This book is dedicated to my wife, Courtenay Carmody, and my two sons, Samuel and Benjamin, whose love and support bring great joy to my life and purpose to my work.
In memory of my mother, Mary Kate Todd, who left us much too early.

–Knox H. Todd

To my supportive wife, Muriel Elleen; our wonderful two children, Julian Franklin and Aurielle Marie; our parents; and siblings for their love and support of my career path.
In memory of my mother, Ruth Marie Wilson Thomas, who fought gallantly in the war against cancer and whose prayers have blessed me over the past five decades.

–Charles R. Thomas Jr.

This book is dedicated to my wife, Bridget Shields, and my two daughters, Lakshmi and Jyothi.
In memory of my father, Alagappa Alagappan PhD, an international civil servant who traveled to 95 countries. He always felt that learning was a treasure that would follow its owner everywhere.

–Kumar Alagappan

Foreword

This second edition of *Oncologic Emergency Medicine: Principles and Practice* has broadened the scope of emergency care for the oncological patient and rightfully so. More patients are living with cancer than ever before. Many cancer diagnoses are associated with greatly extended lifespans. With greater lifespan, cancer survivors are also at risk of acquiring complications from their past medical, radiation, or surgical care, in addition to an underlying cancer.

Today's patient living with a current or prior cancer diagnosis lives within a network of health care providers. The emergency physician and the oncologist must understand not only the underlying pathophysiology of the disease and its treatment, but also appreciate how patients present in distress and how care is optimized to meet the needs of the patient. Indeed, while using best practice options, the team of health care providers personalizes each patient's treatment, stabilization, and recovery to optimize outcomes, seeking to match the expectations of the patient and family.

In this edition, cancer prevention approaches are discussed. Emergency physicians must be comfortable with cancer prevention approaches to minimize future risk for those living with cancer. As in the first edition, the text provides cutting-edge information related to specific oncologic conditions which may present in the emergency department. At times these conditions may be the initial presentation of the cancer. Other times these conditions may represent complications of therapy, disease progression, and/or secondary infection. Many of these conditions require a time-dependent response to minimize additional morbidity or mortality. This text provides unique information (including discussion of new immunologic therapies) that may be covered only superficially by other books or articles in the field.

The palliative aspects of cancer care are also covered. The learning points covered in these chapters are especially cogent in today's changed world of opioid dependence and COVID-19. Guidance is provided regarding the management of pain, communication about the diagnosis/progression of cancer, and discussions regarding hospice and other related factors. These represent key components of doctoring which require great skill and understanding of the patient, as well as the disease.

This edition also seeks to extend our understanding of health disparities and vulnerable populations, international approaches to oncological emergencies, and other topics on the cutting-edge cancer research, treatment, and management. The editors are to be congratulated for extending their earlier work and both recognizing and anticipating the needs of care providers in oncologic emergency medicine. They have provided a powerful tool to enhance the care provided to cancer patients.

Preface

It is with renewed excitement that we present the second edition of *Oncologic Emergency Medicine: Principles and Practice*, the major comprehensive textbook in this emerging field. Against the backdrop of rising numbers of cancer patients and survivors as the US population ages, and of a forecast shortage of cancer care providers, this book is designed to serve as the most authoritative, single-source clinical reference on oncologic emergencies. This comprehensive text was specifically designed to address the complexities of understanding and managing cancer emergencies, with an emphasis on increasing communication and collaboration between emergency physicians and the multiple providers who participate in caring for those with cancer.

The expanded cadre of contributors to the second edition includes a broad spectrum of experts in emergency medicine and nursing, surgical and medical oncology, hematology, diagnostic and interventional radiology, palliative care, psychiatry, critical care, dermatology, ophthalmology, clinical pharmacy, addiction psychology, social work, and health services research.

Emergency departments account for approximately one-half of all hospital admissions, and this proportion is even greater for those with cancer. While the largest portion of the book focuses on a number of clinical oncologic emergencies and their varied presentations to the emergency department, this text offers the opportunity to address more broadly and systematically the vantage point of emergency physicians who work in a critical hub of patient care: the emergency department. Emergency department visits resulting from disease progression as well as toxicities of anticancer treatments serve as an important patient-oriented metric of cancer care quality. This text emphasizes the critical importance of emergency department care within a comprehensive cancer treatment system. The principles of care will be similar whether the emergency department is in a dedicated clinical cancer care facility or a matrix care structure. The methods of executing best practices may differ based on the structure of the cancer care system; however, the vast majority of emergency care for those with cancer is similar across emergency department settings, whether in academic, community, or hybrid practice. The text is structured to cover multiple fundamental areas of emergency care:

Part I is centered on systems issues in oncologic emergency medicine. We discuss the epidemiology of oncologic emergencies, existing models of emergency department care, informatics, the evolving role of quality measures, patient navigation, and the importance of emergency nursing and social work.

Part II considers the role of emergency medicine in primary and secondary cancer prevention, including smoking cessation, alcohol exposure, ionizing radiation and cervical cancer prevention and detection, as well as screening for lung cancer, colorectal cancer, and melanoma.

Part III will seem perhaps the most familiar to readers and includes a discussion of the evaluation and treatment of a variety of oncologic emergencies, organized by organ systems. This section also covers specific conditions common to many cancer types, including febrile neutropenia, thrombosis, and bleeding.

Part IV examines important issues related to treatment toxicity, including chemotoxicity, radiotoxicity, and post-surgical complications, as well as transplant-related issues and toxicities of novel antineoplastic agents such as checkpoint inhibitors and CAR T-cell therapy.

Part V addresses palliative care issues pertinent to the intersection of emergency medicine and oncology. This section discusses end-of-life care, including the role of palliative surgery, the management of symptoms in those with advanced cancer, approaches to opioid analgesic use (and misuse), and the significance of emergency department use at the end of life.

Part VI deals with contextual issues critical to the subdiscipline of oncologic emergency medicine. It incorporates a chapter on the challenges to emergency medicine and oncology posed by COVID-19 and considerations of ethics, health disparities, and ongoing efforts to advance research and education. Finally, we conclude with a chapter by physicians regarding their personal experiences with cancer.

An added feature to this edition are board review questions accompanied by brief and concise explanations of the answers.

The editors and associate editors are extremely proud of this second edition of *Oncologic Emergency Medicine: Principles and Practice* and we wish to thank all of the contributors who have given their time, insight, and experience to create a truly unique text that will serve as a valuable resource for practitioners, researchers, policy makers, trainees, payors, and administrators, as we care for those with urgent cancer needs. We would like to give a special acknowledgment to Ms. Katherine Kreilkamp of Springer for her efficient and diligent role in textbook development. We are deeply indebted to her and to Springer for their support.

Overview

Improving the quality of cancer care and reducing preventable health system use are goals of increasing importance to health practitioners and policy makers in the United States (US) and internationally [1–3]. In 2020, it is estimated that over 1.8 million new cases of cancer will be detected in the United States, over 600,000 deaths will result from cancer, and the estimated annual cost of cancer care is expected to reach to more than $170 billion [4, 5]. Globally, the incidence of cancer is expected to increase more than 60%, to nearly 30 million, between 2020 and 2040 [6]. Furthermore, as global cancer incidence increases, the burden of cancer care is expected to fall increasingly on low-income countries [7]. This will have significant impacts for the healthcare systems in all countries as they address access to primary and specialty for a growing number of oncologic patients.

In the United States, emergency departments (EDs) serve as a significant source of urgent and safety-net care. In 2014, there were 137.8 million ED visits, reflecting an increase of nearly 15% compared to 2006 [8]. Over the last decade, there has been increased scrutiny of EDs as a source of potentially preventable care because of the high cost of care, potential delays in care, and crowding concerns. As policy makers and practitioners strive to improve quality and reduce fragmentation of cancer care, reducing ED visits is frequently a goal of care coordination program and cost reduction effort. There is a particular interest in reducing visits for concerns labeled as "avoidable" or "preventable"; however, no consensus definitions exist to define or identify such visits [9–12].

Approximately 4% of all adult ED visits in the United States are for cancer-related complaints [13]. Reports from Australia, the United Kingdom (UK), Brazil, and South Korea highlight concerns about the growing number of cancer patients and the increasing burden of care on EDs in the management of unscheduled care [9, 14–16]. A 2017 National Health Service (NHS) report emphasizes similar patterns in the United Kingdom with dramatic increases in ED presentations related to cancer and concomitantly high rates of inpatient admissions—often associated with poor patient experience, poor coordination of care, poor communication, and fragmented patient care pathways [17].

Oncologic patients present for care in the ED at all points across the cancer care continuum from diagnosis through treatment, survivorship, and end-of-life (Fig. 1.1) [1]. ED visits in this population can range from medical emergencies for those undergoing cancer treatment to nonurgent administrative decisions such as sending a patient to the emergency department for hospital admission. Symptoms—related to cancer or its treatment—may play a role at all points across the continuum; similarly, oncologic patients may present to the ED for concerns or events that are completely unrelated to their cancer (e.g., motor vehicle collisions, musculoskeletal injuries, lacerations, etc.). Importantly, oncologic patients may incur multiple visits for the same issue or for different reasons.

ED use for oncologic patients reflects a complex interaction of individual and contextual factors—including provider behavior, health system characteristics, and health policies. This complexity is well characterized by Chen et al., who show interrelated causal loops to describe a broad array of factors that influence ED use in this population—individual factors (e.g., access to care/insurance, ability to use services), provider factors (e.g., knowledge, skills, communication, referrals, and access to specialists), health system factors (e.g., bed capacity), and policy factors (e.g., availability of social care) (Fig. 1.2) [18]. While these causal loops are identified based on research derived from the United Kingdom, in the context of a national healthcare system,

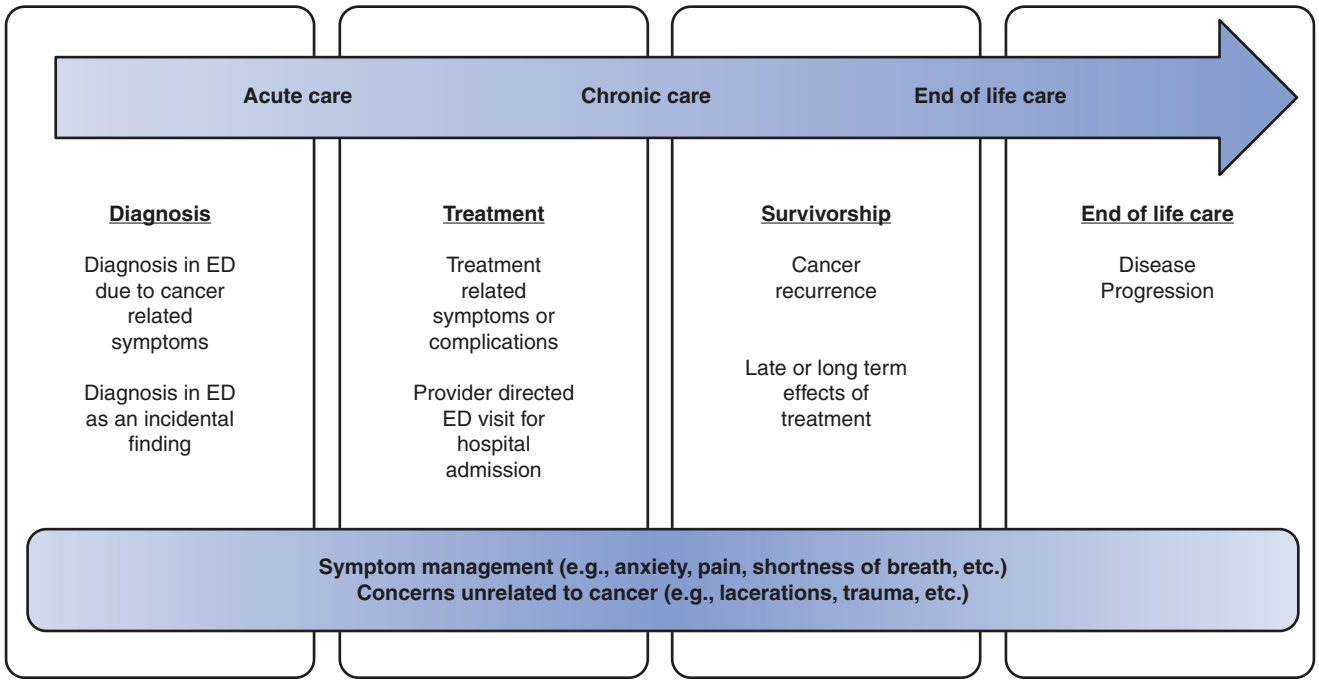

Fig. 1.1 Emergency department visits across the cancer care trajectory, modeled on the Institute of Medicine's continuum of cancer care [1]

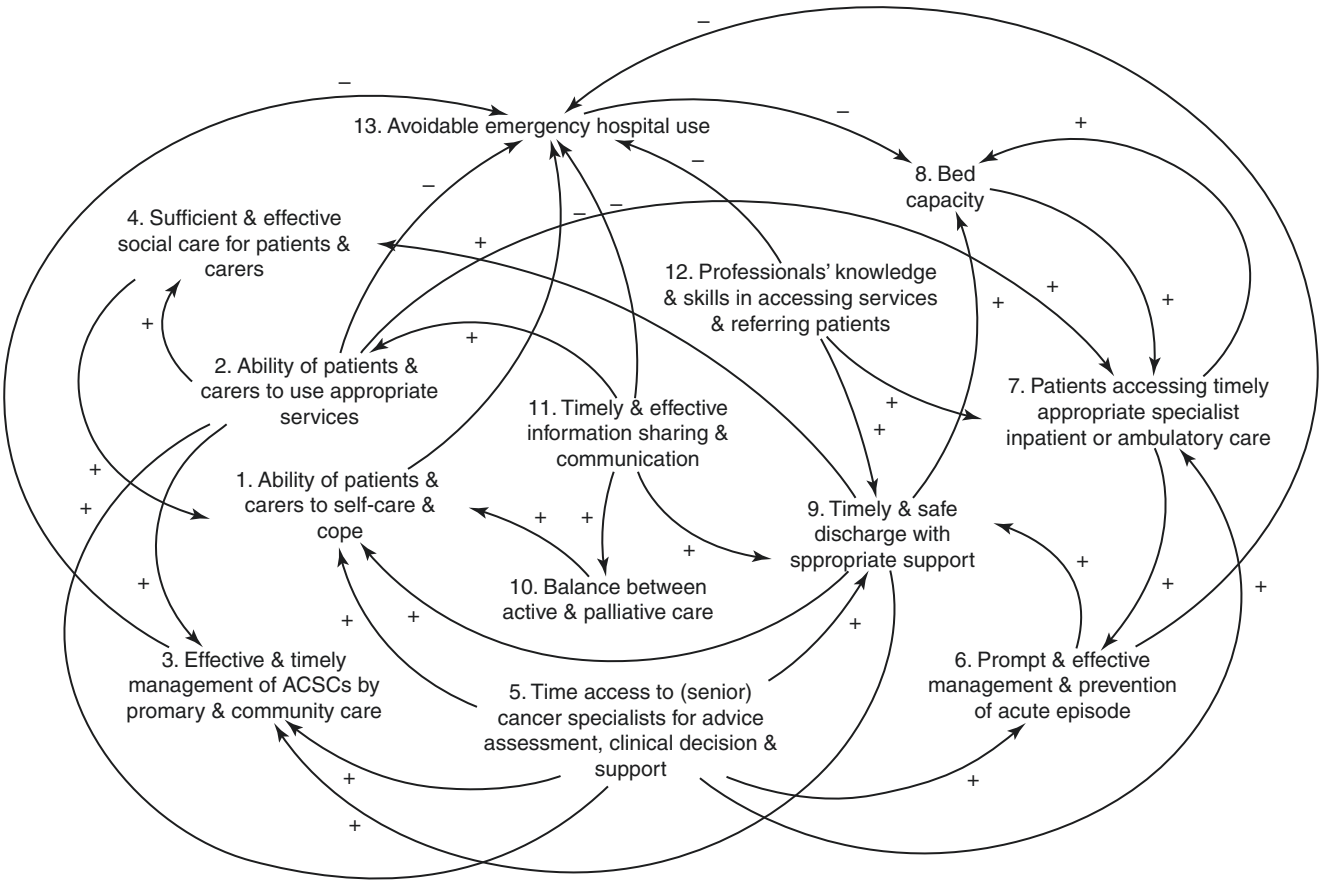

Fig. 1.2 Causal loop diagram of factors that influence ED use by oncologic patients. (From Chen, et al. [18] with permission CC by 4.0)

similar factors apply to ED use across settings. In the United States, access to care is further influenced by insurance status and an individual's ability to pay for care—factors which hold less influence in settings with nationalized healthcare systems.

Early investigations of the ED role in cancer care focused on cancers that were diagnosed in the ED and therefore represent a failure of outpatient detection and potential treatment delays [19, 20]. While these factors remain of concern, more recent studies have moved to enumerate visits in cohorts of patients, describe the type of care provided, and identify potentially preventable ED use [10, 13, 21–23]. Despite these efforts, the epidemiology of ED use by oncologic patients, including patterns and determinants of use, remains poorly understood. Few studies describe the incidence of ED use by cancer patients across cancer types, in population-based samples, and even fewer explore the burden of cancer visits experienced by patients or by ED providers [11]. Numerous studies examine complications, hospital admission, and/or readmission rates for specific cancers, treatment regimens, or procedures, but few of these examine how readmission or complications impact emergency department use [24–31].

In light of the importance of ED visits in the care of oncologic patients, this chapter reviews what is known about ED use among oncologic patients, specifically:

- Distribution (i.e., frequency, incidence, and disposition) of visits
- Determinants of use
- Preventability of visits

Distribution of ED Visits Among Oncologic Patients

Data Sources

In the United States, data sources capturing cancer type, cancer stage, treatment, and health system utilization are not robust. For example, administrative datasets capturing healthcare utilization data may not include cancer diagnosis, treatment information, or complete comorbidity data (e.g., Medical Expenditure Panel Survey (MEPS) [32], Nationwide Emergency Department Sample (NEDS) [33], National Hospital Ambulatory Medical Care Survey (NHAMCS) [34]). Likewise, cancer registries collect robust specific cancer and initial treatment information; however, they may not capture full health services utilization data, including ED visits [35]. The Surveillance, Epidemiology, and End Results (SEER) program includes population-based information about cancer incidence and survival but does not provide related health services data [36]. While researchers may link available datasets to reduce these gaps in information, limitations in diagnosis, treatment, or health service use remain. Therefore, the frequency and incidence of cancer patients visiting EDs in the United States is difficult to ascertain, particularly for large population-based samples [11].

Studies of the incidence and frequency of ED use by cancer patients are based on either the visit-level or patient-level unit of analysis. Visit-level analyses, for example, provide information about the quantity of care provided to cancer patients by EDs and indicate which diagnoses are associated with the visits. Visit-level analyses may not account for multiple visits made by the same patient, and these datasets may lack patient-specific information, such as diagnosis and treatment data. Patient-level analyses, in contrast, can identify characteristics of patients associated with ED use, thus providing more insight into determinants of health system use.

Estimates

Cancer-Related ED Visits In the United States, it is estimated that over 4% of all ED visits are for cancer-related reasons [13, 21]. Geographically, patterns of ED use are consistent across regions of the country (Northeast, Midwest, South, West) [21]. The number of ED visits varies by primary cancer diagnosis. The top cancers associated with ED visits include lung, 10–27% [13, 22, 23, 37, 38]; breast, 6–15% [13, 22, 23, 37, 38]; colon, 6–12% [13, 22, 23, 37, 38]; prostate, 5–11% [13, 22, 23, 37, 38]; multiple cancers, 10% [13]; and female reproductive or genital, 6–7% [13, 22, 23].

Incidence of ED Use Among Oncologic Patients Among all oncologic patients, the presence of any ED visit and the distribution and timing of ED visits are not well established, in part, because estimates depend on a specific precipitating potential triggering event under study. For instance, ED visits may be measured within a particular time frame (e.g., from diagnosis or from treatment, such as surgery, radiation, or chemotherapy), and the time frames vary greatly in the literature [11]. For example, one study of breast cancer patients receiving a mastectomy reported that 3% of the sample had an ED visit within 30 days of surgery [39], while 11% of high-risk patients with head and neck cancer receiving radiation had an ED visit during treatment or within 90 days of treatment completion [40].

Using a standardized 30-day visit rate, studies that examined postsurgical periods reported 2–12% of the sample visited an ED within 30 days after surgery, and a study that evaluated a post-chemotherapy time frame demonstrated 5% of the sample visited the ED [11]. Estimates provided by the

few available population-based studies tend to report higher ED use than those that focus on smaller within-setting study samples [11].

Time from diagnosis offers a consistent measure to examine ED use by oncologic patients across cancer types, although it is important to consider the factors that impact time to diagnosis. As expected, based on differences in diagnostic and treatment patterns, the incidence of ED visits varies by cancer type. Estimates of ED use by cancer type and time from diagnosis at 30, 180, and 365 days from diagnosis are provided in Table 1.1 [23, 41–43].

Multiple Visits A large proportion of cancer patients have multiple ED visits. Between 2009 and 2010, among patients with all cancer types in California, 20% had one ED visit, 8% had two visits, and 7% had three or more visits within 180 days of diagnosis. Among those with at least one ED visit, 44% had two or more visits and 21% had three or more visits [23]. In a national sample of colon cancer patients who visited the ED (55%), 24% had two visits and 25% had three or more visits within 1 year of diagnosis; importantly, those with three or more visits (14% of the sample) accounted for over half the total number of visits [43]. Not surprisingly, these rates of multiple visits are substantially higher than in the general US population where 6.5% have two or more visits to an ED annually [44].

Table 1.1 Cumulative percentage of cancer patients with at least one ED visit by time from diagnosis[a]

	Time from diagnosis		
Cancer type	30 days	180 day	365 days
All	17	35, 44–69 [41]	44
Bladder	21	44	54
Brain	39	60	68
Breast	5	22	31, 15–21 [42]
Colon	20	41	49, 55 [43]
Digestive	26	54	63
Endocrine	7	19	25
Eye	6	18	26
Gynecological	17	36	44
Hodgkin lymphoma	18	43	46
Ill-defined/unknown	36	53	57
Leukemia	26	45	53
Liver	29	54	63
Lung	30	55	64
Male genital (non-prostate)	16	28	36
Melanoma	5	14	22
Myeloma	28	53	63
Non-Hodgkin lymphoma	22	44	51
Oral	12	39	48
Other	20	42	53
Pancreas	37	62	69
Prostate	6	17	25
Respiratory (non-lung)	18	43	52
Stomach	27	55	63
Urinary	21	39	47

[a]These estimates are from four population-based studies that provide data on ED visits by cancer patients and time from diagnosis. Unless specified, data are derived from California's state-based data from 2009 to 2010 [23]

Disposition While inpatient admission rates vary by cancer type, patients with cancer who visit the ED tend to have higher rates of admission (49–63%) and are more than twice as likely to be admitted than non-cancer patients [13, 21, 23, 37, 45].

International Perspective on the Incidence and Frequency of ED Use ED use by cancer patients outside the United States is also characterized by high frequency and incidence. For example, during a 1-year study period at a hospital in Japan, 8% of individuals who visited the ED had a cancer diagnosis [46]. Reports from Australia indicate that 40% of cancer patients visited the ED at least once in the year following diagnosis, and 2.4% of all ED visits were made by cancer patients [47, 48]. One single-site study from Australia reported 38% of breast cancer patients receiving chemotherapy presented to the ED within 30 days of chemotherapy administration [49].

Similarly, over 53% of women in Ontario, Canada, who completed at least one cycle of chemotherapy for breast cancer had an ED visit within 30 days of treatment [50]. Among Canadian women over the age of 65 undergoing surgery for breast cancer, 13% had an ED visit within 45 days of surgery [51]. Another Canadian study examining ED use for head and neck cancer patients undergoing surgery found 8.4% visited in ED within 30 days of surgery [52]. These studies demonstrate that despite an indication of high ED utilization by oncologic patients internationally, similar methodological issues persist, and direct comparison of study results across countries is complicated by a focus on different cancers, conditions, treatments, contexts, and time frames of ED use.

Likewise, studies outside the United States report high frequencies of patients with multiple ED visits. In Taiwan, 12% of cancer patients who visited an ED had multiple visits in a 1-year study period, and for those specifically with head and neck cancer, nearly 70% had more than one ED visit over a 12-year study period [53, 54]. A report from the Bureau of Health Information in New South Wales, Australia, indicates that 10% of cancer patients make three or more visits in the year following diagnosis [48]. A separate Australian study found that up to 63% of cancer patients visiting the ED had multiple visits [47]. Among Canadian breast cancer patients receiving chemotherapy, nearly 37% of those within an ED visits within 30 days of treatment had multiple visits [50].

Determinants of ED Use Among Cancer Patients

The Andersen Behavioral Model of Health Services Use provides an important framework to understand the determinants of ED use among cancer patients [55]. Specifically, in this model, health service use is determined by the complex interaction between predisposing characteristics, enabling resources, and need factors. Predisposing characteristics include demographic factors, individuals' beliefs, and aspects of social structure which are not intended to directly explain but rather to help understand differences in the use of health services [55]. Enabling resources include individual and family factors (e.g., income or health insurance) and community characteristics (e.g., region of residence). Need or illness-level factors include both perceived and evaluated health status including symptoms and diagnoses.

The predisposing, enabling, and need factors associated with ED use and frequent ED use tend to be similar across the literature—whether in studies of specific chronic conditions such as diabetes or those limited to subpopulations such as older adults [56, 57]. In the US general population, predisposing factors associated with higher ED visit rates include age and sex, with higher rates among adults age 65 years and older age and among females compared to males; rates are lower among those living in the West compared to other regions [8]. Enabling factors associated with higher rates of ED use include private insurance and Medicaid compared to Medicare or no insurance and residence in low-income areas [8]. In terms of need, a medical diagnosis—including abdominal pain, chest pain, back problems, urinary tract infections, or skin infections—is most often listed as the primary concern for an ED visit [8].

Identifying predisposing, enabling, and need factors for ED visits among oncologic patients presents challenges due to the previously discussed methodological issues including differences in study populations (e.g., by cancer type, country of residence), treatment, the complications of interest, and time frame studied. Among US studies, there is great heterogeneity in the time period examined (e.g., in the first year after diagnosis vs. within 30 days of treatment), the number of participants (n = 220 to 89,311), and diagnoses included [11, 43]. Some studies focus on older adults precluding the ability to examine age as a determinant of ED use. Many of the available studies focus solely on one or more of the top four most prevalent cancers (i.e., prostate, breast, lung, and colorectal).

Predisposing Factors

Significant predisposing factors for oncologic patients of increased ED include race, age, and gender. Specifically, nonwhite [43] and African American [56, 58] compared with white, non-Hispanic race/ethnicity and older age compared to younger age [43, 56] were associated with more ED use. Additionally, being male compared to female sex resulted in increased rates of ED use [59, 60].

Enabling Factors

As in the general population, enabling factors associated with increased ED use for oncologic patients are area of residence and income level in the community of residence, insurance status, and marital status. Those with urban and metropolitan compared to rural residence had higher levels of ED use [56]. Being eligible for Medicaid due to blindness or disability [61], or residing in a state in which Medicaid copayments increased and prescription drug and other benefits were reduced [41], was associated with more ED use. Being unmarried compared to married [56] and residing in a census tract with low median income [56] were also associated with increased ED use.

Need Factors

Multiple conceptualizations of perceived or evaluated health status are associated with ED use in cancer patients in current literature. Operational definitions of need include reasons for visits, symptoms, chief complaints, and diagnoses and vary across healthcare settings and studies. Ultimately, the underlying symptoms or diagnoses associated with ED visits are need-related determinants of ED use. Cancer patients present to the ED with a variety of complaints but tend to have symptoms or diagnoses related to pain, pulmonary, gastrointestinal, cardiac, and infectious concerns.

