He also has had worsening functional status with recent need for a move to an assisted living facility. His daughter is a physician and advocated for him to be a lung transplant candidate recently with reported decision that he was not a candidate at a major academic center during the last month. He also has not regained function with pulmonary rehab and has been determined to not be a candidate for surgical intervention. In essence, his pulmonology records indicate that they are hoping to achieve stability with his new, worsened, clinical status. You assess that he is demoralized and asks you if there is an alternative to returning repeatedly to the hospital?

Pause and Consider: What Factors About His Presentation Make Him a Candidate for Hospice? If He Elects Hospice, Is He Ineligible for Operative Management of His Fracture?

Assume the Following Has Been Pursued

- *You consult to hospitalist service, and they plan to admit him and further review his pre-operative risk.*
- *A femoral nerve block significantly improves his pain.*

Gather Information You confirm that his FEV1, ongoing oxygen requirements, repeated admission, and need for ongoing steroids and other pulmonary treatments are considered indicative of a more guarded prognosis [23]. *Furthermore, his lack of other options to manage his disease state further supports a hospice admission.*

Patients can revoke hospice due to both changing their mind about goals of care (including when a new treatment becomes available) and be admitted for procedures that are considered to have greater benefit than burden for their quality of life based on their goals of care [12]. *An unstable femoral neck fracture in an ambulatory patient with a prognosis of months to years is likely to have significant impact on Mr. R's quality of life, and operative intervention (if he is considered a candidate) may allow him to have greater mobility and less pain over the time that he has remaining. In addition, COPD is historically difficult to prognosticate, and the factors mentioned above generally have been used to assess prognosis in terms of years rather than months* [23].

Consider palliative medicine consultation in addition to assessment of pre-operative risk and orthopedics consultation to help review possible treatment options, confirm goals of care, and promote shared decision-making.

Conclusion

Hospice offers an important resource for patients reaching the end of their lives and their families. Emergency physicians should be skilled at identifying patients eligible for hospice services and addressing this topic as part of a goals of care discussion, as well as assessing the unmet needs of hospice patients who present to the ED from a setting where hospice care is being delivered [24, 25]. Cancer represents a disease where hospice may eventually become appropriate based on the patient's goals and overall clinical status. Therefore, just as it is necessary to recognize common oncologic emergencies in order to provide excellent care, recognizing hospice eligibility, exploring reasons for presentation from hospice settings, confirming goals of care, utilizing resources within ED IDT and PC teams, and collaborating with hospice teams in providing care across settings are all important skills for the emergency provider to have at the ready for this patient population with complex care needs. This chapter has sought to review the basic steps in this process and underlines how the ED is a critical setting for assessing the needs of patients at pivotal points in their disease trajectory and offers an important opportunity to insure the delivery of ongoing goal-concordant care.

Communication

62

Bonnie K. Marr, Kate Aberger, and Rebecca Goett

Introduction

This chapter will focus on how we communicate with the oncologic patient and their families in the emergency department (ED). Clinicians will learn how to facilitate discussion of emotionally charged topics with patients in a compassionate, effective, and timely way.

It can be argued that communication is as important as the technical aspects of treating disease [1–5]. Patients are suffering and they come to us for help. As physicians, we seek to understand the person with the disease and their wishes for the management of what ails them [6–8]. We can learn to harness our empathy – detecting another's emotions and experiencing their feelings of suffering – and learn to respond to this suffering with compassion. This type of communication can have positive measurable outcomes, for both the patients and us [9–13].

The main skill that palliative physicians practice frequently is a *goals of care* conversation. Although lengthy care discussions may seem impractical in the ED, there are methods to help acute care providers engage patients in these difficult conversations in brief but effective ways. We will use cases to illustrate "abbreviated goals of care conversations" [14] and give the reader some concrete examples of techniques to incorporate into everyday practice.

Components of an initial assessment by the emergency physician not only are vital to the provider determining a differential diagnosis and treatment plan but are also essential elements to consider in reviewing options with the patient and family in shared decision-making. As we are doing our initial resuscitation, we ask ourselves: Is this a reversible process? Is this a treatable process (but one that will not reverse the underlying disease), or is this patient actively dying [15]? Having transparent dialogue with a patient or family and building a shared plan for ongoing management help ensure clear communication about what next steps and expected outcomes may be in order to help patients and families feel prepared. Frequently the emergency physician has mere minutes to build rapport with a patient and gather information about his/her preferences for care. How do we identify those in need of deeper conversations? How do we recognize patients with unmet palliative care/communication needs? General guidance exists for emergency providers regarding when palliative care consultation and interventions should be considered. George et al. has developed a screening tool (Fig. 62.1), and the Centers to Advance Palliative Care has an initiative called "Improving Palliative Care in Emergency Medicine" or IPAL-EM, which also offers a screening tool [16–18].

Prognosis

In order to recognize a worsening prognosis, we must first look at the trajectory of the patient's illness (Fig. 62.2) [19].

Prognosis is generally based on two variables: (1) disease state and (2) functional status. In the oncologic patient, there are a few guidelines that we can follow. As shown above, terminal illnesses such as cancer usually preserve functional status until near the end. Then a precipitous acceleration of illness occurs once functional status begins to decline. Therefore, functional status is key to prognosticating in cancer patients. The median survival times for multiple brain metastasis, malignant hypercalcemia, malignant pericardial or pleural effusion, carcinomatous meningitis, malignant ascites, and malignant bowel obstruction are relatively short (weeks to months) and can be estimated with some degree of accuracy [15].

Regardless of medical specialty, discussing prognosis with the patient is a challenge. The emotional and psychological impact of the information imparted and the lack of precision possible under most circumstances make it fraught [18]. For this reason, it is important to ask permission prior to sharing this information. If a patient or family is focused on prognosis, it is often useful to ask: "Why are you asking me about this now?" This will usually lead to the patient or family talking about their anxiety or fear, which you can then address. We provide prognosis in terms of "hours-to-days," or "days-to- weeks," or "weeks-to-months," or "months-to-years," with the provision that these are estimates. Using

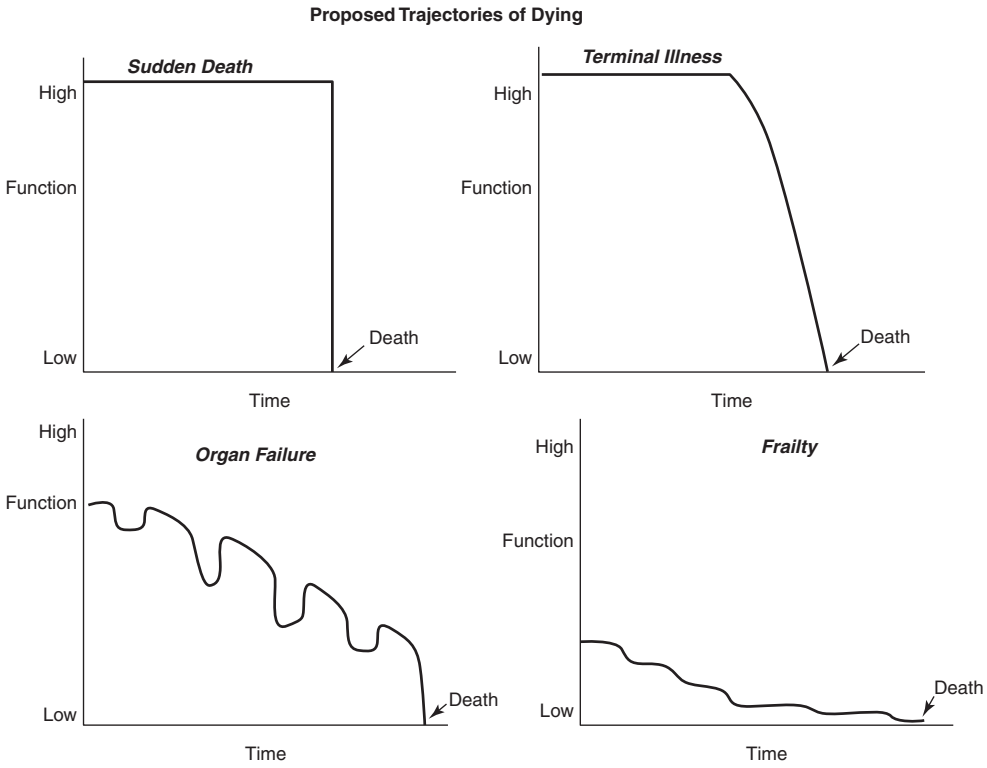

Fig. 62.2 Proposed trajectories of dying. (From Lunney et al. [19], with permission John Wiley & Sons)

specific numbers of hours, days, weeks, months, or years leaves more room for error and introduces potentially emotionally traumatic sequelae if the patient were not to live as long as forecast. Conversely, some patients and families will be upset if the patient lives beyond that estimation and perhaps express confusion and lack of faith in medical information.

When you find that further conversation is needed, you must set the stage and prepare. The emergency physician should facilitate communication among the various multidisciplinary teams involved in the patient's care. Palliative care teams, where available, can also assist in complex decision-making. Consider utilizing pre-existing decision tools to determine if a palliative care consult may be helpful [16–18].

The Building Blocks of Effective Communication

Preparation

Good communication begins prior to entering the room. Gather as much information as possible. Examine the medical record carefully. Make contact with the treating oncologist or primary doctor. Tell them what you have found. Ask what their goals are for the patient, and discuss your plan to discuss your findings with the patient. Tell the specialist your concerns and ask for their recommendation. You can tell your colleague the exact words you plan to use: for instance, "I am worried this cancer is progressing, I want to talk with you about the possibility of things not going the way we had hoped."

Capacity

Assess the patient's capacity. Medical decision-making capacity is the patient's ability to understand the benefits and risks of, and the alternatives to, a proposed treatment or intervention (including no treatment) [20–22]. Capacity is the basis of informed consent. If you feel the patient does have capacity, prepare them by asking permission to have a "difficult conversation." Tell them it will be helpful to have someone with them either in person or on the phone. It is generally recommended not to speak to the patient alone unless you have express permission from them. If the patient does not have capacity, or you are worried that they may be too emotionally burdened to have the conversation, find the legal next of kin.

Physical Space

Be sure that you have a quiet, separate place to have the conversation. Try to make it as private and comfortable as

Table 62.1 The REMAP Guide

Reframe	*What is your understanding of what the doctors have told you about your dad's health?* If their understanding differs from the clinical realities, consider a follow-up statement such as *Unfortunately, we are in a different place now. Is it okay if we talk more about what we are seeing and what the next steps may be?*
Expect emotion	Stop talking and listen! Consider responding to emotion directly. Examples include the following: *I can see you are really concerned about this. Is it okay if we talk more about what this means?* Or *I cannot imagine what it has been like to hear all this news.* Do not be afraid of silence
Map out the future	Try and identify what the patient's goals are before making any recommendations. *Given what we have just discussed about the illness your dad is dealing with right now, what do you think would be most important to him right now?* Or *thinking about what you dad put in his advanced directive and your knowledge of him as his loved one, is there anything he would want to avoid? What would his reasons be? What values in life are most important to him?*
Align with values	*Now that I have a better understanding of what is important to your father, let's talk more about treatment options*
Propose a plan	Give specific recommendations, rather than a menu of options. *From what you have told me, I recommend... How does that sound to you?*

Adapted with permission from VitalTalk https://www.vitaltalk.org/guides/transitionsgoals-of-care [23]

possible. Have tissues available. Have a planned strategy for how the conversation should unfold.

Take a moment, ground yourself, clear your mind of any prior encounters, and rid yourself of preconceived ideas. Make a conscious effort to focus on being an advocate for the patient and meeting them where they are in the journey of serious illness. Also, body language speaks volumes. Walk in, make eye contact, and introduce yourself. Sit down if possible, or if not, assume a pose that says you are not rushed. Allow the patient to speak for the first minute without interrupting.

Conversation Templates

Most of these difficult conversations follow a template, and steps can be tailored to the patient depending on their immediate need (Tables 62.1 [23] and 62.2 [14]).

Responding

Do we flinch internally when we hear a family say, "I want everything done" or "He is a fighter"? We must learn to recognize these statements as possible emotional responses rather than cognitive responses (Table 62.3) [24]. Instead of this putting an end to the conversation, we should explore what "everything" means to this particular family.

If we can respond to their emotions with inquiry and recognition instead of continuing to give medical information, we can open up dialogue in a way that will help the family process what is happening emotionally. Once their emotions are realized, often discussions about care can move forward. If not, best to continue resuscitative efforts as appropriate, and prepare the family for further discussions by the inpatient or palliative care teams.

Table 62.2 Approaching 5-min ED goals of care conversations systematically as a procedure

Phase	Action
Minutes 1–2	Elicit patient understanding of underlying illness and today's acute change If available, build on previous advance directives or documented conversations Acquire sense of patient's values and character (to help frame prognosis and priorities for intervention) Name and validate observed goals, hopes, fears, and expectations
Minutes 3–4	Discuss treatment options, using reflected language Continually re-center on patient's (not family's) wishes and values Recommend a course of action, avoiding impartiality when prognosis is dire
Minute 5	Summarize and discuss next steps Introduce ancillary ED resources (e.g., hospice/observation unit, social work, chaplain)

From Wang [14], with permission Elsevier

Effective Use of Silence

Sitting in silence may feel as though it goes against the grain of a provider's role in a dynamic conversation. Physicians may infer that a pause in the conversation means that there should be further explanation or that more active direction is needed. However, the use of silence and pauses in the conversation aids communication. Silence allows the patient or family time to process information, cope with associated emotions, and utilize the time to formulate next questions or communicate concerns. If a provider jumps in too soon to fill this proverbial "space," the patient and/or family may not have the opportunity to move through these steps, if needed. After a pause, it can be helpful to incorporate a "check-in" and offer to repeat any needed pieces of information. It is appropriate to also acknowledge the difficulty of absorbing the information proffered and to offer support.

Table 62.3 Responses to patients' and caregivers' reactions)

But he was doing great when I visited him last!	Medical	*He is now in septic and cardiac shock*
	Emotional	*I cannot imagine what a shock this is for you. Unfortunately he is very sick. He has a very serious infection and his heart is failing. We are all hoping for a different outcome, but we are worried that he is dying*
Do everything possible!	Medical	*Ok, we will do CPR, intubation, dialysis, and any other procedure*
	Emotional	*I hear you, and we will provide him with the most aggressive care. It sounds like this has been a hard/long journey and this is a terrifying time. Can I ask, has your father ever imagined his health worsening to what we see now?*
He needs a feeding tube for nutrition so he can get stronger!	Medical	*We know from studies that feeding tubes do not help in the end of life*
	Emotional	*Most people think of food as love. We think it is inhumane to withhold food from people we love. But your father's body is shutting down from his illness, and he does not feel hunger like he used to. Artificial nutrition is not the same as food and will not give him strength. A feeding tube in his stomach may deprive him of the joy of tasting his favorite foods. Can we talk instead about ways to increase his pleasure around the food he may want?*
You want me to pull the plug? You want me to stop/withdraw care? You want me to let him die?	Medical	*We will continue to do everything*
	Emotional	*I hear your concern. It feels like we are making this decision, but really it is his body that has decided. He is dying a natural death from this illness. I will do everything I can to aggressively make sure your father does not suffer as his body goes through the natural process of dying*

Adapted from Aberger and Wang [24], with permission Springer Nature

Language, Diversity, and Culture

These intense conversations are difficult in any language. If the patient only speaks a language you do not, it adds another layer of complexity. We find, of course, that live interpreters are best, if available. Family members should not be used for these sensitive conversations because often, as family members, they are subject to the emotional content of the information and might not be able to translate the conversation. If language line phones are the only option, it helps to prepare the interpreter for the type of discussion you are going to have as they can also become discomforted when discussing these sensitive topics, and it may help to organize the conversation.

Cultural considerations should always be explored. We find that no one is an expert on all cultures, but sensitivity and curiosity are essential. When in doubt, ask. Ask openly about custom or tradition. Apologize if you find you have overstepped or assumed incorrectly. Some cultures cannot talk about death directly, so exploring which words are acceptable may take an extra few minutes. This is essential in establishing trust and rapport.

Spiritual and Religious Considerations

Spiritual and religious needs are also diverse and should be explored. Here again, curiosity and sensitivity are key. Ask about needs, beliefs, and customs. Recognizing spiritual distress is also very useful in having these conversations. Often families will respond to our bad news or recommendations with the phrase, "We are hoping for a miracle." This is another phrase that may invoke our discomfort. If we can recognize and manage our own reactions, we can use the following communication protocol to open this statement up, thus broadening and continuing our discussion. It is called the AMEN protocol (Table 62.4): "Affirm, Meet, Educate, No matter what" [24, 25]. This is a powerful tool to keep the conversation going rather than continuing attempts to "solve an issue."

Table 62.4 AMEN communication tool for miracles [24, 25]

*A*ffirm/*M*eet and Reflect	Demonstrate respect and communicate empathy for what the patient/family values and wants
Learn more	Get curious and ask to hear more about the miracle, hopes, or values framed through the patient/family religious/cultural beliefs
Broaden the care plan	Determine what else is important so you can discuss different care plan options from the perspective of patient/family values and goals
*E*ducate	Educate about the medical situation and options
*N*o matter what	Reassure the family of your support no matter what happens

Case Studies: Starting with Common Dilemmas and Gradually Layering in Complexity

Case Study 1: The Rapidly/Actively Dying Patient

The patient is a 62-year-old male with metastatic lung cancer who presents with altered mental status. Labs show pancytopenia with a platelet count of 5. He becomes more lethargic and requires intubation. His pupils are unequal and you suspect an intracranial hemorrhage.

Approach to Goals of Care for the Actively Dying Patient

If the patient is declining rapidly, goals of care are needed quickly. Think briefly about the trajectory of their illness and where they fall on it. This will lead to an initial prognosis. We can use this prognosis to guide our discussions – if prognosis is hours to days, we likely need to start conversations now in the ED. Even if we proceed with full life support resuscitative measures, we need to initiate discussions about the strong possibility of further decline or death.

A useful mnemonic is ABCD [18]. We need to consider this when the patient is chronically ill, actively dying, or at the end stages of their illness.

A: Advanced directives: Does this patient have any? POLST, MOLST, prior PC involvement?
B: Better symptom management
C: Caregiver? Who is the next of kin?
D: Is the patient decisional?

You identify the family, including the next of kin. They state their loved one has been declining and he expressed the desire that "when my time comes, let me go." They are tearful but agree with your recommendation based on prognosis, and his past expressed wishes to the family for comfort measures only.

Communicating with the Family of an Actively Dying Patient

Studies confirm the importance of the explicit explanation of impending death signs and the importance of avoiding both vague explanations about future changes and excessive warning of sudden change [13, 26]. Research tells us that generally families also want to know a patient's relief of suffering, advice on how to care for the patient, allowance of time for the family to grieve, and that providers take care to ensure that family members cannot overhear conversations between the medical staff outside the room at the time of patient death [27].

Families will often have questions about what to expect – whether the patient can hear or is aware of their presence and if the patient is suffering due to a lack of nutrition or hydration. It is important to answer all these questions and concerns. We encourage families to spend time and speak to the patient with acknowledgement that the patient may hear or sense their presence. The patient's religious and cultural traditions may also offer resources. Social work and pastoral care also should be considered.

Case Study 2: Stable Patient with Progression of Disease

Breaking Bad News Worsening disease despite treatment [28, 29]

The patient is a 64-year-old male with past medical history of hypertension and colon cancer post resection with chemotherapy, years ago. He presents to the ED with cough and shortness of breath. He has no hemoptysis or fever but is tachycardic. You do a CT scan to rule out pulmonary embolism. No embolism is found, but multiple pulmonary nodules are seen, suspicious for metastatic disease.

Before You Go in the Room Preparation is key. Do a thorough chart check, or call his primary care provider or oncologist to confirm this is possibly a new disease progression. If you find no evidence showing prior metastatic disease, you have to discuss the results with the patient.

In the Room Make sure the patient has capacity and has support present or by phone. First ask broadly what they know about their cancer. As stated in the previous case, asking this sets where to begin the conversation [17, 23].

Some patients have an understanding that their cancer has returned or spread to other parts of their bodies. Other patients and family may believe the cancer is "cured" or in remission, or that the cancer has spread, but they believe that current treatment is curative rather than palliative. If they disclose this, you can ask about treatment. What do they hope to get out of their treatment?

Once you know where to begin the conversation, discuss the results simply. Often begin with a "headliner" [23] that is concise and gets the critical information across such as "I have the results from the CT, it looks like the cancer might have spread/returned/is getting worse." Using a VitalTalk "I'm worried…" statement [23] here can also be effective in conveying the results and your sympathy. Although you often need to give more information after this statement, pause for the patient's response.

Next, Gauge Where the Patient Is Emotionally

If there is tension or silence, you may need to circle back to discuss future steps. Tell the patient you will return. Alternately, if the patient immediately and rapidly begins asking questions, this may be part of an emotional response to the news. He may not want further medical details, but

fear and anxiety are driving him to ask. Name the emotion you are seeing.

When you gauge that he is ready to discuss disposition and plan, start by recognizing the difficult nature of the conversation: "Whenever you are ready, I'd like to discuss what's going to happen next" [23]. In addition, offer palliative and/or spiritual care services, explaining what they do and the essential support they can give in the difficult days/months ahead.

After Discussion

If the patient is not actively dying and is stable for transport, it may also be appropriate to consider transfer to a hospice inpatient unit or home hospice. Provide guidance to the family that it is possible the patient may die during transport with more specific information tailored to the individual patient's clinical condition and estimated distance/time in transport. Some family members may elect against transport for these reasons.

Case Study 3: Death Disclosure of Sudden and/or Unexpected Death

You receive a call from paramedics reporting a cardiac arrest in the field. On arrival, emergency medical service (EMS) providers state they found the 73-year-old male after an unwitnessed cardiac arrest at home. He was undergoing chemotherapy for prostate cancer. EMS states that the son found the patient not breathing this morning and called 911. EMS intubated him and began ACLS protocol with pulseless electrical activity on the monitor for 20 min. In the ED, you continued CPR for over 15 min without a return of pulses, and the monitor now reveals asystole. Your team pronounces the patient in the ED. The charge nurse informs you that the family has arrived and is in the waiting room.

Before You Go in a Room

Establish your Team. The ED is hectic; however, nurses, residents, and other staff involved in resuscitation often want to participate in family meetings. Calling outside staff that can assist with bereavement (e.g., spiritual care, chaplains, or counselors) may also be helpful when available. Discuss beforehand which team members will likely stay with family afterward for instructions or family support.

Set the Room. Quiet is often hard to come by in the ED, but a family room is ideal. Social worker's or nurse manager's offices can also suffice, depending on the size of the family. Have one of your team members or staff escort the family to a quiet place. The person placing family in the room should ideally not be you in order to avoid questions or forcing you to disclose news in the hallway or in front of other patients. Also, this staff member can identify a "head" of the family or next of kin. Staff can ask that designated loved one who they think should also be in the room when the meeting begins. In addition, this co-worker can report back to you who and how many family/friends there are and their current emotional state.

In the Room [23, 30]

Introduce. Introduce yourself to every person in the room. Find the lead family member and place yourself next to them; this will be the person you primarily interact with. First, ask what they know so far, for example, the son watching CPR in progress has a better understanding of the severity of their loved one than the son called at work by the nursing home stating, "Your family member was transferred to the ED." Asking this establishes where to begin the conversation.

Deliver. Then give a "warning shot" stating you have difficult news. Very briefly without jargon, describe what happened today. Usually the events can be summarized in no more than two to four sentences. When disclosing a death, use the word "died" and then pause for silence. Traumatic, sudden, or pediatric deaths often produce more raw emotional responses. These will be discussed in more detail shortly.

Comfort. Find phrases that you feel comfortable saying during this difficult conversation such as "I wish this hadn't happened," "I'm sorry for your loss," or "I can't imagine how you feel." Some physicians feel their expressions of sympathy sound contrived or even condescending. However, empathy can facilitate further dialogue with the bereaved and is usually appreciated.

After Discussion

Assist. After allowing loved ones to process the event, ask for any questions. Discuss next steps and hand off the conversation to one of your colleagues. Social workers or case managers can obtain more information about the patient. Nurses or patient assistants can accompany them to their loved one for viewing. Special instructions are needed for traumatic deaths, such as no touching the deceased. Sometimes law enforcement may need to further discuss the death with medical providers.

Hand Off. Leaving the room, especially when it is still full of emotional people, can be awkward. Introduce the staff that will stay behind, and ensure the team is available for any questions. If you are in a family room, you can offer the space to the bereaved to take their time to contact family, and delegate and discuss who and when (or if) a family member will see the deceased.

Case Study 4: Managing Requests to Withhold Information

Your patient is a 78-year-old female admitted from home with a chief complaint of shortness of breath and not eating for the past 2 weeks. Past medical history includes breast cancer s/p chemo, stopped 2 months ago due to weight loss and weakness. Patient is alert and oriented to person, place, and time. She says she is not hungry and just tired all the time. Her chest X-ray shows worsening metastatic disease in lungs.

You discuss the results first with her daughter, her primary caregiver and health proxy. Her daughter asks information not be disclosed to the patient.

Requests for non-disclosure can be complex and often reflect a family's member's efforts to protect the patient from emotional harm. The flow of information may have been agreed upon within the family already (e.g., the patient does not want to know), but we must explore this prior to making assumptions.

The following modified approach is proposed by Chaitin from the Palliative Care Network of Wisconsin [31]:

Before You Respond Remain calm and monitor your inner reactions. Explore the request for non-disclosure with curiosity. For clinicians this can be frustrating, but expressing how *you* feel can quickly end the conversation. Recognize and check your emotions. Remember, the calmer you remain, the more information you will obtain from the family as to why they do not want their loved one to be informed.

Gain Knowledge

Psychosocial and Cultural Aspects. Use open-ended questions to gain insight. "Can you tell me more about your request?" "How does your loved one [your family] typically handle difficult information?

The Disease Itself. Inquire what the patient knows about their disease. Does the family think the patient already knows or suspects the results and would rather not talk further about it? Or is the patient completely unaware? Frequently, both the family and patient may be frightened and attempt to protect each other by not talking about "bad news."

Plan. There is no one right way. As the clinician, you can recommend first asking the patient if she would like to know or discuss her health. If so, we prepare the family by reassuring them that we will be gentle and slow. We will share small pieces of information and continue to ask the patient permission to continue.

Ask the patient in a neutral way (e.g., listing options so the patient does not feel pressured to choose only one specific way). Having family present and rehearsing beforehand are also helpful so the family feels they still support the patient. For this case, "Your family brought you to the hospital because you were short of breath and not eating. We took tests to figure out why. Some patients want to know all their tests and results, others prefer the doctors talk with family about what is happening and how to best help them. What do you think?"

Case Study 5: When There Are Disagreements Among Physicians

An 83-year-old male presents with SOB, cough, fatigue, and weakness. PMH includes prostate cancer on chemotherapy. Chest X-ray today reveals worsening metastatic disease with new pleural effusion. In the past year, the patient has had multiple ED visits and admissions with a diagnosis of advanced metastatic disease and a pattern of overall decline. Patient shows little understanding of disease progression.

When questioned about his cancer, the patient states: "I am a fighter, and I'm going to beat it and be cured." When you speak with his oncologist, she feels the patient can live for years, and his chemotherapy overall is going well.

Before You Respond [32–34] When dealing with a response that is discordant, emergency clinicians must first remain calm and try to understand the other clinician's viewpoint. Sometimes in an established provider-patient relationship, there can be discrepancies in prognosis understanding. This can be due to several reasons (e.g., the clinician-patient bond) that make it difficult to acknowledge that the disease is progressing, regardless of treatment. Also sometimes patients can take away or naturally choose to accept only the positives during care discussions despite clinicians delivering information to the contrary.

Gain Knowledge Begin by using open-ended questions to gain insight on how the oncologist or primary clinician is interpreting the patient's status. Ask how past planning and prognosis discussions between him/her and the patient have progressed. Using "I'm worried" statements such as "I'm worried today that he's doing worse" can help "third space" the disease so the oncologist does not feel confronted or feel a sense of failure [23]. It is hoped that the oncologist can reflect on the overall trajectory of the patient's disease and give insight into the current negative results.

Plan State to the oncologist that you will share today's results with the patient and ask him/her: "Based on these results, how can we best help the patient?"

Acknowledge their difficulty in reframing their expectations for the patient such as "Seems like you have

known the patient a long time. This must be difficult for you." If the patient is not to be discharged, tell the oncologist that as the ED clinician, you want to include them in further plans. "Would you mind if I conferred with you in the next steps? From the ED, we are planning to...." In addition, state that you are consulting palliative care, stating they will provide an additional level of support during this admission. If the oncologist disapproves of the plan, remember: it is his/her opinion. Ultimately your obligation is to the patient, not the oncologist.

Case Study 6: Dying in Isolation

You care for a 63-year-old female with a chief complaint of shortness of breath, cough, and fever. She has a past medical history of COPD and lung cancer. She is alert and oriented, but hypoxic on room air and febrile. You are concerned about a COVID-19 infection. In the ED, the patient becomes more hypoxic and has increasing oxygen demands. She is ultimately intubated and awaits admission to ICU. The patient's family arrive several hours later, but are not allowed in. They beg for information about her condition and ask to see the patient.

Before You Discuss You first have to prepare for your meeting. Communication and goals of care conversations have evolved during COVID-19 due to the unpredictability of the pandemic. Communication between patients, clinicians, and family varies widely. Supporting a patient's loved ones can take place on voice or video calls as visitors are often not allowed. Communication tools are available from CAPC and VitalTalk for periods of social upheaval [23, 35]. These conversations are best led with an effort to first identify patient values. Recommendations regarding specific interventions such as mechanical ventilation or CPR can then be made. Having the family see the patient via video chat can be helpful in explaining the seriousness of illness or prognosis. Establishing regular video visits for family can help ease distress for both loved ones and the patient.

Case Study 7: Telephone Death Notification [36–38]

Your patient is in cardiac arrest in the ED. Resuscitation was unsuccessful. The patient is a nursing home patient with past medical history of colon cancer and dementia; it is unknown if the family has been informed. You call the next of kin.

Identify When calling next of kin, first introduce yourself, and inquire if the nursing home has already called. If this patient was admitted from home, ask if they knew the patient was in the hospital. Again, this gives you a marker for where to begin the conversation.

Clarify Sometimes the information can be incorrect, or the person listed defers to another family member. Therefore, first clarify the relationship between the patient and the person on the phone. State that the patient is seriously ill and ask if they are able to come to the hospital. Ask how and when they are arriving, and encourage them to have another person accompany them, if possible.

****If at this point the family member is unable to get to the ED and the news must be delivered over the phone, take the following steps. ****

Ability If information must be delivered over the phone, ask if they are somewhere where they can sit down and talk. If not (e.g., they are driving or in a public space) make a definitive time to call them back, sooner rather than later.

Headliner State you have difficult news. Briefly, in one or two sentences, summarize what happened before the patient reached the ED today. Gather this information from the patient's history.

Deliver Briefly state the patient's ED course and without using jargon, state the outcome. Using the word "dead" or "died" is essential. "We attempted to restart her/his heart and help her/his breathing with breathing tubes and medicines, but despite our best efforts your [name relation to patient] died. I'm sorry."

Pause Offer condolences. Resist the urge to fill the silence with medical information.

Support Once you feel they are able to discuss more, ask for any questions, and allow for their emotional reaction as a natural response to the news.

Case Study 8: Death of a Child [39, 40]

A 6-year-old male child was admitted in cardiac arrest. The child was found by her mother in bed unresponsive; CPR was started. The response time to the hospital was 10 min. In ED, CPR continued; the patient was intubated and ACLS performed, but the patient remained asystolic. His mother is able to tell you that he was born prematurely with a seizure disorder. At age 3 he developed asthma and then leukemia. He has had multiple admissions for his complex medical problems. His leukemia was in remission after several treat-

ments. Resuscitation efforts were continued without success for 10 min; you pronounced him dead at 9:04 a.m.

Before You Go in the Room The death of a child is tragic and traumatic for all involved in his care. 22% of pediatric deaths occur in EDs [39]; therefore it is likely that we will all experience this multiple times during our careers.

Establish a private place to inform loved ones, even in situations where the family witnessed the resuscitation. Have a staff member, not yourself, accompany the loved ones to a family room. It's important to avoid an emotional confrontation in the hallway or in front of other patients or children. This staff member can also identify the head of the family, limit who should be in the room, and describe the family's emotional state. Go in with a small team. Pediatric deaths affect everyone working in the ED, and having a few of your colleagues with you for the family discussion is helpful for everyone.

In the Room Introduce yourself and identify the staff members with you. Then, carefully and slowly, tell them you have tragic news. Be succinct, tell them despite your best efforts their little boy has died, and then pause.

Expect heightened emotional reactions [41, 42]. Most adults have the inherent need to protect children, so with the death of a child, their loss can sometimes manifest itself as a sense of shame. Rarely, this is acted out in anger. Always try to have colleagues present and a safe exit strategy from the room.

Other loved ones may have many questions surrounding the death, especially if it was unexpected. Listen carefully: do they need more information, or are they experiencing an emotional reaction? It is vital to continue to listen and convey your sympathy. Keep answers as short as possible. Assure families that they are not to blame for their loss. Expect the unexpected reaction. Keep the door open or unblocked in case of a violent or flight reaction from loved ones [41]. Realize anger is not directed at you personally. Most families will question their last interactions with their child and what they could have done differently. Bring a chaplain if available.

After Discussion After delivering the news, hold a debriefing session with your ED team. Team members need to understand their emotions, as well as help one another validate each other's reactions.

Some Additional Tips

Communicating with Children

We should use developmentally appropriate language to answer a child's questions about the condition of a loved one and the circumstances surrounding their absence from the home. It is crucial to tell children the truth and not craft a less alarming reason for their absence or illness/death, such as "Grandpa went to sleep" or "has a cold." This may result in the child having difficulty trusting adults in the future or becoming scared to go to sleep or alarmed when a loved one becomes ill [43].

Child life specialists and social workers can provide guidance under these circumstances and provide literature and education to parents dealing with difficult news. Palliative care teams often have staff specializing in pediatric needs.

Explore resources that are available for parents with the assistance of the ED interdisciplinary team. The "Parenting at a Challenging Time" or PACT program offers an online toolkit to support children of parents with a serious illness that includes communication tips (https://www.massgeneral.org/assets/MGH/pdf/cancer-center/pact-toolkit.pdf) [44].

It also may be helpful for parents to engage the counselor at their school and/or their pediatrician to provide ongoing counseling and support.

Communication at Sign Out

Important considerations at sign out are in addition to pre-existing checklists and required safety checks, such as name, location, and allergies, to name a few. We should include goals of care, capacity, next of kin, and plan of care (Table 62.5) [45, 46].

Takeaways: Keeping the Connection

In the ED, dealing with the "sickest of the sick" on a daily basis can be exhausting, especially to clinicians with limited training in delivering difficult news to patients/families, end of life care, or psychosocial care. For each low acuity patient that arrives in the ED, there might be two or three nursing home residents with "failure to thrive" or sepsis. Depersonalization, cynicism, and exhaustion can set in with studies showing emergency medicine clinicians at highest risk [47]. The challenge is to connect with our patients, maintain empathy, and be professional. To create a supportive environment for clinicians, there are four areas to consider: connection to patient's families through communication

Table 62.5 Tips for sign out/hand off [45, 46]

Any goals of care discussions to date and treatment plan
Time frame of a time limited trial of a particular treatment
Review of the surrogate medical decision-maker(s)/healthcare proxy and their corresponding contact information
Any contact and recommendations of outpatient providers, including the medical oncologist
Review of resources that have assisted with the care to date and their next steps, including palliative care consult
Most recent communication with the patient and/or family and outline of future updates or further discussion

skills; reflection of both self and department; and engagement with peers [47–51].

Reflection and Engagement [47, 48]

The ED works as a team; communicating with colleagues and other providers is essential. A natural response after a difficult case is to immerse ourselves in an endless pile of paperwork without reflection. To help counter these clinical work patterns, providers can adapt brief steps that can be incorporated into practice:

- *Debriefing* after every resuscitation or difficult case.
- *Moment of silence after every death*. No exceptions.
- *Leaving the department for a break on a clinical shift*. No matter how short.
- *Death Rounds*. Creating a ritual during faculty meetings or resident conferences around department deaths can also be useful for staff.

The Words We Use: Cultivating Patient-Centered Care

Our job in the ED is to determine what is best for our patients, medically and emotionally. Providing education on hospice and palliative medicine, which includes communication skills, to all ED clinicians including nurses, residents, and social workers, can focus care based on the patient's wishes. Find supportive palliative care staff who can champion patient-centered care within your department. Many education models exist. To launch this process clinically, you can begin by:

- *Using words* such as quality of life, patient's wishes, and comfort-focused care
- *Avoiding words* such as withholding, withdrawing, and phrases such as "nothing we can do"
- *Expressing* your thoughts and feelings when meeting with families and patients such as "I'm worried about…" or "I wish…" [23]

Actions such as these establish an environment of being conscientious and willing to engage. Integration of these communication skills and principles is realizing there is no magical finish line where all clinicians will gain resilience or cultural change. Rather, these practices require constant practice in order to maintain a "muscle memory" of patient-focused care.

Palliative Care Research

63

Paul L. DeSandre and Gretchen E. Bell

Introduction

Research addressing the emergency department (ED) care of the seriously ill is growing. At the time of this writing, a simple PubMed (NLM) search for articles combining the "Title" terms "Palliative" and "Emergency" shows a marked increase since 2008 (Fig. 63.1). In order to better understand relevant historical studies and identify future directions for palliative care (PC) research in the ED, we expanded our search and identified three articles addressing research opportunities, priorities, and cancer-specific concerns. Those articles span a range of 10 years with common themes, providing the structure for this review of relevant research in the field.

The first of those three articles appeared in 2006 at the beginning of the increase in related publications. This article provides a list of research opportunities for emergency clinicians derived from consensus statements on end-of-life care from the 2004 National Institutes of Health state-of-the-science conference and the National Institute of Nursing Research 2006 Areas of Research Opportunity [1]. The next article, published in 2011, defined a set of research priorities for PC in the ED. These priorities for research were the product of an expert consensus workgroup conference titled "Improving the Quality and Efficiency of Emergency Care Across the Continuum: A Systems Approach," sponsored by the Agency for Healthcare Research and Quality (AHRQ) and the American College of Emergency Physicians (ACEP). From this workgroup, four key research questions emerged: Who are the patients requiring PC in the ED? What is the role of the emergency clinician for these patients? What is the impact of PC integration in health care utilization? What are the educational priorities?

The six categories of research priorities proposed to address these questions were descriptive, attitudinal, screening, outcomes, resource allocation, and education of clinicians [2]. The third article, from 2016, offered a specific research agenda for the emergency care of patients with cancer. In this agenda, important PC research needs focused on addressing health care use and patient management [3]. For this chapter, in order to include a broader perspective beyond cancer patients in the ED, we use the six categories of research priorities from the second article as a framework. We provide further categorization using evidence-based medicine terminology to describe research methods as described by Greenhalgh [4]. With this combined structure, our goal is to present essential information on the growing body of research devoted to improving the care of patients with serious illness in the ED (Table 63.1).

Descriptive Studies

Descriptive studies of PC in the ED provide information on existing characteristics of patients, circumstances of their care, and unmet needs. Studies of this type began around 2002 with substantial increases in recent years. The vast majority of these studies are of cohort design. Descriptive studies should provide an accurate depiction of patients with serious illness and their prehospital and ED experience. In reviewing the related literature, four categories emerge: (1) general PC; (2) cancer; (3) pediatric PC; and (4) coordination and access to care.

General Palliative Care

While the range of topics is broad and the methods variable, general descriptive PC research has focused on defining patient characteristics and the provision of PC in the ED. Two systematic reviews describe available findings, one in 2015 [5] and another in 2019 [6]. The first addresses the prevalence of advance directives in the ED. The second describes the impact of PC services on ED use. In the first article, Oulton et al. found an overall low rate of advance directives completion with wide variation. Certain variables were associated with a higher likelihood of completion of advance directives. These included patients who were older, were in poor health, belonged to a specific religion, were widowed, had children, were a resident of an institution, or had a primary care provider. These characteristics suggest awareness and understanding of the consequences of illness, which may have encouraged the completion of advance directives at some point prior to needing ED evaluation. The second systematic review by Bone et al. looked at the impact of PC services on ED use and found that the provision of PC or hospice services was associated with lower ED use in the last year of life for patients ≥65 years of age. The majority of included studies were from the United States with almost no information from low- to middle-income countries.

The remaining publications were of either cohort or cross-sectional design. These articles address the range of models of provision of care and the substantial PC needs in the ED. Quest, et al. describe four types of ED PC integration based on 11 successful programs: traditional consultation, basic integration, advanced integration, and ED-focused advanced integration [7]. A 2010 single-site cross-sectional survey of 50 functionally impaired adults ≥65 years old in the ED found the majority of patients exceeded severity of needs assessments for physical symptoms, finances, mental health, and access to care [8]. In 2012, patients dying in EDs in France and Belgium were reported as having a lack of palliative interventions despite 80% having died in the context of withholding or withdrawing of life-sustaining interventions [9]. From the same year, a US study from a large urban ED reported that 84% of the patients seen by PC consultants died while in the ED. Common patient characteristics for consultation included young age, sudden critical illness or traumatic event, or were imminently dying [10]. Yet another

Table 63.1 Palliative care research in the emergency department [2, 4]

Research priority[a]	Year	First author	Objectives	Type of Study[b]
Descriptive				
General palliative care	2015	Oulton [5]	Determine the prevalence of ADs among ED patients, with a focus on older adults, as well as factors associated with rates of AD completion	Systematic review
	2019	Bone [6]	Review factors associated with ED attendance during the last year of life in older adults	Systematic review
	2013	Quest [7]	Describe clinical examples of ED and PC integration, including ED-provided subspecialty PC practice	Cross-sectional
	2010	Grudzen [8]	Identify the palliative care needs of seriously ill, older adults in the ED	Cohort
	2012	Van Tricht [9]	Describe proportion of dying patients who received PC in the ED	Cross-sectional
	2012	Lamba [10]	Describe most commonly requested ED-PC services and understand why ED-PC consults are currently requested	Cohort
	2017	Blackwell [11]	Critique the feasibility of experience-based co-design of a methodology for quality improvement interventions to improve PC experiences in the ED	Qualitative: experience-based co-design
	2015	George [12]	Develop a simple content valid screening tool for use by EPs to identify patients with significant PC needs and establish content validity	Qualitative: modified Delphi technique with expert panel
	2019	Köstenberger [13]	Determine the prevalence of patients presenting with palliative symptoms in an Austrian ED	Cohort
Cancer	2020	Chen [14]	Describe characteristics of cancer patients who utilize emergency medical services	Cohort
	2010	Barbera [15]	Describe the most common reasons for visits made to the ED during the final 6 months and the final 2 weeks of life in patients who die of cancer	Cohort
	2011	Mayer [16]	Examine why patients with cancer present to the ED	Cohort
	2015	Henson [17]	Explore factors associated with ED attendance by cancer patients in their last month of life	Systematic review and meta-analysis
	2016	Elsayem [18]	Examine the presenting symptoms associated with risk of ICU admission and hospital death in patients with cancer admitted through an ED	Cohort
	2017	Rivera [19]	Estimate the proportion of ED visits made by cancer patients, understand their clinical presentation and examine factors related to inpatient admission. National dataset	Cohort
	2018	Henson [20]	Identify socioeconomic and clinical factors associated with ED attendance at EOL and the relationship with prior ED use among cancer decedents	Cohort
	2019	Caterino [21]	Understand common characteristics of patients with cancer seeking emergency care and identify opportunities for care optimization	Cohort
	2019	Verhoef [22]	Compare EOL trajectories of hematologic malignancy and solid tumor patients who died <3 months after ED visit	Cohort
Pediatric palliative care	2018	Gaucher [23]	Describe the characteristics of pediatric PC patients with pediatric ED visits	Cohort
	2018	Rocha [24]	Identify factors associated with emergency visits and hospitalizations in patients with congenital syndrome of Zika virus. Identify the clinical interventions performed from the PC perspective	Cross-sectional
Coordination and access to care	2002	Ausband [25]	Determine the prevalence of PC protocols among EMS agencies in the United States and what proportion of the population is covered by those protocols	Cross-sectional
	2014	Carron [26]	Describe situations where prehospital physicians managed PC situations	Case report
	2013	Wallace [27]	Identify patients receiving specialist PC services who attend the ED and determine if these presentations are potentially avoidable	Cohort
	2013	Hjermstad [28]	Register the reasons patients with advanced cancer attend the ED, the interventions performed during their hospital stay, and symptom intensity upon admission and discharge. Assess patient attitudes toward ED attendance	Qualitative: mixed cohort and structured interviews
	2018	Kao [29]	Investigate the factors for ED use during out-of-hours periods of palliative home care services among advanced cancer patients	Cohort
	2018	Lipinski [30]	Evaluate the use of PC services in patients with heart failure who present to the ED	Cohort

Table 63.1 (continued)

Research priority[a]	Year	First author	Objectives	Type of Study[b]
	2019	Green [31]	Examine the decision-making process that leads to patients with palliative care needs to seek emergency care	Qualitative: narrative interview
	2014	Shin [32]	Compare the symptom burden and survival rate of patients admitted to an acute palliative care unit from an ED to those transferred from an inpatient unit	Cohort
	2017	Spilsbury [33]	Determine how the association of community-based PC with ↓ED visits in the last year of life varied by patient factors	Cohort
Attitudinal				
Provision of palliative care in the ED	2009	Wiese [34]	Explore the attitudes and beliefs of prehospital EPs about their experiences in dealing with PC patients in out of hospital emergency situations	Cohort
	2012	Gruzden [35]	Explore attitudes and beliefs among attending EP's provision of PC services in ED	Qualitative: semi-structured focus groups
	2013	Lamba [36]	Elicit the perceived barriers by EP to providing PC in the ED	Cross-sectional
	2015	Weil [37]	Explore the understanding of PC by healthcare professionals caring for patients with advanced cancer attending the ED	Qualitative: focus groups and semi-structured interviews
	2019	Côté [38]	Propose implementation strategies for pediatric palliative care in the ED	Qualitative: semi-structured focus groups
	2009	Smith [39]	Explore the attitudes, experience, and beliefs of EPs about PC in the ED	Qualitative: focus groups
	2015	Russ [40]	Investigate staff experience and attitude toward PC provision in a public metropolitan ED	Cross-sectional
	2018	Wright [41]	Identify EP's priorities for improvement in ED-based PC for older adults	Qualitative: semi-structured interviews
	2013	Grudzen [42]	Identify hospital level factors from the administrative perspective that affect the availability and delivery of PC services in the ED	Qualitative: semi-structured interviews
	2015	Rivera [43]	Explore the perceptions and barriers encountered by practicing EPs in providing PC in Puerto Rican EDs	Cross-sectional
	2019	Argintaru [44]	Describe perceived barriers and facilitators to GOC discussions by EM physicians/residents	Cross-sectional
	2010	Smith [45]	Understand the experiences of acutely symptomatic, terminally ill patients seen in the ED	Qualitative: semi-structured interviews
	2018	Cooper [46]	Raise awareness of the experience of PC patients and families/caregivers together with the insights of clinicians caring for them increasing understanding of why implementation of good practice remains difficult	Systematic review
	2019	Di Leo [47]	Explore issues with delivering ED-PC from the perspective of both providers and patients	Qualitative: focus groups and semi-structured interviews
End-of-life care in the ED	2017	Fernandez-Sola [48]	Define the attributes of dignity in EOL care in the ED, based on the opinions of physicians/nurses	Qualitative: focus groups and semi-structured interviews
	2019	Giles [49]	Examine the experiences, perceptions, and needs of nurses providing EOL care in the ED setting in relation to sudden and unexpected deaths	Qualitative: descriptive survey
	2019	Alqahtani [50]	Explore challenges from a staff perspective of safe appropriate high-quality EOL care for people diagnosed with non-malignant diseases who present to the ED	Systematic review
	2020	Mughal [51]	Describe, understand, and explain the perceptions of ED nurses on provision of EOL care	Systematic review
Educational needs	2011	Meo [52]	Characterize the level of formal training and perceived educational needs in PC of EM residents	Cross-sectional survey
	2012	Lamba [53]	Characterize EP's perceived educational and formal training needs for PC-related skills	Cross-sectional survey

Research priority[a]	Year	First author	Objectives	Type of Study[b]
Screening				
General	2020	Kistler [54]	Identify existing triggers for PC consult, how they compare between settings, and common criteria used to identify those in need of PC consult	Systematic review
	2008	Mahony [55]	Identify chronically ill older patients with PC, homecare or hospice needs, and ↑ linkage with these services	Cohort
	2016	George [56]	Evaluate the methods, tools, and outcomes of PC screening and referral projects in the ED	Systematic review
	2001	Mion [57]	Improve case finding of at-risk older adults and provide comprehensive assessment in the ED setting with formal linkage to community agencies	Cohort
	2011	Glajchen [58]	Improve PC referral among frail, elderly patients in the ED	Cohort
SPEED	2011	Richards [59]	Develop and validate a novel palliative medicine needs assessment tool for patients with cancer in the ED	Cohort
	2019	Reuter [60]	Assess the feasibility and reach of a novel care pathway utilizing electronic health record embedded screening and automatic triggered consultation to deliver ED-based palliative care services for patients with active cancer	Cross-sectional
P-CaRES	2015	George [12]	Develop a simple content valid screening tool for use by EPs to identify patients with significant PC needs and establish content validity	Qualitative: modified Delphi technique with expert panel
	2016	Bowman [61]	Assess acceptability and reliability of a brief novel content – validated screening tool for unmet palliative care needs – the Palliative Care and Rapid Emergency Screening (P-CaRES) Project, a brief novel content among EPs of different roles and experience levels	Cross-sectional
	2017	Ouchi [62]	Assess the performance and determine the acceptability of a content-validated palliative care screening tool	Cohort
	2020	Tan [63]	Optimize the use of electronic health records by creating a clinical decision support (CDS) tool to identify the high-risk patients most likely to benefit from primary PC and provide point-of-care clinical recommendations	Qualitative: focus groups and survey
Surprise question	2018	Ouchi [64]	Evaluate the prognostic value of the suprise question (SQ) in elderly ED (>65) patients for predicting 12-month mortality	Cohort
	2019	Verhoef [65]	Evaluate the prognostic value of the surprise question (SQ) in patients with advanced cancer visiting the ED and study the yield of adding other predictors for approaching death	Cohort
	2019	Aaronson [66]	Evaluate the prognostic value of the SQ in symptomatic heart failure patients presenting to the ED	Cohort
	2019	Ouchi [67]	Determine the association of the surprise question with actual 1-month mortality among undifferentiated older adults admitted from the ED	Cohort
	2019	Haydar [68]	Determine the utility of the modified SQ (30 days versus 1 year) to predict in-hospital mortality and resource utilization for hospitalized ED patients	Cohort
Other ED screening projects	2014	Ouchi [69]	Observe prevalence of ED-initiated palliative care consultation for advanced dementia following quality improvement intervention	Cohort
	2015	Kistler [70]	Evaluate the impact of ED-initiated palliative care referral on the proportion and timing of consultation	RCT
Outcomes				
General	2019	Grudzen [71]	Measure the impact of primary PC education for ED providers on disposition, healthcare utilization, and survival times	RCT
	2020	Yash [72]	Measure the current quality of EOL care in ED to identify gaps, formulate improvements, and implement the improved EOL care protocol	Cohort
	2014	Lamba [73]	Highlight needs and opportunities for better integration of EM and PC	Expert opinion
	2016	da Silva Soares [74]	Examine the effectiveness of ED-based PC interventions on hospital admissions, LOS, symptom severity, QOL, use of other healthcare services, and PC referrals for adults with advanced disease	Systematic review
	2020	Wilson [75]	Assess the effect of ED-based PC interventions on patient- and family-reported outcomes, healthcare utilization, and survival for adult patients	Systematic review

   1. Overview: non-systematic review
   2. Expert opinion

study from 2012 compared a month of ED-initiated PC consultations 4 years apart in a large urban ED in the United States. They found that most patients were admitted through the ED, yet consultations initiated in the ED were only 3% in 2005 and 6% in 2009 [11]. A similar study from 2019 assessed ED patients with unmet PC needs in Austria, based on a previously validated screening tool [12], with only 5.5% receiving PC consultation [13].

Cancer

In the cancer population, most of the descriptive studies focus on patient characteristics and ED use. One study showed the prehospital Emergency Medical Service (EMS) use in cancer patients appears to be greater among older patients, those with higher acuity, CNS cancers, or neurological or cardiac symptoms [14]. Lung cancer is consistently

found to be the most common type of presenting cancer, as well as the cancer most likely associated with in-patient death following ED use. Overall, lower socioeconomic status and symptom distress, particularly pain and dyspnea, are among the most common reasons for ED presentation [15–20]. In a 2019 multicenter prospective cohort study from 18 EDs, Caterino et al. found that nearly half of cancer patients presenting to the ED were ≥65 years old, and those presenting with uncontrolled pain from outpatient settings were associated with only 8% of specialist PC involvement [21]. Comparing hematological to solid tumor malignancies, those with hematological malignancies appear to have a substantially higher likelihood of in-hospital, ICU, and ED death [22].

Pediatric

There is a relative paucity of descriptive research addressing pediatric PC in the ED. Two 2018 studies, one from Canada and the other from Brazil, demonstrate missed opportunities and the need for greater access and collaboration. The Canadian study is a retrospective review of patients followed by the pediatric PC team who presented to their ED. Of the 290 patients studied, 40% died during that hospitalization with nearly 20% dying within the first 72 hours of admission. Two-thirds had completed advance directives on arrival to the ED, but less than 40% had goals of care discussions within that hospitalization [23]. The Brazilian study assessed patients presenting to the ED with congenital Zika virus syndrome. Affected children have a limited lifespan and require frequent ED visits, hospitalizations, and aggressive procedures throughout their life. Of the 92 patients followed in their specialty clinic who presented to the ED, only two hospitalized patients received PC specialty consultation [24].

Coordination of Care and Access to Palliative Care

The remaining descriptive articles of PC in the ED come from a variety of international sources examining access and coordination of care. Two publications studied emergency medical service (EMS) issues. The first, in 2002, surveyed a cross section of EMS agencies from 121 of the 200 most populous US cities and found only 5.8% of those agencies had protocols to care for patients with PC concerns [25]. The other article from 2014 used case reports to encourage increased PC education for EMS personnel and improved collaboration with healthcare systems [26].

Five studies from several different countries demonstrate a need for better access to PC services, particularly after usual business hours and even when previously connected to outpatient PC services [27–31]. One of these studies reviewed medical records of 500 heart failure patients presenting to two EDs in Canada during an 8-month period in 2013. Among those who died within 1 year, 41% received specialist-level PC, and 76% of those patients received services only in the last 2 weeks of life [30].

Two remaining descriptive studies showed benefits of PC specialty involvement. The first compared characteristics of patients directly admitted to an inpatient acute PC unit directly from the ED (12% of 2568 patients) versus those admitted elsewhere in the hospital. They found that while the ED patients had higher symptom burden and higher medical acuity on admission to their unit, they were more likely to be discharged to the community alive [32]. The second article used a regional Australian database of deceased patients with serious illness and found a 50% reduction in ED use in the last year of life for those enrolled in the PC community-based programs versus those not enrolled in these programs [33].

Attitudinal Studies

Studies exploring attitudes and perceptions of PC in the ED have identified barriers to care and opportunities for improvement. Nearly all related studies have occurred within the past decade. The majority of these studies viewed the provision of PC in the ED through the lens of healthcare workers, patients, and caregivers. A smaller number of studies focus specifically on end-of-life care, and the remainder target emergency medicine resident training needs.

Provision of Palliative Care in the Emergency Department

An early study assessed the emergency care of patients with PC needs from the perspective of 150 prehospital emergency physicians in Germany. A large majority (89%) reported experience with patients having advanced cancer with acute PC needs, but half were uncomfortable with the associated psychosocial challenges and felt that additional training would be useful [34]. Within the ED, several studies investigated PC-related attitudes of healthcare workers. Some targeted emergency physicians specifically [35, 36], and others included interprofessional physicians involved in the care of palliative patients with ED visits [37, 38]. The remainder included a more general group of providers and healthcare workers in the ED [39–41], as well as healthcare administrators [42]. Common and informative themes emerged from this collection of studies of healthcare provider attitudes. Among emergency physicians, there is a perceived lack of understanding, lack of training, and discomfort in providing

PC in the ED. The role of the emergency physician was also viewed as more fixed within a culture of stabilization rather than a focus on quality of life. Common themes for emergency physicians included recognition of the complexity of medical decision-making and medicolegal practice concerns in the ED that inhibit consideration of withholding or withdrawing life-sustaining interventions. They also communicated a concern that PC-related questions should have been addressed prior to the ED visit by a primary care provider. In contrast to these findings, a cross-sectional survey of ED residents and faculty reported a high degree of comfort with addressing goals of care and that this skill was within their scope of practice. Specialist PC clinicians in the ED are viewed overall as beneficial for their skills, time, and ability to intervene; but availability is inconsistent, and in some environments specialists are unavailable [35, 36, 43, 44]. Beyond the attitudes of emergency physicians, a broader view from ED-based healthcare providers found similar themes, such as a lack of understanding and a desire for additional training and education, but showed a greater association of PC with end-of-life care than in the physician groups. In addition to medicolegal constraints and a discordant culture of "life-saving" rather than palliation, these studies emphasize the need for greater communication and documentation to prevent undesired outcomes, such as cardiopulmonary resuscitation or intubation in a patient who would not want such interventions [39–41].

Investigations of barriers to care and opportunities for improvement widen the view further, including attitudes of interprofessional clinicians and administrative healthcare professionals, as well as patients and family caregivers. Certain barriers to providing PC in the ED were identified as similar to those seen by ED providers, such as a lack of understanding of PC, a culture of "aggressive care," and medicolegal concerns. PC in the ED was seen as desirable overall and an opportunity for improved patient and family satisfaction, more meaningful care, and decreased costs [37, 38, 42]. When including interviews with patients and family caregivers, in addition to healthcare workers' perceptions of care in the ED, common recommendations for improvement included a need for a more accommodating environment of care, better communication and coordination of care, and greater education and training among ED providers [45–47].

End-of-Life Care in the Emergency Department

Physicians and nurses provide care for the dying and deceased in the ED routinely. As would be expected, studies have demonstrated their support for preserving the dignity of patients dying in the ED, yet they also identified several challenges that threaten their ability to accomplish this goal. Among those challenges are a suboptimal physical environment of care (e.g., little space, limited privacy) and inadequate resources, communications, and coordination of care. Finally, ED provider role ambiguity and insufficient education and training are of concern. Improvement priorities included enhanced communication and symptom management skills, standardized care protocols, adequate space and resources, as well as better ED-PC integration [48–51].

Educational Needs

Two cross-sectional surveys assessed perceived educational needs of emergency medicine residents. The first, published in 2011, surveyed 159 residents at all levels of training from six emergency medicine programs in New York City. Half of those surveyed described having some PC training prior to residency. By the second year of residency, nearly all reported ED experience in managing terminal illnesses and with patients who died. PC was seen as an important competency by 71% of respondents, but only 24% had a "clear idea of the role of PC in emergency medicine." The priorities for additional training included advance directives and medicolegal issues at end of life [52].

The second study from the following year surveyed both residents and faculty from a single program. Approximately half of those surveyed felt they received minimal training in pain management, hospice care, withdrawing/withholding life-sustaining interventions, and management of the dying patient. Similar to the prior study, PC was valued as an important competence by 88% of respondents, and 90% desired more training. Specific topics identified for additional training included discussion of code status and symptom management at end of life. Bedside teaching was the preferred learning modality [53].

Screening

General

The most recent systematic review of triggered PC consults is from 2020 [54]. The authors limited inclusion criteria to prospective quantitative analyses of triggers for consultation for adult patients in the ED and inpatient settings since 2008. All retrospective studies, guidelines, reviews, case reports, editorials, and commentaries were excluded. Overall, three-quarters of the studies were judged to be of moderate to high degree of bias, using the Newcastle-Ottawa scale for nonrandomized studies and the Cochrane risk of bias tool for randomized controlled trials. They concluded that nurses are frequently the primary operators of the trigger tools, and the primary categories focus on advanced illness states and the need for goals of care clarification. Future randomized con-

trolled trials of high quality are still needed to define best practices and to distinguish primary from specialty PC needs. While the ED is included as a primary setting in this systematic review, only one study met their rigorous inclusion criteria. That study, published in 2008 by Mahony et al., demonstrated a low risk of bias [55].

In 2016, previous to the abovementioned systematic review, George et al. published a different systematic review of screening and assessment specific to the ED. Seven studies were included that met their criteria, which included the intervention of "a PC screening tool, assessment, or referral modality aimed at identifying patients appropriate for PC " [56].

The early studies utilize trained professionals within the ED to screen for PC patients with unmet needs. The earliest of these is from 2001. This study created a case finding strategy for at-risk patients ≥65 years old using a triage risk screening tool by the ED nurses, followed by a geriatric assessment tool performed by a geriatric clinical nurse specialist. While not specifically identifying a PC purpose, this study was successful in increasing referrals for supportive services to these elderly patients with unmet needs by sixfold during the 18-month study period and was able to demonstrate modest reductions (2–7%) in repeat ED use at three of four sites within 30 days [57]. Two later studies evaluated unmet PC needs for patients ≥65 years old with the goal of increasing early PC consultation. The first, by Mahony et al. and mentioned in both systematic reviews, used PC nurse practitioners. The second, by Glajchen et al., used a PC social worker. Both studies applied advanced illness criteria with needs assessments to determine which patients would likely benefit from early consultation. In the first study, of 291 patients who had needs assessments completed by the nurse practitioner, 90% were admitted to the hospital, most did not have advance directives, and a median of 68% died within 6 months. Of the deceased, those enrolled in hospice were more likely to die in their place of residence [55]. The second study reported on a group of patients identified by the social worker as having high unmet PC needs and therefore presumed high likelihood of benefit for early PC consultation. Among those recommended for PC consultation in the ED, only half formally received PC consultation, yet 80% died within the 8 months of study enrollment. The biggest reason for not receiving a PC consultation was reluctance on the part of the primary treating physician or the family [58]. Subsequent studies began to integrate the screening process into ED practice.

Speed

In 2011, the Screen for Palliative and End-of-life care needs in the Emergency Department (SPEED) tool was validated as a multidimensional system assessment tool to identify cancer patients on ED arrival who would benefit from PC consultation [59]. This tool was adapted and simplified into a five-question tool (5-SPEED) and integrated into an ED-based palliative intervention program as part of the initial bedside nurse assessment [60].

P-CaRES

In 2015, a broader, yet straightforward tool was developed to identify any patient who might benefit from PC consultation. First, content validity was established using a modified Delphi technique with experts from hospice and palliative medicine [12]. Next, using surveys and case vignettes, the tool demonstrated acceptability and reliability with emergency physicians in the Palliative Care and Rapid Emergency Screening (P-CaRES) project [61]. Finally, the tool was tested among emergency physicians in a convenience sample at a single institution over a 3-week period as an immediate look back on patients from their shift who were ≥65 years old. They found that 32% of patients screened positive for PC consultation, 70% of physicians found the screening tool acceptable to use, and the average time to completion was only 1.8 minutes per patient [62]. Most recently, as part of the Primary Palliative Care for Emergency Medicine (PRIM-ER) project, the P-CaRES tool was adapted into a clinical decision support tool to automate, within the electronic medical record system, the identification of and initiation of services for older adults with unmet PC needs [63].

The Surprise Question (SQ)

The question "would you be surprised if this patient died in the next 12 months?" has shown some utility as a simple tool to predict 1-year mortality. In the ED, the SQ has been used as a possible identifier of patients who might benefit from early PC consultation. In a 2018 study, ED physicians were asked the SQ in a convenience sample of 207 patients ≥65 years old. The SQ alone had a sensitivity of 77% and specificity of 56% in predicting 1-year mortality [64]. Another study included all patients entering through the ED with advanced cancer over a 14-month period. Physicians were asked the SQ retrospectively, and if responding "would not be surprised," they also asked for an estimate of the Eastern Cooperative Oncological Group (ECOG) functional scale. Among 245 patients studied, the median survival was only 3 months. The SQ alone had a sensitivity of 89% in predicting 1-year mortality. The combination of the SQ and ECOG decreased sensitivity to 40% but increased specificity to 92% [65]. The SQ was also used to assess prognostic accuracy in heart failure patients in the

ED and exhibited a sensitivity of 79% and specificity of 57% [66]. Two recent studies adapted the SQ to "would you be surprised if the patient died in one month?" One assessed the prognostic value in all patients ≥65 years old (sensitivity 20%, specificity 93%) [67], and the second assessed its prediction for in-hospital mortality (sensitivity 32%, specificity 85%) [68]. Overall the SQ shows promise as a simple and easily adaptable tool to help in identifying patients with unmet PC needs.

Other ED Screening Projects

Several other trigger-based efforts have been used to identify patients in the ED who would likely benefit from PC consultation. In one, the Functional Assessment Staging (FAST) criteria of >7 was used to identify patients ≥70 years old with advanced dementia and found a disconnect between the predetermined criteria for PC consultation and the ED physician interpretation of appropriateness for consultation [69]. Another used the National Comprehensive Cancer Network (NCCN) guidelines to identify patients with advanced cancer, resulting in earlier PC consultation [70].

Overall, several screening tools appear to be helpful in identifying patients in the ED who may benefit from palliative approaches to care. Challenges remain for efficient integration of PC and in distinguishing primary from specialty-level needs.

Outcomes Research

For the purposes of this discussion, outcomes research refers to ED-initiated PC interventions and patient- and family-reported outcomes, healthcare utilization, and survival. Though studies exist dating from the 1990s, the majority were published in the last 5 years and include several published protocols for ongoing, large multicenter trials [71, 72]. The studies examine the impact of integrated PC models and differing strategies for clinical integration as described by the Improving Palliative Care in Emergency Medicine (IPAL-EM) project from the Center to Advance Palliative Care (CAPC). These include the following models: traditional consult, basic integration, advanced integration, and ED-focused advanced integration [7, 73].

There are two systematic reviews, the first published in 2016 by da Silva Soares et al., followed by Wilson et al. in 2020. The 2016 article considered only studies involving at least one member of a PC team and used hospital admission as their primary outcome. It found insufficient evidence to support the effect of ED-based PC interventions on the outcomes of interest, with the exception of one study suggesting a reduction in hospital length of stay. They urged efforts to provide better evidence in the future through adequately powered and well-conducted randomized controlled trials [74]. The 2020 systematic review reported on the efficacy of ED-based palliative interventions on various outcomes. They noted that the existing evidence was conflicting with marked heterogeneity in design, population, and investigated outcomes, thus limiting a high-level analysis. Nonetheless, they concluded that compared with usual care, ED-initiated PC improves quality of life without decreasing survival time and likely decreases healthcare utilization metrics, such as length of stay [75].

Traditional Model of Consultation

The traditional model of consultation involves contacting a specialist to assist in patient care. Three particular studies show evidence of benefit from PC specialist consultation, focused primarily on the timing of consult. The first, from 2016, found that ED-initiated referral for advanced cancer patients led to earlier symptom control and decreased hospital length of stay compared to referrals initiated while inpatient [76]. A second study, from 2019, looked at adults presenting from long-term care facilities who were triaged as Emergency Severity Index Level 1 (most urgent). They found that formal PC involvement resulted in less aggressive care in 85% of cases; however most of these interventions occurred late in the hospital course with only 9.1% occurring while in the ED. They concluded that this was a missed opportunity to ensure goal-concordant care earlier in the hospital course [77]. A third study from the same year compared the in-hospital mortality of cancer patients directly admitted to the hospital versus those admitted from the ED. The ED patients had a higher overall in-hospital mortality, but PC consults within the first 3 days of admission were associated with decreased mortality when compared to later consultation. This supported a benefit to early PC consultation for ED patients with cancer and urgent-level severity of illness [78].

Basic Integration

Basic integration describes ED and PC programs working collectively to meet objectives with at least some focused initiatives [7]. A randomized controlled trial from a single center in 2016 compared ED-initiated PC consultation to usual care for advanced cancer patients. Quality of life was improved without shortening survival, but with no clear impact on healthcare utilization metrics [79]. Another study from 2016 investigated the feasibility of an educational intervention to identify patients with less than 6 months prognosis. Of the patients identified, 91% of the patients met

hospice eligibility criteria, which succeeded in substantially increasing the number of days enrolled in hospice from baseline [80]. A second feasibility study from 2019 in Singapore tested a care model for metastatic cancer patients. It was designed as a tripartite ED-PC-hospice collaboration, which succeeded in earlier access to PC while, in the ED, including direct admission to a PC unit and to comfort care rooms [81].

Advanced Integration

Studies focused on advanced integration involve targeted screening criteria to identify at-risk patients and a higher level of ED engagement in designing protocols and providing care. The majority of these studies were of cohort design and contained educational interventions to improve general PC skills performed in conjunction with efforts to increase collaboration between emergency and PC providers. In Ireland, Tiernan et al. instituted a four-part intervention including a flagging system for patients known to the service, a screening checklist, education, as well as proactive PC engagement and found patients were 10.5 times more likely to receive a PC consult while in the ED after the intervention with subsequent decreased healthcare utilization [82]. The last study by Weng et al. from Taiwan describes a multi-stage intervention with strong educational components, including an inpatient hospice rotation for the residents, monthly ED interdisciplinary team meetings, and a dedicated cell phone app facilitating communication. This resulted in an increase in DNR orders and hospice consults from the ED [83].