A systematic review of symptoms experienced by cancer patients visiting the ED identified 28 reported symptoms, including psychological (such as anxiety), gastrointestinal, neurological, respiratory, dermatological, and urological symptoms, pain, fever and infection, edema, bleeding, fatigue, and altered nutritional status [62]. The primary reasons for visits defined as chief complaints (not diagnoses) for oncologic patients tend to be related to pain, respiratory distress, fever, and gastrointestinal issues [21, 37, 45].

In recent population-based studies, diagnoses (most frequently ICD9 or ICD10) are generally used to identify "reasons" for an ED visit [10, 13, 23]. In a national sample examining cancer-related ED visits between 2006 and 2012, pneumonia was the single diagnosis associated with the most ED visits, accounting for 4.5% of cancer-related ED visits [13]. Diagnoses that each represented between 3 and 4% of visits were nonspecific chest pain, urinary tract infections,

septicemia, and chronic obstructive pulmonary disease [13]. Abdominal pain, fluid and electrolyte disorders, congestive heart failure, cardiac dysrhythmia, and intestinal obstruction without hernia each represented between 2 and 3% of the diagnoses for ED visits by cancer patients [13].

Importantly, diagnoses differ by the disposition of the visit (e.g., to home vs. inpatient admission). In California, the top three diagnoses for ED visits made by individuals within 180 days of cancer diagnosis who were admitted to the hospital were septicemia (8%), cardiovascular problems (7%), and complications from surgery (5%), whereas the top three for visits that resulted in discharge home in the same sample were abdominal pain (7%), cardiovascular problems (6%), and urinary, kidney, and bladder complaints other than a urinary tract infection (5%) [23].

Regardless of visit disposition, the top ten diagnoses cumulatively account for less than 40% of all visits, underscoring the variability and complexity in precipitating factors for ED visits among cancer patients [13, 23]. Furthermore, ICD codes are limited in their ability to capture precipitating factors associated with ED use; moreover, the specific codes selected to categorize diagnoses into clinically meaningful groups vary with different algorithms used to group ICD codes to represent, for instance, surgical complications or chemotherapy-related complications.

Additional studies identify need factors associated with ED use including comorbidities, specific treatments, time to treatment, cancer stage, and survival. ED use is increased among patients having a greater number of comorbidities [43, 61, 63], a diagnosis of depression compared to no depression [64], and a radical prostatectomy compared with no treatment [56], having external beam radiation therapy with androgen deprivation therapy or external beam radiation therapy plus brachytherapy compared to radical prostatectomy [65], and having no therapy compared to radiation therapy [43, 58] and in those experiencing more severe symptoms [63], those surviving less than 1 year from diagnosis compared to surviving 1 year or more [59], and those receiving chemotherapy versus no chemotherapy [43, 61]. Cancer stage is also considered a need factor that could influence ED use. However, evidence of the impact of cancer stage on more or less ED use is unclear [11]. Additionally, among African American men with a prostate cancer diagnosis compared to white men, having a longer time to treatment was also a determinant of ED use [58].

International Perspective on Determinants of ED Use

The reasons for ED visits reported in international studies are similar to those reported in US studies. A single-site study from Brazil found the most common complaints were abdominal pain (18.4%), back pain (8.5%), dyspnea (8.5%), weakness/fatigue (8.1%), fever (7.0%), and nausea/vomiting (4.8%) [66]. A separate single-site Australian study which focused on breast cancer patients receiving chemotherapy found the most common reasons for an ED visits were non-neutropenic fever presentations (27%), neutropenic fever (24%), pain (14%), drug reaction (10%), and infection (6%) [49]. A Canadian population-based study of ED visits for women over the age of 65 years undergoing curative surgery for nonmetastatic breast cancer identified diagnoses associated with visits to be infectious disease (19%), musculoskeletal trauma/wound (13%), other (12%), surgical site issues (12%), process of care (4%), and other noninfectious diagnoses (40%) [51]. In Taiwan, Tsai et al. found pain (27.8%), fever (11%), shortness of breath (9%), abdominal distention (4.6%), and nausea/vomiting (4.2%) to be the most frequent presenting complaints [54].

Identified predictors of ED use are more robust in some international studies, likely due to comprehensive health service use data available in nationalized health systems. In a UK study including all cancer diagnoses, Abel et al. evaluated predisposing, enabling, and need factors associated with increased ED use finding the following independent predictors: women diagnosed with cancers of the bladder, brain, colorectal, stomach, and lung; men diagnosed with oral cancer, lymphoma, and melanoma; younger age compared to older age for acute leukemia and colon, stomach, and esophageal cancers; older age compared to younger age for laryngeal, thyroid, oral, and Hodgkin lymphoma and melanoma; low SES for most cancers, especially oral, anal, laryngeal, and small intestine cancers [67].

An examination of ED visits made by cancer patients in New South Wales, Australia, found that having neurologic or lymphohematopoietic cancers (compared to the skin), having comorbidities, and living in a socioeconomically disadvantaged area increased the likelihood of an ED visit [48]. Dufton et al. identified being born outside Australia and cancer diagnoses of the head and neck, upper gastrointestinal, colorectal, lung, skin, or breast as determinants of ED use [16]. In a population-based sample of older breast cancer patients in Canada, Westley et al. reported significant determinants of ED visits, within 45 days of surgery, were localized or regional versus in situ disease, mastectomy versus lumpectomy, operation before definitive oncologic control, lower institutional volume, having more than five prescriptions, benzodiazepine use, anticoagulant use, cardiovascular disease, diabetes, past hospitalization, and lower income [51].

Preventability of ED Visits Among Cancer Patients

One of the primary purposes of examining reasons for ED visits is to determine whether or not care could have been prevented or more optimally delivered in an alternate setting.

Despite persistent attention to preventable ED use, there is no consensus definition, generally, or applied specifically to oncologic patients [11]. Two previous approaches used to identify potentially preventable or avoidable ED visits are the Agency for Healthcare Research and Quality's classification of Ambulatory Care-Sensitive Conditions (ACSC, now referred to as Prevention Quality Indicators) and the New York University's Billings algorithm [68, 69]. Both of these methods use discharge diagnoses to determine and define the reason for a preventable visit. The ACSC identifies 16 conditions that are considered potentially preventable with proper primary or ambulatory care. The Billings algorithm categorizes visits into four groups: nonemergent, emergent but primary care treatable, emergent with ED care needed but potentially avoidable if timely and effective ambulatory care had been available, and emergent when ED care was truly needed and the visit was not preventable [68]. Using such definitions, it is estimated up to 56% of all ED visits (not restricted to cancer patients) can be considered avoidable [70, 71].

Neither the ACSC nor Billings classifications are oncologic specific, and they may not adequately capture preventable use among oncologic patients. As an example, febrile neutropenia, a common chemotherapy-related side effect, is not included in either method [10, 11]. In an attempt to capture cancer-specific diagnoses, in 2016 the Centers for Medicare & Medicaid Services (CMS) established a quality metric that identifies diagnoses associated with potentially preventable ED use by cancer patients—including anemia, dehydration, diarrhea, emesis, fever, nausea, neutropenia, pain, pneumonia, or sepsis within 30 days of outpatient chemotherapy treatment [72].

Using claims data, Panattoni et al. developed a specific method to identify potentially avoidable use among oncologic patients and specified 18 diagnoses from either the CMS proposed Admissions and Emergency Department Visits for Patients Receiving Outpatient Chemotherapy Measure and/or the Symptom Tracking and Reporting PRO tool as representing potentially preventable ED visits in the year after chemotherapy, radiation, or both [10]:

- Anemia
- Appetite loss
- Constipation
- Cough
- Dehydration
- Diarrhea
- Dyspnea
- Dysuria
- Emesis
- Fatigue
- Fever
- Flushing
- Nausea
- Neuropathy
- Neutropenia
- Pain
- Pneumonia
- Sepsis

Using these potentially preventable diagnosis codes, they identified pain, fever, and dyspnea as the most prevalent potentially preventable diagnoses for cancer patients, accounting for approximately 40% of ED visits using primary diagnosis coding, and over 63% if all coding place fields were included [10].

When considering the specific diagnoses included in these methods, the concept of what is preventable remains ambiguous. Certainly, diagnoses such as sepsis, pneumonia, or dyspnea may represent clinically significant events that justify treatment and possibly admission to the hospital. Given that the diagnoses listed above may be present in over half of cancer-related ED visits but these patients might actually have serious life-threatening conditions, risk stratification methodologies are needed to truly identify patients where ED visits could be safely avoided [10, 22]. A particularly unique event to consider is patients who obtain their initial diagnosis in the ED, which is estimated to occur in 12–32% of oncologic patients [67, 73–75]. In these situations, the reason for the visit may have been directly related to symptoms that led to a diagnosis or could have been an incidental finding during the treatment of an unrelated complaint. In either circumstance, it is difficult to establish whether these visits were potentially avoidable based on diagnosis codes and even more difficult to determine if limited access to care or cancer screenings contributed to a diagnosis in the ED.

International Perspective on Preventable ED Use

Identifying potentially preventable ED visits is also challenging in international settings. Some literature, particularly from nationalized healthcare systems, focuses on a cancer diagnosis in the ED as a particular subset of preventable ED use [74, 76]. This may be a useful indicator of overall cancer care and screening in a health system, yet as described above, the ability to establish the true preventability of those visits is unclear. In a population-based Canadian study, Barbera et al. report that nearly 7% of visits were potentially avoidable and based on a definition of avoidable care that encompasses device problems, constipation, repeated prescriptions, follow-up visits, or laboratory examinations [77].

A single-site study from France specifically examined the appropriateness of referrals (based on the need for medical exam within 24 hours) to the ED for oncologic patients and the potential preventability of those visits based on presenta-

tion and treatment [78]. In this study, 33% of visits were categorized as having a high likelihood of being avoidable and 14% as having a moderate likelihood of being avoidable. Individual chart review was used to identify the driving factors for each visit (e.g., care provided at a preceding healthcare contact, an issue with a previous discharge process, patient not understanding a plan of care, etc.) to establish the likelihood of a visit being avoidable. Similarly, Oh et al. examined ED visits in a single South Korean hospital using expert review of medical records to determine if visits met the criteria they considered avoidable. They defined avoidable as a problem that could be resolved at a primary care office, out-patient clinic, or over the telephone and considered visits due to hospice referral, chemotherapy or radiotherapy, or surgery as unavoidable. Among the most common chief complaints (i.e., pain, GI symptom, dyspnea, altered mental status, other neurologic symptom, fever/chills, bleeding, edema/swelling, general weakness, urinary symptoms or constipation, and URI symptoms), the percentages of avoidable and non-avoidable visits varied within each category [15]. For example, 60% of visits for pain were classified as avoidable, while 40% were unavoidable. Likewise, 53% of visits for dyspnea were deemed avoidable, while 47% were unavoidable.

Ultimately, the ability to evaluate ED visits and the extent to which they are potentially avoidable are dependent on a country's health system and available data sources. Even in countries with robust national health systems and data collection processes, defining avoidable ED visits remains a problem, particularly for the oncologic patient population. It should be noted that approaches requiring extensive individual chart review would be difficult to apply to population-based samples. Consensus definitions of avoidable visits and efficient, effective care systems for oncologic patients are important internationally; however, further work is needed to reach these goals.

Conclusion

One of the greatest ongoing challenges to providing high-quality cancer care, for the United States and internationally, is the management of acute complications of cancer and rapidly developing treatments [79]. The need for well-coordinated care for end-of-life and palliative care is well established, but there is also a need to address acute oncologic needs [3]. Evaluating ED use by oncologic patients requires examination of both the incidence and frequency of visits by cancer patients. By understanding the volume of care provided by EDs, as well as the percentage and types of visits, health providers and systems are better able to prepare for the required treatments and partner with policy makers to establish consensus definitions of preventable and non-preventable ED use in this population. This information is essential to developing successful innovative oncologic care models which may include interventions such as telemedicine, enhanced symptom management support systems, care pathways, and oncologic-specific urgent care or emergency departments.

EDs provide a significant amount of care for oncologic patients, with 4% of all ED visits categorized as cancer related and over 40% of cancer patients having at least one ED visit within a year of diagnosis. While a few select hospitals and health systems have developed oncologic-specific EDs, urgent cares, or walk-in clinics to address unscheduled concerns, the majority of patients receiving cancer treatment must rely on general EDs for acute and unscheduled needs [3].

Determinants of ED use include a complex constellation of predisposing, enabling, and need factors, with most studied at the individual level. Less is known about broader contextual determinants of ED use in cancer patients—including provider, health system, and health policy factors—in part because of limitations in extant data to study ED use in oncologic patients. Future research is recommended to address these gaps. Based on available data, definitions of truly preventable and avoidable ED visits remain unclear. However, available data demonstrate the magnitude of potentially avoidable visits may be significant and warrants further investigation. Furthermore, examinations of reasons for visits for symptoms including pain, dyspnea, nausea, and concerns for bacterial infection may have a significant impact on enhancing cancer care, and addressing these concerns may help to reduce unnecessary ED visits [22].

Models of Care

2

Michael G. Purcell

Introduction/Background

Both the emergency medicine and oncologic communities recognize that cancer patients require specialized emergency care and are better served by professionals who are knowledgeable about their unique needs. Within emergency medicine, this is highlighted by the relatively recent formation of the Society for Academic Emergency Medicine Oncologic Emergencies Interest Group and the Comprehensive Oncologic Emergencies Research Network (CONCERN). Patients often relate stories of being told in their local emergency department (ED) to go to their cancer center for further treatment after emergent conditions have been excluded. Conversely, oncologists rarely have access to EDs with specific oncologic expertise. Patients express concern that emergency physicians in the community are not completely comfortable caring for complex oncologic patients and lack adequate knowledge regarding the management of their disease processes and treatments. As a result of their patients' prior experiences in these less specialized settings, oncologists are often hesitant to recommend such EDs with limited oncologic expertise to their patients. Many oncologists who work in large centers are requesting urgent and emergent after-hours services by personnel who are trained in handling oncologic emergencies. With overcrowding and prolonged waits for treatment that characterize many of our nation's EDs, those with cancer and complex care needs, including immunocompromised, intractable pain, and end-of-life care needs, may best be served in regionalized EDs specializing in oncologic care.

The numbers of cancer patients and survivors among the general population are increasing. The life expectancy of cancer patients has increased significantly in the last six decades. In 2017, there were an estimated 15,760,939 persons living with cancer in the United States alone. In 2020, an estimated 1.8 million additional Americans will be diagnosed with cancer. The 5-year survival rate was estimated to be 67.4% between 2010 and 2016 [1]. With the advent of new therapies and treatment modalities, this survival rate could conceivably increase.

Comparative survival data from the MD Anderson Cancer Registry (The University of Texas MD Anderson Cancer Center, Houston), established in 1944, demonstrate a marked improvement in survival rates for most malignancies. Examples include breast cancer, the 10-year overall survival rate having increased from 25% in 1944 to 76.5% in 1995 for patients treated at MD Anderson. For prostate cancer, the most common malignancy in men, the 10-year survival rate increased from 8.5% in 1944 to 82.5% in 1995. Acute myeloid leukemia was simply fatal in 1944, with a median survival from diagnosis of 8 weeks and a 99% mortality rate at 12 months, but by 2004, the long-term survival rate had increased to over 25%. Remission rates in acute myeloid leukemia patients under age 60 years have reached 65% [2]. Thus, there are many cancer survivors seeking medical care in primary care offices and EDs around the country.

To further highlight the need for such specialized care, there will be an estimated 26 million persons in the United States who either have active cancer or who have been previously diagnosed with cancer in 2040 [3]. Seventy-three percent of this population will be over the age of 65. This ever-growing and aging population will continue to seek emergency care both during and following the diagnosis and treatment of their cancer. Currently, about 4% of all ED visits are made by patients with a cancer diagnosis [4]. This population has a high rate of admission, 59%, when compared to the 16% admission rate for those without cancer [3]. This stems from infection, therapy side effects, manifestations of the malignancy itself, as well as a plethora of hematologic and metabolic derangements. With increasing prevalence, 5-year survival rate, and age of the patient, there

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_2

will be an increasing need to have providers more familiar with cancer and its therapy. This may be best accomplished by personnel with additional experience and training in treating and managing this population.

Several other factors have increased the population of oncologic patients and survivors seeking acute care. In the last few years, more oncologic patients have been receiving treatment as outpatients. Leukemia and stem cell transplant patients spend less time in the hospital and often receive the majority of their chemotherapy in outpatient treatment centers. These patients are no longer universally admitted to the hospital for neutropenia if there is no evidence of infection. Instead, they make frequent trips to the hospital for treatment and laboratory evaluations. Often, patients arrange temporary housing in the area of the oncologic treatment center. This practice has also increased the need for unscheduled acute care. Furthermore, cancer patients and survivors have a combination of medical problems that may or may not be related to their cancer history and a wide range of potential residual medical issues related to their prior disease and/or treatments. Meanwhile, oncologic care is becoming increasingly specialized. Oncologic practice is focusing on emerging treatments and targeted therapies. As more treatment options become available, more expertise is needed in each oncologic subspecialty. With increasing treatment options, there are more potential side effects and treatments available for the supportive care of these patients.

Cancer patients not only suffer from complex medical problems related to their disease and therapy but also are particularly vulnerable emotionally. Patients suffering from a life-threatening illness often have stronger bonds with their medical providers that may be associated with higher expectations for care and an increased sensitivity to their care providers' words or actions; conversations can take on a greater meaning and become more emotionally charged than under normal circumstances [5].

Caring for patients with advanced cancer is stressful for clinicians, and discussing bad news often evokes strong emotional feelings. Not all physicians are formally trained for these difficult communication tasks. End-of-life talks are time-consuming and stressful in any environment, but this is compounded in the ED, where the cancer patient's needs must compete with the treatment demands of other patients. Furthermore, delirium may be far more common in this population than previously thought, which may prevent meaningful discussions in the ED [6]. Unfortunately, evaluation in the ED often reveals progression of the underlying malignancy and may raise the topic of transition to palliative care. Most emergency physicians feel ill-equipped to have this discussion due to the brief nature of their relationship with the patient and lack of depth of understanding of the patient's disease and its progression and possible therapeutic options. At the same time, the patient, faced with new knowledge about disease progression manifested by the symptoms that prompted the emergency visit, may have multiple questions and a high level of anxiety. At this time, the patient is at high risk for feelings of abandonment, especially if the emergency physician is unable to answer questions or provide adequate reassurance that the patient's primary oncologist will be available to them in a timely fashion [5]. Nursing staff may also be unprepared to care for patients who are actively dying, and they may lack the skills to manage end-of-life symptoms.

Despite these needs, there are very few acute care facilities dedicated entirely to the care of cancer patients. MD Anderson and Memorial Sloan Kettering Cancer Center (New York) have such centers. The Ohio State University Wexner Medical Center has an integrated Oncologic Pod within its main ED. Other institutions with a large percentage of oncologic patients are developing resources to provide the specialized care these patients need and to mitigate the difficulties these patients can present to a busy ED. Some institutions are opening fully integrated cancer units within their EDs. They are examining ways to quickly recognize acutely ill oncologic patients so that high-risk patients are treated expeditiously while maintaining an appropriate triage system so that other patients do not perceive oncologic patients as receiving preferential treatment [7].

In this chapter, we describe several models for providing care for oncologic patients in the emergency setting. The models range from EDs at large, dedicated cancer centers (MD Anderson and Memorial Sloan Kettering) to a fully integrated Oncologic Pod that resides within a more traditional ED (The Ohio State University Wexner Medical Center, Columbus, Ohio). These models illustrate some of the pivotal issues of institutions embarking on this endeavor.

Table 2.1 Common issues essential to all oncologic ED models

Recognition and expeditious treatment of oncologic emergencies such as neutropenic fever, spinal cord compression, tumor lysis syndrome, and pulmonary embolism
Appropriate management of pain for patients who are not opioid naïve
Management of frequently needed procedures such as thoracentesis and paracentesis
Early recognition and proper management of patients who have do not resuscitate (DNR) orders or are near the end of life
Knowledgeable management of complications of cancer treatment (chemotherapy, immunotherapy, radiation, CAR-T, and other novel therapies)
Proper communication regarding disease progression with the patient and oncologist
Adequate support from end-of-life services such as palliative care and hospice
Consistent and reliable method of communication with the patients' oncologists
Support for patients who are new to the institution and attracted by the cancer ED designation

Table 2.1 lists common issues that are considered essential to all models of care. Different models for providing emergency care to cancer patients are derived from the variable needs and characteristics of each practice, such as the prevalence of cancer types, the physical and administrative organization of the local oncologic services, and the resources available.

The University of Texas MD Anderson Cancer Center

The Emergency Center at MD Anderson Cancer Center is dedicated exclusively to the care of cancer patients. It is located in the main hospital building and is designated a level III ED by the The Joint Commission and the Centers for Medicare & Medicaid Services. Ninety-eight percent of patients treated in MD Anderson's ED have cancer or a cancer history. The ED has a large role in the inpatient services provided at MD Anderson. Thirty-nine percent of hospital admissions come through the ED [8].

However, MD Anderson did not open its doors with an ED in place. The ED developed gradually as a response to the needs for acute care for the large number of outpatients being treated at MD Anderson. Initially, urgent and emergent services were provided in an open ward. No doctors were assigned to the area, and when a patient requiring emergent care arrived, the patient's physician was notified and sent to the ward to evaluate the patient. This situation was not optimal for acutely ill patients or for patients scheduled in the clinic, and the lack of individual patient rooms made it difficult to maintain patients' privacy and confidentiality [9]. The system was also disruptive for oncologists, who already had full clinical schedules. Eventually, full-time physician coverage was established, initially provided by the Department of General Internal Medicine. In 1986, the ED was formally opened. Initially, it had 23 private rooms and provided care to approximately 14,000 patients per year. In 2007, the emergency center moved to its current expanded location. In 2011, MD Anderson established an academic Department of Emergency Medicine, the first such department dedicated entirely to oncologic emergency medical care, education, and research. The MD Anderson ED currently has 45 private rooms, a six-chair unit, and a two-chair triage bay. The ED is equipped with two resuscitation rooms in which critical care is provided to patients with high acuity that arrive from the clinics, walk-in, or arrive by ambulance. The ED now sees over 26,000 patient visits annually. All of the patients have cancer or are cancer survivors, except for an occasional family member of a patient or an employee.

The ED is staffed with full-time faculty members, the majority of whom are board certified in internal medicine or emergency medicine. Some faculty members are board certified in surgery, pediatrics, or infectious disease or palliative medicine. The physicians are faculty at the University of Texas and have similar academic obligations for research, administration, and teaching as other MD Anderson faculty members. The Department of Emergency Medicine recently initiated an oncologic emergency medicine fellowship, now in its eighth year. Mid-level providers are utilized in the ED, but provide a relatively small portion of the care delivered.

The department's 19 faculty members provide round-the-clock coverage. Coverage ranges from two to six physicians with an additional mid-level provider at the busiest times. The ED employs approximately 75 registered nurses with a nurse-to-patient ratio of approximately 1 to 3.

Care and treatment decisions are made by the emergency medicine faculty. However, oncologists do provide a call schedule, and there is frequent communication on an as-needed basis between the emergency physicians and primary oncologists. Oncologists do not routinely round in the ED unless they have admitted patients boarding there. The electronic medical record provides full access to the patient's medical record. Oncologists can notify the ED staff of a patient's pending arrival with the addition of important clinical information by entering a note in the medical record. After patients are seen, a note is generated by the emergency physician notifying the primary oncologist that the patient was seen. If consultation is warranted, the oncologist is contacted by phone.

The average ED length of stay is just over 6 h for a non-admitted patient and over 9 h for an admitted patient. The ED admits 51% of the patients presenting for treatment. Approximately 30% of unique patients have hematologic tumors (leukemia or lymphoma) or have received stem cell transplantation, comprising 50.3% of all patient visits; the remainder have solid tumors [7].

Of all the patients visiting the ED in 2010, hematologic patients averaged 2.2 visits per patient, and solid tumor patients averaged 1.8. Of these patients, 12% had four visits or more, with a range of 1–31 visits per patient. Most patients were receiving multiple medications and presented with several complaints. The complexity of their illness and frequent requirements for intravenous fluids, antibiotics, electrolytes, and blood products results in a prolonged length of stay compared to other EDs. The high level of acuity is reflected in the 10.9% mortality rate associated with admission of these patients [7]. The mortality rate is higher for patients with hematologic tumors (13.6%) than for patients with solid tumors (9.8%).

Patients present to the oncologic ED with a multitude of different complaints. At MD Anderson, the most common chief complaint is fever, present in 23% of patients. This is closely followed by abdominal pain, generalized pain, shortness of breath, nausea and vomiting, weakness and fatigue, back pain, chest pain, bleeding, cough, and diarrhea.

Memorial Sloan Kettering Cancer Center

Memorial Sloan Kettering has an Urgent Care Center (UCC), dedicated solely to the care of oncologic patients. The number of patient encounters per year in the UCC has steadily increased from 14,800 in 2000 to 21,800 in 2013. Although the UCC receives Memorial patients who arrive from the community via ambulance, general 911 calls from the community are not brought to Memorial. The physical size of the unit has grown over time. Originally an eight-bed unit with an adjunct clinic space, the UCC now consists of 19 telemetry beds and 4 transfusion chairs. Turnover of these beds occurs more than four times per day.

The driving forces behind this growth are an increase in the number of patients receiving treatment at Memorial Sloan Kettering and the continued transition of oncologic care away from the inpatient setting. As cancer treatment paradigms change, the UCC is key to the institution's ability to provide acute evaluation and management to an increasingly large and complicated outpatient population. The recent addition of a freestanding same-day surgical center and the continued expansion of the outpatient bone marrow transplantation program are examples of the trend toward outpatient treatment of cancer patients.

The clinical staff consists of 13 full-time board-certified internal medicine physicians, some of whom have completed subspecialty training in palliative care, anesthesia/critical care, and infectious disease. UCC physicians are considered academic faculty who are responsible for teaching medical students and residents from Weill Cornell Medical College, as well as participating in clinical research.

Patients treated in the UCC reflect the spectrum of disease seen at Memorial. Most patients have solid tumors (72%) and are evaluated for acute complications of their disease and treatment. The most common chief complaints include dyspnea (17%), fever (14%), pain (11%), nausea (10%), and fluid/electrolyte disturbances (9%). The average length of stay in the UCC is 4 h, and slightly more than half of the patients seen in the UCC will require admission to the hospital. Occasionally, patients with advanced disease who have been treated at other institutions or individuals with a suspected but unconfirmed cancer diagnosis seek to transfer their care by visiting the UCC. Emergent problems are acutely managed; however, referral for expedited outpatient evaluation is the preferred pathway, as the UCC is not intended to be the first point of contact for a new patient.

The UCC has attempted to integrate successful models of care from emergency medicine as volume and throughput have increased. A modified Emergency Severity Index (ESI) tool is used for triage. Patients are assigned a score of 1–5 based on the need for a lifesaving intervention, the presence of a high-risk situation, the number of resources a patient will require, and predefined vital signs. Specific triaging emphases that reflect the unit's focus on oncologic include with the rapid identification any of the following conditions: recent bone marrow transplantation, febrile neutropenia, and potential spinal cord compression. During peak hours, a UCC physician assists the triage nurse, a model that has been associated with faster throughput and improved patient outcomes in non-cancer EDs [10].

As many patients are referred internally by treating oncologists and surgeons, an electronic "UCC Notification Order" allows these individuals to communicate the most likely diagnosis, the need for admission, and which tests and consultants will expedite care.