ED-Focused Advanced Integration

Three studies describe ED-focused advanced integration efforts. An organizational level case report by Rosenberg et al. described the institutional development of an ED-based PC team which resulted in increased frequency of DNR orders, improved patient satisfaction, and decreased cost, without impacting the inpatient PC team's consultation volume [84]. A complex multi-step quality improvement initiative by Gruzden et al., the Geriatric Emergency Department Innovations in Care through Workforce, Informatics, and Structural Enhancements (GEDI WISE) model, implemented workforce enhancements, including role redefinition and education of existing providers, and was associated with expedited PC referrals and decreased geriatric ICU admissions from the ED as compared to baseline [85]. Finally, Liberman et al. successfully employed an advanced illness management program, which involved screening by an ED case manager followed by primarily ED-led goals of care conversations and PC available for support. They found an increase in home hospice discharges compared to baseline (39.3% vs 0% respectively) [86].

The remaining outcomes studies focus on improving end-of-life care and communication strategies.

End-of-Life Care

There is, in general, a lack of high-tier evidence regarding best practices for optimization of end-of-life care, specifically for ED patients. Many of the current practice recommendations for emergency care are based on evidence from other settings. A European observational study by Sedillot et al. suggested a five-step protocol for ventilator withdrawal, and two case reports examine end-of-life care transition [87]. A 2013 study by Shlamovitz et al. described improved symptom management after using ketamine for palliative sedation in an ED patient [88]. Wang suggested a systematic approach for comfort care transitions based on an extensive literature review [89]. A descriptive study by Economos et al. evaluated the appropriateness of end-of-life care provided to decedent ED patients based on published guidelines from the French Agency for accreditation and assessment, concluding that the majority of emergency providers recognize when a patient is actively dying and adjust treatments accordingly, with decreased provision of non-beneficial care [90]. Chor et al. described implementation of a protocolized care bundle aimed at reducing variability in the quality of end-of-life care received in a single institution in Singapore. They found that 74% of patients received opioids for pain and dyspnea and over 90% were allowed visitors; however the study lacked comparison data [91]. Finally, a 2020 randomized controlled crossover trial from Thailand compared high-flow nasal cannula to conventional oxygen therapy for relief of dyspnea and hypoxemia respiratory failure and showed significantly decreased dyspnea in the high-flow nasal cannula group compared to conventional therapy [92].

Communication

Best practices for ED-based goals of care conversations remain unclear, but a few studies have provided structure for future consideration. The first, a small Australian study evaluating the implementation of a form designed to guide and document conversations, found that while most physicians supported having the form, recommendations for its ideal format and content varied [93]. A subsequent systematic review found a similar lack of consensus with goals of care conversations in identifying patient candidates, as well as the content and documentation of these conversations [94]. Brief negotiated interview techniques have been successful for other patient care concerns in the ED, and a growing interest

is developing in using these techniques as a structured approach to improve serious illness conversations in the ED [95, 96].

Resource Allocation

In this section, we examine studies describing the interface between emergency care and available internal and external support services. While many studies use decreased ED attendance as a surrogate metric for improved quality of care, we focus here primarily on studies describing collaborative efforts with the ED through improved care coordination or dedicated resources. Organizationally, these studies can be grouped by the timing and location of the resource in relation to the ED visit: (1) community-based care before or after ED attendance, including work done in the field of emergency medical services, or (2) hospital-based resources provided either during ED attendance or after admission. Quality improvement research predominates with most having a descriptive design.

Community-Based

Improved access to community-based PC services can lead to a significant reduction in ED use. In a scoping review of initiatives to reduce inappropriate or non-beneficial hospital admissions at end of life, Taylor et al. note that eight out of ten included studies observe a reduction in ED utilization for patients receiving community-based services [97]. This was also observed by Wiese et al. in a 2008 German cross-sectional study examining emergency calls by cancer patients/families in the last 6 months of life [98]. Similar reductions in patterns of emergency service utilization were found in a 2016 US case control study on the impact of hospice services [99], a 2017 Canadian cohort study comparing palliative intent versus standard homecare nursing [100], and a 2018 Finnish study describing the impact of a growing outpatient PC clinic [101]. This last study also noted improved quality of documented advance care plans in palliative clinic patients.

The first interface for many palliative patients with emergency care is through emergency medical services. Several descriptive studies illustrate the potential benefits of close collaboration between EMS and palliative resources. A case report by Lamba et al. presents four case scenarios highlighting the need for improved collaboration and offers suggestions such as identifying PC champions and creating an action plan via an EMS dashboard [102]. A multicenter German cohort study by Wiese et al. found that emergency providers who were experienced in PC transported significantly fewer patients to the ED [103]. Montgomery et al. describe a quality improvement initiative between EMS and community care providers in Edmonton allowing 61% of calls initiated for symptom crisis to be cared for at home when they would have traditionally required transfer [104]. Two qualitative studies by Kamphausen et al. and Patterson et al. note the impact of resource availability on avoiding unwanted transfer, particularly the importance of up-to-date documentation [105, 106]. There is no conclusive evidence on the best mechanism for communicating care preference across care settings. A small study by McQuown et al. on the transport of DNR orders with patients from extended care facilities found that while 68% of patients had DNR order, only 28% were transferred with the patient and not all of those were recognized by the receiving providers [107]. Lakin et al. found that while emergency physicians perceived advance care planning documents to be very useful, only 31% were very confident they could locate them in the electronic medical record [108]. The most studied method of communicating advance care plans is likely the physician order for life-sustaining treatment (POLST). However, a recent cohort study by Vranas et al. found that the majority of completed POLST forms had no impact on treatment intensity as they were often out of date, were not accessed, or did not indicate a desire for treatment limitations, thus limiting their utility [109].

Within the ED

In many healthcare systems, specialty PC services are a limited resource, and evidence on how to best expand care for emergency patients is also fairly limited. A cohort study by Purdy et al. demonstrated decreased ED attendance and in-hospital deaths after implementing a care initiative including two hospital-based nurses whose role included identifying appropriate patients and facilitating discharge [110]. Lafond et al. described an institutional effort to improve care of terminal ED patients by allocating an ICU comfort care bed to facilitate rapid transfer. This resulted in a reduction in the number of patients dying on stretchers in the ED [111]. A cohort study by Liberman et al. demonstrated reduced 30-day re-visit and admission rates by embedding a specialist care coordinator in the ED who identified patients to be safely discharged with community resources [112].

Due to the events of the COVID-19 pandemic, there has been a surge of renewed interest in allocation of PC resources to include the ED. Several articles describing institutional responses appeared in the literature only months after the pandemic was declared. Chidiac et al. from the UK describe service capacity development by targeted palliative education of the generalist workforce, use of symptom management guidelines, and close partnership with community hospices [113]. The University of Washington's contingency and cri-

sis plan for the ED included an embedded PC specialist for screening and assistance with ED goals of care discussions [114]. Colombia also dedicated a PC team within the ED for early goals of care conversations, noting a reduction in patients desiring full aggressive medical therapy from 82.7% to 18.2% following intervention [115].

After the ED

Gruzden et al. published a protocol for a multicenter randomized control trial comparing the effectiveness of specialty outpatient PC versus nurse-led telephonic palliative care, which will be the first of its kind [116]. Several descriptive studies of bereavement programs show potential benefit. One study from 1999 observed decreased grief intensity in high-risk participants [117]. A more recent study from 2019 noted the positive impact of a bereavement program also on clinicians [118].

Education for Clinicians

Death Disclosure

Early efforts to improve PC skills in the ED focused on the difficult and ubiquitous experience of performing a death disclosure. In 2002, Quest et al. used a structured curriculum for 16 evenly split first- and second-year EM residents to teach and practice death disclosure. The intervention was a combination of large group and small group didactics, followed by a standardized patient (SP) experience. While there was positive feedback and improved comfort with the intervention, the competency assessments of the residents were concordant between faculty and SP, but discordant with the resident self-assessments. Resident self-assessments of competency tended to be higher than faculty or SP assessment [119]. The same assessment tool, identified as the affective competency score (ACS), was later used to evaluate fourth year medical students rotating in the ED. It again demonstrated concordance with faculty and SP, but similar discordance with student self-assessment. Together, these findings support the use of the ACS as a valid and reliable tool for faculty and SPs to assess death disclosure [120].

A similar approach using the aptly named GRIEV_ING mnemonic was studied first with residents, then with paramedics. In the first study, 20 residents received a 2-hour educational session, including small group, role-play, and a didactic lecture. The residents were followed to assess retention after 3 months. Assessments of self-confidence and competency (by a trained SP and blinded audio rater, with high inter-rater reliability) improved from before and after the intervention with stability over time [121]. The GRIEV-ING mnemonic was later studied with 30 paramedics, limiting assessments to pre-/post-intervention, and found again an increase in self-confidence and competency (assessed by a trained SP) [122].

EPEC-EM

The Education in Palliative and End-of-life Care for Emergency Medicine (EPEC-EM) project is a comprehensive curriculum designed to facilitate teaching primary PC skills to EM clinicians. In 2010, Gisondi et al. published an adaptation of the curriculum for EM residents at a single academic medical center. The 14 curricular modules were divided into equal parts of synchronous (lectures) and asynchronous (electronic media) teaching strategies and demonstrated similar knowledge transfer, supporting selectively flexible approaches to delivering the curriculum [123]. The same year, Ponce et al. demonstrated improved comfort with prehospital personnel in a pilot study using the EPEC-EM modules as a training method for death disclosure and family-witnessed resuscitation [124]. A later study used selective topics from EPEC-EM to study the effect of EM resident behaviors and retention of information over a 6-month period after a brief educational intervention (4 hours of didactic learning in a single day). Based on comparison survey results, residents did not retain information on opioid conversions and dyspnea in the dying patient but retained knowledge of hospice qualifying diagnoses. This resulted in an observed 88% increase in direct ED to hospice referrals during the study period [125]. A more recent study used a simulation-based intervention focusing on rapid assessment of PC patients in the ED, derived from an EPEC-EM module. Residents demonstrated an increase in both the perceived importance of primary PC skills for EM physicians and self-reported confidence in using these skills [126]. In both of these last two studies, time limitations were identified as possible barriers to clinical implementation.

Training Efforts

Taking a broad view of how EM training programs in the United States incorporate PC principles, Kraus et al. surveyed the leadership from over 100 programs, representing 6 states where fully half of residency programs are located. They published in 2016 that a slight majority of EM programs taught PC skills. The following factors were associated with PC teaching: familiarity with EPEC-EM, HPM consult availability in the ED, and access to an HPM rotation. The topics of greatest importance were crucial conversations, pain management, and care of the imminently dying. The most effective teaching methods were

bedside teaching, HPM faculty mentorship, and case-based simulation. An interesting disconnect was noted between senior resident self-perception of competence and the following topics: the dying child, withdrawing and withholding life-sustaining treatments, and ethical and legal considerations of care. Faculty and resident barriers to implementation of the curriculum included a lack of subject expertise and a lack of interest [127]. By comparison, a Canadian study surveyed 26 programs (out of 36) and found that a minority of programs had any structured curriculum in PC. Of those, 100% were lecture or seminar-based approaches. Half had an elective rotation in HPM available, but only one had a mandatory rotation. Identified barriers to the incorporation of PC skills into the curriculum included lack of time and concerns of assuring that the content was relevant and current [128].

Two additional efforts deserve mention. The first used experts from HPM and EM to define content areas and competencies for primary PC skills and applied their recommendations to the EM Milestones for residency training [129]. The second provides the protocol of an expansive project currently underway looking at the impact of a comprehensive program of education and skills in primary PC for ED providers: the Primary Palliative Care for Emergency Medicine (PRIM-ER). This project will lead to a randomized controlled study of the effect of their interventions in 33 EDs across the country [71].

Summary

In this chapter, we have presented an overview of the rapidly growing research addressing the interface of PC within the ED. For structure, we relied on guidance from a 2011 workgroup of experts from both fields who created six priorities for research efforts: descriptive, attitudinal, screening, outcomes, resource allocation, and education for clinicians. Further categorization used study descriptions from the methodology sections for each referenced article (see Table 63.1). While a true analysis of the hierarchy of evidence was beyond the scope of this chapter, recent robust and well-powered study designs show promise in the emerging literature to guide future best practices in the ED care of patients with serious illness.

Kenneth V. Iserson

Introduction

Bioethical issues often arise when treating emergency department (ED) and prehospital care patients. Actual or anticipated bioethical dilemmas commonly occur among patients with hematologic and oncologic diseases, and these dilemmas may require slightly different approaches than in other ED patients due to attitudes toward and the nature of the disease processes. Bioethical dilemmas raised by emergency hematologic-oncologic patients fall into four categories (Table 64.1): decision-making, treatment demands and refusals, system problems, and notifications.

Bioethics can be a nebulous concept, so the first order of business will be to lay the groundwork by describing bioethics and discussing how it fits into our societal and professional value systems. Then, I will briefly review basic ethical (foundational) theories and the methods used to think through ethical dilemmas, followed by a discussion of the mid-level ethical principles with which clinicians may be more familiar. While they may appear superficial or oversimplified, these mid-level principles provide an easy way to think about the issues posed in bioethical dilemmas and policy development. Therefore, when treating emergency patients with hematologic and oncologic illnesses, we use them to convey common moral themes, such as decision-making, demands for and refusals of treatment, and system constraints. Finally, I will move into the area of virtues to discuss notifications to patients and survivors.

Table 64.1 Categories of bioethical issues encountered when working with patients with hematologic-oncologic diseases and their families

Decision-making (*autonomy*)
1. Dying. Surrogates and advance directives (living will, medical power of attorney, prehospital advance directives)
2. Decision-making capacity
Treatment demands/refusals (*beneficence, nonmaleficence*)
1. Demands to "do everything"
2. Palliative care decisions (demand to do "nothing"—Comfort care only)
3. Refusal of analgesics
4. Refusal of possibly beneficial treatment (including decisions based on religious beliefs)
System dilemmas (*distributive justice, confidentiality*)
1. System problems (inability to pay, intentional/unintentional release of patient information, undocumented alien, "wrong" insurance or medical system/group)
2. Collegial problems (refusal to see patient, abandonment, etc.)
3. Research protocols
Notification (*honesty with sensitivity*)
1. Notifying patient/family of diagnosis
2. Notifying survivors of death

How Bioethics Fits into Our Societal and Professional Value Systems

Bioethics, or clinical ethics, describes how we apply professional and societal values in an organized way to find reasoned and defensible solutions for moral dilemmas. Moral dilemmas are those situations in which an individual must make a decision between conflicting or competing values. The resolutions to such dilemmas, however, do not always hinge on determining right versus wrong or good versus evil. Rather, moral dilemmas more often deal with "gray areas," where the situations or resolutions initially seem to be equivalent, i.e., situations with seemingly equal merit or apparently equal injury. In these more ambiguous situations, we use ethical values to help determine a morally acceptable course of action.

In a pluralistic society, we derive these values from a variety of sources, including the general cultural, philosophical, and religious moral traditions, the social norms embodied in law, and our professional oaths and ethical codes. Each of these sources claims moral superiority. The goal of bioethics is to help us understand, interpret, and weigh these competing moral values [1].

Case Study 1

The following case represents an example of how bioethics can be applied when a cancer patient presents to the ED.

An exsanguinating adult leukemic patient, awake and still with medical decision-making capacity, arrives in the ED and explicitly states that, owing to long-standing religious beliefs, she wants no blood or blood products. The physician, with a professional duty and moral commitment to preserve life, does not personally agree with the patient's decision. Yet, society (through the benchmark of court decisions) has repeatedly sided with the patient's right to refuse such treatment.

In this case, the patient's autonomy and right to practice her religion are recognized as the overriding values. The case becomes somewhat less clear when the patient lacks decision-making capacity, is a minor, or appears to be under external pressures (such as from relatives) to make what is a life-threatening decision. In my experience, however, when clinicians truthfully tell patients that they will die quickly without the transfusion, most consent. Some clinicians, steeped in the idea of patient autonomy, forget that informed consent includes informing the patient of all the relevant benefits and risks—including death.

Values in Emergency Medicine

Values describe the standards that individuals, institutions, professions, and societies use to judge human behavior. We learn values, usually at an early age, through indoctrination into the birth culture, from observing behavior, and through secular (including professional) and religious education. They are moral rules derived from ethical principles that promote those things we think of as good and minimize or avoid those things we think of as bad. Societal institutions incorporate and promulgate values, often attempting to retain old values even in a changing society.

In pluralistic societies, clinicians must be sensitive to alternative beliefs and traditions, since they treat people with multiple and differing value systems. Not only religious but also family, cultural, and other values contribute to patients' decisions about their medical care; without asking the patient, there is no way to know what decision they will make [2].

Although many people cannot answer the question "What are your values?", physicians can get concrete expressions of patients' uncoerced values by asking what they see as their goal of medical therapy and why they want specific interventions. In patients who are too young or who are deemed incompetent to express their values, physicians may need either to make general assumptions about what a normal person would want done or to rely on surrogate decision-makers [2].

Institutions, including healthcare facilities and professional organizations, have their own value systems. Healthcare facilities often have specific value-related missions. Religiously oriented or affiliated institutions may be the most obvious of these, but charitable, for-profit, and academic institutions also have specific role-related values. Professional organizations' values often appear in their ethical codes [3].

Clinicians also have their own ethical values, based on religious, philosophical, or professional convictions. While conscience clauses permit clinicians to "opt out" when they feel that they have a moral conflict with professionally, institutionally, or legally required actions, they are generally required to provide timely and adequate medical care for the patient—which may be particularly difficult to achieve in emergency medicine [3].

Virtues in Emergency Medicine

Virtues describe admirable personal behavior that Aristotle and other philosophers claim is derived from natural internal tendencies [4]. The virtuous person concept can be summed up with the ancient saying: "In a place where there are no men, strive to be a man!" [5]. Virtuous behavior stems from a sense of duty and the perception that it is the right thing to do, rather than from a desire to garner personal benefits. These ideal, morally praiseworthy character traits (e.g., showing kindness) are evident across many situations throughout the person's lifetime. Virtues that may be inherent in emergency medicine clinicians include courage, safety, impartiality, personal integrity, trustworthiness, and fidelity [1].

Courage allows one to fulfill an obligation despite reasonable personal risk. The courageous clinician also advocates for patients against incompetent practitioners and those who attempt to deny them care, autonomy, or confidentiality. *Safety* balances unreasoned courage. *Impartiality* prompts the emergency physician (EP) to provide unbiased, unprejudiced, and equitable treatment to all patients, without regard to their race, creeds, customs, habits, or lifestyle preferences. *Personal integrity* incorporates *trustworthiness*, which prompts clinicians to protect their sick and, often, vulnerable emergency patients' interests by exercising ethical principles. *Truth telling* (fidelity, honesty) prompts clinicians to provide patients with the known facts, but tempered with humility and sensitivity.

Bioethics, Religion, and Law

Religion Organized religions have long been recognized as the guardians of a society's values. Religious values have therefore been an important component of ethical deliberations in medicine, as elsewhere in society. Modern secular bioethics incorporates many religion-originated decision-making methods, arguments, and ideals [6]. Although various religions may appear to be dissimilar, most have as a basic tenet (no matter how it is stated) the Golden Rule: "Do unto others as you would have them do unto you." Religious values are important from two perspectives: the patient's in the exercise of autonomy and the practitioner's in placing limitations on what he or she can morally do. Given the overwhelming importance of patient autonomy in modern Western bioethics and law, however, a practitioner's religious convictions can only guide his or her actions. If their values differ, clinicians must follow the patient's wishes, as long as they are legal and practicable, and they do not violate medicine's basic ethical precepts.

Law Laws are rules of conduct established by legislatures, administrative agencies, courts, or other governing bodies. They often vary from locale to locale and are enforceable only in the jurisdiction where they prevail. Law and bioethics both provide rules of conduct to follow based on societal values. But, while good ethics often makes good law, good law does not necessarily make good ethics [6].

So, how does bioethics differ from law? The law, unlike bioethics, is relatively rigid and, particularly in the case of scientific and medical issues, can lag years or even decades behind modern developments. Societal values are incorporated both within the law and within ethical principles and decisions. By contrast, ethics is more inclusive within a culture, incorporating the broad values and beliefs of correct conduct. The primary differences between law and bioethics are shown in Table 64.2 [3].

Table 64.2 Relationship between the law and bioethics

Bioethics	Function	Law
✓	Case-based (casuistic)	✓
✓	Existed from ancient times	✓
✓	Changes over time	✓
✓	Strives for consistency	✓
✓	Incorporates societal values	✓
✓	Basis for healthcare policies	✓
	Some unchangeable directives	✓
	Formal rules for process	✓
	Adversarial	✓
✓	Relies heavily on individual values	
✓	Interpretable by medical personnel	
✓	Ability to respond relatively rapidly to changing environment

Emergency physicians often look to the law for answers to thorny dilemmas. Yet, except for the rare cases of "black-letter law" wherein very specific actions are mandated, clinicians can best resolve these issues by turning to bioethical reasoning, using bioethics consultations, or applying previously developed institutional bioethics policies.

Modern bioethics developed because the law often has remained silent or inconsistent on matters vital to the biomedical community. The rapid increase in biotechnology, the failure of both the legal system and legislatures to deal with new and pressing issues, and the increasing liability crisis drove the medical community to seek answers to the difficult questions that practitioners have to work through on a daily basis [3].

Oaths/Codes

Medical ethics, or bioethics, differs from ethics in other fields just as medicine differs from other professions. This is because physicians treat ill people who are dependent on them and vulnerable to exploitation. For this reason, physicians have used ethical codes since ancient times to guide their behavior. Modern physicians who deliver critical hematologic and oncologic emergency medical services still rely on this guidance to help resolve dilemmas.

Many healthcare professional organizations, including most involved with emergency care, have developed their own values statements, which they often incorporate into their ethical codes. These codes (and the associated oaths) promote moral standards that their members presumably agree with and are expected to follow. The interpretation of those principles often evolves, albeit sometimes slowly, as the larger society changes. For example, although the American Medical Association's Code of Ethics was first published in 1847, it was not until 2001 that it stated that the physician's primary responsibility should be to their patient. While existing medical professional codes differ markedly (Table 64.3), all try to provide a "bottom line"—that is, a minimally acceptable course of action [2].

Some professional oaths and codes conflate bioethics and professional etiquette. However, these two areas differ markedly: professional etiquette deals with standards governing the relationships and interactions between practitioners, while bioethics is concerned with basic moral values and patient-centered issues [7]. Specifically, bioethics deals with relationships between providers and their patients, providers and society, and society and patients.

Review of Basic Ethical (Foundational) Theories

Foundational ethical theories embody grand philosophical ideas that attempt to coherently and systematically answer two

Table 64.3 Comparison of the ethical precepts contained in the Hippocratic Oath and five ethical codes used by emergency medicine professional organizations

Principle or concept	Society for Academic Emergency Medicine	American College of Emergency Physicians	Emergency Medicine Residents' Association	American Medical Association	American Osteopathic Association (adopted by the American College of Osteopathic Emergency Physicians)	Hippocratic Oath

fundamental questions: What ought I do? How ought I live? Philosophers continue to elaborate or reconstruct fundamental ethical theories based on ancient ethical systems. Many were developed in India and China or within the Jewish, Christian, Islamic, and Buddhist religions. Clinicians generally have difficulty directly applying these theories to individual situations. Rather, they rely on "casuistry," a case-based application of bioethical values (described later in this chapter).

There are two main "foundational" theories of ethics: utilitarianism and deontology.

Utilitarianism, sometimes called consequentialism or teleology, is one of the more functional and commonly used ethical theories. Based on writings by John Stuart Mill and Jeremy Bentham, it focuses on getting good or valued results rather than using the right means to achieve those results. This theory promotes achieving outcomes that benefit the majority in the most impartial way possible. In its simplest form, this theory proposes achieving the greatest good (or the greatest sum of pleasure or the least amount of pain) for the greatest number of people. It is often advocated as the basis for broad social policies. Health planners often employ concepts of utility to develop more equitable health delivery systems. Such systems attempt to encourage and maximize the use of treatment that results in the most beneficial outcome for the least resource expenditure. Nevertheless, trying to define what is "good" or who comprises the affected community exposes the major problems with this theory [8].

Utilitarian principles apply to ED triage systems that regulate the resources given to each patient to maximize overall benefit. However, physicians should not use the utility concept as an excuse to deny an individual patient needed and available resources merely to add to society's greater good. In doing this, the physician would be abandoning the traditional healer's role and violating the bioethical principle of beneficence.

Deontology (rule-based ethics) is based on moral absolutes—something is either right or wrong. Adherents hold that certain unbreakable moral rules govern the most important aspects of our lives, even if following the rule leads to results that may not be "good." One example of a list of "unbreakable" rules is the Ten Commandments. The philosopher Immanuel Kant is often identified with this theory.

However, major problems can arise in applying rule-based ethics. The first is that moral rules may vary depending on one's culture or subculture. This can lead to great divisiveness over the interpretation of what might seem, at first glance, to be an obvious and straightforward rule. For example, does the common stricture "Do not kill" prohibit passive euthanasia (allowing death without intervening) or physician-assisted suicide (providing a patient with a lethal medication prescription)? The rigidity inherent in rule-based ethics causes difficulties when confronted with real-life situations. For some individuals, however, such a system provides necessary guidelines on how to conduct oneself in life.

Other commonly cited ethical theories include:

Natural Law

This system, often attributed to Aristotle, suggests that man should live life according to his inherent human nature, in contrast to man-made or judicial law. Natural law is often associated with particular religious beliefs, especially Catholicism. The claim that the medical profession has an inherent morality mirrors natural law.

Virtue Theory

This theory asks what a "good person" would do in specific real-life situations. It stems from the writings of Aristotle, Plato, and Thomas Aquinas in which they discuss such timeless and cross-cultural character traits as courage, temperance, wisdom, justice, faith, and charity. The Society for Academic Emergency Medicine adopted a virtue-based Code of Conduct.

Mid-Level Ethical Principles

"Mid-level principles" that guide clinical practice and bioethical thought are derived from ethical theories, but are more specific and less abstract. Instead, these ethical principles are "action-guides," basically, role-specific duties that physicians owe to patients, consisting of various "moral rules" that comprise a society's values [9].

By melding medicine's goals with societal morality, law, religious values, and societal expectations for the profession, Beauchamp and Childress popularized the most commonly cited mid-level principles: autonomy, beneficence, nonmaleficence, and distributive justice. These four principles provide a handy medical ethics template and a practical, although often difficult to apply, checklist to use when considering the moral implications of specific cases [8, 9].

A question that naturally arises is whether ethical principles are universal. For individual clinicians, the bioethical principles they follow, and the values that stem from them, do not change because of geography. Clinicians practicing or teaching within cultures other than their own have a responsibility to continue applying their core ethical principles while being sensitive to the local population's values [10].

I will discuss autonomy in more depth (below), since it directly affects many decisions and ethical dilemmas that emergency clinicians face when caring for patients with hematologic-oncologic problems. These include whether a patient has the capacity to make his or her own decisions, who can act as surrogate decision-makers, and what is the role of advance directives. The other principles—and virtues—will be discussed in relationship to specific ethical dilemmas, such as demanding and refusing treatment, constraints imposed by healthcare systems, and patient/survivor notifications.

Decision-Making Capacity

Autonomy means, as Justice Cardozo said, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body" [11]. Physician adoption of patient autonomy has been a major change from the millennia-old tradition of medical paternalism (or parentalism), that is, doing what the physician thinks is good for the patient regardless of what the patient desires. Grounded in the moral principle of respect for persons, autonomy recognizes the right of adults with decision-making capacity to accept or reject recommended healthcare interventions, even to the extent of refusing potentially lifesaving care. Physicians have a concomitant duty to respect their choices. Over the past several decades, autonomy has become the predominant value in US medicine and society, although paternalism is still the prevailing attitude in most of the world.

One important, and often misunderstood, aspect of autonomy is that individuals who retain decision-making capacity can voluntarily and verbally assign decision-making authority to other people (e.g., family) for a specific decision or time period, such as when they are in the emergency department. Since patients may exercise their autonomy only if they have decision-making capacity, emergency clinicians must be able to determine this at the bedside so that if necessary, surrogate decision-makers may become involved.

While autonomy has become ingrained in US medical professionals, clinicians need to be sensitive to *communitarianism,* which is a counterbalance to autonomy. Communitarianism considers the larger picture of the patient's life, including his or her family and community, when puzzling through a bioethics case or developing public policy. This principle generally holds that the community's welfare outweighs an individual's rights or good and thus requires that deliberations involve communal (e.g., family, elders) discussions [8]. Many cultures rely on communitarian deliberations when making medical choices and use this pattern for public policy decisions. When making bedside ethical decisions, physicians should determine, whenever possible, not only their patient's individual values but also whether the patient subscribes to an individualistic or a communitarian ethic [6].

Evaluating Decision-Making Capacity

Many ethical dilemmas in emergency medical care revolve around ascertaining a patient's decision-making capacity. In clinical settings, the question of decisional capacity is most often linked with consent to (or, more often, refusal of) a medical procedure.

Capacity refers to a patient's decision-making ability that, in the ED, EPs determine at the bedside rather than by the courts, a psychiatrist, or a lawyer. ("Competence" is a legal term and can only be determined by the court.) Decisional capacity is always related to the type of decision involved, although it is unclear whether it should be based on the potential seriousness or irreversibility of the outcome of a patient's decision (e.g., refusing lifesaving intubation) or on the complexity of the information needed to make the decision (e.g., whether to enter an experimental cancer treatment protocol). In current practice, most clinicians and ethicists use the seriousness or irreversibility of the outcome as the key to determining decisional capacity.

Table 64.4 Components of decision-making capacity

1. Knowledge of the options
2. Awareness of consequences of each option
3. Appreciation of personal costs and benefits of options in relation to relatively stable values and preferences

From Buchanan [38]. © 1995 by Galen Press, Ltd. All rights reserved. Used with permission of Galen Press, Ltd., Tucson, AZ

To have adequate decision-making capacity in any circumstance, an individual must understand (a) the options, (b) the consequences of acting on the various options, and (c) the personal costs and benefits of these consequences related to a relatively stable framework of personal values and priorities (Table 64.4) [12]. Assessing this last criterion can be especially difficult when clinicians have poor verbal skills in the patient's language. An easier, albeit incomplete, method of assessing this criterion is to ask the patient "why" a particular decision was made. This often provides an approximation of the last (and most important) criterion for assessing decisional capacity.

Disagreement with the physician's recommendation is not in itself grounds for determining that the patient is incapable of making his own decisions. In fact, even refusal of lifesaving medical care may not prove that the person is incapable of making valid decisions if he or she makes it on the basis of firmly held religious beliefs, as when a Jehovah's Witness patient refuses a blood transfusion.

Patient Consent

If a patient has decision-making capacity, a clinician who respects a patient's autonomy must get the patient's consent for any intervention. The consent need not be associated with a formal document, although an appropriate level of explanation is always required.

There are three general types of consent: presumed, implied, and informed. Presumed consent, sometimes called emergency consent, covers the necessary lifesaving procedures that reasonable people would usually wish to have performed on them. *Presumed consent* conjoins a patient's "best interest" with physician beneficence. Stopping hemorrhage and securing an airway in an unconscious, unknown patient

are common examples of procedures performed under this type of consent. *Implied consent* occurs when a patient with decision-making capacity simply cooperates with a procedure, such as holding out their arm to give blood or to allow placement of an intravenous line. Indeed, this is the most common type of consent in medical practice [13].

Informed consent occurs when a patient who retains decision-making capacity is given all the pertinent facts regarding a particular procedure's risks and benefits, understands them, and voluntarily agrees to undergo the procedure. The requirement for informed consent varies in practice and law from area to area and even among practitioners and institutions in the same area. If a patient lacks decision-making capacity, get a surrogate decision-maker involved.

Advance Directives and Surrogate Decision-Makers

Advance directives loosely include durable powers of attorney for healthcare, living wills, prehospital advance directives [14], and similar documents initiated or approved by physicians, such as prehospital DNAR, inpatient DNAR forms, and Physician Orders for Life-Sustaining Treatment (POLST). They do not, however, include nonstandard and indecipherable directives [15–17]. The standard and generally recognized documents often express the patient's autonomous wishes about the treatment he or she will receive. However, they only go into effect if the patient lacks decision-making capacity. Otherwise, ask the patient what he or she wants done.

When patients do not have the capacity to make medical decisions for themselves, someone must make the decision for them. Four major classes of decision-makers have been proposed, and actually used, in these situations: family, bioethics committees, physicians, and courts.

Traditionally, and usually in practice, the family, especially the spouse, makes medical decisions when a patient does not have decision-making capacity. A typical prioritization list of those empowered to act as surrogate decision-makers is often stipulated in state statutes, similar to Arizona's landmark law (Table 64.5) or in a hospital's policy. When no surrogates exist, all potential surrogates refuse to act in that capacity, or an irresolvable conflict exists between surrogates at the same level (such as siblings), the court will intervene.

Surrogates make decisions in one of two ways. The first is *substituted judgment*, which is used when the surrogate is not certain what the patient would want done in a particular situation. Substituted judgment attempts to determine and act in accordance with the patient's values based on the patient's prior statements and behavior, without advance directives or other explicit direction. This is the most worrisome type of surrogate decision-making, because it is based on the most ambiguous grounds. The second way, or *best interest* standard, is used when the patient has never had adequate decision-making capacity, and the surrogate must simply act in the patient's best interest. Unless there is already a court-appointed guardian, these cases often end up being resolved in a courtroom.

Table 64.5 Statutory surrogate decision-maker list: an example

Arizona Revised Statute: Living Wills and Health Care Directives Act, Title 36, Chap 32. 1992. Revised 2005
1. The patient's *spouse*, unless the patient and spouse are legally separated
2. An *adult child* of the patient. If the patient has more than one adult child, the healthcare provider shall seek the consent of a majority of the adult children who are reasonably available for consultation
3. A *parent* of the patient
4. If the patient is unmarried, the patient's *domestic partner* if no other person has assumed any financial responsibility for the patient
5. A *brother or sister* of the patient
6. A *close friend* of the patient. For the purposes of this paragraph, "close friend" means an adult who has exhibited special care and concern for the patient, who is familiar with the patient's healthcare views and desires, and who is willing and able to become involved in the patient's healthcare and to act in the patient's best interest
7. If the healthcare provider cannot locate any of the people listed [above], the patient's *attending physician* may make healthcare treatment decisions for the patient after the physician consults with and obtains the recommendations of an *institutional ethics committee*. If this is not possible, the physician may make these decisions after consulting with a second physician who concurs with the physician's decision. For the purposes of this subsection, "institutional ethics committee" means a standing committee of a licensed healthcare institution appointed or elected to render advice concerning ethical issues involving medical treatment

Children pose a special situation. Individuals less than the age of majority (and unemancipated) are usually deemed incapable of making medical decisions for themselves, although clinicians normally explain the situation to the child and ask for his or her assent. In most cases, the same rules for decision-making capacity that apply to adults also apply to children. The more serious the consequences, the more important it is that the child understands the options and consequences and can articulate the values involved in making their decision. Especially in cases involving religiously or culturally based refusal of potentially lifesaving treatment or when the parents disagree, the court or child protective services may intervene on the child's behalf.

Methods of Applying Bioethics Principles

To apply bioethical principles to a clinical situation, one first must recognize that a bioethical dilemma exists, which is not always an easy task. Once identified, addressing the problem brings its own challenges. Clinicians adhere not only to basic bioethical principles but also, at least tacitly, to a number of

professional, religious, and social organizations' ethical oaths, codes, and statements. This complexity can produce a confusing array of potentially conflicting bioethical imperatives.

When dealing with bioethics cases, clinicians need to use ethical reasoning, which includes the application of foundational theories, mid-level principles, and case-based reasoning. This helps us systematically identify elements within moral problems that we otherwise might overlook.

Casuistry, or case-based ethics, attempts to define problems and correct courses of action based on the intricacies of a particular case. It puts an emphasis on what Aristotle called *phronesis*, or "practical wisdom," and is the basis for the emergency rapid decision-making model, described below. To use this method, examine each case for its similarities and differences with select previous cases paradigms, for which you have determined a suitable course of action. Where the present case is similar enough to the paradigm, use the same course of action. When significant differences exist, clinicians must apply the broader mid-level principles derived from rule-based, utilitarian, and other ethical systems, usually giving the most weight to patients' autonomy and values.

In practice it can be difficult to identify and extract the most appropriate and useful principles to apply to a particular case. Some principles may appear too vague, or perhaps several conflicting principles appear to apply to a given case. The key is to prepare for bioethical problems as one would for critical medical events, by reading about, reflecting on, and discussing how to approach these issues. This leads not only to increased personal preparation but also to more general policies that provide guidance for dealing with difficult bioethical issues [2].

Prioritizing Conflicting Principles: The Bioethical Dilemma

Applying bioethical principles can be confusing. When two or more seemingly equivalent principles or values appear to compel the clinician to act in different ways, a bioethical dilemma exists. This situation is often described as being "damned if you do and damned if you don't," where any potential action appears, on first reflection, to be an option between two seemingly equivalent "goods" or "evils." In bioethics, although there may be disagreements regarding the optimal course of action using a specific set of values, there is often general agreement as to what constitutes ethically wrong actions. While we theoretically have a duty to uphold each bioethical principle, none routinely "trumps" another.

Working through bioethical dilemmas generally requires a case-based approach. The key is to use paradigm and analogy (the first step in the rapid decision-making model, described below). Thus, when faced with a troubling case, first identify relevant mid-level principles and alternative courses of action. Then, compare it to similar but much clearer paradigms, that is, cases having resolutions with which virtually any "reasonable person" will agree. Identifying such cases may be difficult; it takes experience and a significant knowledge base. Using bioethics committees and bioethical or legal case databases may help.

Application to Emergency Medicine: The Rapid Decision-Making Model [18, 19]

When faced with bioethical dilemmas, emergency clinicians often must make ethical decisions with little time for reflection or consultation. Ethical problems, like clinical problems, require action for resolution. For that reason, a rapid decision-making model was developed, based on accepted bioethical theories and techniques (Fig. 64.1). It provides guidance for emergency medicine practitioners who are under severe time pressures and wish to make ethically appropriate decisions [18, 19].

When using this approach, the clinician must first ask: "Is this an instance of a type of ethical problem for which I have already worked out a rule?" Or, at least, is it similar enough to such cases that the rule could be reasonably extended to cover it? In other words, if there had been time in the past to think coolly about the issues, read about them, discuss them with colleagues, and develop some rough guidelines, could they be used in this case? Just as with the indications for any clinical emergency procedure, EPs should be prepared with a course of action for at least the most common ethical dilemmas likely to occur in the ED. If the case in question does fit under one of those guidelines arrived at through critical reflection, and there is not time to further analyze the situation, then the most reasonable step would be to follow that rule—if it is still appropriate. In ethics, this step follows from casuistry or case-based reasoning.

If the case does not fit under any previously generated ethical rule, the practitioner should consider if there is an option that will buy time for deliberation. If there is such an option, and it does not involve unacceptable patient risks, then it would be the reasonable course to take. Using a delaying tactic may afford time to consult with other professionals, the bioethics committee, and the family.

If there is no acceptable delaying tactic, the clinician should weigh what she considers the best option using a set of three tests, drawn from three different philosophical theories, to help make a decision:

Impartiality Test "Would you be willing to have this action performed if you were in the other person's (the patient's) place?" A version of the Golden Rule, it helps correct one obvious source of moral error—partiality or self-interested bias.

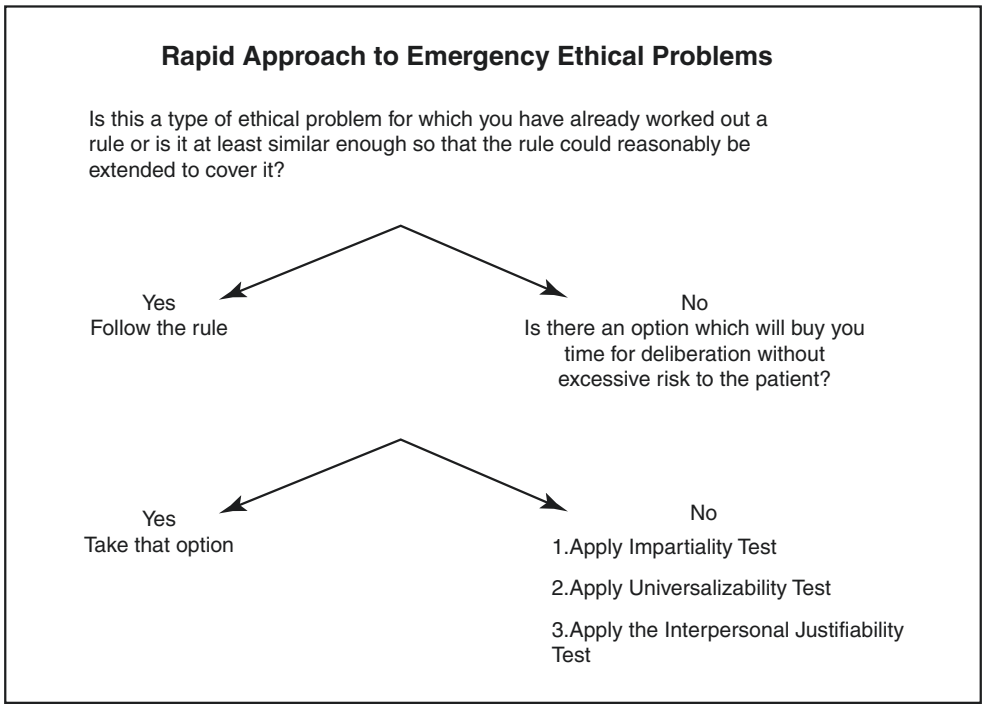

Fig. 64.1 Rapid decision-making model. (From Iserson [39], Figure 2, pg 45. © 1995 by Galen Press, Ltd. All rights reserved. Used with permission of Galen Press, Ltd., Tucson, AZ)

Universalizability Test "Would you be comfortable if all clinicians with your background and in the same circumstances act as you are proposing to do?" This generalizes the action and asks whether developing a universal rule for the contemplated behavior is reasonable—an application of Kant's categorical imperative. This helps eliminate not only bias and partiality but also short-sightedness.

Interpersonal Justifiability Test "Can you give reasons that you would be willing to state publicly? Will peers, superiors, or the public be satisfied with the answers?" This uses a theory of consensus values as a final screen.

When ethical situations arise in cases for which no time exists for further deliberation, it is probably best to go ahead and act on the previously determined ethical rule or take the course of action for which the clinician was able to answer all three tests in the affirmative with some degree of confidence. Once the crisis has subsided, clinicians can hone their ethical decision-making abilities by reviewing the decision with colleagues and bioethicists. As an example:

Case Study 2

An elderly man arrives at the ED with a diminished state of consciousness and a diminished respiratory rate. The EMS personnel who are bagging him say that they were told that he has "cancer," but had no additional information. No one accompanied him. Upon removing his shirt, they find "Do Not Resuscitate" tattooed over his left chest. What should the EP do?

The first step, as with the clinical situation, is for the EP to ask herself whether she has previously encountered—personally, through reading, or at conferences—this type of case. A number of these cases describing nonstandard advance directives, including tattoos, bracelets, and necklaces, have been described in the medical literature [15–17]. If she is aware of this, do they give her an ethically justifiable plan of action? For several reasons, nonstandard tattoos cannot be honored. The reasons include the unreliability of knowing whether the patient really wouldn't have wanted resuscitation in the current situation and whether the patient's situation since the tattoo was placed has changed. If she knows this and agrees, she should resuscitate.

If she does not believe that this case fits under any previously generated ethical rule, she should consider buying time for deliberation. Naloxone, artificial ventilation, and hydration would allow time to search for the patient's identity, medical records, and a possible surrogate if still needed. As described elsewhere in this chapter, initiating these interventions does not mean that they cannot be withdrawn if additional information makes that choice reasonable.

If the EP does not feel that this is reasonable, she can select what she considers the best ethically appropriate option and use the three tests to evaluate that choice. (Impartiality Test) If we assume that she chooses not to resuscitate, she should ask herself (Impartiality Test) whether she would want to have clinicians let her die (the patient is being kept alive with bagging) if she was the patient with an

uncertain diagnosis, history, and wishes. That is unlikely. If she says no, then she must go to another choice, such as to resuscitate. (Impartiality Test) Would she approve of that choice for herself? (Universalizability Test) Would she approve all other EPs resuscitating in similar situations? (Interpersonal Justifiability Test) Would she be willing to defend this action to her peers, superiors, or the public? If all three answers are in the affirmative, she should proceed with the assurance that she will be within the spectrum of ethically appropriate actions.

Bioethics Committees and Consultants

Another resource for complicated ethical dilemmas is to use your institution's bioethics committee. Most US hospitals now have multidisciplinary committees or bioethics consultants to help resolve bioethical dilemmas. Bioethics committees and consultants have four roles: (a) education, (b) policy development (proactive ethics), (c) retrospective case review, and (d) concurrent case review (ongoing clinical cases in which they often mediate between dissenting parties) [20]. Some experienced committees and consultants also perform "stat" consultations that can assist in emergency department cases.

Other Principles and Virtues

Other mid-level bioethics principles and virtues often guide clinician behavior. They also may conflict with the principle of autonomy or with each other, posing a bioethical dilemma. In their practice, emergency clinicians commonly use the principles of beneficence and nonmaleficence, as well as the virtue of truth telling. When developing policy, they often use the principle of distributive justice. Therefore, it is instructive to examine how these principles relate to specific clinical scenarios with ED patients, including those with hematologic or oncologic illnesses.

Beneficence is the principle of doing good or producing benefits. This principle is one of the medical profession's universal tenets. Society's view of physicians as altruistic reflects the profession's long history of beneficence. In addition, all medical students are taught the basic tenet of nonmaleficence: *primum non nocere* (first, do no harm). This stems from recognizing that physicians can harm, as well as help, their patients.

Clinicians use the principle of distributive justice to develop policies, including triage protocols, affecting patient groups and healthcare systems. Truth telling is the virtue that guides clinicians in what and how they communicate with patients and families, rather than the decisions they must make.

Beneficence

Clinicians enter the healthcare field to help others—to be beneficent or to do good. While ED interventions for hematology-oncologic patients will not provide a long-term solution, they often relieve symptoms or provide time to begin more definitive treatments. However, when opportunities to clearly benefit a patient present themselves, clinicians feel intense anguish when a patient or surrogate decision-maker refuses the interventions. This sets up a struggle between patient autonomy and physician beneficence. Probably the most common ethical dilemma in modern US medical practice, it exemplifies physician paternalism, that is, the desire to do what he or she thinks is best for the patient no matter what the patient (or surrogate decision-maker) wants.

Yet, when made by patients with decision-making capacity, clinicians should respect these refusals. That does not mean that the clinician should not clearly explain the options, potential outcomes, and costs involved. If the patient holds firm to the decision, the clinician must follow the patient's wishes, even if they conflict with his or her own values. This is the most difficult part of adhering to patient autonomy.

The only exceptions to this are when a surrogate makes a decision that the clinician believes is contrary to the patient's expressed wishes or is masking (possibly illegal) ulterior motives, or when a child is involved. In any of these situations, obtain legal assistance immediately. In the case of a child, including religion-based refusals of treatment, most courts will order clinicians to institute therapy if any reasonable chance of benefit exists.

Beneficence: Withholding and Withdrawing Treatment

As noted above, resuscitating patients who present to the ED with unknown illnesses and injuries is both ethically appropriate and virtuous behavior. A common fear, and unfortunate misunderstanding, is that once treatment is initiated, it cannot be withdrawn. Actually, there is a much higher ethical and legal bar to withholding treatment in uncertain cases than there is to withdrawing treatment once complete information is known [21, 22].

Withholding Treatment

Not infrequently, a patient is brought into the ED in extremis, unable to interact with clinicians, and without any history or direction about care. For example, the patient may be in cardiorespiratory failure or the patient may have metastatic cancer and now is suffering from hypercalcemia, a frequent terminal event. While some have advocated that allowing the patient with hypercalcemia to have a "good death" may be humane and medically appropriate [23], EPs

do not have this option. Without knowing the patient, the disease prognosis, or any prior wishes, they are obligated to intervene to preserve life. This obligation is based on the principles of beneficence and nonmaleficence, which are societal values placed on EPs. Our society sees the entire emergency medical care system as being the caregivers of last resort. Arbitrary decisions to do less than everything reasonable to preserve a life signal a lapse in this entrusted function. Unknown and unknowing patients deserve the presumption of life.

Withdrawing Treatment

Contrary to popular myth, if the EP (or inpatient physician) later learns that, given the patient's condition or wishes, lifesaving interventions such as ventilation and vasopressors are not appropriate, it is both ethical and legal to withdraw them. This follows the dicta to use only beneficial interventions and to preserve a patient's autonomous wishes. Morally, withdrawing treatment is identical to initially withholding it. That is, withdrawing an IV drip or stopping a ventilator is equivalent to withholding the next drop of medication or the next ventilation. The problems that generally arise with withdrawal under these circumstances are emotional, not ethical [21].

Even though treatment has been withdrawn, clinicians must continue to provide analgesia and any other appropriate care. Healthcare professionals never cease providing care.

Beneficence Versus Patient Autonomy: Refusing Lifesaving Treatment

As the relatively common case described in Case 1 demonstrates, the ethical dilemma is produced by the tension between the physician's motivation of beneficence and the patient's (or surrogate's) desire to determine which treatments to authorize based on his or her values. In this case, the decision is religiously based.

Beneficence Versus Patient Autonomy: Refusing Analgesia

Physicians are expected to follow the medical maxim "cure sometimes, relieve often, comfort always" [24]. In some cases, patients or their surrogates may refuse analgesics to relieve acute pain. This may be due to misguided concepts of drug abuse and addiction or to a fear that taking analgesics will hasten death. Rarely, refusal may stem from religious or cultural values.

The final decision may come down to a balance between autonomy and beneficence. While there may be unique instances when analgesics should be withheld, at least in the short term (e.g., so that the patient can be awake when relatives arrive), beneficence generally outweighs any countervailing argument and the patient should receive analgesia.

Nonmaleficence

The principle of nonmaleficence includes not doing intentional harm to patients, preventing harm, and removing harmful conditions. Nonmaleficence is the profession's protective shield for patients. The following two situations demonstrate how this may not only conflict with other principles, such as autonomy, but also how it forms the basis for the rules regarding clinical research.

Nonmaleficence: Demands to "Do Everything"

No one gets every possible medical intervention. Yet, ED clinicians commonly hear surrogates demand that they "do everything," even for terminally ill hematology-oncologic patients for whom further intervention will not change the disease course and may prolong an unpleasant dying process. This request, often coming from distraught and guilt-stricken relatives, poses difficult ethical dilemmas for clinicians. While patient autonomy plays a key role in any decision, surrogates may be unaware that clinicians' interventions must not harm the patient without providing them with a countervailing benefit (nonmaleficence).

The "do everything" request usually presents as one of three scenarios: where a patient knowingly requests intervention, where a patient asked for intervention via an advance directive, or where surrogates ask for the intervention.

The first situation occurs when a patient with decisional capacity who is informed of the options selects a probably non-beneficial and definitely painful course of therapy. In the ED, that may mean intubating and ventilating a terminal cancer patient in severe pain. These decisions fall under the question of patient autonomy, and even if the physician thinks she would not make the same decision herself, she should help the patient implement this choice.

The second scenario occurs when a patient has left instructions via an advance directive to "do everything." This directive carries much less weight than the patient's actual informed decision, described above, because the exact situation with which the medical team is presented could not have been anticipated. Nevertheless, clinicians should make all reasonable efforts to comply with the patient's wishes. The following case illustrates just such a dilemma for the EP.

Case Study 3

A patient with decision-making capacity completed a new Durable Power of Attorney (naming her husband as surrogate) and a Living Will upon entering the hospital three weeks earlier for the treatment of metastatic breast cancer. Both documents indicate that she wants everything possible done to save her life. She now comes to the ED with mark-

edly diminished consciousness, bradycardia, dehydration, but a normal respiratory rate. Her husband accompanies her. Suspecting hypercalcemia, the EP prepares to initiate normal saline hydration and appropriate laboratory studies when he receives a call from the patient's oncologist who tells him to do no studies or interventions. When informed about the advance directives and the potentially correctible condition, he says that he and another physician agree that nothing more should be done for this patient, despite what any documents or surrogates say.

Although some institutional policies now suggest that two physicians can initiate a Do Not Attempt Resuscitation order that countermands a patient or surrogate's wishes, this violates both ethical and legal norms. The EP's role is to provide potentially beneficial treatment (and care) whenever practicable. Admitting physicians may later wish to do otherwise, but that is between them, the family, the bioethics committee, and, ultimately, the legal system.

The third situation occurs when families of a terminally ill patient demand non-beneficial care for their relative. Emergency physicians are usually reluctant to provide this, since it only prolongs the predictable dying process. On the other hand, to be beneficent, clinicians frequently admit end-stage cancer patients if they come for pain relief that cannot be provided at home, to temporarily relieve a family of the stress of caring for the patient (respite care), as an interlude to get a patient into a hospice or nursing facility, or who are in the terminal stage of the disease presaging death. However, interventions which simply prolong dying usually violate the ethical principle of nonmaleficence.

Legally, the representative for a patient lacking decisional capacity can make any informed decision that the patient could make about healthcare. After explaining the options and that the interventions will not be beneficial, physicians should abide by these surrogates' requests, even if they seem unreasonable. Note, however, that a physician is never required to offer any treatment through a surrogate that they would not offer directly to a patient, such as cardiopulmonary resuscitation in an imminently dying metastatic cancer patient. This is a struggle between autonomy and nonmaleficence, and the medical team's responsibility is to follow the legal surrogate's instructions to the extent that they would follow a patient's instructions. The assumption is that in most cases, the patient believed that this individual would best represent his or her wishes. When clinicians question whether the agent is acting in the patient's best interest, they can ask a court intervene.

Nonmaleficence and Autonomy: Research Protocols

The horrors inflicted under the guise of scientific research during World War II led to the Nuremburg Code and subsequently the Helsinki Declaration, enumerating basic ethical principles for research studies [25]. Based on autonomy, the respect for persons as individuals, these research principles arose from the desire to no longer harm research subjects, as had been done both during WWII and subsequently in the civilian sector.

Research is vital to medicine. In the past, most medical care, including that in emergency medicine, has relied on experience that was unsupported by investigation, so-called nonvalidated practice. Recently, however, clinicians have begun to use evidence-based medicine, which requires research. Over the past three decades, research done within emergency medicine and that done elsewhere but applied to emergency medical practice has improved the elegance of patient encounters, significantly benefiting ED patients. In hematology-oncologic, research has driven diagnostic and treatment breakthroughs, and EPs can often assist in these projects.

Yet some aspects of clinical research and research oversight fall short of meeting the ethical standards of safety and patient benefit. Overall, emergency medicine research has been and continues to be a moral endeavor. Even more important than the institutional safeguards, such as the institutional review boards (IRBs), is the individual researcher's moral compass, which must serve to protect the subject-patients of clinical research. Perhaps the greatest moral lapse has been the lack of attention to key populations, such as women and children, within emergency medicine research, with the result that patients most needing acute intervention are the ones who suffer [26].

Funding availability, both from private industry and from government agencies, still drives research agendas. This raises questions about clinical researchers' fiduciary responsibility to their subject-patients.

Finally, the moral responsibility to ensure that any research protocol and its execution are ethical extends to the journals in which the research is published [27]. While emergency medicine has an excellent record of ethical research, a large percentage of human research studies published in the major EM journals fail to mention either IRB review or informed consent [26, 28].

System Constraints: Distributive Justice and Confidentiality

Distributive or comparative justice suggests that comparable individuals and groups should share similarly in the society's benefits and burdens. In contrast to the judicial system's retributive and compensatory justice, this basic bioethical principle does not apply to individual practitioners for ad hoc use in limiting healthcare resources for individual patients [29]. Rather, it is meant to be used at the policy-making level to allocate limited healthcare resources.

For example, triage decisions conform to this principle when they are applied uniformly and impartially to all

patients [30]. Other typical issues in emergency medicine for which distributive justice plays a part in designing policies and protocols include admission prioritization; how to work with patients who cannot pay for treatment; have the "wrong" insurance, or belong to the "wrong" medical system or group for the particular hospital or clinic; intentional or unintentional release of patient information; and how to work with patients who are undocumented aliens.

Other principles have also had long-standing importance to medical practice, one of the most important being confidentiality, that is, the nondisclosure of patient information. Based on a respect for persons (as is autonomy), patient confidentiality has been a cornerstone principle of the medical profession since antiquity. The *Hippocratic Oath*, for example, states, "Whatever, in the course of my practice, I may see or hear (even when not invited), whatever I may happen to obtain knowledge of, if it be not proper to repeat it, I will keep sacred and secret within my own breast." Confidentiality presumes that, unless they first obtain the patient's permission, physicians will not reveal to any other person or institution what patients tell them during the medical encounter. Various US federal and state laws have both emphasized (e.g., Health Insurance Portability and Accountability Act of 1996, HIPAA) and carved out exceptions (mandatory reporting) to this stricture. With the advent of minimally secure electronic medical records, the ability to maintain patient confidentiality has become even more difficult.

Note that privacy, often confused with but related to confidentiality, is a patient's right to sufficient physical and auditory isolation such that he or she cannot be seen or heard by others during interactions with medical personnel.

Truth Telling (Fidelity)

Truth telling remains a somewhat controversial virtue within the medical community. While many champion absolute honesty to the patient, honesty must be tempered with sensitivity and compassion; it should not equate to brutality. In recent years, poor role models, a lack of training in interpersonal interactions, and bad experiences may have diminished the perception of truth telling as a physician virtue. There are multiple tales of the champions of absolute fidelity who, nevertheless, were appalled by their own physician's lack of sensitivity when relating unfavorable medical news to them [31].

The degree to which physicians fail to disclose the truth varies with the circumstances. When failure to disclose the truth will do physical harm to the patient, such as in the infamous Tuskegee experiments on patients known to have syphilis, it is not only immoral but also probably illegal to withhold the information. Likewise, if failure to disclose information is strictly for the physician's benefit, such as telling a patient who calls in the middle of the night to "take two aspirins and call in the morning," although there is a strong suspicion of serious disease, there are serious ethical and legal deficits in the clinician's behavior. The issues become somewhat murkier when truth telling involves a third party, such as a sex partner who the patient has exposed to an infectious disease [32].

The following cases demonstrate two scenarios involving this principle that commonly occur with ED hematology-oncologic patients. The first deals with relating a probable diagnosis to a woman in a strong communitarian culture. The second deals with death notification, emphasizing the need for strong communication skills and sensitivity.

Truth Telling and Communitarianism: Diagnosis Notification

Case Study 4

A 54-year-old Hispanic woman comes to the ED with her family because of a persistent cough and poor health for at least the past several weeks. Before the patient can be examined or any tests performed, the patient's husband intercepts the EP and tells him that if the patient has a life-threatening disease, she is not to be told because "she doesn't want to know." The adult children agree. The evaluation shows that the woman has a hard new breast lump, honeycomb lesions, and multiple pulmonary nodules consistent with cancer. The physician has a policy to tell the truth to all his patients but believes that the family might be accurate in their assessment.

Many patients come from cultures that embrace communitarianism, rather than autonomy. Communitarianism stresses the interactions between group members, which may be just the family, but may also include elders, religious figures, or the entire tribe, group, or community. In this case, the family implied that the patient was part of such a culture.

Doing good in these cases often means respecting the patient's personal or cultural desire not to be explicitly informed about a serious disease. This is the norm for many Asians (particularly Japanese), Hispanics, and Native Americans. The enormity of this information (and slight possibility of error in this case), coupled with the minimal physician-patient relationship established in the ED, might also suggest that, at least at this stage, stating the presumed "diagnosis" could be avoided.

The question for the physician is, how much does the patient want to know? The best way to find out is to ask her both what she wants to know and, if she does not want to know anything, with whom does she want the physician to speak. If she wants the information, the physician is obligated to gently tell her what he knows about her illness,

including the next steps in the diagnostic process. If she designates someone else to receive this information, this fully complies with the patient autonomy principle and should be followed.

Truth Telling: Survivor Notification

Nowhere in emergency medicine is truth telling with sensitivity more important than when the clinician must deliver the news of a death, which is often an emotional blow, precipitating life crises, and forever altering the survivors' world. Emergency physicians must repeatedly do death notification as part of their daily work.

Case Study 5

A 63-year-old man who had been in remission with lung cancer presents to the ED in cardiac arrest. Bystanders had told the EMS personnel that he had been at the store when he suddenly became dyspneic and collapsed. They administered ACLS for 20 minutes without success. Without vital signs or cardiac activity, you pronounce him dead with a probable diagnosis of pulmonary embolus. You are notified that his wife and an adult child have arrived and were waiting in a side room. They do not know he is dead; it was unexpected.

Kind but direct notification has been shown to be what most US and Canadian families desire. Other cultures prefer more indirect notifications. Come in, sit (or kneel) so that you are at eye level with the key recipient—in this case, the wife. Be sure that you or someone on your team has definitively identified the people as the decedent's family. Then say, "I'm sorry, but I have very bad news. Despite doing everything we (includes paramedics) could, your husband died." Truth telling and survivor understanding require that you use a "D" word, no matter how difficult that is. Otherwise, the message you relay may not be clearly understood. "Pass on," "No longer with us," "Gone to another place," and other euphemisms will not work. Take a deep breath and say "died" [33].

The wife then asks two things: "What did he die from?" and "Can you call his brother in another state and tell him?" The first answer is generally straightforward. No matter what your clinical suspicion is, truthfully tell her that you cannot be sure and that finding out will require an autopsy. (In some situations, a medicolegal autopsy might be automatic. If not, you can encourage the family to ask for one.) Telling the brother also requires truth telling. Gently inform a survivor who is distant from the ED about the death. Don't say that he or she is "critically ill." That way they won't make a heroic, sometimes dangerous, attempt to get to the hospital "in time" [34].

Excellent communication skills represent the basis for correctly delivering tragic news to survivors. Directness, truth, consistency, and clarity are the key factors in delivering information about a sudden, unexpected death—and complying with the virtue of fidelity. Perceptive survivors can easily tell which notifiers care and which are only "going through the motions" [33, 34].

Poor clinician-patient communication disappoints both the patients and clinicians. Often, this failure is due to clinicians:

- Using highly technical language
- Not showing appropriate concern for problems voiced by patients
- Not pausing sufficiently to listen
- Not verifying that the listener has gotten the information presented
- Using a generally impersonal approach to the interaction, including their manner of speech [35]

Delivering the news about sudden unexpected death provokes strong emotions in both the notifier and survivors. Communication is improved if the notifier acknowledges those emotions, being prepared to vocalize and demonstrate their sadness and to recognize and acknowledge it in the survivors. Using the voice to communicate does not always mean talking. In some instances, para-verbal behavior is what is called for. These sounds, such as mmmmm, ahhhh, or mhmmm, are often sufficient to show that a person is listening and understands, particularly if they are accompanied by appropriate nonverbal cues, such as nodding the head.

It often takes imagination to put oneself in the position of a grieving survivor, especially when wide cultural or age differences exist. Even if you cannot learn to empathize with survivors, you can learn to behave appropriately, speak correctly, and assist them in their time of grief. Imagination, studying people, advance planning, or taking the lead from experienced mentors is the only way to successfully perform this necessary, but tragic task [33, 34].

Future Bioethics in EM and the Role for Emergency Physicians

No patient can receive every possible diagnostic or therapeutic intervention. The clinician's traditional role has been to determine which resources would most likely benefit particular patients. As these resources become more costly and, in some cases less available, insurers, healthcare institutions, and families have become part of this decision-making process. In the future, bioethics discussions will become increasingly vital to protect patients and the integrity of the healthcare system.

The bioethics field includes teachers, writers, and clinicians. Many individuals in the field are involved in more than one of these areas. People enter the field with a variety of backgrounds, the most common being medicine (e.g., physicians, nurses, and physician assistants), legal, religious, and philosophy. Many, if not most, individuals have additional training before embarking on a leadership role within bioethics. This may include fellowships, serving on an institutional bioethics committee, or working with an experienced mentor.

Those in clinical ethics need a grounding in the "Mid-Level Principles," as described in this chapter and elsewhere. In addition, especially for a leadership role, they should have a knowledge of group dynamics, negotiation, compassionate listening, and writing. All come into play in working with patients, families, other surrogates, treating clinicians, and healthcare institutions. Very few clinicians are reimbursed for their time doing clinical ethics.

Emergency physicians, partially due to their training and type of practice, have unique qualifications for clinical bioethics. Aside from their ability to negotiate (e.g., for admissions, consultations, special testing), they work with and are usually sensitive to the differences among multiple socioeconomic and cultural groups. Similarly, they work with and are generally familiar with a wide variety of healthcare professionals, institutions, and systems. All these elements often arise in the course of bioethical consultations, policy making, and clinical education.

Health Disparities

65

Marcia A. Perry and Joel Moll

Introduction

The impacts of inequities and social determinants of health that lead to healthcare disparities and leave many patients vulnerable to poor outcomes have been well documented in patient care. Factors such as access to care, societal bias and stigmatization, lack of autonomy, and social determinants of health, among others, contribute negatively to the effectiveness of the care provided.

The National Academy of Medicine 2002 report *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care* concluded that minority patients generally receive lower quality healthcare than white patients in the United States, regardless of insurance status or ability to pay [1]. The report noted that these disparities in quality of care were associated with more deaths among racial minorities than whites. These findings are part of the impetus to examine how structures, processes, and behaviors in our healthcare system may be contributing to disparities among multiple vulnerable groups.

Concepts and Definitions

Healthy People 2020 defines Health Equity as: "The attainment of the highest level of health for all people. Achieving this requires valuing everyone equally with focused and ongoing societal efforts to address avoidable inequities, historical and contemporary injustice, and the elimination of health and healthcare disparities" [2]. Health inequities are differences in health that are not only unnecessary and avoidable but are considered unfair and unjust. Health inequities are rooted in social injustices that make some population groups more vulnerable to poor health than other groups. As a result of health inequities, disparities arise in the presence of disease, health outcomes, or access to healthcare and therapies between population groups. Healthcare disparities are related to provider-patient relationships, provider and systemic bias, social determinants of health, and patient variables such as mistrust of the healthcare system due to past experience. The Minority Stress Model explains that minority groups experience chronic high levels of stress from stigmatization that can contribute to poor outcomes and disparities [3, 4].

Provider and systemic bias can either be explicit or implicit. Explicit bias is often easier to recognize as the outward expression of prejudice. Implicit bias, the unconscious attribution of qualities or values to a member of a certain group, can be much more difficult to recognize. These biases are shaped by experiences and based on learned associations between particular qualities and social categories. Many physicians have different exposures and backgrounds than the patients they serve. Unconscious attitudes and stereotypes affect behaviors and decisions in healthcare. In order to have greater awareness of bias in patient care, it is critical for physicians to receive education, feedback, and coaching on equitable practice.

The population of the United States is becoming increasingly more diverse, with racial and ethnic minority populations predicted to surpass the white majority by 2050. It is critically important that healthcare professionals are educated specifically to address issues of culture in an effective manner that will lead to equitable patient care. Emergency department (ED) patients are from multiple different identities and cultures. Achieving cultural competence in each culture and sub-culture is challenging and not feasible. Cultural *humility* is a more feasible and achievable goal for clinicians [5, 6]. Cultural humility is a lifelong process of self-reflection and self-critique that can inform understanding of cultural differences and how differences require sensitive approaches to healthcare. It requires that clinicians acknowledge how history, culture, and community intersect in the patient's

experience. By understanding the power of storytelling and the power of intent, and by active listening and asking deeper questions, we gain a true understanding of the depth of the determinants of health so that we can provide the equitable care patients need and deserve.

Disparities and Cancer Care for Vulnerable Populations

Many vulnerable populations access the healthcare system through the ED, providing both an opportunity and obligation to providers in this setting to deliver equitable care. Patients who present to the ED and are diagnosed with cancer tend to have more advanced conditions, leading to worse outcomes [7, 8]. In one study, patients initially diagnosed with cancer in the ED were 75% more likely to present at stage 4, and 176% more likely to die within 2 years of presentation than those receiving a cancer diagnosis in other settings [7]. ED-diagnosed patients were more often black or from impoverished urban areas [7].

The American Society of Clinical Oncologic has published policy statements outlining the following strategies to eliminate cancer health disparities [9].

- Access to quality healthcare – address economic barriers for minorities and the underinsured as well as healthcare delivery.
- Improve healthcare provider, public, and policy maker awareness of racial and ethnic disparities in access to cancer care and outcomes.
- Diversify the oncologic workforce.
- Conduct research to understand the differences in quality of cancer care provided to underserved and ethnically diverse population compared to whites.
- Diversify clinical trials.
- Enhance patient involvement in their care.

Application of these strategies to emergency medicine can help reduce these inequities. As advocates for our patients, we should work consciously to decrease bias, be intentional in diversifying our work force, engage patients in clinical trials, conduct healthcare disparity research, and use cultural humility to provide patient-centered equitable care.

The following cases illustrate concepts of healthcare disparities in vulnerable populations.

Case Study 1

A 56-year-old transgender female arrives to the ED with non-traumatic mid lower back pain. There is no associated weakness, parethesias, or bowel or bladder dysfunction. There is no fever, no past history of intravenous drug use (IVDU). Patient denies medications except estrogen and spironolactone as gender-affirming therapy. Patient was seen and discharged with ibuprofen.

She returns 2 weeks later as the back pain has worsened, and she has now noted some blood in her urine. A clean catch UA shows >100 RBCs and 5 WBCs. She denies dysuria but has some hesitancy. She is placed on nitrofurantoin and discharged.

She returns a week later very uncomfortable and unable to urinate with bilateral flank pain. Bladder scan reveals a markedly distended bladder. She is much improved after decompression with a catheter. A renal CT scan shows multiple lytic lesions in the lumbar spine and a markedly enlarged and irregular prostate, findings consistent with metastatic prostate cancer.

Sexual minorities are a diverse group of individuals without a strict heterosexual identity (lesbian, gay, bisexual, queer or questioning) and/or whose gender identity is different or fluid from their sex-based gender. It is important to recognize that someone's sexual or gender identity may be different from their expression or their behavior. One estimate is that 4.5% of Americans identify as a sexual minority [10] and at least 0.6% as transgender [11]. However, 8.7% of women and 8.2% of men have had same-sex sexual behavior [12].

Sexual minorities have specific health needs intrinsic to their sexual orientation, gender identity, and behavior, in addition to healthcare requirements of the general population. Sexual minority patients face several barriers that may contribute to healthcare disparities, affect their visibility, and impact their relationship with physicians. Historical mistreatment and discrimination, combined with current implicit and explicit bias, can adversely impact the ED experience or decision to seek care at all. Several studies have reported that sexual minorities commonly have negative experiences in the ED, especially in the transgender community [13, 14]. Healthcare benefits and rights may not be extended to sexual minorities. There is not protection against job discrimination in many states, nor at the federal level. Many sexual minorities fear that disclosure of their identity may affect their employment and also their healthcare coverage. Sexual minorities consistently have less access to healthcare, are less likely to be insured, and are more likely to live in poverty.

Transgender patients may have additional identity barriers. They may be listed as their gender assigned at birth in the health record, rather than their gender identity. Many transgender patients do not have identity documents with their preferred identity, with the biggest barrier being cost [15]. This can lead to awkward interactions when the patient appears different than the gender listed in electronic health records (EHR). Importantly for the patient in the case above, the EHR and provider may not have triggered reminders for prostate screening if the patient was listed as female. The patient may not have had gender-affirming surgery to remove

her penis, and even if so, most surgeries do not remove the prostate.

Most emergency physicians receive little if any training on sexual minority health in residency [16] and have limited knowledge from medical school [17]. Emergency medicine residents often do not ask about sexual behavior or identity when pertinent, such as the evaluation of an abdominal or GU complaint [18]. Practicing emergency medicine physicians demonstrate poor knowledge of transgender health [19]. Although limited, research suggests that knowledge gaps contribute to important unmet needs in sexual minority patients with cancer [20, 21].

Competent care of sexual minority patient involves not only knowledge, but importantly communication and attitude. When approaching a sexual minority patient with a known or possible diagnosis of cancer, communication and inclusion are important initial considerations. Using language and terminology that is open and not inadvertently offensive is paramount to establishing a trusting and effective relationship. An inclusive environment should be established by using neutral terminology rather than assuming heterosexual and gender concordant identity. Patients should be permitted to include their spouse or significant other if desired, as with any heterosexual couple. When in doubt, ask the patient to define relationships and preferred name.

When taking a history, it is important to focus on information needed for competent care of the patient and avoid irrelevant questions. In the above case, it is clearly relevant to inquire whether the patient has had gender-affirming surgery as it may relate to their presentation or management of genitourinary complaints. In addition, placement of a catheter may be more complex if the penis has been removed and the area has been reconstructed. But for the same patient with an ankle sprain, asking about gender-confirming surgery is more likely curiosity than medical necessity. Similarly, performing a physician exam that is unnecessary due to inappropriate focus is not only unethical but a violation of the patient's trust and would be a damaging experience.

Sexual minorities have been largely overlooked in research on cancer disparities. Disparities have been found with cancers associated with viral infections in men who have sex with men (MSM) [22], including elevated risk for anal cancer, especially in HIV-positive MSM [23]. Although it is postulated that lesbians may have higher rates of breast and reproductive cancer due to possible increased nulliparity, lack of routine collection of sexual orientation data has made determination problematic [24]. Gender-affirming hormone therapy has not been definitely linked to increased breast and reproductive cancer risk in a small number of studies [25]; however, there is some suggestion that when it occurs, breast cancer in transgender females may occur at a younger age (median 51.5 years) [26]. Sexual minorities have higher rates of tobacco abuse, and limited data shows this may translate into higher rates of lung cancer [27, 28].

Evaluation and management of a sexual minority with known or possible cancer diagnosis in the ED can add additional complexities and requires basic competency in treatment of this patient population. Competency in sexual minority healthcare requires the acquisition of knowledge and skills, as well a positive therapeutic attitude, to provide equitable and optimal care.

Key Points

- Sexual minority patients are a diverse group along a continuum of sexual orientation not strictly heterosexual and/or gender identity different than gender assigned at birth.
- Sexual minorities face many healthcare and legal barriers than can adversely affect access to care and may adversely affect outcomes.
- Emergency physicians receive little training on healthcare of sexual minorities. Basic understanding of healthcare needs, barriers, terminology, and inclusive communication are important to deliver more equitable care.

Case Study 2

A 48-year-old black male with no significant past medical history presented to an urgent care center for rectal bleeding. He is self-employed and has no health insurance. He plows snow in the winters and does lawn care in the summers.

He had stable vitals, has a normal hemoglobin, and was diagnosed as having hemorrhoids after a small external hemorrhoid tag was noted on exam. He was prescribed a cream to shrink the hemorrhoid and was discharged. He has intermittent small amounts of blood in his stool over the next 2 years.

Two years later he presented his local ED stating that his "hemorrhoid was acting up," and he was prescribed a rectal suppository for internal hemorrhoids after a small hemorrhoid tag was again noted. He was told to follow up in the gastrointestinal (GI) clinic if bleeding returns. He called the GI clinic a month later to schedule an appointment and was told they would not see him without insurance and told him to go to the county hospital clinic. The county hospital clinic had no appointment for 6 months. During that 6-month period, he lost his mother, and his adult daughter moved back home, so he missed his appointment due to multiple competing home issues.

One year later, a family member visiting from out of town noted that he had lost weight and was jaundiced, and convinced him to go to the urgent care center. He was sent from the urgent care center to the ED for work-up of anemia and jaundice. After 6 hours in the ED, he was diagnosed with metastatic cancer, which was later confirmed as metastatic colon cancer. He underwent two rounds of chemotherapy before his death.

Colorectal cancer is the third leading cause of cancer deaths in the United States for both men and women. It is largely preventable by timely screening of at-risk groups. The gold standard screening tool, screening colonoscopy, was previously recommended by the American College of Physicians for individuals 50 and over. Due to a recent increase in young individuals under age 50 with colorectal cancer, and a significantly higher risk of colorectal cancer in blacks, it was further recommended that blacks be screened starting at age 45 years. Recently, the American Cancer Society changed screening recommendations to start at age 45 in all individuals irrespective of race and ethnicity. The patient above was not initially referred for colorectal cancer screening and subsequently encountered significant barriers to diagnosis. Minority groups have a lower rate of endoscopic screening recommendations [29]. Socioeconomic status and access to healthcare help account for racial and ethnic disparities in colorectal cancer screening [29]. Patients are more likely to be referred for endoscopy if over age 55, white, with a family history of colon cancer, married, more education, an income greater than $65K, more frequent doctor visits, and female. Hispanic patients were 34%, and blacks 26% less likely than whites to receive a referral for screening colonoscopy. In summary our patient finds himself in the at-risk group for disparate referral for several reasons: he is under 50, is black, has a low education level, is in the low-income category, has no insurance, and is male.

Along with the new recommendations for a lower threshold for screening to age 45, improved education of emergency physicians on risk factors for colorectal cancer in vulnerable populations as described above is needed to lessen cancer healthcare disparities. This patient had several missed opportunities to receive referrals for screening and avoid what may have been a preventable death.

Key Points

- Colorectal cancer screening should begin at age 45.
- Referral for colorectal cancer screening should be done from the ED for at-risk patients.
- At-risk patients can be identified through social determinants of health questions.

Case Study 3

A 26-year-old female with a history of schizophrenia presents to the ED. She was previously seen in the ED at age 18 after sexual assault and was examined and treated. Eight months later she presented with a complaint of pregnancy and not feeling the baby moving. She had a flat abdomen and a negative pregnancy test and was discharged with a diagnosis of paranoid delusions and referred to psychiatric resources. Over the next few years, she was seen and admitted several more times for delusional psychosis. She was then managed well in the outpatient psychiatric clinic; however, she began presenting again to the ED with abdominal pain and swelling at the age of 24. She had multiple negative pregnancy tests and referrals to psychiatry. Finally she presented to the ED with a court-appointed guardian who insisted on a more thorough medical evaluation because the guardian was convinced that the patient was indeed pregnant. An ED physician who had seen her in the past felt that she had a protuberant abdomen and performed an abdominal ultrasound. Ultrasound revealed a large ovarian mass and the patient was subsequently diagnosed with ovarian cancer.

Patients with mental illness are at increased risk for cancer care disparities. Cancer incidence is similar in individuals with or without schizophrenia. Patients with schizophrenia are 1.5–2 times more likely to die of their cancer than patients without mental illness [30]. Patients with schizophrenia are also more likely to present at advanced stages of disease, are offered surgery at lower rates, and receive fewer chemotherapy sessions [30]. Patients with schizophrenia and other disabilities are often unable to advocate for themselves and are also at increased risk of experiencing physician bias. The 2016 Medscape Lifestyle Report surveyed 15,800 physicians across 25 specialties and found that 40% of physician admitted to bias toward specific types of patients. A higher proportion of emergency physicians reported bias (62%), and that their bias influenced patient care (14%) than any other specialty [31].

Educating emergency physicians regarding unconscious bias with ongoing discussion of methods to mitigate bias is one way to address and decrease the risk of disparate treatment in vulnerable populations.

Key Points

- Patient with schizophrenia are more likely to die of their cancer than patients without mental illness.
- Physician bias exists and emergency physicians admittedly have a high level of bias against patients with mental illness.
- Raising awareness of physician bias and how bias affects clinical decision making is key to helping physicians mitigate bias

Case Study 4

A 24-year-old black female first-year medical student presented to the ED with left chest and breast pain during her first month of medical school. No breast exam was done. Her ED evaluation included a normal chest radiograph and ECG, and she was told to follow up with student health services. At her follow-up she was told it was likely anxiety as

experienced often by early medical students. While at home for a holiday break, she saw her primary care physician for persistent left breast pain and a lump was palpated on exam. A biopsy was arranged and she received the unfortunate diagnosis of triple-negative breast cancer. She subsequently underwent left breast mastectomy followed by chemotherapy and radiation therapy.

Breast cancer is more prevalent among white women than black women. However, black women have a higher risk of breast cancer before the age of 40, higher risk of more aggressive cancer, and higher risk of poor outcomes. This largely unexplained disparity in breast cancer outcomes is an area of ongoing research [32]. Williams et al. explored the contribution of social factors (including minority stress) to breast cancer disparities in black women. They conceptualized that increased exposure to psychological stress, low socioeconomic status, and early life adverse exposures that black women experience may be the cause of current disparities in breast cancer incidence and mortality. Increased exposure to psychological stress resulting in epigenetic changes may increase breast cancer risk over one's lifetime. Discrimination and racism as a distinct social exposure experience by racial minorities is an area requiring additional research to separate the factors driven by racism and bias from those driven by socioeconomic status [32].

Key Points

- Black women have a higher incidence of breast cancer than whites before age 40, as well as a higher mortality risk.
- Discrimination, bias, and racism (and other minority stressors) are likely significant contributors to disparity in breast cancer and should be further studied.

Summary

Emergency physicians are trained to work in a high stress, fast-paced environment where the focus is on not missing life-threatening conditions. It is challenging yet necessary for us to find time to address social determinants of health and other barriers to good health and good outcomes. As the safety net for vulnerable population, emergency physicians must develop the skills to identity those at risk for healthcare disparities, consider and address their needs, and strive to eliminate healthcare disparities. Education, research, and advocacy are important priorities for health equity.

Emergency Oncology in the United Kingdom

66

Tim Cooksley

Introduction

In the United Kingdom (UK), over 350,000 new cases of cancer are diagnosed a year, contributing to around 28% of UK deaths [1]. In the UK, patients with cancer account for 15% of all acute inpatient stays and its delivery consumes nearly half of the spending on patients with cancer [2].

Cancer care has become increasingly specialised, and advances in therapy have resulted in a larger number of patients receiving care as an outpatient. As a result of these advances in care and the increasing number of patients receiving cancer therapies, there has been a significant increase in the number of patients presenting with unscheduled cancer-related emergencies [3].

The management of emergency oncologic patients presents many challenges. There are toxicities of targeted and immune therapies with which acute care physicians may not be familiar. Early recognition of acutely unwell cancer patients at risk of clinical deterioration is important not only to instigate treatment but also to facilitate decisions regarding whether escalation of care and cardiopulmonary resuscitation is appropriate [4]. This requires an understanding of the patient's underlying prognosis and goals of care, which often requires oncological advice.

In the UK, there have been two strategies adopted to improve the care of acutely unwell cancer patients – the development of specialist admission units in tertiary cancer units and the evolution of "acute oncologic services" to support patients admitted to non-cancer hospitals.

Acute Oncologic Services

In 2009, following a series of reports recognising that a significant proportion of cancer patients presenting to UK Emergency Departments (ED) received sub-optimal care, the UK National Chemotherapy Advisory Group (NCAG) recommended that every UK hospital with an ED established an acute oncologic service [5]. As a result of the varying demands and resources available across the UK to develop acute oncologic services at each hospital, there has been a wide range of models employed to deliver this strategy. The core of all acute oncologic teams has been an acute oncologic specialist nurse coordinating the service often supported by visiting oncologists.

The fundamental principles of an acute oncologic service are to promote education, awareness and early access to specialist oncologic input. It aims to drive integrated working between acute care physicians, surgeons, medical specialists and oncologists. Acute oncologic supports the variety of ED presentations from initial diagnosis, treatment complications and end-of-life issues. These encompass the three clearly defined types of acute oncologic presentation:

- Type 1 – Patients who present with a new diagnosis of cancer
- Type 2 – Patients who present with toxicities related to cancer treatments
- Type 3 – Patients who present symptoms and complications related to the cancer itself

Despite many national initiatives targeting early diagnosis of cancer in the UK, around a quarter of new cancers continue to be diagnosed during an emergency admission [6]. These patients traditionally were at risk of poorly coordinated care with late referrals to oncologic and palliative care services. Acute oncologic services have played a fundamental role in supporting the management of these patients and ensuring diagnostic pathways are completed in a timely fashion. This is especially pertinent in patients presenting

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_66

with malignancy of unknown origin who often experienced fractured diagnostic journeys with lack of continuity and clinical accountability [7].

A yearly review of a regional network acute oncologic service covering seven hospitals in the North West of England reported 3013 new patient admissions, of which 19% were type 1 admissions, 30% type 2 and 51% type 3 [8]. Acute oncologic models reduced the length of inpatient hospital stays and delivered significant cost savings [8, 9].

Specialist Cancer Admission Units

Case Study

The Christie National Health Service (NHS) Trust is a tertiary oncologic hospital and is one of the largest in Europe. It has 250 beds including a 21-bed Oncologic Assessment Unit (OAU) and a 7-bed Critical Care Unit. It is the lead cancer centre for patients in Greater Manchester and Cheshire but provides many national services.

The OAU is a hybrid urgent care centre/observation unit based on the UK Acute Medical Unit (AMU) model of care, and 30–35% of patients are discharged directly with the rest admitted to downstream inpatient wards [10]. *The OAU does not admit patients with symptoms suggesting an acute cardiac event or those who may require emergency surgery. These patients are diverted to their local ED.*

A general AMU acts as a 24/7 hub for all emergency medical admissions to hospital and provides a gateway to medical specialties, including oncologic. Its core processes are similar to those in an ED including initial assessment by a competent clinician, early review by a senior clinician, diagnosis with early access to diagnostic tests, assessing and stabilising physiological instability (for a period of up to 48 hours), care delivered by a specialist multi-disciplinary team and triage to appropriate downstream wards if the patient requires an anticipated inpatient stay of greater than 48 hours.

The OAU currently admits around 450–550 patients a month. Patients are admitted to the unit through three main routes:

1. **Via *a hotline/paramedics*** *– All patients receiving treatment at The Christie have access to a specialist helpline, run by nurse specialists. Patients are advised that if they develop symptoms, such as fever post-chemotherapy, they contact the hotline for advice and assessment. If they are triaged as having a condition related to the cancer or its treatment, they are admitted to the admission unit for assessment. This is often facilitated by the hotline contacting an ambulance to transfer the patient to the hospital.*
2. **Via *inpatient clinics/chemotherapy/radiotherapy.***
3. **Via *referrals from other hospitals*** *– Patients under the care of The Christie or with an acute cancer presentation at another hospital who need urgent chemotherapy/specialist inpatient care are referred to The Christie and transferred to the admission unit.*

The OAU is staffed and supported by acute care physicians and advanced nurse clinicians with expertise in emergency oncologic presentations, medical and clinical oncologists, haematologists, supportive and palliative care physicians, visiting medical specialists with interests in complications of cancer therapy, experienced acute oncologic nurses and allied health-care professionals. This model facilitates timely and high-quality tertiary acute oncologic care with a focus on personalised emergency cancer care. It also facilitates innovations that are essential to the delivery of emergency oncologic care, such as triage nurse-led delivery of first-dose intravenous antibiotics in patients presenting with sepsis [11]. *One of the strengths of our centre is significant acute care physician and specialist experience in managing acutely unwell patients with immune-mediated toxicity alongside oncologic colleagues, as well as managing the multitude of medical presentations. This ensures high-quality outcomes for acutely unwell cancer patients.*

Ambulatory Care

Ambulatory care is recognised as a key tenet in ensuring the safety and sustainability of acute care services. The fundamental basis for ambulatory care is that patients presenting with acute illnesses can be stratified as low risk for developing complications and therefore do not require traditional inpatient care [12]. The NHS targets that 25% of all acute medical presentations are managed through this route.

There are an increasing number of acute cancer presentations that can be risk assessed for care in an emergency ambulatory setting. These include low-risk febrile neutropenia, incidental pulmonary embolism, cancer-associated DVT, chemotherapy-related acute kidney injury, chemotherapy-induced nausea and vomiting, indwelling line infections, acute management of pain crises, malignant hypercalcaemia and other electrolyte abnormalities, asymptomatic brain metastases and malignant pleural effusion [13–15].

Ambulatory models offer the opportunity to integrate palliative and supportive care with oncologic and acute services. Ambulatory enhanced supportive care models have shown utility in the management of low-risk febrile neutropenia [16]. This appears to facilitate improved access for patients to expertise in cancer care and immediate management of the complications of cancer treatment with the goal

of preventing downstream complications and future emergency presentations.

Modelling of ambulatory emergency oncologic services with integrated expert supportive and palliative care services is key for providing high-quality, personalised and sustainable emergency oncologic care. It enables a greater number of patients to have their cancer complications managed at their cancer treating centre and aims to reduce attendances at overcrowded general EDs.

UK Role in International Emergency Oncologic Research

The optimal medical management of many cancer-related emergencies is a key area for further research. Many practice patterns are based on expert opinion or prior experience rather than clinical trials. These include traditional presentations such as the management of opioid-related constipation and rescue therapy for chemotherapy-induced nausea and vomiting.

Prospective trials into the emergency management of immune-mediated toxicities of immune checkpoint inhibitors examining optimal doses of steroids for those presenting with life-threatening toxicities and the timing of steroid-sparing agents, such as infliximab, are essential. It is key that these studies are not only multi-national but supported by acute care physicians working in emergency oncologic settings.

The care model used for patients with oncologic emergencies needs to be tailored to the local medical and oncologic environment; therefore, it naturally follows that different medical systems have developed different processes to care for these patients. A key for successful emergency oncologic models is the underlying goal of care being provided to these patients by clinicians who are knowledgeable about their needs and have integrated communication with the primary oncologists. Acute care of the oncologic patient is gaining recognition as an important international area that could be improved upon with increased training, research and emphasis on integration into the oncologic system. International collaboration is needed to achieve this.

COVID19 and Acute Cancer in the UK

At the time of writing, the impact of COVID19 on emergency oncologic is unclear. The COVID19 pandemic has resulted in the redeployment of many acute oncologic staff into non-oncologic-based roles to help with its management. The impact and duration of these changes is not yet understood.

Furthermore, the outcomes relating to acutely unwell cancer patients with COVID19 and their optimal management is a new challenge for those working in emergency oncologic. Modelling so that patients with SARS-CoV-2 are not co-located with those without will have significant implications for the delivery and modelling of acute cancer services in the UK and internationally. The specialist cancer ER in Asan, Seoul, South Korea, has already been reconfigured to become an infectious diseases/COVID19 ER for the foreseeable future.

It is too early to speculate as to the long-term impact on emergency oncologic services of COVID19, but no current chapter relating to this subject would be complete without a brief caveat suggesting that significant changes in modelling may be necessary.

Cancer Pain Management in Low-Resource Settings

67

Shiraz Yazdani and Salahadin Abdi

Case Study

A 68-year-old female in a low-resource setting presents to a general practitioner clinic with severe back pain. Upon performing a history and physical examination, the provider finds a large mass on her left breast that is highly suspicious for a malignant process. The patient states that she has had the mass for several years but did not seek care due to fear of being shunned by her community for having this abnormality. Further diagnostic testing reveals an invasive ductal carcinoma which has metastasized to the liver and bony structures including vertebral bodies, causing an acute vertebral compression fracture, which explains the patient's severe back pain. The patient begins treatment for her malignancy with a local oncologist but continues to have severe back pain despite conservative measures. Due to lack of available trained personnel, she is unable to undergo vertebral augmentation to treat her compression fracture. Her team attempts to control her pain with a combination of opioids and adjuvant medications. However, due to regional restrictions on opioid importation, her treatment options are limited to tramadol, codeine, and immediate-release morphine sulfate. Healthcare providers attempt to get approval for transdermal fentanyl in order to improve her pain control but are unable due to the cost to the hospital and clinic system for importing this medication. They also find a provider who can perform vertebral augmentation to improve her pain, but that facility is several hours away and the patient states that she cannot afford to travel there. Furthermore, there is a lack of governmental assistance programs to help patients such as her travel to seek more advanced care.

Introduction

Despite advances in the treatment of cancer, a large proportion of oncologic patients report disease-related pain at some point during the evolution of their disease process. The incidence of cancer-related pain increases with more advanced disease. Suffering from this pain can significantly impact a patient's activities of daily living and quality of life [1]. Despite advances in the treatment of various cancer disease processes, as well as the numerous etiologies of cancer pain, uncontrolled pain remains a significant issue. The prevalence of pain has been reported as 64% in those patients with advanced disease. Even in cancer survivors, the prevalence has been as high as 33% [2]. Treatment of cancer and cancer-related pain varies based on geographic differences in availability of information, training of healthcare workers, and availability of resources (equipment for interventional procedures, medications for pharmacologic treatment, appropriately trained providers for non-pharmacologic management, etc.). In certain settings, resources can be limited. This can lead to significant alterations in the availability and applicability of treatments for cancer pain. The vast differences in resources can be attributed to unequal distribution of power, income, goods, and/or services [3]. These differences occur within and between countries. Certain populations have been reported to be at higher risk for such inequalities including those with low-income, minorities, and underserved women [4]. On a global scale, many low- and middle-income countries experience this low-resource environment, and patients in those countries may suffer from untreated or undertreated cancer pain. The primary countries associated with the most readily available resources include Western Europe, North America, and Oceania [5]. Roughly, countries can be classified according to their human development index as compared to other countries. This composite includes components of life expectancy, education, and per capita income [6]. Although diagnosis and treatment in these settings may be challenging, it is critical to strive to provide the same level of care across the board. In an effort to highlight this goal, the

United Nations has released Sustainable Development Goals for 2030. These goals call for a reduction in premature mortality by a third using appropriate prevention and treatment modalities [7]. In this chapter, we highlight cancer pain and its treatment, ranging from etiologies and modalities of treatment to challenges and opportunities in low-resource settings.

Etiologies of Cancer Pain

Understanding and treating the etiologies of cancer pain requires a detailed understanding of the assessment of the cancer pain patient [8]. This is particularly important in the low-resource setting, as patients in these settings can present unique challenges in terms of education levels, expectations, social situations, family dynamics, and cultural belief systems. Beginning at the most basic level of assessment lies the chronicity of pain. Even at this level, patients in low-resource settings may present in a later stage of chronicity due to low access to care [9]. This lower level of access leads to many patients in low-resource settings to be diagnosed at later stages of disease [10], which is associated with higher levels of pain. Additionally, cancer pain is a unique type of pain that often evolves at a rapid pace. It requires consistent re-evaluation and re-assessment. These constant changes may be from a change in the disease process (e.g., tumor growth or metastasis), response to treatment (e.g., reduction of tumor burden), treatment of pain generators (e.g., nerve blocks), adverse reactions to treatment (e.g., chemotherapy-induced peripheral neuropathy), side effects from medications (e.g., myalgias), or a combination of any of these issues. This constant re-assessment requires significant resources but is critical in treatment as the etiology of pain can shift quickly in a patient with cancer (Fig. 67.1).

The most basic place to begin with the etiologies of cancer pain is determining the pain's cause and pathophysiology. Syndromes are often used to describe commonly associated states in cancer pain [11], but a universal classification system for these syndromes has not yet been determined [12]. A simple way to classify different types of pain is whether they are related to tissue damage (somatic nociceptive, visceral nociceptive) or nervous system disorders

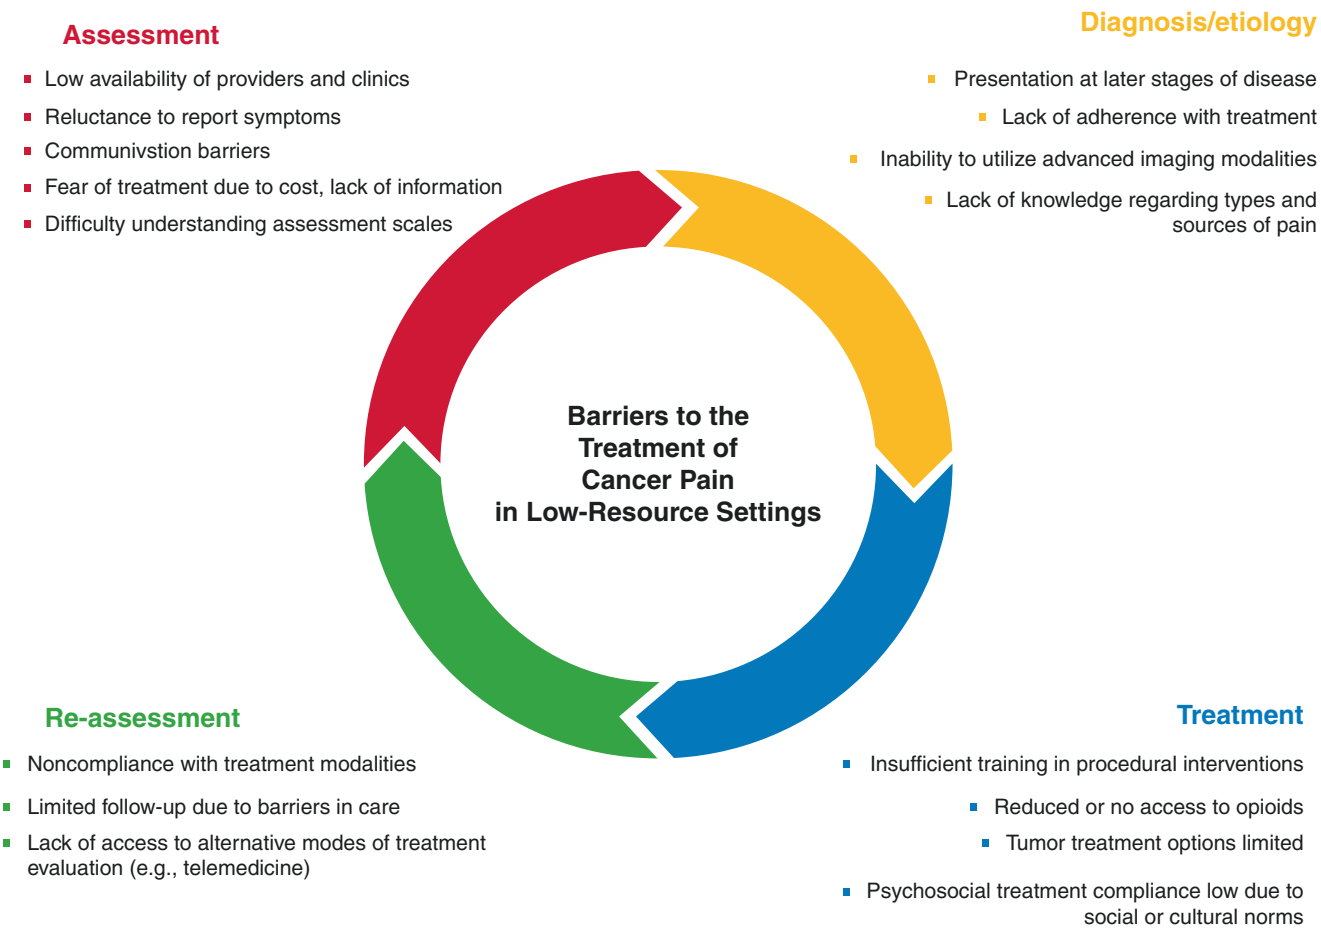

Fig. 67.1 Barriers to the treatment of cancer pain in low-resource settings

(neuropathic). The majority of cancer pain is directly attributable to tumor burden, with other causes being treatment-related or non-cancer-related [13].

Somatic Nociceptive Pain

Pain related to tissue damage is often described as achy or throbbing. This type of pain is often well localized. It can come from a variety of tissues including skin, muscle, and other types of soft tissue. This is the most common type of pain in cancer patients. Oftentimes, it is due to bony disease or metastases [14]. Somatic nociceptive pain generators include various tumor-related sites. This can be from bony disease including primary bone tumors, bone marrow expansion in hematologic malignancies, and bony metastases (e.g., vertebral body metastasis from prostate cancer). Spinal pain can manifest from tumor burden in the vertebral body, bony destruction, vertebral body fractures, and/or spinal cord compression. Soft tissue tumors lead to various pain types at the site of the tumor, including facial pain, headaches, and pleural pain. Further pain etiologies include paraneoplastic pain syndromes such as osteomalacia, osteoarthropathy, and myalgias.

Visceral Nociceptive Pain

In contrast to somatic nociceptive pain, visceral nociceptive pain is often poorly localized. Depending on which organ is affected, it can also be referred to different regions in the body. The characteristics of visceral pain can include a distended feeling and a generalized, dull pain. For example, pain in the myocardium is often referred to the upper extremity. Pain in the gallbladder may be referred to the shoulder. Pain in the ureter may be referred to the lower quadrant. Any organ can be affected but more common sources of visceral pain include hepatic metastases, intestinal obstruction, or venous distension due to tumor burden [15]. Visceral nociceptive pain generators include various syndromes and can result from hepatic distension, intestinal distension, and/or obstruction, peritoneal carcinomatosis, perineal pain, adrenal pain, and ureteral obstruction.

Neuropathic Pain

This third type of pain arises from cancer or cancer treatment affecting the nervous system. This can result in nerve irritation or damage. Abnormal nerve firing may result in dysesthesias, allodynia, hyperesthesias, hypoesthesias, and anesthesia dolorosa. This type of pain is often described as burning, shocking, or lancinating. Neuropathic pain can result from a direct nerve insult (e.g., a tumor compressing a nerve) or inflammatory mediators from adjacent soft tissue destruction. Certain cancer treatments may lead to neuropathic pain states as well, such as chemotherapy-induced peripheral neuropathy or radiation neuritis. Furthermore, surgical treatment of tumors can lead to pain states such as phantom limb syndrome [16]. Certain treatments may also lead to other pain-causing disease states to manifest themselves, such as immunosuppression from chemotherapy leading to post-herpetic neuralgia and subsequent neuropathic pain. Other painful neuropathic states can include leptomeningeal metastases, glossopharyngeal neuralgia, trigeminal neuralgia, various plexopathies (cervical, brachial, lumbar, etc.), peripheral mononeuropathy, malignant radiculopathy, and paraneoplastic sensory neuropathy [17].

Challenges and Opportunities for Cancer Pain Management

The low-resource setting provides numerous challenges and opportunities in the setting of treating cancer pain. The best approach may be to analyze the usual goals and approach for the treatment of cancer pain and then consider the challenges that are presented in a low-resource setting. At that point, the opportunities to optimize care can be elucidated.

The first goal in treatment should be accurate assessment of pain. This can be quite challenging at baseline due to, as previously mentioned, the complex interaction of disease burden, treatment effects, and pain management interventions [18]. Also at play is the fact that non-cancer-related pain etiologies have been reportedly involved in as high as 9% of pain diagnoses [19]. The practitioner should have the patient characterize the pain. This can include temporal features, intensity, quality, relieving and precipitating factors, location, and radiation. Even this simple assessment presents a challenge in the low-resource setting. Due to lack of education, descriptors of pain may be limited. In some settings, lower literacy rates can severely affect accurate assessment. Using functional scales such as the complex disability indices can prove difficult. Lack of trust between certain populations and healthcare workers can lead to inaccurate reporting of pain. This has been reported with indigenous people [20]. An additional confounding factor in determining the etiology of pain in the setting of cancer in low-resource settings is the lack of education and subsequent differences in expectations between the patient, family, and healthcare providers. Communication is essential in order to optimize treatment [21]. The opportunities presented here are self-evident. Increased education to the public can improve communication between patients and healthcare workers. This can also help build trust between the two. Successful public marketing campaigns aimed at improving the image of the health-

care system in general should be a goal. If available, utilizing local trusted figures or champions can help bridge the gap between patients and healthcare workers. Healthcare workers should be well educated in regional differences in social norms, cultural beliefs, and patient-family expectations so that there is not a disconnect when planning the goals of care.

Next, the practitioner should understand the nature of the pain. This not only includes the cause but also the relationship to the pathophysiology of the related cancer or cancer treatment and any associated syndromic features. This presents a challenge as many of these patients may have not undergone appropriate testing due to lack of equipment or financial issues. For example, if a tumor-related vertebral compression fracture is suspected but the area in which the patient and healthcare worker reside does not have access to advanced imaging such as magnetic resonance or computed tomography, the diagnosis cannot be confirmed and treatment may be indefinitely delayed. This is further complicated by the fact that many patients in low-resource settings present at later stages of disease. It has been shown that lower- and middle-income countries have higher mortality rates, leading to significant cancer survival gaps. This is oftentimes due to diagnosis at a later stage and lack of access to prompt treatment (Fig. 67.2) [20, 22].

The challenges here are more systemic in nature and, therefore, more difficult to address. Access to early diagnosis necessitates earlier access to care. This could mean higher numbers of available clinicians to make the diagnosis as well as more healthcare facilities in which to assess, diagnose, and treat a larger number of patients. This also entails facilities with more advanced imaging modalities with which to diagnose patients. Local healthcare workers would also require more nuanced education on the assessment and treatment of cancer and cancer pain. Unfortunately, implementing a large-scale change such as this requires significant funding. Public financing plays a crucial role in this type of implementation. In high-income countries, this type of funding is what has led to modern, sustainable healthcare infrastructures. In most of these countries, universal healthcare is now also standard, leading to increased access to care and health equity across the population. Aid to low- and middle-income countries by countries with higher GDP has been critical in maintaining access to healthcare. However, as income in countries providing aid has increased, the proportion of aid provided, sadly, has not (Fig. 67.3) [3].

Additional challenges in this realm include appropriate access to cancer treatment modalities. Stereotactic radiotherapy, for example, may not be available in a low-resource setting. However, this type of therapy is ideal in some scenarios, such as localized bone tumors [23]. Again, the primary opportunity here comes at great financial cost. Public funding campaigns may be utilized to help fund improvements in cancer treatment modalities. Additional aid from other countries can be sought as well. Some have suggested greater debt relief to low- and middle-income countries so that they can use their government income to improve healthcare infrastructure. Generalized improvements in government infrastructure and strengthened internal tax capacity are systematic improvements that may eventually lead to benefits in the healthcare system.

Once the underlying cause of pain is elucidated, its effects on the patient's quality of life and psychosocial well-being should also be determined and addressed. This can include effects on activities of daily living, physical functioning and capacity, mood, coping, stress levels, familial effects, social interactions, sleep quality, and sexual function. This also ties in with general psychiatric well-being, including anxiety and

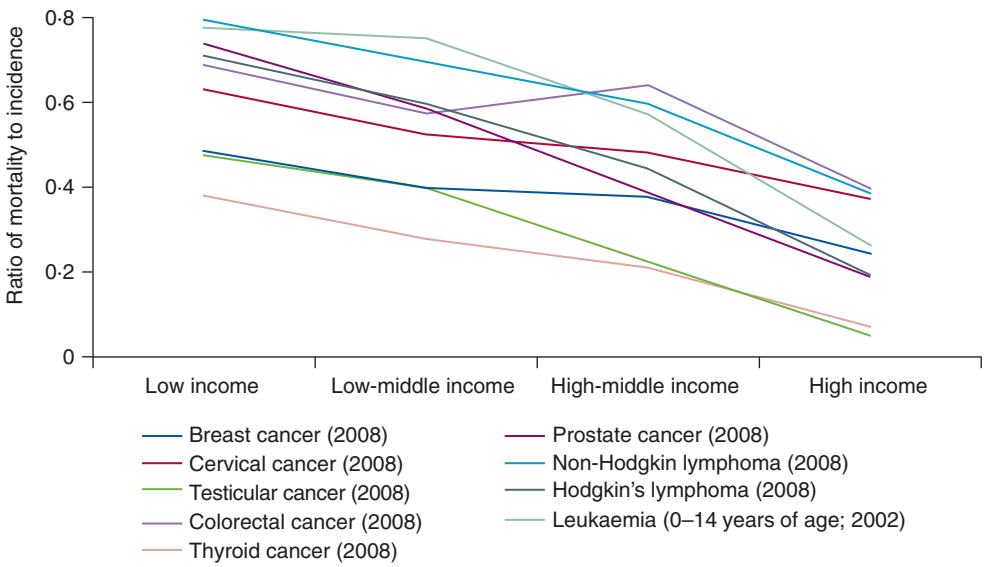

Fig. 67.2 Ratio of mortality to incidence in a specific year by cancer type and country income. People with cancer who live in higher-income countries are often less likely to die from their cancer, compared to people who live in lower-income countries. (From Farmer et al. [22], reprinted from the Lancet with permission Elsevier)

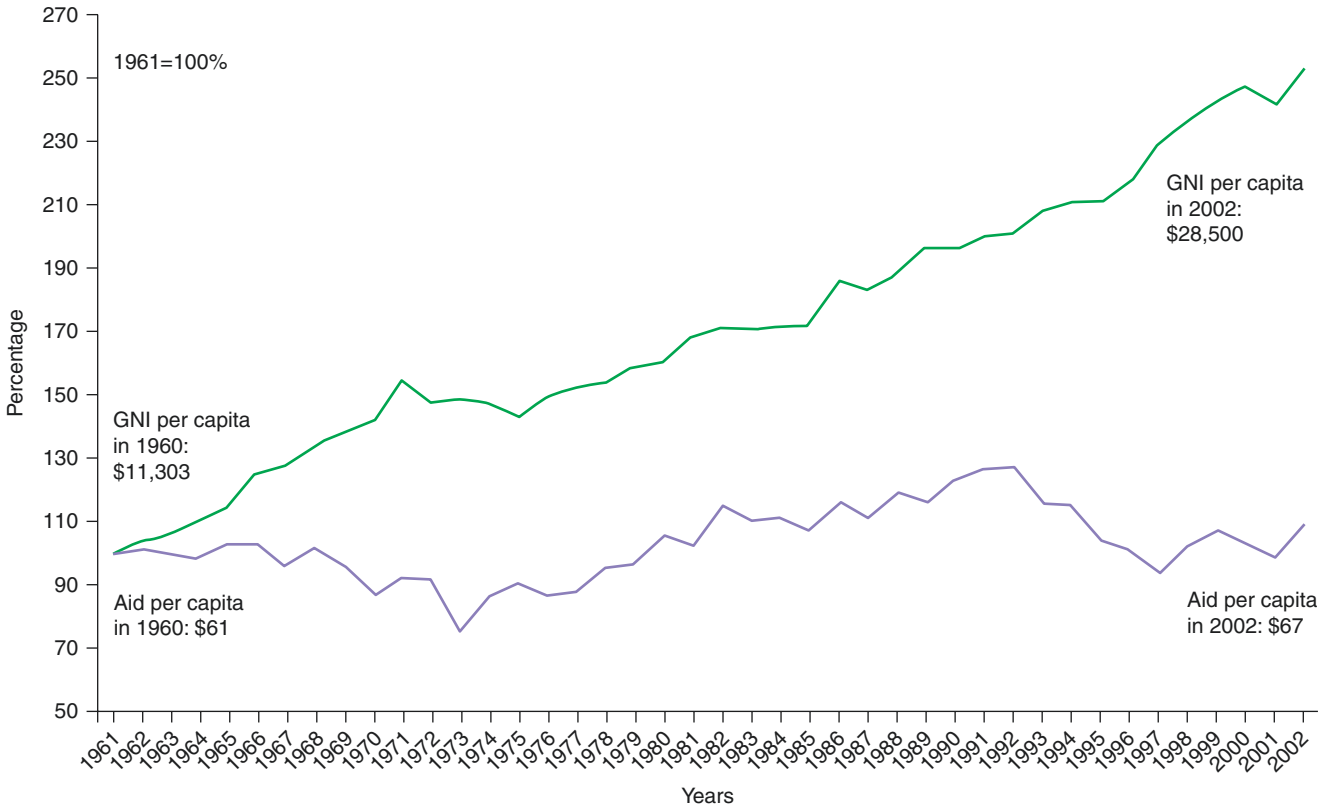

Fig. 67.3 The growing gap: per capita aid from donor countries relative to per capita wealth, 1960–2000. Calculated in $US at 1998 prices and exchange rates. GNI = gross national income. (From Marmot, et al. [3], with permission Elsevier)

depression. Assessment of substance use disorders, personality disorders, and spiritual well-being should also be carried out. This is an area that can prove quite challenging in low-resource settings. Due to lack of education, a cancer diagnosis often carries a stigma and inherent fear factor. There have been reported cases of patients believing it is contagious [24], leading to the patient hiding the diagnosis so that they are not shunned by the community. This, of course, leads to a lack of care until the disease is at a late stage or, in more severe cases, until the patient has passed away from the disease.

Once an accurate diagnosis is made, the treatment plan can begin to be formulated. In an ideal setting, this involves a multidisciplinary team that focuses their efforts on treating the patient, disease process, and symptoms such as pain at the same time. This team can include, but is certainly not limited to, an oncologist to treat the disease of cancer, an internist to treat other underlying medical comorbidities, a psychiatrist to treat coexisting anxiety and/or depression, a physiatrist to coordinate rehabilitative modalities, a pain specialist to perform interventional procedures and optimize pain medication regimens, a radiation oncologist to evaluate for therapeutic radiotherapy, a pharmacist to monitor for medication optimization and interactions, a nutritionist to plan an ideal diet for health and recovery, and even a palliative medicine specialist or hospice physician in cases of end-stage disease. Coordinating such a large team requires considerable resources, which may not be available in limited or low-resource settings. Challenges in these scenarios involve not only availability of specialists, but education in general. Due to limited resources, healthcare providers in these settings may have to play the role of many of these specialists. However, they may lack the education to properly execute these roles. In some cases, the education may be extremely superficial; in others, it may be absent altogether. Opportunities to improve education are vast but require significant long-term commitment from the institutions in that specific infrastructure. There is no short-term solution or "band-aid" for appropriate training. In fact, rushed training may lead to inaccurate diagnoses and improper treatment decisions, leading to patient harm. Appropriate training may require outsourcing, at least on a temporary basis, until educational institutions can provide appropriate teaching and mentorship for trainees.

An additional area which requires education for both the healthcare provider and the patient population is palliative and hospice care. The challenges and opportunities surrounding healthcare provider training are covered above. From the patient population perspective, there are many myths and stigmas present regarding end-of-life care. These

may be tied to certain religious or spiritual beliefs. For example, fatalism (the belief that events in life are predetermined) can lead patients and their families to forego treatment, even at the end stages of disease, because they believe what is transpiring is "meant to be." This can lead to suffering from multiple untreated or undertreated symptoms, including pain. At the end of life, all patients deserve to have the best quality of life they can be given. This requires debunking these myths and removing the stigmas surrounding cancer in many low-resource settings. Many campaigns focus on the word "cancer" and exposing the public to it so that it is not a taboo word or diagnosis. Exposing the community to patients who are cancer survivors is also crucial to show the community that cancer is survivable with appropriate diagnosis and treatment. Using local, well-known figures is an effective method to increase exposure and improve education about cancer diagnosis and treatment.

Managing Cancer Pain

Part of the treatment plan centers around appropriate, multimodal pain management. This includes pharmacologic management, including opioids as clinically indicated, non-pharmacologic management, and interventional procedures. Disease-modifying treatments such as chemotherapy and radiotherapy can significantly affect the patient's pain. However, covering the details of these treatments is beyond the scope of the current chapter. Briefly, these treatments can be considered part of the pain management plan if their administration has a viable chance of reducing tumor burden and thereby reducing the effects of pain by the tumor. Of course, these treatments are not without contraindications and adverse effects. Formulating a plan to treat pain with disease-modifying treatments requires careful coordination between the pain specialist, oncologist, and radiation oncologist.

Non-opioid Pharmacologic Management

The World Health Organization released the cancer pain ladder as a schematic for the basis of cancer pain treatment almost 35 years ago. At the first step of the ladder is non-opioid pharmacologic management. This can include non-steroidal anti-inflammatories and acetaminophen. Non-steroidal anti-inflammatories have been shown to be particularly effective for bony pain from primary or metastatic tumors. This can also be applied to osteolytic lesions. These modalities can also be combined with opioid treatment, although the combination may not be necessarily more effective than opioid monotherapy [25].

These therapies have the benefit of being widely available, even in low-resource settings. However, they come with significant risks. Acetaminophen carries an inherent risk of hepatotoxicity and must be used with caution in patients with compromised liver function. In low-resource settings, one unique consideration is the undertreatment of alcoholism. Alcoholism is a common issue in many regions, and treatment requires long-term rehabilitation – an effort which requires substantial community resources [26]. In settings where resources are limited, alcoholism may be undertreated and treatment with any medications which may compromise hepatic function should be prescribed with caution. Non-steroidal anti-inflammatory drugs have their own set of cautions to consider. They can adversely affect the gastrointestinal, renal, and cardiovascular systems [27]. In low-resource settings, patients should be carefully screened for abnormalities in any of these symptoms prior to treatment with non-steroidal anti-inflammatory drugs. As mentioned earlier in the chapter, patients in low-resource settings avoid seeking healthcare for a multitude of reasons. This presents major issues not only with cancer diagnosis and treatment, but with medical comorbidities as well. If a patient delays seeing a healthcare provider for cancer care, it can be assumed that the same patient likely did the same for other medical problems. Undiagnosed or undertreated hypertension, diabetes, renal disease, coronary artery disease, peripheral vascular disease, and peptic ulcer disease may all be present in patients presenting for care. A thorough history and physical and appropriate diagnostic modalities are critical in ensuring these patients will not be harmed if they are prescribed non-steroidal anti-inflammatory drugs. Some of these risks may be mitigated by using a selective cyclooxygenase-2 inhibitor and/or combining treatment with a proton pump inhibitor [28].

Certain adjuvant medications have been effectively used in conjunction with acetaminophen, non-steroidal anti-inflammatory drugs, and opioids. These adjuvants consist of a variety of classes of medications and treat various types of cancer and treatment-related pain. Being non-opioid, their use should be considered in certain low-resource settings in which opioids may be unavailable due to cost, restrictions, or stigmas. Anticonvulsants such as the gabapentinoids (gabapentin and pregabalin) are often used given the high prevalence of neuropathic components in cancer pain. These N-type calcium channel blockers are often well tolerated and widely available. Gabapentin has been in use for decades and is generally available. Pregabalin is newer but is now available in generic form. Other anticonvulsants such as carbamazepine, topiramate, oxcarbazepine, valproate, and lamotrigine may also be used for neuropathic pain. These medications may not be as available as the gabapentinoids and some have the potential for significantly greater

adverse effects. Antidepressants, specifically tricyclics and serotonin-norepinephrine reuptake inhibitors, can be effective in neuropathic cancer pain as well. Many of these medications have been widely available for quite some time as well and have low associated costs. They can be particularly helpful in treatment-related neuropathic pain states such as chemotherapy-induced peripheral neuropathy. Another class of medication are topical adjuvants. This can include lidocaine cream, lidocaine patches, lidocaine liquid, capsaicin cream, capsaicin patches, non-steroidal anti-inflammatory cream, doxepin cream, and doxepin elixir. Although many of these are now available in generic form, any medication with a transdermal application system increases the manufacturing cost. Additionally, a patient may require multiple patches. In a low-resource setting, this may not be ideal for pain that may be chronic or expected to continue for the long term. For bone pain, glucocorticoids, bisphosphonates, and calcitonin are often used. Glucocorticoids have a host of adverse effects, especially with long-term use, and should be used with caution. Additionally, their use should be coordinated with the treating oncologist due to risk of immunosuppression. Bisphosphonates are considered generally safe, although there is a risk of osteonecrosis and renal injury. These concerns should be addressed with a careful history and physical examination, the challenges of which are outlined above [29].

Opioid Pharmacologic Management

Opioids remain the mainstay of treatment of cancer pain, particularly in advanced stages of disease. They have significant risks associated, including respiratory depression, nausea, constipation, pruritus, etc. The risk of respiratory depression remains the biggest clinical concern, as this can be life threatening. This risk is compounded by the concurrent use of benzodiazepines. Patients with cancer pain are often prescribed benzodiazepines due to the high incidence of anxiety surrounding a cancer diagnosis as well as cancer treatment. Careful risk stratification is needed to mitigate the risks surrounding opioids. These risks have been highlighted in recent years in the midst of the opioid epidemic. Overuse, misuse, and diversion remain significant concerns in the prescription of opioid analgesics [30]. Patients should undergo a risk assessment before beginning treatment with opioids. This can help identify high-risk patients and guide the clinician in appropriate prescribing for a particular patient. Consistent reassessment should be performed, as patients can shift between risk stratification categories over time. Additionally, patient education is critical when it comes to opioid management. Tempering expectations and explaining the risks of opioid use as well as the differences between addiction, physical dependence, and tolerance are vital in maintaining a healthy provider-patient relationship, especially in the setting of chronic opioid use. Monitoring patients consistently for appropriate outcomes is also important to ensure that the medication prescribed is helping them achieve their goals and outcomes. Outside of arbitrary pain scores such as the visual analogue scale, functional outcome measures should be utilized. Examples include the Short-Form 36, the Brief Pain Inventory, and the Patient Global Impression of Change [31].

Selection of opioids remains largely dependent on regional availability and clinical familiarity and training. Pure mu-opioid agonists remain the most commonly used and available. Initial selection will also depend on the severity of pain and the patient's tolerance to opioid agonists. In opioid naive patients, a starting point may include tramadol, a weak mu-opioid agonist with serotonin-norepinephrine reuptake inhibition effects or codeine. Tramadol's unique mechanism of action may make it more suitable for patients with a larger component of neuropathic pain. Caution should be used in those patients with renal dysfunction or those who are prone to seizures, as tramadol can reduce the seizure threshold. Codeine's mechanism of action relies on its conversion to morphine. In certain patient populations, hypermetabolism of codeine may lead to potentially toxic doses of morphine [32]. In the next tier of opioids, hydrocodone is most commonly available in North America and, to a lesser extent, in Europe. The immediate-release form is paired with acetaminophen (now limited in the United States to 325 mg acetaminophen per tablet), and the newer extended release form is hydrocodone without any paired medications. Caution should be used, as mentioned previously, with acetaminophen use. The extended release form is newer and currently brand name only, signifying that it is a higher cost and may be more difficult to obtain. In low- and middle-income countries, hydrocodone is scarcely available. Other opioid options include oxycodone, oxymorphone, morphine, and hydromorphone. Each of these is available in short acting, as well as long-acting, formulations. If cancer pain is continuous, a long-acting formulation is preferred with an immediate-release formulation given additionally for breakthrough pain. Caution should be used with hepatic dysfunction in any of these medications, but particularly with morphine due to accumulation of its metabolites [33]. Fentanyl is a potent opioid most commonly available as a transdermal patch for long-acting analgesia. It is also now available in a transmucosal formulation for rapid onset action. However, due to its unique routes of administration, manufacturing costs cause the cost to the patient to oftentimes be higher than other opioids. This is particularly problematic in low-resource settings. Availability of fentanyl products may also be an issue, although the transdermal fentanyl patch has been used long enough now that it is widely available. Methadone is a unique opioid agonist that also has an effect on the N-methyl-D-aspartate receptor. This medication has a long and variable half-life, which can be helpful in

continuous pain but may also pose an issue if it is to be discontinued as it persists in the system for an extended period of time. Its NMDA activity is beneficial when treating pain with a neuropathic component. It also lacks active metabolites, making it relatively safer for those patients with renal dysfunction. It does carry unique considerations, including the potential for QT interval prolongation. This should be monitored closely in order to prevent risk of torsades de pointes. Another issue is the stigma associated with its use. Since it is used in rehabilitative programs for opioid addiction, patients may be hesitant to use it for their cancer pain. In the low-resource setting, stigma with opioid use is already a major issue and the additional stigma with methadone may cause patients to decline treatment with it.

In the cancer pain population, routes of administration of opioids play an important role in treatment. Many types of cancer and cancer treatment may affect gastrointestinal absorption, leading to inadequate analgesia with oral opioids. Consideration should also be given to opioid metabolism and accumulation of metabolites in those patients whose hepatic and renal systems may be affected by disease or treatment. Patients undergoing multiple surgeries may be nil per os frequently, necessitating the use of alternative routes of administration such as intravenous, transdermal, or mucosal. Adjustments in doses may need to be frequent and require timely reassessment. When changing doses, several days may need to elapse for steady state blood concentrations to change with long-acting opioids. This may be up to 1 week in the case of a unique medication such as methadone.

Management of side effects is also crucial in opioid treatment for cancer pain. Opioid induced constipation remains a major issue for many patients, so much so that they may want to decrease doses in order to improve this side effect. Dietary adjustments and over-the-counter stool softeners and stimulant laxatives may be used in mild cases. Peripheral opioid antagonists such as naloxegol may be used for more severe cases. Opioid antagonists such as methylnaltrexone and naloxone may also be considered in select cases. Unfortunately, the availability of these antagonists is highly variable, especially in low- and middle-income countries. Other side effects to consider include mental clouding, somnolence, pruritus, nausea, and urinary retention. These can normally be ameliorated by dose adjustment and adjuvant treatment (e.g., a stimulant for mental clouding and a 5-HT3 antagonist for nausea).

Opioid Consumption in Low- and Middle-Income Countries

Despite significant data indicating that cancer pain continues to be often undertreated, there remain significant barriers in treatment of pain in low-resource settings such as low- and middle-income countries. The barriers to appropriate care are numerous and include low priorities given to pain relief. Additionally, national guidelines on pain treatment are often lacking or outdated. This is accompanied by social stigmas surrounding cancer, cancer treatment, and cancer pain, as highlighted previously in this chapter. On the topic of opioids, availability remains the major issue. This may be due to governmental restrictions on the import of opioids as well as restrictions on use due to fear of misuse, overuse, addiction, and diversion [34]. Policy issues causing decreased availability include lacking national guidelines on opioid imports, tight regulations on import and use due to fear of misuse and cultural beliefs and/or stigmas, and inadequate health governance. Clinical barriers to opioid use include lack of prescribers, lack of education in the healthcare worker community as well as the patient population, stigma and fear, and limited number of clinics available to see the appropriate number of patients and spend enough time with them for opioid education. Systemic resource issues also contribute and may include lack of resources to store and appropriately distribute opioids, low or absent numbers of pharmacies (especially in rural regions), and inconsistent stock.

As morphine equivalents remain the standard by which all opioids are judged, global consumption via morphine equivalents is a metric used by the World Health Organization to study global opioid use (Fig. 67.4) [35].

Low- and middle-income countries accounted for 84% of the world's population in 2018 [36]. The disparity in availability of morphine and other opioids in relation to patients in need is highlighted in the map above, from a report in The Lancet Commissions. This figure is a dismal reminder of the glaring disparity between high-income and low−/middle-income countries. In the United States, Canada, and Western Europe, the population remains over-served by at least hundreds of percentage points greater than their need. In low- and middle-income countries, the population remains underserved usually below 15% and even below 1% in some countries. In addition to the systemic issue related to opioid use in low- and middle-income countries, one additional issue remains inconsistent availability of a medication that a patient may be currently using. Month to month, stock changes may require clinicians to alter the medication used. For example, a patient may be stable on transdermal fentanyl for 3 months, and, the following month, the country no longer has that medication available. Although opioid rotation is an established practice, it is often a slow and inaccurate process and may lead to periods of uncontrolled pain. This is especially troublesome when applied to a patient who was doing well on one medication but now has to switch to one which may be less ideal because the country where they reside does not have policies or procedures in place for stable stocks of medications.

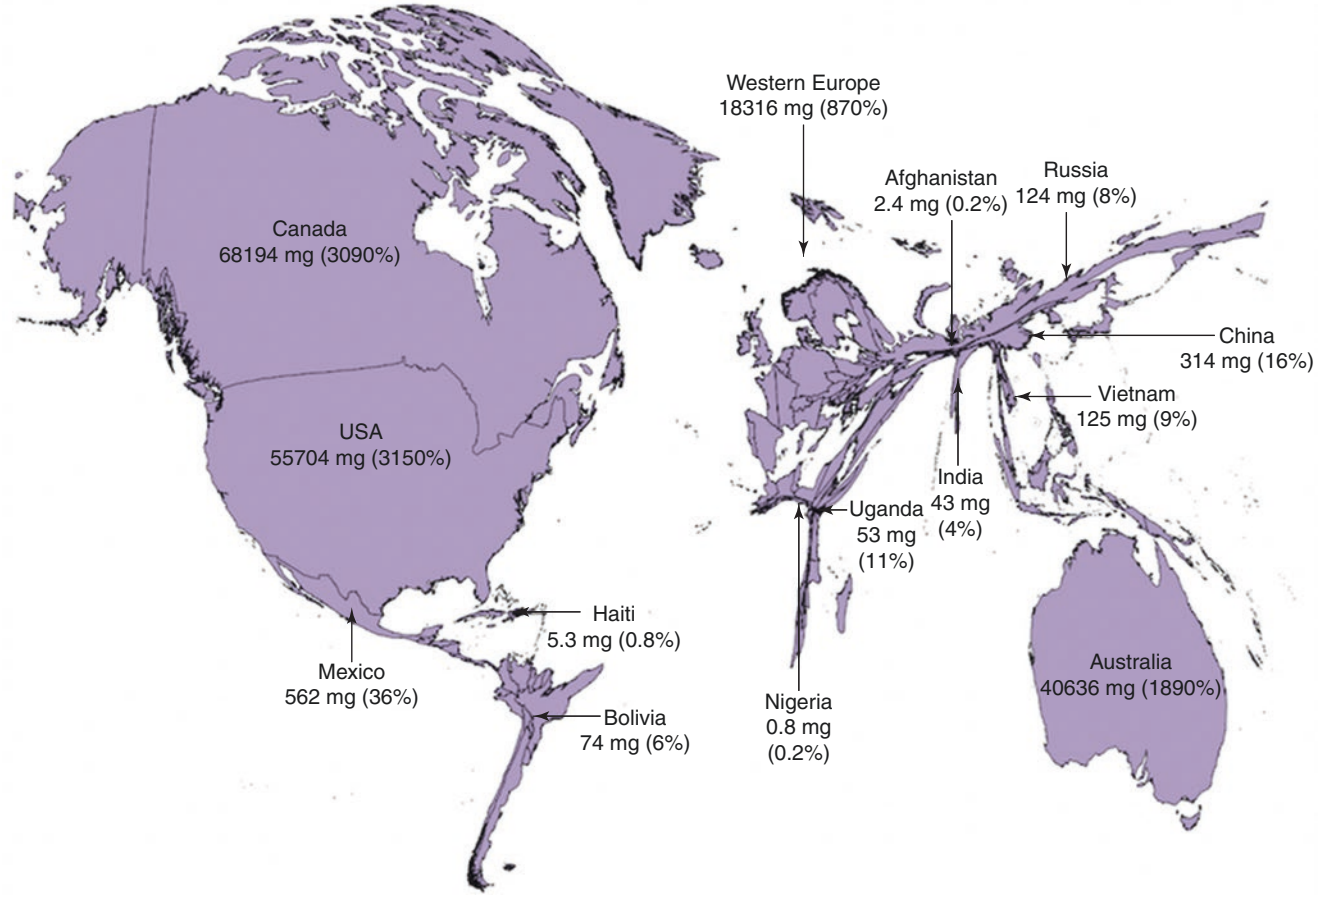

Fig. 67.4 Distributed opioid morphine equivalent (morphine in mg/patient in need of palliative care, average 2010–2013) and estimated percentage of need that is met for the health conditions most associated with serious health-related suffering. Non-pharmacologic Management

Non-pharmacologic, non-interventional treatments for cancer pain are becoming more commonly used as they offer potential benefits with minimal side effects. This can include psychotherapy, physical therapy, and acupuncture. This category also encompasses programs which may assist with associated components of cancer pain such as pain education, support groups, family stress changes requiring therapy, financial programs to assist with pharmacologic or interventional treatments for pain, etc. Disparities in low-resource settings can significantly affect response to these treatments. One study has shown a favorable response to patient coaching in the management of cancer pain in ethnic minorities [37]. Educational programs are critical in reducing disparities between groups in low-resource settings. As previously mentioned, lack of education leads to propagation of myths and stigmas which delay care and lead to diagnosis in later stages of disease with greater disease-related suffering. Dispelling myths surrounding physical manipulation methods such as physical therapy and acupuncture is also vital, as these modalities can significantly improve functionality in cancer pain patients. Family counseling is also an important component of cancer pain treatment, especially when approaching the end of life and with involvement of palliative care.

Interventional Procedures

Interventional procedures can play a crucial role in the treatment of cancer pain. As pain interventions have advanced, practitioners have been able to perform more advanced procedures without increasing the invasiveness of these procedures. The types of procedures performed depend on an accurate diagnosis of the underlying cause of pain. Special consideration must be given to any areas surrounding a tumor or metastases, given that these areas are highly vascular and the risk for bleeding may be increased. Additionally, consideration must be given to the patient's oncologic treatments, as certain therapies may interfere with clotting ability and wound healing. The use of corticosteroids must also

carefully be weighed with the cons of such medications, especially on a repeated basis.

For head and neck tumors, peripheral nerve blockade is available as a treatment modality to assist with pain management. Examples of such blocks include trigeminal nerve blocks, stellate ganglion blocks, occipital nerve blocks, and cervical nerve root blocks and/or epidural steroid injections. For upper and lower extremity tumors, somatic nerve blockade can provide temporary relief or pain management surrounding surgical resection. Sympathetically mediated pain can be treated using stellate ganglion or lumbar sympathetic blocks. Post-surgical syndromes such as post-mastectomy pain syndrome and post-thoracotomy pain syndrome can be treated with peripheral nerve blockade, such as intercostal nerve blocks. Splanchnic nerve or celiac plexus blockade (and ablation) is commonly used for visceral abdominal pain. Similarly, superior hypogastric plexus blockade (and ablation) can be used for visceral pelvic pain. Pain at the perineum and rectum can be treated by blocking the distal end of the sympathetic chain, at the ganglion impar.

More advanced therapies include vertebral augmentation, which is used to treat tumor or osteoporosis-related vertebral compression fractures. Newer technologies allow for radiofrequency ablation of tumor sites in the vertebral body prior to polymethylmethacrylate injection. Implantable therapies such as dorsal column stimulation and intrathecal drug delivery systems are available as well. In cancer pain, intrathecal drug delivery systems allow for the use of intrathecal opioids to effectively treat pain while lowering some adverse effects of oral or transdermal opioids. For severe, refractory cases of pain, advanced functional neurosurgical techniques such as cordotomy can be employed.

Most of these interventions are performed under image guidance—commonly fluoroscopy or ultrasound. Computed tomography guidance may be used in select cases.

Barriers to the use of interventional techniques remain present in low-resource settings. The setting and equipment needed to perform such interventions may not be readily available. The cost to set up a procedure suite to perform these interventions is much higher than that of acquiring most pharmacologic treatments. Additionally, the training required for the practitioner remains substantial. Specialists who can perform such procedures may not be readily available in low-resource settings, and systematic infrastructure changes will need to be implemented before this issue can be resolved.

Recommendations

In order to overcome barriers in care in low-resource settings, several changes can be undertaken in a systematic, stepwise fashion in order to improve access to care. The first place to begin is changes in policy. This can occur on a local, regional, and national level. Policies need to be in place to improve access to care for cancer pain patients. This includes dedicating resources, financial and otherwise, to the development of appropriate healthcare facilities, training of healthcare personnel, advocating to local and national community leaders, and working with national and international groups in order to implement these policies. These groups and organizations can be small, local focus groups or large, international organizations such as the Pain & Policy Studies Group [38]. These policies need to be aimed at increasing availability of care for cancer pain patients and avoiding restrictions usually placed on issues such as opioid importing and regulations.

Availability of pharmacologic treatments is another area that is high yield in terms of increasing care to cancer pain patients. In addition to the policy changes mentioned above, infrastructure needs to be put in place to obtain, store, and properly dispense medications to alleviate pain and suffering. This includes having licensed healthcare providers who are well trained in these treatments and are able to dispense them to patients appropriately. Consistency also needs to be maintained on medication stocks so that fluctuations do not occur regularly. In countries with tight regulations on opioids in particular, exceptions should be made for those suffering from cancer pain so their treatment is not delayed or prevented.

Improving education is critical in improving care for these patients. This applies to both healthcare workers and the population in general. In regard to healthcare workers, they need to be familiar with the tenets of cancer pain treatment and feel comfortable applying principles commonly used as the standard of care around the world. There also need to be enough healthcare workers so that a small number do not get overwhelmed by a large patient-to-healthcare worker ratio. A high ratio can lead to inadequate time with the patient, increasing the potential for misdiagnosis and inappropriate treatment choices. An example of healthcare worker education occurred in Uganda, with the 9-month Clinical Palliative Care Course. This course allowed clinicians to learn the basics of palliative care in 9 months, thereby greatly increasing access to care for their patients [39]. Educating the public is also crucial in order to debunk any myths and remove stigmas associated with cancer. This will allow earlier access to care and more effective treatments to take place. Local community leaders should be involved in advocacy and education campaigns. Cancer survivors should be highlighted so that the community can see cancer as a treatable diagnosis, instead of one that always leads to mortality.

Implementation of these recommendations can be challenging and requires coordination between healthcare providers, local leaders, and government figures. It also takes

time to implement such changes, but even on a small scale, the benefits can be seen. Beginning with a few goal-oriented tasks (e.g., leading a community campaign to improve education about breast cancer on a local level and implementing policy changes to remove restrictions on morphine prescribing for cancer pain patients on a national level) can yield palpable results that can affect patient outcomes. Broader changes, such as strengthened tax capacity in order to improve healthcare budgets to build more facilities to improve access to care, certainly take more time but are part of the ultimate goal.

Conclusions

Low-resource settings provide unique challenges and opportunities in the treatment of cancer pain patients. One must start with the basics of assessment of cancer pain, including a detailed understanding of the etiologies of cancer pain. The types of cancer pain include somatic nociceptive, visceral nociceptive, and neuropathic pain. These can be affected by cancer disease states in a variety of ways including direct tumor-related pain, mass effect on structures adjacent to the tumor, destruction of tissues surrounding the tumor, and paraneoplastic pain syndromes. Treatment of cancer can also lead to certain pain states such as chemotherapy-induced peripheral neuropathy. Appropriate diagnosis leads to an effective treatment choice. The WHO ladder begins the first step of treatment with non-opioid pharmacologics and adjuvant medications, then moves on to the next step of opioid treatment for increasing or refractory pain. Interventional treatment modalities also play a critical role in effective cancer pain management. These may range from guided nerve blocks to implantable therapies such as intrathecal drug delivery.

The challenges presented in low-resource settings begin before the patient even presents. Prejudices against the healthcare system cause patients to avoid care or seek alternate care until their disease is at a more advanced state. This leads to a significantly more complex pain picture on initial presentation. Many treatment modalities that could have been utilized at an earlier state may now not be appropriate in such cases. Increasing public education in order to improve trust between the community and the healthcare system can ameliorate this issue. Healthcare providers must present a unified message with local, regional, and national leaders.

As the patient continues on his or her treatment journey, limited resources may adversely affect proper diagnosis and treatment. Modalities such as advanced imaging and modern therapies may not be available in low-resource settings, leading to poor treatment options for cancer patients. The opportunities here are more difficult to seize, as many of these issues are related to systemic issues such as lack of financial support and governmental restrictions. Improvements to access of care will require longer-term solutions such as increased external aid and changes in local, regional, and national policies. This will allow improvement in healthcare infrastructure, which is necessary in order to provide better care to patients. Included in such improvements are a larger number of treatment centers, advanced imaging equipment, and better training for healthcare personnel. Medication availability to treat cancer pain is also highly variable in low-resource settings. This is linked to both financial support and strict laws in regard to opioids in certain countries. Unfortunately, this often leads to undertreatment of cancer pain as patients may not have access to the opioids they need; even if they do get access, it may be temporary as supplies are often inconsistent. There are many opportunities here to improve access to care, but again they require systemic changes such as improved funding and changes in the country's laws.