Oncologic patients have an inherent risk for developing sepsis. An institutionally derived algorithm is used to screen all electronically documented vital signs for sepsis. When potentially significant abnormalities are identified, an alert is triggered, prompting a clinician to assess the patient for the possibility of sepsis. This process is time sensitive and requires the clinician to either document a reason for exclusion (dehydration, arrhythmia, end-of-life/palliative care, etc.) or acknowledge the alert and initiate the sepsis management protocol within 30 min.

Patients who arrive critically ill and in need of an immediate intervention such as endotracheal intubation, cardiopulmonary resuscitation, or initiation of vasopressor support are frequent challenges in cancer EDs. At Memorial Sloan Kettering, the primary oncologist has often already established and documented the goals of care in the electronic medical record. If the patient has previously consented to a do not resuscitate (DNR) order, this information is displayed in the header at the top of the screen, next to the patient's name and medical record number. This order must be confirmed and renewed with each hospitalization, as per New York State law. For critically ill patients without previously established advanced directives, the UCC clinician will rapidly determine the goals of care with the patient, healthcare proxy, and primary physician at MSK. For individuals who decline life-sustaining interventions, the UCC clinician will enter a DNR order and initiate palliative care. Preexisting order sets for narcotic analgesia and a palliative care consultant facilitate care. A medical ethics consultation service is available 24 h a day for encounters in which the goals of care are difficult to establish.

A Fast-Track Pathway is used for patients with a low Emergency Severity Index (ESI) score. One of the most common diagnoses in this group is a new, suspected, or incidentally identified thromboembolic disease. If anticoagulation is indicated, the patient is often discharged on rivaroxaban with close follow-up in the Anticoagulation Management Clinic.

In July 2013, the UCC opened an observation unit, intended for patients who were unsuitable for discharge but had an expected duration of care lasting less than 24 h. Although the observation unit is physically located in the hospital, this nine-bed unit is considered an outpatient service and is staffed by UCC physicians and mid-level provid-

ers. During the first 6 months of the program, roughly 10% of UCC visits ($n = 1013$) resulted in patient placement in the observation unit. The proportion of admissions to the hospital from the UCC with a length of stay less than 24 h dropped significantly after observation unit implementation (2.4–1.1%). The most common reasons for observation unit placement are fluid and electrolyte disorders (14%), pain control (14%), dyspnea (13%), and fever (9%). Interventions for patients in the observation unit include placement or revision of drainage catheters (pleural, biliary, genitourinary tract, abscess); endoscopy and transfusion in patients with hemodynamically stable gastrointestinal bleeding; correction of uncomplicated electrolyte derangements; administration of intravenous (IV), antiemetics, IV antibiotics (for treatment of cellulitis, pneumonia, and uncomplicated febrile neutropenia), or IV analgesia; and the management of severe constipation. Approximately one-third of patients placed in the observation unit require admission to the hospital for ongoing care. Extending the observation period to 48 h may decrease this number.

Approximately 15 patients a week are seen in the UCC for elective palliative paracentesis, performed by the UCC clinical staff. Drainage of symptomatic pleural effusions is performed in the observation unit by pulmonary medicine. Patients with low-risk febrile neutropenia are either discharged or placed in the observation unit for 24 h.

When possible, management decisions are made with input from a patient's primary oncologist or surgeon, who is notified automatically by e-mail during check-in and discharge. While these individuals may be off-site, they are able to review all relevant clinical data, including lab findings, chart notes, and radiology and telemetry results. An electronic status board, visible on all computer terminals within the institution and on overhead monitors in the UCC, facilitates a quick grasp of key metrics related to an individual patient and overall throughput at any given time. This tool facilitates communication about arrival and waiting times, identification of treating or covering UCC staff, pending diagnostic tests and consultants, disposition (admitted/discharged/observed), and bed status.

The Ohio State University Comprehensive Cancer Center: Arthur G. James Cancer Hospital and Richard J. Solove Research Institute

In April 2015, the Ohio State University Wexner Medical Center (OSUWMC) opened a new, specialized pod in the ED to care for its cancer population. The ED, which houses the newly named Oncologic Pod, currently cares for all patients that arrive to OSUWMC seeking emergency care: approximately 82,000 patients per year. The Oncologic Pod currently evaluates, manages, and treats approximately 11,000 oncologic and hematology patients per year, which reflects over 13% of emergency visits to the OSUWMC ED. With opening of the Oncologic Pod, the ED dealt with many challenges as illustrated in Table 2.2, beginning with patient identification. The hematology and oncologic patients are identified immediately upon arrival during the triage process. Patients who arrive to the ED are asked two screening questions: "Have you seen a cancer doctor or doctor at the James in the last 12 months?" and "Are you currently undergoing active treatment for cancer?". An affirmative answer to either question allows for preferential placement into the Oncologic Pod, which is fully integrated within the ED.

Table 2.2 Challenges to an integrated Oncologic Pod

Early identification of the hematology and oncologic patient
Equitable triage and placement for all ED patients
Identification of febrile neutropenia and other subtle, life-threatening oncologic emergencies
Waiting areas for the immunocompromised patient
Available bed space
High ESI level in the cancer population
High admission rate in the cancer population

One of the many challenges that the ED initially faced was the development of triage criteria to effectively triage cancer patients to the Oncologic Pod while maintaining equity among all patients that presented for evaluation. The Oncologic Pod originally opened with 10 beds and 5 additional chairs for a total of 15 treatment spaces that were allocated to the care of cancer patients. Ten of the rooms were private, four had private bathrooms, and two had negative airflow. The other five spaces were treatment bays with lounge chairs for infusions. With rising acuity and increasing number of cancer patients arriving to the ED, these treatment bays were renovated to include telemetry and actual ED beds, instead of the initially planned chairs. Additionally, the ability to flex up to 19 treatment spaces was created through the addition of four hallway beds. Patients may be placed in a hallway bed to facilitate early treatment while awaiting placement in a room or treatment bay. On days when a larger number of oncologic and hematology patient visit than the 15-bed/19-treatment space pod can accommodate, additional patients will be evaluated in the remainder of the ED when space is available. If a high acuity patient arrives to the ED and the Oncologic Pod is full, then that patient may be placed in a bed outside of the Oncologic Pod to facilitate prompt treatment of the emergent medical condition. Similarly, when there are fewer Oncologic Pod patients, non-cancer patients will be evaluated as needed in the Oncologic Pod. This will ensure equal access to emergency care for all patients, regardless of their disease state.

After the initial triage process, patients are either placed in an available treatment space or escorted to the waiting

room. The waiting room represented an additional challenge. With the steadily rising number of ED visits by cancer patients, concerns arose in placing what could certainly be an immunocompromised population in the main ED waiting room. The main ED population often sought care for viral or bacterial illnesses. Such illnesses could prove life threatening for the immunocompromised cancer patient. Out of concerns for patient safety, an additional waiting area for cancer patients was created that allowed for better isolation and distancing. The cancer population viewed this as a significant improvement in their ED encounters. Hand sanitizer and facial masks are readily available for patient use in this area.

After patients are placed into a treatment space, they are cared for by a multidisciplinary team in the Oncologic Pod. This team is composed of physicians, advanced practice providers, nurses, patient care associates, patient experience representatives, social workers, case management, and dedicated emergency medicine trained pharmacists. All physicians that care for these patients are either board certified in emergency medicine or board eligible for the American Board of Emergency Medicine certifying board exam. The physician group provides 24/7 oversight of the Oncologic Pod. There are 16 hours (two, 8-hour shifts) of dedicated physician coverage in the Oncologic Pod. This runs from 9 a.m. until 1 a.m. During this time period, the dedicated physician is responsible only for care in the Oncologic Pod. Additional physician staffing throughout the department enables this physician to dedicate all of their time on shift to the cancer population. From 1 a.m. until 9 a.m., an emergency physician provides oversight in the Oncologic Pod as well as an adjacent ED area. The decision for this staffing model was based on ED arrival times of the cancer population at the OSUWMC ED, which consistently demonstrated fewer arrivals in the 1 a.m. to 9 a.m. time period on all days of the week.

To assist the physician in caring for patients, a group of advanced practice providers (APPs) staff the Oncologic Pod. This group, a mixture of both nurse practitioners and physician assistants, is dedicated solely to the care of patients in the Oncologic Pod. The APP staff provide 48 hours of coverage daily in the Oncologic Pod. This is broken down into four, 12-hour shifts with overlapping coverage. During the onboarding process, the APP staff are cross-trained in the ED and the cancer center. This includes time in the Oncologic Pod as well as rotating with the hematology, oncologic, and neuro-oncologic services. Depending on provider preference, they may also spend time with radiation oncologic or one of the many surgical services for the hospital. The off-service onboarding process prepares the APP staff for the variety of cancers and treatments that they may encounter in their role as providers. Their time onboarding in the ED further prepares them for the variety of presentations that they may encounter in their role. The APP team evaluates the vast majority of patients in the Oncologic Pod. If there is an influx of patients, then resident physicians, who staff the adjacent pod, are readily available to assist in evaluating the cancer population. Additionally, they have 24/7 access to a board-certified emergency physician. Through the combination of onboarding, monthly meetings, CME, and personal education, the APP staff is more than adequately prepared to deal with any oncologic emergency that comes through the door.

The work of the providers would be naught without additional staff. The Oncologic Pod has a dedicated nursing staff. The vast majority have had training either in the care of the oncologic patient or in an ED. The nursing staff is acutely aware of the presence of ports and use of other intravascular access devices. They are attuned to the needs of this particular population including aggressive symptom control and need for expeditious evaluation of a fever. The nursing staff is aided by patient care associates, up to three at a time, who help with additional tasks in the area. To help complement the immediate patient care side, 24-hour social work is available for the patients. Every cancer patient who is roomed in the ED is evaluated by a social worker to discuss living situations, safety, and advanced directives. The social work team is readily available to assist the population around the clock. Case managers also help with coordination of care. They are available to connect the differing care teams as well as to establish appointments for patients being discharged from the Oncologic Pod. Finally, the Oncologic Pod has a dedicated pharmacist, trained in emergency pharmacology. They help with a variety of issues, including antibiotic selection, antibiotic dosing, symptom control, and any other pharmacotherapeutic questions the treatment team may have. They are a valuable resource as cancer treatments continue to evolve.

One important scenario to emphasize is the patient with neutropenic fever. These patients are often difficult, but critical, to recognize. Current guidelines recommend that these patients receive antibiotics within 1 hour of triage and be monitored for 4 hours following antibiotic administration [11]. Many of these patients may appear well and traditionally have had to wait with other patients for further evaluation. Unfortunately, a prolonged time to antibiotics can result in deterioration and development of sepsis. To improve the management of these patients, the Oncologic Pod has the criterion that any patient with a fever who has received chemotherapy or radiation in the prior 2 weeks will be evaluated under the ED Sepsis Alert process. This process brings together a multidisciplinary team (physicians, nursing, radiology, pharmacy, etc.) to expedite initiation of IV antibiotics and diagnostic work-up for this high-risk population of patients.

As treatments advance, there is the ongoing need for increasing flexibility in triage. With the FDA approval of CAR-T therapy, new challenges arose. For this reason, any

patient on CAR-T therapy in the James Cancer Center is provided with a card to present upon arrival to ANY ED. This details their therapy and possible side effects including complement release syndrome and neurologic side effects. The card also contains a number for outside hospitals to call for guidance on treatment. At the OSUWMC ED triage, a third screening question was recently added to help identify this population upon ED arrival. Other oncologic emergencies may be harder to identify. However, with the Oncologic Pod screening pod questions at triage, patients are immediately flagged as cancer patients upon arrival. This gives the Oncologic Pod physician and APPs, as well as the provider in triage, the opportunity to review the patient chart, chief complaint, and triage note. These providers are able to work with the triage nurses and charge nurses to expedite care of the cancer population including ordering CT scans, labs, or symptom control in triage. They can also increase or decrease the ESI or recommend that a certain patient get the next available treatment space if there is a concern for other subtle oncologic emergencies.

Other challenging scenarios that the Oncologic Pod has encountered include the arrival of patients without a clinical cancer diagnosis. An inpatient service was designed that handles the care for patients without a definite cancer diagnosis but identified as being at high risk for malignancy (i.e., new, large lung mass or abdominal mass). This facilitates the care of patients with a presumed diagnosis of cancer who may be attracted to the cancer ED, either based on outpatient imaging or as transfers from outside hospitals. This allows for patients who are not already receiving their cancer care at the James Cancer Center to be seen in the Oncologic Pod to facilitate transition of their care to the cancer center. Additionally, if patients do not require hospital admission for this work-up, a James Diagnostic Clinic can facilitate an expedited work-up for outpatients. The Oncologic Pod serves as the first point of contact of the James Cancer Center for one to two patients per day, so this is not an unusual scenario. While there is month-to-month fluctuation, this number has generally increased since the genesis of the Oncologic Pod in 2015.

As patient volumes rose over time, it became apparent that there was not only a growing need for emergent cancer care but also the need for acute, unscheduled visits. The acute, unscheduled visit encompassed patients who might need to see a provider, though do not necessarily need an ED encounter. This could range from fever in patients not on cytotoxic chemotherapies, anemia, thrombocytopenia, electrolyte abnormalities on routine labs that need follow-up, ED follow-up, or even clinic overflow when patients are not able to see their primary team. This necessitated the development of an additional eight-bed treatment space, the Immediate Care Clinic (ICC). The ICC is a 24/7 treatment space that opened in 2018. Patients established with the James Cancer Center, or in the process of establishing care, can be referred to the ICC by their provider, the ED, or the nursing triage line. Certain exclusion criteria were created to prevent those with true emergencies from arriving at the ICC. Such patients are redirected to the ED for emergent care. The ICC is staffed by the same APP group as the Oncologic Pod. It is overseen by the Oncologic Pod emergency physician. The ICC admission rate is consistently below 30%. It serves as an intermediary between the ED and outpatient worlds. This allows for lower acuity patients to be seen promptly when ED volumes are high and prevent unnecessary ED visits, increased charges to the patient, and increased overall healthcare costs.

It is one thing to establish an Oncologic Pod for cancer patients, and yet another to ensure that quality standards are being met. In order to assure that patient care is performed at the highest professional standards, there are regular evaluations of specific ED metrics. This occurs both at the level of the Department of Emergency Medicine and at the hospital level. A monthly scorecard containing information such as patient arrivals, door to provider, length of stay, admission rate, and new patient contacts is disseminated to the administration of both the hospital and ED. It is regularly reviewed by the Department of Emergency Medicine administration in conjunction with nursing leadership. It is also reviewed semiannually at the hospital level in forums such as the Patient Quality, Safety, and Reliability Committee and the Medical Staff Advisory Committee and with the Chief Medical Officer of the James Cancer Center. To ensure that patient voices are heard, patient experience representatives are available to speak with patients. Additionally, all patients who arrive are provided with a direct phone number to the patient experience representative line in the event they wish to express gratitude or concern about their ED stay. These accolades and concerns are reviewed and addressed on a weekly basis in a multidisciplinary meeting including patient experience, physician leadership, and nursing leadership. These measures ensure that high-quality care is being delivered to the patients and that all needs and expectations are met.

Current and Future Considerations for the Cancer Emergency Department

Increasing specialization has resulted in a fragmentation of medical care and cancer care is no exception. Many oncologic patients are treated by several physicians who are all specialists in cancer therapy. One patient may have one or more surgeons, a medical oncologist, a radiation oncologist, and a palliative care physician. This does not include other specialists for chronic issues or problems that develop during treatment, including cardiologists, nephrologists, endocrinologists, and pulmonologists. Patients are often confused as

to which doctor is "in charge" and whom to ask which question. The role of the emergency physician in a comprehensive cancer center has some similarities to that of a primary care physician. The ED physician often explains the roles of the different providers and facilitates communication between the various specialties involved in the patients' care. Another important role is that of a safety net, by providing care to the patients when they cannot wait for an office visit or when the office visit results in the discovery of a problem that is beyond the scope of the oncologist or specialist. In these roles, the ED supports both oncologists and patients. Physicians specializing in oncologic emergencies use unique skills and knowledge of potentially dangerous complications of different treatment modalities and the best supportive therapies as well as understanding of the disease process of multiple different malignancies and their associated emergencies. Also valuable are expertise in pain management, procedures commonly needed in cancer patients, and skillful management of palliative and end-of-life care. This skill set, which currently can only be obtained through experience, helps doctors who specialize in the acute care of cancer patients make decisions regarding the aggressive or supportive nature of care provided in the cancer ED.

Several themes are prevalent in the acute care of cancer patients. One of the concerns expressed by physicians seeking to provide acute care to oncologic patients is access to the complete medical record and the expertise of the oncologist. The ED physicians must have a significant understanding of the treatment paths and modalities of the patients they are seeing. In order to make appropriate decisions, communication must be available with the oncologist and other supportive services. With more knowledge and experience, the emergency physician can be more effective in support of the patients and the oncologists and be more confident in their independent decision-making. A method of documentation and a process of communication that make the primary oncologist aware of all visits to the ED are optimal. At MD Anderson, an online medical record documents the visit and outcome, and is accompanied by an e-mail notifying the oncologist of the emergency visit, closing the communication loop. Memorial Sloan Kettering has gone one step further by posting the ED tracking board throughout the institution. At the The Ohio State University Wexner Medical Center, oncologic teams are notified of emergent visits by e-mail. They are also available to discuss patient care in real time through a variety of modalities.

Another common concern is that caring for this group of patients is very labor intensive. These patients are often very ill; many of them are not independently ambulatory. Most of the patients are on multiple medications and have numerous comorbidities and several complaints. Due to the complexity of their illness, their stay in the ED is longer than that of other populations. Many of the patients require electrolytes or blood replacement as an incidental finding or the reason for the visit. These processes add to the time in the ED and the nursing workload. The ubiquitous admission rate of over 50% and the high mortality rate of patients admitted through the ED are further testimony to the high acuity level of the patients [3].

An ED that treats only cancer patients does not have to devise a triage method to identify the cancer patients from the non-cancer patients, and recognition of neutropenic fever, sepsis, and infection with underlying immunocompromised is routine. Other problems, such as managing intractable pain and mixing and adjusting large doses of opioids, are a frequent occurrence. However, these are issues that EDs—who want to support a large cancer population but cannot be dedicated solely to that population—contend with. A frequent issue more unique to a cancer ED is the arrival of patients with a recent diagnosis of suspected or confirmed malignancy. One of the challenges of working in a cancer ED is handling a group of patients with varying degrees of illness, varying knowledge about their condition, and different stages of diagnosis who have recently received difficult news and are emotionally charged. In all of the functioning cancer EDs interviewed, avoiding having the cancer ED serve as the intake portal for the cancer institute has been a common theme. Another frequent challenge is patients with late-stage cancer with no prior relationship to the parent institution. Many of these patients have received treatment at other centers and when told that no further treatment options exist, go to the cancer ED hoping for a salvation therapy. These patients are often too sick to be discharged and, without the evaluation of an oncologist in the emergency center, will ultimately be admitted to the hospital for an expert opinion and transition to supportive care or hospice. A consulting service that is available to see such patients in the ED would make this process more satisfactory.

Therapeutic procedures frequently utilized in cancer patients necessitate the development of certain services. Oncologic patients have a frequent need for invasive procedures such as thoracentesis, paracentesis, stenting, and percutaneous drainage. Some of these procedures can be done by ED physicians, but they are time-consuming and difficult to perform in a busy ED. Several institutions have dedicated teams to help facilitate these procedures. Another common diagnosis is the incidental finding of pulmonary embolus on CT scans. Many of these patients are handled in the emergency centers at Memorial Sloan Kettering, MD Anderson, and OSUWMC.

The optimal medical management of many cancer-related emergencies is an excellent area for further research. Many practice patterns are based on expert opinion or prior experience rather than clinical trials. Formal training for treatment of oncologic emergencies is still up and coming, though models do exist [12]. Otherwise, this skill set currently must be learned through work experience. Examples of frequently treated problems that could be better supported by research are treatment of hyponatremia and hypercalcemia of malignancy, rescue treatment of chemotherapy- or radiation-induced nausea and vomiting, chemotherapy- or radiation-induced diarrhea and mucositis, chemotherapy-induced peripheral neuropathic pain, pain related to colony-stimulating growth factors, dosage of steroids and radiation in malignant spinal cord compression, and acute management of narcotic-induced constipation. Other important areas include treatment of therapy-associated skin rashes and management of medical problems with unique complications, such as venous thromboembolism and acute coronary syndrome in thrombocytopenic patients and anticoagulation of patients who have metastatic disease to the brain.

In summary, the care model used for patients with oncologic emergencies must be tailored to the local medical and oncologic environment; therefore, it naturally follows that different medical systems have developed different processes to care for these patients. A constant among the models discussed here is the underlying goal of care being provided to these patients by clinicians who are knowledgeable about their needs and have integrated communication with the primary oncologists. Acute care of the oncologic patient is gaining recognition as an important area that could be improved upon with increased training, research, and emphasis on integration into the oncologic system.

Informatics

3

James P. Killeen, Christian J. Dameff, Jeremy S. Bass, Brian Khan, Ammar Mandvi, and Nathan Yung

Introduction

Clinical informatics is the study of information technology as it applies to clinical care within the health system. The American Medical Informatics Association (AMIA) considers informatics when used for healthcare delivery to be essentially the same regardless of the health professional group involved. *Clinical informatics* is concerned with information use in healthcare by clinicians. Clinical informatics includes a wide range of topics ranging from clinical decision support (CDS) to visual images; from clinical documentation to provider order entry systems; and from system design to system implementation and adoption [1]. In this chapter, our goal is to introduce the reader to new and old concepts that will allow the user to assess information and knowledge to meet the needs of healthcare professionals and patients. The reader will be able to characterize and evaluate information technology, so that they are better able to refine clinical workflow processes, develop new processes, implement those processes, and refine clinical decision support systems [2]. Knowledge of these elements will aid providers in clinical care to their patients. We will discuss workflow, clinical decision support, information technology systems, and communication, concluding with a discussion of cancer registries and research.

Workflow Process Redesign and Quality Improvement

Workflow has been studied both as a concept and a phenomenon. As a concept, workflow is defined as the sequence of physical and mental tasks performed by people within and between work environments. The flow of information, objects, and people using information and objects through space and time represents the phenomena of workflow. Clinical workflow studies aim to model a simplified version of work in the complex healthcare setting [3]. The simplification achieved by modeling aids in making complex systems more comprehensible as a result of the explanatory nature of such models [4, 5].

Multilevel perspectives are useful to understand workflow comprehensively in the complex system of healthcare [6]. Workflow can occur sequentially or simultaneously and at various levels (individual or organization). Workflow occurs interorganizationally, between clinic employees, and for individual employees before, during, and after a patient encounter. Cognitive workflow occurs as cerebral processes in collecting data and making decisions.

An example of workflow can be illustrated in the ordering of a medication. The workflow of ordering a medication includes communication between the provider and the patient, the provider's mental processes, and the physical action by the provider of writing the prescription on paper or electronically into an electronic health record and sending the order electronically or the patient taking the paper prescription to the pharmacy. In this example, one can see the use of cognitive, individual, organizational, and intraorganizational workflow.

Any time there is a change in practice, particularly related to health information technology, workflow changes occur. Delays in patient care, billing, and communication are prone to occur if the workflow is unaccounted for, overlooked, or oversimplified. All healthcare organizations, regardless of size, must identify a person or group to monitor and assess current and anticipated workflow. Workflow information should be collected as early as possible, ideally before implementing a health IT system, and continually assessed including post implementation as a form of continuous process improvement.

Workflow Analysis

Workflow analysis may be used to improve the outcome of healthcare processes and products, including the practice of healthcare informatics. Institute of Medicine landmark reports call for the use of workflow analysis in an effort to improve healthcare quality, efficiency, effectiveness, and safety [7]. Analysis of workflow requires a reduction of a complex process into analyzable parts in a stepwise fashion.

Various tools can be used during workflow analysis, and a single approach will likely capture a small subset of the complexity. Methods to capture workflow data include qualitative, quantitative, and mixed methods [8]. Qualitative methods focus on naturalistic observation of subjects and activities using artifact collection, spatial analysis, and interviews. Quantitative methods are a more structured approach. Time-motion studies can track the efficiency and quality of healthcare workflow, quantifying the time involved in tasks by observation, self-reporting, or automation to collect temporal data [9]. Questionnaires and surveys are also used as workflow analysis methods. Data collected from the electronic medical record including audit logs, a form of metadata, is a new and emerging area of data collection for workflow methodology.

Visualizing workflow is an important tool as it provides users with cognitive support for visualizing detailed processes, showing parallel processes and allowing different perceptions of processes [10]. The most common method of visualization is flowcharting (process mapping). Flowcharting shows how processes really happen, rather than how they are expected or supposed to happen. This method helps one understand what contributes to different types of flows for the same process, find ways to improve the flows, and identify ways that health IT will affect workflows. Flowcharting is accomplished in five general steps: (1) decide on the process to examine; (2) create a preliminary flowchart; (3) add detail to the flowchart; (4) determine who needs to be observed and interviewed; and (5) do the observations and interviews [11]. An example of a flowchart from a patient being diagnosed with cancer and undergoing treatment and follow-up is shown in Fig. 3.1.

Workflow Redesign

The goal of workflow redesign is to create workflow that supports improved outcome of workflow activities (patient care). Workflow reengineering requires deliberate steps including changes to the mental and physical steps of people who move through a workflow process and changes to the steps in the interactions among organizations involved in a process. Karsh and Alper suggested a system to ten steps of process redesign as seen in Table 3.1 [12]. Broadly, process redesign is achieved by assessing the current state, envisioning the desired future state, planning to get to the future state, carrying it out, and evaluating the outcome.

Quality Improvement

Quality improvement in healthcare is a continuous method for improving process performance. Several quality improvement methodologies are used in healthcare. The Plan-Do-Study-Act (PDSA) is a prominent method that leads quality improvement cycles. The "plan" phase includes identifying a problem and potential solutions. "Do" involves a polar testing of a solution. The "study" phase evaluates if the change was successful. "Act" involves adopting, adjusting, or abandoning the implemented solution. Lean is another process improvement strategy that emphasizes value to customers by utilizing root cause analysis to eliminate waste and improve process flow. Six Sigma is another process improvement methodology that emphasizes quantitative and statistical approaches in continuous quality improvement at the project level to reduce process variations and eliminate defects.

Conclusion

Workflow is the sequence of tasks performed by various people within and between work environments. Workflow analysis is an integral part of quality improvement implementation and health informatics. In this chapter, we have outlined workflow analysis tools, a framework for workflow redesign, and gave an overview of quality improvement methodologies.