Many of the recommendations in this chapter take significant time, effort, and resources to implement. However, even small-scale changes can make significant differences in cancer pain patients' quality of life and outcomes. Low-resource settings provide settings in which the effects of these smaller-scale improvements can provide relatively significant effects.

Angela B. Creditt and Kevin Sing

In the United States, overall cancer incidence has been relatively stable over the last decade, ranging from 400 to 500 cases per 100,000 individuals [1]. Cancer death rates, however, have dropped by 29% from 1991 to 2017 as significant therapeutic advances have been achieved. Major developments in precision medicine, immunotherapies, and targeted therapies occur on a yearly basis, revolutionizing the delivery of oncologic care. For example, the 5-year overall survival of advanced melanoma in the interleukin era was 5–10%; with the combination of nivolumab and ipilimumab, that number has reached over 50% [2]. Thus, while disease-specific oncologic emergencies continue to occur, providers now contend with an array of new medications, as well as the life-threatening toxicities they can bring.

The development of new treatment strategies and a subsequently declining mortality rate has resulted in an increased number of visits to the emergency department (ED). In fact, most cancer patients will seek urgent care at least once during the course of their disease. Additionally, almost 60% of cancer patients who receive care in the ED will be admitted to the hospital [3]. Depending on hospital protocols and bed capacity, hospitalists may often assume the role of primary provider for cancer patients with hematology-oncologic physicians consulting to assist with management and treatment. Given the various specialties that will participate in the care of these patients, it is imperative that physicians receive thorough education on the identification and treatment of acute, and potentially life-threatening, oncologic morbidities.

Development of an Oncologic Emergency Medicine Curriculum

Medical students, residents, fellows, practicing physicians, and advanced practice providers – all have the potential to provide care to cancer patients, all can affect the outcome of these patients, and all will benefit from education on oncologic emergencies. However, each requires a different fund of knowledge and different educational approach. Undergraduate and postgraduate medical curricula must address core clinical competencies [4], but they are unique to each group of learners. For example, resident education is tailored toward milestones (on knowledge, clinical skills, attitudes, and other attributes) outlined by the Accreditation Council for Graduate Medical Education (ACGME) and the American Board of Emergency Medicine (ABEM) [5]. Here we will discuss and outline curriculum development as it pertains to an emergency medicine residency program. From this, adjustments can be made based on institutional differences or for other residency programs that will benefit from learning more about oncologic emergencies, such as internal medicine and family medicine. The second half of this chapter discusses special considerations for undergraduate medical education, hematology-oncologic fellowships, and continuing medical education.

Emergency Medicine Residency

Problem Identification and General Needs Assessment

Adult (age ≥ 18 years) cancer-related visits to the ED have been increasing; there were 3.3 million visits in 2006 and 4.8 million in 2012. 4.2% of all adult ED visits in the United States were made by a patient with a cancer diagnosis, and this number is likely higher in facilities with an associated cancer treatment center. Furthermore, cancer-related ED visits are more common among older patients and are associated

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_68

with a significantly higher inpatient admission rate (59.7% compared to 16.3% of non-cancer-related visits) [6]. Given the prevalence of cancer-related visits and potential severity of illness, physicians must be prepared to provide high-quality care to these patients, including prompt identification and treatment of disease-specific and therapy-related oncologic emergencies.

Over their postgraduate medical training, emergency medicine residents face the challenging task of mastering a broad base of knowledge encompassing all medical disciplines with a focus on the acutely ill or injured and emergent resuscitation of critically sick patients. Under this umbrella falls oncologic emergencies. The specific topic of oncologic emergencies has few resources dedicated to offering curriculum direction or suggested programs that may guide educators on effective teaching methods. Yet, in 2016, the *Model of the Clinical Practice of Emergency Medicine* (EM Model) added "oncologic emergencies" as a required curricular component requiring residents and practicing emergency physicians to obtain core fundamental knowledge on this subject in order to provide proper treatment and patient care [7]. What the EM Model did not do is provide education objectives or an outline of what content should be covered in the curriculum.

Beyond the EM Model, the ACGME, the body responsible for accrediting all graduate medical training programs, publishes "common program requirements" for each residency and fellowship. Essentially, these requirements are basic standards for the knowledge, skills, and attitudes deemed necessary that residents should acquire to appropriately take care of patients [8]. From this, each specialty has its own document outlining program requirements specific to that discipline. For emergency medicine, it states:

> The curriculum must contain the following educational components: a set of program aims consistent with the Sponsoring Institution's mission, the needs of the community it serves, and the desired distinctive capabilities of its graduates...competency-based goals and objectives for each educational experience designed to promote progress on a trajectory to autonomous practice...a broad range of structured didactic activities.

Additionally, it describes the competencies and milestones, such as professionalism, patient care and procedural skills, medical knowledge, etc. that educators must use to track and evaluate individual residents [9]. While the ACGME program requirements provides a comprehensive curricular foundation, as does the EM Model, it does not provide specific educational objectives or itemized curricular components that should be taught to each learner.

To supplement this, emergency medicine residency programs frequently utilize either *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*, 9th edition (McGraw-Hill Education/Medical; 2019), or *Rosen's Emergency Medicine*: *Concepts and Clinical Practice*, 9th edition (Elsevier; 2018), as a reference or guideline for educational components. Each textbook includes a section on oncologic emergencies; see Table 68.1 for specific topics covered. Both resources include content on the more commonly known oncologic emergencies, while *Tintinalli's* seems to have a more diverse list of topics. Neither currently discusses newly identified cancer-related emergencies such as immunotherapy toxicities.

Table 68.1 Topics included in emergency medicine textbooks

Textbook and chapter	Conditions discussed
Tintinalli's emergency medicine: A comprehensive study guide Chap. 239, emergency complications of malignancy	Airway obstruction Bone metastases and pathologic fractures Spinal cord compression Malignant pericardial effusion Superior vena cava syndrome Hypercalcemia of malignancy Hyponatremia due to syndrome of inappropriate anti-diuretic hormone (SIADH) Adrenal crisis Tumor lysis syndrome Febrile neutropenia Hyperviscosity syndrome Thromboembolism Nausea and vomiting Extravasation of chemotherapeutic agents
Tintinalli's emergency medicine: A comprehensive study guide Chap. 240, Emergency Complications of Malignancy	Emergencies related to local tumor effects Emergencies related to biochemical derangement Emergencies related to hematologic derangement Emergencies related to therapy
Rosen's emergency medicine: Concepts and clinical practice Chap. 115, Selected Oncologic Emergencies	Febrile neutropenia Metastatic spinal cord compression Malignant pericardial disease Hypercalcemia Tumor lysis syndrome Leukostasis Superior vena cava syndrome

Another core component of emergency medicine in general but also particularly as it relates to patients with cancer is palliative and end-of-life care. The 2016 EM Model notes that clinical knowledge in healthcare coordination, including end-of-life and palliative care, advanced directives, coordination with hospice, and organ donation, is integral to the practice of emergency medicine [7]. Yet, there is a perceived deficit in knowledge of palliative and end-of-life care by emergency residents and physicians [10], and only 59% of residencies have been found to teach these competencies in their program [11]. In part, this could be due to barriers within the ED such as perceived lack of time, lack of experience or expertise among faculty, and lack of faculty interest in palliative care. Additionally, the majority of programs

have access to hospice and palliative medicine consultants, thereby potentially negating opportunities for clinical education [11].

In 2007, a formal curriculum entitled The Education in Palliative and End-of-Life Care for Emergency Medicine (EPEC-EM) was created with the support of the National Institutes of Health. The EPEC-EM was developed by emergency physicians and nurse educators to enhance education in these essential clinical competencies as it specifically relates to the field of emergency medicine. However, despite this initiative, there remains a general lack of formal palliative care training in emergency medicine residency programs across the country. Emergency residents and physicians feel palliative care skills are important and desire more dedicated training in this field [11].

Given the lack of a generalizable detailed emergency medicine curriculum and related literature, it is difficult to define precisely the didactic education residents currently receive on oncologic emergencies. Furthermore, clinical exposure likely varies considerably based on characteristics of the residency program. For example, those who train at an institution with an affiliated cancer treatment center likely see a significantly higher cancer patient population than those without a center. This will ultimately translate to improved clinical experience and knowledge, confidence in workup and diagnosis, and an enhanced ability to manage emergent conditions affecting cancer patients, thereby resulting in higher-quality care and improved patient outcomes.

Goals and Objectives

Based on the problem identified and needs assessment outlined above, the overall goal and specific objectives for an oncologic emergency medicine curriculum can be developed. These objectives will help establish curricular content and learning approaches, help focus the learner, and provide a foundation for evaluation. The overall goal for a curriculum dedicated to oncologic emergencies is to expand and develop resident physician knowledge, clinical skills, and behaviors to effectively diagnose and treat patients who present with an oncologic emergency, thereby improving medical decision making and patient clinical outcomes. Specific objectives include the following:

- Identify and manage emergent medical conditions that occur in cancer patients, including local tumor effects, complications related to cancer treatment, hematologic derangements, and biochemical abnormalities.
- Understand novel cancer therapies, associated side effects, management, and treatment options.
- Exhibit proficient clinical skills through consideration of relevant differential diagnoses, workup, and management based on a cancer patient's medical history and clinical presentation.
- Recognize the following conditions: neutropenic fever, superior vena cava syndrome, tumor lysis syndrome, malignant spinal cord compression, blast crisis, immunotherapy and CAR-T cell toxicities, hypercalcemia, pulmonary embolism, hyperviscosity syndrome, malignant pericardial effusion, bone marrow transplant complications, and radiation therapy complications. See Table 68.2 for a more conclusive list of conditions.
- Learn supportive treatment plans for patients who need symptomatic care (i.e., nausea, vomiting, cancer-related pain, etc.) and understand when to include consultants such as palliative medicine and hematology-oncologic specialists to optimize patient management outside of the ED.
- Demonstrate sensitivity and commitment to ethical principles by assessing goals of care, including advanced care directives, and the patient's emotional state during their ED visit.
- Understand appropriate disposition including: discharge home, admission to the hospital or hospice, and transfer to higher level of care.

Table 68.2 Suggested oncologic emergency medicine educational topics

Local tumor effects	Airway hemorrhage, airway obstruction, bone metastases and pathologic fractures, brain metastases, malignant pericardial effusion, malignant pleural effusion, malignant spinal cord compression, superior vena cava syndrome
Complications related to cancer treatment	Bone marrow transplant complications, chemotherapy adverse effects, extravasation of chemotherapeutic agents, immunotherapy and CAR-T cell toxicities, radiation therapy complications, symptom management (i.e., nausea and vomiting, pain control)
Hematologic derangements	Blast crisis, hyperviscosity syndrome, leukostasis, neutropenic fever, pulmonary embolism
Biochemical abnormalities	Adrenal insufficiency, hypercalcemia, hyponatremia secondary to syndrome of inappropriate anti-diuretic hormone (SIADH), tumor lysis syndrome

Educational Strategies

While every resident has gained a foundation of knowledge in oncologic from medical school, their awareness and understanding of cancer-related emergent conditions may vary considerably (see the section on medical school education later in this chapter). Therefore, to achieve curriculum objectives, appropriate educational content and teaching methods should be selected. Learners can obtain lower-level knowledge through formal lectures, suggested reading

assignments, and asynchronous online modules. Case-based problem-solving exercises and other small group modules, such as simulation, that rely on active participation by learners can then be implemented to enhance clinical reasoning skills. Finally, bedside teaching and on-shift clinical education must occur to cement knowledge learned through didactic instruction.

Ideally, the majority of education will occur during weekly resident conferences in a set educational block dedicated to oncologic-related topics in emergency medicine. The amount of time allotted to this block is dependent on several factors, such as 3- versus 4-year residency programs and how often the didactic curriculum is repeated during a resident's postgraduate education. In general, a minimum of 8 to 10 hours of fundamental oncologic emergency training using variable teaching methods is necessary to enhance knowledge retention. These methods can (and should) include PowerPoint® (Microsoft, Redmond, WA) lectures, small group education including problem- or case-based and team-based learning, simulation and role playing, flipped classroom, and bedside teaching.

Utilizing PowerPoint lectures for a portion of teaching in oncologic emergencies allows for the delivery of concrete, structured information to a large group of people. This provides a knowledge base to residents than can then be augmented using other learning techniques. In particular, small group learning creates high-yield and interactive didactic sessions that yield improved learner engagement, teamwork, clarification of knowledge gaps, and opportunities for resident assessment. Ideally, the small group session would be resident directed with a faculty leader available to answer questions, clarify any points of confusion, provide additional information as needed, and keep the group focused and on track [12].

Small group sessions can be conducted using team-based learning, case-based learning, or simulation/role play. In team-based learning, residents first complete an educational assignment. Subsequently, in conference they are tested on pre-class material via an individual readiness assurance test (iRAT), then a group readiness assurance test (gRAT), followed by a group exercise challenging residents to apply their knowledge to a scenario as a team. A single instructor is required to review learning points and clarify any confusion. Team-based learning has been shown to improve learning outcomes and examination scores as well as communication and teamwork skills [12]. Case-based learning utilizes vignettes of real or hypothetical patients to facilitate a discussion at each decision point. Throughout the case, an instructor asks questions to highlight different learning objectives, such as clinical presentation, development of a differential diagnosis, treatment, etc. This technique can also be used to tackle more challenging objectives within the oncologic emergency medicine curriculum, such as communication with a patient and/or their family or discussions on goals of care and do-not-resuscitate orders [13]. See Table 68.3 for an example case that can be used for case-based small group learning.

Table 68.3 Example case for small group learning

Case presentation	
History of presenting illness	A 67-year-old male with a history of hypertension, hyperlipidemia, coronary artery disease, and prostate cancer (last chemotherapy was 6 month ago) presents to the ED with back pain that began 6 days ago. Reportedly his pain extends from his mid- to lower back, is described as aching and sharp with occasional radiation into his legs bilaterally, and associated with intermittent tingling in his right foot. He says he thinks he may have injured himself while walking his dog but denies fall or specific injury. Additionally, he endorses back pain a few years ago but is unsure if his pain today feels similar. Patient denies fever, chills, bowel or bladder dysfunction, saddle anesthesia, weakness, numbness, history of intravenous drug abuse, or other symptoms
Medical history	Hypertension, hyperlipidemia, coronary artery disease, prostate cancer
Surgical history	Denies
Social history	Drinks alcohol socially, denies tobacco and illicit drug use
Physical exam	Vital signs: BP 156/95 HR 87 RR 98% SpO2 98% on RA T 37.0 General: Awake and alert, mildly cachectic male in no acute distress Skin: Clean, dry, intact, no rash Head: Atraumatic, normocephalic Eyes, ears, nose, throat: Pupils are equal round and reactive to light Neck: Supple, full range of motion, trachea is midline Cardiovascular: Regular rate and rhythm, no murmur, no edema Respiratory: Clear to auscultation bilaterally, non-labored Abdomen: Soft, nontender, nondistended Back: Limited range of motion secondary to pain, tenderness to palpation in the lumbar and thoracic spine Musculoskeletal: Strength is 5/5 to bilateral lower and upper extremities with full range of motion throughout Neurologic: Alert and oriented, sensation is within normal limits, difficulty ambulating secondary to pain without ataxia, deep tendon reflexes 2/4 bilaterally, normal Babinski reflex
Stop: Ask the following questions...	
What is your differential diagnosis?	Malignant spinal cord compression Spinal stenosis Herniated disc Musculoskeletal strain Bone metastasis

Table 68.3 (continued)

What tests would you order for this patient?	Complete blood count Comprehensive metabolic panel Magnetic resonance imaging (MRI) of the cervical, thoracic, and lumbar spine with and without contrast Or computed tomography (CT) scan of the thoracic and lumbar spine (if not at MRI-capable facility)
At this time, provide learners with the lab work and imaging requested for analysis	
What is the diagnosis?	Malignant spinal cord compression
How would you manage this patient?	Administer intravenous dexamethasone 10 mg STAT Consult neurosurgery to evaluate for possible operative intervention Consult radiation-oncologic for emergent radiation therapy Provide pain control Admit to hematology-oncologic or medicine service (if not an operative candidate)
Perform case debrief	
What went well? What did not? Are there any questions pertaining to this case? Has anyone taken care of a patient with malignant spinal cord compression? If so, what were barriers to care? Any general comments or concerns?	
Briefly discuss malignant spinal cord compression	
Include pathophysiology, clinical presentation, diagnosis, and intuition-specific management as well as management pathways based on other clinical scenarios (i.e., at rural ED)	

Simulation, on the other hand, provides more realistic, high-fidelity learning using mannequin simulators or standardized patients. Simulation delivers engaging, team-based active learning that can expose residents to more critical patient scenarios and has been shown to improve comfort in performing procedures, clinical performance, and knowledge retention [12]. Neutropenic fever with sepsis, malignant pericardial effusion with tamponade, spinal cord compression with progressive neurologic deficit, and airway obstruction secondary to a mass are scenarios that are particularly suitable for simulation.

A novel approach to resident education and small group learning known as the "flipped classroom" is also a valuable method for teaching oncologic emergency medicine. With this method, traditional in-class lectures and "homework" are reversed in that learners are assigned content to review at home prior to weekly didactic conference. This homework might include completing an online module, watching a video-recorded lecture, listening to a podcast, or reading a journal article or assigned textbook section to facilitate meeting an educational objective. In conference, instead of a traditional PowerPoint lecture, learners are asked to apply their new knowledge through small group activities requiring them to work through a problem or patient case, with the assistance of a skilled group leader. When successful, this technique creates a framework of core knowledge that is reinforced and cemented through an interactive process [14].

Lastly, longitudinal education in oncologic emergencies throughout the year is helpful to cement knowledge gained through patient encounters and didactic education. This can be done with on-shift bedside teaching, oral board cases, and teaching rounds. Some institutions utilize group sign-out or have a specified time dedicated to a short period of education on a selected topic. This topic could be something selected previously by the scheduled instructor or it could be based on a case encountered during the shift. Additionally, sending a podcast, new journal article, or other nugget of information to residents via email can also enhance their education.

Considering the variable teaching methods outlined above, a curriculum in oncologic emergency medicine that is learner-centered, facilitates engagement, and optimizes knowledge retention can be easily developed. See Table 68.4 for an example of a 10-hour curriculum.

Table 68.4 Example of an oncologic emergency medicine curriculum

Oncologic emergency medicine didactic block		
Day 1		
Subject	Teaching method	Time
Introduction to oncologic emergency medicine	Flipped classroom Pre-conference assignment: Sadik, et al., "attributes of cancer patients admitted to the ED in one year" [3] and/or Rivera, et al., "trends in adult cancer-related emergency department utilization" [6] Alternative method: PowerPoint lecture	30 min
Hematologic derangements and cancer	PowerPoint lecture Including neutropenic fever, blast crisis, hyperviscosity syndrome, leukostasis. Alternative method: Flipped classroom, team-based learning	40 min
Biochemical abnormalities and cancer	PowerPoint lecture Including hypercalcemia, tumor lysis syndrome, hyponatremia (syndrome of inappropriate anti-diuretic hormone), adrenal insufficiency. Alternative method: Flipped classroom, team-based learning	40 min
Break (10 min)		
Immunotherapy and its toxicities	Flipped classroom Identification of immunotherapy agents and CAR-T cell therapies. Toxicities related to these novel agents and potential treatments. Alternative method: PowerPoint lecture, team-based learning	30 min

(continued)

Table 68.4 (continued)

Oncologic emergency medicine didactic block		
Cancer prevention and diagnosis in the ED	PowerPoint lecture and team-based learning Guest from hematology-oncologic to discuss the role of the ED in prevention and diagnosis of management. Alternative method: Flipped classroom	30 min
Neutropenic fever Immunotherapy toxicity Biochemical abnormalities and cancer Difficult communication	Small group: Mix of case-based, team-based learning, and role play Residents will be divided into four small groups, each group will rotate through each small group session. Difficult communication (and breaking bad news) will be done via role play. Alternative method: Simulation, flipped classroom, oral boards, role play	2 hours 30 min at each station
Day 2		
Subject	Teaching method	Time
Topics in palliative care	PowerPoint lecture and group discussion Guest from palliative medicine to review relevant topics including breaking bad news, end-of-life care in the ED, goals of care discussions, etc. Alternative method: Flipped classroom	1 hour
Supportive care in the ED	PowerPoint lecture Outline treatment plans for symptomatic care (i.e., nausea and vomiting). Discuss pain control as it relates to the cancer patient – This may include palliative medicine guest and/or clinical pharmacist. Alternative method: Flipped classroom, team-based learning	30 min
Emergencies related to local tumor effects	Flipped classroom Including superior vena cava syndrome, malignant airway obstruction, spinal cord compression, brain metastasis, malignant pericardial effusion and tamponade, acute airway hemorrhage. Alternative method: PowerPoint lecture, team-based learning, case-based learning	50 min
Break (10 min)		
Chemotherapy, radiation, and associated toxicities	PowerPoint lecture Including extravasation of chemotherapy agents, medication-specific side effects, radiation complications, bone marrow transplant complications. Alternative method: Flipped classroom, team-based learning	30 min

Table 68.4 (continued)

Oncologic emergency medicine didactic block		
Airway obstruction Spinal cord compression Malignant tamponade Topics in palliative care	High-fidelity simulation modules Residents will be divided into four small groups, each group will rotate through the four different simulation sessions. Mannequins for difficult intubation and pericardiocentesis are needed. Alternative method: Case-based learning, team-based learning, oral boards	2 hours 30 min at each station

Implementation

For an oncologic emergency medicine curriculum to be successful, attention must be given to factors important to implementation success. The curriculum developer must ensure that sufficient political and financial support, resources, and administrative structures are in place [4].

First, support should be obtained from curriculum stakeholders. This will include the residency program director and the faculty leader of resident didactic curriculum, followed by the program's core faculty members. Because this curriculum will require preparation and teaching from those responsible for residency education, it is important that core faculty members support the initiative. Additionally, it would likely be beneficial to discuss the curriculum with the hematology-oncologic chair, fellowship program director, or other departmental leaders to ensure that the educational objectives and overall curriculum not only meet the educational needs of the residency, but also properly support the needs of the institution and local cancer population. Furthermore, support should be gained from learners. Adult learners need to understand why learning about oncologic emergencies is important. Having support from learners will foster successful curriculum implementation, particularly when independent learning is required, such as with flipped classroom modules.

Next, adequate resources should be identified. Resources will typically include personnel, facilities, time, and funding (if needed).

Personnel	Curriculum developer/director, expert faculty educators to teach didactics and lead small group activities, simulation director to coordinate simulation sessions, and administrative staff to communicate schedules and collect evaluation reports are all necessary for an oncologic emergency medicine curriculum. If faculty are not experienced with oncologic emergencies, consider faculty development sessions to facilitate enhanced knowledge and skill (see "Continuing Medical Education" further in this chapter).

Facilities	Resident conference room for didactic lectures, small group discussions, and flipped classroom activities. Simulation center for role playing and case-based learning. Clinical site (i.e., ED) to provide an appropriate volume and variable patient presentation to enhance clinical skills. Equipment, including a computer with projector, iPAD for simulation modules, simulation mannequin, software for learning modules, etc.
Time	Curriculum director will need time to coordinate curricular details, analyze evaluations, and provide feedback. Learners require time for independent learning, to attend educational sessions, and to provide feedback. Faculty need time to prepare and teach. Given that oncologic emergencies will be part of an existing resident didactic curriculum, this time is likely already part of core faculty protected hours and professional obligations.
Funding	Depending on the institution, funding may be required to purchase necessary equipment or software to support curriculum implementation. However, intuitions may already have budgets allocating resources for these items or necessary facilities/equipment may already exist and simply need redeployed to accommodate educational activities.

Before beginning a new oncologic emergencies curriculum (or making modifications to an old curriculum), it is advantageous to anticipate and address potential barriers that may occur. Barriers may relate to people, time, education strategies, finances, or other resources [4].

Educators	Competing demands from other job responsibilities or teaching obligations may limit faculty involvement. Limited knowledge of oncologic emergency medicine due to rapidly evolving treatment strategies may require that educators participate in developmental sessions or independent continuing education endeavors.
Learners	Residents may not understand the importance of each educational objective and therefore not actively participate in didactic education. A successful curriculum implementation necessitates comprehensive knowledge retention and achievement of clinical skills and therefore requires that residents take ownership of their own learning by investing time in studying oncologic emergencies outside scheduled conferences.
Time	Providing comprehensive didactic education in only 5 hours a week during residency is a challenging task. Additionally, residents are not always available to attend conference due to variable clinical rotation requirements, duty hour restrictions, or dispersal to different clinical sites.
Education strategies	When using a flipped classroom teaching strategy, if learners do not complete the pre-conference assignment, it limits the likelihood of a successful in-conference session. In addition, quieter residents or those who do not like to speak in groups may not benefit from in-conference discussion [14].
Funding or other resources	There may not be funding to support a curriculum developer/director or to purchase equipment or software that will enhance resident education.

Once support has been gained, resources allocated, and barriers addressed, it is time for curriculum implementation. Typically, this type of curriculum will not need a formal pilot period prior to full implementation. However, it may be worthwhile to pilot simulation and case-based learning sessions with fellow faculty members or residents to ensure they are designed appropriately to achieve educational objectives and knowledge retention. If flaws are discovered, adjustments can be made accordingly. Once piloting is complete, the new or improved oncologic emergency medicine curriculum should be scheduled into the overall resident didactic program.

Following implementation, a plan should exist for curriculum maintenance and enhancement based on feedback and evaluation. A curriculum developer may consider the first year of implementation a "pilot" cycle during which time achievement of goals and objectives is assessed, feedback from residents and faculty obtained and contribution to milestones analyzed. This information can then be used to refine the curriculum for subsequent cycles with a strategy in place for continuous improvement [4].

Evaluation and Feedback

Importantly, consideration should be given to maintaining and enhancing the oncologic emergency medicine curriculum over time. Evaluation helps judge whether goals and objectives were met, provides information that can be used to improve or alter the curriculum, allows for the assessment of resident achievement, and can serve as data for possible publication. Evaluation methods and questions should be developed based on the desired outcome and information sought [4].

The development of feedback should be methodical. First, the curriculum director should identify users of the evaluation, including residents, faculty instructors, program director, and the curriculum developer. Depending on the institution, this may also include the department chair, a hematology-oncologic representative, and individuals or organizations providing financial contributions. Additionally, consider how the evaluation will be used [4]. For the oncologic emergencies curriculum, this will include performance assessment of both the learners (i.e., residents) and the entire program.

Users	Residents will use evaluation and feedback information to understand and improve their own performance and clinical skills. Faculty instructors/small group leaders will use the data to enhance their teaching methods and delivery, thereby improving learner satisfaction. Curriculum developer/director will use the data to discover strengths and weaknesses of the program resulting in improved educational strategies. Program leadership will use resident evaluations and feedback to assist with assessment of achievement of clinical competencies and milestones.

Availability of resources will dictate evaluation questions and methodology [4]. For the purposes of an oncologic emergency medicine curriculum, necessary resources are not extensive, minimizing a potential barrier in obtaining feedback.

Resources	An online platform is needed to serve as a channel for residents and other individuals to complete evaluations. This can be done through residency management software (e.g., New Innovations®, Uniontown, OH). Administrative support staff or the curriculum director is needed to assist with evaluation requests and data analysis.

Evaluation questions should be congruent with curriculum objectives and relate to a specific learner, process, or clinical outcome [4]. During the first year of curriculum implementation, evaluations should be completed at the end of a pre-conference assignment, following a lecture, small group learning exercise, or simulation session, and after the curriculum is complete. This will allow the developer to assess the effectiveness of the curriculum and make necessary changes. In the subsequent years, evaluations can be tailored more toward the instructor, teaching method, and learner.

Resident Evaluation questions	Questions will be answered as strongly agree, agree, neutral, disagree, strongly disagree, and not applicable: The resident appeared to complete pre-conference assignments. The resident was engaged and paid attention to presentations. The resident performed adequate history and physical exam. The resident developed an appropriate differential diagnosis and management plan. The resident demonstrated clinical reasoning skills during case-based learning activities. The resident actively participated in small group activities. The resident communicated effectively with other residents in their group. The resident demonstrated professionalism and respectability toward peers and faculty instructors.
Faculty evaluation questions	Questions will be answered as strongly agree, agree, neutral, disagree, strongly disagree, and not applicable: I was impressed by the faculty member's overall knowledge of oncologic emergencies. The content presented is relative to my education and practice. The presentation was evidence based and without bias. The faculty member was an effective teacher with clear educational objectives. The faculty member communicated effectively with residents during small group education.
Curriculum evaluation questions	What do residents identify as major strengths and weaknesses of the oncologic emergencies curriculum? How could the curriculum be improved? What was the perceived effectiveness of the PowerPoint lectures, small group learning, simulation sessions, pre-conference assignments, and flipped classroom modules in providing valuable education on oncologic emergencies?

Finally, adequate data should be collected to ensure useful analysis. Failure to collect important information or low response rates can compromise the value of an evaluation. Data collection, therefore, should be designed to maximize response rates, practicality, and efficiency of evaluation completion. Following collection, data must be analyzed and reported. When considering how to report assessment information, it is helpful to consider the needs of users. Specifically, residents will benefit from immediate feedback to allow for the information to be processed while the experience is still fresh in their mind [4].

Data collection	Electronic collection of individual and curriculum assessment should be utilized. This can be implemented within an already existing generic evaluation method or a more specific approach can be developed. Each component as well as the overall oncologic emergencies curriculum should be evaluated separately. During the first year of implementation, it is advantageous to obtain specific data on instructional strategies, teaching methods, individual instructors, and overall program content, to maximize curricular enhancement and address unforeseen issues.
Data analysis	Analysis of completed evaluations should occur in real time to optimally facilitate necessary changes while the memory of curriculum details and experience are fresh.
Reporting of results	Immediate formative feedback should be given to residents following any small group activity involving direct observation by a faculty member. If significant concerns are appreciated, this information should be given to the residency program director. Reported feedback should be constructive, using succinct, clear language. A summary of formative and summative information must be given to the curriculum director so that improvements can be made and unmet curricular needs assessed.

While the general process of evaluation and feedback can be cumbersome, it is essential to assess resident learner performance and to guide effective education.

Medical School Education in Oncologic

Acquiring knowledge and clinical skills that will enable physicians to optimally care for cancer-related emergencies begins with undergraduate medical education. Medical

school is essential to provide a foundation of cancer knowledge that can be expanded upon during residency. However, delivering a comprehensive oncologic curriculum to medical students is challenging due to the field's multidisciplinary nature and lack of data on effective teaching approaches [15, 16]. To better characterize oncologic education, surveys of medical students across the United States suggest the following: students are significantly more confident in the basic science of cancer than in workup/diagnosis, treatment, and interacting with oncologists; pre-clinical oncologic education is often fragmented and varies considerably among intuitions [16]; and few schools have mandatory clinical clerkships dedicated to oncologic [15, 16]. Cancer was also found to be under-emphasized in medical school curriculums [15]; it is the second leading cause of death in the United States (behind heart disease) [17], yet it reportedly receives the fourth most curricular time among the six most common causes of death [15].

Another component introduced during medical school and relevant to caring for patients with cancer-related emergencies is palliative and end-of-life care. Palliative care can (and should) include patient and family communication to discuss goals of care, pain and symptom management for critically ill and dying patients, coordination of care, and optimizing quality of life. US medical schools are not currently required by the Liaison Committee on Medical Education (LCME) to teach palliative care, though it does necessitate that curricula include instruction on end-of-life care. The Association of American Medical Colleges (AAMC), however, does recommend that undergraduate medical students learn about shared decision making, communication of bad news, advanced directives, end-of-life wishes, do-not-resuscitate orders, and palliative care [18].

Surveys collected every 5 years since 1975 find dramatic variability among medical schools on the amount of time spent teaching end-of-life care, ranging from 2 to 80 hours over 4 years. Less than one-third reported a clerkship dedicated to end-of-life care, and of these, only one-half are required. All but one responding medical school provided dedicated palliative care education. Another survey reports that of 47 responding medical schools, 30% had a required course, 19% had a required rotation, 15% offered an elective, and 7% offered no course or rotation. The remaining 29% of schools integrated palliative care teaching within another mandatory rotation. Fourth-year students receiving formal training in palliative care reported superior competence and knowledge in caring for the critically ill and dying [18].

This analysis of undergraduate medical education in oncologic and palliative care indicates that medical schools can benefit from a more defined curriculum. With enhanced cancer survivorship, the need for cancer-related knowledge and skills among generalists and specialists will increase proportionally [16]. However, given the limited amount of didactic time available for any one area of medicine, developing an effective oncologic curriculum is challenging. Neeley et al. suggest the following [15]:

1. Improve the organizational structure and coordination of oncologic didactics across all years of medical school to avoid redundancy or accidental omission of content and to ensure there is balance among the types of cancer covered and types of educators who are teaching.
2. Request multidisciplinary contribution to curriculum development to facilitate a more inclusive approach to teaching cancer management.
3. Avoid pure disease-site and organ-system-specific courses; instead supplement them with education on general principles of oncologic, survivorship care, palliative medicine, and the role of primary care physicians in cancer prevention, diagnosis, and management.
4. Create a multidisciplinary oncologic clerkship that provides broad exposure to caring for patients with cancer and incorporates outpatient oncologic exposure for students who plan to pursue non-oncologic fields of medicine.
5. Support the development of national guidelines for medical school education in oncologic, as has been established in Europe, Canada, and Australia.

Another consideration is to create a course to supplement oncologic education similar to the one developed by the European School of Oncologic (ESO). This elective 5-day training program is dedicated to improving medical students' oncologic knowledge and clinical skills. The program includes education in prevention, epidemiology, clinical presentation, diagnosis, and multimodal therapeutic management. It also includes sessions on oncologic emergencies and palliative care [19].

Finally, optimal medical school education in oncologic must include palliative medicine training. According to Horowitz et al. and Head et al., the following must be considered for our undergraduate medical education: 1) palliative care education cannot be limited to electives; it should be integrated into existing courses, such as the practice of clinical medicine, ethics, and pharmacology, as well as in relevant clinical clerkships; 2) basic principal palliative care competency requirements should be established and implemented in all medical schools; and 3) palliative care training should provide developmentally appropriate education for students to achieve these competencies at each stage of schooling [18, 20].

Hematology-Oncologic Fellowship Training

While many cancer patients with concerning symptoms seek treatment at urgent care centers or emergency departments, they may also present to their oncologic clinic or call an oncologic provider after hours. Oncologists also routinely manage these patients after hospital admission. It is thus vital for hematologists and oncologists to be expert in the diagnosis and management of oncologic emergencies.

Though some experience is gained during internal medicine residency, fellows require more advanced and specific knowledge when they begin treating cancer patients early in their fellowship. Currently, hematology-oncologic fellowships in the United States either disperse inpatient clinical duties (including consult and bone marrow transplant services) throughout all 3 years or concentrate them into a more intense first year of fellowship. Didactics and continuity clinics supplement this training. While these experiences provide fellows with gradual hands-on knowledge and understanding of the diagnosis and management of oncologic emergencies, the establishment of a dedicated educational module early in fellowship would enhance learners' confidence in clinical care.

Oncologic emergencies are broad and encompass every system of the human body. For disease-specific emergencies, they can be categorized and taught via systems [21]. Systems categories include metabolic and endocrine (e.g., hypercalcemia, tumor lysis, adrenal), hematologic (e.g., leukostasis, hyperviscosity), neurologic (e.g., vasogenic edema from brain metastases, malignant spinal cord compression, paraneoplastic syndromes such as Lambert-Eaton), cardiovascular (e.g., pericardial effusion, superior vena cava syndrome), and pulmonary (e.g., pleural effusion, airway obstruction, and hemorrhage). The other major type of oncologic emergencies is treatment-related. This subject is particularly important to hematology-oncologic fellows because their exposure from residency didactics and clinical experience is limited. Some examples include immunotherapy-related adverse events, coronary effects from fluoropyrimidines, arrhythmias from ibrutinib, pulmonary toxicity from bleomycin, thrombotic microangiopathy from gemcitabine, and cytokine release syndrome from CAR-T or blinatumomab.

Ideally, a module in oncologic emergencies would include short, case-based didactic sessions at the beginning of fellowship. Cased-based learning has been shown to promote effective learning through increased engagement and authentic clinical practice scenarios [22]. In case-based learning, specific scenarios that resemble realistic patients are created for learners to solve and generate discussion regarding management and treatment plans. This allows fellows to connect theory to a practice situation, thereby integrating basic science and clinical management resulting in active learning and enhanced retention of knowledge [22]. For example, oncologic pharmacists can be incorporated into case-based learning sessions to provide training on specific chemotherapies and medication toxicities to which most fellows likely would not have had extensive exposure. Educational modules on treatment-specific chemotherapy and other pharmaceutical toxicities can then be incorporated into lectures and clinical discussions spread throughout the year. The goal of these sessions would be to reinforce concepts and management strategies to broaden clinical knowledge and skills throughout fellowship.

Including such a module would be a relatively small change that can be made to most hematology-oncologic fellowships without sacrificing the overall curriculum or other valuable learning concepts. Then, instead of progressive learning over several years, fellows will achieve a better knowledge base earlier in fellowship resulting in enhanced quality of care for cancer patients with emergent conditions. To facilitate widespread implementation of this module, the American Society of Hematology (ASH) and American Society of Clinical Oncologic (ASCO) may be able to help. The ASH and ASCO work with the ACGME to create and enforce program requirements and milestones; they also provide workshops and various online programs for both program directors and fellows. These societies could create a recommended oncologic emergencies module that would enable individual programs to then implement this didactic program in a way that suits their specific educational needs with regard to clinical environment, time, and staffing requirements.

Feedback is fundamental to this process. Once the introductory oncologic emergencies module is complete, learners should be asked to provide feedback and evaluate the teaching methods and educational concepts, and instructors to promote effective change. This should be repeated at the halfway point and the end of the first year of fellowship to gather additional comments or critiques as fellows gain further knowledge and clinical experience. Participation should be confidential so opinions can be voiced freely. Improvements and changes can then be made for the new fellows and the entire educational process can be continually refined.

Oncologic Emergency Medicine Fellowships

As the cancer population grows, more and more will seek emergent care. Understanding this need, two oncologic emergency medicine fellowships have been developed, one at The University of Texas MD Anderson Cancer Center and another at The Ohio State University [23].

The University of Texas MD Anderson Cancer Center opened an academic ED within its comprehensive cancer center in 2010. This 40-bed center provides care to almost 26,000 patients with cancer-related conditions annually (approximately 70 patients per day). Their oncologic emergency medicine fellowship was then established in 2011 to provide additional training in the diagnosis, treatment, and multidisciplinary management of ED cancer patients [24]. This fellowship is 1 year (with an optional second year) dedicated to expanding the knowledge of those interested in pain and symptom management, palliative care, and oncologic emergencies. Each fellow works three 10-hour shifts per week in the ED under faculty supervision, completes in-office research and administrative work 2 days per week, attends weekly didactic presentations for 2 hours, and attends faculty meetings and/or graduate medical education curricular lectures on a weekly basis. Second-year fellows pursue their selected clinical track and a research project. Fellow performance is assessed by the program director through biannual evaluations and faculty observation. Additionally, program feedback is obtained through biannual evaluation of the curriculum [23].

The James Cancer Hospital at The Ohio State University Wexner Medical Center opened its own oncologic ED in 2014. This 15-bed department sees approximately 13,000 patients with cancer each year and functions as an integrated component of their general ED. Their 1-year oncologic emergency medicine fellowship was established in 2017. Each fellow completes 7 months of training in the James ED and 1 month of education with each of the following services: oncologic, hematology, neuro-oncologic, and palliative medicine. Fellows also receive 1 month of protected time to conduct research and work on other scholarly projects. Additionally, each fellow can create their own niche and explore individual interests by pursuing an administration, research, or education path within the fellowship [23].

Continuing Medical Education

Beyond residency and fellowship, practicing physicians must continue to educate themselves in oncologic emergencies. This is important not only to provide quality patient care but also to properly educate learners on this topic at the bedside. Unfortunately, opportunities in continuing medical education specific to cancer-related conditions are limited. Most education focuses on febrile neutropenia, hypercalcemia in malignancy, superior vena cava syndrome, hyperviscosity syndrome, and tumor lysis syndrome, and there is little vetted information on more innovative topics such as immunotherapy toxicities. Nationwide, there are some educational opportunities within professional organizations' yearly conferences, such as the American College of Emergency Physicians (ACEP) Scientific Assembly or Society of Academic Emergency Medicine (SAEM) Annual Meeting. Additionally, there are two conferences dedicated specifically to oncologic emergency medicine: MD Anderson Cancer Center's Oncologic Emergency Medicine conference and Memorial Sloan Kettering Cancer Center's Emergencies in the Cancer Patient course.

National and Institutional Research Efforts

69

Cielito Reyes-Gibby and Jenny L. Ren

Introduction

Advances in cancer diagnosis and treatment have led to increasing life expectancy of cancer patients. The number of cancer survivors in the United States has more than tripled over the past 30 years to over 16.9 million Americans [1]. As cancer evolves to a chronic disease, and with toxicities arising from cancer treatments including surgery, chemotherapy, radiation, and newer cancer therapies, both disease and symptom management of the cancer patient continue to increase in complexity. Many of these patients receive care in emergency departments as most cancer therapies are provided on an outpatient basis. Rapidly identifying the risk profiles of these patients, along with understanding the timing, sequence, duration, and treatment of disease processes and treatment effects, is the most important challenge faced by practitioners in oncologic emergency medicine.

The National Institutes of Health (NIH) invests about $41.7 billion annually to support medical research in the USA [2]. The majority (80%) of this funding supports extramural research awarded through almost 50,000 competitive grants supporting more than 300,000 researchers from more than 2500 universities, medical schools, and other research institutions in every state. Table 69.1 shows the different NIH institutes and centers and their years of establishment [3]. Each fiscal year, these institutes or centers are required to prepare for the US President and US Congress its best professional judgment on the optimum funding needed to make the most rapid progress in their area of science, including funding research investigators, research training, and education of new investigators. In 1937, the National Cancer Institute became the first institute to be established. No institute is dedicated solely to emergency medicine. Advancing

Table 69.1 Institutes and centers established at the National Institutes of Health (US Department of Health and Human Services)

Institutes and Center	Acronym	Year established
National Cancer Institute	NCI	1937
National Heart, Lung, and Blood Institute	NHLBI	1948
National Institute of Allergy and Infectious Diseases	NIAID	1955

the science of oncologic emergencies will require collaboration with scientists from different disciplines, building upon existing research infrastructure and investing on research training for ED practitioners. In this chapter, we review research focusing on oncologic emergencies and present the study limitations identified by the authors, present two ongoing research programs at a national and institutional level, and offer future directions.

Limitations of Published Oncologic Emergency Research

This review discusses common limitations of published oncologic emergency research. We searched PubMed using the following terms: {[Emergency (Title/Abstract) or EM (Title/Abstract) or EMS (Title/Abstract) or ED (Title/Abstract)) and [Cancer (Title/Abstract) or Neoplasia (Title/Abstract) or Oncolog* (Title/Abstract)] and limited to publications within the last 10 years. After review of 444 abstracts, we included 48 articles on cancer patients presenting to the emergency department (Table 69.2) [4–51]. Of note, knowledge gaps in emergency care of cancer patients have already been published in the 2016 "Cancer and Emergency Medicine: Setting the Research Agenda" that identified four main research opportunities and priorities to advance the understanding of oncologic emergency care: (1) collection of epidemiologic data, (2) care of patients with febrile neutropenia, (3) information on acute events such as dyspnea or pain, and (4) palliative care in the ED setting [4]. The topics of most, if not all, included articles in this review touch on one or more of these themes.

Table 69.2 Limitations of published studies on oncologic emergencies

Author-Year	Title	Study type, population	Findings	Limitations
Brown et al. 2016 [4]	The emergency care of patients with cancer: Setting the research agenda	Research agenda	Identified research opportunities and priorities to advance understanding of emergency care: (1) collect epidemiologic data, (2) care of patient with febrile neutropenia, (3) acute events like dyspnea and acute pain, and (4) palliative care in the ED	—
Philip et al. 2018 [5]	The experiences of patients with advanced cancer and caregivers presenting to emergency departments: A qualitative study	Cross-sectional study, 19 patients with advanced CA and ED visit, 10 informal caregivers	ED presentations largely prompted by worsening symptoms or to expedite hospital admission – Many directed to ED by PCP. ED experience: Anxiety, uncertainty with communication, the general environment, symptom management delays. Long waits common. Patients felt relief at receiving care	Limited number of EDs, only two services, English-speaking only
Coyne et al. 2017 [6]	Application of the MASCC and CISNE risk-stratification scores to identify low-risk febrile neutropenic patients in the emergency department	Retrospective cohort study, 230 patients from 2 academic EDs	Presenting with chemo-induced febrile neutropenia, CISNE identified 23% as low risk, highly specific (98.3%) for low-risk cohort for all outcomes (inpatient LOS, upgrade in LOC, clinical deterioration, positive blood cultures, death). Median LOS shorter for low- vs. high-risk patients (3-day difference). MASCC score was much less specific (54.2%) in identifying a low-risk cohort	Misclassification bias (especially for patient symptoms), retrospective study based on chart review, missing data, both sites NIH CA centers, thus increased disease relative to general ED population
Adler et al. 2019 [7]	Validation of the emergency severity index (version 4) for the triage of adult emergency department patients with active Cancer	Analysis of observational cohort, 1008 patients from CONCERN (18 EDs)	ESI scores among ED patients with active CA indicate higher acuity than general ED population. ESI associated with patient disposition/resource use. No significant association between ESI and non-ED based outcomes (hospital LOS, 30-day mortality)	Academic, urban setting. 21% of total ineligible, excluded as too ill or unable to consent, fewer high acuity patients. Resource use not well defined in ESI handbook, underestimated. English-speaking only

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Caterino et al. 2019 [8]	Analysis of diagnoses, symptoms, medications, and admissions among patients with cancer presenting to emergency departments	Observational prospective cohort study, 1075 adults with active CA from CONCERN (18 EDs)	Mean age 62 (47% > 64), 51.8% female, 73.9% with CA treatment in preceding 30 days, 62.7% had advanced or metastatic CA. 5 most common ED diagnoses were symptom-related. 7.6% placed in observation, 57.2% admitted. 25% admissions had LOS of 2 days or less. Pain during ED visit present in 62.1%, mean pain score 6.4/10. Pain in 72.2% during prior week. ED opioids given to 59.1% with moderate/severe pain. Outpatient opioids for 47.4% patients (with pre-ED pain), including 57% with quite a bit or very much pain. ED nausea present in 31.3% (47.6 received antiemetics). Antibiotics given to 26.5% (73.3% admitted vs. 54.1% not receiving antibiotics)	Large, urban, academic centers, more CA centers. Community ED differs in patient characteristics, resources, outcomes. May have underestimated severity within participating academic institutions. Didn't enroll all presenting CA patients. Some too ill/couldn't participate. Many non-English-speaking CA patients with limited English report inferior treatment outcomes. Underestimated illness severity, 2 possible effects: (1) symptom severity/frequency, admission rate, hospital LOS, other variables related to severity may represent lower severity, and (2) ceiling effect as more challenging to improve outcomes in healthier group. Couldn't identify use of healthcare services in other hospitals, thus underestimated ED revisit/readmission rates
Mueller et al. 2016 [9]	Frequent emergency department utilizers among children with cancer	Retrospective cohort, PHIS database	Frequent utilizers account for 58% of ED visits. They differed from infrequent users by CA type: 39.3% of frequent users had ALL and 16% had CNS tumors (vs. 21.9%, 24.8%, respectively). Frequent use associated with age 5–9 or 1–4 or age < 1 vs. 15–19. Also Hispanic vs. white, non-Hispanics, urban residence. Few children received no meds, lab, imaging during ED visit	Possible patient undercount as some are diagnosed/treated as outpatients. Only tertiary facilities, possible underestimation of prior care
Richards et al. 2011 [10]	Palliative care symptom assessment for patients with cancer in the emergency department: Validation of the screen for palliative and end-of-life care needs in the emergency department instrument	Prospective observational cohort study, 53 patients	53% subjects male, age 24–88. Most common CA diagnoses were breast, colon, and lung. The SPEED instrument demonstrates reliability and validity	Patient population in tertiary center ED may not generalize to other EDs. English-speaking patients in tertiary center
Ahn et al. 2018 [11]	Comparison of the MASCC and CISNE scores for identifying low-risk neutropenic fever patients: Analysis of data from three emergency departments of centers in three continents	Retrospective, 571 patients from 3 tertiary CA ED centers in USA, UK, S. Korea	MASCC: 89.1% classified as low risk, CISNE: 10.5%. MASCC had more discriminatory power in detecting low risk. Risk scores should be used in conjunction with clinical judgment to identify patients suitable for outpatient management	Misclassification bias due to retrospective nature. Tertiary centers are less generalizable

(continued)

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Delgado-Guay et al. 2016 [12]	Characteristics and outcomes of patients with advanced cancer evaluated by a palliative care team at an emergency center. A retrospective study	Retrospective case control, 400 patients	Median age 56 years old, 56% female, 61% white, no demographic differences between ED and inpatients. Median time from admission to palliative care 12 h for ED patients vs. 24 h for inpatients. For ED vs. inpatients, symptoms included uncontrolled pain (83%/45%), N/V/constipation (41%/19%), dyspnea (29%/19%). At follow-up, improvement in pain, sleep, Well-being, fatigue, anxiety, appetite, dyspnea, nausea, depression, drowsiness. After PC consults, discharge/admission destinations for ED patients were home (33%), home hospice (7%), inpatient hospice (4%), regional hospital floor (33%), and PC unit (23%). Median duration of hospitalization 92 h for hospitalized ED patients and 125 h for inpatients. Referral to PC from ED led to earlier delivery of PC with earlier control of symptoms. ED patients receiving PC consults had shorter hospitalizations than those receiving PC referral as inpatients	Retrospective – Impossible to estimate causality between PC service involvement in ED patients and outcomes. Highly specialized CA center, unique patients. Difficult to describe all interventions provided by PC to ED patients vs. inpatients. Need multicenter prospective studies at national/international levels
Banala et al. 2017 [13]	Discharge or admit? Emergency department management of incidental pulmonary embolism in patients with cancer: a retrospective study	Retrospective cohort, 193 patients	Selected ED CA patients with incidental PE can be treated safely with low-molecular-weight heparin and discharged. Of 193 patients, 70% discharged, 30% admitted. 30-day survival rate: 99% for discharged, 76% for admitted. 98% received ED anticoagulant (90% LMWH). Incident saddle PEs had higher 30-day mortality. Age, comorbidity, race, CA stage, tachycardia, hypoxemia, and incidental PE location associated with hospital admission	Single center, limited numbers. Retrospective. No randomization of treatment. Health outcomes related to PE not well distinguished from those related to advanced CA. Need larger RCT
Batalini et al. 2017 [14]	Cancer complaints: The profile of patients from the emergency department of a Brazilian oncologic teaching hospital	Cross-sectional, 277 ED visits	Pain was most common complaint (40% visits) > constitutional symptoms (17%) > GI complaints (11%). Abdominal pain most noted pain type (18.4%) with highest rate of recurrence > back pain. Cervical CA (14.8%), breast (11.6%), lung (7.6%). Majority of patients visited ED less than once a month	Single site. No staging data. Patients may visit ED for more than 1 complaint and symptoms overlap. No longitudinal follow-up. Importance of research to finding new therapies
Baugh et al. 2016 [15]	Emergency department management of patients with febrile neutropenia: Guideline concordant or overly aggressive?	Retrospective cohort, 173 ED visits to Dana-Farber Cancer Institute	25% of visits low risk, 75% high risk. Management overall was guideline concordant in 70%, discordant in 98% low-risk patients vs. 7% high-risk patients. Of 52 guideline-discordant cases, 83% involved low-risk cases with more aggressive treatment than recommended	Single-center study. Retrospective chart review. Model may lack important unmeasured covariates. Nonadherence could be due to awareness gap or factors not captured in chart review. Couldn't tell if management plan driven by ED or oncologist. Did not power the study to detect differences in clinical outcomes between risk groups

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Brown et al. 2017 [16]	An exploration of medical emergency team (MET) intervention at the end of life for people with advanced cancer	Case control, 100 patients	Cohort without MET intervention had better quality of death score vs. MET patients. Within MET cohort, if MET influenced EOL decision-making (n = 19), had a significantly higher quality of death score vs. MET patients where MET did not influence care	Retrospective chart review. Misinterpretation of quality of death indicators. Single CA center. No record of EOL discussions, family members'/friends' perceptions of quality of death. Need prospective observational study to enhance understanding of MET in EOL CA care
Elsayem et al. 2017 [17]	Advance directives, hospitalization, and survival among advanced cancer patients with delirium presenting to the emergency department: a prospective study	Prospective cross-sectional observational study, 243 randomly selected CA patients from MD Anderson ED	Group A = delirium diagnosed by both CAM and MDAS; group B = MDAS only; group C = neither. Hospitalization rates for A 82%, B 77%, C 49%. ICU rates: 18%, 14%, 2%. Advance directives: 52%, 27%, 43%. Median overall survival: 1.23 month, 4.7 months, 10.45 months. Overall survival did not differ between groups A and B, but group C survival exceeded other groups. Delirium assessed by either CAM or MDAS was associated with worse survival and more hospitalization in patients with advanced CA. Many advanced ED CA patients with delirium lack advance directives	Single-center study. Number of patients small. Did not adjust for comorbidities or illness severity. Did not follow patients longitudinally to evaluate whether further interventions were done during hospitalization or if patients discharged to hospice
Elsayem et al. 2016 [18]	Delirium frequency among advanced cancer patients presenting to an emergency department: A prospective, randomized, observational study	RCT, 243 English-speaking patients with advanced CA from MD Anderson ED	Median age 62. 9% had CAM+ delirium, median MDAS score 14. Patients with delirium had poorer performance status than patients without (but 2 groups did not differ in other characteristics). 10% of age > 64 patients had CAM+ delirium vs. 8% age < 65. Mild delirium in 82%, moderate in 18%. Physicians identified delirium in 59% of CAM+ patients	Single center, small sample. Unblinded ED physicians to potential of delirium in their patients, thus bias favoring more frequent recognition. Selection bias: Excluded unstable patients, refusal, dementia. Could have higher delirium prevalence than those consenting, thus underestimates prevalence of delirium. Did not enroll patients at night
Elsayem et al. 2016 [19]	Presenting symptoms in the emergency department as predictors of intensive care unit admissions and hospital mortality in a comprehensive cancer center	Retrospective cohort, 9246 patients, 16,038 visits to MD Anderson ED	Main presenting symptoms: Pain, fever, dyspnea. 58% admitted to hospital at least once (range 1–13), 13% admitted to ICU at least once, 11% died during hospitalization. Independent predictors of hospital death: Presenting symptoms of respiratory distress or altered mental status, lung CA, leukemia, lymphoma, nonwhite race. Patients who died had longer LOS than those discharged alive	Retrospective, single center. No data on whether patients had advanced progressive or limited disease or whether they were treated for cure or palliation. No tumor staging. Used only main presenting symptoms, many patients had multiple or secondary symptoms. Systematic symptom assessment will allow better understanding of multiple symptoms and their impact on QOL
Kyeremanteng et al. 2019 [20]	Outcomes and cost of patients with terminal cancer admitted to acute care in the final 2 weeks of life: a retrospective chart review	Retrospective cohort, 130 patients who visited ED within 2 weeks of death, the Ottawa Hospital	85% had metastatic disease. 71% of admitted patients did not have advanced care directives. 18% receiving palliative care. Patients hospitalized for 7 days on average. Hospitalization costs 2.5 times estimated hospice cost	Retrospective, single-center study, small sample size. Chart review – Not all data recorded. Cost calculations based on crude estimates

(continued)

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
El Majzoub et al. 2019 [21]	Adverse effects of immune checkpoint therapy in cancer patients visiting the emergency department of a comprehensive cancer center	Retrospective review, 257 ED patients receiving immune checkpoint therapy from MD Anderson ED	25% of visits related to immune-related adverse effects. Diarrhea was most common reason for visit. Proportions of visits associated with diarrhea, hypophysitis, thyroiditis, pancreatitis, or hepatitis varied significantly by immune checkpoint therapy agent. Colitis associated with better prognosis; pneumonitis with worse survival	Single institution, limited size. Physicians performing data abstraction not blinded to outcomes or previous abstraction results when performing data confirmation. EMR may be erroneous. Underestimated true survival (used last confirmed contact when death unverified). Immunotherapy always changing (available agents, approved indications, patient characteristics)
Mueller et al. 2019 [22]	Identifying patient-centered outcomes for children with cancer and their caregivers when they seek care in the emergency department	Cohort, 26 caregivers or children with CA from IU Riley Hospital for children Heme-Onc clinic	More important outcomes included system-level issues (e.g., cleanliness, timeliness) and oncologic-provider or ED-provider level issues (ability to access port-a-caths, quality of communication). Also identified outcomes that were within control of patient/caregiver, such as improving their sense of preparedness	Need future research on development and validation of patient-centered outcomes tool. Single institution – Data may not be representative. Small sample size
Peyrony et al. 2020 [23]	Antibiotic prescribing and outcomes in cancer patients with febrile neutropenia in the emergency department	Cohort, 249 patients	Median age 60, 67.9% hematological malignancy, 10.4% admitted to ICU, 9.8% died during hospital stay. 32.4% of low-risk patients presented at least 1 complication, including 11 deaths. Time to antibiotic initiation in ED not associated with outcome after adjusting for performance status and shock index. Inadequate ED antibiotic regimen associated with higher ICU admission and death during hospital stay (OR = 3.5). An inadequate ED antibiotic regimen in patients with FN was significantly associated with higher ICU admission or death during hospital stay	Retrospective, interpretation bias during chart abstraction. Antibiotic appropriateness may vary between centers. Possible missed confounders. Single-center – External validation needed
Reyes-Gibby et al. 2017 [24]	Cohort study of oncologic emergencies in patients with head and neck cancer	Prospective cohort, 298 patients	History of HTN, normal or underweight BMI, and probably depression predicted increased risk for ED presentation. BMI and severe pain associated with higher frequency of ED presentations	Small sample size. HPV status missing. Limited to patients with HNSCC from 1 tertiary care CA center. Possibly did not capture all ED visits (e.g., other hospital ED). Lack of data on etiology of pain
Reyes-Gibby et al. 2016 [25]	Risk for opioid misuse among emergency department cancer patients	Cross-sectional, 209 patients	On basis of SOAPP-R (screener and opioid assessment for patients with pain-revised) cutoff of 18, 34% patients had high risk of misuse. 15% and 4% of all patients reported past or current use of illicit substances, respectively. Total number of annual opioid prescriptions differed between high- and low-risk groups. Depression, poor coping, and illicit substance use were associated with high risk of opioid misuse	Single center. Patients already receiving opioids – May have affected survey responses. Patient self-report. Number of opioid prescriptions is imperfect representation of actual dosage/pill count. Future studies of patients with CA-related pain should include multiple measures of risk (risky medication-related behaviors, structured interview). Potentially inaccurate alcohol and smoking status. Nonrespondents had higher pain scores

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Tanriverdi et al. 2014 [26]	Single center experience on causes of cancer patients visiting the emergency department in Southwest Turkey	Retrospective cohort, 102 patients, 304 ED visits	65% patients male, 52% over age 65. 30% lung CA, 32% with dyspnea, 53% with metastasis, 30% with multiple metastatic lung lesions, 68% had poor ECOG performance status	Small sample size, single center
Yang et al. 2016 [27]	Cardiac troponin is a predictor of septic shock mortality in cancer patients in an emergency department: a retrospective cohort study	Retrospective cohort, 375 ED CA patients with septic shock	Creatine kinase myocardial band fraction and troponin-I significantly higher in patients who died in ≤7 days and ≤28 days than in those who did not. The SOPED (septic oncologic patients in emergency department) scoring system, which incorporated troponin-I, was more prognostically accurate than were other scores for 7-day mortality	Single center, small sample size, retrospective. Results should be verified in large well-designed multicenter clinical study. Advances in management of sepsis occurred during study time. Prognosis of CA patients with septic shock probably not generalizable to non-CA
Lamb et al. 2019 [28]	Hodgkin lymphoma detection and survival: Findings from the Haematological malignancy research network	Cohort, 971 patients	Median diagnosis at age 41.5, 55.2% male, 31.2% stage IV. 43% had moderate to high or high-risk prognostic score. 18.7% admitted via ED prior to diagnosis. Relationship between age and ED admission was U-shaped: More likely in patients <25 and > = 70. Compared to patients admitted via other routes, those via ED had more advanced disease and poorer survival. After adjusting for clinically important prognostic factors, no difference in survival remained	Lack of primary data, could not investigate patterns or referrals from primary care, Hodgkin lymphoma is rare
Mayer et al. 2011 [29]	Why do patients with cancer visit emergency departments? Results of a 2008 population study in North Carolina	Observational, 2008 NC DETECT ED visit data, 37,760 ED visits, 27,644 CA patients	77.2% of patients had 1 ED visit in 2008. Mean age 64, slightly more men. Among visits, Medicare 52.4%, Medicaid 12.1%. >1/2 visits weekends or evenings, 44.9% during office hours. Top 3 complaints: Pain, dyspnea, GI issues. Lung, breast, prostate, and colorectal CAs had largest proportions. 63.2% visits resulted in hospital admission. Patients with lung CA were more likely to be admitted than other CA types	All data collected for other purposes. No associations between county of residence, site of usual healthcare, and location of ED (NC DETECT didn't allow identifying information). No data on whether patients were under clinical care or where. No race/ethnicity data. Some visits that were CA-related may have been missed, some visits that were not CA-related may have been included. Not possible to identify visits by patient to multiple EDs. Limitation to categorization of presenting symptoms (not exhaustive/completely inclusive). Not possible to tell if some patients visited local EDs because routine care was at a CA center far from home. If healthcare services had been available, could those patients have avoided an ED visit? Need more info about these patients before and after their visits

(continued)

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Mueller et al. 2016 [30]	Characteristics of children with cancer discharged or admitted from the emergency department	Retrospective, 26,770 ED visits, 17,943 children with CA from 39 children's hospitals	Half of children with CA visited ED within 1 year after their first CA hospitalization in pediatric health information system (PHIS). 56% of ED visits resulted in admission. Fever and neutropenia were most common reasons for visits (34.6%). Risk factors: "Other" race/ethnicity, history of transplant, and ED visits reasons including neutropenia, bloodstream infection, pancytopenia, dehydration, or pneumonia	Some patients diagnosed and treated as outpatients. PHIS does not include data on disease status, treatment, or time since last treatment for patient when they visit ED. discharge ICD-9 codes limits understanding of chief complaints to ED, thus lacks key data for anticipatory guidance. Extrapolated reasons for ED visit from ICD codes rather than the initial complaint. Only single diagnosis evaluated per patient encounter, but children with CA may present to ED with multiple problems
Mueller et al. 2020 [31]	Variation in hospital admission from the emergency department for children with cancer: a pediatric health information system study	Retrospective cohort, 60,054 ED visits for children with CA, using PHIS data	62.5% admitted, primary diagnosis – Fever. Largest variability in admission rates. Less variability among hospital admission rates for neutropenia and febrile neutropenia. Admission rates by day of the week did not demonstrate significant variability and no differences seen between weekend and weekday	ICD codes may not accurately identify all CA patients, leading to over/underestimate of ED cases. PHIS data set did not reliably detect ED chief complaint – Extrapolated from ICD9 codes. Variability in coding by hospital, PHIS did not include all hospitals that treat children with CA. No access to important clinical data. Did not account for holidays
Patel et al. 2017 [32]	Evaluation of emergency department management of opioid-tolerant cancer patients with acute pain	Retrospective cohort study, 216 patients Opioid-tolerant CA patients who received opioids in ED over 2 years	61.1% of ED patients received adequate initial PRN dose of opioids. Of patients taking <200 OMEs per day at home, 77.4% received an adequate initial dose. 3.2% of patients taking >400 OMEs per day at home received an adequate dose. Patients with ambulatory 24-hour OME greater than 400 had 99% lower odds of receiving an adequate initial dose of PRN opioid in the ED compared to patients with ambulatory 24-hour OME less than 100	Retrospective study. Assumed patients were taking meds as prescribed. May have been skewed to higher ambulatory use. Not all ED visits studied were primarily for pain-related complaints. Didn't assess whether CA was active/ inactive during study period. Not enough patients at extremes of age pain scores not routinely documented
Sadik et al. 2014 [33]	Attributes of cancer patients admitted to the emergency department in one year	Retrospective review, 408 ED CA patients	58.8% male, median age 57.9, 65.3% had metastatic disease. Hospitalization rate 59.6%. Most common symptoms were dyspnea, pain, fever, and N/V. Most common CA sites were lung, GI, and breast. Initial evaluation found progressive disease, chemotherapy effects, infections, radiotherapy effects, extravasation, anemia, and unknown. During follow-up, 46.8% patients died after admission to ED. 1-year overall survival of all patients was 7.3 months	Retrospective. Survival data collected from diverse sources, including telephone surveys

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Seow et al. 2016 [34]	Does increasing home care nursing reduce emergency department visits at the end of life? A population-based cohort study of cancer decedents	Retrospective cohort, 54,576 EOL cancer decedents in Ontario, Canada	Of decedents using home care nursing services in last 6 months before death, 85% had ED visit, and 68% received EOL home care nursing. Patients receiving EOL nursing vs. standard nursing had reduced ED rate. In last month of life, receiving EOL nursing and standard nursing rate of >5 hours/week was associated with fewer ED visit rates of 41%. Temporal association between receiving end-of-life nursing in a given week during the last 6 months of life and of more standard nursing in the last month of life was associated with a reduced ED rate in the subsequent week	Retrospective – No causality. Administrative databases limited – No data on caregiver support, patient clinical/psychosocial, physician care, symptom severity, or privately obtained home care services. Does not analyze reasons for ED visits. Canadian system
Scholer et al. 2017 [35]	Improving cancer patient emergency room utilization: A New Jersey state assessment	Retrospective cohort, 37,080 ED CA visits in New Jersey	Most frequent diagnosis: Lung CA (30%), most common complaint: Pain. Patients who visited ED predicted by race, age 65–75, number of diagnosis, insurance payer, CA type. Comorbidities increase mortality, being transferred to SNF/ICF, using home healthcare services. Readmission is affected by race, income, and type of CA	No causality. Secondary data collected for other purposes. No hospital/ED facility ID information or revisits. Need ability to link healthcare data from SEER, Medicare, Medicaid, to allow a more comprehensive view on participating events, sequelae after ED visit, and effect of multimodal treatment
Qdaisat et al. 2020 [36]	Evaluation of cancer patients with suspected pulmonary embolism: Performance of the American College of Physicians Guideline	Retrospective, 380 patients	56% received CT pulmonary angiogram (CTPA) per ACP guideline, 21% received CTPA not per guideline. Pulmonary embolisms (PEs) were in 6% low-risk, 10% intermediate-risk, and 25% high-risk patients. ACP guideline had NPV of 99% and sensitivity of 97% in predicting PE	Retrospective. Inclusion of only patients who underwent CTPA
Grudzen et al. 2016 [37]	Emergency department-initiated palliative care in advanced cancer: a randomized clinical trial	RCT, 136 patients	QOL higher in palliative care group. Median estimates of survival were longer in PC group, but not significantly. No statistically significant differences in depression, admission to ICU, or discharge to hospice	Variable length of survival in cohort. Need future trial that limits enrollment to patients at similar CA stage. Unable to ascertain whether ICU admit/hospice referral was a reflection of patient's goals of care or if reflection of what team offered the patient. Missing data – Many patients did not survive for follow-up

(continued)

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Vandyk et al. 2012 [38]	Emergency department visits for symptoms experienced by oncologic patients: a systematic review	Systematic review, 18 studies cited in Medline, Embase, PsycINFO, and CINAHL	Of 28 symptoms reported, most common were febrile neutropenia, infection, pain, fever, and dyspnea. Definitions provided for individual symptoms were inconsistent. ED visits resulted in hospital admissions 58% (median) of the time in multi-symptom studies and 100% of the time in targeted symptoms studies. 13% (median) of ED visits captured in multi-symptom studies (range 1% to 56%) and 20% (median) of visits in targeted symptoms studies (range 4% to 67%) resulted in death	Few symptoms were defined adequately to compare data across studies (gap in CA symptom reporting). Symptom definitions inconsistent or not provided. Combined prevalence of any symptom could over−/under-represent actual ED use. Need better use of standardized definitions to improve reliability/validity of reporting/facilitate synthesis across studies. Need research exploring the impact of risk of exposure to communicable disease on health of oncologic patients visiting EDs. Sample sizes varied significantly. Sometimes repeat visits by single patients were excluded possible that patients who needed ED care most were under-represented. Mortality inconsistently reported (rates collected at different intervals). In most articles, unclear whether authors identified confounding factors or if analyses took them into account
Baugh et al. 2019 [39]	Near-universal hospitalization of US emergency department patients with cancer and febrile neutropenia	Observational, 348,868 ED visits	94% of ED visits resulted in hospitalization. Private, self-pay, and other insurance were less likely to be hospitalized than those with public insurance. Hospitalization was least likely at non-metropolitan hospitals and metropolitan non-teaching hospitals. 26% of variability in hospitalization rate was attributable to which hospital the patient visited	Case ascertainment depended on diagnostic codes, which may be subject to error. Codes used to specify neutropenia did not specify a definition. Lack of a single discharge code describing FN may have also led to an underestimate of the true number of cases. NEDS does not track revisits by the same patient
Huang et al. 2020 [40]	Review article: End-of-life care for older people in the emergency department: A scoping review	Review, 14 articles	Definitions pertaining to EOL care in the ED vary. Older people presenting to ED at EOL were mostly female, triaged in urgent or semi-urgent category, presented with diagnoses of advanced CA, cardiac and pulmonary disease, and dementia with symptoms including pain and breathlessness. Multiple tools pertaining to EOL exist and range from predicting mortality and assessing functional status, comorbidities, symptom distress, palliative care needs, quality of life, and caregiver's stress. Outcomes for older people enrolled in specific EOL intervention programs included lower admission rates, shorter ED length of stay, increased palliative care referral and consultations, and decreased Medicare costs	Limited evidence exists regarding the definition, clinical profile, care delivery and outcomes for older people requiring EOL care in the ED

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Lee et al. 2015 [41]	Emergency visits among end-of-life cancer patients in Taiwan: a nationwide population-based study	Retrospective cohort, 32,772 ED CA patients in Taiwan	81.5% ED visits in mortality group; higher ED utilization significantly monthly to EOL. Most frequent CA types were digestive and peritoneum CA (35%), breast (17.7%), and H&N (13.3%). Older patients, males, metastatic disease, and respiratory or digestive CA were more likely to use ED services at EOL. Use of an ED service in nearest community hospital to replace centers for dying CA patients would be more acceptable in emergency situation	If patient suffered prolonged hospitalization in last 6 months of life, may underestimate ED utilization. Loss of detail in claims data mining. Possible confounders not controlled, including socioeconomic status and family support
Mills et al. 2019 [42]	Factors affecting use of unscheduled care for people with advanced cancer: a retrospective cohort study in Scotland	Retrospective cohort, 2443 CA deaths in Tayside, Scotland	Of those dying from CA, 77.9% attended unscheduled care in the year before death. Among these, 10.7% A&E only and 33.1% both (along with GP). 19.7% attendances in last week, 36.7% last 4 weeks, 60.3% last 12 weeks of life. Age, sex, deprivation, and CA type not associated with unscheduled care attendance. Rural areas less likely to attend unscheduled care. Pain was most frequent coded clinical reason for presenting. Of those dying from CA, 21% were frequent users (> = 5 attendances/year) and account for over half of unscheduled care attendances	Variable clinical coding of reason for attendance. Non-specific/ missing coding
Panattoni et al. 2018 [43]	Characterizing potentially preventable cancer- and chronic disease-related emergency department use in the year after treatment initiation: a regional study	Cohort, 5853 eligible patients, 2400 visits within 1 year of treatment	27% had at least 1 ED visit. 49.8% of ED visits had a potentially preventable diagnosis. The prevalence of potentially preventable ED visits was generally high, but varied depending on the diagnosis code fields and the group of codes considered	Claims records are imperfect proxies in CA. Validation studies needed to determine best uses and methodological approach to measuring potentially preventable ED use. Commercially insured population – can't extrapolate to Medicare, Medicaid, or other regional groups. Excluded ED visits with a direct transfer to inpatient hospitalization, likely undercounts all potentially preventable adverse outcomes. Other issues beyond symptoms may influence ED use – Fear, cultural background, insufficient language/ communication skills, delays in seeking help, nonadherence, and lack of social support

(continued)

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Rivera et al. 2017 [44]	Trends in adult cancer-related emergency department utilization: An analysis of data from the nationwide emergency department sample	Observational, 7 survey cycles from Nationwide emergency department sample (NEDS), 29.5 million CA patients, 696 million adult ED visits	Of all adult ED visits, 4.2% were by patients with CA. Most common were breast, prostate, and lung CA. Most common primary reasons for visit were pneumonia, nonspecific chest pain, and urinary tract infection. Adult CA-related ED visits resulted in inpatient admissions more than non-CA-related visits. Septicemia and intestinal obstruction were associated with highest odds of inpatient admits	Inherent limitations of data set. If a patient with CA visited ED and CA code not documented, then patient was misclassified into nonCA visit group. No separate CA staging/ treatment codes in NEDS data set other than maintenance chemo or radiotherapy, thus not possible to distinguish type of treatment or whether patients were receiving active treatment, already completed, or advanced disease. Lack of detailed staging and treatment data – Unable to examine reasons for CA-related visits at points along CA continuum. Primary reason for visit based on codes – Not enough detail. Need more detailed data on reason for visits to ED and those related to patient's CA (date of diagnosis, CA type/stage, previous treatment, and clinical outcomes)
Tang et al. 2017 [45]	An analysis of emergency department visits and the survival rate for colorectal cancer (CRC) patients: a nationwide population-based study	Retrospective cohort, 6532 ED visits by 3347 colorectal patients in Taiwan	Top three most common reasons ED visits: Ill-defined conditions, abdominal pain, and intestinal obstruction. Overall survival rates of colorectal patients in the ED visit group at 3, 5, and 10 years were 0.65, 0.56, and 0.47, respectively, without significant differences from rates among colorectal CA patients who did not visit the ED	Did not differentiate end-stage patients from general patients with CRC. Unable to detect actual reason for ED visit. ICD system designed for general purposes, not fit to describe CA-associated problems
Liao et al. 2017 [46]	Effects of multidisciplinary team on emergency care for colorectal cancer patients: A nationwide-matched cohort study	Observational study, 45,418 patients with newly CRC diagnosis, Taiwan National Health Insurance Research Database	Odds ratio (OR) by probability of emergency care used for participation in multidisciplinary care groups (MDT) within a year of CA diagnosis was less than that for nonparticipation. Significant benefits of MDT in CRC care	Secondary database. Patient ED care by urgency level not addressed
Yap et al. 2018 [47]	Patterns of care and emergency presentations for people with non-small cell lung cancer in New South Wales, Australia: A population-based study	Retrospective cohort, 647 NSCLC cases in Australia	58.6% male, median age 73. ED presenters (34.5% of cases) were more likely to have a high Charlson comorbidity index score, be an ex-smoker who had quit in the past 15 years, and be diagnosed with distant metastases. Almost all patients had visited their general practitioner ≥3 times in the 6 months prior to diagnosis. Nearly one-third (29.5%) of patients did not receive any anti-CA treatment; however, there were no differences between emergency and non-emergency presenters in the likelihood of receiving treatment. Those less likely to be treated were older, had no private health insurance, and had unknown stage disease recorded	45 and older sample, not whole NSW population. Could not directly infer that patients who visited ED in month/month prior to diagnosis were detected as a result of ED presentation. No access to more detailed TNM staging or ECOG performance status. 19% unknown stage

Table 69.2 (continued)

Author-Year	Title	Study type, population	Findings	Limitations
Hryniewicki et al. 2018 [48]	Management of immune checkpoint inhibitor toxicities: a review and clinical guideline for emergency physicians	Review, 50 articles via PubMed	Inhibition of immune checkpoints may lead to loss of peripheral tolerance and subsequent unleashing of immune system on nontumor cells, leading to unintended tissue damage and multisystem organ dysfunction. Most commonly affected organ systems are dermatologic, GI, endocrine, and pulmonary. Treatment can range drastically depending on severity of irAE (immune-related adverse events): Supportive care, high-dose steroids, additional immune modulators (infliximab, IVIG)	Further studies needed to analyze outcomes of different treatment strategies in patients presenting with potential immune-related adverse events
Knight et al. 2017 [49]	Acute oncologic care: A narrative review of the acute management of neutropenic sepsis and immune-related toxicities of checkpoint inhibitors	Review	Outpatient management of low-risk febrile neutropenia patients identified by the MASCC score is a safe and effective strategy. Immunotherapy with "checkpoint inhibitors" has significantly improved outcomes for patients with metastatic melanoma, and evidence of benefit in a wide range of malignancies is developing. Timing of the onset of the adverse events is dependent on the organ system affected and unlike anti-neoplastic therapy can be delayed significantly after initiation or completion of therapy	Further research into optimal management, strategies, and pathways of acutely ill CA patients is required
Bowers et al. 2017 [50]	Ketamine as an adjunct to opioids for acute pain in the emergency department: a randomized controlled trial	RCT, 116 patients	Patients receiving ketamine reported lower pain scores over 120 minutes than patients receiving placebo. Total opioid dose was lower in the ketamine group. Satisfaction did not differ between groups. Fewer patients in the ketamine group required additional opioid doses. More patients reported light-headedness and dizziness in the ketamine group	Cohort with chronic pain and long-term outpatient opioid use may react differently to the adjunctive ketamine usage than patients with new-onset acute pain. ED environment allows for less precise control of variables. Subjectivity of patient-reported values. Sometimes a time point was missed
Northfield et al. 2019 [51]	Taking care of our own: A narrative review of cancer care services-led models of care providing emergent care to patients with cancer	Review, 22 studies	Overarching outcomes associated with the most commonly described models of care (telephone advice services and/or unplanned care and assessment units) were improved coordination of care/continuity of care, prompt access to specialist care, reduced utilization of EDs, fewer hospital admissions, and reduced cost	Methodological weaknesses of included studies and variations in study designs, settings, and models of care. Future studies should explore patient and caregiver CA experiences

CA cancer, *CAM* Confusion Assessment Method, *CISNE* Clinical Index of Stable Febrile Neutropenia, *ECOG* Eastern Cooperative Oncologic Group, *EOL* end of life, *ESI* emergency severity index, *HNSCC* head and neck squamous cell carcinoma, *HTN* hypertension, *LMWH* low-molecular-weight heparin, *LOS* length of stay, *MASCC* Multinational Association of Supportive Care in Cancer, *MDAS* Memorial Delirium Assessment Scale, *NIH* National Institutes of Health, *OME* oral morphine equivalent, *RCT* randomized control trial, *SEER S*urveillance, Epidemiology, and End Results Program

The most commonly cited limitation of all articles was generalizability. Majority of studies were conducted in an academic, urban setting (community hospital ED cancer prevalence and care may differ) [5–8] at tertiary cancer centers [9–12] or a single center (which may have limited the number of patients in the study) [13–27]. Selection bias was identified for including only English-speaking patients [5, 7, 8, 10]. Furthermore, patients that were too ill or unable to consent were deemed ineligible, which may have underestimated the severity of patients presenting to the ED [7, 8, 18, 25]. As a result, many studies reported the lower bounds of severity and acuity and therefore may contribute to a ceiling effect (when it is more challenging to improve outcomes in a healthier subset) [8].

Most studies were retrospective [6, 9, 11–13, 15, 16, 19–21, 23, 26–36], often relying on chart review, which may lead to misclassification bias when data were misinterpreted or missing [6, 11, 16, 20, 21, 23, 25, 28, 29, 36, 37]. Additionally, many of the studies reported a lack of longitudinal follow-up, complicated by different timing and measures of mortality rates [14, 17, 21, 29, 35]. Some studies claimed they could not track revisits by the same patient, possibly counting some patients more than once, or they were unable to identify visits by the same patient to different EDs [24, 29, 38, 39].

Another common limitation identified by the authors was the inaccuracy and/or inadequacy of diagnostic codes – there was no standardization of definitions of chief complaints, as well as limited categorization [19, 29–31, 38–45]. Therefore, the true number of cancer patients presenting to emergency centers may not be accurately represented [31, 39, 44]. It was also difficult to account for multiple symptoms, as health records and ICD-9 codes often only reported the main presenting symptom used to assess ED admissions [14, 19, 30]. The databases used for many of these retrospective studies were secondary data and thus limited in the types of information recorded [28, 29, 34, 35, 46]. Many articles reported lack of staging information [14, 19, 44, 47] and disease or treatment status [19, 30–32, 37, 44, 45, 47] (e.g., advanced, progressive, or limited disease, new diagnosis or continued care, active or inactive cancer). It was also unclear whether multiple models lacked unmeasured confounders or if the analyses were adjusted for their potential confounding effect [15, 23, 38, 41, 43]. This would include factors such as socioeconomic status, family support, cultural background, delays in seeking help, medical nonadherence, and lack of social support.

Other limitations focused on the evolving field of cancer treatment, which may have altered findings throughout the duration of the study. For example, two articles focusing on immunotherapy discussed the rapidly changing field and newly identified immune-related adverse events [21, 48]. Another two articles pointed out that sepsis management of cancer patients in the ED also changed during the respective studies [27, 49]. Multiple papers also called for novel research on pain in patients with cancer presenting to the ED [14, 24, 25, 32, 50]. These authors pointed out that their population had a mix of chronic and acute pain complaints, and their results may have been confounded by possible opioid tolerance in some patients [25, 50]. In addition, pain scores were not routinely documented [32] and no data had been published on the etiologies of cancer pain [24]. Patient-reported pain scores and satisfaction levels also have an inherently subjective nature [25, 50]. Lastly, some publications identified the gap in knowledge on patients' goals of care and how that may influence their experience in the ED [37, 51].

Overall, there is a need for larger, prospective cohort studies of oncologic patients presenting to the ED that would allow for understanding readmissions/revisits and re-hospitalizations, multicenter randomized control trials, and inclusion of diverse populations. There is also a need for more accurate, standardized recording of diagnoses of patients presenting to the ED, including a systematic assessment of those with multiple symptoms. Given the rapid advances in cancer treatment, developing risk profiles of cancer patients, along with understanding the timing, sequence, and duration of toxicities of cancer treatment, is needed.

Training Opportunities

Given the large amount of existing federal funding in support of cancer research, there are many opportunities for academic emergency physicians to partner with their colleagues in other specialties who study cancer-related emergencies. This is particularly true for academic departments of emergency medicine situated in one of the 41 National Cancer Institute-designated comprehensive cancer centers. These centers offer a number of institutional research training programs (e.g., National Research Service Awards – T32 grants) that can deliver formal research training to junior academic emergency physicians who wish to pursue traditional research careers.

The Comprehensive Oncologic Emergencies Research Network (CONCERN)

In March 2015, the National Cancer Institute and the Office of Emergency Care Research sponsored a 1-day workshop, titled "Cancer and Emergency Medicine: Setting the Research Agenda," in Bethesda, MD. The goal of the workshop was to identify research opportunities and determine research priorities for issues related to the emergency care of

Table 69.3 Partial list of workshop recommendations from the March 25, 2015, workshop titled "Cancer and Emergency Medicine: Setting the Research Agenda," in Bethesda, MD, sponsored by the National Cancer Institute and the Office of Emergency Care Research

Topic[a]	Areas of concern			
Emergency department (ED) use by cancer patients	Definition of a cancer patient	Definition of a cancer-related ED visit	Electronic medical records	Options for ED care
Febrile neutropenia	Definition of febrile neutropenia; objective response	Optimal treatment strategies	Effects of timing of antibiotic therapy	Biomarker and risk stratification
Acute pain	Optimal treatment strategies	Coordination of care with outside providers	Barriers, skills and attitudes of ED providers	Biomarkers and risk stratification
Palliative care	Use of life-sustaining therapies	Disposition pathways/ follow-up care	ED and community hospice partnership	Larger cohort studies

[a]Acute dyspnea and spinal cord syndrome were also among the acute events discussed

the cancer. Twenty-six participants representing the fields of emergency medicine (8), oncologic (3), internal medicine (1), oncologic EDs (4), operations (1), and palliative care/ emergency medicine (3) were invited to the workshop. Representatives from the National Cancer Institute (4), the National Institute of Nursing Research (1), and the Office of Emergency Care Research (1) were also in attendance and participated in the discussion. The results of this one day workshop have been published [4]. Table 69.3 shows some of the research recommendations from the workshop (not an exhaustive list) (https://epi.grants.cancer.gov/events/emergency-medicine/).

This 1-day workshop led to the formation of CONCERN. Currently, more than 20 medical centers are represented. Membership is open to new members interested in collaborative research in cancer and emergency medicine. There are no membership requirements [52].

CONCERN objectives include: (1) identify knowledge gaps in the emergency care of cancer patients and define the scope, (2) accelerate knowledge generation and translation through multicenter research collaborations across oncologic and emergency medicine, (3) expand knowledge around treatment of oncologic emergencies in the emergency medicine setting, (4) translate research findings into national guidelines and community emergency care settings, (5) develop collaborative educational efforts in the area of cancer and emergency medicine, and (6) provide mentoring and consultation to new and established investigators working in the area of cancer and emergency medicine.

The first project included a multi-institutional prospective data collection which has been completed. The results have been published [7, 8], with additional publications currently ongoing. Periodic meetings via teleconference allow members to pursue collaborative projects and potential funding mechanisms are discussed. To date, plans are underway for a workshop at the National Institutes of Health campus in 2020. The goal of the workshop is to provide a 5-year research progress update, set new/revised research priorities, and establish new research collaborations at the intersection of cancer and emergency medicine. Priority Setting Questions to be addressed within each session include:

1. What are the gaps in knowledge/science around prevention and management of cancer-related emergency department visits?
2. What are specific research questions to address these gaps?
3. What are the resources, collaborations, and support needed to move this science forward?

Program in Oncologic Emergency Medicine (POEM), Department of Emergency Medicine at MD Anderson Cancer Center

Established in 2010, MD Anderson's Department of Emergency Medicine (DEM) is the first academic department in a comprehensive cancer center dedicated to the development of oncologic emergency medicine as a distinct discipline. The department's vision is to be the premier resource for education, research, and clinical care in the emerging discipline of oncologic emergency medicine. DEM presents a unique and exciting opportunity for exploring areas of research to improve the care of cancer patients and to identify gaps in current diagnostic and treatment approaches. The emergency center provides emergent and urgent treatment for MD Anderson patients and for employees and visitors injured on the MD Anderson premises. Every day, the emergency center provides service to approximately 70 patients with cancer-related conditions and is a vital safety net for MD Anderson patients. The emergency center features 44 rooms, including those designated for isolation, cardiovascular emergencies, and gynecologic emergencies. It is staffed by Department of Emergency Medicine physicians, mid-level providers, registered nurses, patient-service coordinators, and patient-care assistants.

In 2015, the MD Anderson Program in Oncologic Emergency Medicine was established to improve patient

outcomes by providing an interdisciplinary research hub that serves as a framework for developing emergency care research and implementing research-driven practice in caring for cancer patients who present in the emergency center. The Program integrates existing and newly developed research initiatives, with reduction in oncologic emergencies as its primary focus.

The Program's mission is to improve the care of patients with cancer and to reduce their need for emergency care during survivorship. Its vision is to be a locus for promoting evidence-based multidisciplinary and translational research in oncologic emergencies for a broad spectrum of clinicians and researchers across the institution and beyond. The Program is highly complementary to the disease-specific and treatment-specific centers at MD Anderson, none of which support specific research in oncologic emergencies.

Program Goals

POEM's program goals are to (1) facilitate the conduct of synergistic and collaborative projects focusing on oncologic emergencies, (2) develop and train physician scientists and graduate students in oncologic emergency research, (3) accelerate knowledge generation and synthesis by bringing together clinicians and scientists from diverse disciplines, and (4) establish synergy with existing centers and departments at MD Anderson.

To Facilitate Synergistic and Collaborative Projects Focused on Oncologic Emergencies

MD Anderson offers a breadth of resources to the Program, ranging from existing research and clinical databases, a large patient population, a substantial "core" support infrastructure, and multifaceted, experienced faculty. Publicly available databases can augment institutional data repositories.

Data Repositories Program researchers can capitalize on existing databases within the department and institutional data sources, including genomics, tumor registry, pharmacy, bioinformatics and biostatistics, and radiology and laboratory data, along with patient demographic, disease, and treatment data. The Program links these various databases together to create a powerful, comprehensive repository of personalized patient data (Fig. 69.1). Research protocols approved by MD Anderson's Institutional Review Board facilitate data collection and analysis. For example, prior to MD Anderson's adoption of Electronic Privacy Information Center (EPIC) for patient data across the institution, a locally developed database (the Zero G/Whiteboard) was utilized for collection of ED patient data. It included, for example, demographic information, body mass index and weight loss, type of cancer, primary and secondary presenting symptoms (chief complaints), number and frequency of emergency visits, symptom severity, and final disposition (e.g., admitted to hospital or discharged home). These data were linked to other institutional databases (see Fig. 69.1).

To Develop and Train Physician Scientists and Graduate Students in Oncologic Emergency Medicine Research

PubLab and Manuscript Advancement and Development Group (MAD): POEM's objectives were to build the literature in oncologic emergency medicine to improve patient care, and to build upon the expertise of DEM clinical faculty as thought leaders in this new discipline. There is a dearth of EM faculty trained in research. "Pub-Lab" was created as a

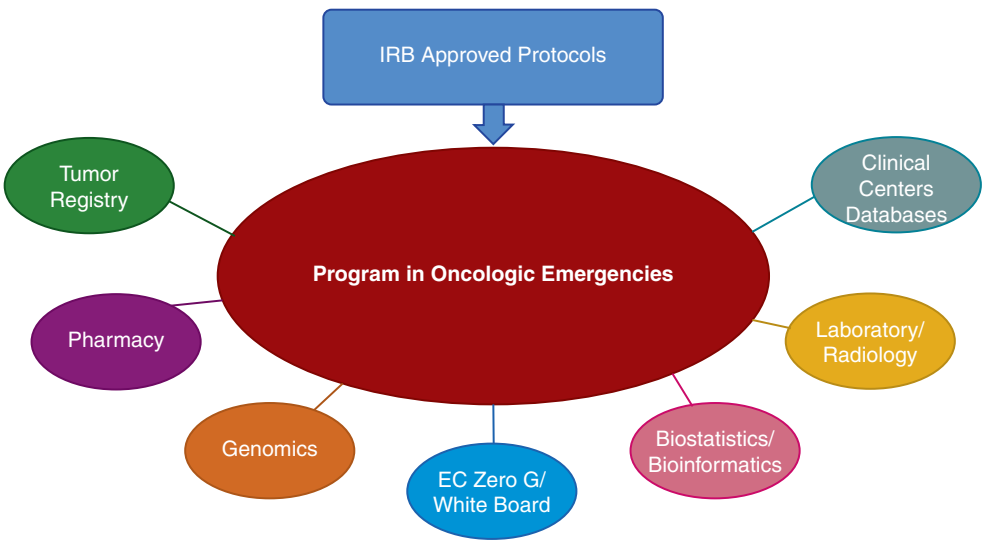

Fig. 69.1 Data repositories. The Program in Oncologic Emergency Medicine (POEM) databank links existing databases within the department and institutional data sources, including genomics, tumor registry, pharmacy, bioinformatics and biostatistics, radiology, and laboratory data, along with patient demographic, disease, and treatment data, to create a powerful, comprehensive repository of personalized patient data

series of regular meetings where the faculty discuss research articles, bring research ideas, or work in progress for publication. A faculty member trained in research provides guidance, and to optimize mentoring time, "mass-mentoring" groups were formed with each group comprised of faculty who are interested in a subject area/topic. MAD has up to four faculty and a mentor. Published studies from this group mentorship are in Table 69.2.

To Accelerate Knowledge Generation and Synthesis by Bringing Together Clinicians and Scientists from Diverse Disciplines

POEM builds upon existing scientific platforms, including scientific conferences and meetings both at local and national levels. January 2020 was the 7th Oncologic Emergency Medicine Conference at MD Anderson. Sponsored by DEM, among the aims of the conference was to fill the knowledge gap in oncologic emergency medicine by providing information in an interactive forum to enhance the decision-making of healthcare providers. Faculty from diverse disciplines served as speakers including the faculty in DEM. Each year includes presentations on innovative cancer therapies, e.g., immune checkpoint inhibitors, its related side effects and treatment, and management of immune-related adverse events were the highlights for 2020.

To Establish Synergy with Existing Centers and Departments at MD Anderson

As of October 20, 2020, there were 8,128,524 cases of COVID-19 in the United States with more than 218,986 deaths (and rising) [53]. Perhaps, one of the most lethal viruses, SARS-CoV-2, which causes COVID-19, has both an alarming contagion spread and disease severity that often requires emergency care. Our understanding of SARS-CoV-2 infection is rapidly evolving, with its clinical presentation and management barely understood. Cancer patients are expected to be particularly vulnerable to CoVID-19, given that their immune defenses are often deficient or compromised. Early and late toxicities from cancer treatment experienced by cancer patients also add complexity to their care. With little known about COVID-19, research of COVID-19 patients presenting to the ED was quickly established in DEM, and a protocol was immediately developed and obtained approval from the Institutional Review Board. Developing a protocol and a research project allowed for a cohesive method of collaborating with the different centers and departments at MD Anderson and provided synergy and a multidisciplinary approach (radiologists, oncologists, hospitalists, infectious disease) to understanding how to provide care to cancer patients with COVID-19.

Future Directions

Despite the continued rise in the number of cancer patients and the increasing complexity of cancer treatment, there is a dearth of research on oncologic emergencies even for disease complications that have been a concern for decades (acute pain, acute dyspnea, etc.). We have illustrated a couple of research efforts that created opportunities for research collaboration and engaged experts from many disciplines and institutions. Moreover, we also illustrated how the creation of a program in one academic cancer center has facilitated a timely response to research opportunities surrounding the COVID pandemic, for example. In recent years, transformative advances have emerged in the use of innovative therapies for cancer patients (immune therapies, gene therapies, gene editing, etc.). These approaches are some of the most promising treatment modalities but with unknown side effects or complications to the cancer patients. Because many cancer therapies are provided on an outpatient basis, the ED provides a safety net for cancer patients. The provision of care for those who present to the ED has to be guided by evidence.

COVID-19

70

Knox H. Todd

Introduction

As of November 17, 2020, the World Health Organization reports 54,771,888 cases of COVID-19 worldwide and over 1,324,249 deaths [1]. The cumulative death total in the USA is almost one-quarter million [2]. Despite the promise of an effective vaccine in 2021, new cases and deaths may double in the coming months [3]. In addition to this toll, livelihoods have been destroyed, poverty rates and food insecurity are rising, and even our ability to gather with loved ones is curtailed.

Sadly, the USA has fared much worse than other developed countries during the pandemic. Basic public health measures to contain the COVID-19 epidemic (e.g., social distancing and mask wearing) have been interpreted as political acts in a highly polarized country. It is hoped that scientific reason will inform future developments in the USA, not the least to protect the most vulnerable among us, including those with cancer.

Longstanding inadequacies of our public healthcare systems and declines in longevity and well-being among US citizens have become more glaringly obvious during the pandemic, as has evidence of racial/ethnic disparities, driven by structural racism and workplace exposure to SARS-CoV-2 [4, 5].

In the midst of the pandemic, with rapid and ongoing changes in recommendations for management and the likelihood that a vaccine is forthcoming, it is difficult to discuss treatment issues with confidence in a traditional textbook. Alternatively, readers are directed to the large number of up-to-date online resources for guidance on current evaluation and clinical management (e.g., CDC, WHO, etc.). This chapter will briefly review real and potential impacts of the COVID-19 pandemic on the emerging field of oncologic emergency medicine. Among other questions, we will review COVID-related risk factors and health disparities, impact on treatment and cancer care systems (including cancer prevention, research, and economic effects), workforce mental health issues, and advances in emergency department (ED) palliative care.

Epidemiology

Cancer patients are at high risk for severe COVID-19 for a number of reasons. Age, obesity, and smoking are common risk factors for both cancer and COVID-19 morbidity and mortality. Advanced cancer causes declines in functional status (another risk for poor outcomes) and anticancer therapies alter immune responses to viral infection [6].

Giesen et al. recently reviewed risk factors for severe COVID-19 disease among cancer patients [7]. Patient-related factors included higher age, male sex, higher ECOG scores, the number of comorbidities, and smoking [8–14]. Cancer-related risk factors included a history of cancer [15], hematologic malignancies vs. solid tumors [10, 11, 16–21], lung cancer vs. other solid tumors [22], active cancer [9, 17], metastatic cancer [8, 22], and cancer treatment within 4 weeks of COVID-19 disease onset [23–25]. In addition, lymphopenia and granulocytosis were associated with an increased risk of severe disease or death [8, 13, 18, 25–27]. Whether cancer is an independent risk factor for poor outcomes in patients with COVID-19 is unclear at this time.

Initial reports from China by Liang et al. suggested that COVID-19 patients with cancer had higher rates of ICU admission and death; however, at the time of their publication, the investigators had evaluated only 18 patients with cancer from a cohort of 1590 subjects [28]. A subsequent study using propensity matching compared 232 adult cancer patients to 519 non-cancer controls admitted with COVID-19 to 9 area hospitals in Wuhan, China [8]. Over an approximately 1-month follow-up period, those with cancer were more likely to experience severe disease (64% vs. 32%) and death (20% vs. 11%). Risk for disease severity and death were greatest for patients receiving recent chemotherapy

K. H. Todd (✉) (Retired)
Department of Emergency Medicine, MD Anderson Cancer Center, Houston, TX, USA

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_70

(within the past 2 weeks). In addition to known clinical risk factors for poor outcomes, the investigators identified a number of novel risk factors for disease severity among cancer patients, including advanced tumor stage, elevated tumor necrosis factor alpha (TNF-α) and N-terminal pro-B-type natriuretic peptide (NT-proBNP), and decreases in CD4+ T cells and albumin-globulin ratios. They recommended heightened attention to infection control procedures during treatments, considering delays of adjuvant chemotherapy or elective surgery in endemic areas (with continuation of oral medications), and intensive risk stratification for patients with cancer and COVID-19, using the above identified biomarkers.

A study of 105 cancer patients and 536 without cancer admitted to 14 hospitals in Hubei Province, China, reported a higher risk for multiple poor outcomes (i.e., disease severity, ICU admission, mechanical ventilation, and death) among those with cancer [22]. Patients with hematologic, lung, or metastatic malignancies were at higher risk, as were those undergoing surgery vs. receiving only radiotherapy.

A more recent study performed COVID-19 surveillance among 1081 consecutive patients with solid tumors receiving treatment with intravenous, subcutaneous, or intramuscular agents at the National Cancer Institute of Milan (The COVINT Study) [29]. They found that over 2 months of epidemic spread in Milan, only 11 patients (1%) had confirmed, and 73 (6.7%) suspected, COVID-19. They concluded that when protective measures were followed in administering chemotherapy, COVID-19 contraction rates in cancer treatment facilities were relatively low.

A subsequent analysis comes from the LEOSS (Lean European Open Survey on SARS-CoV-2-Infected Patients) Study registry, in which a retrospective cohort of 435 cancer and 2636 non-cancer patients were assessed for COVID-19 morbidity and mortality [30]. For 435 cancer patients identified at the time of COVID-19 detection, progression to severe disease was seen in 55% and ICU admission in 27.5%, with a COVID-19-related mortality rate of 22.5%. Male sex, advanced age, and active malignancy were associated with higher mortality. After adjusting for confounding factors, mortality rates for those with and without cancer were similar. Despite this finding, cancer patients *as a group* are at higher risk of poor outcomes, as they are older and tend to have multiple comorbidities.

Analyses of UK Coronavirus Cancer Monitoring Project data provide more specificity for cancer as a risk factor for poor outcome. Investigators found that all-cause case fatality rates for patients with cancer who were hospitalized for COVID-19 rose with increasing age and the presence of hematologic malignancies [21]. After controlling for age and sex, those with hematologic malignancies receiving recent chemotherapy had an approximate doubling of mortality risk (OR 2.09, 95% CI 1.09–4.08).

Health Disparities

For the USA, COVID-19 represents the latest chapter in the long and tragic history of national health disparities. The pandemic has focused attention on persistent inequities experienced by US subpopulations facing persistent and collective discrimination (e.g., specific racial/ethnic groups and those of low socioeconomic status). As is true historically for other communicable and non-communicable diseases (e.g., tuberculosis, pellagra, HIV), to address the COVID-19 pandemic, we must understand its differential impact on these groups and focus our efforts to ensure more equitable monitoring and treatment, incorporating what we already know about the social determinants of health [31].

Current observational studies provide abundant evidence of disparities in both risk and outcomes for COVID-19. In retrospective cohort studies within a Louisiana integrated-delivery health system, researchers found that while Blacks comprised only 31% of those they served, 77% of those hospitalized were Black, as were 71% of those who died [32]. The authors note that in addition to a higher incidence of COVID-19 risk factors (e.g., obesity) among Blacks, most service workers in New Orleans and surrounding areas are members of minority groups, with many service sector occupations related to food preparation and serving.

Similarly, an analysis of data from Sutter Health, an integrated California healthcare system, found that among 1052 confirmed COVID-19 cases, after adjusting for age, sex, comorbidities, and income, Blacks were 2.7 times as likely as Whites to be hospitalized [33]. The authors posited that Blacks were more likely to be tested at a later stage of illness, as evidenced by their testing occurring more often in hospital EDs than in office or clinic settings.

In an observational cohort study of 2186 US adults with invasive cancer and COVID-19, Rivera et al. found that while remdesivir was associated with improved outcomes, Black patients were approximately one half as likely to receive this therapeutic agent as Whites [34]. Of note, remdesivir is most often administered within a clinical trial. Although an observational study, these findings suggest that racial inequity, particularly as related to clinical trial enrollment, continues to influence COVID-19 treatment.

Using publicly available datasets, Tirupathi et al. reported that Black and Latinx COVID-19 incident rates were disproportionately higher than their population percentage in 14 states and 9 states, respectively, and that while Blacks constitute 13.4% of the US population, they accounted for 22.4% of COVID-19 deaths [35].

Geographic disparities are also important to consider in the context of the COVID-19 pandemic. Initial waves of the virus impacted predominantly urban areas; however, the disease is now widely distributed in the USA, with less densely populated parts of the country experiencing disproportionate

levels of hospitalization and death. Rural health disparities result from multiple factors: poor access to healthcare (e.g., higher levels of the uninsured, long travel distances, lack of public transportation, poor Internet connections, lack of specialty care) and lower socioeconomic status (e.g., higher unemployment, lower median household incomes, lower proportions with post-secondary education), among other factors.

Dr. Robert Rodriguez, an emergency physician recently named to President-Elect Biden's COVID-19 Advisory Board, recently wrote of his experiences in volunteering to care for critically ill patients in his hometown of Brownsville, Texas, contrasting it to his current work environment in San Francisco: "My experiences over the past 2 months have shed light on another disparity—the enormous differential in emergency and critical care physician surge capacity between cities with robust medical academic institutions and communities that are situated far away from large medical schools" [36]. As part of his critique, he noted the bureaucratic barriers (e.g., credentialing paperwork, malpractice insurance) to urban physicians volunteering to serve in rural COVID-19 hot zones.

In rural and urban areas, for many of those with low-paying service jobs, social distancing or telecommuting are not options, and adverse social determinants of health are a large factor in observed COVID-19 health disparities [37]. This poor state of affairs is exemplified by the title of a recent JAMA editorial discussing COVID-19: "Failing Another National Stress Test on Health Disparities" [38]. While health disparities were widely recognized before COVID-19, the pandemic has served to highlight their importance and further focus our attention on this ongoing national tragedy.

Treatment

As noted in the Introduction, we will cover treatment issues in only a cursory fashion. Given the time interval required for publication, recommendations made today are likely to be misleading by the time this text is available. As a recent review of COVID-19 emergency medicine response noted: "When we are practicing at the bleeding edge of a viral pandemic that didn't exist 6 months ago, practitioners are often forced to work with less than robust data sets" [39]. Our readers are best referred to online sources from emergency medicine, oncologic, and federal/state organizations for the latest updates on evaluation and treatment.

In terms of management lessons learned during the pandemic, EDs have met multiple challenges involving isolation protocols and staff safety, patient/provider education, public health reporting, staff and space allocation, and communications – not to mention the widely publicized (real and potential) shortages of personal protective equipment and ventilators – as well as varying policy recommendations from federal, state, and professional authorities. Screening and testing criteria also evolved over time, as did criteria to justify hospital admission.

However, EDs, in part due to past experience with previous mass casualty incidents and epidemics, adapted rapidly to enhance surge capacity. They established separate "hot" and "cold" zones for COVID and non-COVID care, respectively, and in some cases, utilized separate tent and drive-in facilities to further segment care and augment capacity. In particularly stressed areas, adaptions could be primitive (e.g., using bandannas or handkerchiefs and plastic trash bags as a substitute for sophisticated personal protective equipment) [40]. Social media-driven efforts were conducted to raise funds for PPE in order to ameliorate inequalities in supply distribution As voiced by one emergency physician, "I think it should not have required a social media presence of health care workers, and for health care workers to get sick and themselves die from coronavirus, in order for hospitals to have received the standard equipment that they deserve" [40].

One of the most difficult decisions, and one for which lessons continue to be learned, surrounds questions of oxygenation and intubation. The risk of spreading viral-laden droplets and aerosols during oxygenation and intubation procedures complicates decision-making. In addition to standard protective equipment, powered air-purifying respirators (PAPR) are commonly used to reduce these exposures [41]. With more vigorous non-invasive oxygenation efforts, patient positioning techniques ("proning") [42], and recognition that tolerance of low patient oxygen saturation levels ("happy hypoxemia") can occur [43], intubation procedures are often delayed. ED airway management has improved markedly over the past decades and the COVID-19 experience is likely to further improve and standardize our airway practices [44]. Figure 70.1 presents an algorithm from NorthShore University HealthSystem intended to reduce aerosol exposure risk and maximize alternative oxygenation strategies for COVID-19 [39].

Pharmacologic approaches to both ED and oncologic patients continue to evolve. Beyond remdesivir, corticosteroids, and anticoagulants, the potential roles of convalescent plasma, monoclonal antibodies, antivirals, interleukin and cytokine blockers, histamine antagonists, kinase inhibitors, and protease antagonists in COVID-related disease management remain unclear [45]. The ED's place in future vaccine distribution systems over the coming year(s) is, as well, unclear; however, there is no doubt that emergency care providers will be among the first recipients of any new vaccines.

Cancer centers have also adapted rapidly to the challenges of treating vulnerable and potentially immunocompromised patients in the midst of a viral pandemic. Broom et al.

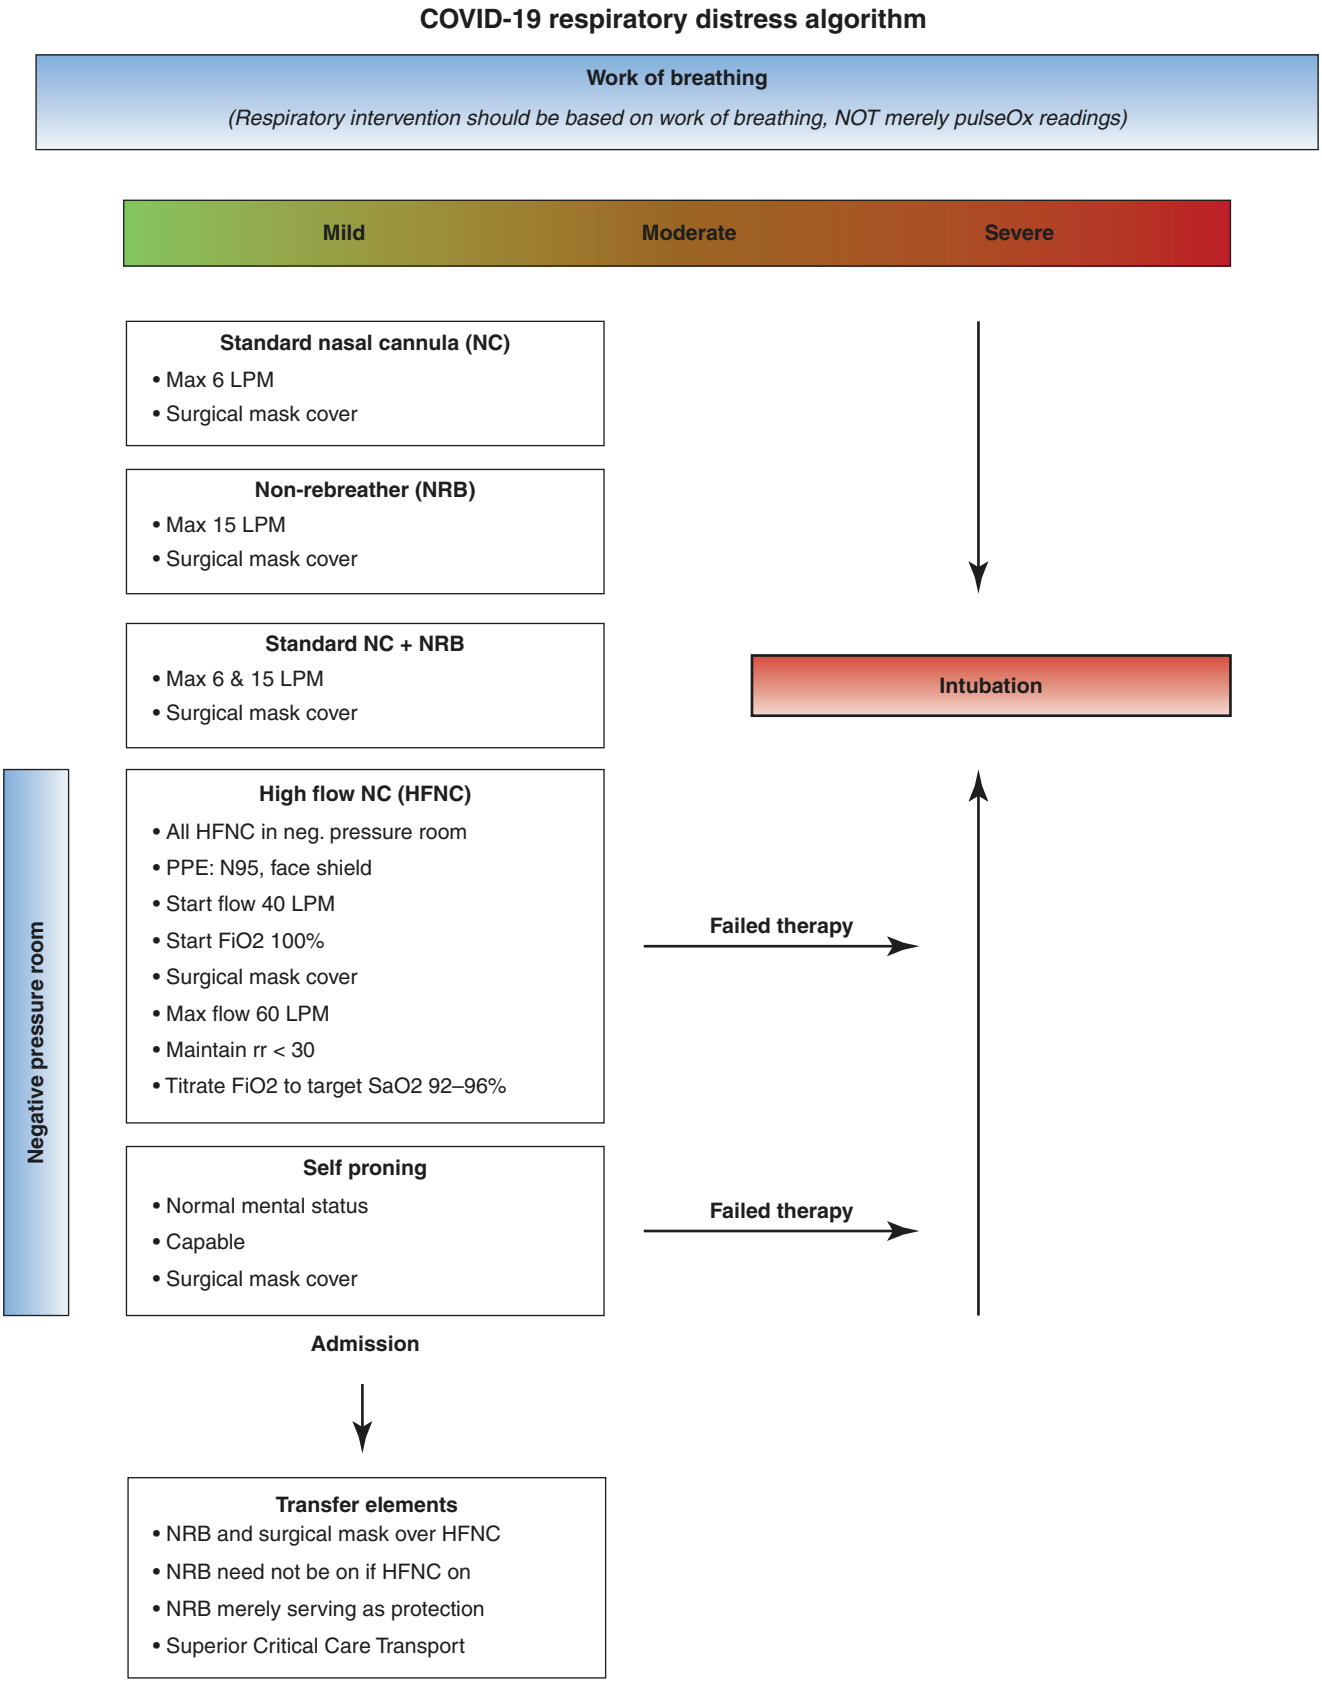

Fig. 70.1 Example COVID-19 resiratory distress algorithm. (From Leiker and Wise [39] with permission Elsevier)

recently provided an excellent review of modifications in cancer care resulting from COVID-19 [46]. In their review, they recognize that rapidly implemented responses to the pandemic may result in enduring changes to the cancer care system (for both better and worse). They touch on key principles to consider in understanding and managing such broad changes, including: (1) recognition that a return to "business as usual" after the pandemic is unlikely, (2) safety for patients and staff is a priority, (3) the pandemic requires a heightened focus on the negative consequences of immune-altering therapies, (4) the need for rapid evaluation of changes in practice, (5) ramifications (both interpersonal and economic) of increased telemedicine use, and (6) increased scrutiny of value of life assessments in the context of limited resources, particularly for the elderly, patients with palliative care needs, and those with multiple comorbidities.

Percival et al. reviewed early modifications of care for particularly fragile patients with hematologic malignancies served by the Fred Hutchinson Cancer Consortium [47]. Their overarching goal was to balance the risks surrounding the underlying hematologic malignancy and its treatment (often involving myelotoxic and lymphotoxic therapies) with evolving understanding of COVID-19 morbidity and mortality.

Aside from stringent infection control measures (i.e., strict control of access to healthcare sites, increased use of telemedicine, limiting the physical presence of caregivers), they increased their emphasis on oral and/or outpatient options, choosing therapies that reduce the risk for bone marrow toxicity and deferring therapy, if possible. There was also a marked reduction in clinical trial participation and a more nuanced calculation of risk-benefit for experimental therapies. Increased use of granulocyte colony-stimulating factor (G-CSF) and antibiotic prophylaxis was emphasized in an attempt to limit febrile neutropenia, as were stringent transfusion thresholds (given decreased donor availability), increased use of anti-fibrinolytics to decrease risks of spontaneous bleeding in thrombocytopenic patients, and delayed therapy for patients with positive coronavirus tests, when possible.

Given limited testing capacities, they proposed screening asymptomatic patients for coronavirus only prior to planned procedures, inpatient admission, stem cell transplant (HSCT), and chimeric antigen receptor (CAR)-T cell therapy. Finally, as in the ED, they increased attention to early discussions of patient and family goals of care, encouraging frank assessments of risk for those with limited expectations of benefit from more aggressive therapies. The ongoing reevaluation of cancer regimens in the COVID-19 era, with potential de-escalation of therapy when appropriate, holds the promise of more cost-effective, patient-centered care in the future [48].

A summary of general consensus measures [48] taken in response to the pandemic by seven comprehensive cancer centers in Europe is presented in Table 70.1. These measures are specific to a particular point in time in the evolution (as well as our understanding) of the pandemic and they will, no doubt, change over time.

Throughout the healthcare system, efforts to respond to the challenges of COVID-19, particularly in the context of cancer care needs, have had both positive and negative consequences. In prioritizing our response to the epidemic, certain aspects of cancer care have necessarily been deprioritized, occasionally resulting in suboptimal or delayed care.

Indeed, medical lawsuits in Spain may have resulted from delayed diagnosis and treatment of cancer during the pandemic [49]. The story noted that while hospitals were focused on COVID-19 treatment, cancer and other serious illnesses might have been neglected. While Spanish prosecutors are investigating such cases, physicians interviewed for the article stated that their overwhelming workload makes such errors inevitable, and specifically that when forced to rely on telemedicine only to evaluate patients, their ability to detect cancer will necessarily suffer.

In April of 2020, Denise Grady of the *New York Times* reported similar instances of COVID-19 collateral damage, in the story of a 53-year-old male with a hematologic malignancy whose death may have been caused by delays in chemotherapy due to COVID-related shortages of blood products. The article cited an American Cancer Society Cancer Action Network survey conducted at the beginning of the pandemic reporting that one-half of cancer patients and survivors experienced some impact of the pandemic on their care [50]. The survey found that 27% of patients in active cancer treatment report treatment delays, with 13% reporting no knowledge of when treatment might be rescheduled. Fully 40% of those in active treatment expressed concern regarding their ability to receive adequate care.

System Impacts

Healthcare system stresses (e.g., lack of surge capacity) and altered patient behaviors related to the pandemic (e.g., avoiding ED and office visits) are likely to lead to delayed cancer diagnoses at later stages and with poorer outcomes. Early data in the pandemic era reveal dramatic drops in cancer-related patient encounters. London et al. examined patient encounter data from 21 healthcare institutions (20 from the USA and 1 from the UK) and reported a 57% decline in US cancer-related visits and a 50% decrease in UK visits due to the pandemic [51]. Patient visits for new cancer incidence declined by 74% and 65%, respectively. They also report profound decreases in screening for breast (89%) and

Table 70.1 General consensus measures taken by cancer centers in response to COVID-19

Category	Measure
Hospital wide	Construct a hospital-wide crisis team responsible for coordinating measures between departments
	Encourage patients not to arrive early. Offer to text patients when you are ready to see them, so they can wait outside or in the car
	Instruct patients not to visit the hospital if they have symptoms indicative of possible COVID-19 (unless urgent attention is required)
	Call patients the day before planned hospital admissions, to discuss the presence of any COVID-19-related symptoms
	Screen patients at the entrance for symptoms of COVID-19 and fever
	Quickly isolate patients with COVID-19 in specialized departments, with the intent of relocation to regional collaborating hospitals (if possible)
	Reduce preclinical research activities to a bare minimum
	Stop patient inclusion for clinical studies or trials requiring additional actions and/or visits. Consider a tumor type-specific "exception list" of particularly successful studies for which inclusion continues
	Discuss each patient with a multidisciplinary team to consider alternative treatment modalities with the fewest visits or lowest capacity problems or that are the shortest in duration
	Therapeutic adjustments (versus regular guidelines) should be discussed in a multidisciplinary team meeting
	Conduct multidisciplinary team consultations remotely if possible or include only one representative of each discipline to limit the number of people participating in the meetings
	Inform patients about a possibly increased risk associated with anticancer therapy during the COVID-19 pandemic
	Enable telephone or video consultations for healthcare professionals who need to self-isolate
	When postponing procedures or contact moments, anticipate future capacity problems
	Do not prescribe corticosteroids as anti-emetics (if avoidable), and limit their use in patients treated with immune-checkpoint blockade, to reduce vulnerability to COVID-19
	With each patient, discuss resuscitation status to anticipate future decisions about intensive care
Outpatient clinic	Critically triage second opinions
	Do all follow-up appointments by phone (except when physical examination is necessary)
	When possible, reduce or delay the number of radiological-response evaluations
	Prioritize oral or subcutaneous treatments above infusion-based treatments to reduce time spent in the hospital
	Perform blood tests outside the hospital (e.g., at a general practice or at home), when possible
	Have oral medications delivered to the patient's home, rather than being picked up at the pharmacy
Day care	Consider omitting supportive treatments (e.g., no bisphosphonate infusion, except in the case of hypercalcemia)
	When possible, organize the administration of intravenous maintenance treatments at home
	When administration at home is impossible, consider temporary breaks or reductions in the frequency of intravenous maintenance treatments for less-aggressive metastatic cancers on a per-patient basis
Radiotherapy	Consider hypofractionated regimens for patients with limited additional benefit of regular regimens
	Create capacity for radiation as replacement of surgery
Surgery	Consider postponement of surgeries with high morbidity and mortality during the pandemic
	Consider other treatment modalities with equal benefit (e.g., radiation for prostate cancer, curative chemoradiation for other tumor types, or brain irradiation for metastases)
Others	Consider outsourcing of interventions (e.g., follow-up endoscopies) to private clinics

From van de Haar [48], with permission Springer Nature

colorectal cancer (85%). The impact of deferring cancer treatment and screening is difficult to estimate, and it is unclear how long these visit levels will remain depressed; however, it seems likely that we will see future increases in delayed cancer diagnoses and later-stage cancer presentations to the ED.

With regard to trends in radiology use, Norbash et al. examined imaging volumes in six US academic medical systems and a large national private practice consortium. As expected, they reported large decreases (40–70%) during early stages of the pandemic, with the largest decreases occurring in screening mammography and bone density scanning [52]. Interestingly, in discussing a pandemic-induced increase in telecommuting by radiologists, they noted the potential for a new source of tension between frontline and remote healthcare workers, stating that: "An unfavorable byproduct of radiologist distancing at work and by telecommuting may be the impression of radiologists utilizing technologists, nurses, and residents as human shields while maximizing radiologists' physical perimeter. The optics are potentially damaging in the long term for the larger radiology team beyond radiologists and may counteract loyalty and high-performance interdependence" [52].

This sentiment above reflects a possible negative consequence of the move toward telemedicine; however, COVID-19 continues to foster the dramatic growth of such virtual care. In part, this impetus derives from reductions in both practice regulations and reimbursement barriers [53]. As part of the US federal stimulus package passed in March of 2020 (The Coronavirus Preparedness and Response

Supplemental Appropriations Act or CPRSA), rules surrounding reimbursement for telemedicine were substantially relaxed [54]. Prior to CPRSA, CMS only reimbursed telehealth services when patients received care in urban or rural locations with a known health professional shortage. Recipients must also have had a prior established relationship with the physician, a limited number of services were covered, and only certain HIPAA-compliant platforms were allowed. After CPRSA, these requirements were loosened and CMS specified that telehealth services would be reimbursed at the same levels as in-person services. Private insurers generally followed suit, thus the use of telemedicine skyrocketed.

While the virtual delivery of medical care has many positives, there are, of course, negative consequences. In physically distancing ourselves from patients, we may also distance ourselves emotionally [46]. We have discussed how an inadequate assessment might lead to failures of diagnosis, but there are also failures of rapport- and trust-building between patients and clinicians that might be increased by use of virtual interfaces. Geographic and socioeconomic inequities in Internet connectivity may also serve to increase health disparities. It is possible that the popularity of telemedicine among providers and patients will sustain its current levels of use; however, it is also possible that future reductions in reimbursement, in addition to anti-competitive medical market forces, will counterbalance this trend.

With regard to cancer research, the COVID-19 pandemic has caused profound disruption. Most clinical trials were suspended, while the research enterprise has shifted its focus to pandemic-related themes. Many NIH-supported research programs were allowed latitude to shift in scope toward COVID-19 research with federal encouragement [55]. At the same time, there has been a drastic reduction in cancer-related philanthropy. As only one example, the American Cancer Society projects a $200 million (25%) decrease in donations over 2020 [56].

This disruption in the research enterprise does have a potential upside. As cancer research efforts pivot toward COVID-19, they may allow a more precise assessment of treatment toxicities and outcomes. As van de Haar and colleagues have outlined, four research priorities should drive current efforts: (1) to collect real-world data on how adjustments and de-escalation of treatment impact patients; (2) assess symptomatic and asymptomatic COVID-19 among those receiving chemotherapies, targeted therapies, or immune-checkpoint inhibitors; (3) develop epidemiologic models to estimate the cumulative incidence of COVID-19 among those with cancer within a specific timeframe; and (4) estimate COVID-19 morbidity and mortality in patients with cancer who are treated with chemotherapy, targeted therapy, immune-checkpoint blockade, and/or G-CSF [48]. COVID-19 thus provides a unique opportunity to focus on the impact of treatment de-escalation, which for ethical reasons might otherwise be difficult.

Prevention

As noted above, the pandemic has caused large shifts in our ability to maintain current cancer care practices. At the national level, both the Welsh and Scottish governments suspended breast, cervical, and colon cancer in March of 2020, while Northern Ireland suspended screenings 1 month later [57]. In the USA, the Centers for Medicare and Medicaid Services lowered the priority for cancer screening programs at the outbreak of the pandemic [58]. Patient fear of exposure to the virus also served to decrease rates of cancer screening.

Tobacco prevention programs have experienced a similar COVID-related deterioration. Tobacco consumption has likely risen during the pandemic at the same time that access to healthcare has been disrupted. It is thus likely that tobacco-related morbidity and mortality will rise over the coming months and years [59]. Smokers are of particular interest, as the pandemic may both increase smoking behaviors in some (due to boredom and lack of social contacts during quarantine) and decrease such behaviors in others (due to a desire to maintain health in the face of external threats) [60].

Smoking may also impair the ability to utilize masks effectively (envision a mask dangling around the neck surrounded by cigarette smoke plumes) and increase mucous membrane viral exposure through contaminated fingers, while encouraging smokers to be outdoors (perhaps thereby decreasing exposure risk). Fewer visits to smoking cessation resources may mean a drop in use of nicotine patches and smoking cessation medications. Compounding these issues, medical care for chronic smoking-related conditions has been curtailed. Consistent with these expectations, EDs have indeed reported fewer admissions and delayed admissions for myocardial infarction and stroke since the pandemic began [61].

Surprisingly, initial reports suggested that smoking might have a protective effect against COVID-19, given that the prevalence of current smokers among hospitalized patients in China was unexpectedly low [62]. A cross-sectional analysis of patients presenting in New York City with COVID-19 found that smoking was not a risk factor for critical illness, and that it might even serve as a protective factor for hospital admission [63].

As another example of screening trends, Murray et al. report large reductions (as much as 58%) in referrals to Irish dermatologists for evaluation of pigmented skin lesions at the height of the pandemic [64] (Fig. 70.2). Interestingly, they also reported decreases in Internet searches (as a proportion of total searches) for both skin cancer and melanoma,

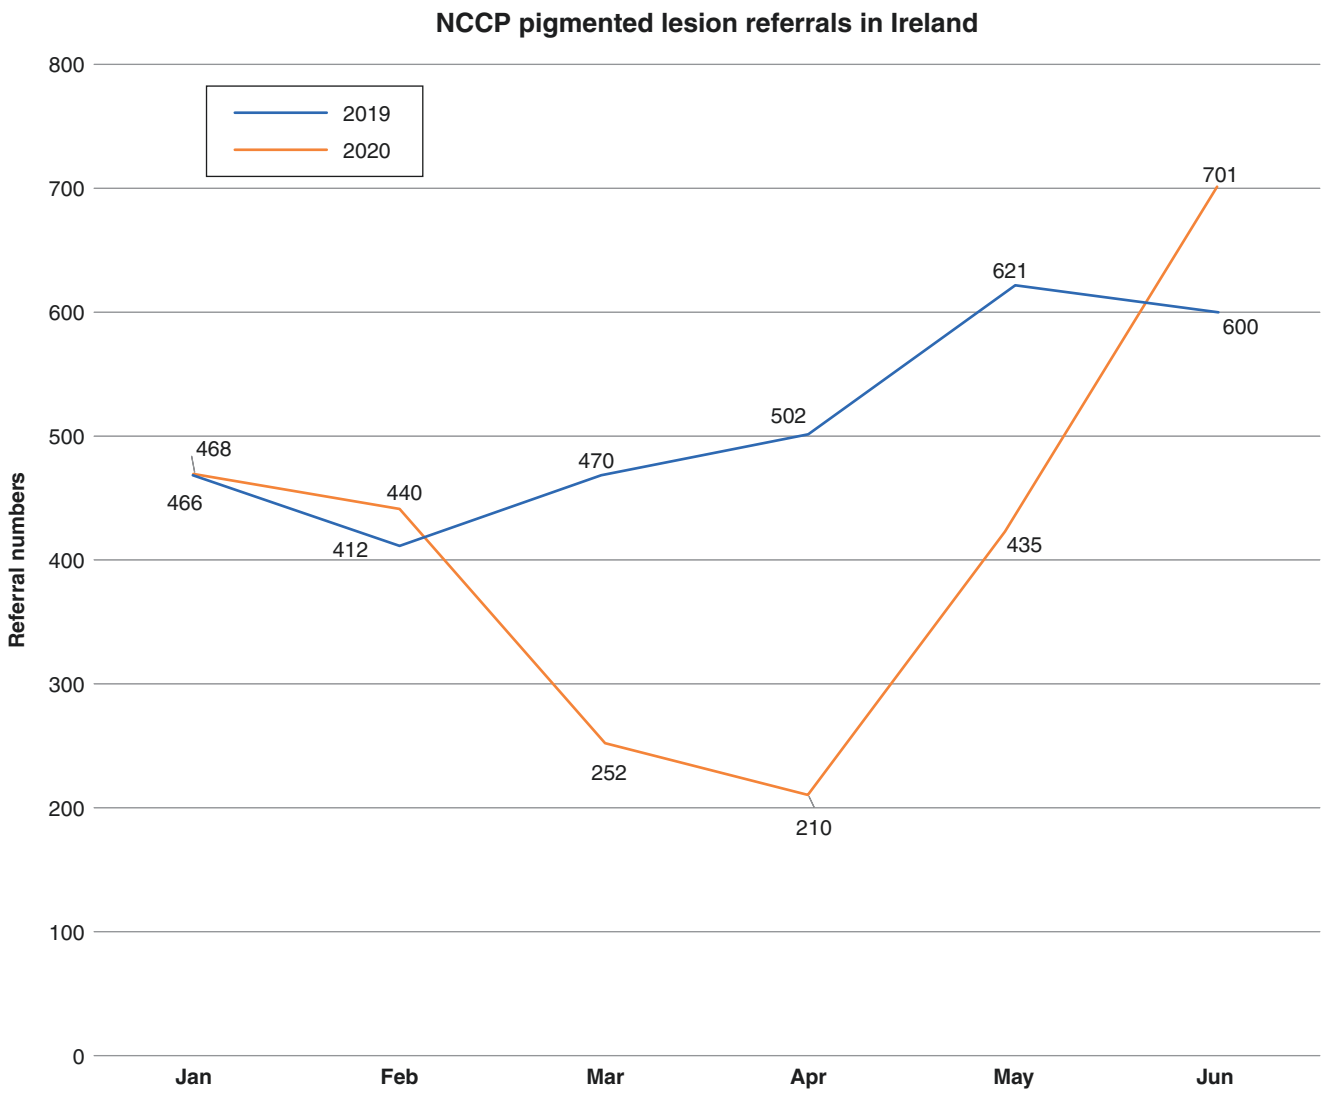

Fig. 70.2 National pigmented lesion referrals recorded from the NCCP Ireland during 2019 and 2020 of the months of January to June. (From Murray et al. with permission John Wiley)

as COVID-19 search activity swamped all other terms. Earnshaw et al. note similar declines in skin cancer referral (as much as 56%) [65]. They also make the valuable point that data regarding declines in cancer detection rates will assist in planning for the inevitable increase in diagnoses (often at later stages of disease) that will occur during any eventual pandemic recovery stage.

Economic Considerations

During the early months of the pandemic, while the numbers of COVID-19 visits to US EDs increased, the total number of ED visits plunged dramatically. Figure 70.3 illustrates this fall in patient volume for both academic and community EDs in one Massachusetts system [66] and others report similar findings [67, 68]. Data from the National Syndromic Surveillance Program show that national ED visits declined by over 40% during the early months of the pandemic, with the steepest declines among children and females and in the Northeast [69].

The public avoided the ED if possible, given the graphic images of ED chaos depicted in the media, the fear of contracting the virus, and a desire to avoid overburdening the system. In addition, while the public remained at home, injury rates outside the home (e.g., traffic injuries) decreased and fewer communicable diseases (other than COVID-19) required emergent care.

With this decrease in ED visits, the number and proportion of lower-acuity presentations fell, as did the need for a number of non-critical (and highly reimbursed) ED procedures. Most subspecialties experienced a fall in ED consulta-

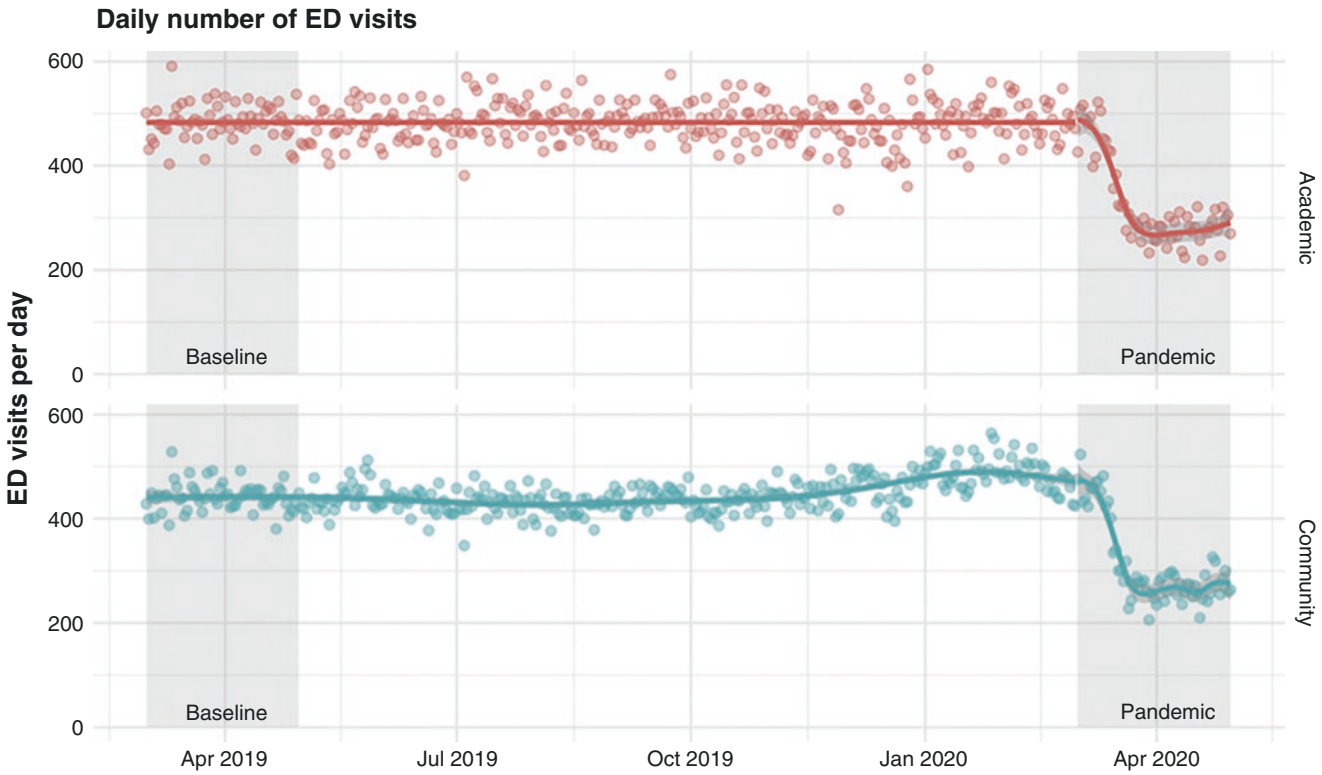

Fig. 70.3 Daily number of ED visits over time across the five included hospitals, separated by academic and community hospitals. (From Baugh et al. [66], with permission Elsevier)

tions, as well. Given that many hospitals cancelled elective surgeries and other procedures, the rate of ED visits for post-procedural complications declined in a similar fashion.

Case Study

Your sister, a 58-year-old breast cancer survivor and her spouse decided to take a rafting trip with two other couples. Before traveling, they decided to obtain tests for coronavirus and drove to a nearby free-standing ED where their nasopharyngeal samples were taken. The results were subsequently negative and they very much enjoyed the trip with friends.

Your sister's spouse paid $150 in cash for testing while your sister gave the clerk her insurance card. Two weeks after returning from vacation, she received a bill for $5000, leaving her responsible for substantial charges that the insurer did not cover. She leaves a message for you with her story and asking how such a discrepancy in charges is possible. How do you explain this?

Fortunately, you remember that the New York Times *has published a number of articles by Sarah Kliff on the issue of surprise medical billing* [70, 71]. *Surprise billing occurs when billing services used by "out-of-network" emergency physicians or other clinicians seek payment directly from patients when there is a gap in coverage. Patients often have no knowledge (or way of knowing) that this might occur when seeking care in the midst of an emergency. The issue has been festering for years without resolution; however, given increased attention to billing issues during the pandemic as well as the economic crisis, it is likely to be resolved by legislation that will ultimately decrease payments to physicians and EDs.*

After a quick review, you understand that wide variations exist for similar services, even in the same geographic area. Variations exist for a number of reasons, but the underlying reason is that the government does not regulate healthcare prices. Each facility negotiates with a number of insurers, and patients served by smaller insurers tend to pay larger bills. Those patients whose insurers have not negotiated with the charging entity may be responsible for the entire amount of the charge and these fees can be enormous. This can occur when a patient is served by an out-of-network provider, either the entire facility or an individual physician (e.g., *emergency physician, anesthesiologist), who is providing services as an independent contractor and charging separately.*

In coping with surprise medical billing for coronavirus testing, Sarah Kliff offers a number of recommendations [71]*: (1) obtain your test at a public site (e.g., state, county, or city-operated), (2) use your primary care physician or a*

federally qualified health clinic, (3) avoid hospitals and free-standing EDs (these locations charge facility fees, which are substantial).

While ED visit rates have more recently waxed and waned with pandemic trends, the impact on emergency physician and hospital finances has been overwhelmingly negative. Telemedicine use has expanded, replacing the need for many ED and office visits, and thus far, regulation of telehealth continues to be relaxed with many restrictions on reimbursement lifted. It is difficult to know whether these trends will continue, but to the extent they substitute for lower acuity, privately insured, and more profitable ED visits, emergency physician compensation is likely to fall [72]. The trend toward fewer high-margin ED visits may portend less need for emergency physicians and ED closures in low-margin settings, both urban and rural.