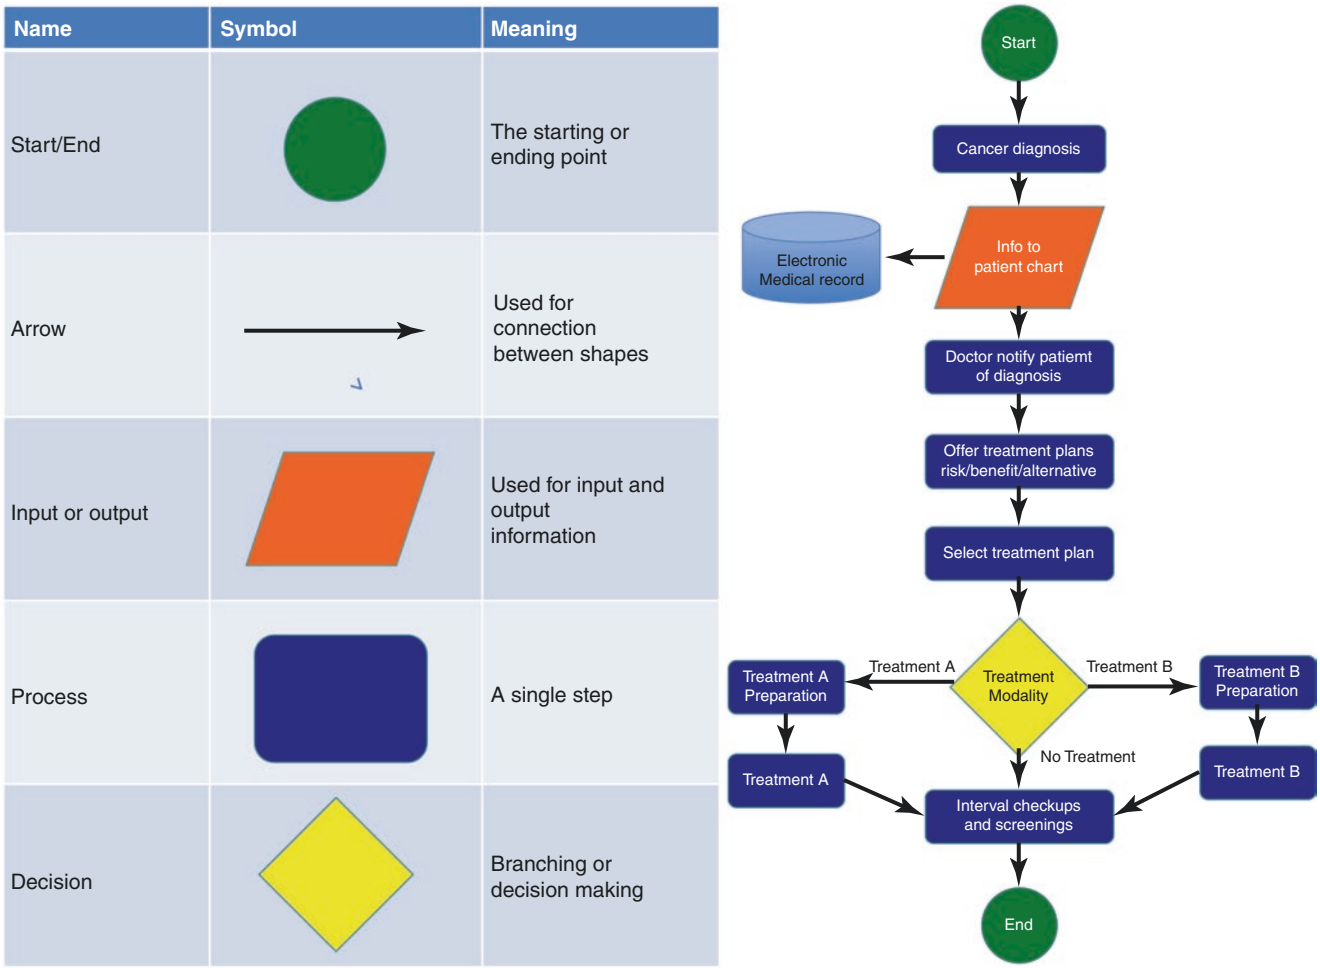

Fig. 3.1 Example flowchart of a patient being diagnosed with cancer, undergoing treatment and follow-up

Table 3.1 Karsh and Alper's ten steps of process redesign [12]

Ten steps of process redesign	
Step 1	Decide what system will be the subject of analysis
Step 2	Produce a preliminary work system map
Step 3	Use the preliminary workflow map to determine who should be represented on the team that will carry out the analysis
Step 4	Conduct an initial scan of the system with the team
Step 5	Determine boundaries of the system under study
Step 6	Determine performance expectations for each step in the system
Step 7	Begin formal data collection to review and update the workflow map. Gauge the current performance of the system, and determine baseline measures that will be used to evaluate the effectiveness of the redesign
Step 8	Analyze the data
Step 9	Once hazards (i.e., causes of failure modes or variance) have been identified, control strategies should be developed
Step 10	Analyze redesign ideas. Decide on a redesign idea, pilot testing, and implementation

Clinical Decision Support

The Office of the National Coordinator for Health Information Technology (ONC) defines clinical decision support (CDS) as providing clinicians, staff, patients, or other individuals with knowledge and person-specific information, intelligently filtered or presented at appropriate times, to enhance health and healthcare [13]. CDS are set of tools and logic to assist providers in making uncertain decisions. All medical decisions come with some percentage of uncertainty: diagnosis, testing, natural progression of disease process, treatment, and subsequent effects. CDS has evolved to remove some of the cognitive burden involved in medical decision-making.

There are some fundamental concepts we will review in order to leverage additional tools to aid in CDS. The first is the concept of expected value and expected utility. *Expected value*

(mathematical expectation, mean or average) is the random variable in a simplification of the weighted average and intuitively is the arithmetic mean of many independent realizations of that variable [14], whereas *expected utility* concerns people's preferences about choices that have uncertain outcomes (gambles). The expected utility states that the subjective value associated with an individual's gamble is the statistical expectation of that individual's valuations of the outcomes of that gamble, where these valuations may differ from the dollar value of those outcomes [15]. *Expected utility theory* is a theoretical approach to making optimal decisions under risk [16].

An example of these two concepts: in the presence of risky outcomes, a decision-maker does not always choose the option with higher expected value investment. Suppose there is a choice between a guaranteed payment of $1.00 and a gamble in which the probability of getting a $100 payment is 1 in 80 chances and the alternative, far more likely outcome (79 out of 80) is receiving $0. The expected value of the first alternative is $1.00 and the expected value of the second alternative is $1.25. According to expected value, people should choose the $100-or-nothing gamble; however, as stressed by expected utility, some people are risk averse enough to prefer the sure thing, despite its lower expected value. People with less risk aversion would choose the riskier, higher-expected-value gamble [15].

Expected value of gambling:

- If you gamble and win, you get $100.00.
- If you gamble and lose, you get nothing ($0.00).
- If you don't gamble, you are guaranteed $1.00.

$$\text{Formula}: \$100 * \left(\frac{1}{80}\right) + \$0 * \left(\frac{79}{80}\right) = \$1.25$$

Similar to engineering as it relates to healthcare, diagnostic inferences models have two elements: *tests* and *conclusions. Tests* include any source of information that can be used to determine the health of a system. *Conclusions* typically represent faults, including hardware fault modes, functional failures, specific non-hardware failures, and specific multiple failures. A conclusion may also indicate the absence of a failure indication (no fault). With this model, one can revise and refine opinions with imperfect information, comparable to a differential diagnosis. There are three characteristics to consider in making a diagnosis: detection, localization, and isolation, as defined in Table 3.2. In developing a diagnosis, the reader should focus on concepts emphasizing a structured approach to system testing and diagnosis. These include:

Table 3.2 Characteristics considered when making diagnoses

Characteristics	Definition
Detection	The ability of a diagnostic strategy to identify that a failure in some system has occurred
Localization	The ability to say that a fault has been restricted to some subset of the possible causes
Isolation	The identification of a specific fault through some test, combination of tests, or diagnostic strategy

- Maximizing reuse of design and test data, information, knowledge, and software
- Integrating support equipment and manual testing, to provide complete coverage of diagnostic requirements
- Integrating available diagnostic information, to minimize required resources and optimize performance

Capturing the relationships between tests and diagnosis provides a knowledge representation that can be processed by a reasoning system for health management. Initially, equal quality among test results is assumed and that every test outcome reflects the state of the unit being tested. In practice, this assumption is often relaxed to allow a measure of confidence to be associated with each test [17, 18].

Concepts of CDS include *heuristics*, which are patterns of bias in CDS. Heuristics is any approach to problem solving that employs a practical method that is not guaranteed to be optimal, perfect, or rational, but is nevertheless sufficient for reaching an immediate, short-term goal. Heuristics can be mental shortcuts that ease the cognitive load of making a decision [19]. Heuristics are the strategies derived from previous experiences with similar problems. These strategies depend on using readily accessible, though loosely applicable, information to control problem solving in people, machines, and abstract issues [20]. Some of the more common heuristics that apply to healthcare can be seen in Table 3.3 [21–27].

Cost-effectiveness analysis is a form of analysis that compares the relative costs and outcomes (effects) of different courses of action. Cost-effectiveness analysis is distinct from cost-benefit analysis, which assigns a value to the measure of effect. Typically, the cost-effectiveness analysis is expressed in terms of a ratio where the denominator is a gain in health from a measure (years of life, sight-years gained) and the numerator is the cost associated with the health gain. Cost-utility analysis can be used in decision analysis to define the "value" of an outcome node by adjusting the value of the outcome based on the perceived utility of that outcome for the patient. The most familiar outcome measurement is quality-adjusted life years (QALY) [28].

Table 3.3 Common heuristics in healthcare

Heuristics	Definition	Example
Availability	Overestimating the probability of unusual events because of recent or memorable instances [21]	*The last patient I saw with symptom X had disease Y, so we should test for Y*
Representativeness	Overestimating of a rare disease by matching patients to "typical picture" of that disease [22]	*He has features of the rare disease X, so we should test for it*
Anchoring	The failure to adjust probability of a disease or outcome based on new information, like "premature closure" [23]	*I was told in sign out that he had condition X, so I didn't consider it might be condition Y, despite lab results*
Value-induced bias	Overestimating the probability of an outcome based on value associated with that outcome [24]	*It would be horrible to miss a brain tumor in this patient with new onset headache, so we should get a head CT*
Affect heuristic	A mental shortcut that uses emotion to influence the decision. Emotion is the affect that plays the lead role that makes the decision or solves the problem quickly or efficiently. It may be used while judging the risks and benefits of something [25]	Your "gut decision" about the presentation of a patient
Familiarity heuristic	A mental shortcut applied to various situations in which individuals assume that the circumstances underlying the past behavior still hold true for the present situation and that the past behavior thus can be correctly applied to the new situation [26]	*I am familiar and comfortable with the Arrow Triple Lumen kit by Teleflex; I now need an arterial line kit, so I will choose the Teleflex brand since I am familiar with their other products*
Simulation heuristic	A simplified mental shortcut in which people determine the likelihood of an event happening based on how easy it is to mentally picture the event happening [27]	When the provider can easily "mentally undo" the sequence of events that led to a specific outcome like the placement of a chest tube or a cardiac arrest resuscitation

So, what makes a good test? Most would say a test with a high sensitivity and high specificity. Sensitivity is the measure of the proportion of actual positives that are correctly identified. Specificity is the measure of the proportion of actual negatives that are correctly identified. Sensitivity is the extent to which actual positives are not overlooked (minimizing false negatives), and specificity is the extent to which actual negatives are classified as such (minimizing false positives). The *positive predictive value* (PPV) and *negative predictive value* (NPV) describe the performance of a diagnostic test. A high result can be interpreted as indicating the accuracy of such a test [29]. The false-positive rate is the proportion of all negatives that still yield positive test outcomes, i.e., the conditional probability of a positive test result given an event that was not present. *False-positive rate* is equal to the significance level. The specificity of the test is equal to 1 minus the false-positive rate. *False-negative rate* is the proportion of positives yielding negative test outcomes with the test, i.e., the conditional probability of a negative test result given that the condition being looked for is present.

Of note, false positives should be differentiated from the phenomenon of *overdiagnosis* [30]. The finding of an insignificant pulmonary nodule or an adrenal "incidentaloma" on a chest CT ordered for a patient with a suspected pulmonary embolism is an example of overdiagnosis. The use of CDS tools has the potential to minimize, or at least standardize, the use of advanced imaging technology in such cases.

By reviewing the 2 × 2 tables shown in Table 3.4, we can design the most efficient CDS questions or tests.

Key elements of CDS are best described in a quote from Wyatt and Spiegelhalter: "Active knowledge systems which use two or more items of patient data to generate case-specific advice" [31]. More specifically, leveraging a good foundational knowledge base along with patient-specific information such as vitals or laboratory results and using the most appropriate mode of communication will assist the user to make the most appropriate choice. As the user designs and builds their CDS, it is important to consider the following targets:

1. What are the desired outcomes/clinical targets of CDS?
2. How will the CDS tool improve efficiency?
3. Are we looking for early detection/screening of the CDS?
4. Can CDS assist in the diagnosis or treatment protocol?
5. Can CDS provide preventative adverse outcome?
6. Can CDS provide follow-up management?
7. How does CDS provide cost reductions/conveniences?

Other design considerations should include the target audience. Which member of the healthcare team is the target for CDS? Is the intervention targeted to patients or families? Also consider the level of control of the CDS (preemptive, suppressible, hard-stop, or interruptive). Preemptive or active CDS is a rule based upon simple logic or systems-based upon probability. Active CDS includes rules and alerts. Respectively, hard-stop or suppressible control levels either prevent the user from taking an action altogether or allow them to proceed only with the external override of a third party. Interruptive CDS occurs when a process is interrupted

Table 3.4 Table to derive sensitivity and specificity

Total Population	Condition Positive	Condition Negative	Prevalence
Predicted Condition Positive	***True positive***	***False positive***	Positive Predictive Value $\frac{True\ Positives}{True\ Positives+False\ Positives}$
Predicted Condition Negative	***False Negative***	***True Negative***	Negative Predictive Value $\frac{True\ Negatives}{False\ Negatives+True\ Negatives}$
	Sensitivity $\frac{True\ Positive}{True\ Positives+False\ Negatives}$	Specificity $\frac{True\ Negative}{True\ Negatives+False\ Positives}$	
	False Negative Rate $\frac{False\ Negatives}{True\ Positives+False\ Negatives}$	True Negative Rate $\frac{True\ Negatives}{False\ Positives+True\ Negatives}$	
True positive	Sick people correctly identified as sick		
False positive	Healthy people incorrectly identified as sick		
True negative	Healthy people correctly identified as healthy		
False negative	Sick people incorrectly identified as healthy		

Table 3.5 Example categories of clinical decision supports

Therapeutic duplication
Single and cumulative dose limits
Allergies and cross allergies
Contraindicated route of administration
Drug-drug and drug-food interactions
Duplicate orders
Contraindications/dose limits based on patient diagnosis, age, weight, prior laboratory, or radiology studies

and requires the user to acknowledge its information by taking one or more actions, such as in computerized order entry (CPOE) systems. Three types of interruptiveness are on-demand (link to formulary from within order), in-line or modeless (unread lab result notification on sidebar), and popup or modal (alerts or reminders requiring acknowledgment).

Table 3.5 shows some examples of CDS categories.

When designing CDS, the user should always ask themselves the following questions to make sure they have addressed the five "rights" to assess their success [32]:

1. Right information – quality of knowledge base
2. Right person – target of CDS
3. Right format – implementation of CDS (speed, ease of use, comprehensibility)
4. Right channel – mode of CDS
5. Right time – workflow integration

Do I have the right information for the question? Have I accessed the right knowledge base and provided the correct resources and references? Who is my target audience, and have I reached them successfully? Do I have my question in the right format? Am I providing them with knowledge only, or is my aim to stop the user's process or redirect them? Do I have my CDS in the correct spot to provide the user the correct additional knowledge to make an informed decision?

Having created a CDS plan or outline, the user will most likely need to submit a proposal to a CDS committee that oversees all CDS and provides continuous feedback for the system. Many institutions may have forms to complete or submit. You will see in Fig. 3.2 that the example CDS form request follows the "5 Rights."

David Bates summarized the goals and expectations for CDS in his 2003 AMIA article (Table 3.6) [33]. He believes it is key that information systems provide decision support to users at the time they make decisions, thus promoting improved quality of care. Providers make many errors, and clinical decision support should help identify and avoid such errors.

Clinical Decision Support Request Form

Person submitting the request	
Purpose of goal for the CDS	
Evidence-based need	**RIGHT** information *What are the clinical grounds and supporting evidence for the CDS?*
Intended audience	**RIGHT** person *Who will see it? - e.g., physicians, RNs, pharmacists, etc.*
Clinical champion(s)	*Who will be the clinical champion (s) responsible for the success of implementing this alert?*
Primary stakeholders	*Who are the primary group (s) or committee (s) that have a stake in this CDS? This is important, as they may need to sign off prior to enabling CDS.*
Established level of consensus?	*Do we know whether stakeholders all agree on need for CDS?*
Clinical criteria for the CDS	**RIGHT** time – workflow integration *When should the CDS be triggered?*
Impact on patienr care	*What is expected to change as a result of the CDS?*
Impact on workflows	**RIGHT** channel – mode of CDS *What groups, activities and workflows is the CDS limited to? What is the frequency that it will occur?*
Urgency	*What is the urgency for this CDS? Why is it urgent?*
Monitoring success of the CDS	**RIGHT** format – implementation of CDS (speed, ease of use, comprehensibility) *What specific outcomes will be used to determine success of the CDS?*
Future clinical review	*What is the expected frequency and method for future clinical review of the CDS?*

Fig. 3.2 Example of a clinical decision support (CDS) form request that follows the "5 Rights"

Table 3.6 Ten commandments for effective clinical decision support [33]

1.	Speed is everything – expect sub-second latency
2.	Anticipate needs and deliver in real time – e.g., showing relevant labs with med orders
3.	Fit into users' workflow – external tools are not as good as those at POC
4.	Little things can make a big difference – "usability matters – a lot," "make it easy to do the right thing"
5.	Physicians resist stopping – do not tell doctors to not do something without offering an alternative
6.	Changing direction is easier than stopping
7.	Simple interventions work best – try to fit guidelines onto a single screen
8.	Asked for additional information when you really need it – "likelihood of success is inversely proportional to the number of extra data elements needed"
9.	Monitor impact, get feedback, and respond. Evaluate your CDS
10.	Manage and maintain your knowledge-based systems. Keep up with clinical care

Information Technology Systems

Telehealth

The desire to constantly improve the access, delivery, and quality of healthcare has resulted in the application of novel technologies to nearly all domains of medicine. Telehealth, also referred to as telemedicine, is defined by CMS as the electronic transmission of patient information from one distant site to another and has evolved to also include electronic communication between patients and providers in order to facilitate healthcare. Telehealth can employ many different types of technology to achieve patient to clinician communication including telephonic, short message service (SMS), fax, email, and real-time audio-video communication utilizing Internet connectivity and computers.

The utility of telehealth is vast and constantly evolving. Commonly cited benefits include improved clinician access in rural areas where such expertise is not available, decreased healthcare costs, and increased healthcare system workforce resilience, as well as patient and provider convenience [34]. During the COVID-19 pandemic, telehealth was utilized as a mechanism to reduce the use of one-time use personal protective equipment [35]. Some patients report preferring telehealth in place of traditional in-person visits for certain encounters, such as for birth control prescriptions [36]. Immunocompromised patients, including oncologic and rheumatology patients, have utilized telehealth to limit pathogen exposure associated with in-person visits at healthcare facilities.

Case Study 1

A 65-year-old female with a history of acute promyelocytic leukemia (APL) presents by ambulance to a rural hospital emergency department (ED) with complaints of altered mental status and worsening rash. Her husband at bedside reports 1 day of fever, increasing confusion, and, most recently, epistaxis. On examination of her skin, a diffuse petechial rash is discovered.

The clinician at bedside recognizes the patient is likely in disseminated intravascular coagulation (DIC) likely due to her APL. Basic supportive interventions are initiated, and diagnostic testing is ordered to confirm the suspected diagnosis. The clinician recognizes that this patient would benefit from specialty consultation and transfer to a higher level of care. A tablet computer mounted on a bedside cart is then used to connect a live video communication with an oncologist hundreds of miles away. After consultation with the oncologist, a live encounter with the patient and spouse is performed by the remote physician. Written treatment recommendations are captured and electronically transmitted by the electronic health record (EHR) from the oncologist to the emergency physician, and transfer to a quaternary care center is initiated.

History of Telehealth Although telehealth is widely used today all across the globe, its origins began over 60 years ago with the application of live video to facilitate psychiatric evaluations [37]. The National Aeronautics and Space Administration (NASA) researched telehealth heavily throughout the 1960s–1970s, culminating in pilot studies delivering healthcare to astronauts during space travel [38]. The birth of the Internet in the early 1990s, coupled with increased use of consumer video conferencing applications such as Skype in the early 2000s, further advanced the adoption of real-time audio-video communications as a way to deliver healthcare.

Today, there are hundreds of software and hardware telehealth products and services. Many telehealth encounters are performed on smartphones or tablet computers, as such devices have become ubiquitous in many parts of the world. The integration of telehealth with remote biometric sensor technology has also created new opportunities, such as telehealth intensive care units (ICU) and remote stroke consultation. Although many clinicians today do not incorporate telehealth into their practice, some have elected to only practice by telehealth, often citing increased flexibility and consumer demand.

Technology The safe evaluation and care of patients in any environment or by any medium requires some basic standards in place, such as clear audio, adequate visuals, and

timely data access. These specific standards initially led to the development of specialized telehealth hardware such as high-definition cameras and microphones. Early hardware was often large, bulky, fragile, and expensive. Early telehealth efforts were hindered by lagging pixelated video and fragmented audio. As Internet bandwidth increased and wireless technology decreased barriers to bringing devices to patients' bedsides, older hardware was replaced with smaller, cheaper, and better-quality devices, often affixed to carts.

Along with advances in hardware came new specialized healthcare software: the electronic health record (EHR). The replacement of paper medical records by digital records further aided telehealth adoption, as patient records could be stored on servers or in the cloud to be accessed by clinicians quickly and remotely. Most modern EHRs also support computerized provider order entry (CPOE) allowing rapid electronic ordering and reporting of diagnostic tests and ordering of medication prescriptions. Some EHR vendors have now started building telehealth directly into their products.

Telehealth Regulation Telehealth in the United States, like much of healthcare generally, is highly regulated at both state and federal levels. Restrictions on telehealth traditionally fall under three main categories: allowable locations/applications, requirements of service, and billing. Rural patients without access to robust care were seen as the greatest beneficiaries of telehealth. This led to regulations limiting telehealth services in urban areas where the need was postulated to be less. Furthermore, limits on what types of encounters (ambulatory vs. inpatient) qualify for telehealth are commonplace. The requirements of service are also used to tier the classification for reimbursement of telehealth. For example, a simple telephone audio-only call may not qualify as telehealth despite robust history gathering. Regardless of what type of telehealth tier is being utilized, the patient must verbally consent to telemedicine services. The business viability of telehealth has heavily relied on reimbursement policy set by agencies such as the Centers for Medicare & Medicaid Services (CMS). Many telehealth services are not reimbursed at the same rates as corresponding in-person encounters.

Many federal and state telehealth regulations were revisited and changed to respond to the COVID-19 pandemic of 2020. This led to the single greatest expansion of telehealth services in history and ushered in a new era where telehealth is commonplace and widely accepted. One of the most notable changes regarded the enforcement of patient privacy and security requirements from the 2009 Health Insurance Portability and Accountability Act (HIPAA). Although HIPAA still applies broadly, the enforcement of high encryption standards in video conferencing software was deferred. This allowed free consumer-focused telecommunication applications such as Skype (Microsoft Inc., Redmond Washington), Zoom (Zoom, San Jose California), and Hangouts (Google, Mountain View California) to be used instead of expensive niche telemedicine platforms.

Oncologic Emergencies and Telehealth The use of telehealth in the prevention of oncologic emergencies is growing. Telehealth may be deployed to reduce exposure to infectious disease in cancer patients at higher risk (e.g., immunocompromised), and telehealth has the obvious potential to reduce ED visits among cancer patients. Telehealth can also facilitate continuity of clinician-patient care, bringing in valuable context from the patient's own specialist when traveling. Remote video consultation and evaluation by oncologic specialists in both regular and emergent capacities can also aid in the diagnosis and treatment of patients. Many rural locations lack robust medical care systems and specialist oncologic expertise can be scant. Much more research is needed on the impact of telehealth on patient outcomes.

Conclusion Telehealth provides powerful tools in the care of oncologic patients during emergencies. Rapid technological developments will continue to change how clinicians care for patients. Changes in the regulation of telehealth have greatly expanded its applications and viability as a regular component of healthcare in the twenty-first century. Leveraging telehealth to assist in the care of patients with oncologic emergencies will prove more common and more powerful in the years to come.

Security

As healthcare continues to innovate and advance, the use of technology to care for oncologic patients continues to evolve and grow. From Internet-connected medical devices to artificial intelligence and machine learning, healthcare is increasingly digitized, connected, and complex. In this era of hyper-connected healthcare, it is important to focus not only on the care of oncologic patients but also on cybersecurity and privacy of sensitive patient data.

Case Study 2

After a long and busy shift in the ED, an attending physician posts on social media the following statement: "Just had the honor to treat one of our nation's last surviving World War II veterans in the Emergency Department at General Hospital! Despite his chronic lymphocytic leukemia, Albert is going to be okay! #VeteransRock #CancerSucks." The next day, he is

Table 3.7 18 HIPPA patient identifiers

Name
Address (all geographic subdivision smaller than state, including street address, city-county, and zip code)
All elements (except years) of dates related to an individual (including birthdate, admission date, discharge date, date of death, and exact age if over 89)
Telephone numbers
Fax number
Email address
Social Security number
Medical record number
Health plan beneficiary number
Account number
Certificate or license number
Vehicle identifiers and serial numbers, including license plate numbers
Device identifiers and serial numbers
Web URL
Internet Protocol address
Finger or voiceprint
Photographic image – photographic images are not limited to images of the face
Any other characteristic that could uniquely identify the individual

called into an administrator's office and is subsequently terminated from his employment for violating the hospital privacy policy.

Health Insurance Portability and Accountability Act (HIPAA) The Health Insurance Portability and Accountability Act (HIPAA) was a law passed by the US Congress in 1996 that, among other things, provided regulation around the security of protected health information (PHI) [39]. Beyond defining PHI, this law provided 18 "identifiers" (Table 3.7) constituting sensitive data elements that can be used to identify and subsequently violate the privacy of patients. Additionally, the law established a reporting and enforcement mechanism to ensure parties responsible for protecting PHI could be heavily fined if they suffered a breach or were negligent in securing the data.

Today, HIPAA continues to be a very important part of healthcare regulation. It remains regularly enforced, leading many hospitals to devote significant resources to the protection of PHI and compliance with federal regulation. When PHI is lost or exposed, it is termed a breach. Breaches of greater than 500 patient records often result in mandatory reporting to the federal government as well as the patients whose records were compromised. Common causes of breaches include (1) failure to dispose of paper records properly, (2) loss of computers containing PHI, (3) hacking of records by malicious actors, and (4) loss or records by a third party that was trusted with records (e.g., healthcare contractor or business affiliate).

Conclusion In the care of oncologic patients, as with other patients, the security and privacy of their PHI is important. As healthcare continues to become more digitized, the risk of exposing this information increases. Federal law protects patient data privacy, and failure to protect these data can lead to significant harms to patients, providers, and organizations. Oncologic patients can be at particular risk of PHI breach as they are often high utilizers of healthcare resulting in more records and can carry sensitive diagnoses.

Communication

Order Sets

AMIA defines an *order set* as a predefined template. Order sets are lists of orders that frequently include medication, laboratory, nursing, diet, activity, and other orders. They existed prior to the advent of electronic health records as paper templates. A common example is an admission order set. This would frequently include an admission order, a diet order, nursing orders, vital signs, activity orders, IV orders, medication orders, laboratory orders, radiology orders, consultation orders, and provider preferences. Order sets allow physician to easily select from commonly used orders to save time and ensure consistency for certain procedures, such as a surgery, admission, or discharge [40].

AMIA indicates that order sets have been "…the standard of care in hospitals for many years. While in the past, it took the form of pen and paper, today, it is, indeed, electronic" [41]. The Institute for Safe Medication Practices (ISMP) has developed guidelines around order sets [42]. The ISMP indicates that well-designed order sets have the potential to "integrate and coordinate care by communicating best practices through multiple disciplines, levels of care, and services, modify practice through evidence-based care, reduce variation and unintentional oversight through standardized formatting and clear presentation of orders, enhance workflow with pertinent instructions that are easily understood, intuitively organized, and suitable for direct application to current information-management systems and drug-administration devices, decrease the potential for medication errors through integrated safety alerts and reminders, and reduce unnecessary calls to prescribers for clarifications and questions about orders" [42]. The ISMP goes on to state that order sets that "are not carefully designed, reviewed, and maintained to reflect best practices and ensure clear communication, they may actually contribute to errors" [42].