In its long-running biannual national survey of US physicians, the Physicians Foundation focused exclusively on the pandemic [73]. In the first of its three-part survey, conducted from July 15–26, 2020, they report that 8% of physicians (estimated to represent approximately 16,000 medical practices) had closed their practices permanently because of the epidemic and 43% have reduced their office staff, with 72% reporting loss of income and 59% expecting that COVID-19 would lead to a reduction in the number of independent practices in their communities. Similarly, a September 2020 survey of primary care practitioners found that 54% have furloughed employees and 28% have permanently reduced staff; 19% report that clinicians have retired early; and 15% state they are leaving (or planning to leave) their practice. Such losses in community-based medical practices will only increase stresses on ED capacity.

Cancer centers, particularly larger centers with a national or international clientele, have experienced large declines in service demand and face large pandemic-related economic losses. As in other parts of the healthcare system, the declines are in patient encounters that tend to be more profitable, as care moves out of the hospital and elective procedures are postponed or cancelled. In addition to patient fears of viral exposure, many patients who would seek cancer care nationally or internationally are electing to remain near their homes for treatment. Parking garages (a large source of income for many centers), restaurants, hotels, rental services, and the travel industry at large are all experiencing losses related to cancer center business turndowns.

The pace of economic recovery at these centers after the pandemic is an open question. It seems likely that cancer patients will be less willing to travel such great distances if care is available locally, and cancer treatment services have become more dispersed geographically over time. When seeking cancer care out of state, costs for travel, lodging, and lost wages alone are estimated to be double that for in-state care [74]. The disruption and suspension of many clinical trials during the pandemic will also lead to economic losses that may be slow to recover.

Workforce Mental Health

Emergency medicine practice is stressful. Our specialty has long recognized the intense nature of our practice and the challenges it poses to its practitioners. Among medical specialists, emergency physicians experience one of the highest rates of burnout. Emergency physicians suffer from practice-related anxiety, depression, and depersonalization with some frequency [75].

COVID-19 has only heightened these issues, particularly in areas of early pandemic spread. Studies of Chinese healthcare workers found high rates of mental distress for those involved in the COVID-19 response; moreover, emergency providers experienced the greatest risk for multiple negative outcomes [76]. During the pandemic, particularly in the New York area, emergency physicians faced staff, space, and personal protective equipment shortages. Clinical practice was conducted in an atmosphere of crisis, and emergency physicians often found themselves treating friends and colleagues. Initial reports estimated a 46% emergency physician seroconversion rate (admittedly using a limited sample of physicians from at a single New York ED) [77]. A deluge of news from around the world heightened a sense of emotional and social crisis. Physicians often responded to institutional mandates that were delivered without a sense of consent. Contradictory guidelines regarding PPE were a particular source of anxiety. Would I contact the disease? Would I infect my family? Not surprisingly, it is predicted that our specialty will experience an increase in anxiety disorders and PTSD as a result of COVID-19 [78].

To better quantify COVID-related stress among emergency physicians, Rodriguez et al. conducted a cross-sectional survey among academic emergency physicians from seven EDs [79]. The 426 respondents reported high levels of anxiety for themselves and their families. In terms of measures to relieve this anxiety, they desired more widely available PPE, rapid coronavirus testing, and clear communication regarding ED protocols related to COVID. Providing more specificity, Wong et al. outlined a number of practical initiatives, both individual and administrative, to combat mental distress within the emergency medicine workforce (Table 70.2) [80].

Table 70.2 Potential solutions for COVID-19-related emergency provider stressors, ordered by Maslow's hierarchy of needs

Maslow's level of need	COVID-19 concerns	Recommended strategies
Level 1: Physiologic (e.g., food, sleep, physical and mental health)	Extra workload demands around COVID-19 preparation and treatment Physical strain of protective equipment (dehydration, heat, exhaustion) Housing needs during isolation/quarantine periods Inadequate or disrupted sleep patterns Physical symptoms of COVID-19 disease for healthcare workers who contract the virus	*Individual* Time for basic bodily care and refreshment/relaxation and stress-management breaks Avoid maladaptive behaviors with negative physiologic effects (e.g., excessive alcohol, prescription drugs) Physical health and fitness (exercise programs, walking outside, mobile applications) Online mental health technologies (telepsychiatry, mobile applications, PTSD coach) *Administrative* Provision of respite for staff members requiring isolation (e.g., housing, childcare) Supplementation of readily available water and nutritious food while on clinical duty Careful attention to individual work schedules to maximize rest and sleep between shifts Facilitation of testing and treatment for individuals who develop symptoms or become ill Virtual wellness and information town halls Early and confidential recognition, detection, and referral for treatment of psychiatric symptoms (e.g., cognitive-behavioral therapy)
Level 2: Safety (e.g., personal security, financial security, resources)	Fears of personal safety around infection and lack of adequate personal protective equipment Lack of clarity around viral transmissibility (airborne versus droplet) Concerns for job security and potential debt, especially if an individual becomes infected with COVID-19 Feelings of being undersupported and underequipped to provide safe care	*Individual* Peer consultation and supervision of PPE donning/doffing *Administrative* Alternative strategies to produce/distribute PPE (local manufacturers, donations, recycling) Clear and consistent messaging and shared decision-making with healthcare workers regarding infection rates, risk, and strategies to minimize risk Contingency plans for healthcare workers who cannot work during quarantine period or if they fall ill after contracting COVID-19 to provide job and financial security without negative consequences
Level 3: Love and belonging (e.g., friendship, family, social connectedness)	Possible separation from family members Risk of exposure to loved ones, especially those who are at high risk Physical isolation from friends, colleagues	*Individual* Increase peer social support with regular contact with colleagues, family, and friends Seek out and share social support virtually *Administrative* Acknowledgment and affirmation of healthcare worker stressors and concerns Creation of specialized collaborative partnerships or teams focusing on COVID-19 Online-based group support networks and mental health checks Resources for significant others and family members of healthcare workers to support their loved ones during epidemic
Level 4: Esteem (e.g., respect, status, self-determination/control, fairness)	Pressure to serve as source of definitive information for nonmedical family and friends Constant pressure to maintain clinical acumen with increasing volume and acuity Ethical challenges in triaging resources (ventilators, staffing, bed capacity)	*Individual* Limit worries to actual (rather than anticipatory) threats Foster a spirit of patience, fortitude, tolerance, and hope Channel concerns through productive output (scholarly efforts, peer coaching, teaching, educational materials on COVID-19) *Administrative* Create specialized ethics teams/protocols for information and mentorship in decision-making Use patient-centered resources for difficult decisions Highlight exemplary behavior and celebrate individual contributions and efforts Create clear, transparent, fair, equitable, and accessible policies

(continued)

Table 70.2 (continued)

Maslow's level of need	COVID-19 concerns	Recommended strategies
Level 5: Self-actualization (e.g., desire for higher achievement)	Tension between public health priorities and individual patient care Advocacy for larger system changes to minimize the effects of the epidemic	*Individual* Focus on efforts within one's individual control Accept situations one cannot change Contribute to productive efforts for change *Administrative* Sharing of information across institutions/systems Peer mentorship for clinical, administrative, and academic duties related to COVID-19 Creation of volunteering, innovation, and service opportunities to support response efforts (e.g., creation of new devices/tools, clinical strategies)

From Wong [80], with permission Elsevier

Palliative Care

Emergency physicians encounter patients with unmet palliative care needs during almost all clinical shifts [81]. Given that the majority of hospital admissions originate in the ED, critical and timely decision-making by emergency physicians often determines the subsequent intensity and trajectory of treatment for life-limiting illnesses, including intubation and intensive care utilization. During the COVID-19 pandemic, questions of medical futility and appropriate goals of care have become more prominent and efforts to address unresolved palliative care issues have received increasing attention.

Early in the pandemic, the University of Washington implemented an institution-wide plan to address COVID-19-related palliative care needs [82]. Focused on the ED, the intensive care unit, and acute care services, it provided strategies to identify goals of care, manage distressing symptoms, and support family members. In the ED, the palliative care service conducted daily huddles with staff, provided consultations for patients with poor prognosis and at risk for intubation or CPR, supported implementation of DNR orders when appropriate, and embedded a palliative care specialist to screen patients. The palliative care service also provided telephonic coaching and support 24 hours/day, 7 days/week.

In responding to the early surge of COVID-19, New York-Presbyterian Columbia University Irving Medical Center developed a psychiatry-palliative care liaison team (including trainees) to provide ED palliative care services [83]. During the peak of the epidemic, this service provided a 24-hour coverage for palliative care needs, allowing emergency providers to better meet the overwhelming demand for medical care and establishing a model to provide future surge capacity. For 110 ED patients seen by the palliative care team, the median age was 81.5 (range 46–101), two-thirds were community dwelling, and few presented with advance directives or Medical Orders for Life-Sustaining Treatment (MOLST) [84]. Ninety-one of 110 patients (83%) were considered "full code" on arrival to the ED, falling to 20 of 100 (18%) after the initial ED palliative care consultation.

In a qualitative study, emergency medicine researchers interviewed representatives from 52 hospitals in the USA to identify ED-palliative care innovations driven by the pandemic [85].

Table 70.3 summarizes these innovations in systems, staffing, and technology. Respondents reported that such innovation was welcomed by clinicians and positively impacted patient care trajectories.

Conclusions

In this brief review, we have discussed a number of challenges posed by the COVID-19 pandemic and its impact on the evolving subdiscipline of oncologic emergency medicine. Beyond direct negative outcomes due to infection among our patients, we are concerned that degradation of our screening and prevention efforts, in addition to pandemic-related barriers to appropriate cancer treatment and research, will have long-lasting effects well into the post-pandemic era. At the same time, the pandemic has exposed faults within the healthcare system and society that, when recognized and confronted, hold the promise of a better future.

In the USA specifically, the politicization of science, with its long and dark history, has become increasingly overt. This anti-science effort must be resisted and counteractions taken against it by physicians, researchers, and cancer patients. The stark evidence of health disparities associated with COVID-19 should give rise to further efforts to reduce and eliminate such inequities. Given resource constraints posed by the virus, our health systems have an opportunity to re-examine the consequences of overly aggressive cancer therapies, as well as the inferior provision of palliative care. A necessary redesign of our cancer care system in response to COVID-19 has many lessons for the larger healthcare system and society at large.

Table 70.3 Summary of innovations in ED palliative care

Type of innovation	Example of innovation	Innovation detail
Model of care delivery	Embedded PC clinician in the ED	PC clinician seated in the ED dedicated only to ED consults
	Strengthened ED presence	Achieved through daily rounding, EMR chat function
	Mobile PC consult service	Dedicated service focused on ED and ICU needs
Staffing	PC attendings with extenders	Residents with focused GOC or ACP training
	PC attending with PC fellows	Triage cases based on complexity to appropriate clinician
	PC extender with psychosocial partner	Pair volunteer non-PC physician with social worker or child life specialist who perform all consults together
Technology-enhanced PC-ED	Off-site tele-PC	Centralized team of either RNs or PC physicians for all hospitals in a health system
	Blended on-site tele-PC	Triage patients based on their capacity to engage to either in person or tele-PC
Primary PC training and education	Trainings and tools	COVID-specific conversation training; collated resources (with apps, Google Docs, provided laminated cards)
Case identification and task stratification	Proactive case identification	Remotely screen ED track board, daily rounding
	Formal triggers (for primary PC or specialty consult)	Automated or manual – encompassing age, marker of underlying illness, marker of acute illness
	Focused, abbreviated consults	Task-oriented consults focused on specific patient needs
	Nursing-initiated consults	Consults to PC triggered by nursing staff using clear trigger criteria

The Physician and Cancer: In Their Own Words

71

Marshall T. Morgan, Patrick J. Crocker, Burton F. Dickey, Sherry-Ann Brown, and Knox H. Todd

Introduction

The word, "cancer" is, in itself, a powerful term that should never be underestimated. It carries a certain shock value – a sense of doom and gloom that seems qualitatively different from other diagnoses. This is as true for physicians as it is for laypersons. In this collection of prose and poetry, four physicians tell us stories of their cancer experiences, with the goal of communicating what matters. We hope these illness narratives help our readers care for themselves and for others in a more human, and humane, manner.

Editor's Note

Marshall Morgan was my mentor and friend. He headed the UCLA emergency medicine program where I trained, and throughout our careers we met frequently to share stories of our lives, usually over a meal and always over a glass of bourbon. By example, Marshall taught me the importance of empathy. Professionally, one of the things I most admired in Marshall was that although he was generally the smartest person in the room, you didn't realize it until later. The day after he felt the first symptoms of cancer, Marshall took time to write the words below. These were included in his memorial service a short time later.

M. T. Morgan (Deceased)
Division of Emergency Medicine, Department of Medicine, UCLA Medical Center, Los Angeles, CA, USA

P. J. Crocker

The Difference a Day Makes

Marshall T. Morgan, MD (1941–2015)

Yesterday morning thinking about my future I made the reasonable estimate that I would live in a functioning active state into my mid-to-late 80s (I am 73). I considered: When should I retire (not now: my wife is still working and I like my job)? On the other hand, I spend too little time with my children and grandchildren, so maybe sooner than later.

Last night, I developed an unusual RUQ pain with a strong pleuritic component and no tenderness. I consulted my physician and we decided I should go to the ED. The ED workup, which would have taken a week as an outpatient but was done in 4 hours, revealed a large number of liver lesions and a mass hugging the lesser curvature of the stomach.

Today, unlike yesterday, I am contemplating a much shorter future for myself (disappointingly I have young grandchildren). I will undergo EGD tomorrow in an attempt to get a tissue diagnosis and soon will face the question of chemotherapy, whether to undergo chemotherapy.

As an emergency physician I have been the messenger to others on the day that made the difference. Some, like the 60-year-old gentleman with a large palpable right upper quadrant mass, were not surprised at all, but resigned. Others whose imaging was done in the expectation of finding a gallstone or kidney stone were shocked as I was. Interestingly, when there were tears, it was family members, not the patient, who shed them.

I have shed no tears. Most of my thoughts have been around changing the expectation of my remaining life span and hoping that I will be spared severe pain and disability

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_71

for some time, so I can enjoy my family, my friends, and this wonderful planet to the greatest extent possible before I leave them behind.

M.T.M.

Editor's Note

Pat Crocker is a true pioneer of emergency medicine in Central Texas, having served as Chief of Emergency Medicine at both Austin's Brackenridge Hospital and later, Dell Children's Medical Center. He now lives in Kerrville, Texas, and recently published two books of stories from his rich career [1, 2]. On reviewing his second book: *More Letters from the Pit: Stories of a Physician's Odyssey in Emergency Medicine*, I wrote:

> …Pat Crocker captures the stories of our lives as emergency physicians. These accounts of the highs and lows in caring for patients over his remarkable career are delivered in often stark, and occasionally grim, terms. Physician readers will recognize these stories immediately, if not as their own, then as those that might have been. For readers with a non-medical background, reading these pages opens a rich window into the human theater that is emergency medicine. For our families and loved ones, reading this book will help you understand why we might be less talkative than usual when returning from a long clinical shift. My hope is that after reading this book, conversations about our work become easier. At times tragic, at times humorous, More Letters from the Pit conveys a profound understanding of the gratitude we owe our patients and a sense of wonder at the mysteries of chance and providence that bring us together in the crucible that is the modern emergency department [2].

Thomas J.

Patrick J. Crocker, DO

I have found that some of the great saves are not those accompanied by that adrenalin rush of the ER we in the field seem to crave. No blood and guts. Instead they're ones fighting foes that threaten to kill your patient from the inside out. Cases that require thought, planning, an engaged patient, and a whole team of multidisciplinary players. These kinds of saves can roll out over months and the ending uncertain for years. But they are no less gratifying than the others.

I first met Thomas as Marcia and I prepared to build our new house. We had decided on polished concrete floors, and our builder who referred us to him thought he was the best in the business. And so we drove out to meet him, see his shop, and let him show us some samples of his work.

The shop was located out on a country road. Rather an informal place surrounded by beautiful old oak trees and, of course, displays of his handiwork. We walked around a bit and saw no one, so went inside to the office area. No one there either. "Hello," I called out. And then a little shuffling from a back room and he emerged from behind a curtain.

He smiles and says hello. A firm handshake. He's about my height, fit, slender, and rangy. I can tell by looking at his sloping shoulders and biceps he works for a living. And obviously doesn't think concrete work is enough exercise so he hits the weights regularly too. He seems a bit rough around the edges. I suspect he likes to party, ride motorcycles, and an occasional bar scuffle may not be beyond him. I like him immediately.

He's anxious to show us his craft and we walk around his shop seeing what he can do. He is a master. This guy turns concrete into something almost indistinguishable from marble. Creates beautiful concrete countertops, tabletops, and sinks. It only takes us a few minutes to agree this is our man and we tell him we'll let the builder know to call him.

The work on the house goes forth and I get to know Thomas better. He proves to be a very likeable sort. Smart, hardworking, and honest. A man of his word. After dealing with a few issues that cost him some profit, I thanked him for being one of the few honest folks in the construction business that I've ever met. We became friends over the months of building.

One day we're talking about medicine, my experiences at the trauma center, and he asks if I could be his doctor. He's a hardworking guy but without medical insurance so I said sure, but I can't see him at the ER. I told him I would do a physical, get some labs, and get him on the right track. He hadn't seen a doctor in a decade and it was past time. He agreed and I told him to call when he was ready. The physical would be in my office at the new house.

Months pass and I don't hear from him. I supposed the same distaste for doctors and health care that kept him away for a decade had not yet been overcome. And then a day later, the phone rings. He wants to know if I could have a look at his elbow following an injury. And I of course said come on over. And he does.

It's a sad conundrum for physicians to help patients like this. In my case, my malpractice insurance only covers me for cases in the hospital. I'll be going bare to help him out but he deserves it. I also trust him to believe that no matter what the result may turn out to be, I did my best. Nevertheless, we will have the conversation that my no-cost assistance comes with the agreement he forgo the right to sue me. I hate to

bring this up with someone I now consider a friend but I also have to protect my family. He will understand.

Thomas shows up a few hours later sporting his usual smile and laugh. He's still ten feet away but I can already see his elbow is a mess. He tells what he can remember of the incident, which isn't much. He was at the Burning Man festival and then woke up in jail. We both laugh. He says all he really knows is when he was released he found a police citation in his pocket. I laugh to myself at this one. Good luck, Nevada police, you'll probably never be seeing Thomas again. This is *pure* Thomas!

After I examine him I conclude he has probably torn part of his bicep insertion and wrenched the joint pretty badly. I get him set up with an orthopedist I went to medical school with. As he is captive in my office I ask him about that physical I was to perform for him. I say, "Dude, you're 50 years old and a smoker. We need to do this for you. Don't be a stupid shit and put this off any longer." We are obviously frank with each other. I also point out he won't be working for a while and it's the perfect time to go get that lab work done. And that I'll want a chest X-ray. I'm not going to take responsibility for a smoker's health at his age without one. He laughs his laugh and agrees, and the next day follows up as he said he would. Thomas is a man of his word.

Two days later all the lab work has returned and is normal. I didn't expect to find much but when a patient hasn't seen a physician in so long you never know. I also get unwelcome news.

One of the radiologists saw my name on the chest X-ray order and decided to call me directly. He spills the news that it shows a mass in his right lung and it looks like whatever it is has spread to the lymph nodes in the right side of the chest. This means most likely cancer and fairly advanced. This is horrible. I worry it's a death sentence for him.

I give him a call, trying not to alarm him but tell him what I have found. Bad news is something I dread giving patients. But we must deal with the facts. No exceptions. I tell him to head back to the radiologist for an enhanced CT scan of his chest. We'll try to nail this down as best we can as soon as possible. Thomas takes the news straight up. He knows I'm worried. I order a CT scan of his chest and he returns to the radiologist.

Late that afternoon the radiologist is on the phone again. He's confirming on the CT scan this appears to be lung cancer, spread to the lymph nodes on the right side. Even worse it appears to have involved the aorta. This may make the cancer inoperable, I fear.

Before I tell Thomas the bad news I call one of the oncologists I've known for years. I consider him one of the best and would trust him with my family members. We discuss the case and he isn't too hopeful. Statistically, he suspects a small cell carcinoma, too advanced for surgery, and a very low survival rate. I feel crushed for Thomas. He does add, however, that given his young age, he thinks we should go for broke on this one, try for a save. Not palliation where we might just try to give him some more time on earth but go for a straight-up cure. He asks me to send him over to the office.

A PET scan is ordered and the oncologist and I speak again. Yes, definitely a cancer. Thomas will now need a biopsy of the lesion to nail down the type and characteristics of the cancer. He again takes the news in a levelheaded fashion and then asks the question I dread. "How long do you think I've got Doc?" I hedge a bit, let him know it's not good news, but the oncologist wants to go for a cure. And Thomas is now determined to get that cure. I add one other thing, "You must quit smoking NOW. The oncologist says there's no hope if you keep smoking." He says he will quit today.

The rest of the story unfolds over the following weeks, pretty much as predicted. The biopsy confirms small cell carcinoma and the prognosis is not good. The big decision is what to do for Thomas. Surgical removal is not possible.

A patient's active involvement in their healthcare is something I treasure. I believe an active participating patient leads to better outcomes. Thomas and the oncologist talk over treatment options, all of which are aggressive. Thomas and I review everything. Before starting treatment Thomas wants to consult with some other specialists. I agree, but say, "Let's not waste a lot of time." We'll be thorough but I want to get things started. Thomas is making his survival his only project, tracking down every available approach. He even includes an herbalist. Checking into supplements that might increase his chance of survival or at least keep him healthier through the chemo process.

A couple of weeks pass as other consultants see him. He finds another very aggressive oncologist who wants to press for a cure also. The two oncologists disagree a bit on therapy, as they don't want to kill him during the process, but finally agree to take the chance. And so does Thomas. The goal is a cure if possible. A combination of chemotherapy and radiation that will begin immediately.

Through 5 rigorous months of therapy, including prophylactic brain radiation to kill any cancer cells hiding there, Thomas and I talk from time to time. I give him my encouragement. I learn he's still hanging in there, still determined despite feeling poorly. We talk about the predictable baldness, all the economic stress of this kind of major therapy, and the supplements.

Multiple PET scans and follow-ups occur. The tumor shrinks but remains visible on the scans. After a year, however, it hasn't progressed and we start to consider that maybe this is residual dead tumor and scarring. Another year goes by without any change and happily the tumor ultimately is considered dead. I'm elated for Thomas.

So this case had none of the adrenalin we ER doctors seem to crave. It was a very satisfying result nonetheless. The excitement of blood and guts substituted for a thorough approach by a great team of doctors and a very determined patient.

I am again convinced that fate plays a role in our lives. Also that thoroughness and an unflinching determination to cover all your bases from the start, every time, save patient's lives. As usual, all of the what if's churn through my mind. What if I had let Thomas's initial reluctance to skip the chest X-ray rule? Just entered a note, "Patient refuses chest X-ray at this time." Covered my ass with a simple note and left his hanging in the breeze. I just can't approach patients like that and glad I didn't.

I recall a patient I saw years before who presented with a complaint of a shoulder rash. On examination I found a very large melanoma lesion. I explained what was wrong and what we needed to do. She refused, saying she would treat the lesion with over-the-counter peroxide. We talked for about 15 minutes, me attempting to convince her that peroxide treatment was not only ill-advised but would result in her death. She was adamant. Unbelievable.

And I entered that CYA, cover your ass, note in the chart, "Patient refuses referral for an apparent advanced melanoma despite counseling" and had her signed out against medical advice. A sad addition to her medical record. My ass was covered, but hers wasn't. I consider such encounters personal failures every time. I have failed to engage my patient in a fashion that led them to the appropriate care.

Thomas remains happy, healthy, and tumor-free. We talk once in a while. Someday when we're both motivated he'll give me some concrete finishing lessons. We'll build a tabletop together.

And though the danger of getting too close to your patient and their tragedy and crossing that line between empathy and self-preservation is one I wrestle with almost daily, sometimes you have to cross it for a friend.

Editor's Note

As a fellow chair at MD Anderson, I will always be indebted to Burton Dickey for his advice on managing my department within a byzantine modern cancer center and for his ever-quick wit and humor that sustained me through interminable administrative meetings. When I asked Burton to write about his experience with multiple myeloma (from which he is in remission and doing well), he told me: "Don't expect anything sentimental or melodramatic; that's not me. Just the facts." What follows is his advice on what to do (and what not to do) for physicians facing a cancer diagnosis.

Advice for a Physician (or Anyone Else) with Newly Diagnosed Cancer

Burton F. Dickey, MD

I was diagnosed with multiple myeloma 8 years ago and today am fortunate to be healthy and in complete remission. Quite a few physicians, including my friend Knox Todd, have asked what I learned. My advice comes down to three simple suggestions. First, read about your disease – a lot. Second, do what grandma told you to do – eat well, sleep plenty, and exercise. Third, know when to let go – more about that later.

When you are first diagnosed with cancer, it is likely to be a shock. Many cancers are diagnosed in someone without any symptoms on the basis of a test. Even when a symptom is present, the diagnosis of cancer as the underlying cause may not have been apparent. With the diagnosis, one's mind immediately goes to the questions of "How much time do I have left?" and "How good or bad will that time be?" In my case, the possibility of myeloma was identified by my cardiologist on a routine blood test as part of an annual visit to have my cholesterol-lowering statin medication adjusted. A complete blood count showed low hemoglobin, white cells, and platelets, indicating that my bone marrow was failing or being replaced by tumor or infection. I am fortunate to work at the MD Anderson Cancer Center and was evaluated later that afternoon by a hematologist friend, then referred for a bone marrow biopsy the next day. Some of the possible diagnoses had a fairly grim prognosis and others were not so bad. My mind raced through the possibilities until I received the diagnosis of myeloma with a sense of relief when the biopsy was read the next day. Of course myeloma can have serious complications such as renal injury and bone involvement, and it can have a poor prognosis depending on its genetic drivers, but it was more tractable than some of the other possibilities. I was fortunate to have a "low-risk" tumor genetic profile and no renal or bone complications and began standard-of-care treatment almost immediately.

My first piece of advice is to read. This is advice you are unlikely to need since you will be able to think of almost nothing else initially, and will be intensely interested in treatment options, prognosis, etc. Working as a pulmonologist in a cancer hospital, I had a superficial understanding of myeloma, particularly since the focus of my practice is on pulmonary complications (such as pneumonia, bronchiectasis, and obliterative bronchiolitis) of hematologic malignancies (including leukemia, lymphoma, and myeloma).

Nonetheless, I began to read deeply both the classical and cutting-edge literature of myeloma. I will never know as much as my oncologist, who has spent her entire career focused on myeloma, but I think my reading served both me and her well. In clinic visits, she could move quickly through the basics because I now knew most of them, and we could focus on more subtle questions. I believe that most physicians appreciate a knowledgeable patient for exactly this reason and, even when challenged, appreciate the possibility of thinking through a routine issue in a new light. In a few situations, my challenges led to a change in care. After about 2 months of reading almost nothing but the myeloma literature, I settled back into a more normal schedule of reading the medical literature with a focus on pulmonary and general internal medicine, but also with a particular eye out for new developments in myeloma.

My second piece of advice is to remember what grandma told you. Hopefully you already have good habits of eating, sleeping, exercising, and balancing work and home life. If so, I suggest continuing with little change, and if not, talking to your grandma about common sense habits. There is a lot of advice on the Internet about outlandish diets that can beat back cancer, but with little or no evidence to support them. I have always eaten three conventionally balanced meals a day, with dinner routinely eaten with my family, and we didn't change anything during most of my illness. After high-dose cytotoxic chemotherapy, nausea is a problem so supplementation with commercial nutritional drinks may be necessary transiently, but sticking for the most part with a routine balanced diet preserves one of life's pleasures and a foundation of good health. Sleep is similar – most of us know how beneficial a full night of sleep is and what the main components of good sleep hygiene are. Some excess fatigue resulting from cancer therapy is common, so a nap can be helpful. Possibly the most important area of lifestyle management during cancer treatment is exercise. Of course this is important throughout life, but cancer and its treatment can lead to debility and frailty, so every effort should be made to prevent that. Besides, it is my impression that regular exercise minimizes symptoms from treatment and improves mood. Work is another important issue. I have always derived great pleasure from work from its intellectual interest, the companionship of colleagues and patients, and a sense of contribution. Depending on the side effects of treatment, continuing to work at either a full or reduced level may be possible, and for me it was an ongoing source of stability and pleasure. While cancer obviously imposes a strain on one's family and friends, it can also draw them closer as an unexpected benefit.

Having talked about all the things you can do to contribute to your well-being in the first and second points, I'll now pivot and remind you that you can't do it all. Clearly, others will need to administer chemotherapy and radiotherapy and perform surgery. However, beyond that, there is a time to stop challenging the judgment of others or pushing yourself through difficult spots. For me, the most glaring example of knowing when (or when not) to let go was when I became septic during the neutropenia that followed high-dose chemotherapy and autologous hematopoietic transplantation. This was performed as an outpatient, and while it was a difficult couple of weeks, I was grateful to be in my own home with my wife as caregiver. However, late one night I developed lower abdominal pain and the urge to urinate every few minutes. I knew my neutrophil count was low, so it should have been obvious to head to the emergency room. Nonetheless, I experienced an irrational fear of a crowded emergency room in which I would end up feeling worse instead of better. When we finally went at 7 AM, I was quickly placed in a comfortable room in the emergency center; a compassionate colleague had taken a history, performed an exam, diagnosed diverticulitis, started antibiotics, and ordered placement of a Foley catheter that immediately relieved the urinary retention resulting from the diverticulitis. My experience of the rest of the hospital stay was equally caring and comfortable, and I've wondered in retrospect why I initially had such dread and delayed the obvious need for care. I suspect that part of it was due to clouded thinking from sepsis, but another part was probably an excessive desire for independence and reluctance to let go and be cared for by others. Thus, my third piece of advice is to recognize that while you can be a powerful agent in your own care, you can't do it all and it's important to trust the skill and good will of others.

In summary, I have been fortunate in my encounter with cancer, and hope that you are as well if it enters your life. I believe I did some things to aid my recovery, but also a few things that interfered, and hope you can learn from my experiences.

Editor's Note

Perhaps the most rewarding thing about editing a textbook is learning from your authors. In reading Dr. Sherry-Ann Brown's work in the area of cardio-oncologic, I was introduced to another facet of this poetic scientist's work. She has published a number of works exploring the more spiritual side of clinical practice, and two of her poems from *The Healer Speaks: Poems For Patients, Students, Doctors, Nurses, Therapists, & Everyone Impacted By Medicine* are reproduced below [3]. These poems speak to her personal relationship with cancer patients and give voice to the often-unspoken dialogue between patient and physician (of which neither may be fully aware).

Excerpts from *The Healer Speaks*

Sherry-Ann Brown, MD, PhD, FACC, FAHA

Somebody Tell Me

What will kill me?
When will I know?
When will I die?
What will I die from?
Is it cancer?
Is it heart disease?
Is it crossing the street?!
Somebody tell me!

Give me a disease of the heart.
What can I do?
How can I prevent this?
How can I fight this?
Tell me my risk of having heart disease.
At least then I could walk faster,
I could skip; I could jump; I could run!

I could eat better.
I could have my vegetables,
My fruits, and my fish.
I would even have my nuts,
And extra-virgin olive oil.

I would even stop smoking.
Well, I would try.
Because I would want to
Run away
From both cancer
And heart disease.

I don't know if I really could,
But I surely would try.
And I might even tell those around me
To try too.
We might even try together.
Maybe as a community,
We could do this together.
Tell me,
Tell us.
What is our risk of heart disease?
Tell us as a community.
Tell us as a population.

What can we do
As a team
To grow old together?
It's not so much about dying,
As it is about living.

How is it that heart disease
Kills more people
In this country
And in this world.
Than cancer?

Then why am I more afraid of cancer?

I suppose it's because with cancer,
It comes so soon!

Where did this cancer come from?
She's so young.
He's so young.
I am so young!
Why cancer?
Why me?
When will I die?

What will kill me?
How will I know?
When will I know?

Oh, the agony.
Breathe.
Just breathe.
Relax.
And live.
Truly live.
Love to live.
And give all.
Till it's time.

The Healer Speaks

The Healer Speaks
My dearest patient:
When I see the hurt in you,
I want to reach out
And wrap myself around you,
To protect you.
I cannot myself take the pain from you,
I cannot shield you from the damage
Of deterioration and injury.
Yet, when you hurt I hurt,
When you heal I heal.
You shouldn't hurt alone.
I am honored to hurt with you.
I am honored to hurt for you.

The Patient Speaks
My dearest doctor:
Do not hurt for me.
Do not hurt with me.
Let me hurt without you,
For my hurt is temporary,
And I will heal.
Whether physically,
Or perhaps spiritually.
I fear your hurt is irreversible,
And you may not heal.
While you protect me,
Who will protect you?
Since I cannot protect you,
How will you protect yourself?

The Healer Responds
My dear patient:
I suspect You are right.
Thank you for releasing me,
To protect myself too.
To care for myself too.
To heal myself too.
To gain healing
In the midst of others too.
Thank you for helping me see
That first I have to take care of me.

Multiple-Choice Questions

1. Patients with the following cancers have the highest incidence (of at least one) of ED visits within 1 year of diagnosis:
   (a) Breast, prostate, and melanoma
   (b) Pancreas, brain, and lung
   (c) Colon, prostate, and eye
   (d) Oral, melanoma, and endocrine
   (e) None of the above
2. Which cancers are associated with the most ED visits?
   (a) Lung, breast, prostate, and colon
   (b) Pancreas, brain, and lung
   (c) Leukemias and melanoma
   (d) Cervical, prostate, and breast
   (e) None of the above
3. Limitation(s) of using ED visit-level data to explore ED use by oncologic patients generally include:
   (a) Visit-level data may not be able to account for multiple visits made by the same patient
   (b) Visit-level data provides no information regarding the quality of care
   (c) Visit-level data cannot capture the incidence of ED use by all patients with cancer in a given sample or population
   (d) A and C
   (e) B and C
4. What is the most common method used to identify potentially preventable ED visits in cancer patients?
   (a) Ambulatory care sensitive conditions
   (b) The Billings algorithm
   (c) Panattoni's methodology
   (d) Prevention quality indicators
   (e) None of the above
5. Which of the following statements about ED use by oncologic patient is false?
   (a) Oncologic patients visit the ED across the cancer care trajectory.
   (b) Underlying symptoms and the diagnoses associated with an ED visit are considered *need*-related determinants of ED use.
   (c) Oncologic patients have lower rates of admission and lower rates of multiple ED visits than the general US population.
   (d) ED use by oncologic patients reflects a complex interaction of individual and contextual factors (e.g., provider behavior, health system characteristics, and health policies).
   (e) None of the above.
6. Which of the following data elements is not a HIPAA identifier?
   (a) Internet Web Address
   (b) Birthdate
   (c) Insurance plan number
   (d) IP address
   (e) Gender
7. What is the term for an information system that collects and analyzes data from a census of cancer cases?
   (a) Health information exchange
   (b) Electronic medical record
   (c) Cancer registry
   (d) Computerized physician order entry
8. Who do you want to identify first when designing an order set?
   (a) EMR analyst
   (b) Nursing
   (c) Patients
   (d) Users (i.e., physicians)
   (e) Clinical champion
9. A 34-year-old man smokes a pack of cigarettes when he goes out on weekends with friends. He has smoked more than 100 cigarettes in his lifetime. This man is best classified as a:
   (a) Current smoker
   (b) Daily smoker
   (c) Nonsmoker
   (d) Insufficient information to classify smoking behavior
10. A 58-year-old woman with chest pain is placed in observation status in the ED's chest pain center. She smokes 30 cigarettes daily. After several hours in the

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5

chest pain center, she becomes agitated and says she wants to walk out to the ambulance bay to smoke a cigarette. The most appropriate course of action is to:
(a) Offer her a nicotine patch
(b) Offer her a small dose of oral diazepam
(c) Have her sign out against medical advice
(d) Offer her a nicotine patch and 2 mg nicotine gum

11. Which of the following statements is true regarding ED-initiated tobacco control?
(a) Clinical trials have not demonstrated the efficacy of ED-initiated treatment.
(b) Nicotine replacement therapy and motivational interviewing have been shown to help ED smokers achieve abstinence.
(c) National bodies that accredit EDs and emergency medicine residencies require emergency care personnel to treat tobacco dependence.
(d) Although clinically effective, ED-initiated tobacco control is expensive.

12. A true statement about Screening, Brief Intervention, and Referral to Treatment (SBIRT) is:
(a) SBIRT was developed to facilitate the treatment of opioid-use disorder, then adapted to tobacco.
(b) SBIRT requires smokers to receive pharmacotherapy, such as nicotine gum or patches.
(c) SBIRT requires individuals with substance-use disorders to be referred to programs for post-ED care.
(d) SBIRT should be avoided for individuals with co-occurring serious mental illness or other substance-use disorders. These individuals should be referred to intensive outpatient programs.

13. When does alcohol use most commonly begin?
(a) Adolescence
(b) College-aged adults (18–22 years old)
(c) Middle aged adults
(d) Elderly

14. Which of the following types of cancers is *not* known to be linked to alcohol use?
(a) Breast
(b) Rectal
(c) Uterine
(d) Larynx

15. Which racial/ethnic group suffers from the highest rate of alcohol-attributable injury?
(a) Latino
(b) Asian
(c) Black
(d) Native American

16. Which diagnostic criteria for alcohol-use disorder was added to the DSM-5, from the DSM-IV?
(a) Tolerance
(b) Craving
(c) Legal problems
(d) Withdrawal

17. An extensively sun-damaged 60-year-old female presents after spraining her ankle. On examining the lower limb, you note a large very suspicious pigmented lesion on her calf. If you were to perform a skin biopsy to get a histological diagnosis, what would be the most appropriate?
(a) Punch biopsy of one edge
(b) Total excision of lesion with a 2-mm margin
(c) Shave biopsy of half the lesion
(d) Incisional biopsy of part of the lesion

18. Which of the following is *not* a high-risk melanoma phenotype?
(a) Red hair
(b) Multiple nevi (>100)
(c) Dark skin
(d) Pale eyes

19. What is the strongest predictor of melanoma mortality?
(a) Size in centimeters of the melanoma
(b) Breslow thickness
(c) Age of the person
(d) Age when it occurs

20. In the ABCDE mnemonic, which of the below is incorrect?
(a) Aggravating – really unsightly to look at
(b) Border – irregular
(c) Color – multiple colors
(d) Diameter – over the size of a pea or growing
(e) Evolution – changing over time in size or height

21. How long does HPV vaccine protection last?
(a) 5 years
(b) 7 years
(c) 9 years
(d) At least 10 years

22. What are the US recommendations for cervical cancer screening on age of starting and method?
(a) At the age of sexual debut, cervical cytology
(b) At the age of sexual debut, cervical cytology and HPV testing
(c) 21 years, cervical cytology
(d) 21 years, cervical cytology and HPV testing

23. In the United States, what types of treatments are recommended for CIN2/CIN3?
(a) Observation

(b) Ablation
(c) Excisional procedure (e.g., LEEP or CKC)
(d) Hysterectomy

24. What will happen with most women who become infected with HPV?
(a) Develop cervical cancer in 10 years
(b) Develop significant preinvasive disease in 5 years
(c) Have persistent HPV infection
(d) Clear the infection spontaneously within 18–24 months

25. A 65-year-old male presents to the ED with several days of progressive diffuse, colicky abdominal pain, with nausea, vomiting, and abdominal distension. He has been obstipated for several days and denies any rectal bleeding. He was diagnosed with ulcerative colitis and pancolitis 25 years ago. After his initial diagnosis of ulcerative colitis, he was maintained on chronic mesalamine therapy with infrequent flares of disease requiring short courses of steroids. He moved into the area 10 years ago and failed to establish contact with a local gastroenterologist. His last colonoscopy was over 10 years ago. In the ED, he appeared pale with a blood pressure of 95/60 mmHg, a heart rate of 110/minute, and temperature of 100.5 °F. Physical examination revealed a thin male in mild distress. On abdominal examination, he demonstrated a distended abdomen with diffuse tenderness and absent bowel sounds. Laboratory results show a mild lactic acidosis and decreased hemoglobin with normal LFTs. Plain films reveal a diffusely distended colon and small bowel with a point of transition in the sigmoid colon and absence of air distally. What is the most likely cause for this patient's diagnosis?
(a) Toxic megacolon
(b) Acute pancreatitis
(c) Ascending cholangitis with underlying primary sclerosing cholangitis
(d) Colon cancer
(e) Acute diverticulitis

26. The following symptoms of colorectal cancer are often suggestive of advanced disease, with the exception of:
(a) Large bowel obstruction
(b) Perforation
(c) Hematochezia
(d) Pneumaturia
(e) Abdominal pain or perirectal pain

27. A 53-year-old man presents to the ED with complaints of constipation and occasional blood in his stool. He has been told he has hemorrhoids in the past. Upon further questioning, he admits to a 10-pound weight loss and constipation with intermittent diarrhea. His only medication is aspirin and HCTZ. Orthostatics in the ED are negative and his rectal examination is positive for blood. Abdominal films reveal a preponderance of stool. Hgb is 11.5 with a normal MCV. What is the best next step?
(a) Admit for further workup
(b) Discontinue aspirin
(c) CT colonography
(d) Consult GI for outpatient colonoscopy

28. A 74-year-old woman with a recent diagnosis of colon cancer presents to the ED after being found by her daughter on the kitchen floor. The patient states she was eating and suddenly developed abdominal pain, became lightheaded, and fell trying to get to the telephone. Hip films in the ED reveal a right trochanteric fracture. On physical examination, the patient complains of right hip and right lower abdominal pain, and she appears to be guarding on her abdominal examination. Orthopedic surgery has evaluated the patient and want clearance to take her to the OR. What should the next step be?
(a) Obtain a cardiac risk assessment
(b) Upright abdominal series
(c) Larger bore IV and fluid resuscitation
(d) Oncologic evaluation

29. A 68-year-old male presents to the ED with large volume hemoptysis and respiratory distress about 18 months after radiation therapy for an early-stage primary lung cancer of the right upper lobe. A CT chest scan is obtained and shows a right upper lobe opacity unchanged from previous imaging and consistent with typical postradiation changes. No other airway abnormalities are identified. What is the best next step?
(a) Bronchoscopy to identify and isolate the bleed
(b) Bronchial artery embolization
(c) Thoracic surgery consultation for lobectomy
(d) Intubation, followed by bronchoscopy to identify and isolate the bleed

30. A 75-year-old male smoker presents to the pulmonologist with dyspnea during minimal exertion for 4 weeks. Spirometry showed reduced peak expiratory flow rates and moderate obstruction. A CT chest without contrast showed a large, tumor obstructing the left mainstem bronchus and causing collapse of the entire left lower lobe. When considering therapeutic bronchoscopy, what are the main features associated with improvement in symptoms?
(a) Greater dyspnea, good functional status
(b) Greater dyspnea, poorer functional status

(c) Minimal dyspnea, poorer functional status
(d) Minimal dyspnea, good functional status

31. An 81-year-old male with a history of advanced stage primary lung cancer of the right lower lobe treated with chemotherapy and radiotherapy presents for surveillance 1 year after treatment. On review of the CT, there appears to be a local recurrence of the tumor with growth into the right bronchus intermedius and complete collapse of right lower lobe. The tumor has completely invaded and destroyed the right lower lobe bronchi. Which one of the following factors is a predictor of successful therapeutic bronchoscopy?
(a) Presence or absence of necrosis
(b) Size and extent of endobronchial invasion
(c) Patency of the lobar bronchi distal to the obstruction
(d) Type of lesion (intraluminal, extraluminal, mixed)

32. A 62-year-old woman is undergoing rigid bronchoscopy under anesthesia for a bleeding tumor in the left mainstem. While the bronchoscopist is coagulating the surface of the tumor with argon plasma coagulation, the patient suddenly develops ventricular fibrillation and arrest. What is the rare but dreaded complication that could have caused this event?
(a) Idiosyncratic reaction to intravenous anesthetics
(b) Gas embolism from argon plasma coagulation
(c) Perforation of the left atrium
(d) Myocardial infarction

33. A 49-year-old man with retroperitoneal sarcoma on chemotherapy is in the ED with a 3-day history of abdominal pain, distension, and fever of 38.5 °C. His lactic acid is 4 mg/dL, and the blood pressure is 70/50 mmHg. He takes extended release morphine, 60 mg q12h and immediate release morphine. His absolute neutrophil count is 100/μL. He denies confusion. The triage nurse found that he was alert, and oriented x 3. His wife says he sleeps more and is withdrawn. She has not noticed agitation or hallucinations. You decide to reevaluate his mental status with the mini-mental status examination (MMSE). Which domain(s) of this test are most helpful to confirm hypoactive delirium?
(a) Orientation to time, place, and self.
(b) No specific domain is better than the other.
(c) The test will be unremarkable so the patient has no delirium.
(d) Attention/concentration (backward spelling or serial 7 subtractions and 5-min memory recall of three phrases).

34. A 62-year-old man with recent diagnosis of esophageal adenocarcinoma has arrived in the ED with acute onset garbled, nonsensical speech. Time of onset was 1 hour before your bedside examination, which reveals aphasia and right pronator drift. There is no history of atrial fibrillation, seizure, or migraine. CT of head shows no intracranial hemorrhage (ICH) or areas of vasogenic edema. EKG reveals sinus rhythm. His BP is 145/80 mmHg. You determine that the patient probably has an acute ischemic stroke in the left middle cerebral artery or one of its branches. There is no evidence of thrombocytopenia, active bleeding, or abnormal coagulation tests. The most important therapeutic decision at this point is to:
(a) Admit to the floor on telemetry and consult neurology to see later.
(b) Give ASA 81 mg stat and order MRI brain to confirm diagnosis.
(c) After a quick checklist to ensure there is no absolute contraindication and discussion with patient or proxy for consent, start IV thrombolytics or transfer to a dedicated stroke center for thrombolytic therapy.
(d) Start intravenous heparin and transfer to ICU.

35. Paramedics brought a 26-year-old woman who was found unresponsive in her bedroom. She has acute myeloid leukemia in relapse. Her mother said she had been complaining of headaches for 2 days. There are no signs of intentional or accidental drug overdose and no history of illicit drug use or suicidal attempts. She was intubated on the spot for airway protection. Her Glasgow Coma Scale score is 9, pupils measure 3 mm and both react to light, and bilateral Babinski reflexes are present. The paramedics report she has been seizing despite repeat doses of lorazepam (total of 4 mg). You witness the patient hyperventilate and arch her body, while the blood pressure rises from 100/75 to 190/110 mmHg, with bradycardia. Her pupils dilate for 15 seconds. She then returns to baseline. CT scan of brain showed an epidural hematoma with mass effect and acute hydrocephalus. This episode is more likely to represent:
(a) Convulsive status, refractory to benzodiazepines
(b) Nonconvulsive epileptic status
(c) Plateau wave
(d) None of the above

36. A 34-year-old woman with acute myeloid leukemia in relapse was found unresponsive. She had complained of headaches for 1 week. She was intubated and her Glasgow Coma Scale score is 9, pupils measure 3 mm and both react to light, and bilateral Babinski reflexes are present. She has been seizing despite repeat doses of lorazepam (total of 4 mg). You witness the patient hyperventilate and arch her body, while the blood pressure rises from 100/75 to 190/110 mmHg, with brady-

cardia. Her pupils dilate for 15 seconds. She then returns to baseline. CT scan of brain showed an epidural hematoma with mass effect and acute hydrocephalus. Laboratory studies reveal a platelet count is 45,000/μL and INR 1.25. The most important treatment sequence is:
(a) Start osmotherapy, replace coagulation factors, and emergently consult neurosurgery for hematoma evacuation.
(b) Supportive care only, get an EEG and transfer to ICU with antiepileptic drug therapy.
(c) Transfer to ICU and start osmotherapy. Consult neurosurgery to see later.
(d) Keep in the ED, start osmotherapy with mannitol or hypertonic saline and consult neurosurgery.

37. A 64-year-old female with metastatic breast cancer presents to the ED with new back pain. The patient is ambulatory, but this week finds herself holding on to furniture or using a cane when she walks. Physical assessment reveals spinal tenderness in the L2–L3 vertebral area. X-ray findings identify osteoarthritic changes, but no other significant abnormalities. What is the next appropriate step for patient evaluation and management?
(a) Obtain CT spine
(b) Obtain MRI spine
(c) Refer to outpatient pain management services
(d) Administer zoledronic acid (zoledronate)

38. Upon review of MRI imaging, a patient is found to have a vertebral body metastasis on the T8 vertebral body. The imaging identifies a deformation of thecal sac without cord abutment. What is the grade of epidural disease based on Bilsky's grading system, and what is the likely treatment for the finding?
(a) Grade 1C; radiation therapy
(b) Grade 2; radiation therapy
(c) Grade 1B; radiation therapy
(d) Grade 1C; long-term corticosteroids

39. An 84-year-old male with prostate cancer presents with new-onset back pain, hyperreflexia, bilateral weakness in lower extremities, and urinary incontinence. The clinician has a high suspicion of metastatic spinal cord compression (MSCC), which is confirmed via MRI. Which finding provides indication of poor prognosis for this patient?
(a) Presence of MSCC
(b) Bilateral weakness in lower extremities
(c) Hyperreflexia
(d) Urinary incontinence

40. When determining medical treatment for identified metastatic spinal cord compression (MSCC), all of the following patients would be appropriate candidates for corticosteroid therapy, except:
(a) A 66-year-old male with metastatic lung cancer
(b) A 58-year-old female with metastatic breast cancer
(c) A 77-year-old male with diagnosed prostate cancer
(d) A 33-year-old male without a cancer diagnosis, presenting with back pain and scrotal edema

41. Which hormonal profile of endocrine disturbance is most common in a patient with pituitary apoplexy?
(a) Low cortisol, high prolactin, and diabetes insipidus.
(b) Low cortisol, diabetes insipidus, and other pituitary hormones normal.
(c) Low cortisol, no diabetes insipidus, and low growth hormone.
(d) Normal cortisol, diabetes mellitus, and low TSH.
(e) No hormonal disturbance is present.

42. The most common cranial neuropathy causing diplopia in patient with pituitary apoplexy is:
(a) IV nerve (trochlear nerve) palsy
(b) V nerve (trigeminal nerve) palsy
(c) IX nerve (glossopharyngeal nerve) palsy
(d) III nerve (oculomotor nerve) palsy
(e) II nerve (optic nerve) dysfunction

43. Hemorrhage within a pituitary tumor on an MRI of the sella is best conformed by the presence of which of the following features?
(a) Isointense on T1-weighted images for the first 3 days, turning hyperintense thereafter
(b) Hyperintense on T1-weighted images for the first 24 hours, turning hypointense until day 7, then turning hyperintense again
(c) Hyperintense on T2-weighted images until day 7, turning hypointense thereafter
(d) Isointense on T1-weighted images for the first 3 days, turning hypointense thereafter
(e) Hypointense on T1-weighted images both before and after gadolinium contrast is given

44. Which of the following is *not* a factor predisposing patients to develop pituitary apoplexy?
(a) Coagulopathy
(b) Hypertension
(c) Use of rivaroxaban
(d) Pregnancy
(e) Use of a dopamine antagonist

45. A 65-year-old male heavy smoker presents with 6 weeks of progressively worsening hoarseness, dysphagia, and dyspnea with a 20-pound weight loss over that period. He is seated in the tripod position and has

biphasic stridor on examination. What is the most appropriate next step in management while awaiting an otolaryngology consult?
(a) CT neck soft tissue with contrast
(b) Emergent intubation in the ED
(c) Intravenous steroids
(d) Intravenous saline bolus

46. A 74-year-old male with a history of advanced squamous cell carcinoma of the base of tongue treated with concurrent chemoradiation 6 years prior presents with acute bleeding from the mouth this morning. He had been at work when he had brisk bleeding from his mouth which resolved spontaneously after approximately 5 minutes. His vitals are within normal limits other than mild tachycardia and his hemoglobin is 8.7 g/dl. He is no longer having any active bleeding and is breathing comfortably on room air. What is the next appropriate step in management?
(a) Urgent intubation
(b) CT angiogram of head and neck
(c) GI consultation
(d) Discharge with close outpatient follow-up

47. A 62-year-old male nonsmoker presents to the ED with an enlarging right neck mass over the past few months. He has not noticed any dysphagia, odynophagia, voice changes, or dyspnea. His vital signs are normal. On CT neck, he is noted to have a 3 cm cystic mass of the right neck. What is the most likely diagnosis?
(a) Branchial cleft cyst
(b) Lymphoma
(c) Abscess
(d) Metastatic squamous cell carcinoma

48. Which of the following features on presentation is most suggestive of sinonasal malignancy rather than acute bacterial sinusitis?
(a) Bilateral nasal congestion
(b) Facial pain and pressure for 14 days
(c) Facial paresthesia
(d) Purulent nasal drainage

49. A 48-year-old female presents with lower extremity claudication several months after beginning therapy with a new medication for acute lymphocytic leukemia. Which is the most likely medication responsible for her premature peripheral artery disease?
(a) Doxorubicin
(b) Trastuzumab
(c) Ponatinib
(d) Ibrutinib

50. A 53-year-old male presents with dyspnea and chest discomfort 28 days after initiation of pembrolizumab to treat non–small cell lung cancer. Which of the following is true regarding myocarditis induced by immune checkpoint inhibitors?
(a) Troponin is always abnormal.
(b) Symptoms usually appear within the first few months of therapy.
(c) Cardiac MRI is always required for diagnosis.
(d) ECG never appears normal.

51. A 74-year-old female is hospitalized with new systolic heart failure 10 years after doxorubicin therapy for breast cancer. Which of the following options have been suggested for prevention of anthracycline-induced cardiac dysfunction?
(a) Angiotensin-converting enzyme inhibitors
(b) Beta blockers
(c) Dexrazoxane
(d) All of the above

52. A 62-year-old male is admitted with stress cardiomyopathy following infusion with 5-fluorouracil for rectal adenocarcinoma. When is stress cardiomyopathy most commonly reported to associate with chemotherapy?
(a) Initial chemotherapy infusion
(b) Last chemotherapy infusion
(c) Second chemotherapy infusion
(d) Mid-cycle chemotherapy infusion

53. A 56-year-old male with a history of non–small cell lung cancer presents with worsening shortness of breath due to a large loculated pleural effusion. He had undergone three thoracenteses recently for symptomatic recurrent pleural effusions. The last thoracentesis was aborted early due to chest pressure after draining 300 ml of pleural fluid. Pleural studies reveal lymphocytic rich exudative with negative cytology. What is the best next step?
(a) Repeat therapeutic thoracentesis.
(b) Perform pleuroscopy/medical thoracoscopy, pleural biopsy, and talc pleurodesis.
(c) Insert a chest tube and perform chemical pleurodesis.
(d) Perform pleuroscopy, pleural biopsy and insert an indwelling pleural catheter.

54. A 78-year-old female with a history of coronary artery disease, diabetes, and HFrEF of 35% underwent an AICD placement successfully and was transferred to the recovery room. While patient was in the recovery room, he developed acute onset dyspnea and left-sided chest pressure requiring supplemental oxygen. His SPO_2 was varying between 85% and 89% on 4 liters of supplemental oxygen. Stat chest X-ray at the bedside showed a moderate pneumothorax on the left side.

Patient undergoes a left chest tube placement with improvement in symptoms. Which statement is correct regarding the management of pneumothorax?

(a) Large chest tube (20–24 F) helps in resolution of pneumothorax.
(b) There is no evidence that large chest tubes (20–24 F) are better than small bore chest tubes (10–14 F) in the management of pneumothoraces.
(c) Positive pressure helps resolve pneumothoraces rapidly.
(d) Endobronchial valves have no role in the treatment of persistent air leaks from pneumothorax.

55. Which statement regarding permissive hypercapnia in patients with ARDS using low tidal volume ventilation is incorrect?
(a) Rise of $PaCo_2$ increases tissue oxygenation by right shift of oxygen–hemoglobin dissociation curve.
(b) Hypercapnic acidosis increases cyclic mechanical stretch, epithelial injury, and cell death.
(c) Hypercapnic acidosis increases epithelial injury and cell death compared to normocapnia.
(d) Hypercapnic acidosis reduces cyclic mechanical stretch, epithelial injury, and cell death.

56. A 68-year-old MALE with history of squamous cell lung carcinoma presented to ED with complains of moderate hemoptysis (30–40 cc) for the past 5 days. He remains hemodynamically stable with oxygen saturation of >95% but continues to have cough blood clots. Which of the following would be the best approach to the treatment?
(a) Nebulized tranexamic acid (TXA)
(b) Cough suppressants and supportive care
(c) Emergent surgical consultation
(d) Therapeutic bronchoscopy

57. A 34-year-old homeless female with stage IV breast cancer, undergoing doxorubicin treatment presents to the ED with a swollen right lower extremity, with erythema of the calf and foot, and exquisite tenderness to right calf. What test should be ordered, and once the diagnosis is made what would be the appropriate therapy?
(a) D-dimer, if positive, start a TSA (target specific anticoagulation) and follow-up with oncologist as scheduled.
(b) DVT ultrasound, if positive DVT, CTPA of the chest to rule out pulmonary embolism, and then initiate lovenox at 1 mg/kg to bridge to vitamin K antagonist. Ultimately discharge patient home with follow-up.
(c) DVT ultrasound, if positive for DVT, admit to the hospital for further workup and treatment.
(d) DVT ultrasound, if positive for DVT, discharge with target-specific anticoagulation (TSA).

58. A 65-year-old male with diabetes and hypertension, as well as a new diagnosis of pancreatic cancer, presents to the ED with shortness of breath. He looks ill, panicking, visibly short of breath, with a blood pressure of 85/45, heart rate of 120 beats per minute, SpO_2 of 88% on room air, SpO_2 of 94% on 6 L nasal cannula, and a temperature of 37 °C. STAT laboratory results demonstrate an elevated troponin and elevated pro-BNP, and bedside ultrasound demonstrates an enlarged right ventricle without an effusion. What is the next step in management of this patient?
(a) CTPA of the chest to confirm diagnosis of pulmonary embolism
(b) Obtain D-Dimer, if elevated, CTPA of the chest to confirm pulmonary embolism
(c) Interventional radiology consultation of direct thrombolysis
(d) Systemic fibrinolysis

59. A 66-year-old female with a history of non–small cell lung cancer is sent to the ED after being told she has a pulmonary embolism seen incidentally on a routine follow-up chest CT scan. It is a single subsegmental pulmonary embolism with no evidence of right heart strain on CT scan. She also has no leg swelling or calf pain. Her vital signs are within normal limits and she has no complaints. What is the best next step in management of this pulmonary embolism?
(a) Since it was an incidental finding, discharge without patient follow-up.
(b) Obtain basic laboratory results, initiate intravenous heparin infusion and admit to telemetry.
(c) Patient is Hestia, high risk for outpatient management. Start lovenox in the ED, so the admitting team can bridge to a vitamin K antagonist.
(d) Obtain basic laboratory results, if creatinine clearance is normal discharge on rivaroxaban and follow-up with the oncologist in 1 week.

60. A 65-year-old male with hyperlipidemia, hypertension, and a 50-pack year smoking history presents with unilateral left lower extremity swelling for 4 days. He has associated left calf tenderness, and tenderness along the left deep venous system. He had a cough a few weeks ago with some blood tinged sputum but that has resolved. His vital signs are normal, and he has obvious left lower extremity swelling and some redness. Homan's sign is positive, D-dimer is elevated,

and subsequent left leg duplex ultrasonography demonstrates partially occlusive thrombosis of the popliteal vein. A diagnosis of DVT is made. What is the best next step in this patient's care?

(a) Obtain CTPA of chest to evaluate for lung cancer, and if positive, admit to the hospital for workup of his cancer and initiation of anticoagulation.
(b) Discharge home on anticoagulation and inform the patient that he must follow up with his primary care physician to be evaluated for malignancy as well as additional other causes of VTE.
(c) First-time DVTs do not require any further evaluation; the patient can complete 3 months of anticoagulation and follow-up as needed.
(d) Obtain CTPA to evaluate for pulmonary embolism, if positive, consult interventional radiology for IVC filter and admit the patient on lovenox for bridging to vitamin K antagonist.

61. A 62-year-old man with squamous cell carcinoma of the lung presents to the ED with weakness, nausea, and shortness of breath. His cancer is stage IV, and he has had three cycles of treatment with pembrolizumab, carboplatin, and paclitaxel. He had been a long-time smoker and has chronic obstructive pulmonary disease (COPD). In the ED, he is tachypneic with a respiratory rate of 30/min. He is not hypoxic on room air by pulse oximetry. His vital signs are otherwise normal. His physical examination is normal except for signs of dehydration. What is the differential diagnosis?
(a) Diabetic ketoacidosis
(b) Pneumonia (bacterial or viral, including COVID-19)
(c) Immune pneumonitis
(d) Pulmonary embolism
(e) COPD exacerbation
(f) B, C, D, and E
(g) All of the above

62. A 65-year-old man with advanced melanoma has received 2 cycles of the combination of nivolumab and ipilimumab, and now presents to the ED with headache, general weakness (too weak to get out of bed), nausea, and loss of appetite. He was brought in by ambulance. On arrival, his vital signs are: BP 89/40 mmHg, pulse 89/minute, respiratory rate 18/minute, oxygen saturation on room air 96%, and temperature 96.5 °F. He is listless but easily arousable and is oriented to time, place, and person. Initial supportive care is initiated including intravenous normal saline bolus. His complete blood count with differential is normal, but the comprehensive metabolic panel shows a serum sodium of 128 mEq/L, chloride of 93 mEq/L, and bicarbonate of 28 mEq/L. His electrocardiogram shows no ST segment changes suggestive of myocardial ischemia. What is the next step(s) to diagnose the cause of his symptoms?
(a) Stat random cortisol level and adrenocorticotropin level
(b) TSH and free thyroxine
(c) MRI of the sella
(d) All of the above

63. A 36-year-old woman with papillary thyroid carcinoma presents to the ED with numbness and tingling of hands and feet. She was discharged home from the hospital 2 days ago after she underwent total thyroidectomy 4 days ago. She complains that her left calf is painful after she had a leg cramp when she woke up that morning. Her vital signs are normal. Her surgical wound is within normal limits of a postoperative status. No hypoxia. No chest pain. No dyspnea. No edema. What is the most likely diagnosis?
(a) Deep venous thrombosis in the left leg
(b) Anxiety attack and hyperventilation causing numbness and tingling of hands and feet
(c) Hypothyroid symptoms due to postsurgical hypothyroidism
(d) Postoperative hypoparathyroidism

64. A 55-year-old woman with metastatic colon cancer has had her 3 cycles of chemotherapy with panitumumab, 5-fluorouracil, and oxaliplatin 4 days ago. She presents to the ED for general weakness and muscle cramping. She is irritable and has been crying. Her CBC-diff showed mildly depressed blood counts that do not require transfusion. Her complete metabolic panel shows sodium 133 mEq/L, potassium 3.3 mEq/L, calcium 8.0 mg/dL, and magnesium 0.3 mg/dL. Which of the following statement is true?
(a) Stat EKG, and monitor cardiac rhythm while electrolyte abnormalities are corrected with intravenous infusions since the patient is at high risk for cardiac arrhythmia.
(b) Hypomagnesemia causes PR shortening and thereby increases the risk for torsade de pointes.
(c) Hypomagnesemia is caused by the nephrotoxic effect of oxaliplatin and is unrelated to 5-fluorouracil and panitumumab.
(d) All of the above are true.

65. One of the following is the least effective endoscopic hemostatic modalities for GI bleeding related to tumors:
(a) Cryotherapy
(b) Argon plasma coagulation
(c) Nd-YAG laser

(d) Endoscopic clips
(e) Hemostatic powders (when available on the market)

66. In patients who need palliation of their symptoms due to duodenal obstruction from pancreatic cancer, an enteral stent should be placed if their life expectancy is expected to be greater than 6–12 months.
(a) True
(b) False

67. All of the following are potential causes of fulminant hepatic failure in a patient with cancer, except:
(a) Chemotherapy
(b) Innumerable hepatic metastases
(c) Total parenteral nutrition
(d) Malignant infiltration of the liver with lymphoma or adenocarcinoma
(e) Polypharmacy/drug-induced liver injury

68. Which of the following is *not* an indication for ERCP for biliary decompression?
(a) Intolerable pruritus
(b) Intolerable jaundice
(c) Acute cholangitis
(d) Abnormal LFTs without symptoms
(e) Hyperbilirubinemia that interferes with chemotherapy dosing

69. Current management of adhesive small bowel obstruction includes nonoperative management for up to 3 days, as long as the patient does not deteriorate with symptoms suggesting intestinal ischemia.
(a) True
(b) False

70. Advanced malignant disease in the upper gastrointestinal tract can result in gastric outlet obstruction. The most common malignant cause of gastric outlet obstruction is:
(a) Pancreatic cancer
(b) Periampullary cancer
(c) Advanced gastric cancer
(d) Duodenal and jejunal cancer

71. The classic presentation of neutropenic enterocolitis is a patient with absolute neutrophil count <1000 cells/μL, new-onset abdominal pain, and fever. Most commonly it occurs:
(a) 1 week after receiving cytotoxic chemotherapy
(b) 2–3 weeks after receiving cytotoxic chemotherapy
(c) 4 weeks after receiving cytotoxic chemotherapy

72. Acute radiation enteritis usually occurs between 2 and 6 weeks postradiation therapy. Clinical manifestations include nausea, vomiting, abdominal pain, and diarrhea associated with blood and mucus. Possible complications include:
(a) Systemic sepsis
(b) Gastrointestinal bleeding
(c) Bowel obstruction
(d) All of the above

73. A 30-year-old woman with colon cancer and Lynch syndrome. She had metastatic colon cancer that has started to progress after first-line cytotoxic chemotherapy. She has just received the third cycle of ipilimumab and nivolumab 3 days ago. She presents to the ED with severe watery diarrhea. She had more than 8 bowel movements in the past 24 hours. Her blood pressure is normal, but she is tachycardic. Her bowel sound is hyperactive. Her right upper quadrant tenderness is unchanged. Which of the following are true?
(a) The patient may have grade 3 immune-mediated colitis, and CT scan of the abdomen and pelvis is indicated.
(b) Call the gastroenterology consult team to arrange for colonoscopy and biopsy.
(c) Collect stool samples for culture and various other tests for infectious diarrhea (including *C. difficile* toxins).
(d) All of the above.

74. A 65-year-old patient with advanced VIPoma currently on long-acting pegylated octreotide now presents to the ED with worsening of chronic diarrhea. Over the last week, his stool frequency gradually increased to 6 times per day. He feels weak and dehydrated. Which of the following is true?
(a) This is a chronic problem, and the patient can be discharged from the ED after intravenous hydration with isotonic crystalloid solutions and replacement of electrolytes.
(b) Intravenous octreotide is not helpful since the patient is already on long-acting octreotide injections.
(c) Consult interventional radiology to evaluate whether reduction of tumor burden by chemoembolization is possible.
(d) None of the above.

75. A 55-year-old man with acute myeloid leukemia, who had allogeneic hematopoietic stem cell transplant 3 weeks ago, presents to the ED with severe diarrhea, nausea, and vomiting for 2 days. He has had 10 watery large volume bowel movements in the past 24 hours despite taking loperamide around the clock. What is the appropriate management if he is hypotensive, tachycardic, and hypokalemic?

(a) Obtain blood cultures, urine culture, and urinalysis; initiate intravenous fluids 30 mL/kg; and start broad-spectrum empirical antibiotics.
(b) Collect stool sample for *C. difficile* toxin assay, multiplex PCR for gastrointestinal pathogens, and stool culture.
(c) Discuss with the stem cell transplant team to consider starting intravenous glucocorticoid therapy.
(d) All of the above.

76. A 22-year-old woman with acute lymphoblastic leukemia, s/p 2 cycles of hyper-CVAD chemotherapy presents to the ED for sudden onset fever, chills, and mild epigastric abdominal pain. She had a CBC-diff the day before, and her absolute neutrophil count was 100 per microliter. She reports that she has had 2 watery bowel movements in the past 8 hours. Which is the following is true?
(a) CT scan of the abdomen and pelvis is indicated to diagnose neutropenic enteritis.
(b) Prescribe a lidocaine containing gastrointestinal cocktail to control esophageal and gastric pain from chemotherapy, and loperamide for mild chemotherapy-induced diarrhea. No further investigation of the gastrointestinal tract is needed.
(c) Initiate intravenous cefepime for neutropenic fever in the ED, prescribe loperamide for the mild diarrhea, and discharge the patient on home intravenous antibiotic therapy.
(d) None of the above.

77. A 56-year-old woman with glioblastoma multiforme presents to the ED with complains of not having a bowel movement for over 4 days. She has had intermittent constipation in the past and this feels similar. She also complains of nausea. Her vital signs are normal and her examination is unremarkable, except for mild dehydration. What is the best next step in management?
(a) Give her ondansetron for her nausea and hydrate her with intravenous fluids.
(b) Give her metoclopramide for her nausea and hydrate her with intravenous fluids.
(c) Obtain a plain radiograph to evaluate for bowel obstruction and stool burden, and hydrate her with intravenous fluids.
(d) Hydrate her with intravenous fluids.

78. A 22-year-old woman with breast cancer with metastasis to the bone presents to the ED with constipation of over 1-week duration. She has a history of chronic constipation since being diagnosed with metastatic bony disease. She is on a chronic opioid regimen. She recently increased the dose of her opioid due to uncontrolled cancer pain. After a thorough workup, including a digital rectal examination, you conclude that she has uncomplicated, likely opioid-induced constipation. What is the best next step in management?
(a) Give the patient methylnaltrexone.
(b) Give the patient senna and bisacodyl.
(c) Encourage the patient to eat more fiber.
(d) Disimpact the patient in the ED.

79. An 80-year-old male with metastatic prostate cancer to the bone presents to the ED with constipation. He has not had a bowel movement for over 1 week and is complaining of lower back pain, which he attributes to the constipation. The review of systems reveals tingling of the lower extremities. A thorough physical examination reveals mild weakness of lower extremities and bony tenderness over the spine but otherwise normal. What is the best next step in management?
(a) Give the patient analgesics and start IV fluid hydration, while you await laboratory results.
(b) Give the patient a milk and molasses enema.
(c) Order an emergent MRI of the spine to evaluate for malignant spinal cord compression or conus syndrome.
(d) Order and emergent CT of the abdomen to evaluate for intra-abdominal pathology.

80. A 62-year-old male presents with constipation for over 2 weeks. On arrival to the ED, he is noted to have a temperature of 38 °C (100.4 °C), a heart rate of 140 beats per minute, and blood pressure of 100/60 mmHg. He complains of diffuse abdominal pain and nausea. On physical examination, he is ill appearing and has a diffusely tender abdomen with distention and rebound tenderness. What is the most important next step in managing this patient?
(a) Obtain a CBC, chemistries, and a CT of the abdomen with contrast.
(b) Send a sepsis workup, including lactic acid.
(c) Give the patient an IV fluid bolus and obtain a stat upright portable chest radiograph.
(d) Call a surgical consult.

81. All of the following drugs are associated with thrombotic microangiopathy (TMA), except:
(a) Cisplatin
(b) Gemcitabine
(c) Anti-VEGF therapy
(d) Ifosfamide

82. All of the following are effective therapies for methotrexate (MTX) toxicity, except:
(a) IV hydration to increase urine output
(b) Bicarbonate to increase solubility of MTX in the urine

(c) Dialysis to clear MTX
(d) Glucarpidase to metabolize MTX into inactive compounds

83. All of the following may be used in the treatment of SIADH, except:
(a) Normal saline
(b) Salt tablets
(c) Vasopressin receptor antagonists
(d) Fluid restriction

84. Which one of the following is true about tumor lysis syndrome?
(a) Rasburicase may be used in the treatment of established TLS to decrease serum uric acid levels.
(b) Allopurinol will help to breakdown uric acid in the bloodstream.
(c) Preemptive dialysis is an established treatment for the prevention of TLS.
(d) Routine alkalization of the urine is part of the treatment of established TLS.

85. A 63-year-old man underwent radical prostatectomy 1 week ago. His Foley catheter was removed 36 hours ago. He initially voided well, but experienced hematuria and a weak stream after a bout of coughing. He now presents to the ED complaining of lower abdominal pain and an inability to void for 10 hours. After initial evaluation, the ED provider should:
(a) Proceed with an urgent CT scan of the abdomen and pelvis.
(b) Place a 22-French Foley and irrigate the bladder until clear.
(c) Place an 18-French Foley and initiate continuous bladder irrigation.
(d) Contact the urology service, immediately.

86. Continuous bladder irrigation (CBI) is indicated in the patient with persistent gross hematuria:
(a) If the patient passes large clots
(b) When there is difficulty irrigating clots from the bladder
(c) Once all sizeable clots have been evacuated from the bladder
(d) After anticoagulation has been discontinued

87. In a patient with ureteral obstruction and infection, the factor that triggers decompression of the urinary system with retrograde ureteral stenting versus percutaneous nephrostomy tube placement is the:
(a) Active use of anticoagulants
(b) Service line availability
(c) Etiology of the obstruction
(d) All of the above

88. A 75-year-old woman underwent right partial nephrectomy for a 3 cm renal carcinoma. One week later she presents to the ED with gross hematuria and right flank pain. She is hemodynamically stable with a normal WBC, creatinine, and a hemoglobin of 11 g/dl. The next step is to:
(a) Discharge home with follow-up within 1 week.
(b) Monitor the patient in the ICU.
(c) Proceed with a CT angiogram.
(d) Obtain a CT urogram and urine cytology.

89. A 68-year-old female recently diagnosed with metastatic ovarian cancer was found to be confused with muscle weakness and diminished reflexes. Which laboratory abnormality would be the cause of the symptoms?
(a) Hypocalcemia
(b) Hypercalcemia
(c) Hyperchloremia
(d) Hypochloremia

90. A 45-year-old female who has been undergoing carboplatin and paclitaxel for ovarian cancer presents with a temperature of 38.0 °C for at least an hour. What other laboratory abnormality would you need to diagnose febrile neutropenia?
(a) ANC $\leq$ 500 cells/mm^3
(b) ANC $\geq$ 500 cells/mm^3
(c) ANC $\leq$ 300 cells/mm^3
(d) ANC $\leq$ 400 cells/mm^3

91. Which of the following is *not* a noninvasive method for control of bleeding in a patient with advanced cervical cancer?
(a) Palliative radiotherapy
(b) Vaginal packing
(c) Percutaneous uterine artery embolization
(d) Volume replacement

92. A 58-year-old patient with a history of ovarian cancer treated with intraperitoneal cisplatin and paclitaxel presents to the ED with vomiting, constipation, abdominal distension, and abdominal pain. CT scan shows bowel thickening and mesenteric stranding. The patient's temperature is within normal limits. What would be the most likely diagnosis?
(a) Diverticulitis
(b) Intestinal obstruction
(c) Chemotherapy-induced enterocolitis
(d) Pelvic inflammatory disease

93. A 72-year-old female with history of hypertension and a 30-pack year smoking history presents with left leg pain and inability to ambulate. She has had pain in her

mid-left tibia for the past 4 weeks and while walking to the restroom this morning, felt a pop with associated deformity. On physical examination, her left leg is grossly deformed, but the skin is intact. Her compartments are soft without associated numbness or tingling, and distal pulses remain palpable. Radiographs show a large lytic lesion in the tibial diaphysis with a displaced pathologic fracture. What is the most likely diagnosis, and how should additional workup in the ED proceed?

(a) Primary bone sarcoma. CT of the chest, abdomen, and pelvis with laboratory workup assessing for myeloma and primary sarcoma. Leg should be immobilized in a short leg splint.
(b) Primary bone sarcoma. CT of the chest, abdomen, and pelvis with laboratory workup assessing for myeloma and primary sarcoma. Leg should be immobilized in a long leg splint.
(c) Metastatic disease. CT of the chest, abdomen, and pelvis with laboratory workup assessing for myeloma and metastatic disease. Leg should be immobilized in a short leg splint.
(d) Metastatic disease. CT of the chest, abdomen, and pelvis with laboratory workup assessing for myeloma and metastatic disease. Leg should be immobilized in a long leg splint.

94. A 65-year-old male with history of metastatic prostate cancer to the left femoral neck, 8 weeks status post left total hip replacement, presents to the ED with inability to bear weight. He was standing up after using the toilet earlier this morning and felt a sudden pop in his left hip. He is neurovascularly intact. Laboratory results are not concerning for infection. What are radiographs likely to show? What is the most likely position of his leg on physical exam? What is the most appropriate management in the ED?

(a) Posterior dislocation of left total hip replacement. Shortened, flexed, adducted, internally rotated. Conscious sedation and closed reduction
(b) Anterior dislocation of left total hip replacement. Shortened, flexed, abducted, externally rotated. Conscious sedation and closed reduction
(c) Vancouver B periprosthetic fracture. Shortened, slightly externally rotated. Buck's traction
(d) Vancouver C periprosthetic fracture. Shortened, slightly externally rotated. Buck's traction

95. A 48-year-old female with history of diabetes and soft-tissue sarcoma in her left lateral thigh, who received preoperative radiation and is now 3 weeks status post radical resection, presents to the ED with her son, who status she "doesn't seem like herself." On examination, she has marked erythema and induration about her surgical incision with multiple hemorrhagic bullae. There is a focal area of wound dehiscence distally with "dishwater" fluid draining. She is oriented to person, but not place or time. She has a WBC of 34,000/mm^3, hemoglobin of 9.8 g/dL, sodium of 128 mmol/L, and CRP of 320 mg/L. CT does not show any evidence of gas. What is the most likely diagnosis and what is the most appropriate next step?

(a) Cellulitis. Empirical antibiotics and potentially surgery
(b) Abscess. Admission to the hospital and surgery within the next 24–48 hours
(c) Necrotizing fasciitis. Emergent surgical consult and surgery
(d) Suture reaction. Oral antibiotics and discharge home

96. A 68-year-old male with acute myelogenous leukemia on chemotherapy presents with acute onset pain and swelling in his right leg. Pain started earlier this morning. He states he may have bumped his leg on the dresser, but he does not recall any significant trauma. Pain has continued to increase throughout the day and has been unresponsive to oral analgesia. He is alert and oriented. He has marked swelling about his leg. He has decreased sensation on the dorsum of his foot. Peripheral pulses remain palpable. Pain is exacerbated anteriorly by passive plantar flexion of his great toe. The leg is firm and incompressible. He has WBC of 1600/mm^3, hemoglobin of 7.3 g/dL, and platelet count of 8000/mm^3. Radiographs are unremarkable. What is the most likely diagnosis and what additional tests are necessary prior to any definitive intervention?

(a) Pathologic fracture. CT scan should be obtained to better clarify the fracture.
(b) Compartment syndrome. No additional studies are needed.
(c) Abscess. MRI should be performed to both confirm diagnosis and assess for additional pathologic findings.
(d) Compartment syndrome. A manometer (i.e., Stryker needle) should be used in all four compartments of the leg to confirm diagnosis prior to surgery.

97. DRESS/DIHS (drug reaction with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome) is most commonly characterized by which of the following?

(a) Skin pain, skin blistering, targetoid lesions, fever
(b) Maculopapular rash, facial edema, fever, eosinophilia
(c) Urticaria and angioedema
(d) Pustules, fever, neutrophilia

98. Which of these statements regarding immune-related cutaneous adverse events (ircAEs) to immunotherapy is false?
    (a) The most common manifestations are pruritus and maculopapular rash.
    (b) They can be distinguished from cutaneous adverse drug reactions to regular medications by skin biopsy.
    (c) They may be associated with prolonged progression-free survival and overall survival.
    (d) They can occur at any time during or even after treatment.
99. Which of the following skin morphologies can reflect cutaneous blood vessel lumen occlusion (i.e., thrombosis/embolic)?
    (a) Macular purpura
    (b) Palpable purpura
    (c) Ecchymoses
    (d) Retiform purpura
100. Which of the following is *not* a criterion of SCORTEN severity illness score for predicting mortality in SJS/TEN?
    (a) Number of mucosal sites involved
    (b) Heart rate >120
    (c) Age >40
    (d) Initial percentage of epidermal detachment >10%
101. A 4-year-old girl undergoing chemotherapy for acute lymphoblastic leukemia and is known to be neutropenic presents with new onset abdominal pain and tenderness in the right lower quadrant on physical examination. A rare but potentially fatal complication of pretreatment is diagnosed on ultrasound. The findings on ultrasound that would support this include:
    (a) A "target sign" found in the right lower quadrant
    (b) A blind ended bowel loop with a noncompressible hyperemic bowel wall
    (c) A cystic structure in the periumbilical region
    (d) A thickened bowel wall located in the right lower quadrant
    (e) A "whirlpool sign" in the right lower quadrant
102. A patient who recently started chemotherapy for Burkitt's lymphoma with high tumor burden is being monitored for complications of therapy. Laboratory testing of the blood would be expected to show:
    (a) Low potassium
    (b) Low calcium
    (c) Low phosphorus
    (d) Low urea nitrogen
    (e) Low sodium
103. As pediatric oncologic patient survival rates increase due to advances in medications and treatment protocols, delayed mortality is most notably due to:
    (a) Sepsis
    (b) Suicide
    (c) Arrhythmias
    (d) Interstitial lung disease
104. Pediatric cancers present in many ways, typically with vague complaints. Which of the following is not a typical presentation seen?
    (a) Fatigue
    (b) Weight gain
    (c) Bone pain
    (d) Fever
    (e) Pallor
105. A 69-year-old man is in the ED with worsening shortness of breath. His wife also states that he appears more confused lately and has not had an appetite in the last couple of days. His white blood sound count is 120,000/mm^3 with 93% blasts. He has a history of acute myeloid leukemia with plans to start treatment in the next few days. On physical examination, the patient is only oriented to self, oxygen saturation is 92% on room air, heart rate is 113, but afebrile. Chest radiographs indicate bilateral infiltrates, but no focal lesions or consolidations, pneumothorax, or pleural effusion. Oncologic was consulted and will see the patient. Meanwhile, what is the initial management in the ED?
    (a) Antibiotics
    (b) Hydroxyurea
    (c) Isotonic intravenous fluids
    (d) Leukapheresis
106. A 75-year-old woman with a history of ALL is brought to the ED by her family for "acting funny." Her daughter reports that her mother has seemed more confused over the past few days, and now is not using her right hand to feed herself. On physical examination, vital signs are all within normal limits. The patient is disoriented and has right-sided weakness. CBC is notable for WBC 60,000/mm^3, platelet count 6000/mm^3, and hemoglobin 6.5 g/dL. Which of the following is the best initial diagnostic test to obtain?
    (a) CT head without contrast
    (b) MRI brain
    (c) Lumbar puncture
    (d) EEG
107. A 39-year-old man without major past medical history is sent in from the local urgent care for abnormal laboratory work. He reports feeling run down and fatigued with a decreased appetite and nonproductive cough for the past few weeks, and thought he maybe had the flu. His vital signs are notable for a heart rate of 128 and a respiratory rate of 30 but are otherwise within normal limits. He appears pale, dry, and tachypneic with mild retractions, but denies shortness of breath. His paper-

work from urgent care shows a WBC count of 205,000/mm^3, hemoglobin of 7 g/dL, platelets of 18,000/mm^3, creatinine of 3 mg/dL, a bicarbonate of 12 mmEq/L, a lactate of 4 mmol/L, troponin of 1.9 ng/mL, and a venous blood gas with a pH of 7.25 and a PCO_2 of 27 cmH_2O. His EKG shows sinus tachycardia with lateral ST segment depressions. You start IV fluids and send a page to the on-call oncologist immediately. What is the best way to manage this patient while waiting for the oncologist to return your page?

(a) Give aspirin 324 mg and start a heparin drip
(b) Transfuse packed red blood cells to a goal hemoglobin of 8–10 mg/dL
(c) Administer empiric antibiotics
(d) Intubate

108. A 56-year-old man with history of hypertension and chronic back pain presents with a triage complaint of "back pain." He is moaning a lot and not providing a lot of answers to your questions. His family reports that they knew something was wrong when he did not go to his methadone clinic today. Vital signs: temperature 37.3 °C (99.1 °F), heart rate 104 beats per minute, blood pressure 156/93, respiratory rate 27 breaths per minute, oxygen saturation 94% on room air. You obtain lab work that demonstrates a WBC count of 87,000/mm^3, hemoglobin of 5.9 g/dL, platelets of 9000/mm^3, potassium of 5.6 mmol/L, CO_2 of 15 mmol/L, a creatinine of 2.7 mg/dL, a calcium of 7.6 mg/dL, and a phosphorus of 6 mg/dL. His chest X-ray is clear, and his lumbar spine X-ray is consistent with degenerative joint disease. You consult the on-call oncologist who asks for a manual differential, uric acid, LDH, coagulation studies, initiation of intravenous fluids, and admission to the hospitalist. What is the appropriate next step in this patient's care?
    (a) Initiate sodium bicarbonate infusion
    (b) Obtain a noncontrasted CT scan of the head
    (c) Transfuse 2 units of packed red blood cells and 1 pack of platelets
    (d) Administer IV calcium
109. For patient with cancer and acquired factor VIII inhibitors, eradication of the tumor is crucial to controlling the inhibitor.
    (a) True
    (b) False
110. Which one of these antineoplastic therapies has been associated with low antithrombin levels?
    (a) Bevacizumab
    (b) Hydroxyurea
    (c) L-Asparaginase
    (d) Thalidomide
111. Which mutation is associated with thrombosis in myeloproliferative neoplasms?
    (a) BCR-ABL
    (b) CALR
    (c) JAK2
    (d) MPL
112. A rare cause of bleeding in patients with myeloproliferative neoplasms is acquired deficiency of factor:
    (a) V
    (b) VII
    (c) X
    (d) XI
113. A 19-year-old woman with a history of sickle cell disease presents with pain in her legs. She says it is her typical pain crisis and denies shortness of breath, chest pain, or nausea. Laboratory testing reveals the following: WBC count, 10,000/mcL; Hgb, 4 g/dL; and reticulocyte count, 0.5%. Electrolytes are normal. She responds well to pain medication. Which of the following treatments is helpful for her condition?
    (a) Antibiotic therapy
    (b) Exchange transfusion
    (c) Oxygen administration
    (d) Transfusion of packed red blood cells
114. A 24-year-old man presents to the ED after 1 week of worsening left shoulder pain. He has had pain over the past 2 months intermittently. He denies any fever, trauma, swelling, or rash. He has a history of sickle cell disease. His vital signs are normal. You order an X-ray of the left shoulder. What finding is likely to be demonstrated on the X-ray?
    (a) Avascular necrosis
    (b) Fracture of the humerus
    (c) Osteomyelitis
    (d) Tumor in the lung
115. A 19-year-old male presents to the ED 1 week after his last visit complaining of pain in his legs that is typical of his symptoms on prior visits. When should laboratory tests including a CBC, reticulocyte count, LFTs, bilirubin, LDH, and electrolytes be considered?
    (a) The patient is being admitted.
    (b) You suspect another diagnosis.
    (c) The patient appears toxic.
    (d) All of the above.
116. A 38-year-old woman with a known history of sickle cell disease comes into the ED 1 week after her last uneventful pain crisis. She complains of 3 days of nonproductive cough and gradual onset severe central chest pain radiating to both shoulders. She admits to being short of breath on exertion. Her vitals show a temperature of 38.2 °C, heart rate of 108/min, blood

pressure of 126/78 mmHg, and an oxygen saturation of 92% on room air. She is short of breath on examination and her lung sounds are clear. She has a normal cardiovascular exam. A chest X-ray is ordered. Which of the following chest radiograph findings is likely to be present?
(a) Multilobar infiltrates
(b) Pneumothorax
(c) No acute pathology
(d) Rib fracture

117. A 19-year-old man presents to the ED with acute change in mental status. Over the past 3 weeks, he has been experiencing progressive fatigue, easy bruising, and new bleeding from his gums. In the days prior to admission, he developed headache in the left periorbital area and recently complained to his family of double vision. His physical examination is concerning for an obtunded patient who is responsive to questions but incoherent. He has esotropia of the left eye. Initial laboratory results demonstrate anemia, thrombocytopenia, and an elevated white count that is predominantly lymphocytic. His other leukocyte lineages are suppressed, including neutrophils, with an absolute neutrophil count of 400 cells per μL. CT head demonstrates acute inflammation of the left nasal sinus and associated periorbital fat stranding with a radiologist impression of acute invasive fungal sinusitis. Which of the following is the best next step?
(a) Order STAT MRI
(b) Start liposomal amphotericin B
(c) Start micafungin
(d) Order NP swab for culture

118. A 62-year-old woman with metastatic cholangiocarcinoma currently receiving gemcitabine plus cisplatin presents to the ED for fever and abdominal pain. Her second cycle of chemotherapy was given in the outpatient cancer infusion center via her port approximately 1 week ago. On initial evaluation, she is febrile but alert and stable. She notes severe right lower abdominal pain which comes in waves. She states for several days she has noted diarrhea; however, today it became maroon in color before stopping. Initial laboratory work demonstrates a hemoglobin of Hgb 9.2 mg/dL, a platelet count of 112,000 per μL, and an ANC of 250 cells per μL. She is started on empiric cefepime and metronidazole. Which of the following is the best next step?
(a) CT scan of the abdomen
(b) Add IV vancomycin to the empiric antibiotics
(c) Give colony-stimulating factor for neutropenia
(d) Send stool C difficile toxin assay

119. A 65-year-old woman with metastatic breast cancer receiving chemotherapy presents to the ED with fever, chills, and night sweats. She has a tunneled internal jugular central venous catheter in place through which she has been receiving chemotherapy as well as intravenous fluids and total parenteral nutrition per home nursing due to dehydration and poor oral intake. Vital signs are notable for an oral temperature of 38.4 °C, BP 100/60 mmHg, and HR 72 bpm. She appears chronically ill but is in no acute distress. The insertion site for the catheter is notable for mild erythema but no induration or drainage. There is no tenderness to palpation along the subcutaneous tract of the catheter. Which of the following is the best next step?
(a) Start empiric IV vancomycin and cefepime
(b) Draw 2 sets of blood cultures from the central venous catheter
(c) Obtain 2 sets of blood cultures from separate peripheral venous sites
(d) Coordinate immediate removal of the central venous catheter

120. A 54-year-old man with a history of hematopoietic stem cell transplant (HSCT) 6 months ago presents with worsening cough and dyspnea on exertion over the past 3 weeks. His HSCT has been complicated by graft-versus-host disease, requiring chronic immunosuppression including high-dose corticosteroids. The patient is currently taking valganciclovir and fluconazole; he was also supposed to be taking trimethoprim-sulfamethoxazole, but this was held approximately 2 months back due to acute kidney injury. In triage, he is notably hypoxic with the pulse oximeter reading 86% on room air. A chest radiographic demonstrates diffuse ground glass opacities. With which of the following opportunistic infections is this patient's clinical presentation most consistent?
(a) CMV pneumonia
(b) HSV pneumonia
(c) *Pseudomonas aeruginosa* pneumonia
(d) *Pneumocystis jirovecii* pneumonia

121. A 16-year-old male with leukemia presents to the ED with a temperature of 38.5 °C and a mild, dry cough. His vital signs are otherwise within normal limits, and his laboratory results are unremarkable. His fever resolves without treatment and he feels otherwise well. In addition to initiating antibiotic therapy, what is the next step in this patient's care?
(a) Apply the MASCC score to risk stratify the patient
(b) Apply the CISNE score to risk stratify the patient

(c) Place the patient in observation status
(d) Admit the patient for ongoing antibiotics and close monitoring

122. A 43-year-old female with a history of osteosarcoma presents to the ED with a temperature of 39 °C. It has been approximately 7 days since her last chemotherapy and she is found to be neutropenic. She reports using a mask and gloves at all times and is wondering how she developed this infection. What is the most likely source?
(a) She likely has a noninfectious cause such as drug or tumor fever.
(b) She probably contracted her infection from her kids.
(c) She most likely developed the infection from endogenous flora.
(d) She likely became infected during her last infusion center visit.

123. The following are considered safe discharge criteria for patients with febrile neutropenia except:
(a) Residence ≤4 hours or ≤100 miles (160 km) from clinic or hospital
(b) Access to a telephone and transportation 24 h/d
(c) Family member or caregiver at home 24 h/d
(d) No history of noncompliance with treatment protocols

124. A patient with leukemia has been diagnosed with low-risk febrile neutropenia is cleared for discharge, but he is very concerned that he will not be receiving intravenous antibiotics. What does the evidence say regarding the use of oral versus intravenous antibiotics in febrile neutropenia?
(a) Oral antibiotics are inferior to intravenous antibiotics in all cases.
(b) Oral antibiotics and intravenous antibiotics are equally effective.
(c) Oral antibiotics are noninferior to intravenous antibiotics in cases of low-risk febrile neutropenia.
(d) Oral antibiotics are never indicated in patients with hematologic malignancies.

125. A 70-year-old man with acute myeloid leukemia presents to the ED after suddenly developing fever, diffuse abdominal pain, and diarrhea. You are very concerned for neutropenic enterocolitis and consult the hematology/oncologic and surgical teams. Based on the above presentation, your diagnostic approach should include:
(a) Immediate surgical consultation and transfer to the operating room for bowel resection.
(b) Evaluation for GVHD and *C. diff* as well as CT imaging to help characterize the diagnosis.
(c) Bedside ultrasound to make a definitive diagnosis followed by administration of antibiotics and admission.
(d) Immediate administration of broad-spectrum antibiotics and ICU admission, CT imaging is unnecessary at this time.

126. A 70-year-old man with acute myeloid leukemia presents to the ED after suddenly developing fever, diffuse abdominal pain, and diarrhea. On physical examination, he has right lower quadrant abdominal pain with associated guarding and bowel sounds are present. Laboratory evaluation reveals a white blood cell count of 1200 cells/μL (ANC = 100/dl), a hematocrit of 23%, and 40,000 platelets/μL. Computed tomography (CT) scan of the abdomen and pelvis shows thickening of the colonic wall with diffuse pericolic edema and pneumatosis. What additional information will help guide a decision regarding surgery?
(a) Extent of bowel wall thickening
(b) Persistent GI bleeding
(c) Involvement of the cecum
(d) Chemotherapeutic regimen

127. Risk factors for neutropenic enterocolitis in the above patient include all of the following, except:
(a) Specific chemotherapeutic agent
(b) Timing from last chemotherapy
(c) Route of administration of chemotherapy
(d) Tumor type (i.e., solid vs. hematogenous)

128. Blood cultures and stool studies for *Clostridium difficile* and other enteropathogenic organism are pending for the above patient. Besides broad-spectrum antibiotics and close hemodynamic monitoring, what additional therapies might the patient benefit from?
(a) Recombinant granulocyte colony-stimulating factor (G-CSF)
(b) Corticosteroid
(c) Rasburicase
(d) Recombinant factor VIIa

129. What are the three domains of biopsychosocial model?
(a) Hypothalamus–pituitary–adrenal axis
(b) Predisposing, precipitating, and perpetuating factors
(c) Childhood trauma, anger, and impulsive behavior
(d) Environmental, financial, and psychosocial factors

130. Cancer patients have a higher risk for suicide as compared to general population, because:
(a) Cancer is common in older frail people.
(b) They have financial crisis due to cancer treatment.
(c) They lose their job due to the disease.
(d) In addition to general risk factors of suicide, they have the burden of adverse effects of cancer treatment.

131. How do you differentiate depression from side effects of cancer treatment?
(a) Hopelessness and loss of interest in previously enjoyable activities

(b) Poor sleep
(c) Fatigue
(d) Weight loss

132. What would you do as the first step when discharging a low-risk suicidal patient?
(a) Give a prescription of antidepressant
(b) Arrange a follow-up with a therapist
(c) Making sure patient has no access to weapons
(d) Giving him a suicide hot line number

133. All the following information about delirium in in the cancer patient present are correct, except:
(a) Delirium is different from altered mental status.
(b) May be interpreted as worsening pain.
(c) Most delirium cases in ED are of the agitated (hyperactive) type.
(d) It is frequently missed by ED providers.

134. What are the most common causes of delirium in the cancer patient presenting to ED:
(a) Brain metastasis
(b) Liver failure
(c) Renal failure
(d) Side effects of medications
(e) Paraneoplastic syndrome

135. What is the most important step in the management of the cancer patient with delirium in the ED?
(a) Give benzodiazepine intravenously.
(b) Intubate the patient.
(c) Give any of the atypical antipsychotic medications such as olanzapine.
(d) Assure safety of the patient.
(e) Give haloperidol.

136. Which of the following statements about palliative sedation is correct?
(a) Haloperidol is commonly used for this procedure.
(b) Refractory delirium is the most common indication for this procedure among cancer patients.
(c) When stated, it should be continued until the patient die.
(d) May be started if the patient (or family) wishes to shorten life.

137. Transalar herniation can lead to infarction in which territories?
(a) Anterior cerebral artery (ACA)
(b) Middle cerebral artery (MCA)
(c) Posterior cerebral artery (PCA)
(d) A and B
(e) A, B, and C

138. What is the most common cause of massive hemoptysis worldwide?
(a) Bronchogenic carcinoma
(b) Trauma
(c) Postoperative complication
(d) Pulmonary fibrosis
(e) Pulmonary tuberculosis (TB)

139. What is the approximate attenuation in Hounsfield units (HU) of acute blood products on CT?
(a) −1000
(b) −100
(c) 0
(d) 40
(e) 1000

140. At least what percent of bone mineral density must be lost in order for radiographs to detect lytic lesions?
(a) 10%
(b) 30%
(c) 50%
(d) 70%
(e) 90%

141. A 48-year-old female with history of ovarian cancer presents with lethargy. Her husband who accompanies her notes that she was scheduled for a chemotherapy infusion today in clinic but she was "too sick to go through with it." Her vital signs: temperature 101.2 °F (38.4 °C), pulse 112 bpm, respirations 24 bpm, blood pressure 88/50, and pulse oximetry 98% on room air. She looks chronically ill, was lethargic but awake and spontaneously breathing, and was unable to provide much history. The abdomen appears distended and is generally tender to palpation. An IV is placed, a Foley is inserted with clear urine returned, and fingerstick glucose is 120. You perform a bedside ultrasound that shows the following finding on the left side only (Fig. 1). In addition to obtaining blood cultures, administering broad-spectrum antibiotics and 30 ml/kg of crystalloid fluids, what action should you take?

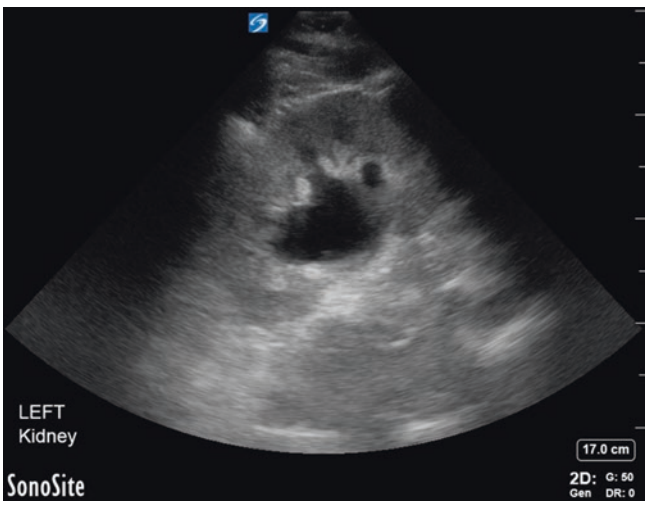

Fig. 1 Ultrasound findings

(a) Initiate dobutamine, and hold the fluids with concern for cardiogenic shock.
(b) Consult a urologist to request an emergent nephrostomy.
(c) Consult a general surgeon to request an emergent laparotomy.
(d) Consult a vascular surgeon for catheter-directed thrombolysis.
(e) Place an NG tube, make the patient NPO, and obtain a CT abdomen-pelvis to evaluate for a bowel obstruction.

142. A 22-year-old male with a history of metastatic testicular cancer presents with chest pain that began approximately 3 hours ago when he woke up. It is sharp, worse with lying flat, and partially relieved with sitting up, associated with shortness of breath and dizziness. Vital signs: temperature 98.7 °F (37.0 °C), pulse 104 bpm, respirations 20 bpm, blood pressure 103/76 by automatic cuff, and oxygen saturation 97% on room air. ECG shows sinus rhythm, rate of 104, normal axis, mild (<1 mm) ST segment elevation in all the precordial leads without depressions, and no TW inversions. The patient is thin, awake, alert, and oriented, with no obvious abnormality on cardiopulmonary examination. Bedside echocardiography reveals the following finding (Fig. 2). Which of the following management options should be considered?
(a) Catheter-directed thrombolysis
(b) Cardiac catheterization
(c) Placement of a left-sided pigtail catheter for tension pneumothorax
(d) Left thoracentesis
(e) Pericardiocentesis

143. A 39-year-old female with history of breast cancer who is currently undergoing chemotherapy presents to the ED with leg swelling for 1 week. Her vital signs were only remarkable for sinus tachycardia of 108 bpm. Upon examination, you find 3+ edema on the right lower extremity up to the mid-thigh. There is significant right calf and thigh tenderness with overlying erythema. Which of the following would confirm the suspected diagnosis?
(a) A noncompressible common femoral artery
(b) A noncompressible common femoral vein with an echogenicity in the lumen
(c) A compressible common femoral vein with the presence of luminal flow
(d) A compressible popliteal artery with luminal echogenicity

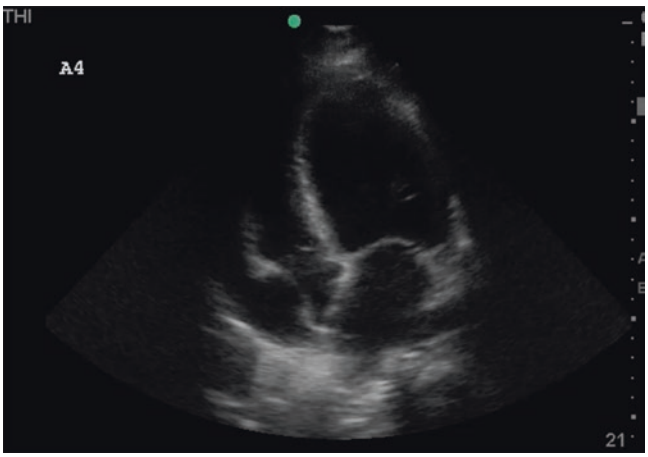

Fig. 2 Ultrasound findings

144. A 50-year-old female with breast cancer presents with shortness of breath and dyspnea on exertion. She is currently receiving doxorubicin as a chemotherapeutic agent. She has not previously had symptoms like this. Examination is remarkable for hypoxia to 90% on room air, jugular venous distension (JVD) and symmetric bilateral lower extremity edema, and obvious orthopnea. Which of these findings would confirm the suspected diagnosis?
(a) Diffuse B lines and bilateral pleural effusions on POCUS lung examination and a decreased left ventricular ejection fraction on cardiac ultrasound.
(b) Diffuse A lines on POCUS lung examination and a normal left ventricular ejection fraction on cardiac ultrasound.
(c) Diffuse A lines on POCUS lung examination and a hyperdynamic left ventricular ejection fraction on cardiac ultrasound.
(d) Significant free fluid in the abdomen on RUSH examination and a dilated IVC.
(e) Focal B lines and unilateral pleural effusion on POCUS examination of the right lung and a normal left ventricular ejection fraction on cardiac ultrasound.

145. A 50-year-old African-American female with breast cancer is receiving paclitaxel as part of her chemotherapy regimen. On a follow-up visit, she complains of symmetrical paresthesias in her legs which began in her toes a few weeks ago. She has tried over the counter pain medications with no relief. Her past medical history is significant for diabetes for which she takes metformin. She takes no other medications at this time. Which is the best evidenced-based treatment option?
(a) Gabapentin 300 mg po every 8 hours
(b) Duloxetine 30 mg po daily for 1 week then increase to 60 mg po daily
(c) Baclofen 10 mg, amitriptyline 40 mg, and ketamine 20 mg in pluronic gel apply to affected area three times daily
(d) Acupuncture

146. A 42-year-old male presents to the ED following extravasation of vincristine. The needle has been removed prior to presentation to the ED and the area of extravasation is red, swollen, and painful to touch. At this time, there is no ulceration and the affected area appears to not be progressing. Which of the following is the appropriate management for this patient?
    (a) Administer hyaluronidase to areas of extravasation
    (b) Do not elevate arm
    (c) Apply cold compress
    (d) Consult plastic surgery to evaluate the area
147. What is the most important agent for management of a patient with anaphylaxis secondary to cisplatin?
    (a) Epinephrine IM 0.5 mg into the deltoid muscle
    (b) Diphenhydramine 50 mg IV
    (c) Epinephrine IM 0.01 mg/kg IM into lateral aspect of thigh (max dose 0.5 mg)
    (d) Hydrocortisone 50 mg IV
148. A 34-year-old female who received her first cycle of fluorouracil, methotrexate, and cyclophosphamide as part of her chemotherapy regimen for breast cancer. The following day she presents to the ED with complaints of severe fatigue and confusion. Her husband states she was in her normal state of health until she woke up this morning with acute confusion. Her vital signs are normal with the exception of a slighted elevated blood pressure at 185/93 mmHg. Her home medications include sertraline 50 mg orally daily for depression and tramadol 50 mg orally as needed for pain. She has no other significant past medical history. A noncontrast CT scan of the brain in the ED is unremarkable. A recent MRI from 1 week ago showed no brain metastasis. What is the most likely cause of the patient's confusion?
    (a) Undiagnosed brain metastasis
    (b) Severe SIADH resulting in hyponatremia
    (c) Infection
    (d) Head trauma
149. Radiation treatment to the heart is associated with injury to:
    (a) Valves
    (b) Myocardium
    (c) Coronary arteries
    (d) All of the above
150. Radiation injury to the heart is influenced by:
    (a) Radiation dose
    (b) Volume in the therapy field
    (c) Daily fraction size
    (d) All of the above
151. Radiation injury to the lung can occur outside the radiation treatment field.
    (a) True
    (b) False
152. Radiation injury to the kidney generally spares the glomeruli.
    (a) True
    (b) False
153. With medical support, the LD 50/30 for total body radiation exposure is generally thought to be 5 cGy.
    (a) True
    (b) False
154. Lymphocytes may serve as a surrogate biomarker for radiation dose during an acute exposure incident.
    (a) True
    (b) False
155. Bone marrow transplant is a proven treatment for acute radiation exposure.
    (a) True
    (b) False
156. At least what percentage of pediatric patients undergoing hematopoietic stem cell transplant will experience oral and/or gastrointestinal mucositis?
    (a) 25%
    (b) 45%
    (c) 65%
    (d) 85%
    (e) 95%
157. Which of the following costs has *most contributed* to the economic burden related to oral and gastrointestinal mucositis?
    (a) Administration of antimucositis agents
    (b) Invasive procedures implemented for diagnosis of mucositis
    (c) Extended inpatient hospitalizations related to potential sequelae of mucositis
    (d) Additional time spent by physicians and clinical staff managing patient symptoms of mucositis
    (e) Enteral feeding tube intervention
158. Which of the following agents is appropriate for the prophylaxis of oral mucositis in a patient undergoing chemoradiation therapy for cancer of the head and neck?
    (a) Benzydamine mouthwash
    (b) Oral antibiotics
    (c) Hyperbaric oxygen therapy
    (d) Prebiotic supplementation
    (e) Fat-modified diet
159. Which of the following statements is true regarding mucositis?
    (a) Patient-reported duration and severity of mucositis are typically shorter and less severe compared to that reported by physicians.
    (b) Endoscopic evaluation is preferred for the diagnosis of gastrointestinal mucositis.
    (c) Early intervention with intravenous fluid hydration and/or enteral feeding tube placement is critical in

patients experiencing rapid, continuous weight loss and can reduce the risk of hospitalization or treatment break.
(d) Geriatric patients are at low risk of developing oral and gastrointestinal mucositis.
(e) Bacterial flora present in the oral and gastrointestinal mucosae have no impact on the pathogenesis of mucositis.

160. A 54-year-old male with a history of an allogeneic HCT 6 months ago for acute myeloid leukemia presents to the ED with profound melena. Vital signs showed a BP of 90/60, HR of 120, RR 18, and T 36.8 °C. CBC showed Hgb of 6 g/dL, Hct of 19%, WBC of 9.3/uL, and platelets of 150,000/uL. You decide to transfuse packed red blood cells.
(a) Washed RBC
(b) Genotypically matched RBC
(c) Leukoreduced RBC
(d) Irradiated RBC
(e) Both C and D

161. A 64-year-old man with AL amyloidosis who is undergoing autologous stem cell mobilization with high-dose G-CSF presents to the ED with lightheadedness and severe abdominal pain. Which of the following complications of high-dose G-CSF do you suspect?
(a) Pancreatitis
(b) Esophageal rupture
(c) Splenic rupture
(d) Mesenteric ischemia

162. A 52-year-old man with B-cell acute lymphoblastic leukemia receives nonmyeloablative conditioning followed by growth factor-mobilized blood cell transplantation from an HLA-matched unrelated donor. GVHD prophylaxis consists of cyclosporine, sirolimus, and mycophenolate mofetil. Twenty-one days after transplant, the patient develops new anorexia, early satiety, nausea, and low-volume diarrhea (approximately 300 mL/day). Despite scheduled antiemetics and diet adjustment, his GI symptoms persist. The patient has lost 5.0 kg over 1 week. The patient and donor were both CMV seropositive. Which of the following represents the best approach to treating this patient?
(a) Discontinue mycophenolate mofetil as this is the most likely cause of GI symptoms.
(b) Treat empirically with ganciclovir for presumed CMV enteritis.
(c) Refer to gastroenterology for consideration of endoscopic studies to evaluate for acute GVHD and test for viral infection.
(d) Treat empirically with prednisone at 2.0 mg/kg/day.

163. A 22-year-old patient with peripheral T-cell lymphoma presents to the ED with language incoherence noticed by his wife and gait change of 12-hour duration. The patient feels well and states he feels it is normal since he recently underwent CD19-chimeric antigen receptor (CAR)-T-cell therapy.
(a) Calculate the immune effector cell-associated encephalopathy (ICE) score since the symptoms can be a delayed presentation of immune effector cell-associated neurotoxicity syndrome (ICANS).
(b) Call the stroke team.
(c) Refer the patient to neurology clinic.
(d) Discharge the patient without further evaluation since the patient feels normal.

164. A 65-year-old patient with advanced melanoma has received 3 cycles of the combination of nivolumab and ipilimumab, and now presents to the ED with chest pain. He has no risk factors or family history of coronary artery disease. His electrocardiogram shows no ST segment changes suggestive of myocardial ischemia or pericarditis. What is the best next step in management?
(a) Discharge the patient if normal initial troponin level.
(b) Obtain D-dimer and 3 sets of cardiac enzymes. Initiate aspirin and anticoagulation (if no brain metastasis). Rule out myocarditis from immune checkpoint inhibitors.
(c) Start the patient on dexamethasone.
(d) None of the above.

165. A patient with acute myeloid leukemia presents to the ED with fever, hypotension, renal failure, and transaminitis. What is the appropriate management if the patient presents a card stating he is on oral therapy with enasidenib, which was started 3 weeks ago?
(a) Draw cultures, initiate intravenous fluids 30 mL/kg, and start broad-spectrum antibiotics.
(b) Admit to the intensive care unit.
(c) Consider the diagnosis of differentiation syndrome and initiate dexamethasone therapy after discussion with the oncologist.
(d) All of the above.

166. A patient with acute lymphoblastic leukemia presents to the ED for sudden onset fever, chills, and shortness of breath about 15 minutes upon reaching home after receiving blinatumomab infusion in the ambulatory treatment center. What is the best next step in management?
(a) Assess the patient's airway for vital signs and respiratory status and administer oxygen support.
(b) Evaluate for acute infection, probable neutropenic fever, and empirically start broad-spectrum antibiotics.

(c) Treat with corticosteroid, antihistamines, and inhaled beta-agonists for a delayed infusion reaction syndrome or cytokine release syndrome.
(d) All of the above.

167. What is one of the key indicators of poor quality care with regard to ED visits at the EOL?
(a) More than 2 visits in the last 6 months of life
(b) Avoidable visits in the last year of life
(c) More than 1 ED visit in the last 30 days of life
(d) Less than 1 ED visit in the last 6 months of life

168. What is the benchmark population value rate that regions should strive to be below for patients with cancer accessing ED care?
(a) 50%
(b) 80%
(c) 10%
(d) 30%

169. Which of the following is not among the 3 most common reasons for ED visits for patients with cancer at end of life?
(a) Fever
(b) Pain
(c) Shortness of breath
(d) Nausea

170. Research has shown that receipt of palliative care services is associated with various outcomes. Which of the following is not one of them?
(a) Better symptom control
(b) Improved knowledge of expectations
(c) Shorter survival
(d) Decreased chemotherapy use

171. Patients can develop tolerance to which adverse effect of opioids?
(a) Respiratory depression
(b) Constipation
(c) Pruritus
(d) All of the above

172. Which of the following statements is true about neuropathic pain?
(a) Peritoneal carcinomatosis generally causes neuropathic pain.
(b) Anticonvulsants require close titration of dosing when treating neuropathic pain.
(c) Topical lidocaine patches should be worn continuously for maximum treatment of neuropathic pain.
(d) Corticosteroids are contraindicated in neuropathic pain.

173. Which opioid does not follow first-order kinetics?
(a) Morphine
(b) Dilaudid
(c) Methadone
(d) Fentanyl

174. A 40-year-old woman presents to the ED in severe pain that she rates as 8/10. Her only past medical history is breast cancer. Twenty minutes after receiving a dose of IV morphine, she has no adverse side effects of the morphine but her pain remains 8/10. What is the best next step for her pain control?
(a) Repeat the same dose of IV morphine at this time.
(b) Re-assess the patient in 30 minutes because the first dose has not had sufficient time to work.
(c) Increase the initial dose by 50–100% and administer a second IV dose at this time.
(d) Switch to intramuscular morphine for more reliable absorption.

175. A 61-year-old man with a history of metastatic prostate cancer currently receiving radiation presents to the ED complaining of constipation. He is taking morphine daily for pain control but does not take medications to prevent constipation. After ruling out stool impaction and bowel obstruction, you discuss the case with the patient's oncologist and determine the patient is safe for discharge. You plan to send him home with a prescription to ease his constipation? Which of the following is true regarding medications for opioid-induced constipation prophylaxis?
(a) Methylnaltrexone is considered the best first-line agent for opioid-induced constipation prophylaxis.
(b) Stimulants and osmotic agents are often used together.
(c) Stimulants act by increasing water content in the large bowel.
(d) Polyethylene glycol is considered a bulk-forming agent.

176. The risk factors for a substance abuse problem developing in a person being treated for cancer pain with opioids include all of the following except:
(a) Older age
(b) Male gender
(c) Personal psychiatric history
(d) Family history of substance abuse

177. Pseudo addiction refers to a syndrome in which a person in poorly controlled pain develops aberrant behaviors that are uncharacteristic of them under normal circumstances and are expected to resolve when adequate pain control is provided. Which of the following are true of pseudo addiction:
(a) Pseudo addiction is mutually exclusive from actual loss of control of one's medications and the development of drug abuse.
(b) The behaviors always resolve with the provision of improved analgesia alone.
(c) It is best thought of as similar to secondary alcoholism.

(d) The original concept came from a large clinical trial.

178. In a study examining documentation of alcohol problems in 100 alcoholics with advanced illness, how many had their alcohol history noted in their medical record?
(a) 80%
(b) 60%
(c) 55%
(d) 30%

179. Disulfiram (Antabuse) has been shown to work in some highly selected patients with alcoholism. Which of the following characteristics does not predict the likelihood of a response to Antabuse?
(a) Older than 40 years of age
(b) Shorter drinking histories
(c) Socially stable
(d) Highly motivated

180. A 70-year-old patient with advanced lung cancer, enrolled in hospice care, presents to the ED with severe shortness of breath. The patient's goals are to focus on comfort and quality of life and to stay at home, but his caregiver panicked and called 911 when his breathing worsened. On physical examination, the patient reports severe dyspnea and appears very uncomfortable with a RR of 35 with accessory muscle use. The most important next step is to:
(a) Intubate the patient
(b) Place the patient on BIPAP
(c) Administer a test dose of morphine 2 mg IV and reassess for symptomatic improvement
(d) Get a STAT chest X-ray

181. In patients with advanced cancer presenting in respiratory distress, noninvasive ventilation
(a) Should always be used as a first step
(b) May be beneficial to some and can be utilized if consistent with the patient's goals of care
(c) Is rarely helpful and should not be considered
(d) Leads to recovery with discharge to home in nearly all patients

182. Diagnoses that commonly lead to dyspnea in patients with advanced cancer include:
(a) Pleural effusions
(b) Anemia
(c) Tumor burden in lungs
(d) All of the above

183. A 60-year-old patient with advanced pancreatic cancer is brought in by EMS after being found down in her home. She was with her friend at the time of the event. EMS arrived and found the patient in cardiac arrest, with an initial rhythm of PEA. ACLS protocol was initiated, the patient was intubated, and eventually ROSC was achieved. The patient's spouse has now arrived in the ED and says that the patient was DNR/DNI and did not want to be kept alive on machines at this stage of her illness. The most appropriate next step would be to:
(a) Walk into the room and remove the ETT.
(b) Counsel the patient's spouse that extubation is not allowed.
(c) Provide emotional support to the patient's spouse, counsel him on the patient's expected prognosis off the ventilator, and then start gathering the appropriate medications for extubation.
(d) Explain that extubations are only possible in the ICU.

184. Which of the following statements is true regarding outcomes treatments in cancer patients?
(a) Most patients with stage IV lung cancer understand that chemotherapy will cure their cancer.
(b) Less than 5% of hospitalized older patients with end-stage cancer knew that the CPR success rates were <10%.
(c) Physicians tend to rate more end-of-life items as significantly more important than patients.
(d) More than 60% of seriously ill older adults consider inability to "get out of bed" as a better quality of life than death.

185. Which of the following statements is *not* true regarding healthcare professional's concerns about family-witnessed resuscitation?
(a) Some hospitals may have inadequate resuscitation space per patient volume.
(b) Family-witnessed resuscitation causes additional stress to healthcare workers and thus negatively impacts their performance.
(c) Family members are not expected to understand the procedures and may interfere resuscitation efforts.
(d) Presence of family members may increase the potential for litigation in the future.
(e) The family members generally understand that resuscitation does not always result in positive outcome.

186. What is the most likely precipitating cause of in-hospital CPR in cancer patients?
(a) Anaphylactic reaction
(b) Respiratory failure
(c) Arrhythmia
(d) Cardiac arrest
(e) Hypovolemia

187. Which of the following conditions may have a worse outcome if a patient with such condition were to require CPR?
(a) Lymphoma

(b) Breast cancer
(c) Colorectal cancer
(d) Genitourinary cancer
(e) Head and neck cancer

188. Which of the following are considered by experts to be essential components of goals-of-care conversations in the ED?
(a) Identify the minimum quality of life the patient is willing to live for.
(b) Identify the surrogate decision maker if patient lacks capacity.
(c) Respond to emotion to reduce the anxiety/stress from discussing goals of care.
(d) Make a recommendation based on patient's baseline function, minimum quality of life acceptable, and prognostic estimates.
(e) Understand the baseline physical function and quality of life of the patient.
(f) All of above.

189. When should palliative care be started?
(a) Patients planning for tumor resections and starting chemotherapy
(b) Actively dying patients in ED
(c) Patients with chronic life-limiting illnesses such as congestive heart failure or chronic obstructive pulmonary disease
(d) When all cancer treatments have stopped
(e) A and C

190. Who would be the most effective ED palliative care champion?
(a) Medical students
(b) Quality control personnel
(c) Spiritual care personnel
(d) Hospital legal representatives
(e) ED volunteers

191. A 77-year-old man with advanced dementia, lung cancer with metastases to brain, presents from a nursing facility with increasing shortness of breath. He is bedbound and dependent on nursing care. There is a do not resuscitate/do not intubate order on his chart. His current vital signs are BP, 90/54; P, 105; R, 28; and T, 101.0 °F. Oxygen saturation is 89% on 4 L O_2 by nasal cannula. What is the most appropriate next step for patient management?
(a) Referral to in-patient hospice
(b) Intubation and admission to ICU
(c) Oxygen, antibiotics, and consult palliative care team
(d) Bereavement counseling
(e) Admit to hospitalist team for comfort care

192. In which scenario should an urgent consult to palliative care consult team be of most benefit in the ED?
(a) A patient with severe malignant bowel obstruction who refuses surgical intervention
(b) A patient with severe back pain and suspected acute cord compression
(c) A new diagnosis of multiple metastases from a breast malignancy
(d) A patient with severe vomiting after chemotherapy for lung cancer

193. In which scenario should hospice services referral be appropriately considered in the ED?
(a) A patient with dementia and prostate cancer
(b) Elderly patient with multiple myeloma and fall at home with hip fracture
(c) A patient with a chronic lymphocytic leukemia and a large left middle cerebral artery cerebrovascular accident or stroke
(d) Homeless patient with alcohol dependence and liver cirrhosis with a lung mass
(e) Any patient where expected survival is 6 months or less

194. A 43-year-old female has had evidence of worsening pain with known history of metastatic breast cancer to brain, lung, and bones. She has undergone radiation therapy as well as received steroids to manage her symptoms. You find that after repeated bolus IV doses of opioid analgesia, her pain remains uncontrolled and initiate a PCA. Her nurse tells you that she has improved; however, that she has been in the room frequently offering support and reassessing her symptoms. After clarifying goals of care, she has elected hospice with her family and her goal is to just get the pain under control. What level of hospice care does she likely require?
(a) Home hospice
(b) Facility-based care
(c) Continuous hospice care
(d) Inpatient unit care

195. A 75-year-old male has had progression of known prostate cancer and no longer has further traditional treatment options available per discussion with his oncologist after he presents to you with worsening back pain. After further discussion, he wants to pursue hospice, but remembers that there is a medication that has worked to provide longer life for patients in his situation and is off-label. He asks you if this medication will be covered by hospice?
(a) Yes, this medication is covered.
(b) No, it is not covered; it is a treatment that is meant to treat his underlying terminal condition.
(c) Call his oncologist to discuss.
(d) Look up the medication yourself to determine if it is effective or not.

196. A 50-year-old woman with a past medical history significant for recent diagnosis of metastatic pancreatic cancer not considered amenable to surgical intervention. She has experienced a rapid decline in clinical status, including obstructive jaundice, and due to this as well as complicating comorbidities of lupus with need for systemic immunosuppression, she was not considered a candidate for further therapies. She elected hospice and presents to the ED from home with bilious emesis. Further evaluation reveals likely SBO mechanical obstruction and she is not a candidate for surgical intervention. Her symptoms are temporized by a nasogastric tube (NGT), and she wishes to return home in lieu of admission but has severe ongoing nausea. What level of hospice is likely best able to control her symptoms at this point?
    (a) She can return home; the hospice IDT should be able to manage her symptoms there.
    (b) Continuous care should be able to transition her to home from the hospital.
    (c) Respite care is the best option because her husband does not know how to manage a nasogastric tube.
    (d) Inpatient unit care is most appropriate given her severe ongoing symptoms for stabilization prior to returning home.
197. Which of the following can emergency clinicians always rely on for appropriate guidance when faced with ethical dilemmas?
    (a) Institutional and medical board policies
    (b) The American College of Emergency Physicians' (ACEP) Code of Ethics
    (c) The American Medical Association or American Osteopathic Association ethical statements
    (d) None of the above
198. What are "values"?
    (a) The standards that individuals, institutions, professions, and societies use to judge human behavior.
    (b) The correct way of thinking about issues.
    (c) A patient's normal view of medicine, society, and his or her family.
    (d) A sense of duty to patients required of all healthcare workers.
199. Withholding treatment in the ED:
    (a) Legally differs from withdrawing treatment.
    (b) Morally differs from withdrawing treatment.
    (c) Requires clinical information that is often unavailable immediately.
    (d) Should never be done.
200. When using the "rapid approach to ethical problems" in the ED to decide on a course of action:
    (a) Always consult with the bioethics committee/consultant before acting.
    (b) Assume that each ethical problem in the ED requires a unique solution.
    (c) Test your chosen action against your religious values.
    (d) When practicable and safe for the patient, buy time to consult on possible options.
201. Which one of the following statements is false?
    (a) Members of the LGBTQ community can be more difficult to research due to lack of standard collection of sexual orientation and gender identity in the health record.
    (b) Members of the LGBTQ community are less likely to live in poverty and more likely to have health insurance.
    (c) Sexual orientation relates to identity rather than sexual behavior.
    (d) Lack of employment discrimination protection is common, and in many states, you can be fired for being gay or transgender.
202. The minority stress model
    (a) Only applies to racial and ethnic minorities
    (b) Has not been shown to contribute to cancer disparities in minority groups
    (c) Does not apply if all patients are treated equally
    (d) Is thought to explain the negative effects of chronic stigmatization and high levels of stress on a minority group's health status
203. Cancers are with worse outcomes in the black community include:
    (a) Colon cancer
    (b) Breast cancer
    (c) Lung cancer
    (d) All of the above
204. Which of the following is not true?
    (a) Minority populations will overtake the majority white population by 2050.
    (b) Cultural humility is a lifelong process of self-reflection and self-critique that can inform understanding of cultural differences and how differences require sensitive approaches to healthcare.
    (c) Outright discrimination is also known as implicit bias.
    (d) Minority groups are often underrepresented in cancer clinical trials.
205. Which of the following is true regarding bias:
    (a) Biases are shaped by experiences and based on learned associations between particular qualities and social categories.
    (b) Raising awareness of physician bias and how they affect clinical decision-making is key to helping physicians mitigate bias.
    (c) Patients with schizophrenia and other disabilities are often unable to advocate for themselves and

are also at increased risk of experiencing physician bias.
(d) All of the above.

206. Choose the correct statement about WHO analgesic ladder:
(a) Provides a simple approach toward treating pain in only 50% of the patients.
(b) The first step of the ladder represents the use of nonopioid and opioids analgesics to treat mild pain.
(c) The second step represents the use of weak opioids with or without nonopioid analgesics, and with or without adjuvants to treat moderate pain.
(d) States to administer pain medications on-demand instead of around-the-clock.
(e) Intravenous and rectal dosing of drugs is preferred whenever possible.

207. Cancer pain can be characterized as:
(a) Neuropathic pain
(b) Somatic (nociceptive) pain
(c) Sympathetic pain
(d) A and C
(e) All of the above

208. Choose the correct statement about methadone:
(a) Rapid titration is safe.
(b) Withdrawal symptoms are more severe than morphine.
(c) Sedation and respiratory depression can outlast the analgesic action.
(d) Never used in opioid addiction.
(e) Lacks interactions with multiple medications that the patients may be on.

209. Which of the following is true regarding tramadol?
(a) Has a dose limit of 800 mg/d
(b) No effect on norepinephrine or serotonin
(c) Inhibits the reuptake of norepinephrine and serotonin
(d) Is a peripherally acting analgesic
(e) Has strong opioid characteristics

210. The specialties of emergency medicine and oncologic are organizing to establish professional groups to organize activities around oncologic emergency medicine, including educational, research, and policy initiatives. Which groups below are representative of these efforts?
(a) American Academy of Emergency Medicine Oncologic Emergency Medicine Interest Group
(b) Society for Academic Emergency Medicine Oncologic Emergencies Interest Group
(c) American College of Emergency Physicians Oncologic Emergency Medicine Section
(d) NIH-supported Comprehensive Oncologic Emergencies Research Network (CONCERN)
(e) B and D
(f) A and C

211. Of the options below, which factors pose barriers to establishing quality metrics for oncologic emergency medicine?
(a) Gaps in existing ED measures
(b) Fragmented measure development
(c) Difficulty defining the episode of oncologic emergency care
(d) Measurement without a clear mechanism for improving ED care
(e) Challenges in obtaining ED quality data
(f) All of the above

212. The first patient navigator program was:
(a) Developed by the Dana Farber Cancer Center in 2005
(b) Developed by The University of Texas Cancer Center in 1994
(c) Developed by Harlem Hospital in 1990
(d) Developed by the Intermountain Healthcare system in 2002

213. In what year was Emergency Nursing established as a specialty practice by the American Nurses Association?
(a) 1970
(b) 1986
(c) 1992
(d) 2011

214. In addition to the acute medical needs that prompt ED visits and invite the interventions of ED social workers, oncologic social workers serve to address the unique psychosocial stressors that accompany a cancer diagnosis. These may include:
(a) Adjustment to a new cancer diagnosis
(b) Alterations in role and identity
(c) Changes in caregiver needs and family roles
(d) Impact on work and finances
(e) Goals of care planning
(f) All of the above

215. All of the following statements regarding radiation are true, except:
(a) Radiation is the passage of an electromagnetic wave through space.
(b) Nonionizing radiation includes radio waves, microwaves, and ultrasound.
(c) X-rays and gamma rays are examples of ionizing radiation.
(d) Gamma rays are produced when electrons are emitted from electron clouds as a result of electron excitation.

(e) Radiation is considered ionizing if it is of high enough energy to remove electrons from an atom.

216. Which of the following statements regarding lung cancer screening is true?
   (a) Gays, lesbians, and bisexuals have higher rates of smoking, thus higher levels of lung cancer screening than their heterosexual counterparts.
   (b) Geographically in the United States, the South has 40% of lung cancer screening-eligible patients and a screening rate that is one-third that of the Northeast.
   (c) The NCI-funded National Lung Screening Trial (NLST) failed to demonstrate mortality reduction with lung cancer screening.
   (d) The 1986 Mayo Lung Project found a benefit in overall mortality for subjects receiving lung cancer screening.
217. The most common tumor causing proptosis in adults is:
   (a) Optic nerve glioma
   (b) Lymphoma
   (c) Orbital rhabdomyosarcoma
   (d) Meningioma
218. Superior vena cava syndrome (SVCS) represents one of the most common oncologic emergencies seen in the ED.
   (a) True
   (b) False
219. All of the following regarding radioactivity are true, except:
   (a) One Sievert (Sy) is equivalent to 1000 roentgen equivalent man (rem).
   (b) One gray (Gy) is equivalent to 1 J of energy deposited in 1 kg of tissue.
   (c) Radioactivity is measured in curies (Ci) in the English measurement system.
   (d) Radioactivity is measured in Becquerel (Bq) in the SI system.
   (e) A Becquerel (Bq) is equivalent to one disintegration of an atomic nucleus per second.
220. Which of the following are true statements?
   (a) The antidote for fluoropyrimidine toxicity is oral capecitabine.
   (b) Treatment of 5-FU toxicity is largely supportive.
   (c) 5-Fluorouracil is the oral prodrug of capecitabine.
   (d) Hand-and-foot syndrome is a characteristic adverse effect of uridine triacetate.
   (e) Uridine triacetate toxicity is generally attributed to genetic polymorphisms.

Answers

1. (b) Over 60% of patient with pancreas, brain, and lung cancer have at least one ED visit within 1 year of diagnosis. Overall, 44% of all cancer patients have one ED visit within 1 year of diagnosis. Less than 30% of those with melanoma, prostate, eye, or endocrine cancers have a visit within 1 year of diagnosis.
2. (a) Approximately 4% of all ED visits are cancer-related, and lung, breast, prostate, and colon are the most frequent cancers associated with ED visits.
3. (d) Visit-level data only provide information about patients who visit the ED and do not capture all patients with cancer. While visit-level data may provide valuable information regarding the quality, type of care, and related diagnosis, visit-level data are unlikely account for multiple visits made by the same patient.
4. (e) Current methodologies generally utilize ICD codes and diagnoses to identify potentially avoidable ED visits; however, no common consensus definition exists to define which diagnoses or visits made by cancer patients are preventable.
5. (c) While specific visit and admission rates vary by cancer type, oncologic patients have higher rates of admission from the ED and higher rates of multiple ED visits than the general US population.
6. (e) HIPAA defined 18 potential identifiers. Of the above choices, gender is the least likely to uniquely identify a patient and does not meet these definitions.
7. (c) A cancer registry is an information system that collects and analyzes data from a census of cancer cases. Registry data can be used to define and monitor cancer incidence, investigate treatment patterns, evaluate efforts to prevent cancer, and improve survival.
8. (e) Polling providers for preference, along with scouring the literature for recommendations and guidelines, are often first steps in designing an order set. Usually, one or more clinical "champions" are identified to begin the process of consulting literature, guidelines, experts in the domain, and practitioners in the affected departments.
9. (a) A current smoker is someone who has smoked at least 100 cigarettes lifetime and currently smokes every or some days.
10. (d) The patient is experiencing nicotine withdrawal after several hours of not smoking. She would benefit from nicotine replacement therapy. Combination treatments that include a short-acting medication (nicotine gum) supplemented by a long-acting medication (nicotine patch) are often more efficacious in treating nicotine withdrawal than patch alone.
11. (b) Both nicotine replacement therapy and motivational interviewing are efficacious. Tobacco control, in general, is among the most cost-effective treatments in all of medicine. National bodies do not mandate tobacco treatment in the ED, although the Model of the Clinical Practice of Emergency Medicine does require EM residents be taught the principles of tobacco dependence treatment.
12. (c) SBIRT does require smokers to be referred for post-ED treatment of tobacco dependence. Although tobacco pharmacotherapy may begin in the ED, SBIRT does not require it. Adding nicotine replacement to SBIRT is consistent with the newer treatment model known as Screening, Treatment Initiation, and Referral (STIR). SBIRT was initially developed to treat individuals with alcohol-use disorders, then adapted to tobacco and other substances. There are no contraindications to delivering SBIRT, although patients should of course be able to engage in a meaningful conversation with the interventionist.
13. (a) Alcohol use most commonly begins during adolescence. As youth transition into late adolescence, alcohol use typically increases.
14. (c) Evidence supports a dose-dependent relationship between alcohol use and cancers of the breast, rectum, and larynx. Uterine cancer is not known to be closely linked to alcohol use.
15. (d) Native American populations have the highest rates of alcohol-attributable injuries such as MVCs and falls compared to other racial/ethnic minority groups. Black and Latino populations have the highest rates of recurrent or persistent alcohol dependence, once it has developed. Among all racial/ethnic minority groups, Asians populations have the lowest reported rates of alcohol use.

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5

16. (b) The DSM-5 removed the category of alcohol-related legal problems, which was present in the DSM-IV, and replaced it with the criteria of craving. Both tolerance and withdrawal were previous criteria for alcohol dependence in the DSM-IV. They are also criteria for alcohol-use disorder in the DSM-5.
17. (b) Total excision. All the other options may be useful for smaller lesions where total removal with the technique may be possible in depth and width, but risk base transection occurring or sampling error where the segment sampled of a lesion does not give an accurate reflection of its true nature (mild dysplasia abutting in situ melanoma in the same lesion). If uncertain regarding diagnosis or management, dermatology or teledermatology referral can be an alternative solution.
18. (c) The presence of a darker skin type on the Fitzpatrick scale is less likely to develop melanoma.
19. (b) Increasing Breslow thickness correlates strongly and negatively with 10-year survival.
20. (a) "A" in the ABCDE patient mnemonic stands for asymmetry, not aggravating.
21. (d) It is unclear if protection is life-long, but it is at least 10 years. Because the vaccines do not provide protection against all cancer-associated HPV types, routine cervical screening is still recommended, including routine screening in vaccinated women.
22. (c) Guidelines recommend screening for cervical cancer between the ages of 21 and 65. Cervical cancer screening should not be performed in women younger than 21 years of age, regardless of the age of onset of sexual activity. From ages 30–65, cervical cytology and HPV testing are recommended.
23. (c) Observation is preferred to treatment for women with CIN 1. In general, women with CIN2/3 are treated because of the higher risk of progression to invasive cancer. Treatment to remove abnormal areas of the cervix may be through ablation (with cryotherapy or thermal ablation) or excision of the precancerous area. Excisional procedures include loop electrosurgical excision procedure (LEEP), cold knife conization (CKC), and CO_2 laser conization. In the United States, excisional treatment is preferred to ablative treatment.
24. (d) Approximately 80% of individuals with HPV will clear the infection spontaneously within 18–24 months of infection. In women with persistent HPV infection, 3–5% will develop significant preinvasive disease, and <1% will develop cancer.
25. (d) This patient presents with a likely bowel obstruction from colon cancer. Important considerations include his history of ulcerative colitis and lack of subsequent follow-up. Long-standing ulcerative colitis is associated with a significant increased risk of colon cancer and regular screening for dysplasia is recommended. Toxic megacolon may also present with systemic toxicity and colon dilation. Bloody diarrhea and distension are seen throughout the entire colon without a point of transition. Acute diverticulitis may have a systemic toxic presentation but distension is unlikely. While underlying ulcerative colitis is strongly associated with primary sclerosing cholangitis and ascending cholangitis, bowel obstruction is unlikely and a cholestatic pattern is seen with liver function tests.
26. (c) Occult fecal bleeding and hematochezia do not necessarily indicate the presence of advanced colon malignancy, and they are found in some individuals with early colorectal cancer.
27. (d) The patient has symptoms worrisome for colon carcinoma and will need a definitive diagnosis to guide therapy. CT colonography is a useful diagnostic method; however, the risk of radiation and need for further studies, such as colonoscopy, should be considered. Colonoscopy is the most accurate diagnostic method, can localize and provide a definitive tissue diagnosis, and can remove polyps.
28. (b) Upright abdominal series to look for free air. The patient has a history of colon cancer and suddenly developed abdominal pain suggestive of a bowel perforation. If she is unable to tolerate an abdominal series, a CT of the abdomen and pelvis would be the next step.
29. (d) Stabilization of a patient with hemoptysis and respiratory distress begins with establishing a protected airway in the form of endotracheal intubation. Once intubated, further steps to identify and isolate, such as with an endobronchial blocker or selective mainstem intubation, can be performed.
30. (c) Patients with greater dyspnea and poorer functional status derived the most benefit from therapeutic bronchoscopy based on data published from the AQuIRE registry. (Ost DE, Ernst A, Grosu HB, et al. Therapeutic bronchoscopy for malignant central airway obstruction: Success rates and impact on dyspnea and quality of life. *Chest*. 2015;147(5):1282–1298.)
31. (c) Patency of the lobar bronchi distal to the obstruction. Patency of distal airways, either on CT or on bronchoscopy, has been identified as predictors of a successful therapeutic bronchoscopy to relieve MCAO. (Ost DE, Ernst A, Grosu HB, et al. Therapeutic bronchoscopy for malignant central airway obstruction: Success rates and impact on dyspnea and quality of life. *Chest*. 2015;147(5):1282–1298; Giovacchini CX, Kessler ER, Merrick CM, et al. Clinical and radiographic predictors of successful therapeutic bronchoscopy for the relief of malignant central airway obstruction. *BMC Pulm Med*. 2019;19(1):219-019-0987-3.)
32. (b) Gas embolism is a reported complication of the use of argon plasma coagulation especially when used with

high flow rates and longer pulse durations. (Reddy C, Majid A, Michaud G, et al. Gas embolism following bronchoscopic argon plasma coagulation: A case series. *Chest*. 2008;134(5):1066–1069.)