The astute observer will note that order sets have been used for many years to standardize workflows, remind providers, and make suggestions about clinical care that has been vetted by best practices and evidence. In the case of patients presenting to the ED, oncologic patients present a

unique challenge. These patients are frequently immunosuppressed, which leaves them susceptible to several unique conditions, such as those infections that only spread in the immunocompromised state (i.e., neutropenic fever) and that may present with various metabolic derangements, such as tumor lysis syndrome. Given the infrequency with which emergency physicians encounter these conditions and the morbidity and mortality associated with them, these cases are ripe for use of order sets. Oncologic emergencies also demonstrate the need for collaboration in design of order sets. Many large healthcare organizations have informatics teams of healthcare practitioners that work in concert with information systems (IS) personnel to develop content for their electronic health record (EHR). The oncologic emergency is an example where various stakeholders and specialties work together to develop content. Polling providers for preference, along with scouring the literature for recommendations and guidelines, is often the first step in designing an order set. Usually one or more clinical "champions" are identified to begin the process of consulting literature, guidelines, experts in the domain, and practitioners in the affected departments. Their next step is usually to form a working group of affected stakeholders. In this case, ED providers, oncologists, and nursing would likely comprise the group. The two specialties would then discuss recommendations for order sets and request feedback from their respective departments. Much like the legislative reconciliation process, the groups then rejoin, find common ground, and resolve differences. This design would then be submitted to IS for testing and, later, implementation. Once implemented, as indicated by the ISMP, a properly verified and scrutinized order set has the ability to standardize and improve care.

Transition of Care Tools

The order set itself is one way of communicating care standards. The literature on emergency physician to ambulatory provider and vice versa communication is sparse, but it demonstrates differences in communication preferences [43]. Transitions of care are a topic of much discussion and are heavily scrutinized by The Joint Commission [44]. This is especially the case after an ED visit. While not all visits to the ED or hospital are avoidable, there has been increased attention in recent years on avoiding as many visits as possible.

One factor contributing to avoidable ED visits is provider-to-provider communication. Open and clear communication decreases errors and costs [45]. Some health systems have found communication to be so important for patient care that caseloads have been limited to ensure that provider-to-provider communication takes place [46]. With all the focus on communication, one might assume this problem would have been resolved. However, communication is regularly cited for the last 15+ years as one of the major factors in malpractice cases, regulatory citations, and poor patient reviews [47].

Healthcare organization management has taken this seriously and imagined a variety of solutions. After the HITECH Act was signed into law, electronic health records (EHRs) adoption greatly increased. It was theorized that EHRs would foster provider-to-provider communication. Communication increased, but it was mostly asynchronous communication (i.e., email, text messages, assigning providers to notes, etc.). This was a different form of communication than existed previously, which was largely sharing information face-to-face or via telephone [48]. If these communications methods were equal in terms of patient care, this chapter would end early. Interviewees have indicated that EHRs allow for easier and more frequent asynchronous communication, though this does not remove the need for physician-to-physician communication. Learning from each other is much less likely to occur through an email as opposed to a phone call. Proposed solutions involving the EHR include building infrastructure to allow for "preferred mode of contact" and standardizing communications [48]. EHRs may assist with this, but if the workflow hasn't been designed prior to initiation, it's easy for staff to use more and more asynchronous communication.

In addition, proper configuration of EHRs is necessary to ensure that the right information flows to the right person, in the right format and channel, at the right time. These rights are collectively known as the "5 Rights of Clinical Decision Support" [49]. This is usually referenced regarding tools in the EHR, though the rights apply to any information in an EHR. Globally, it applies to communication in general. The authors recommend a similar approach to that applied for workflow analysis, order set design, and other aspects of informatics. This is to perform a thorough analysis of the situations in question, engage stakeholders and leaders, form consensus, test, implement, and review. The advantage of engaging leaders (or the early adopters) in the department or division is the outsized influence they may have on those resistant of adoption. It equally applies in the design of EHR implementation, design, and flow of information. It is *critical* to find the consensus on the preferred method of communication. When differences occur, technology may assist to resolve the issue of differing preferences.

At the authors' institution, the EHR was utilized to engage clinicians, administrators, researchers, and stakeholders by considering a patient visit for particular specified reasons as a "unit of communication." For a given patient visit, different stakeholders wished to be notified in different ways. Some clinicians preferred a text notification, while others preferred an email. Administrators preferred a spreadsheet or interactive database. Informatics personnel coordinated with lead-

ership in IS, the ED, ambulatory space, and leadership to develop a system that would create reports and send notifications to a group of providers. Review of the system after implementation demonstrated increased satisfaction for all parties involved. An additional bonus was closer to real-time data on those presenting to the ED for the identified reasons. Before this system, monthly SQL queries were necessary to create spreadsheets and graphs to monitor patient care. The new system utilized EHR tools and allowed those involved in care to easily identify the individuals affected, as well as relevant data to inform care processes.

The agreement on the pre-implementation of this plan led to less utilization of resources to better understand trends in the healthcare system. It also led to improved adherence with notification, as the prior system would not always notify the provider. Prior to implementation, ED staff was to send a secure email to the identified individuals. Adherence with this was poor, as the event was not common enough for the ED providers to implement the event in their workflow. For a variety of technical reasons, an order set for this scenario could not be implemented. However, enhanced communication was fostered utilizing the methods outlined in this chapter.

Research and Registries

Cancer Registries

A cancer registry is an information system that collects and analyzes data from a census of cancer cases. Registry data can be used to define and monitor cancer incidence, investigate treatment patterns, evaluate efforts to prevent cancer, and improve survival [50]. This allows public health officials and healthcare professionals to be apprised of cancer-related measures used to guide cancer prevention and control efforts.

Cancer data are collected in two different types of registries. Population-based registries are tied to state health departments, while hospital registries are a part of a healthcare organization's cancer program [51]. Population-based registries collect information on all cases within a certain geographic area from multiple reporting organizations including hospitals, doctors' offices, nursing homes, clinical labs, and ambulatory care organizations, as well as chemotherapy and radiation treatment centers. Hospital registries provide more complex data used to assess clinical care at a particular hospital. These data typically guide education of healthcare providers and focus on patient care. Pooled data can be used to observe trends with specific populations, providers, or locales [52, 53].

Cancer registrars with standardized training aid in collecting data for cancer registries. Registrars prepare accurate and timely data that is reported to the registry. Identifying individuals with cancer, or *casefinding*, is the first step in cancer registration. This is initiated during clinical care when physicians note the cancer site, type, stage, and patient demographics in the medical record. Registrars summarize and record other information for certain registries, such as treatments and follow-up to record recurrence and survival data [52]. The HITECH Act, through the electronic health record meaningful use program, incentivized case-based reporting.

Cancer Surveillance Programs

In 1971, the National Cancer Act was established which mandated collection, analysis, and sharing of cancer patient data in the United States for research, detection, and treatment of cancer. The National Cancer Institute established the first national cancer registry, the Surveillance, Epidemiology, and End Results (SEER) program, in 1973. This large population-based system of cancer registries provides data on cancer incidence, mortality, treatment, and survival [51, 53]. Data are collected regionally, representing 28% of the US population [51].

In 1992, the US Congress established the Cancer Registries Amendment Act which authorized the Centers for Disease Control and Prevention (CDC) to provide regional assistance to improve cancer registries, implement registries in absent regions, model legislation, provide training for registry personnel, set standards, and aid in establishing a reporting and data processing system. The National Program of Cancer Registries (NPCR) was established to accomplish these goals and supports cancer registries in 45 states, representing 96% of the population [53]. The NPCR and the SEER program, together, collect data for the entire United States.

Together with data regarding cancer incidence and death rates, cancer survival measures provide a comprehensive picture of the burden of cancer in a population and support public health efforts to prevent new cancers, extend survival and quality of life after a cancer diagnosis, and reduce cancer health disparities [50].

Quality Measures

4

Tracy E. Spinks and Michael G. Purcell

Case Study: Addressing Unmet Palliative Care Needs in the ED

The medical director of an emergency department (ED) at a tertiary care center reviewed admission data for his cancer population. Over the past 12 months, he—along with colleagues—noticed a trend toward increasing admission rates in this population. On further evaluation of the primary admission diagnoses, the director found that many patients were being admitted for symptom control and palliative care consults. This equated to increasing admissions with prolonged hospital stays and contributed to consistently high hospital capacity. With the resultant decreased bed availability, the other admitted ED patients had longer wait times to arrive in an inpatient bed. The downstream effects directly contributed to ED boarding, longer ED wait times, and decreased patient satisfaction.

To address the issue, the director pulled together a focus group of providers to discuss the daily challenges surrounding cancer patients admitted for symptom control and palliative consults. It became apparent that often there is both discomfort and unfamiliarity of ED providers when it comes to dosing narcotics and antiemetics in this population as they are frequently on long-acting opioids and high doses of breakthrough medicines at home. The focus group expanded to include a member from the division of palliative care. A joint effort led to the creation of palliative care rounds, where the palliative care service would stop by the ED every morning to check in with care providers and assist with any question on symptom control for currently active patients. Additionally, the palliative care service worked to prioritize consults from the ED to help with early, aggressive symptom control and goals-of-care discussions. The primary goal was to improve symptom control and earlier palliative care access among cancer patients, as measured by two metrics: (1) hospital admissions among cancer patients for symptom control and palliative care consults and (2) palliative care consults in the ED.

After a 3-month pilot, the director reviewed the data. Admissions for symptom control and palliative care steadily declined over the 3 months, while palliative care consults in the ED steadily increased. Unintended benefits of the program led to improved emergency provider comfort with higher doses of narcotics and long-lasting opioids, improved relationships with the division of palliative care, and improved patient satisfaction with symptom control. The data were shared at the hospital's quality forum and hailed as a huge success.

Introduction/Background

Quality issues in oncologic emergency care are well-known. Common ED concerns include overcrowding, long wait times (perceived and actual), boarding, ambulance diversions, inadequate access to specialists, and patient handoffs. Additionally, some issues (e.g., receiving a late-stage cancer diagnosis in the ED) are not directly related to the quality of emergency care. Instead, they reflect broader cancer quality issues, such as inadequate access to and utilization of cancer prevention and diagnostic services, insufficient care coordination, fragmented healthcare delivery, poor symptom management, and underutilized hospice and palliative care services.

To address these and other healthcare quality issues, state and federal agencies have adopted quality measures assessing the underlying structures, processes, and outcomes of care for accountability, public reporting, and value-based payment programs. Despite the inherent appeal of public reporting and transparency of healthcare quality, there remains minimal evidence that public reporting of healthcare

quality measures improves overall healthcare quality, reduces utilization, or influences healthcare consumer behavior [1–3]. In view of these observations—and to chart a path forward—it is important to consider the health policy and practice patterns that have contributed to historical issues with healthcare safety, appropriateness, effectiveness, and quality.

This chapter examines the history, current state, and desired future state of health policy for quality in oncologic emergency care. It explores known quality issues and upstream drivers and highlights the important role that quality measures can play in addressing these issues. Additionally, it outlines recommendations for measuring quality in oncologic emergency care and proposes healthcare policy changes and quality measures to drive these changes. Finally, it includes a sample case study describing how ED providers can partner with palliative care providers to reduce ED visits.

History and Current State of Health Policy for Quality in Oncologic Emergency Care

Emergency care lacks formal health policy to support the unique needs of patients with a cancer diagnosis. Existing health policy focuses on providers' duty to treat patients in an emergency along with patient access to emergency medical care. This section describes two key drivers of current health policy for emergency medicine—the no-duty-to-treat principle and the Emergency Medical Treatment and Active Labor Act (EMTALA). The sections that follow explore known issues in oncologic emergency care, contributing factors, and historical efforts to measure the quality of US emergency care.

The No-Duty-to-Treat Principle and the Emergency Medical Treatment and Active Labor Act (EMTALA)

The no-duty-to-treat principle—the controlling law in the USA for over a century—gives physicians significant autonomy in determining which patients they will serve [4]. Several state court cases have supported this principle and have generally held that duty-to-treat begins when the patient-provider relationship is established, regardless of whether the relationship is expressly agreed [5–10]. While the no-duty-to-treat principle remains the controlling law, federal and state entities have established safeguards—through statutes, regulations, and court cases—to prevent discrimination and to ensure access to emergency care [4, 11–18].

Enacted through the Consolidated Omnibus Budget Reconciliation Act of 1986 [19], EMTALA remains the most influential US law affecting emergency care. An "antidumping" law, EMTALA prohibits discriminatory practices in emergency care. The law obligates Medicare-participating hospitals with dedicated EDs to screen, stabilize, and, where necessary, accept transfer patients, regardless of insurance status, ability to pay, or existing relationship with the facility. EMTALA prohibits the transfer of medically unstable patients for any reason except medical necessity (e.g., for specialized emergency care that is unavailable at the transferring facility). EMTALA's screening, stabilization, transfer, and recipient provisions are considered absolute unless modified due to a disaster or public health emergency, such as the 2019 novel coronavirus outbreak [20, 21]. Violations carry heavy fines and can lead to suspension from the Medicare program.

Over time, EMTALA's provisions have been clarified through regulations, court cases, and statutes, including the Patient Protection and Affordable Care Act of 2010 (ACA). These actions clarified hospital responsibilities to staff on-call specialists and defined the physical locations that fall within EMTALA's jurisdiction. Importantly, protections under EMTALA do not apply to outpatients with scheduled nonemergency procedures, and hospitals' stabilization and transfer rights and duties terminate once a patient is admitted as an inpatient [4, 22–31]. Many EMTALA provisions remain controversial. For example, EMTALA facilitates critical access to emergency care but makes no provision for reimbursement of that care. Uncompensated emergency care exceeds uncompensated inpatient and outpatient care combined [32] and remains the burden of emergency care providers [33, 34]. Additionally, EMTALA does not address quality of care. Thus, as long as emergency care is delivered in good faith, misdiagnosis, delays, and medical negligence do not constitute EMTALA violations. EMTALA's stabilization obligations are considered absolute, even when such care is futile due to an underlying condition or when it conflicts with standard of care or a physician's moral and ethical judgment [4, 26, 30].

In summary, the no-duty-to-treat principle and EMTALA represent a strong policy framework to ensure patient access to emergency medical care in the USA. Nearly 35 years after its passage, EMTALA continues to provide essential protections to the nation's most vulnerable residents—the uninsured, underinsured, and disenfranchised—by prohibiting discriminatory emergency care. EMTALA's lasting consequence is the transformation of the US emergency care system into a de facto safety net to address access and financial barriers to primary care. A predictable, albeit unintended, outcome is that EDs are overloaded and inadequately funded to comply with this federal mandate [35]. This compromises

the quality and accessibility of emergency care for all patients, including those with a cancer diagnosis. Quality issues for oncologic emergency care are described in the next section of this chapter.

Known Quality Issues

In pursuing emergency care, patients with a cancer diagnosis encounter a mix of quality issues—both oncologic-specific and generalized. Moreover, many of these issues arise from inadequate access to care or quality issues in primary care and outpatient settings. Six issues that affect cancer patients in the emergency setting are described below: (1) late-stage cancers presenting to the ED; (2) overutilization of emergency services; (3) overcrowding, boarding, and diversion; (4) high costs at the end of life; (5) patient dissatisfaction with emergency care; and (6) caregiver burden. Specific issues for dedicated oncologic EDs are also discussed in this section.

Late-Stage Cancers Presenting to the ED

In a well-coordinated healthcare system, patients receive routine primary care and guideline-based cancer screenings, and cancer is diagnosed at an early stage in the primary care setting. However, many undiagnosed cancers present to the ED each year [36–40], with 11% of breast, prostate, colorectal, and lung cancers diagnosed in US EDs from 2004 to 2013 [41]. This is problematic for several reasons. First, these patients often present with generalized symptoms (e.g., nausea and vomiting, fatigue, and bleeding) that may indicate multiple underlying conditions. Moreover, emergency physicians may lack established relationships and a comprehensive medical background for these patients. Therefore, an accurate diagnosis and treatment may be further delayed until the patient seeks follow-up outpatient care or returns to the ED with continued symptom escalation. Second, cancers diagnosed in the ED tend to be of later stage and, therefore, poorer prognosis. Researchers have observed worsened outcomes, including lower overall survival, higher perioperative mortality and readmissions, and longer length of stay [37, 38]. Third, ED-diagnosed cancers suggest disparities in healthcare. For example, researchers at a Florida safety net hospital observed that African Americans, urban dwellers, and those without private insurance were more likely to have a cancer diagnosed in the ED and were at increased risk for stage IV cancer and death [38]. Similarly, a Michigan study of ED-based lung and colorectal cancer diagnoses noted that cancer diagnoses in the ED were disproportionate among older persons, African Americans, dual-eligible patients (patients eligible for Medicare and Medicaid benefits), and patients with three or more comorbidities. Of note, patients diagnosed with cancer in the ED had significantly more healthcare encounters (inpatient, outpatient, and primary care) in the months preceding their diagnosis [36]. This suggests a gap in the quality, rather than the quantity, of healthcare services. These findings highlight gaps in the nation's population health strategies and indicate opportunities for improvements in screening, early detection, care coordination, and patient education—particularly for more vulnerable populations.

Overutilization of ED Services

Cancer patients present to the ED with acute conditions, including sepsis, spinal cord compression, deep vein thrombosis, and respiratory and gastrointestinal obstruction. Emergency physicians, trained to diagnose and treat acute illness and injury and to stabilize patients for further treatment, are uniquely qualified to manage these emergencies. However, not all emergency visits by oncologic patients represent true oncologic emergencies. Duflos et al. and Wallace et al. observed potentially avoidable emergency visits at 48% and 52% of ED presentations, respectively [42, 43]. Also, Delgado-Guay et al. observed that patients receiving palliative care had a lower rate of avoidable ED visits (23%) [44]. Together, these findings suggest overutilization of emergency services for symptoms associated with progression of disease and treatment side effects that could be managed effectively in the outpatient setting, particularly with palliative care integration. Cancer patients often present with several interrelated symptoms, including pain, fatigue, dyspnea, nausea, dehydration, depression, and cognitive impairment. Chronic pain, in particular, is a frequent complaint among cancer patients visiting the ED. In the absence of highly coordinated multi-symptom management, cancer patients experience frequent ED visits, especially near the end of life [45]. Racial and socioeconomic disparities are a factor here as well [46]. Several observational studies have examined ED service utilization among cancer patients at the end of life. The findings of these studies vary—27–37% of the study populations had an ED visit in the last 14 days of life, and 7–19% of the study populations experienced multiple ED visits in the last 30 days of life [47]. In a 2010 study of hospice enrollees, Carlson et al. observed that patients who disenrolled from hospice were significantly more likely to have an ED visit compared to their continuously enrolled counterparts (33.9% vs. 3.1%) [48].

In the early 2000s, Earle et al. identified frequent ED visits as an indicator of poor quality of care [49, 50]. Aprile et al. concluded that over 50% of unplanned visits at an acute oncologic clinic were repeat presentations [51]. Repeat ED visits suggest healthcare quality issues across care settings.

For example, patients may receive inadequate symptom management, discharge instructions, or follow-up care as part of the initial ED visit. Alternatively, upstream access or care coordination issues may lead patients to seek emergency-based care that could be delivered in a less costly outpatient setting. In other cases, repeat ED visits indicate that patients—particularly those with complex comorbidities, diminished performance status, or poor prognosis—are receiving overly aggressive treatment (e.g., chemotherapy), where the treatment toxicities exceed the potential clinical benefits. Repeat ED visits may also indicate delayed access to hospice and palliative care services or that caregivers are not prepared to manage and cope with the burden of cancer disease at home. These trends highlight the need for more selective use of aggressive treatment, improved symptom management, and earlier introduction of advance care planning. Likewise, greater access to palliative and hospice care, same-day/next-day physician appointments, and 24/7 access to providers may reduce ED utilization by cancer patients, particularly at the end of life. These care delivery approaches are discussed later in this chapter.

Overcrowding, Boarding, and Ambulance Diversion

The demand for emergency services routinely exceeds ED capacity, particularly in large urban areas. Due to coalescing system-level issues, including ED closures, inadequate or delayed access to primary and specialty care, and higher rates of uninsurance and underinsurance, ED overcrowding has worsened over time [52]. ED crowding is worsened by ED "boarding," where admitted patients remain in the ED for hours—*even days*—until a hospital bed becomes available. Sadly, ED boarding has become a routine practice for most EDs and reflects high inpatient census rates and inefficient admission processes [35]. More than an inconvenience, ED overcrowding and extended ED boarding have been associated with poorer quality of care and patient experience and may disproportionately affect older, sicker patients and those requiring specialized inpatient care [53]. Key indicators include treatment delays, patients leaving the ED without being seen, increased risk for medical errors (including medication errors), and multiple poorer outcomes, including longer lengths of stay and higher inpatient mortality rates [53–57].

Unmanaged ED crowding and prolonged ED boarding contribute to ambulance diversion. Once a practice reserved for catastrophic events, diversion has become increasingly common, especially in urban areas. By delaying treatment or by redirecting patients to EDs without the resources and expertise to optimally care for their severity of illness, diversion can place patients with acute conditions at significant risk [35]. Furthermore, extended diversion time has been associated with adverse patient outcomes, particularly for patients with life-threatening conditions [58, 59]. Together, ED overcrowding, extended boarding, and ambulance diversion increase stress among ED providers along with patients' risk for adverse events and poorer outcomes. Accordingly, experts have advocated for stronger standards to reduce these practices [35]. While these findings and recommendations are not specific to oncologic emergency care, they have important implications for cancer patients seeking ED care.

High Costs at the End of Life

In 2010, an estimated $38 billion was spent on end-of-life care for cancer patients in the USA. By 2020, those costs were projected to increase to between $49 billion and $74 billion, representing up to 36% of total spending for cancer care [60]. Underlying factors include healthcare fragmentation, frequent transitions between care settings, inadequate care coordination, no or delayed access to palliative and hospice care, and overutilization of aggressive treatment for patients with advanced disease. Additionally, despite efforts to transition to value-based care, most cancer care is still reimbursed as fee-for-service, which creates financial incentives for providers to deliver high-cost and high-intensity services, even at the end of life. Vera-Llonch et al. estimated total healthcare spending at nearly $126,000 and $129,000 for patients receiving chemotherapy for metastatic lung cancer and metastatic breast cancer, respectively [61, 62]. A study of patients with stage IV breast, colon, lung, and prostate cancers observed that one-third of patients received a high-cost advanced imaging study (computerized topography or CT, magnetic resonance imaging or MRI, positron emission tomography or PET, and nuclear medicine or NM) in the last month of life, with the top 10% receiving three of these imaging studies [63]. A multinational study on site of death found that the USA had the lowest proportion of inpatient deaths among cancer patients (22%) but double the ICU admissions and length of stay in the last 30 and 180 days of life [64]. These findings suggest a higher intensity of care at the end of life in the USA when compared with other developed nations [65]. A recent study of patients with metastatic non-small cell lung cancer in the National Cancer Database indicated that 10.8% and 24.5% of patients initiated first-line treatment within 4 and 8 weeks of death, respectively [66]. Aggressive treatment at the end of life contributes to unsustainable national healthcare spending on end-of-life care without comparable benefit in terms of better survival, quality of life, and access to care. Since Americans have ranked treatment costs and financial burden to family members as their biggest concerns when faced with a life-limiting illness [67, 68], excessive health-

care costs exacerbate emotional distress among patients with a poor prognosis.

Significant geographic and between-hospital variation in end-of-life costs has been observed. A seminal study by the Dartmouth Atlas Project identified the availability of healthcare resources, rather than patient acuity or patient preference, as the most significant contributing factor [69]. A committee convened by the National Academy of Medicine, or NAM (neé Institute of Medicine), attributed 89% of variation in total Medicare spending to variation in acute care and post-acute care [70]. These findings have important implications to begin addressing overutilization of services (including ED visits) at the end of life and suggest that better care coordination may reduce spending for these patients.

Patient Dissatisfaction with Emergency Care

ED overcrowding, poor patient handoffs, and extended wait times—perceived and actual—compromise patient experience and contribute to patients leaving the ED without being seen [45, 71, 72]. Patient experience with ED care has not been systematically measured in the USA. However, researchers within and outside the USA have identified promoters and detractors of patient satisfaction with emergency care, with mixed results [73–75]. Overall satisfaction has been associated with provider interpersonal skills—communication, courtesy, empathy, and competence—and patient perception regarding wait times [75–78]. ED physicians often lack an established relationship with patients and carry heavy patient loads of varying acuity, leading to significant challenges to timely and accurate communication [79]. Patient satisfaction may be improved by training ED providers to initiate more frequent and targeted communication, particularly regarding wait times, and by expanding ED provider access to patient records across care delivery systems.

Some studies have demonstrated higher satisfaction among ED patients of higher acuity (and vice versa) [80–82]. Additionally, lower-acuity patients have expressed greater dissatisfaction with wait times and costs of care than their higher-acuity counterparts [82]. This difference may be attributed to two factors. First, urgent or emergent ED patients likely will be triaged more quickly than their nonurgent counterparts. Second, the fact that lower-acuity patients could be seen more quickly—and at a lower cost—in an outpatient setting may contribute to their dissatisfaction. Redirecting lower-acuity patients from the ED to more appropriate outpatient settings may help address this issue along with easing ED overcrowding and reducing total costs of care.

In 2012, the Centers for Medicare & Medicaid Services (CMS) funded initial work on a Consumer Assessment of Healthcare Providers and Systems (CAHPS) survey for emergency care—the ED CAHPS (formerly Emergency Department Patient Experience of Care, or EDPEC, Survey). Development, testing, and refinement of the survey were completed in 2020. The 35-item survey, which assesses frequency of positive experience with ED processes, staff, healthcare received, and overall experience, received the CAHPS® trademark in March 2020. The ED CAHPS, Version 1.0, includes four composite measures (getting timely care, how well doctors and nurses communicate, communication about medications, and communication about follow-up) and two global measures (overall ED rating and willingness to recommend the ED) for patients discharged to home [83]. Currently, ED CAHPS use is voluntary, and providers are not required to report their results publicly. Nevertheless, early adoption of this survey will yield important insights regarding opportunities to improve patient experience with ED care.

Caregiver Burden

When caring for relatives with debilitating and chronic conditions, such as cancer, family caregivers experience significant financial, social, physical, and psychological distress. As cancer care continues to shift to outpatient settings, caregivers face increasing pressure to help their loved one navigate a complex and fragmented care delivery system and to care for their loved one at home while receiving limited training and support [84]. A 2011 survey from AARP, Inc. and the United Hospital Fund noted that 46% of caregivers of patients with multiple chronic conditions reported performing medical care (e.g., medication management and operating specialized medical equipment) for their loved one. Additionally, 53% of caregivers reported serving as care coordinators [85].

Several studies have described morbidity in caregivers of cancer patients [86]. Braun et al. reported that nearly 39% of caregivers of patients with advanced cancer experienced significant symptoms of depression [87]. Grunfeld et al. observed that caregivers of patients with advanced breast cancer experienced anxiety and depression that matched or exceeded the patient's anxiety and depression [88]. Wright et al. noted that place of death affected caregiver well-being. Death in the ICU or inpatient setting increased caregiver risk for post-traumatic stress and prolonged grief when compared with death at home [89]. Researchers have also described lifestyle interference among caregivers of cancer patients. Wadhwa et al. determined that 25% of caregivers of persons with advanced cancer experienced a change in work status [90], while Mazanec et al. estimated a 23% loss of work productivity among caregivers [91]. This is problematic, since increased lifestyle interference increases caregiver emotional distress [92] and can compromise their ability to provide

logistical and emotional support to the cancer patient [93]. Caregiver emotional distress can also negatively affect patient well-being. Two longitudinal studies of partners of breast cancer patients revealed that patient fatigue, symptom distress, anxiety, and depression increased in parallel with caregiver emotional distress [94, 95].

To prepare family members for caregiver role demands, the NAM recommended that healthcare agencies, including the Department of Health and Human Services (HHS), fund demonstration projects to train caregivers of cancer patients for their demanding role [84]. Federal and state lawmakers have also prioritized caregiver support through recent legislation—the Recognize, Assist, Include, Support, and Engage (RAISE) Family Caregiver Act of 2017 [96] and Caregiver Advise, Record, Enable (CARE) Act, signed into law in 39 states [97]. Yet, additional research and real-world implementation guidance are needed for meaningful change. Experts have identified interventions focused on caregiver skills and decision support, stress reduction, interdisciplinary palliative care, and psychosocial support to reduce caregiver burden, but such interventions remain largely untested [98, 99]. Caregiver training should focus on evolving caregiver needs throughout the continuum of care since short-term caregiver training has shown promising results [100], but caregiver-perceived preparedness, quality of life, and psychological well-being may diminish over time [101]. Professional and patient advocacy organizations can play an important role in developing educational materials and supporting programs to help caregivers manage their distress and provide optimal support for cancer patients [98].

Specific Issues for Dedicated Oncologic EDs

Dedicated oncologic EDs face additional pressures related to access and care coordination. Some patients with a cancer diagnosis seek entry to a comprehensive cancer center through the center's dedicated ED, if one exists [102, 103]. Additionally, EDs at other hospitals may seek to transfer uninsured or underinsured cancer patients to a specialized cancer center through its dedicated ED on the basis of an oncologic emergency that the transferring center is unable to manage. In these cases, the ED may serve as an interface or gateway into specialized oncologic care systems. However, there is no guaranteed access to oncologic care. Under EMTALA, the dedicated oncologic ED has the duty to screen and stabilize the patient in the ED. However, there is no duty to admit the patient, once stabilized, for further treatment of the patient's cancer diagnosis or other health issues. Even if active cancer treatment (e.g., chemotherapy) is required to stabilize the patient, there is no requirement to continue the treatment beyond the initial emergency presentation [104]. Thus, cancer patients may be bounced between multiple care settings, placing them at greater risk for receiving unsafe and poorly coordinated care.

Upstream Drivers

In the preceding section of this chapter, we discussed six quality issues affecting oncologic emergency care and described specific issues for dedicated oncologic EDs. Often, these issues arise when cancer patients seek ED care, but they are more directly associated with inadequate access to care or primary care gaps. Six upstream drivers that compromise ED-based oncologic care are described below: (1) poor care coordination; (2) underutilized advance care planning; (3) inadequate access to palliative care; (4) delayed hospice referral and the hospice reimbursement model; (5) limited availability of immediate and after-hours outpatient care; and (6) unrealistic patient/caregiver expectations regarding prognosis and treatment.

Poor Care Coordination

Fragmented healthcare delivery and inadequate care coordination are common among the elderly, the uninsured and underinsured, and patients with chronic and life-threatening conditions. Cancer patients may experience fragmented care across the cancer care continuum [105–109] as they frequently move between oncologic care, primary care, community and specialty hospitals, EDs, hospice, and long-term care. Indeed, the NAM identified nearly 30 clinical roles and disciplines involved in cancer care [84]. Specific issues relate to follow up on abnormal findings, management of comorbid conditions and symptom burden, medication administration (including chemotherapy), psychosocial support, end-of-life care, and survivorship transitions [105–116]. Increasingly, hospital outpatient departments are the care setting for complex cancer treatment [117], including stem cell transplantation, cancer surgery, and immunotherapy. Shifting these services from inpatient to outpatient settings has many benefits for patients, reduces healthcare costs, and eases the demand for inpatient resources. However, it places patients at increased risk for unmanaged pain, infection, febrile neutropenia, anemia, dehydration, nausea and vomiting, gastrointestinal distress, and dyspnea that lead patients to seek care in the ED. Thus, ED visits and, in particular, repeat ED visits may indicate unmet patient needs in other settings or that caregivers are unprepared to care for their loved one's disease at home. This is especially true at the end of life, when cancer patients present at the ED with poorly managed symptoms or progression of disease.

In the face of inadequate care coordination by the primary oncologic team, ED providers may become de facto onco-

logic care coordinators. However, ED physicians are trained to manage acute injury and illness and to stabilize patients for further treatment. Moreover, emergency physicians may be uncomfortable with addressing end-of-life issues in cancer patients [71]. Therefore, overextended physicians feel increasing pressure to ensure that patients are directed to appropriate follow-up care (including hospice or palliative care) and to close the loop with primary care physicians and oncologic providers. Strong care coordination, starting with a well-defined interface between primary care providers and oncologists [108, 109], is imperative to address fragmented cancer care. Both formal and informal primary care/oncologic relationships can improve care coordination [118], leading to improved handoffs and more appropriate healthcare utilization [119] and lessening the burden on ED care teams.

Underutilized Advance Care Planning

Advance care planning enables patients to consider their end-of-life preferences; to communicate those preferences to their family members, caregivers, and healthcare providers; and to document their preferences regarding life-sustaining procedures in a legally binding advance directive. Ideally, advance care planning begins during treatment planning, is documented by providers using structured templates [120], is informed by educational aids [121], and is revisited throughout treatment at clinically relevant time points (e.g., if the patient's prognosis worsens). In the context of cancer treatment, it should include ongoing communication between patients, caregivers, and providers across care delivery settings. The National Comprehensive Cancer Network (NCCN) recommends early initiation of advance care planning using a tailored approach based on where the patient is in his/her cancer trajectory [122]. For patients with advanced disease, advance care planning is critical to delivering patient-centered care and is essential to align treatment plans with patient values and preferences for quality of life, treatment intensity, and life-prolonging treatment. Early findings indicate that advance care planning has several benefits: reduced aggressive treatment and increased hospice referral at the end of life [123]; fewer ICU admissions; hospitalizations and inpatient deaths in the last 30 days of life [124]; clearer and earlier understanding of patient prognosis [125]; better alignment between patient preferences and care at the end of life [126]; and improved satisfaction and reduced stress and anxiety for patients and their families [127]. Despite fears to the contrary, it is not associated with increased hopelessness and anxiety for patients with advanced disease [128, 129].

Despite the potential benefits of advance care planning, end-of-life care discussions are often delayed until all curative treatment options are exhausted [130] and death is imminent [131]. Furthermore, researchers have observed large proportions of cancer patients presenting to the ED without an advance directive [132, 133]. Even when an advance directive exists, ED providers may be unable to access it in time to honor the patient's wishes regarding life-prolonging treatment when the patient presents with a sudden acute, life-threatening complication or critical decline in health status.

Of note, efforts to improve advance care planning have focused on executing advance directives for patients with poor prognosis. Advance directives are integral to advance care planning. However, advance care planning is much broader [122, 134] and includes thoughtful consideration of patient preferences regarding life-sustaining procedures, treatment intensity, quality of life at the end of life, and place of death. Goswami et al. and Pajka et al. have shown promising results in engaging advance practice nurses and ED staff in advance care planning [135, 136]. Future efforts should focus on coordinated, systematic, and patient-centered approaches to initiate advance care planning much earlier in the trajectory of disease, especially for patients with later-stage diagnoses.

Inadequate Access to Palliative Care

Palliative care addresses the physical and psychosocial effects of the disease and its treatment, thereby easing the burden of cancer throughout the continuum of care. Researchers have proposed early introduction of palliative care as an important strategy to improve symptom management and quality of life [137, 138], to help patients have more realistic expectations regarding their cancer [139], to reduce healthcare spending and utilization of acute care and emergency services [140, 141], and to improve survival in some patients [142]. Conversely, poor health-related quality of life has been associated with worse survival [143–146]. In the twenty-first century, the USA has seen substantial growth in palliative care programs [147–150]. Between 2009 and 2018, outpatient palliative care programs increased among NCI-designated cancer centers (59–95%) and non NCI-designated cancer centers (22–40%) [149]. Similarly, in 2019, inpatient palliative care programs were identified at 72% of hospitals with 50 or more beds (vs 67% in 2015 and 7% in 2001). This growth was concentrated among hospitals that are large (300 or more beds), urban, public or nonprofit, and located in northeastern states [150]. Thus, despite this increased capacity, palliative care services are not readily accessible for many cancer patients or may not be offered on a timely basis. Experts have suggested that palliative care referrals may be delayed due to erroneous perceptions among oncologists that palliative care and curative treatment must follow sequential pathways. Consequently, palliative care needs remain unmet, and patients with distress associated

with advanced disease or high symptom burden frequently seek care in the ED, particularly at the end of life.

To reduce barriers to timely palliative care, researchers have recommended colocation of outpatient oncologic and palliative care [151, 152] along with integrating palliative care with ED services [153–155]. Early studies suggest the benefits of ED-based palliative care programs, including better quality of life, reduced length of stay, lower intensive care, and improved hospice utilization, though the data are conflicting [156–159]. Researchers have identified several barriers to ED-integrated palliative care; these include inadequate palliative care training, an ED culture that favors aggressive treatment, and provider fear of being sued [160–163]. A multi-stakeholder workgroup convened in 2009 by the Agency for Healthcare Research and Quality (AHRQ) and the American College of Emergency Physicians (ACEP) identified four research priorities to address these barriers:

1. Which patients are in greatest need of palliative care services in the ED?
2. What is the optimal role of emergency clinicians in caring for patients along a chronic trajectory of illness?
3. How does the integration and initiation of palliative care training and services in the ED setting affect healthcare utilization?
4. What are the educational priorities for emergency clinical providers in the domain of palliative care? [164]

Interest in these areas has surged in recent years, particularly in testing different models of ED-based palliative care and the impact on healthcare utilization. Perhaps the greatest progress has been in the development and dissemination of guidelines, toolkits, and educational materials to advance palliative care in the ED [163, 165–171]. Continued experimentation and socialization are needed to drive clinical transformation in this important field.

Delayed Hospice Referral and the Hospice Reimbursement Model

Hospice programs that offer team-based comprehensive and interdisciplinary care can improve comfort and quality of life for cancer patients with a life expectancy of 6 months or less. Moreover, hospice referral is associated with higher quality care, including fewer hospitalizations, ICU admissions, and inpatient deaths and lower costs of care [172, 173]. Electing hospice care requires Medicare beneficiaries to forgo curative treatment and is appropriate when the risks or complications of treatment outweigh the potential benefits. Hospice referrals have increased significantly since the Medicare hospice benefit was created by the Tax Equity and Fiscal Responsibility Act of 1982 [174]. Over 1.5 million Medicare beneficiaries, representing over 50% of Medicare decedents, received hospice services in 2018. Cancer patients continued to lag behind their non-cancer counterparts in terms of hospice utilization. The share of hospice decedents with cancer declined from 52% to 26% between 2000 and 2018. In 2018, average and median length of hospice stay for cancer decedents were 53 and 17 days, respectively, versus average and median length of stay for decedents with neurological conditions (151 and 38 days, respectively). Together, these factors indicate that many cancer patients are enrolling in hospice too late to benefit fully from the team-based comprehensive and interdisciplinary palliative care that hospice programs offer [175].

Several barriers have been identified to earlier hospice referral. These include financial incentives to keep patients in the acute care system, provider discomfort with initiating end-of-life discussions, and patient and family difficulty accepting a terminal cancer prognosis [175]. Desired intensity of care remains a significant barrier to earlier hospice enrollment in the USA where patients with a terminal disease (defined as a life expectancy of 6 months or less) must agree to forgo curative treatment to qualify for the Medicare hospice benefit. Once patients are enrolled, Medicare pays hospice providers a per diem rate per enrollee. Under this capitated model, reformed in 2016 to better align reimbursement with the intensity of care delivered [176], hospice providers assume financial responsibility for all care related to the patient's terminal illness. Patients with advanced cancer often benefit from palliative radiation and chemotherapy, opioids, and parenteral nutrition. The treatment costs may be substantial and greatly exceed the Medicare hospice benefit. Accordingly, hospice providers may be discouraged from enrolling high-cost cancer patients, or they may implement restrictive enrollment policies aimed at cost control. These restrictions present many patients and caregivers with the dilemma of electing hospice care or comfort care at the end of life [177].

Concurrent cancer treatment and hospice care has been proposed as an effective remedy to address the limitations of hospice benefit design. In the early 2000s, the Robert Wood Johnson Foundation funded 22 demonstration projects of concurrent curative treatment and palliative care. These projects demonstrated early feasibility of an integrative approach to cancer treatment and hospice care across various patient populations and care settings [178]. Aetna conducted a similar pilot—extending hospice eligibility to patients with a life expectancy of 12 months or less—and observed increased hospice enrollment, lower utilization of acute care services, and a 22% reduction in costs [179]. Through its Comprehensive End-of-Life Care Initiative, started in 2009, the Veterans Health Administration offers concurrent cancer treatment (chemotherapy or radiation) and hospice services with good results. Studies conducted in patients with meta-

static non-small cell lung cancer demonstrated increased hospice utilization, less aggressive treatment at the end of life, and lower costs of care [180–182]. Success was associated with preserved hope and better quality of life among patients along with smoother transitions, stronger care coordination, and more frequent touch points with care teams. Concern regarding compliance with Medicare's either-or policy (i.e., cancer treatment or hospice) was cited as a potential barrier [183]. In 2016, the Center for Medicare and Medicaid Innovation (CMMI) launched the 4-year Medicare Care Choices Model to test concurrent cancer treatment and hospice in the Medicare and dual-eligible population (as authorized under the ACA) [184]. Experts have identified design limitations, including restrictive eligibility criteria. Early findings have revealed both challenges and successes. Hospice attrition initially was high, and beneficiary enrollment is much lower than expected. Advance care planning has been widely utilized. Both patients and caregivers have reported positive experience with care. Perhaps the pilot's greatest success has been improved utilization of hospice services (including counseling and symptom management) among enrolled cancer decedents. This suggests that concurrent cancer treatment and hospice may serve as a bridge to traditional hospice enrollment by offering patients and caregivers more time to process the patient's prognosis and treatment options while receiving supportive care [185, 186]. Additional demonstration projects are needed across federal, state, and commercial insurers to ensure that hospice benefit design promotes better quality of life, timely hospice enrollment, and, where appropriate, concurrent cancer treatment and hospice.

Limited Availability of Immediate and After-Hours Outpatient Care

Experts suggest that many ED visits are for non-emergent complaints that are more appropriately managed in the outpatient setting. Hansagi et al. observed that two-thirds of ED patients in their study were primary care cases, but the patients could not get in to see their physician or were referred to the ED for care [81]. Similarly, in an observational study of ED visits in North Carolina, Mayer et al. found that 44.9% of ED visits occurred during normal clinic hours and fewer than one-fifth of those patients were admitted to the hospital [187]. These findings underscore the need for more immediate access to outpatient oncologic care, such as through same-day/next-day appointments or 24/7 provider access.

The effectiveness of these practices is being tested through oncologic-specific patient-centered medical homes (PCMH). A primary care delivery model, the PCMH is designed to provide comprehensive, well-coordinated, patient-centered care by promoting access to preventive, chronic, and acute care, as well as a systems-based approach to safety and quality [188]. The Patient-Centered Outcomes Research Institute funded a 5-year PCMH model pilot with five medical oncologic practices in Pennsylvania. The pilot demonstrated greater access to specialty care and improved patient experience with shared decision-making but no change in ED visits and inpatient admissions [189, 190]. A broader pilot—Community Oncologic Medical HOME (COME HOME)—funded by CMMI [191] piloted similar approaches, including active disease management, triage and clinical pathways, enhanced provider access, and interdisciplinary teams, to deliver more coordinated cancer care. This pilot, implemented in seven community oncologic practices, produced a 10.2% reduction in ED visits and lower costs of care [192, 193]. These models of care should be studied further to determine the generalizability of these approaches to cancer care in the community and at academic medical centers.

Unrealistic Patient/Caregiver Expectations Regarding Prognosis and Treatment

Patient preference for intensity of treatment is influenced by health literacy, provider mistrust, family dynamics, religious beliefs, and other cultural and religious factors [194]. Cancer patients must have an accurate understanding of their treatment options and prognosis to avoid unnecessary, futile care and make treatment decisions that are consistent with their preferences and values. Indeed, patients that overestimate their prognosis are more likely to receive aggressive treatment of questionable benefit [195], while patients who understand their prognosis prefer symptom-directed care [131]. Several studies have confirmed that patients with advanced disease frequently misunderstand the intent of their cancer treatment and overestimate their prognosis [137, 196–198]. For example, Temel et al. published a study of newly diagnosed patients with metastatic lung cancer in 2011, noting that 32% of respondents considered their cancer curable and that 69% of respondents believed they were receiving curative, rather than palliative, treatment [139]. Likewise, Weeks et al. reported that 69% and 81% of patients with metastatic lung and colorectal cancer, respectively, did not understand that they were receiving palliative chemotherapy [195].

Communication challenges between patients, their caregivers, and providers contribute to patient and caregiver misunderstandings about prognosis or treatment intent. In some cases, patients receive accurate prognostic information, but do not understand or do not accept their prognosis. In other cases, physicians may be reluctant to provide this information, will do so only when asked by the patient, or will provide inflated survival estimates to their patients [195, 198,

199]. Mack and Smith attributed provider communication issues to discomfort with these discussions, uncertainty in estimating prognosis, and concerns regarding reduced hope, patient depression, and cultural appropriateness [200]. In 2013, the NAM recommended five strategies for improving patient-centered communication and shared decision-making for cancer patients:

1. Making more comprehensive and understandable information available to patients and their families
2. Developing decision aids to facilitate patient-centered communication and shared decision-making
3. Prioritizing clinician training in communication
4. Preparing cancer care plans
5. Using new models of payment to incentivize patient-centered communication and shared decision-making [84]

Implementing these approaches will assist providers in communicating more clearly regarding treatment intent and prognosis and will contribute to more realistic assessments among patients and their caregivers. Moreover, physicians should seek to understand their patients' preferences for prognostic information and adapt their communication styles accordingly.

Role of Quality Measures

Healthcare quality measures offer quantitative and qualitative assessments of the healthcare delivery. Experts have developed healthcare quality measures to evaluate the underlying structures and processes, outcomes, patient experience, and, to a limited degree, the costs of care. Moreover, there is increasing interest in measuring caregiver burden and experience with care. Some measures are developed for specific health conditions (e.g., breast cancer) or care delivery settings (e.g., ED), while other measures are crosscutting and apply to multiple health conditions or care delivery settings.

In this section, we describe the history of quality measurement in emergency medicine, provide examples of existing ED quality measures that are relevant to cancer care, and discuss the limitations of these measures.

History of Quality Measurement in Emergency Medicine

National quality measurement for emergency medicine began in the early 2000s as part of CMS' Reporting Hospital Quality Data for Annual Payment Update (RHQDAPU) program. The RHQDAPU program was a voluntary CMS quality reporting program that became the Inpatient Quality Reporting (IQR) program in 2010. The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 (MMA) introduced financial incentives for hospitals to report data on ten quality measures for pneumonia, acute myocardial infarction (AMI), and congestive heart failure via the RHQDAPU program [201, 202]. These measures were developed through the Hospital Quality Alliance, a public/private partnership with membership from CMS, the The Joint Commission, the American Hospital Association, and healthcare consumer groups [203]. In 2004, these data were published as the first national comparative dataset for ED quality. The financial incentives created under the MMA were later strengthened by the Deficit Reduction Act of 2005 (DRA) [204] and expanded to include measures for hospital-based outpatient care under the Tax Relief and Health Care Act of 2006 [205]. In 2015, Congress consolidated physician-focused federal quality programs through the Merit-based Incentive Payment System (MIPS), a key component of the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA) [206].

Over time, ED quality measurement has been expanded through public and private sector efforts. In 2006, the American Medical Association's Physician Consortium for Performance Improvement (AMA-PCPI), ACEP, and NCQA co-developed physician-level ED measures for pneumonia, chest pain, and syncope [207, 208]. Additional independent measure development projects were undertaken by hospitals, by CMS, and by professional organizations, such as ACEP. These efforts focused on specific aspects of care (e.g., timeliness of care and ED communication). Disease-specific measures of morbidity, mortality, and resource use were also developed [208, 209]. At two Performance Measures and Benchmarking Summits convened in 2006 and 2010, participants proposed a wide range of metrics: operational metrics (e.g., ED census), timestamp and interval metrics (e.g., ED length of stay), proportional metrics (e.g., left without being seen), and utilization metrics (e.g., specialty consultations) [210, 211]. Stone-Griffith et al. developed the ED Dashboard and Reporting Application to support data-driven ED performance improvement projects by routinely measuring ED throughput [212].

In parallel, the National Quality Forum (NQF), a nonprofit organization that uses a consensus development process to endorse healthcare quality measures for use in federal public reporting programs, launched a two-phase project endorsing a national measure set for ED care. Between 2007 and 2009, the NQF endorsed 22 measures for ED care, including nine measures that were given time-limited (or temporary) endorsement and pending completion of measure testing and validation [213]. Subsequent projects focused on regionalized emergency care, care transitions, and chief complaint-based performance assessments [214–217]. These measures are included in Table 4.1. Some of these measures have been adopted for CMS public reporting programs,

Table 4.1 National Quality Forum-endorsed measures for emergency care: past and present

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
0004	Initiation and Engagement of Alcohol and Other Drug Abuse or Dependence Treatment	The percentage of adolescent and adult members with a new episode of AOD abuse or dependence who initiate treatment through an inpatient AOD admission, outpatient visit, intensive outpatient encounter, partial hospitalization, telehealth, or medication-assisted treatment (MAT) within 14 days of the diagnosis; the percentage of adolescent and adult members with a new episode of AOD abuse or dependence who initiated treatment and who had two or more additional AOD services or MAT within 34 days of the initiation visit	Health plan	NCQA	Behavioral health (process)	2009	Endorsed	PQRS, QRUR, VBM, QHP QRS	Yes
0025	Management Plan for People with Asthma	Percentage of patients for whom there is documentation that a written asthma management plan was provided either to the patient or the patient's caregiver OR, at a minimum, specific written instructions on under what conditions the patient's doctor should be contacted or the patient should go to the emergency room	Clinician	IPRO	Asthma (process)	2009	Endorsement removed *(October 2012)*		No
0052	Use of Imaging Studies for Low Back Pain	The percentage of patients with a primary diagnosis of low back pain who did not have an imaging study (plain X-ray, MRI, CT scan) within 28 days of diagnosis	Health plan, integrated delivery system	NCQA	Musculoskeletal (process)	2009	Endorsement removed *(April 2017)*	PQRS, QRUR, BPM	No
0090	Emergency Medicine: 12-Lead Electrocardiogram (ECG) Performed for Non-traumatic Chest Pain	Percentage of patients aged 40 years and older with an emergency department discharge diagnosis of non-traumatic chest pain who had a 12-lead electrocardiogram (ECG) performed	Group	AMA-PCPI	Cardiovascular (process)	2007	Endorsement removed *(December 2017)*	PQRS, QRUR, BPM	No
0092	Emergency Medicine: Aspirin at Arrival for Acute Myocardial Infarction (AMI)	Percentage of patients, regardless of age, with an emergency department discharge diagnosis of acute myocardial infarction (AMI) who had documentation of receiving aspirin within 24 h before emergency department arrival or during emergency department stay	Group, clinician	AMA-PCPI	Cardiovascular (process)	2007	Endorsement removed *(February 2016)*		No

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
0093	Emergency Medicine: 12-Lead Electrocardiogram (ECG) Performed for Syncope	Percentage of patients aged 60 years and older with an emergency department discharge diagnosis of syncope who had an ECG performed	Clinician	AMA-PCPI	Cardiovascular (process)	2007	Endorsement removed *(February 2014)*		No
0094	Assessment of Oxygen Saturation for Community-Acquired Bacterial Pneumonia	Percentage of patients aged 18 years and older with the diagnosis of community-acquired bacterial pneumonia with oxygen saturation assessed	Clinician	AMA-PCPI	Pneumonia (process)	2007	Endorsement removed *(December 2011)*		No
0095	Assessment of Mental Status for Community-Acquired Bacterial Pneumonia	Percentage of patients aged 18 years and older with the diagnosis of community-acquired bacterial pneumonia with mental status assessed	Clinician	AMA-PCPI	Pneumonia (process)	2007	Endorsement removed *(December 2011)*		No
0104e	Adult Major Depressive Disorder (MDD): Suicide Risk Assessment	Percentage of patients aged 18 years and older with a diagnosis of major depressive disorder (MDD) with a suicide risk assessment completed during the visit in which a new diagnosis or recurrent episode was identified	Group, clinician	AMA-PCPI	Behavioral health (process)	2009	Endorsed	PQRS, QRUR, BPM	No
0148	Blood Cultures Performed in the Emergency Department Prior to Initial Antibiotic Received in Hospital	Percentage of pneumonia patients 18 years of age and older who have had blood cultures performed in the emergency department prior to initial antibiotic received in the hospital	Facility	CMS	Pneumonia (process)	2007	Endorsement removed *(October 2012)*		No
0151	Initial Antibiotic Received Within 6 H of Hospital Arrival	Percentage of pneumonia patients 18 years of age and older who receive their first dose of antibiotics within 6 h after arrival at the hospital	Facility	CMS	Pneumonia (process)	2009	Endorsement removed *(October 2012)*		No
0173	Emergency Department Use Without Hospitalization During the First 60 Days of Home Health	Percentage of home health stays in which patients used the emergency department but were not admitted to the hospital during the 60 days following the start of the home health stay	Facility	CMS	Care coordination (outcome)	2009	Endorsed	HACRP, HHQRP	Yes
0211	Proportion of Patients Who Died from Cancer with More Than One Emergency Department Visit in the Last 30 Days of Life	Proportion of patients who died from cancer with more than one emergency department visit in the last 30 days of life	Group	ASCO	Cancer-specific (outcome)	2009	Endorsement removed *(October 2016)*		Yes
0277	Congestive Heart Failure Rate (PQI 08)	Admissions with a principal diagnosis of heart failure per 100,000 population, ages 18 years and older	Health plan, integrated delivery system	AHRQ	Cardiovascular (process)	2007	Endorsed	MSSP	No

0286	Aspirin at Arrival	Percentage of emergency department acute myocardial infarction (AMI) patients or chest pain patients (with probable cardiac chest pain) without aspirin contraindications who received aspirin within 24 h before ED arrival or prior to transfer	Facility	CMS	Cardiovascular (process)	2007	Endorsement removed *(August 2014)*		No
0287	Median Time to Fibrinolysis	Median time from emergency department arrival to administration of fibrinolytic therapy in ED patients with ST-segment elevation or left bundle branch block (LBBB) on the electrocardiogram (ECG) performed closest to ED arrival and prior to transfer	Facility	CMS	Cardiovascular (process)	2007	Endorsement removed *(January 2012)*		No
0288	Fibrinolytic Therapy Received Within 30 Min of ED Arrival	This measure calculates the percentage of emergency department (ED) acute myocardial infarction (AMI) patients with ST-segment elevation on the electrocardiogram (ECG) closest to arrival time receiving fibrinolytic therapy during the ED stay and having a time from ED arrival to fibrinolysis of 30 min or less	Facility	CMS	Cardiovascular (process)	2007	Endorsement removed *(November 2016)*	Hospital Compare, OQR	No
0289	Median Time to ECG	Median time from emergency department arrival to ECG (performed in the ED prior to transfer) for acute myocardial infarction (AMI) or chest pain patients (with probable cardiac chest pain)	Facility	CMS	Cardiovascular (efficiency)	2007	Endorsement removed *(August 2014)*		No
0290	Median Time to Transfer to Another Facility for Acute Coronary Intervention	Median time from emergency department arrival to time of transfer to another facility for acute coronary intervention	Facility	CMS	Cardiovascular (process)	2007	Endorsed	Hospital Compare, OQR	No
0291	Emergency Transfer Communication Measure	Percentage of patients transferred to another healthcare facility whose medical record documentation indicated that required information was communicated to the receiving facility prior to departure (subsection 1) or within 60 min of transfer (subsections 2–7)	Facility	UMRHRC	Care coordination (process)	2007	Endorsed		Yes