33. (d) A hallmark of delirium is the fluctuation of attention levels, with repercussions on attention span, the ability to focus, and short-term memory. With multiple contributors to delirium, caregivers can miss this diagnosis.
34. (c) Patients with cancer on active treatment presenting with an acute ischemic stroke and meeting criteria for intravenous thrombolysis should receive this intervention in a shared decision process.
35. (c) Plateau waves are paroxysmal episodes, self-limited, with motor and autonomic manifestations that can be easily mistaken for seizures.
36. (a) It is rare to see spontaneous ICH with these coagulation parameters. She could have an incipient trauma, or hit her head on the floor after a fall (no clues in history) as the cause for the epidural hematoma. To preserve life and function, a hematoma evacuation is the definitive treatment in this case.
37. (b) Magnetic resonance imaging is the preferred imaging modality for MSCC diagnosis. The need for mobility assistance indicates a deficit that should be evaluated immediately. With a high suspicion for this patient, an MRI would be the appropriate next step to determine the definitive presence and extent of involvement of vertebral body metastasis. The need for mobility assistance indicates a deficit that should be evaluated immediately, rather than referred to outpatient pain management. Zoledronic acid is not used in treatment of MSCC.
38. (c) According to Bilsky's grading system, deformation of thecal sac without cord abutment is classified as Grade 1B. In the absence of mechanical instability, the initial treatment recommendation is radiation therapy. Radiation therapy alone has shown promising results for MSCC in maintaining functionality in the absence of neurological deficits. (Bilsky MH, Laufer I, Fourney DR, Groff M, Schmidt MH, Varga PP, Vrionis FD, Yamada Y, Gerszten PC, Kuklo TR. Reliability analysis of the epidural spinal cord compression scale. *J Neurosurg Spine*. 2010;13(3):324–8; Bilsky MH, Laufer I, Burch S. Shifting paradigms in the treatment of metastatic spine disease. *Spine*. 2009;34(22 Suppl):S101–7.)
39. (d) Loss of sensation, dense paraplegia, and incontinence are late findings of MSCC and signal some degree of permanent disability. While weakness and hyperreflexia are late findings of MSCC, urinary incontinence is the strongest indicator of poor prognosis and permanent disability.
40. (d) In spite of improved surveillance and diagnostic practices, 20% of malignant spinal cord compression occurs in patients without a known malignancy. A patient without a biopsy-confirmed cancer diagnosis in need of corticosteroid treatment presents a dilemma. If there is any question regarding the nature of the lesion, tissue diagnosis must be obtained without delay. Steroids are used with curative intent in treatment of plasmacytomas, thymomas, lymphomas, multiple myeloma, and germ-cell tumors. In these circumstances, corticosteroids given before tissue samples are obtained may cause regression of disease, hindering diagnosis and complicating delivery of definitive chemotherapy. In the absence of neurological deficit, corticosteroids may be withheld pending consultation with neurosurgery and oncologic.
41. (c) The most common hormonal deficit in pituitary apoplexy is a low level of growth hormone. The second most common is an acute deficiency of ACTH. Diabetes insipidus is possible, but uncommon, after pituitary apoplexy.
42. (d) Although the most common cranial neuropathy associated with pituitary apoplexy is dysfunction of the optic nerve caused by compression of tumor against the optic chiasm, this causes visual loss but not diplopia. Ocular motility is regulated by the III, IV, and VI cranial nerves, with the oculomotor nerve being the most vulnerable to pressure effects.
43. (a) Note that the hyperintensity on T1-weighted images lasts only until day 14, when it begins to darken (i.e., become hypointense) as hemoglobin is converted to methemoglobin. In T2-weighted images, where even more time-dependent fluctuation occurs, blood is hyperintense for 24 hours, then hypointense until day 7, then hyperintense for a week, and then after day 14, it has the same hypointensity seen on T1-weighted images after day 14.
44. (e) Use of a dopamine agonist (typically for a prolactinoma) is a predisposing factor to pituitary apoplexy in a small percent of patients, but not a dopamine antagonist. The other four factors listed are all even more common precipitators of apoplexy than is a dopamine agonist medication.
45. (c) This patient is likely presenting with advanced laryngeal cancer. These patients can decompensate due to airway compromise. The airway is best managed surgically in the operating room via awake tracheostomy, and attempted intubation in the ED should be avoided. In the meantime, intravenous steroids can be helpful. In an emergent situation, a "slash" tracheostomy or cricothyrotomy in the ED is warranted.
46. (b) This presentation is highly suggestive of a sentinel bleed from arterial bleeding into the pharynx. Patients

will typically present with brisk but short-lived bleeding from the oral cavity. The workup should be expeditious as bleeding can be catastrophic, particularly in the event of a carotid blowout. The next step in management would be CT angiography to assess for the site of hemorrhage and to guide potential endovascular intervention.

47. (d) A neck mass in an adult should be considered malignancy until proven otherwise. HPV-related oropharyngeal carcinoma in particular may present as a cystic neck mass with minimal symptoms from the primary site, typically in a male in their 50s–60s. A fine needle aspiration (FNA) can confirm the diagnosis. Incision and drainage should be avoided unless malignancy has been excluded.
48. (c) Facial paresthesia is not usually associated with acute sinusitis and suggests cranial nerve involvement, likely by an advanced sinonasal malignancy. Nasal congestion, drainage, and facial pressures are more typical of a patient presenting with acute sinusitis.
49. (c) Dasatinib has been linked to the development of pulmonary arterial hypertension, whereas nilotinib and ponatinib have been associated with an increased risk of myocardial ischemia, cerebrovascular accidents, and peripheral artery disease, in some cases requiring revascularization or leading to amputation. Of note, while the vascular toxicity of nilotinib may be related, at least in part, to its adverse effects on body weight and on glucose and lipid metabolism, the vascular toxicity of ponatinib appears to be a new form of microvascular angiopathy.
50. (b) Adverse cardiac events associated with ICI therapy are rare (less than 1% of patients) but can be potentially life-threatening. The most common and well characterized is ICI-induced acute fulminant myocarditis, which typically occurs within 90 days of initiation of therapy, and is often associated with acute hemodynamic failure and death in up to 50% of patients. The most commonly used and studied are nivolumab, pembrolizumab, and ipilimumab.
51. (d) Patients who develop systolic LV dysfunction (LVEF <50%) during anthracycline treatment should be treated with heart failure goal-directed medical therapy, including beta-blockers, angiotensin-converting enzyme inhibitors, or angiotensin II receptor blockers. The most studied agents are carvedilol, metoprolol, and bisoprolol, with notable recent trials showing significant reduction of mean change in LVEF using candesartan versus metoprolol and placebo. Statins, aspirin, enoxaparin, and rivaroxaban/apixaban have some clinical trial data to suggest cardioprotection as well. Dexrazoxane, a cardioprotective agent via iron chelation and topoisomerase II inhibition, may be used if cumulative doxorubicin is >300 mg/m^2 and/or the disease is metastatic.
52. (a) Antimetabolites such as 5-fluorouracil, clofarabine, and capecitabine; lomustine + bevacizumab + cyclophosphamide + etoposide; rapamycin, interferon alpha, and trastuzumab have demonstrated ability to cause cardiogenic shock secondary to stress cardiomyopathy, requiring ionotropic agents in up to 20% of patients. Acute stress cardiomyopathy usual occurs with the initial dose.
53. (d) Perform pleuroscopy and pleural biopsy and insert an indwelling pleural catheter (IPC). This patient has an undiagnosed lymphocytic exudative effusion that is recurrent in nature, which requires pleural biopsy to establish a diagnosis. The diagnostic yield of pleural biopsy is ~97%, compared to 62% after two thoracenteses. Given chest discomfort and presence of loculation, he has a nonexpandable, likely entrapped, lung. Talc pleurodesis in this setting will not be successful given loculation. Placement of IPC at the time of pleural biopsy is recommended to control the symptoms. Considering a repeat thoracentesis lacks utility and moreover could lead to additional loculations.
54. (b) There is no evidence that large chest tubes (20–24 F) are better than small bore chest tubes (10–14 F) in the management of pneumothoraces. Although the initial use of large bore chest tubes is not recommended, they may be necessary if there is a large air leak preventing complete re-expansion of the lung. The most common position of the chest tube is mid axillary line. In patients with persistent air leaks, one-way endobronchial valves are an alternative to surgical intervention.
55. (d) Hypercapnic acidosis reduces cyclic mechanical stretch, epithelial injury, and cell death. In ARDS patients with low tidal volume ventilation, permissive hypercapnia is accepted as increase in $PaCo_2$ and subsequent acidosis increases arterial and tissue oxygenation by a right shift of the oxygen–hemoglobin dissociation curve and possibly by increasing cardiac output and circulating catecholamines. Hypercapnic acidosis reduces cyclic mechanical stretch-induced nuclear factor-κB activation, reduces interleukin-8 production, and decreases epithelial injury and cell death compared to normocapnia. However, the rise of the $PaCO_2$ should occur gradually. Rapid rises should be avoided as the negative effects may exceed the beneficial ones (increased heart rate/blood pressure, arrhythmias, and pulmonary vasoconstriction/worsening hypoxemia).
56. (a) Nebulized tranexamic acid. In a randomized study by Wand et al., inhaled tranexamic acid (500 mg TID) showed a significant reduction in hemoptysis com-

pared to the control (96% vs. 50%) over 2 days. There were no adverse events related to the inhalation treatment. TXA when given as inhalation route is more efficacious because of the rapid onset of action compared to intravenous route.

57. (c) The patient is not low risk by Hestia criteria due to homelessness and poor social support. The patient would benefit from admission for social work.
58. (d) The patient demonstrates hemodynamic instability and would benefit immediately from fibrinolysis.
59. (d) The patient is likely Hestia low risk and can safely be discharged on a TSA (target specific anticoagulation).
60. (b) First-time VTE can be a presenting sign of occult, asymptomatic malignancy, but in a well-appearing patient with normal vital signs and no other complaints can be safely managed as an outpatient given Hestia low risk.
61. (g) The differential diagnosis is quite broad, and would include COPD exacerbation, COVID-19, bacterial pneumonia, immune pneumonitis, and pulmonary embolism. However, do not forget that immune checkpoint inhibitors can induce an insulinopenic diabetes mellitus that can lead to diabetic ketoacidosis. The patient would present with tachypnea and shortness of breath due to metabolic acidosis, along with nausea, dehydration, and general weakness.
62. (d) This patient has immune checkpoint inhibitor-induced hypophysitis. Headache is frequently associated with this immune-mediated adverse effect. This patient has central adrenal insufficiency and central hypothyroidism. Hypotension is due to adrenal insufficiency. Lack of reflex tachycardia is due to central hypothyroidism. Hyponatremia is due to both adrenal insufficiency and hypothyroidism. MRI of the sella will reveal pituitary enlargement. Hormonal measurements will reveal central adrenal insufficiency and central hypothyroidism. (El Majzoub I, Qdaisat A, Thein KZ, Win MA, Han MM, Jacobson K, et al. Adverse effects of immune checkpoint therapy in cancer patients visiting the emergency department of a comprehensive cancer center. *Ann Emerg Med*. 2019;73(1):79–87.)
63. (d) Numbness and tingling of extremities and muscle cramping are frequent symptoms of hypocalcemia. Complete thyroidectomy for thyroid cancer has a significant risk for postoperative hypoparathyroidism and the development of hypocalcemia. (Ramirez AT, Gibelli B, Tradati N, Giugliano G, Zurlo V, Grosso E, et al. Surgical management of thyroid cancer. *Expert Rev Anticancer Ther*. 2007;7(9):1203–14.)
64. (a) Stat EKG, and monitor cardiac rhythm while electrolyte abnormalities are corrected with intravenous infusions since the patient has grade 4 hypomagnesemia and is at high risk for cardiac arrhythmia. Hypomagnesemia causes QT prolongation, and thereby increases the risk for torsade de pointes. Hypomagnesemia is caused by the nephrotoxic effect of oxaliplatin, but inhibition of EGFR in the renal tubules by panitumumab also causes hypomagnesemia. (Haroon N, Raza SM, Bhat ZY. Hypomagnesemia and chemotherapy, diagnostic dilemma, and treatment challenge: case report and literature review. *Am J Ther*. 2016;23(4):e1085–90; Oronsky B, Caroen S, Oronsky A, Dobalian VE, Oronsky N, Lybeck M, et al. Electrolyte disorders with platinum-based chemotherapy: mechanisms, manifestations and management. Cancer *Chemother Pharmacol*. 2017;80(5):895–907.)
65. (d) Often times, the bleeding tumor has several areas of active oozing, and mechanical disruption of the friable tumor with the use of a hemoclip may potentially worsen bleeding and is generally not effective for diffuse mucosal type bleeding. Hemoclips are generally avoided in bleeding from tumors unless there is a focal targeted area of hemorrhage, which is rarely the case.
66. (b) False. Overall prognosis should be considered prior to palliative luminal stenting. If patient life expectancy is anticipated to exceed 6 months, a more durable approach such as a surgical bypass (gastrojejunostomy) should be employed. While generally well tolerated, the main complications of gastroduodenal stenting include stent migration, perforation, and stent obstruction by tumor or food. These obstructions can typically be resolved endoscopically by placing a stent within the originally placed stent; however, the potential for re-intervention is higher after 6 months, and therefore, a surgical gastrojejunostomy should be considered in these patients.
67. (c) While TPN has been associated with elevated liver chemistries, it does not cause liver dysfunction, per se, and therefore is not a cause of liver failure. The rest of the listed causes are potential etiologies of fulminant hepatic failure.
68. (d) Patients with asymptomatic jaundice do not require biliary decompression unless their hyperbilirubinemia interferes with chemotherapy (i.e., some chemotherapeutic regimens require a normal bilirubin). Patients with intolerable jaundice or pruritus or poor nutritional status as a result of hyperbilirubinemia should have elective biliary decompression. Pruritus associated with hyperbilirubinemia can be debilitating and has been managed with antihistamines, corticosteroids, cholestyramine, and other medications with only limited success, and relief of obstruction is the mainstay of treatment. Those patients with signs and symptoms of acute cholangitis require urgent drainage and intravenous antibiotics.

69. (a) True. Nonoperative management consists of bowel rest and decompression using a nasogastric tube or long-intestinal tube, analgesia, and antiemetics, if necessary, and it has been showed to be effective in approximately 70–90% cases.
70. (a) Pancreatic cancer accounts for 15–20% cases, and it is the most common cause. It is often diagnosed when advanced, and it is the most frequent cause of gastric outlet obstruction.
71. (b) Neutropenic enterocolitis most commonly occurs 2–3 weeks after receiving cytotoxic chemotherapy when neutropenia is most profound.
72. (d) Systemic sepsis is due to bacterial translocation through inflamed intestinal mucosa. Gastrointestinal bleeding is also common due to damage of the mucosa, which may lead to bowel obstruction.
73. (d) It is crucial to consider the diagnosis of immune-mediated colitis caused by immune checkpoint inhibitors. The number stools per day puts the patient in Grade 3. A CT scan of the abdomen and pelvis is helpful in assessing bowel wall thickening and the extent of bowel involvement and exclude bowel perforation. Exclusion of infectious diarrhea is an integral part of the diagnostic process. The patient will need colonoscopy and biopsy. Empiric treatment with antimicrobials and glucocorticoid needs to be considered. (Rajha E, Chaftari P, Kamal M, Maamari J, Chaftari C, Yeung SJ. Gastrointestinal adverse events associated with immune checkpoint inhibitor therapy. *Gastroenterol Rep (Oxf)*. 2020;8(1):25–30.)
74. (c) These rare types of neuroendocrine cancer of the pancreas cause severe cholera-like diarrhea. The patients are often severely dehydrated with severe electrolyte abnormalities that are unlikely to be managed satisfactorily in the ED setting. Intravenous hydration and electrolyte replacement often require longer than 2 days. Additional intravenous octreotide would help to suppress tumor secretion of VIP. Chemoembolization to reduce tumor bulk often can reduce the symptom burden of diarrhea. (Dreanic J, Lepere C, El Hajjam M, Gouya H, Rougier P, Coriat R. Emergency therapy for liver metastases from advanced VIPoma: surgery or transarterial chemoembolization? *Ther Adv Med Oncol*. 2016;8(5):383–7.)
75. (d) Although the clinical scenario is consistent with acute graft-versus-host disease as the cause of severe diarrhea, infectious colitis and sepsis must also be excluded and empirical treatments need to be initiated immediately. (Robak K, Zambonelli J, Bilinski J, Basak GW. Diarrhea after allogeneic stem cell transplantation: beyond graft-versus-host disease. *Eur J Gastroenterol Hepatol*. 2017;29(5):495–502.)
76. (a) This patient has neutropenic fever and very probably also has neutropenic enteritis. CT scan of abdomen and pelvis is indicated. The epigastric pain can be from inflammation of the transverse colon. Hospital admission is indicated for neutropenic fever in patients with hematological malignancies. (Rodrigues FG, Dasilva G, Wexner SD. Neutropenic enterocolitis. *World J Gastroenterol: WJG*. 2017;23(1):42–7.)
77. (b) Metoclopramide is a prokinetic as well as an antiemetic and would be appropriate in this instance. The patient's nausea should be addressed before any oral laxatives are given. Ondansetron is known to cause constipation; therefore, it is not adequate in this instance. The patient has an unremarkable examination, and it is unlikely that she has a bowel obstruction. Obtaining a plain radiograph to confirm stool burden might be done, but the likelihood of important findings is low. Hydration with IV fluid alone is not appropriate as it is not likely to relieve her symptoms in the ED.
78. (a) Methylnaltrexone is FDA approved for OIC and could be used in the ED subcutaneously as it is fast-acting. Senna and bisacodyl, as well as fiber, are less likely to work in the acute setting and may cause more abdominal discomfort without producing a bowel movement. Disimpacting the patient is not indicated if there is no evidence of impaction on rectal exam.
79. (c) Constipation can sometimes be the only symptom of cord compression. The subtle examination findings of lower extremity weakness with subjective paresthesias should alert the EP to possible spinal cord compression. An MRI of the spine should be ordered urgently. Giving pain medicine to the patients is adequate, but waiting for laboratory results before ordering the MRI is not appropriate. An enema may work, but constipation is not likely the primary cause in this case and missing cord compression can be catastrophic. A CT scan of the abdomen is not appropriate given the normal abdominal exam.
80. (c) This patient is ill appearing and has an examination consistent with peritonitis. He is also febrile and tachycardic. This patient requires immediate resuscitation and evaluation for free air by an emergent upright chest radiograph. While obtaining laboratory testing, ordering a lactic acid, and calling a surgical consult are all appropriate, they are not the most important next step.
81. (d) Drug-induced TMA manifests as a Coombs (−) hemolytic anemia, relative thrombocytopenia, unexplained renal failure, and de novo or worsening hypertension. Systemic manifestations such as low serum haptoglobin level, increased serum lactate dehydrogenase level, and schistocytes may also be present. All of the drugs listed are commonly associated with drug-induced TMA, except ifosfamide.

82. (c) All of the listed interventions are useful in the treatment of MTX toxicity, except dialysis. While dialysis may clear MTX from the blood, there is a rebound effect as MTX if highly protein bound. Dialysis is not effective in removing drugs that are highly protein bound.
83. (a) Patients with SIADH have impaired water excretion due to inappropriate antidiuretic hormone release. Patients with SIADH will excrete all of the sodium content of normal saline, but will retain some of the water, thereby worsening hyponatremia. Patients suspected of possibly having SIADH should not be started on normal saline initially.
84. (a) Allopurinol will prevent the conversion of xanthine to uric acid, but does not help to metabolize already formed uric acid in the bloodstream. However, rasburicase will effectively metabolize uric acid into allantoin. The use of dialysis in the prevention of TLS is controversial. Bicarbonate base fluids may help prevent uric acid deposition in the kidneys, but may also increase the formation of calcium phosphate crystals and worsen kidney function.
85. (d) Sometimes patients will present with urinary retention or new urinary symptoms following prostatectomy catheter removal. Generally, patients should not have a urethral catheter inserted unless the issue is discussed with a urologist due to a concern for traumatizing or further disrupting a recent vesicourethral anastomosis.
86. (c) Clot irrigation can sometimes require 30–60 minutes, and a reasonable attempt should be made to clear the bladder of clot prior to initiating additional treatments. Once the bladder clot has been completely evacuated, consideration is given to initiate CBI. It is important to note that CBI should not be used unless manual evacuation has ensured that large clots have been evacuated from the bladder since these clots are unlikely to clear with CBI alone and may obstruct the catheter during passage.
87. (d) Upper urinary tract drainage is accomplished by ureteral stenting or nephrostomy tube placement. In the infected patient, randomized data have not supported any difference in meaningful outcome such as time to fever resolution. Ultimately, the decision on which to perform is very nuanced and dependent on patient factors. In the patient requiring urgent intervention, the best measure will depend on what is available first. It is known that there is significant regional variation in stent versus nephrostomy tube placement likely for this reason. Contraindications to each decompression method are first assessed. Nephrostomy tubes will generally be contraindicated in those with coagulopathy and may be more difficult in the patient who cannot be placed prone, has morbid obesity, or lacks hydronephrosis. Ureteral stents will not be feasible in the patient who does not have easy endoscopic access to the ureter – in the oncologic setting, this is due to trigonal invasion of a large pelvic mass or due to prior lower urinary tract surgery.
88. (c) Patients presenting after partial nephrectomy with hematuria may sometimes have developed a pseudoaneurysm or arteriovenous fistula. These patients may present with hemorrhagic shock. In the stable patient, initial resuscitation should be commenced and a pseudoaneurysm/AVM can be ruled out with CT angiography. In the unstable patient, urologic consultation should be obtained immediately. Management should be coordinated with urology and will often involve selective angioembolization by interventional radiology.
89. (b) Patients with hypercalcemia often exhibit symptoms such as dehydration, uremia, muscle weakness, diminished reflexes, and cardiac arrhythmias.
90. (a) Febrile neutropenia (FN) is defined as a single temperature of $\geq$ 38.3 °C (101.0 °F) or a sustained temperature of $\geq$38.0 °C (100.4 °F) for at least 1 hour in a patient with an absolute neutrophil count $\leq$ 500 cells/mm^3 or 1000 cells/mm^3 and likely to fall below 500/mm^3.
91. (c) Acute blood loss in a cervical cancer patient may require vaginal packing, volume replacement with crystalloids and/or blood products, and palliative radiation therapy. Invasive procedures such as percutaneous embolization and endoscopic procedures are reserved when noninvasive methods fail.
92. (c) Necrotizing enterocolitis can present with nausea, vomiting, abdominal distension, diarrhea, and hematochezia. On CT classically bowel thickening, mesenteric stranding, mucosal enhancement, and pneumatosis is seen. Supportive measures are the treatment of choice.
93. (d) The most common cause of bone lesions and subsequent pathologic fractures in patients >40 years old is metastatic disease. Imaging should include CT chest, abdomen, and pelvis to identify the site of primary disease. Fractures of the tibial diaphysis should be immobilized in a well-padded long leg splint that goes well above the knee in order to establish rotational control.
94. (a) Total hip replacements most commonly dislocate posteriorly. They result in a shortened, flexed, adducted, and internally rotated limb. Patients often describe standing from a seated position as the mechanism of dislocation. Pending medical stability, closed reduction is safe and effective in the ED. Periprosthetic fractures are not typically associated with standing from a

seated position, but rather, usually occur in the setting of trauma. Buck's traction has not definitively been shown to increase patient comfort.

95. (c) With a history of diabetes, cancer, and recent major surgery, the patient has three common risk factors for necrotizing fasciitis. These patients often present with altered mental status. With the laboratory values listed, she, at a minimum, has a LRINEC (Laboratory Risk Indicator for Necrotizing Fasciitis) score of 9 (≥6 is highly suspicious for the diagnosis). While necrotizing fasciitis often has soft-tissue gas evident on CT scan, this is not always the case. The sooner this patient undergoes surgery, the better her chances of survival.
96. (b) The patient's history and examination are consistent with compartment syndrome. Patients with leukemia are often thrombocytopenic and prone to significant bleeding in the absence of severe trauma. Pain with passive stretch, paresthesias, and firmness on palpation are all consistent with this diagnosis. Absent pulses are a late finding in compartment syndrome. A Stryker needle is not indicated in this case, as the patient is alert and has characteristic examination findings. Further, he has profound thrombocytopenia, and invasive testing could exacerbate the bleeding that likely caused this event.
97. (b) When a maculopapular drug rash presents with fever, lymphadenopathy, or facial edema, drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) should be considered, and a workup for systemic involvement should be performed. The cutaneous eruption is typically maculopapular and rarely presents with purpura, vesicles, or pustules. The liver is the most common site of visceral involvement, but other systemic findings include interstitial nephritis, pneumonitis, myocarditis, arthritis, cytopenias, atypical lymphocytosis, thyroiditis, and cerebritis. The clinical manifestations typically begin 2–6 weeks after initial exposure to the causative medication necessitating a drug history of the past several months when DRESS is suspected.
98. (b) Over 20% of patients treated with anticytotoxic T-lymphocyte–associated protein 4 (CTLA-4) or anti-programmed death 1 (PD-1)/programmed death ligand 1 (PDL-1), and up to 72% with anti-CTLA-4/anti-PD-1 combination therapy develop immune-related cutaneous adverse events (ircAEs), most commonly pruritus and MPR. These ircAEs may be associated with prolonged progression-free survival and overall survival. Unlike MPR to traditional medications, those to immunotherapy may develop at any time during or months after completion of therapy, with a median onset of 62 days (range 1–1676 days) after initiation of therapy. Cutaneous morphology of immune-related MPR may be indistinguishable from that due to traditional medications, or have overlap with lichenoid, psoriasiform, or eczematous rashes.
99. (d) Purpuric eruptions describe nonblanching skin lesions secondary to hemorrhage into the skin. Purpuric lesions may be flat (macular purpura), small and raised (palpable purpura), or larger and netlike (retiform purpura). It is important to recognize the features of macular purpura, palpable purpura, and retiform purpura as the differential diagnosis varies based on these morphologic differences. Macular purpura typically indicates hemorrhage into the skin secondary to low or dysfunctional platelets or vessel wall fragility in the absence of inflammation. Palpable purpura describes small, raised, nonblanching lesions most commonly found on the lower extremities. Palpable purpura is the classic skin manifestation for cutaneous small vessel vasculitis. Retiform purpura describes cutaneous lesions that have a netlike or stellate (starlike) pattern of purpura often with central necrosis or ulceration, reflecting damage to larger vessels with resultant cutaneous ischemia and hemorrhage. Damage to the vessel may occur either through infiltration of the vessel wall or occlusion of the vessel lumen.
100. (a) The SCORTEN severity of illness score for Stevens–Johnson syndrome and toxic epidermal necrolysis includes the following seven criteria: age >40 years, presence of malignancy, heart rate >20, percentage of epidermal detachment >10%, BUN >10 mmol/L, serum glucose >14 mmol/L, serum bicarbonate level <20 mmol/L. A score above 4 predicted >90% mortality.
101. (d) This patient presents with concern for typhlitis. The characteristic sign on ultrasound is a thickened bowl wall, of greater than 3 mm, which can be measured on ultrasound. The remaining imaging findings are all classic signs of other intra-abdominal pathology. The target sign is associated with intussusception, a noncompressible hyperemic blind-ended pouch is appendicitis, a periumbilical cystic structure may be a pancreatic pseudocyst, and the whirlpool sign is associated with ovarian torsion. Of these, typhlitis is the only treatment associated finding that would present with right lower quadrant pain.
102. (b) Patients with Burkitt's lymphoma, particularly those with high tumor burden at, are high risk for tumor lysis syndrome. This is characterized by elevations in potassium, phosphorus, and urea nitrogen. Calcium is typically decreased. There is no definitive effect on sodium.
103. (b) While all of the above are potential treatment complications, most result in mortality during treatment,

whereas pediatric oncologic survivors have a higher than typical rate of suicide.

104. (b) Fatigue, bone pain, fevers, and pallor are all associated with pediatric cancer diagnoses. Weight loss, rather than weight gain, is also a particularly alarming findings in pediatric patients and requires further investigation.

105. (c) Initial management should begin with IV fluid. Although these patients may sometimes appear fluid overloaded with apparent pulmonary edema on chest X-ray, they are usually not hypervolemic, and IV fluids to mitigate the hyperviscous nature of the patient's blood is a key initial treatment. Antibiotics should not be the initial step in management; however, there should be a low threshold to start antibiotics, especially for gram-negative coverage. The patient will most likely be started on hydroxyurea, but initial treatment should be fluids. Patients with moderate-to-severe symptoms benefit from leukapheresis, which this patient may require. At this time, however, initial management is fluid resuscitation.

106. (a) This patient's presentation is concerning for leukostasis, but acute stroke and intracerebral hemorrhage are both high on the differential. A noncontrast CT head can help distinguish between etiologies and is rapidly available. A CT angiogram would not be appropriate as avoiding contrast is preferable in these patients with multiple insults to the kidneys, and whose renal function is likely to worsen with initiation of chemotherapy as tumor lysis syndrome ensues or worsens. In addition, the thrombocytopenia would contraindicate TPA. While brain MRI could also help establish a diagnosis, it takes much longer to obtain and is not as good as CT at identifying blood. This patient may require an MRI in the future if the CT scan is nondiagnostic, but this is not the best initial test. Meningoencephalitis is also on the differential diagnosis for this patient, especially as she may be immunocompromised. An LP could also help establish a diagnosis of subarachnoid hemorrhage. However, CT should precede LP in this patient for both diagnoses, as well as the more likely causes discussed above. Furthermore, this patient is severely thrombocytopenic, and ideally platelet counts should be a minimum of $20x10^3/\mu L$ prior to invasive procedures. If suspicion for meningoencephalitis is high, treatment should be started immediately and not delayed for LP. Seizure and/or postictal state is a less likely cause of altered mental status in this patient given her history, physical examination, and laboratory findings. EEG is of limited utility in the ED and would delay critical workup and management in this patient.

107. (d) This patient is experiencing hyperleukocytosis with myocardial leukostasis, and acute renal failure with severe metabolic acidosis and compensatory tachypnea. In the setting of his renal failure, it is unlikely that his metabolic acidosis will markedly improve and he does not have much more room for additional respiratory compensation. Intubation and ventilation limit his body's metabolic demand and can help decrease the ongoing ischemia while awaiting leukapheresis. Matching the patient's preintubation minute ventilation on the ventilator is important to prevent loss of compensatory respiratory alkalosis causing worsening acidemia and potential hemodynamic decompensation. Although antiplatelets/anticoagulants are the appropriate management for non-ST elevation myocardial infarctions due to acute coronary syndrome, the likely etiology for this patient's ischemia is clogging of his coronary vessel(s) with leukocytes with additional metabolic demands from tachycardia and tachypnea. His thrombocytopenia is a relative contraindication to antiplatelet and anticoagulant therapies, and he is at a high risk for DIC. While consultation to cardiology would be appropriate, initiation of empiric antiplatelet/anticoagulant therapies is inappropriate. Because the patient's main underlying cause of myocardial ischemia is most likely leukostasis, transfusion of packed red blood cells is not recommended as it will worsen the viscosity of the blood and further impair tissue perfusion. While the patient is likely functionally neutropenic and at risk for infection, his current presentation is not consistent with sepsis. Antibiotics may be appropriate if his chest X-ray demonstrates infiltrates or a focal infection is identified, but are unlikely to help his current presentation improve.

108. (b) Although without a clear focal deficit, this patient is altered and has a profound thrombocytopenia, as well as a high risk of DIC, that could lead to spontaneous intracranial hemorrhage that could potentially require neurosurgical intervention. STAT imaging of the brain is required. While this patient's tachypnea could very well be due to respiratory compensation for a metabolic acidosis given his low serum bicarbonate, his blood pressure is robust. While a sodium bicarbonate drip may be in his near future, it would be most appropriate to obtain a pH prior to initiating it in a nonemergent setting. A transfusion of platelets is appropriate in this patient; however, without knowing whether there is a CNS hemorrhage, it is unclear what his platelet goal should be. Transfusion of packed red blood cells, even if bleeding intracranially, is not appropriate as a contained intracranial bleed is not likely to be high volume, the patient is hemodynamically stable, and red blood cell transfusion will worsen blood viscosity and leukostasis. Although the patient's potassium is slightly high and his serum calcium is low, there is no indica-

tion that the patient has any signs of dangerous hyperkalemia, and his hypocalcemia likely exists in relation to his hyperphosphatemia.

109. (b) False: control of cancer-related factor VIII inhibitors does not required tumor control and immunosuppression should be started if tumor resection or other invasive procedures are initiated.
110. (c) L-Asparaginase is associated with low levels of multiple natural anticoagulants especially antithrombin and patients on this drug who have thrombosis should have their antithrombin levels supplemented.
111. (c) JAK2 in patients with myeloproliferative neoplasms is associated with increased risk of thrombosis. In addition, patients with visceral vein thrombosis often have JAK2 mutations – even with normal blood counts.
112. (a) Acquired deficiency of factor V is rare but can be seen in patients with myeloproliferative neoplasms – a clue can be variable elevations of the INR/aPTT.
113. (d) The patient is presenting in aplastic crisis, with a low reticulocyte count and anemia as a result of a reduction in red blood cell production. An infection caused by parvovirus is often a source of aplastic crisis, and antibiotic therapy is not useful. Exchange transfusion is typically reserved for acute chest syndrome and does not increase the hemoglobin concentration. Oxygen is not beneficial unless the patient displays signs of hypoxia. The patient is most helped by a transfusion of red blood cells to improve her condition.
114. (a) Avascular necrosis is a complication of sickle cell disease. Progressive occlusion of microcirculation leads to increased intraosseous pressure and cell death. A fracture is more likely to occur in the setting of some trauma. Osteomyelitis typically presents with fever and may also have skin changes. The patient is otherwise young, and a tumor is not at an increased risk for tumor production.
115. (d) Laboratory workup is typically not required when the provider is familiar with caring for patients with sickle cell disease who are suffering from an uncomplicated pain crisis. However, laboratory testing should be considered when the patient is being admitted, another diagnosis is suspected, if the patient appears unwell, or if the provider suspects worsening anemia.
116. (a) The patient is presenting with acute chest syndrome, and the classic triad of acute chest syndrome includes fever, hypoxia, and pulmonary infiltrate. Acute chest syndrome often presents with chest pain, shortness of breath, and dyspnea on exertion. Occlusion due to sickling in the pulmonary vasculature causes the patient to become hypoxic, which drives more sickling to occur, which in turn causes more occlusion due to sickling.
117. (b) This patient presents with what appears to be acute lymphoblastic leukemia. It is not uncommon for a patient with acute leukemia to be seen in the ED prior to diagnosis. Although his overall white blood cell count may be elevated, his ANC is <500, and has been so for an unclear amount of time. This is severe neutropenia, and he is at risk for infection due to many pathogens. The patient's headache, ocular exam, and CT findings are all concerning for acute invasive fungal sinusitis. This is an infectious disease emergency and he needs rapid initiation of antifungal therapy. While an MRI may be obtained for characterizing and surgical planning, he needs urgent stabilization now. Both micafungin and amphotericin are antifungal therapies. Micafungin has activity against *Candida* spp. and *Aspergillus* spp. However, it notably does not cover other molds, such as the Mucorales. Amphotericin has broader antifungal coverage that includes molds and dimorphic fungi. Posaconazole, which was not an option, is also a reasonable empiric treatment for acute invasive fungal sinusitis. Finally, pathogenic diagnosis typically requires nasal endoscopy and sinus evaluation by a trained otolaryngologist. Nasopharyngeal swabs are unlikely to recover the offending pathogen and are not used for diagnosis.
118. (a) This is a neutropenic patient presenting with significant abdominal pain. The differential is broad but would include neutropenic enterocolitis, also known as typhlitis. Other considerations would be enteroinvasive pathogens such as *E. coli* or *Shigella* or other causes of colitis (viral, ischemic, etc.). Further, she notes recent decrease in diarrhea, which could be the natural course of illness but also raises flags for possible bowel obstruction, particularly in a patient with intra-abdominal malignancy. CT scan would help to narrow this differential and is the preferred modality for diagnosing neutropenic enterocolitis. In patients with neutropenic enterocolitis, antibiotics should be targeted toward gram-negative and anaerobic bacteria, which are commonly found in the gastrointestinal tract. Resistant gram-positive bacteria, including *Enterococcus*, typically are not involved. While some infections or illnesses will require G-CSF, this should not be a priority until the diagnosis and trend of neutropenia is known. Finally, while she is at risk for *C. difficile* colitis, this is a less common cause of hemorrhagic colitis.
119. (c) The patient is at high risk for central line-associated bloodstream infection (CLABSI) in addition to other infection syndromes associated with receiving cytotoxic chemotherapy. Gram-positive bacteria including *S. aureus*, coagulase-negative staphylococci, and

Enterococcus are common pathogens associated with CLABSI. In addition, the patient is receiving total parenteral nutrition which places her at increased risk for CLABSI due to *Candida* species. A comprehensive workup for undifferentiated fever in an oncologic patient in the ED should *begin* with a complete blood cell count, metabolic panel, and at least 2 blood cultures from separate peripheral sites. Recognizing that peripheral access can be difficult to accomplish in some cases, one set can be drawn from the central venous catheter when necessary. Blood cultures obtained from catheters have traditionally been associated with higher contamination rates than those obtained from peripheral venipuncture. Obtaining 2 sets of blood cultures from the central venous catheter increases the risk of blood culture contamination, which can lead to an incorrect diagnosis of CLABSI and unnecessary removal of the central venous catheter, particularly if coagulase-negative staphylococci are isolated. It is appropriate to start empiric broad-spectrum IV antibiotics, but after blood cultures have been obtained to guide diagnosis and treatment. As the patient is hemodynamically stable, additional workup for CLABSI can be completed prior to discussion with the patient's oncologist and deciding whether catheter removal is indicated to achieve source control.

120. (d) A history of high-dose corticosteroid use for GVHD coupled with the indolent onset of respiratory symptoms and lack of appropriate antibiotic prophylaxis raises the concern for *Pneumocystis jirovecii* pneumonia, which is supported by the chest radiograph findings. The patient reports compliance with taking valganciclovir, which provides effective prophylaxis against CMV and HSV infection. While he is not on prophylaxis for *Pseudomonas*, the typical presentation for Pseudomonas pneumonia would involve a more acute presentation and likely more localized infiltrates.
121. (d) There is no validated risk stratification tool for pediatric febrile neutropenia. Therefore, in the majority of cases, patients are admitted for a period of inpatient observation.
122. (c) It is suspected 80% of infections arise from endogenous flora.
123. (a) For safe discharge, a patient should live no more than 1 hour or more than 30 miles away from the clinic or hospital.
124. (c) Oral antibiotics are noninferior to intravenous antibiotics in cases of low-risk febrile neutropenia. This is true for both solid and hematologic malignancies.
125. (b) Evaluation for potential alternative causes should be performed in most cases. CT is recommended in this instance to help diagnose and characterize the extent of disease as well as rule out other causes. Ultrasound cannot offer a definitive diagnosis.
126. (b) Persistent GI bleeding coupled with other clear surgical indications including abdominal free air. Involvement of the cecum is likely given its limited vascular supply; however, its involvement alone is not an indication for surgery. Degree of bowel wall thickening alone is also not an independent indication for surgery.
127. (c) Route of chemotherapy administration plays no role in neutropenic enterocolitis. All other elements are potential risk factors, especially timing from last chemotherapy (between days 12 and 17). Tumor types tend to be solid in adult and hematogenous in pediatrics.
128. (a) Recombinant granulocyte colony-stimulating factor (G-CSF) may be beneficial; however, data regarding its success have been mixed and it has not shown a reduction in mortality from neutropenic enterocolitis.
129. (b) Three domains of psychosocial model are the predisposing factors, precipitating factors, and perpetuating factors. Predisposing factor is the genetic makeup which makes the basis of vulnerability. Precipitating factor is the ongoing challenges, like substance misuse. Perpetuating factor is an acute event, such as loss of a loved one, that pulls the trigger.
130. (d) In addition to general risk factors of suicide, such as depression, they have the burden of adverse effects of cancer treatment. This may include physical symptoms such as intolerable pain and extreme fatigue. Cancer patients may face other challenges such as altered body image, role reversal, and loss of job which adds to their burden.
131. (a) Poor sleep, fatigue, and weight loss may be present in depression as well as in cancer patients undergoing treatment. Hopelessness and loss of interest in previously enjoyable activities are the key features of depression.
132. (c) First step in managing suicidal patients is his/her safety. Making sure he has no access to any weapon. Everything listed in the question is also essential. Patient should have a follow-up plan, needs an antidepressant and also a hot line number, but removing access to weapon remains the first step.
133. (c) Hypoactive delirium is more frequent than the hyperactive (agitated) type in cancer patients, and it is frequently missed. Most cases of delirium in cancer patients are of the mixed type, which has features of both, hyperactive and hypoactive. All other choices are correct.
134. (d) Although all are causes of delirium in cancer patients, medication's side effects are the most com-

mon. Opioids are the most common, followed by benzodiazepine and anticholinergic medications.

135. (d) Safety of the patient is the most important step in management of delirium as in the case discussed in the beginning of this chapter. Patients with delirium are at risk of hurting themselves or medical staff particularly nurses. Delirious patients may experience frequent falls and may pull IV lines.

136. (b) Refractory delirium is the most common reason for palliative sedation. The purpose of sedation is to control refractory symptoms and not to hasten death. The need to continue sedation should be evaluated frequently, and if symptom has improved, sedation should be weaned off or stopped. Palliative sedation should be differentiated from euthanasia.

137. (d) There are two types of transalar herniation: ascending and descending. Ascending transalar herniation occurs as a result of middle cranial fossa mass effect, leading to superior and anterior temporal lobe displacement across the sphenoid ridge. Descending transalar herniation results from frontal lobe mass effect, leading to posterior and inferior displacement across the sphenoid wing. Transalar herniation can lead to infarction in both ACA and MCA territories secondary to mass effect on the carotid terminus. Subfalcine herniation can cause ipsilateral ACA infarction, and uncal herniation can cause ipsilateral PCA infarction.

138. (e) Massive hemoptysis is defined as expectoration of ≥300–600 mL of blood within a 24-hour period. Pulmonary TB is the most common cause of massive hemoptysis worldwide. Bronchogenic carcinoma is the most common malignant cause of massive hemoptysis. Trauma, postoperative complications, and pulmonary fibrosis are not common causes of massive hemoptysis.

139. (d) Hounsfield unit is a relative quantitative measurement used to interpret radiodensity in CT relative to water, which has a HU of 0. Blood is slightly denser than water with a HU range of 30–60 (depending on its state, e.g., clotted, liquid, acute, subacute). Less dense materials such as air and fat have a HU of −1000 and −100, respectively. Bone is significantly denser, with cortical bone having an approximate HU of 1000.

140. (b) Radiographs are relatively insensitive to detecting lytic lesions compared to cross-sectional imaging such as CT or MRI. Radiographs can identify lytic lesions after loss of 30% or more of bone mineral density. Therefore, normal radiograph findings in setting of high clinical concern for a lytic lesion often warrant further evaluation with cross-sectional imaging.

141. (b) The patient described here presents with an examination and vital signs that are consistent with septic shock. Visualized in the ultrasound image is a kidney which demonstrates hydronephrosis, given to be unilateral. In nononcologic patients, unilateral hydronephrosis is often associated with obstructive ureterolithiasis; however, in oncologic patients, it may also be associated with tumor compression of the ureter. The resulting backflow of urine to the kidney results in dilation of the renal calyx, which can be visualized directly with ultrasonography. Source control in this instance requires placement of either a ureteral stent or a nephrostomy tube to drain the obstructed kidney. Choosing dobutamine is incorrect, but would be considered if a bedside echocardiogram showed significantly decreased LV ejection fraction. A surgical consultation may be indicated in cases where the patient has free fluid within the abdomen suspected to be hemorrhagic in source, or if there were signs of malignant bowel obstruction. There is no indication of massive thromboembolism, which might be considered if bedside sonography shows septal flattening, McConnell's sign, or if the patient is known to have PE with decompensation. A CT should not be considered as the patient has unstable vital signs and would not benefit from awaiting an unnecessary imaging studies.

142. (e) The patient in this scenario presents with nonspecific symptoms common to the oncologic population. Historical features of his pain suggest pericarditis, but this description is not always consistent, and the classic findings of JVD, muffled heart sounds, and pulsus paradoxus are frequently missed on physical examination. His echocardiogram, however, clearly shows a pericardial effusion with right atrial inversion, a finding concerning for pericardial effusion with tamponade. Despite the patient's stable vital signs, he is at high risk for decompensation, and pericardiocentesis should be performed, ideally in a controlled environment with experienced operators, but in the ED if any instability develops. The other options describe the management of massive pulmonary embolus, another etiology of obstructive shock but with different management; ST-segment elevation MI, which is unlikely given the described ECG and patient presentation; pneumothorax and massive pleural effusion for which there is no evidence.

143. (b) The patient presents with unilateral leg swelling. There are multiple causes of edema but, given the asymmetric pattern seen here, a localized pathology rather than systemic pathology is more likely. Deep venous thrombosis (DVT) should be one of the first diagnosis to consider in an emergency setting especially in a patient with risk factors. The patient in this scenario has breast cancer and is undergoing chemotherapy which puts her at higher risk for venous throm-

boembolism. Additionally, she is presenting with leg swelling, tenderness, and overlying skin changes which makes DVT more likely. Using a risk stratification score such as the Well's score, the patient will be scored 4 out of 9, placing her as a high risk for DVT. One of the important sonographic characteristics for DVT is finding a noncompressible vein containing an intraluminal echogenicity which represents a thrombus. Of the choices given, B and C are the only describing venous findings. Of these two choices, B is consistent with DVT as the vein is found to be noncompressible indicating the presence of a thrombus.

144. (a) This patient has clinical signs of heart failure (hypoxia, JVD, symmetric bilateral lower extremity edema along with dyspnea) and is on a chemotherapeutic agent (doxorubicin) that is known to cause cardiotoxicity. The ultrasound findings of diffuse B lines, bilateral pleural effusions, and a decreased left ventricular ejection fraction coupled with her clinical signs and symptoms would confirm the diagnosis of heart failure.
145. (b) Duloxetine. Studies evaluating gabapentin and acupuncture have been conflicting or not shown improvement for chemotherapy-induced peripheral neuropathy (CIPN). Gel formulations have shown promise but the agent with the best evidence for use in CIPN is duloxetine. In 2013, a trial looking at CIPN caused by paclitaxel or oxaliplatin showed improvements in outcomes compared to placebo.
146. (a) Hyaluronidase is indicated for extravasation of vinca alkaloids. In addition, the arm should be elevated and a warm compress rather than a cold compress should be applied. Plastic surgery consultation is only indicated for a large volume vesicant extravasation; severe pain, if healing has not occurred 1–3 weeks after extravasation; or if there is early necrosis present.
147. (c) Epinephrine is recommended for the treatment of anaphylaxis in all current guidelines and injection into the thigh results in more rapid and higher plasma levels than other IM locations. Steroids and antihistamines are considered adjunctive therapy for anaphylaxis.
148. (b) SIADH with severe hyponatremia can occur after only one dose of cyclophosphamide. In addition, the patient is also on sertraline, which can also contribute to SIADH. She likely does not have brain metastasis and the recent MRI was negative. There are no signs of trauma or infection.
149. (d) The mechanism associated with the impact of radiation therapy on the heart and blood vessels is driven by inflammation related to the trauma of injury coupled with late fibrosis and functional instability. Intimal damage to cardiac vessels followed by cell proliferation in a disorganized manner can lead to premature coronary artery disease and atherosclerosis. Damage to cardiac valves can lead to late fibrosis and calcification, which are able to cause both stenosis and insufficiency. Myocardial and pericardial inflammation can lead to muscle dysfunction, cardiomyopathy, and congestive heart failure. Pericarditis can be seen in situations where a large volume of heart receives radiation therapy and acute inflammation can lead to constriction of function. Electrical conduction deficits are seen and thought to be related to fibrosis in conduction pathways. Multiple chemotherapy agents influence cardiac health, and their relationship to injury imposed by radiation therapy remains under evaluation.
150. (d) Acute radiation effects to tissues are influenced by total radiation dose, daily treatment dose (fractionation), and volume of tissue treated. This information is often not immediately available to emergency departments when patients present for evaluation as specific treatment documentation is often in the department shadow record and not directly integrated into electronic healthcare records. The volume of the treatment target influences the number of stem cells directly affected from daily treatment. Daily treatment dose also influences injury to stem cells. Hence, total and daily doses as well as target volume are all directly related to the development of sequelae from the treatment.
151. (a) True. There are reports of radiation injury to the lung tissue outside of the radiation treatment field. Although felt to be spurious at initial review, investigators have suggested that production of nitric oxide gas as a by-product of radiation-induced injury may play a role in generating injury in other parts of pulmonary parenchyma not directly in the radiation therapy treatment region.
152. (b) False. The mechanism of injury is multifactorial as radiation therapy likely has impact in all compartments of the kidney including the glomeruli, mesangium, and endothelium.
153. (a) True. At very high single-fraction total body doses (>10 Gy), death will occur through cerebrovascular syndrome in spite of support within 24–48 hours. The syndrome is due to uncontrollable swelling within the central nervous system associated with compromise of all neuromuscular processes. At total body doses of 5–12 Gy, death without support will occur in 1–2 weeks due to denudation and destruction of the gastrointestinal system associated with profound fluid loss and diarrhea. These cells have a self-renewal capacity measured within a few days; thus, a single total body dose of 10 Gy will eliminate a large portion of the stem cells within the gastrointestinal crypts. Although this dose does not affect differentiated adult cells, the exposure

eliminates the self-renewal potential of the stem cell; therefore, the mucosal surface of the gastrointestinal tract becomes denuded with no barrier for fluid and blood loss within a short period of time, measured in days. At total body exposure doses of 2–5 Gy, death will occur from damage to the hematopoietic system with primary damage to progenitor cells inhibiting self-renewal. Lymphocytes may die an intermitotic death, and this finding may be a surrogate biomarker for acute exposure within the first few hours to days of an incident. However, by day 30, most circulating blood elements are depleted with death often attributed to infection. The term, LD (lethal dose) 50/30, is borrowed from our pharmacology colleagues and reflects the LD of an agent that will cause 50% mortality in 30 days. Although radiation is not a drug, the LD 50/30 is now generally thought to be 5 Gy with modern hospital support.

154. (a) True. At total body exposure doses of 2–5 Gy, death will occur from damage to the hematopoietic system with primary damage to progenitor cells inhibiting self-renewal. Lymphocytes may die an intermitotic death, and this finding may be a surrogate biomarker for acute exposure within the first few hours to days of an incident.
155. (b) False. The use of bone marrow transplant in this setting remains controversial with strong advocates on both sides of the question.
156. (e) The pediatric population is at high risk of developing therapy-related mucositis. Ninety-nine percent of pediatric patients undergoing hematopoietic stem cell transplant will experience oral and/or gastrointestinal mucositis.
157. (c) The largest contributor to increased medical costs for patients with mucositis is extended inpatient hospitalizations, which can occur as a result of the potential sequelae of mucositis, such as infection or nutritional deficiency. A report based on data from 2012 estimated a combined cost of $15,500 for every inpatient hospitalization due to severe mucositis.
158. (a) Benzydamine is currently the only agent for which there is level 1 evidence supporting its use in the management of mucositis. Benzydamine mouthwash can be used both for the prophylaxis and treatment of oral mucositis in patients receiving chemotherapy alone, radiation treatment alone, or concurrent chemoradiation to the head/neck.
159. (c) Significant risks associated with mucositis include severe infections, dehydration, and weight loss, requiring hospitalization. Such infections and severe malnutrition result in unexpected treatment breaks or premature discontinuation of antineoplastic therapies and are associated with increased rates of recurrence and worse survival. Patients should be monitored closely with additional nutritional support including a feeding tube if needed and routine IV hydration.
160. (e) Leukoreduced and irradiated blood products should be given to all HCT recipients due to the risk of transfusion-associated GVHD, which is associated with high mortality.
161. (c) Splenic rupture is a rare but catastrophic complication of high-dose G-CSF.
162. (c) The patient's symptoms may be explained by mild acute GVHD (grade II) involving GI tract. Endoscopic studies should be performed to provide histologically corroboration the clinical suspicion and to rule out viral infection (particularly CMV).
163. (a) The most likely diagnosis is ICANS based on the clinical scenario. The ICE score is a 10-point score that can help the clinician to grade ICANS and further management based on grading.
164. (b) The differential diagnoses include acute coronary syndrome, pulmonary embolism, and immune-mediated myocarditis.
165. (d) Enasidenib is an inhibitor of isocitrate dehydrogenase 2 (IDH2) and can cause a differentiation syndrome that resembles sepsis. It is important to discuss with the oncologist and consider treatment with potent glucocorticoids.
166. (d) Blinatumomab is a bi-specific antibody that can cause an infusion reaction syndrome. Blinatumomab links T cells and malignant B cells and activates the T cells to exert cytotoxic effect on the malignant cells. Blinatumomab also causes a cytokine release syndrome. These leukemic patients are often neutropenic, and neutropenic fever is also likely.
167. (c) More than 1 ED visit in the last 30 days of life. Researchers used administrative healthcare data to describe this key indicator.
168. (d) 30%. It is impossible to have a system where the ED visit rate is zero, given it is entirely appropriate for individuals to visit the ED at the EOL for issues that arise; however, when administrative health data are used to examine systems and health policies, a rate of 30% is accepted as the benchmark for EOL ED visits.
169. (a) Fever. In a study that examined 18 EDs in the United States, pain, shortness of breath, nausea, and abdominal pain were found to be the most common ED diagnoses.
170. (c) Shorter survival. It is a common misconception that palliative care services lead to a faster death; however, studies show that access to early palliative improved quality of life and relieves suffering, without necessarily hastening death and even longer survival.
171. (a) Opioid analgesics have many potential side effects that may make patients or prescribers reluctant to use

the medications or use them in adequate doses to achieve pain control. Patients can develop a tolerance to certain side effects (e.g., nausea or respiratory depression); however, other side effects (e.g., constipation, pruritus) are not decreased with chronic use.

172. (b) Anticonvulsants such as gabapentin and pregabalin require close follow-up for titration. Peritoneal carcinomatosis generally causes visceral pain. Topical lidocaine patches should be worn for 12 hours and then removed for 12 hours. Corticosteroids are often used as adjuvants to treat a variety of pain types and have analgesic effects on pain from bony metastases and neuropathic pain.
173. (c) Opioids, with the exception of methadone, follow first-order kinetics and achieve their peak plasma concentration (and maximal analgesic effect) along a similar timeline: 60–90 minutes for oral/rectal administration, 30 minutes for subcutaneous/intramuscular administration, and 6–10 minutes for intravenous administration.
174. (c) For those patients in more severe pain, or requiring intravenous dosing for other reasons (difficulty swallowing), there are many available intravenous opioids. For the opioid-naïve patient, morphine is a safe, standard drug to start therapy. However, morphine should be used with caution in patients with renal impairment because one of the active metabolites (morphine-6-glucoronide) can accumulate with renal dysfunction. For intravenous dosing of the opioid-naïve patient, a starting dose of 2–5 mg of morphine (or equivalent) is recommended. This dose should be followed by a reassessment at 15 minutes, and if the pain score remains unchanged or increased, the initial dose given should be increased by 50–100%. If the pain score is decreased but still moderate (e.g., 4–7), the same initial dose should be repeated, and if the pain level is low (e.g., 0–3), then the initial dose can be used as needed.
175. (b) Pharmacologic agents to ease constipation are typically divided into five categories: bulk-forming agents, softeners, stimulants, osmotic agents, and peripheral mu-opioid receptor antagonists. Bulk-forming agents increase fecal mass to stimulate peristalsis. Stimulants act by increasing intestinal motility, whereas osmotic agents (e.g., polyethylene glycol, lactulose) act by increasing water content in the large bowel. The NCCN recommends prophylaxis with both a stimulant (or prokinetic) agent and the osmotic agent polyethylene glycol. Bulk-forming agents and stool softeners are unlikely to be effective in isolation. A 2010 Cochrane review recommended the use of polyethylene glycol over lactulose for chronic constipation because of better outcomes related to stool frequency, form, associated abdominal pain, and use of additional products. If constipation persists despite the above medications, the provider can titrate the existing regimen or add an additional agent, such as magnesium hydroxide. Two peripherally acting mu-opioid receptor antagonists may be considered if laxative therapy has failed. Both methylnaltrexone, administered subcutaneously or orally, and naloxegol, an orally active agent, have demonstrated efficacy in reversing opioid-induced constipation.
176. (a) Younger age is a risk factor for substance abuse disorders.
177. (c) If a person engages in aberrant behaviors with their opioids in response to poorly controlled pain long enough, they can become actually addicted. In secondary alcoholism, it is recognized that if a person uses alcohol to self-medicate panic disorder long enough, they can develop alcoholism in addition to their panic disorder.
178. (d) Only 30% had chart documentation suggesting a major need to improve recognition, diagnosis, and documentation of alcohol problems in people with advanced medical illness.
179. (b) Actually, longer drinking histories are predictive of a good response. When one sees these characteristics among others that predict a good response, it is clear why some patients undergoing cancer treatment who want to be able to adhere to their oncologic treatment may be good candidates for Antabuse.
180. (c) Morphine is the first-line agent for dyspnea in dying patients, particularly those whose goals are strictly focused on comfort. Intubating the patient is not in line with his expressed wishes and goals of care. BIPAP can be a useful tool at the EOL and can be considered, but morphine is still first line.
181. (b) Noninvasive ventilation can be a helpful tool for patients with dyspnea near the end of life, particularly if the underlying etiology of the patient's dyspnea is reversible. For some, it can help them through the acute crisis and improve dyspnea. In others, it is burdensome and may simply prolong dying.
182. (d) The etiology of dyspnea at the end of life is complex and often multifactorial. Some causes are treatable and reversible, while others are not.
183. (c) Palliative extubations are medically and ethically appropriate when the patient's condition and goals are not aligned with the use of mechanical ventilation. The process of extubation is relatively straightforward and within the purview of the emergency provider.
184. (b) Heyland et al. found that only 2.7% of hospitalized end-stage cancer or other advanced diseases understood that actual CPR success rates were <10%. (Heyland DK, Frank C, Groll D, Pichora D, Dodek P, Rocker G,

et al. Understanding cardiopulmonary resuscitation decision making. *Chest*. 2006;130(2):419–28.)

185. (e) The reality of what may occur during resuscitation differs than what is usually depicted in movies or on television in which many instances of resuscitations are shown to be successful.
186. (d) According to Giza et al., cardiac arrest is the most frequent precipitating cause in hospitalized patients requiring CPR. (Giza DE, Graham J, Donisan T, Balanescu DV, Crommet J, Botz G, et al. Impact of cardiopulmonary resuscitation on survival in cancer patients. Do not resuscitate before or after CPR? *J Am Coll Cardiol CardioOncol*. 2020;2(2):359–62.)
187. (a) Several studies show that in patients with solid tumors, unexpected cardiac arrest may be related to reversible problems, and those patients may be more responsive to CPR. (Giza DE, Graham J, Donisan T, Balanescu DV, Crommet J, Botz G, et al. Impact of cardiopulmonary resuscitation on survival in cancer Patients. Do not resuscitate before or after CPR? *J Am Coll Cardiol CardioOncol*. 2020;2(2):359–62.)
188. (f) All elements above are essential to goals-of-care conversations. (Ouchi K, Lawton AJ, Bowman J, et al. Managing code status conversations for seriously ill older adults in respiratory failure. *Ann Emerg Med*. 2020:S0196-0644(20)30410-8. doi: https://doi.org/10.1016/j.annemergmed.2020.05.039. Epub ahead of print.)
189. (e) Palliative care applies to *all* phases of a life-limiting condition and is not just for dying patients. In fact, maximal benefit is likely when there is early integration of palliative care into management plans as opposed to only considering such care as a last resort measure when "no more can be done" for the patient. The early integration of palliative care is associated with a higher quality of life, including better understanding and communication, access to home care, emotional and spiritual support, well-being and dignity, care at time of death, and lighter symptom burden. In fact, some evidence suggests that, on average, palliative care and hospice patients may live longer than similarly ill patients who do not receive such care. Palliative care also has the ability to simultaneously improve quality and control the cost of care for the most seriously ill patients.
190. (c) Spiritual care personnel are often fully initiated into palliative care services and serve as valuable champions to link existing resources to ED initiatives. It is important to begin an ED-PC initiative with identified ED "champions" who can effectively build upon lessons learned from other prior successes and failures so that the initiative is tailored to fit the unique ED setting. Integration initiatives in the ED may have a higher chance of success when ED champions are fully engaged with palliative care experts to collaboratively define not only resources and processes but also appropriate metrics to track outcomes and measure impact of the integrated initiative.
191. (c) Oxygen and antibiotics are appropriate interventions while initiating efforts to define prognosis and goals of treatment.
192. (a) Bowel obstruction in patients with advanced cancer is rarely a surgical emergency and typically allows time to consider multidisciplinary aspects of the patient's condition. Palliative care specialists can provide valuable input into the appropriate goals of care. Previous treatment, cancer stage, and prognosis are unique variables to consider in cancer patients with gastrointestinal obstruction. Although accurate prognostication is difficult, it is helpful to attempt to determine if a patient can recover from abdominal surgery and obtain a meaningful quality of life prior to death from their malignancy.
193. (e) Patients may be referred for hospice services if their illness physiologically meets criteria of a prognosis of 6 months or less, should the illness run its usual course, and after counseling regarding the implications of this prognosis and available options, have accepted this prognosis and elect a treatment regimen and plan of care which focuses only on comfort-based treatments and services.
194. (d) The patient clearly has difficult to control symptoms requiring frequent nursing assessments indicating the need for inpatient unit level of care.
195. (b) However, a caveat should be made that there are some "bridge" programs that allow the patient to pursue treatment while receiving some hospice benefits. In addition, some commercial insurance plans may evaluate specific treatment requests in conjunction with hospice care. This is really where nuances can be quite intricate and worthwhile to explore directly with the medical director of the hospice of the patient's choice with palliative care team assistance.
196. (d) The patient has severe, ongoing symptoms that warrant further management with possible parenteral medications and ongoing frequent nursing assessments to stabilize her comfort and treatment regimen that would not be possible in a routine level of care. Continuous care is meant for the short-term stabilization of a new symptom which is likely to be controlled quickly, typically in 1–2 days; however, it is unlikely that she will have her symptoms stabilized in the setting of an acute obstruction with need for ongoing medication titration and assessment of NGT management. Calling the patient's hospice and reviewing her presentation and current goals would likely facilitate this transfer.

197. (d) All these examples are great for guidance on ethical dilemmas; none of them can "always" have guidance for every situation that can occur.
198. (a) Values are an acquired set of norms that individuals, groups, and organizations use as standards to measure others. While some values are pervasive, there is no uniform set of values across all individuals and groups.
199. (c) In an emergency, not all relevant information is available at the time important decisions must be made.
200. (d) Ethical problems can often take some time to work out, but a rapid approach rarely has enough time for a formal ethics consult. Buying some time so a reasonable solution can be derived is often the best that can be done.
201. (b) Sexual minorities consistently have less access to healthcare, are less likely to be insured, and are more likely to live in poverty.
202. (d) The minority stress model explains that minority groups experience chronic high levels of stress from stigmatization that can contribute to poor outcomes and disparities.
203. (d) For the three leading causes of cancer death in the United States, colon, breast, and lung cancer, survival rates for Blacks lag those for Whites.
204. (c) Provider and systemic bias can either be explicit or implicit. Explicit bias is often easier to recognize as the outward expression of prejudice. Implicit bias, the unconscious attribution of qualities or values to a member of a certain group, can be much more difficult to recognize.
205. (d) Many physicians have different exposures and backgrounds than the patients they serve. Unconscious attitudes and stereotypes affect behaviors and decisions in healthcare. In order to have greater awareness of bias in patient care, it is critical for physicians to receive education, feedback, and coaching on equitable practice. Patients with schizophrenia are 1.5–2 times more likely to die of their cancer than patients without mental illness. Patients with schizophrenia are also more likely to present at advanced stages of disease, are offered surgery at a lower rate, and receive fewer chemotherapy sessions. Patients with schizophrenia and other disabilities are often unable to advocate for themselves and are also at increased risk of experiencing physician bias.
206. (c) The second step of the WHO analgesic ladder includes opioid for mild-to-moderate pain as well as nonopioids and adjuvant drugs.
207. (e) A simple way to classify different types of pain is whether they are related to tissue damage (somatic nociceptive, visceral nociceptive) or nervous system disorders (neuropathic). The sympathetic nervous system may play a role in exacerbating pain through activation of the sympathetic nervous system.
208. (c) Methadone can be difficult to administer in the acute setting, given that its peak effect on respiration can occur later than its peak analgesic effect.
209. (c) Tramadol is a mixed-mechanism drug that acts as a weak mu-opioid receptor agonist, but also demonstrates some norepinephrine and serotonin reuptake inhibition.
210. (e) As of early 2020, neither the American College of Emergency Physicians nor the American Academy of Emergency Physicians have formed such groups.
211. (f) All are challenges to developing such quality metrics. Many of these factors stem from substantial shortcomings in the funding, oversight, and coordination of measure development and public reporting for cancer care.
212. (c) The first patient navigator program was created by Harold Freeman in 1990 at Harlem Hospital in New York. He focused on underserved women with breast cancer. The goals of the program were to expand access to cancer screening, improve clinical follow-up among medically underserved women through community outreach, and reduce the time between an abnormal test result and diagnosis and/or treatment. Eliminating barriers to health access, such as lack of insurance or cultural and communication barriers, were also critically important. The navigation program was remarkably successful.
213. (d) The American Nurses Association recognized emergency nursing as a specialty practice in 2011. As a challenging and unique profession, this clinical practice area prepares nurses to provide prompt interventions to stabilize or prevent further patient deterioration. The fast-paced, high-acuity setting commands refined critical thinking, clinical assessment, communication, and prioritization skills.
214. (f) Oncologic social workers routinely address all of these stressors for cancer patients.
215. (d) Gamma rays are emitted from unstable nuclei as part of radioactive decay.
216. (b) Geographically, the South has 40% of screening-eligible patients, but has the lowest density of ACR-designated screening centers, and a 3.5% screening rate. In contrast, the Northeast has the lowest eligible percentage (15.5%) but the highest density and screening rate (10.1%). While gays, lesbians, and bisexuals have higher rates of smoking (thus higher proportions that are screening-eligible), they receive LCS at rates similar to their heterosexual counterparts. The landmark National Lung Screening Trial (NLST) demonstrated mortality reduction with lung cancer screening for the first time. The NCI-sponsored 1986 Mayo Lung Project found no benefit in overall mortality for lung cancer screening. Other contemporaneous NCI trials at

Memorial Sloan Kettering and Johns Hopkins also failed to find mortality benefits.

217. (b) The most common primary cancer affecting the orbit in adults is lymphoma. Orbital lymphoma can be the extranodal manifestation of systemic lymphoma or may be the only site of lymphomatous involvement. Other benign or malignant tumors that can cause proptosis include optic nerve glioma, meningioma, orbital hemangioma, sarcoma, and metastatic lesions. The most important cause of sudden and progressive proptosis in children is orbital rhabdomyosarcoma.

218. (b) False. Superior vena cava syndrome (SVCS) refers to the constellation of signs and symptoms that accompany the occlusion of the superior vena cava, either due to internal or external causes. Although it is commonly described as an oncologic emergency, it is not only nonemergent in the majority of cases but also increasingly found in patients who do not have cancer.

219. (a) Radioactivity is the term used to describe how much energy is being released by radioactive material in a given time. Radioactivity is measured in curies (Ci) in the English measurement system or the becquerel (Bq) in the SI system (SI = International System of Units or Système International). A Bq is equivalent to one disintegration of an atomic nucleus per second. A Ci is equivalent to 3.7 × 1010 disintegrations per second (dps) and is based on the decay rate of radium-226. The unit rad is often used in the English system to describe the amount of ionizing radiation that is absorbed in a cell, tissue, organ, or the body. It is equivalent to 100 ergs of energy deposited in 1 g of tissue. The gray (Gy) is equivalent to 1 J of energy deposited in 1 kg of tissue. One Gy is equivalent to 100 rad. The rem (roentgen equivalent man) is a unit of equivalent dose which is used to measure the long-term biological risk related to ionizing radiation exposure (in the United States). The sievert (Sv) is the international unit (SI) for equivalent dose. One Sv is equivalent to 100, rather than 1000, rem.

220. (b) The fluoropyrimidine derivatives, 5-Fluorouracil (5-FU), and its oral prodrug capecitabine are mainstays of oncologic therapy. The therapeutic and toxicologic effects of 5-FU and capecitabine are attributed to their deleterious incorporation into RNA and DNA and to their inhibition of thymidylate synthetase. Hand-and-foot syndrome is a characteristic adverse effect of 5-FU and capecitabine. Toxicity may result from intentional overdose, iatrogenic overdose, or therapeutic administration. A significant proportion of severe toxicity occurs in the setting of therapeutic administration rather than acute overdose and is generally attributed to genetic polymorphisms. Treatment of toxicity is largely supportive. The antidote for fluoropyrimidine toxicity is uridine triacetate, but its indications are limited, and ideally, the treating oncologist or a toxicologist should be consulted prior to its administration.