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
0292	Vital Signs	Percentage of patients transferred to another healthcare facility whose medical record documentation indicated that the entire vital signs record was communicated to the receiving facility within 60 min of departure	Facility	UMRHRC	Care coordination (process)	2007	Endorsement removed *(September 2014)*		Yes
0293	Medication Information	Percentage of patients transferred to another healthcare facility whose medical record documentation indicated that medication information was communicated to the receiving facility within 60 min of departure	Facility	UMRHRC	Care coordination (process)	2007	Endorsement removed *(September 2014)*		Yes
0294	Patient Information	Percentage of patients transferred to another healthcare facility whose medical record documentation indicated that patient information was communicated to the receiving facility within 60 min of departure	Facility	UMRHRC	Care coordination (process)	2007	Endorsement removed *(September 2014)*		Yes
0295	Physician Information	Percentage of patients transferred to another healthcare facility whose medical record documentation indicated that physician information was communicated to the receiving facility within 60 min of departure	Facility	UMRHRC	Care coordination (process)	2007	Endorsement removed *(September 2014)*		Yes
0296	Nursing Information	Percentage of patients transferred to another healthcare facility whose medical record documentation indicated that nursing information was communicated to the receiving facility within 60 min of departure	Facility	UMRHRC	Care coordination process)	2007	Endorsement removed *(September 2014)*		Yes
0297	Procedures and Tests	Patients who are transferred from an ED to another healthcare facility have communicated with the receiving facility within 60 min of discharge a list of tests done and results sent	Facility	UMRHRC	Care coordination (process)	2007	Endorsement removed *(September 2014)*		Yes
0489	The Ability for Providers with HIT to Receive Laboratory Data Electronically Directly into Their Qualified/Certified EHR System as Discrete Searchable Data Elements	Documents the extent to which a provider uses certified/qualified electronic health record (EHR) system that incorporates an electronic data interchange with one or more laboratories allowing for direct electronic transmission of laboratory data into the EHR as discrete searchable data elements	Facility	CMS	Care coordination (structure)	2008	Endorsement removed *(April 2014)*		Yes

0491	Tracking of Clinical Results Between Visits	Documentation of the extent to which a provider uses a certified/qualified electronic health record (EHR) system to track pending laboratory tests, diagnostic studies (including common preventive screenings), or patient referrals	Facility	CMS	Care coordination (structure)	2008	Endorsement removed *(April 2014)*		Yes
0495	Median Time from ED Arrival to ED Departure for Admitted ED Patients	Median time from emergency department arrival to time of departure from the emergency room for patients admitted to the facility from the emergency department	Facility	CMS	Care coordination (process)	2008[‖,¶]	Endorsement removed *(November 2018)*	Hospital Compare, IQR	Yes
0496	Median Time from ED Arrival to ED Departure for Discharged ED Patients	Median time from emergency department arrival to time of departure from the emergency room for patients discharged from the emergency department (ED)	Facility	CMS	Care coordination (process)	2008[‖,¶]	Endorsement removed *(October 2018)*	Hospital Compare, OQR	Yes
0497	Admit Decision Time to ED Departure Time for Admitted Patients	Median time from admit decision time to time of departure from the emergency department for emergency department patients admitted to inpatient status	Facility	CMS	Care coordination (process)	2008[‖,¶]	Endorsement removed *(November 2018)*	Hospital Compare, IQR	Yes
0498	Door to Diagnostic Evaluation by a Qualified Medical Personnel	Time of first contact in the ED to the time when the patient sees qualified medical personnel for patient evaluation and management	Facility, clinician	LSU	Care coordination (other)	2008[‖,¶]	Endorsement removed *(May 2012)*		Yes
0499	Left Without Being Seen	Percent of patients leaving without being seen by a qualified medical personnel	Facility, clinician	LSU	Care coordination (other)	2008	Endorsement removed *(May 2012)*		Yes
0500	Severe Sepsis and Septic Shock: Management Bundle	This measure focuses on adults 18 years and older with a diagnosis of severe sepsis or septic shock. Consistent with Surviving Sepsis Campaign guidelines, the measure contains several elements, including measurement of lactate, obtaining blood cultures, administering broad-spectrum antibiotics, fluid resuscitation, vasopressor administration, reassessment of volume status and tissue perfusion, and repeat lactate measurement	Facility	HFH	Composite	2008	Endorsed		Yes

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
0501	Confirmation of Endotracheal Tube Placement	Any time an endotracheal tube is placed into a patient's airway in the emergency department (ED) or a patient arrives to the ED with an endotracheal tube already in place (via EMS or hospital transfer), there should be appropriate confirmation of ETT placement and documentation of its performance in the medical record	Population, integrated delivery system, facility, group, clinician	CCF	Pulmonary (process)	2008‖,¶	Endorsement removed *(June 2012)*		No
0502	Pregnancy Test for Female Abdominal Pain Patients	Percentage of female patients aged 14 to 50 who present to the emergency department (ED) with a chief complaint of abdominal pain for whom a pregnancy test ordered	Facility, group, clinician	ACEP	Perinatal (process)	2008‖,¶	Endorsement removed *(May 2012)*		No
0503	Anticoagulation for Acute Pulmonary Embolus Patients	Number of acute embolus patients who have orders for anticoagulation (heparin or low-molecular-weight heparin) for pulmonary embolus while in the ED	Facility, group, clinician	ACEP	Cardiovascular (process)	2008‖,¶	Endorsement removed *(January 2013)*		No
0504	Pediatric Weight Documented in Kilograms	Percentage of emergency department visits by patients <18 years of age with a current weight documented in kilograms in the ED electronic health record; measure to be reported each month	Facility	AAP	Safety (process)	2008‖,¶	Endorsement removed *(January 2013)*		No
0514	MRI Lumbar Spine for Low Back Pain		Population, facility	CMS	Musculoskeletal (process)		Endorsement removed *(April 2017)*	Hospital Compare, OQR	No
0549	Pharmacotherapy Management of COPD Exacerbation (PCE)	This measure assesses the percentage of COPD exacerbations for members 40 years of age and older who had an acute inpatient discharge or ED encounter on or between January 1 and November 30 of the measurement year and who were dispensed appropriate medications	Population, health plan, integrated delivery system, facility, group, clinician	NCQA	COPD (process)	2009	Endorsement removed *(July 2012)*		No
0604	Adult(s) with Diabetes Mellitus that Had a Serum Creatinine in the Last 12 Reported Months	This measure identifies adults with diabetes mellitus that had a serum creatinine test in the last 12 reported months	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Endocrine (process)	2009	Endorsement removed *(December 2013)*		No

0605	Patient(s) with Hypertension that Had a Serum Creatinine in the Last 12 Reported Months	This measure identifies patients with hypertension (HTN) who had a serum creatinine in the last 12 reported months	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Cardiovascular (process)	2009	Endorsement removed *(December 2013)*		No
0644	Patients with a Transient Ischemic Event ER Visit that Had a Follow-Up Office Visit	Patient(s) with a recent emergency room encounter for a transient cerebral ischemic event that had any physician visit within 14 days of the acute event	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Stroke (process)	2010	Endorsement removed *(March 2013)*		No
0649	Transition Record with Specified Elements Received by Discharged Patients (Emergency Department Discharges to Ambulatory Care [Home/Self-Care] or Home Health Care)	Percentage of discharges from an emergency department (ED) to ambulatory care or home healthcare, in which the patient, regardless of age, or their caregiver(s), received a transition record at the time of ED discharge including, at a minimum, all of the specified elements	Integrated delivery system, facility	AMA-PCPI	Care coordination (process)	2010	Endorsement removed *(July 2017)*		Yes
0652	Rh immunoglobulin (Rhogam) for Rh-negative pregnant women at risk of fetal blood exposure	Percent of Rh-negative pregnant women at risk of fetal blood exposure who receive Rhogam in the ED	Group, clinician	ACEP	Perinatal (process)	2011	Endorsement removed *(July 2014)*		No
0660	Troponin Results for Emergency Department Acute Myocardial Infarction (AMI) Patients or Chest Pain Patients (with Probable Cardiac Chest Pain) Received Within 60 min of Arrival	Emergency department acute myocardial infarction (AMI) patients or chest pain patients (with probable cardiac chest pain) with an order for troponin during the stay and having a time from ED arrival to completion of troponin results within 60 min of arrival	Facility	CMS	Cardiovascular (process)	2011	Endorsement removed *(November 2012)*		No
0661	Head CT or MRI Scan Results for Acute Ischemic Stroke or Hemorrhagic Stroke Patients Who Received Head CT or MRI Scan Interpretation Within 45 Min of ED Arrival	This measure calculates the percentage of acute ischemic stroke or hemorrhagic stroke patients who arrive at the ED within 2 h of the onset of symptoms and have a head computed tomography (CT) or magnetic resonance imaging (MRI) scan interpreted within 45 min of ED arrival	Facility	CMS	Stroke (process)	2011	Endorsed	Hospital Compare, OQR	No
0662	Median Time to Pain Management for Long Bone Fracture	Median time from emergency department arrival to time of initial oral or parenteral pain medication administration for emergency department patients with a principal diagnosis of long bone fracture (LBF)	Facility	CMS	Musculoskeletal (process)	2011	Endorsement removed *(January 2015)*	Hospital Compare, OQR	No

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
0664	Patient(s) with an Emergency Medicine Visit for Syncope that Had an ECG	This measure identifies patients with an emergency medicine visit for syncope that had an ECG done as part of their evaluation	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Cardiovascular (process)	2011	Endorsement removed *(December 2013)*		No
0665	Patient(s) with an Emergency Medicine Visit for Non-traumatic Chest Pain that Had an ECG	This measure identifies patients with an emergency medicine visit for non-traumatic chest pain that had an ECG done as part of their evaluation	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Cardiovascular (process)	2011	Endorsement removed *(December 2013)*		No
0666	Ultrasound Guidance for Internal Jugular Central Venous Catheter Placement	Percent of adult patients aged 18 years and older with an internal jugular central venous catheter placed in the emergency department (ED) under ultrasound guidance	Group, clinician	ACEP	Pulmonary (process)	2011	Endorsement removed *(May 2017)*		No
0667	Inappropriate Pulmonary CT Imaging for Patients at Low Risk for Pulmonary Embolism	Percent of patients undergoing CT pulmonary angiogram for the evaluation of possible PE who are at low-risk for PE consistent with guidelines(1, 2) prior to CT imaging	Facility, group	ACEP	Pulmonary (efficiency)	2011	Endorsement removed *(February 2016)*		No
0705	Proportion of Patients Hospitalized with Stroke that Have a Potentially Avoidable Complication (During the Index Stay or in the 30-Day Post-discharge Period)	Percent of adult population aged 18–65 years who were admitted to a hospital with stroke, were followed for 1 month after discharge, and had one or more potentially avoidable complications (PACs)	Population, health plan, facility, group	HCI3	Stroke (outcome)	2011	Endorsement removed *(December 2015)*		No
0722	Pediatric Symptom Checklist (PSC)	The Pediatric Symptom Checklist (PSC) is a brief parent-report questionnaire that is used to assess overall psychosocial functioning in children from 3 to 18 years of age	Population, health plan, integrated delivery system, facility, group, clinician	MGH	Behavioral health (outcome)		Endorsement removed *(March 2015)*		No
1381	Asthma Emergency Department Visits	Percentage of patients with asthma who have greater than or equal to one visit to the emergency room for asthma during the measurement period	Population, health plan	ALMA	Asthma (outcome)	2011	Endorsement removed *(February 2014)*		No

1598	Total Resource Use Population-Based PMPM Index	The Resource Use Index (RUI) is a risk-adjusted measure of the frequency and intensity of services utilized to manage a provider group's patients. Resource use includes all resources associated with treating members including professional, facility inpatient and outpatient, pharmacy, lab, radiology, ancillary, and behavioral health services	Population, group	HealthPartners	Care coordination (cost/resource use)	2012	Endorsed		Yes
1604	Total Cost of Care Population-Based PMPM Index	Total Cost of Care reflects a mix of complicated factors such as patient illness burden, service utilization, and negotiated prices. Total Cost Index (TCI) is a measure of a primary care provider's risk-adjusted cost-effectiveness at managing the population they care for	Population, group	HealthPartners	Care coordination (cost/resource use)	2012	Endorsed		Yes
1609	ETG-Based Hip/Knee Replacement Cost of Care Measure	The measure focuses on resources used to deliver episodes of care for patients who have undergone a hip/knee replacement	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Musculoskeletal (cost/resource use)	2012	Endorsement removed *(July 2018)*		No
1611	ETG-Based Pneumonia Cost of Care Measure	The measure focuses on resources used to deliver episodes of care for patients with pneumonia	Population, health plan, integrated delivery system, facility, group, clinician	Optum	Pneumonia (cost/resource use)	2012	Endorsement removed *(December 2014)*		Yes
1716	National Healthcare Safety Network (NHSN) Facility-Wide Inpatient Hospital-Onset Methicillin-Resistant *Staphylococcus aureus* (MRSA) Bacteremia Outcome Measure	Standardized infection ratio (SIR) and adjusted ranking metric (ARM) of hospital-onset unique blood source MRSA laboratory-identified events (LabID events) among all inpatients in the facility	Population, facility	CDC	Infectious disease (outcome)	2012	Endorsed	Hospital Compare, IQR, VBP, HACRP, IRF QRP, LTCH QRP, PCHQR	Yes
1717	National Healthcare Safety Network (NHSN) Facility-Wide Inpatient Hospital-Onset *Clostridium difficile* Infection (CDI) Outcome Measure	Standardized infection ratio (SIR) and adjusted ranking metric (ARM) of hospital-onset CDI laboratory-identified events (LabID events) among all inpatients in the facility, excluding well-baby nurseries and neonatal intensive care units (NICUs)	Population, facility	CDC	Infectious disease (outcome)	2012	Endorsed	Hospital Compare, IQR, VBP, HACRP, IRF QRP, LTCH QRP, PCHQR	Yes

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
1799	Medication Management for People with Asthma	The percentage of patients 5–64 years of age during the measurement year who were identified as having persistent asthma and were dispensed appropriate medications that they remained on during the treatment period. Two rates are reported. 1. The percentage of patients who remained on an asthma controller medication for at least 50% of their treatment period 2. The percentage of patients who remained on an asthma controller medication for at least 75% of their treatment period	Health plan, integrated delivery system	NCQA	Asthma (process)	2015	Endorsement removed *(August 2016)*		No
1800	Asthma Medication Ratio	The percentage of patients 5–64 years of age who were identified as having persistent asthma and had a ratio of controller medications to total asthma medications of 0.50 or greater during the measurement year	Health plan, integrated delivery system	NCQA	Asthma (process)	2012	Endorsed		No
1824	L1A: Screening for Preferred Spoken Language for Healthcare	This measure is used to assess the percent of patient visits and admissions where preferred spoken language for healthcare is screened and recorded	Facility, group	GWU	Disparities (process)	2012	Endorsement removed *(April 2017)*		Yes
2505	Emergency Department Use Without Hospital Readmission During the First 30 Days of Home Health	Percentage of home health stays in which patients who had an acute inpatient hospitalization in the 5 days before the start of their home health stay used an emergency department but were not admitted to an acute care hospital during the 30 days following the start of the home health stay	Facility	CMS	Care coordination (outcome)	2014	Endorsement removed *(June 2020)*		No
2539	Facility 7-Day Risk-Standardized Hospital Visit Rate After Outpatient Colonoscopy	Rate of risk-standardized, all-cause, unplanned hospital visits within 7 days of an outpatient colonoscopy among Medicare fee-for-service (FFS) patients aged 65 years and older	Facility	CMS	Gastrointestinal (outcome)	2014	Endorsed	ASCQR, Hospital Compare, OQR	Yes
2548	Child Hospital Consumer Assessment of Healthcare Providers and Systems (Child HCAHPS) Survey	The Child Hospital Consumer Assessment of Healthcare Providers and Systems (Child HCAHPS) survey is a standardized survey instrument that asks parents and guardians (henceforth referred to as parents) of children under 18 years old to report on their and their child's experiences with inpatient hospital care	Facility	AHRQ	Pediatric (outcome)	2015	Endorsed		Yes

2605	Follow-Up After Emergency Department Visit for Mental Illness or Alcohol and Other Drug Abuse or Dependence	The percentage of discharges for patients 18 years of age and older who had a visit to the emergency department with a primary diagnosis of mental health or alcohol or other drug dependence during the measurement year *and* who had a follow-up visit with any provider with a corresponding primary diagnosis of mental health or alcohol or other drug dependence within 7 and 30 days of discharge	Population, health plan	NCQA	Behavioral health (process)	2015	Endorsed		No
2687	Hospital Visits After Hospital Outpatient Surgery	Facility-level, postsurgical risk-standardized hospital visit ratio (RSHVR) of the predicted to expected number of all-cause, unplanned hospital visits within 7 days of a same-day surgery at a hospital outpatient department (HOPD) among Medicare fee-for-service (FFS) patients aged 65 years and older	Facility	CMS	Surgery (outcome)	2015	Endorsed		Yes
2689	Ambulatory Care Sensitive Emergency Department Visits for Dental Caries in Children	Number of emergency department visits for caries-related reasons per 100,000 member months for all enrolled children	Integrated delivery system	ADA	Dental (outcome)	2015	Endorsed		No
2695	Follow-Up After Emergency Department Visits for Dental Caries in Children	Percentage of ambulatory care sensitive emergency department (ED) visits for dental caries among children 0–20 years in the reporting period for which the member visited a dentist within (a) 7 days and (b) 30 days of the ED visit	Integrated delivery system	ADA	Dental (process)	2015	Endorsed		No
2723	Wrong-Patient Retract-and-Reorder (Wrong Patient-RAR) Measure	A Wrong-Patient Retract-and-Reorder (Wrong Patient-RAR) event occurs when an order is placed on a patient within an EHR, and is retracted within 10 min, and then the same clinician places the same order on a different patient within the next 10 min	Integrated delivery system, facility, group	NYPH	Safety (outcome)	2015	Endorsed		Yes
2806	Pediatric Psychosis: Screening for Drugs of Abuse in the Emergency Department	Percentage of children/adolescents aged 5 to 19 years old seen in the emergency department with psychotic symptoms who are screened for alcohol or drugs of abuse	Facility	SCRI	Behavioral health (process)	2016	Endorsed		No

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
2863	CSTK-06: Nimodipine Treatment Administered	Proportion of subarachnoid hemorrhage (SAH) patients aged 18 years and older for whom nimodipine treatment was administered within 24 h of arrival at this hospital	Facility	TJC	Stroke (process)	2016	Endorsed		No
2864	CSTK-01: National Institutes of Health Stroke Scale (NIHSS) Score Performed for Ischemic Stroke Patients	Proportion of ischemic stroke patients aged 18 years or older for whom an initial NIHSS score is performed prior to any acute recanalization therapy (i.e., intravenous (IV) thrombolytic (t-PA) therapy, or intra-arterial (IA) thrombolytic (t-PA) therapy, or mechanical endovascular reperfusion (MER) therapy) in patients undergoing recanalization therapy and documented in the medical record, or documented within 12 h of arrival at the hospital emergency department in patients who do not undergo recanalization therapy	Facility	TJC	Stroke (process)	2016	Endorsed		No
2866	CSTK-03: Severity Measurement Performed for Subarachnoid Hemorrhage (SAH) and Intracerebral Hemorrhage (ICH) Patients (Overall Rate)	Proportion of SAH and ICH stroke patients aged 18 years or older for whom a severity measurement (i.e., Hunt and Hess Scale for SAH patients or ICH Score for ICH patients) is performed prior to surgical intervention (e.g., clipping, coiling, or any surgical intervention) in patients undergoing surgical intervention and documented in the medical record, *or* documented within 6 h of arrival at the hospital emergency department in patients who do not undergo surgical intervention	Facility	TJC	Stroke (process)	2016	Endorsed		No
2880	Excess Days in Acute Care (EDAC) After Hospitalization for Heart Failure (HF)	The measure assesses days spent in acute care within 30 days of discharge from an inpatient hospitalization for HF to provide a patient-centered assessment of the post-discharge period	Facility	CMS	Cardiovascular (outcome)	2016	Endorsed		No
2881	Excess Days in Acute Care (EDAC) After Hospitalization for Acute Myocardial Infarction (AMI)	This measure assesses days spent in acute care within 30 days of discharge from an inpatient hospitalization for acute myocardial infarction (AMI) to provide a patient-centered assessment of the post-discharge period	Facility	CMS	Cardiovascular (outcome)	2016	Endorsed		No

2882	Excess Days in Acute Care (EDAC) After Hospitalization for Pneumonia	This measure assesses days spent in acute care within 30 days of discharge from an inpatient hospitalization for pneumonia, including aspiration pneumonia or for sepsis (not severe sepsis) with a secondary discharge diagnosis of pneumonia coded in the claim as present on admission (POA) and no secondary diagnosis of severe sepsis coded as POA	Facility	CMS	Pulmonary (outcome)	2016	Endorsed		Yes
2983e	Potassium Sample Hemolysis in the Emergency Department	Percentage of laboratory potassium samples drawn in the emergency department (ED) with hemolysis	Facility	CCF	Safety (outcome)	2017	Approved for trial use (5)		Yes
3309	Risk-Standardized Survival Rate (RSSR) for Inhospital Cardiac Arrest	This measure estimates a hospital -level risk standardized survival rate (RSSR) for patients aged 18 years and older who experience an inhospital cardiac arrest	Facility	AHA	Cardiovascular (Outcome)	2019	Endorsed		No
3316e	Safe Use of Opioids—Concurrent Prescribing	Patients aged 18 years and older prescribed two or more opioids or an opioid and benzodiazepine concurrently at discharge from a hospital-based encounter (inpatient or emergency department [ED], including observation stays)	Facility	CMS	Safety (process)	2018	Endorsed		No
3357	Facility-Level 7-Day Hospital Visits After General Surgery Procedures Performed at Ambulatory Surgical Centers	Facility-level risk-standardized ratio of acute, unplanned hospital visits within 7 days of a general surgery procedure performed at an ambulatory surgical center (ASC) among Medicare fee-for-service (FFS) patients aged 65 years and older	Facility	CMS	Surgery (outcome)	2018	Endorsed		Yes
3366	Hospital Visits After Urology Ambulatory Surgical Center Procedures	Facility-level risk-standardized rate of acute, unplanned hospital visits within 7 days of a urology procedure performed at an ambulatory surgical center (ASC) among Medicare fee-for-service (FFS) patients aged 65 years and older	Facility	CMS	Urology (outcome)	2019	Endorsed		Yes
3400	Use of Pharmacotherapy for Opioid Use Disorder (OUD)	The percentage of Medicaid beneficiaries ages 18–64 with an OUD who filled a prescription for or were administered or dispensed an FDA-approved medication for the disorder during the measure year	Population	CMS	Safety (process)	2018	Endorsed		No

(continued)

Table 4.1 (continued)

NQF ID	Measure title*	Measure description*	Reporting level	Measure owner*,†	Measure target (type)*	Year endorsed	Current status	CMS program‡	Relevant to cancer care?§
3453	Continuity of Care After Inpatient or Residential Treatment for Substance Use Disorder (SUD)	Percentage of discharges from an inpatient or residential treatment for substance use disorder (SUD) for Medicaid beneficiaries, ages 18 to 64, which was followed by a treatment service for SUD	Population	CMS	Safety (process)	2019	Endorsed		No
3455	Timely Follow-Up After Acute Exacerbations of Chronic Conditions	The percentage of issuer-product-level acute events requiring either an emergency department (ED) visit or hospitalization for one of the following six chronic conditions: hypertension, asthma, heart failure (HF), coronary artery disease (CAD), chronic obstructive pulmonary disease (COPD), or diabetes mellitus (Type I or Type II), where follow-up was received within the timeframe recommended by clinical practice guidelines in a nonemergency outpatient setting	Health plan	IMPAQ	Care coordination (process)	2019	Endorsed		No
3470	Hospital Visits After Orthopedic Ambulatory Surgical Center Procedures	Facility-level risk-standardized rate of acute, unplanned hospital visits within 7 days of an orthopedic procedure performed at an ambulatory surgical center (ASC) among Medicare fee-for-service (FFS) patients aged 65 years and older	Facility	CMS	Musculoskeletal (outcome)	2019	Endorsed		Yes
3488	Follow-Up After Emergency Department Visit for Alcohol and Other Drug Abuse or Dependence	The percentage of emergency department (ED) visits for members 13 years of age and older with a principal diagnosis of alcohol or other drug (AOD) abuse or dependence, who had a follow-up visit for AOD	Health plan	NCQA	Behavioral health (process)	2019	Endorsed		No
3489	Follow-Up After Emergency Department Visit for Mental Illness	The percentage of emergency department (ED) visits for members 6 years of age and older with a principal diagnosis of mental illness or intentional self-harm, who had a follow-up visit for mental illness	Health plan	NCQA	Behavioral health (process)	2019	Endorsed		No

3490	Admission and Emergency Department (ED) Visits for Patients Receiving Outpatient Chemotherapy	The Admission and Emergency Department (ED) Visits for Patients Receiving Outpatient Chemotherapy Measure, hereafter referred to as the chemotherapy measure, estimates hospital-level, risk-adjusted rates of inpatient admissions or ED visits for cancer patients =18 years of age for at least one of the following diagnoses—anemia, dehydration, diarrhea, emesis, fever, nausea, neutropenia, pain, pneumonia, or sepsis—within 30 days of hospital-based outpatient chemotherapy treatment	Facility	CMS	Cancer-specific (outcome)	2019	Endorsed		Yes

Source: This table is based on the authors' analysis of ED quality measures that are currently endorsed or were previously endorsed by the NQF, including measures currently used in CMS reporting programs [218]

Note:

*The measure titles, descriptions, and owners in this table are based on the information listed on the NQF website. These fields may differ from the measure titles, descriptions, and owners when the measures were initially endorsed by the NQF. Furthermore, a measure's use in CMS programs may have changed since the NQF website was last updated (e.g., measures reported under PQRS may now be part of MIPS)

†Measure owners are as follows: AAP, American Academy of Pediatrics (www.aap.org); ACEP, American College of Emergency Physicians (www.ada.org/en); ADA, American Dental Association (www.acep.org); AHA, American Heart Association (www.heart.org); AHRQ, Agency for Healthcare Research and Quality (www.ahrq.org); ALMA, Alabama Medicaid Agency (www.medicaid.alabama.gov); AMA-PCPI, American Medical Association-Physician Consortium for Performance Improvement (www.ama-assn.org/ama/home.page); ASCO, American Society of Clinical Oncologic (www.asco.org); CCF, Cleveland Clinic Foundation (my.clevelandclinic.org); CDC, Centers for Disease Control and Prevention (www.cdc.gov); CMS, Centers for Medicare & Medicaid Services (www.cms.gov); CMS, Centers for Medicare & Medicaid Services (www.cms.gov); HCI3, Health Care Incentives Improvement Institute (www.hci3.org); HealthPartners (www.healthpartners.com/provider-public); HFH, Henry Ford Hospital (www.henryford.com/homepage_hfh.cfm?id=37471); IMPAQ, IMPAQ International (www.impaqint.com); IPRO (www.ipro.org); LSU, Louisiana State University (www.lsuhospitals.org); NCQA, National Committee for Quality Assurance (www.ncqa.org); MGH, Massachusetts General Hospital (www.massgeneral.org); NYPH, New York-Presbyterian Hospital (www.nyp.org); Optum (www.optum.com); Optum (www.optum.com); TJC, The Joint Commission (www. §Relevance to cancer care is based on the authors' analysis of the measure specifications. Some measures (e.g., NQF #0090-Emergency Medicine: 12-Lead Electrocardiogram (ECG) Performed for Non-traumatic Chest Pain) may apply to cancer patients with other comorbidities as well as health status changes. However, the measures are not directly relevant to cancer care

‖Measure was approved for trial use by NQF. NQF's Trial Use Program enables temporary use of electronic measures, or eMeasures, that lack full reliability and validity testing but are otherwise ready for implementation [218]

¶Measure was given time-limited endorsement. Time-limited endorsement is granted to measures that meet NQF evaluation criteria, but have not been adequately field-tested. Measure developers are given up to 2 years to demonstrate the reliability, validity, and feasibility of the measure based on testing at multiple provider sites [219]

including the IQR program and PPS-Exempt Cancer Hospitals Quality Reporting Program (PCHQR). Over time, many of these measures have been retired from federal reporting programs or are no longer endorsed by the NQF. As of July 2020, there are 39 NQF-endorsed ED quality measures, including 9 ED quality measures used in CMS reporting programs. One additional ED quality measure has been approved for trial use (see Table 4.1). ED measures relevant to cancer care and the limitations of those measures are summarized in the following section and in Table 4.2.

Table 4.2 Existing ED measures relevant to cancer care, current gaps, and measure development priorities

Cancer-specific ED measures
Description: Measure aspects of emergency care that are unique to cancer patients. Include measures of the processes, outcomes, structure, efficiency, and costs of care as well as patients' perception-of-care
Rationale: Cancer patients visit the ED throughout the continuum of care and often present with complex, interrelated symptom burden (particularly at the end of life). Many ED measures focus on cardiovascular disease and are not relevant to oncologic emergency care. In addition, many cancer patients experience unique quality of care issues (e.g., late-stage cancers presenting to the ED) that reflect quality issues in other care settings and are not captured in existing measures. Widespread adoption of cancer-specific ED measures will help stimulate improvements in emergency oncologic care
Current measures: Two cancer-specific ED measures have been developed, and one measure is currently National Quality Forum (NQF)-endorsed. They assess overutilization of ED services, due to poor symptom management, aggressive treatment, poor care coordination, or inadequate access to care
Examples:
– NQF measure #3490—Admission and Emergency Department (ED) Visits for Patients Receiving Outpatient Chemotherapy
Health services research priorities: *Listed below by measure type*
Measure development priorities: *Listed below by measure type*
ED outcome measures
Description: Measure the outcomes of emergency care, including the sustainability of health post-ED discharge, timeliness of ED care, and treatment complications during and after ED discharge
Rationale: Cancer patients frequently visit the ED for symptom management (e.g., management of acute pain and fatigue) due to cancer treatment or cancer progression. In addition, ED care delays are associated with ED overcrowding and boarding and, ultimately, poorer outcomes and compromised quality of life. Failure to measure the timeliness of care—in particular, timely symptom improvement—represents a failure to measure the most important outcomes for these patients
Current measures: There are 17 NQF-endorsed ED outcome measures; these measures largely assess overutilization of ED services and patient safety
Examples:
– NQF measure #2882—Excess days in acute care (EDAC) after hospitalization for pneumonia
– NQF measure #3309—Risk-Standardized Survival Rate (RSSR) for Inhospital Cardiac Arrest
Health services research priorities:
– Develop protocols to adopt validated patient-reported outcome surveys as a standard of care for EDs to collect data on symptom burden and quality of life in the ED and post-ED discharge. Focus on minimizing patient burden and leveraging telehealth and other emerging technologies, where possible
– Study clinical and patient characteristics that are associated with repeat ED visits and post-ED discharge health decline in the cancer population
Measure development priorities:
– "Time to" patient-reported symptom improvement in the ED, stratified by chief complaint
– "Time to" cancer diagnosis, for patients presenting to the ED with an undiagnosed cancer
– Sustainability of patient-reported symptom improvement post-ED discharge, stratified by chief complaint
– Repeat ED visits within 2, 7, and 14 days of ED discharge, stratified by chief complaint
– ED length of stay for cancer patients, stratified by (1) patients admitted to an inpatient unit, (2) patients transferred to another facility, and (3) patients discharged home
ED process measures
Description: Assess compliance with established standards of ED care that have been linked to improved patient outcomes, fewer unnecessary services, and more equitable care. Include a wide array of measures, such as adherence to guideline-based diagnostic testing and treatment; protocols around patient intake, discharge, and care coordination; and policies to ensure equitable care for vulnerable patient populations
Rationale: Routine measurement of adherence to guideline-based care can highlight practice variations that contribute to poorer outcomes and higher costs of care. Measuring care coordination by ED providers is important to ensure that patients are guided to appropriate follow-up care and to prevent repeat ED visits and inpatient admissions
Current measures: There are 19 NQF-endorsed ED process measures. Fourteen of these measures are condition- or population-specific; several measures focus on substance use disorder. Two ED process measures evaluate care coordination for patients discharged to outpatient care
Examples:
– NQF measure #0004—Initiation and Engagement of Alcohol and Other Drug Abuse or Dependence Treatment
– NQF measure #0291—Emergency Transfer Communication Measure

Table 4.2 (continued)

Health services research priorities:
– Develop algorithms to identify patients at potential risk of presenting to the ED with an undiagnosed cancer
– Test methods to promote care coordination between outpatient oncologic and ED providers
– Model episodes of oncologic emergency care, with well-defined endpoints and treatment pathways
– Develop algorithms to identify patients at risk for disparities in care that present to the ED
Measure development priorities:
– Screening and diagnosis for high-frequency complications that present to the ED (e.g., pain, fatigue, dyspnea, nausea, dehydration, depression, and cognitive impairment)
– Patients discharged with a referral to an appropriate outpatient oncologic provider
– Advance care planning discussions for patients with advanced cancer
– Cancers diagnosed in the ED, stratified by (1) cancer type and (2) stage of disease
ED cost /resource use measures
Description: Calculate direct and indirect costs (or assess resource utilization) for a specific healthcare service, episode of care, or medical condition. Demonstrate variations in costs across geographic regions, medical conditions, care delivery settings, and providers
Rationale: Cost and resource use measures can increase transparency around cost inefficiencies (perceived and actual), higher costs associated with adverse events, delayed diagnosis and treatment, and individual patient factors, such as comorbid conditions. Furthermore, these measures can provide important insights into cost variation between providers, care delivery settings, and geographic regions, among patients with similar diagnoses, and across the continuum of cancer care
Current measures: There are two NQF-endorsed cost/resource use measures that are relevant to ED care
Examples
– NQF measure #1598—Total Resource Use Population-Based PMPM Index
– NQF measure #1604—Total Cost of Care Population-Based PMPM Index
Health services research priorities:
– Model episodes of oncologic emergency care, with well-defined endpoints and treatment pathways
Measure development priorities:
– Costs of care per ED visit, stratified by chief complaint
– Cost of diagnosing asymptomatic or quasi-symptomatic cancers in the ED
– Costs of managing patient comorbidities in the ED
– Costs of care by adverse event
– Costs of ED care in the last 7, 14, and 30 days of life
ED efficiency measures
Description: Examine the relationship between inputs and outputs in emergency care; they compare resource use (and associated costs) with the level of health outcome achieved
Rationale: Significant resources are expended in managing the complex—and often interrelated—symptoms, comorbidities, and psychosocial needs of patients presenting to the ED, particularly cancer patients
Current measures: There are no NQF-endorsed ED efficiency measures
Examples: None
Health services research priorities:
– Understand the overuse, underuse, and misuse of ED resources in cancer patients; this is largely unstudied beyond the frequency of ED visits. Develop guidelines for appropriate ED resource utilization for cancer patients
– Evaluate the relationship between ED resource utilization and outcomes for cancer patients
– Study the relationship between resource utilization (in the ED and in the outpatient setting) and repeat ED visits for cancer patients. Develop protocols to reduce repeat ED visits for cancer patients, particularly at the end of life
Measure development priorities:
– Efficient utilization of advanced imaging studies for cancer patients
ED patients' perception-of-care measures
Description: Evaluate patients' satisfaction or experience with the healthcare received
Rationale: While restoration of health is of primary importance among cancer patients, equally important is patient (and caregiver) experience with care throughout the cancer care continuum. This is particularly true for patients with advanced cancer whose treatment may be noncurative.
Current measures: One ED patients' perception-of-care survey has been developed, but it is not NQF-endorsed or used in public reporting programs. The Child Hospital Consumer Assessment of Healthcare Providers and Systems (Child HCAHPS) Survey is NQF-endorsed but classified as an outcome measure
Examples:
– Consumer Assessment of Healthcare Providers and Systems (CAHPS) survey for emergency care (ED CAHPS)
Health services research priorities:
– Strategies to address the psychosocial needs of cancer patients with advanced disease and their caregivers
Measure development and research priorities:
– Relevance of the ED CAHPS survey to oncologic emergency medicine
– Survey of caregiver experience with emergency care and overall caregiver burden

Source: This table is based on the authors' analysis of NQF-endorsed ED measures relevant to cancer care [220], current gaps, and measure development priorities as of July 2020

Limitations of Existing Quality Measures for Emergency Departments

Despite the noteworthy efforts to date, the current ED performance measurement landscape has substantial limitations. For example, several ED measures are reported on Hospital Compare. However, these measures are largely provider-oriented, reflect fragmented care delivery, and lack a clear method to address upstream care delivery challenges that often present in the ED. Moreover, there is no nationally mandated public reporting program for emergency care. Hence, patients lack reliable guidance on ED provider performance. Due to these factors, current reporting efforts offer limited potential to improve substantially the quality of ED care for cancer patients. Five limitations of ED quality measurement in the USA are briefly discussed below: (1) gaps in existing ED measures; (2) fragmented measure development; (3) difficulty defining an episode of oncologic emergency care; (4) measurement without a clear mechanism for improving ED care; and (5) challenges in obtaining ED quality data.

Gaps in Existing ED Measures

A robust ED measure set for cancer patients should evaluate multiple dimensions of oncologic emergency care, including access, care coordination, advance care planning, patient and family engagement, and evaluation and management of acute and chronic conditions, as well as psychosocial needs. Routine measurement of outcomes, costs of care, and appropriate resource utilization is also essential. Yet, no existing measure set or quality reporting program adequately measures these aspects of oncologic emergency care. As noted above, 31 ED quality measures are endorsed or approved for trial use by the NQF as of July 2020. Eighteen of these measures are relevant to cancer care, including one cancer-specific measure. Current ED measurement gaps relevant to cancer care span measure categories—process, outcomes, cost/resource use, efficiency, and patients' perception-of-care—and include cancer-specific ED measures. These measurement gaps, together with recommendations to address these gaps, are summarized in Table 4.2.

Fragmented Measure Development

Historically, ED measure development efforts in the USA were academic-led and focused on specific patient populations or clinical conditions. These initiatives were conducted independently of payers and state and federal agencies, leading to a "patchwork of measures" for ED care [208]. These independent measure development efforts have contributed to the fragmented ED quality measurement observed today, which undermines efforts to deliver high-quality, patient-centered care. With few exceptions, existing ED measures have not been widely adopted by providers or payers. Thus, most ED care is not routinely measured, and existing quality measures provide an incomplete view of the nation's ED system. A well-coordinated approach to developing ED quality of care measures for oncologic is discussed later in this chapter.

Difficulty Defining an Episode of Oncologic Emergency Care

Defining an episode of emergency care is challenging for most conditions due to variations in the expected prognosis, treatment time, time to recovery, care teams, and treatment settings. Defining standardized episodes of oncologic emergency care is especially problematic for two reasons. First, cancer patients move frequently and unpredictably between care settings throughout the continuum of care. Therefore, cancer patients may present to the ED before diagnosis (for late-stage cancers presenting to the ED), at any point during treatment, and at the end of life. Second, the sequelae of cancer and its treatment vary greatly across patients. Therefore, cancer patients can present to the ED with symptoms of varying severity, ranging from moderate dehydration to life-threatening sepsis, making it difficult to standardize oncologic emergency treatment pathways across patients. Because episodes of oncologic emergency care can vary so greatly across patients, it is equally difficult to develop quality measures and appropriate benchmarks for care. Focused health service research is needed to develop episodes of oncologic emergency care with well-defined endpoints to support the development of relevant quality measures for this setting.

Measurement Without a Clear Mechanism for Improving Care

Quality measures designed for performance improvement and accountability should align with evidence-based guidelines, should be actionable by clinicians, and have a clearly defined relationship with patient outcomes. Moreover, measures should be reported publicly to inform healthcare consumers and to drive improvements in care. Public reporting of ED performance data has been proposed as a critical lever for improving the nation's emergency care system [35]. Ideally, existing quality measurement programs could be leveraged to measure the quality of emergency care across providers and care settings. However, the current programs are too narrowly focused to support a broad, system-level approach to measuring the quality of emergency care. Additionally, experience with publicly reported ED measures has produced mixed results. Some public reporting initiatives (e.g., AMI performance measures) have generated significant improvements in care,

while others (e.g., pneumonia performance measures) have yielded disappointing results or—even worse—poorer quality of care. In those cases, the measures were misaligned with the existing guidelines, were based on weak evidence, or included arbitrary time points [208]. Additionally, flawed attribution models may generate erroneous conclusions regarding the quality of ED care and impede efforts to address quality of care issues. These limitations must be addressed to ensure that ED quality measures can support meaningful improvements in care, particularly for oncologic where multiple providers and care settings share responsibility for their outcomes of care.

Challenges in Obtaining ED Quality of Care Data

Much has been published in recent years regarding the limitations of existing data to support robust, actionable quality measurement. Historical quality measurement leveraged administrative claims data, which are relatively easy to access but are not designed for quality reporting. At best, they offer an incomplete view of healthcare quality. At worst, the data may be irrelevant, incomplete, or inaccurate. Federal agencies and EHR vendors have promoted EHRs as a viable alternative to address these data issues. However, EHRs were designed to support healthcare operations, rather than quality measurement, and early assessments of EHR-based quality reporting have been disappointing [221–223]. Manual chart review and data entry remains a primary method of collecting data—or supplementing electronic data—to produce quality measures. The level of effort and reporting lag associated with this approach limit access to the data that are critical for timely, actionable, and meaningful ED quality measurement. Moreover, because ED physicians often lack an established and ongoing relationship with their patients, they often lack access to immediate and long-term data on the outcomes of ED care. Potential strategies to address these issues are described later in this chapter.

Desired State of National Quality Measurement for Oncologic Emergency Care

In reviewing the history and current state of national quality measurement for emergency medicine, several important themes emerge:

1. There is widespread acknowledgment of the essential role that EDs serve in the nation's public health system.
2. Quality issues in emergency medicine are well documented, and healthcare experts have developed practical recommendations to address many of these issues.
3. Some quality issues observed in the ED are unrelated to the quality of emergency care and, instead, reflect broader social issues (e.g., inadequate access to healthcare) or quality of care issues in other healthcare settings.
4. Public and private organizations have recognized that quality measurement is integral to ED quality improvement, and early successes in cardiovascular emergency medicine have demonstrated how ED-based national quality measurement can be leveraged to improve patient outcomes.
5. HIT advancements, together with increased adoption of EHRs, offer the potential to give ED providers greater access to the data needed to care for their patients and to evaluate their quality of care on a more real-time basis.

While not specific to oncologic emergency care, these accomplishments represent a solid platform to address existing measurement gaps through national reporting for oncologic emergency care. There are five factors that contribute to the current state of inertia we described earlier in this chapter: (1) gaps in existing ED measures; (2) fragmented measure development; (3) difficulty defining the episode of oncologic emergency care; (4) measurement without a clear mechanism for improving ED care; and (5) challenges in obtaining ED quality data. Many of these factors stem from substantial shortcomings in the funding, oversight, and coordination of measure development and public reporting for cancer care.

In this section, we outline a vision for measuring quality in oncologic emergency care, through the implementation of the NAM's recommendation to create a comprehensive national quality reporting program for cancer care. This includes a well-coordinated approach to developing cancer-specific ED quality of care measures. We also propose healthcare policy changes that will promote better alignment between public reporting and reimbursement for oncologic emergency care and that will promote shared accountability across providers. Additionally, we describe how the NAM's recommendation to implement a learning healthcare system for cancer could address many of the challenges in obtaining ED quality of care data. Finally, we share a sample case study describing how ED and palliative providers can partner with palliative care providers to address upstream gaps in care to reduce ED visits.

Vision for National Quality Measurement in Oncologic Emergency Care

Since 1999, the NAM has promoted national quality measurement as an essential lever to improve the quality of US cancer care delivery. In 2013, the NAM released *Delivering High-Quality Cancer Care: Charting a New Course for a System in Crisis*, which outlined six compo-

nents of a high-quality cancer care delivery system: (1) engaged patients; (2) an adequately staffed, trained, and coordinated workforce; (3) evidence-based cancer care; (4) a learning healthcare information technology system; (5) translation of evidence into clinical practice, quality measurement, and performance improvement; and (6) accessible, affordable cancer care [84]. The report identified the nation's inability to systematically measure and improve cancer care delivery as a primary contributor to existing gaps in cancer quality and offered the following recommendation:

Recommendation 8: Quality Measurement

Goal: Develop a national quality reporting program for cancer care as part of a learning healthcare system.

To accomplish this, the Department of Health and Human Services should work with professional societies to:

- Create and implement a formal long-term strategy for publicly reporting quality measures for cancer care that leverages existing efforts
- Prioritize, fund, and direct the development of meaningful quality measures for cancer care with a focus on outcome measures and with performance targets for use in publicly reporting the performance of institutions, practices, and individual clinicians
- Implement a coordinated, transparent reporting infrastructure that meets the needs of all stakeholders, including patients, and is integrated into a learning healthcare system [84]

Implementation of this national quality reporting program for cancer care would enhance quality measurement within the ED and across other care delivery settings. It would support purposeful, well-coordinated, and patient-centered quality measurement in the ED, with an emphasis on care coordination and shared accountability across providers and care delivery settings. Through public reporting, it would encourage evidence-based care delivery and patient engagement while discouraging unnecessary—*and potentially harmful*—care. By increasing transparency around the outcomes, processes, and costs of cancer care, the national reporting program envisioned in the report could expedite progress toward a high-quality cancer care delivery system, of which the ED is an essential component. Adequate funding, formal leadership, strong collaboration, and HIT enhancements, together with a well-developed framework and a unified strategy, are essential to its successful implementation, as discussed below.

Health Policy for Measuring Quality in Oncologic Emergency Care

As described earlier in this chapter, EMTALA and the no-duty-to-treat principle form the health policy base for emergency care in the USA. While EMTALA facilitates patient access to emergency medical care, it does not regulate the quality of that care. More recently, the MMA, DRA, Tax Relief and Health Care Act of 2006, and MACRA introduced and reformed national quality reporting for emergency care. The quality reporting stimulated by this legislation has done little to promote high-quality oncologic emergency care because it focused largely on other conditions, such as cardiovascular disease.

To advance quality in the nation's oncologic emergency care, national quality reporting for cancer care is essential, as recommended by the NAM. The frequency, complexity, and costs of oncologic emergency care, particularly at the end of life, necessitate a well-coordinated and unified approach to address current measurement gaps in oncologic emergency care. Thus, we offer the following policy recommendations in support of this effort:

- *Leadership and Collaboration*: *Delivering High-Quality Cancer Care—Charting a New Course for a System in Crisis* identified HHS as the appropriate organizer of this work. Through collaboration with patient advocacy organizations, professional societies, payers, and other stakeholders, HHS could ignite national development of quality measures for oncologic emergency care. Designating CMS and the NQF as key partners in this effort could accelerate progress in developing validated cancer-specific ED quality of care measures.
- *Formal Long-Term Strategy*: Create and enforce a formal long-term strategy (with shorter-term milestones) and a well-defined framework for the development and public reporting of measures for oncologic emergency care (as part of a broader strategy and framework for cancer). This long-term strategy would address the needs of all cancer patients, with a particular focus on cancer patients seeking emergency care at the end of life. Moreover, by moving away from quality measurement focused on specific Medicare payment programs, it would promote shared accountability by providers.
- *Research*: Fund health services research and clinical trials to expand the scientific evidence for oncologic emergency care, including:
  - Effective care coordination between outpatient oncologic and ED providers
  - Outpatient care delivery models that reduce unnecessary ED utilization among cancer patients

  - Approaches to mitigate the overutilization of ED services by cancer patients, particularly at the end of life
  - Episodes of oncologic emergency care, with well-defined endpoints and treatment pathways
  - Strategies to address the psychosocial needs of cancer patients with advanced disease and their caregivers
  - Drivers of late-stage cancers presenting to the ED
  - Care delivery models that integrate palliative care with ED services
- *Measure Development*: Fund the development of a robust set of meaningful measures for oncologic emergency care (including performance targets) for use in public reporting. Measure development should focus on the outcomes of care as well as access to care, care coordination, advance care planning, patient and family engagement, and evaluation and management of acute and chronic conditions, as well as psychosocial needs. High-priority measurement gaps are described in Table 4.2. Prioritization of measure development should align with the formal long-term strategy guiding this effort and target likely healthcare disparities. Moreover, measure development should have a well-defined cost-benefit relationship and should foster shared accountability across providers and including patients. Where appropriate, the developed measures should address multiple care delivery settings. Measures available from existing data sources should receive higher priority. However, lack of data should not constitute a barrier to measure development. A formal tool should be developed to assist the collaborative in prioritizing measure development [224].
- *Transparent Reporting Infrastructure*: As recommended by the NAM, implement a reporting infrastructure (including IT infrastructure and reporting methodologies) that promotes transparency of the outcomes that are most meaningful to patients and their caregivers and that meets the information needs of all stakeholders (patients and their caregivers, providers, payers, and state and federal agencies). Public reporting should be understandable by patients and their caregivers to support healthcare decision-making.

Expedited adoption of health policy in support of these priorities would do much to address the existing measurement gaps for oncologic emergency care. With multistakeholder collaboration among organizations that share a vested interest in oncologic emergency medicine as well as proper funding and authority, robust national quality measurement for oncologic emergency care could become a reality within a few years.

HIT Support Through the Learning Healthcare System for Cancer

Providers face significant obstacles in obtaining timely, actionable, and comprehensive data to support the robust quality measurement described herein. Additionally, because ED providers lack an established and ongoing relationship with their patients, they often do not have access to post-discharge and longitudinal outcomes data to support meaningful quality measurement. To advance meaningful quality measurement and public reporting, *Delivering High-Quality Cancer Care: Charting a New Course for a System in Crisis* advocated the creation of a learning healthcare system for cancer [84]. A learning healthcare system streamlines provider data collection and reporting and enables real-time data analysis for performance improvement, quality measurement, and clinical decision support. The cancer-specific learning healthcare system described by the NAM would support more rapid innovation in cancer care delivery by addressing critical data gaps in two ways: (1) by capturing provider-driven clinical data, patient-reported outcomes, and patient and caregiver experience with care in a structured format and (2) by integrating structured, unstructured, and semi-structured data. National endorsement of this recommendation would address many of the data gaps described in this report and would enable development and reporting of quality measures for oncologic emergency care. To be successful, federal incentives to promote HIT adoption (e.g., Meaningful Use) should incorporate the principles of a learning healthcare system for cancer [225]. Likewise, public and private payers should reward providers for participating in a learning healthcare system for cancer. Aligning provider incentives with adoption of a learning healthcare system for cancer would enhance the current IT infrastructure and promote widespread access to the information needed to catalyze national public reporting for oncologic emergency care.

Role of Targeted Quality Measures in Driving Practice Change

As noted earlier in this chapter, quality measures provide a standardized, objective means of evaluating healthcare quality and hold an important role in the US healthcare delivery system. State and federal agencies utilize quality measures to promote provider accountability and to inform the public. Increasingly, payers are using quality measures in value-based payment programs to align reimbursement with quality of care. Because cancer patients experience unique

quality of care issues and because most disease-specific ED measures focus on non-cancer conditions, the existing ED quality of care measures offer minimal opportunity to improve the quality of oncologic emergency care. Despite these limitations, *appropriately selected* quality measures have the potential to inform consumer decision-making and care planning, accelerate improvements in care, and highlight variation between providers and over time within a given practice setting [84]. Additionally, routine quality measurement and reporting enables payers and providers to test whether new care delivery and payment models have a positive effect on the accessibility, quality, and affordability of healthcare.

Public reporting of well-designed quality measures for oncologic emergency care represents a powerful policy lever to encourage more appropriate ED resource utilization, better care coordination, shared accountability, and, ultimately, superior outcomes and patient (and caregiver) experience with care. Lamb et al. observed that the act of measuring performance at the provider level can ignite an interest in self-improvement or a competitive spirit among providers, leading to improvements in care [226]. Pay-for-performance programs are another policy lever that could lead to improvements in the quality of oncologic emergency care. The effectiveness of pay-for-performance programs has been debated extensively, given current measurement gaps across multiple conditions and various aspects of care. However, designing a pay-for-performance program around targeted quality measures for oncologic emergency care (such as those listed as measure development priorities in Table 4.2) could stimulate significant and lasting improvements in care.

Conclusion

In this chapter, we examined the history, current state, and desired future state of health policy for quality in oncologic emergency care. We discussed five quality issues that cancer patients experience when seeking care in the ED, together with upstream drivers. We also described specific issues for dedicated oncologic EDs. We highlighted the essential role of quality measures in addressing these quality of care issues, along with five limitations of the existing quality measures that apply to emergency care. We also shared the quality measures for emergency care that are currently endorsed by the NQF and used in CMS quality reporting programs. We outlined recommendations for national quality measurement for oncologic emergency care, through the implementation of the NAM's recommendation to create national quality reporting for cancer care, as part of a learning healthcare system. We proposed health policy changes—in the form of leadership and collaboration, formal long-term strategy, research, measure development, and transparent reporting infrastructure—to accelerate progress toward national quality measurement for oncologic emergency care. We emphasized the importance of adequate funding, formal leadership, strong collaboration, and HIT enhancements to make this reporting a reality. We also explained how a learning healthcare system for cancer and targeted quality measures can catalyze change and advance progress toward the national reporting program described herein. Additionally, we shared a sample case study outlining a collaborative approach to address unmet palliative care needs in the ED.

The recommendations outlined in this chapter are ambitious but are necessary to accelerate the development of targeted quality measures for oncologic emergency medicine. To be successful, measure developers and other stakeholders must abandon the historical practice of siloed development of highly specific measures that apply to a small proportion of the population or to a single care delivery setting. With adequate funding, unified leadership, and multi-stakeholder commitment, national quality reporting for oncologic emergency medicine could become a reality within a few years, leading to more patient-centered and higher-quality cancer care in the ED.

Patient Navigation

5

David C. Seaberg and Donald Norris II

Introduction

Cancer patients face significant challenges. This is true not only with their illness but also when trying to navigate an increasingly matrix-oriented healthcare system. While advances in cancer treatment have helped save millions of lives over the last three decades, patients face far more complex treatment decisions and follow-up options than ever before. The amount of time required and the types of services cancer patients utilize have expanded across the spectrum of prevention, screening, diagnosis, treatment, and survivorship. As more cancer patients live with chronic illness, the length of time a patient is engaged with the healthcare system, including the emergency department (ED), has increased. Efforts made by healthcare systems to enhance patient experience and coordinate care have become increasingly more important.

Patient navigation is seen as one possible solution to this problem. Patient navigation has been shown to improve timely cancer care [1–4]. Patient navigation programs reduce gaps in care by improving access to cancer services, improving the timeliness of the provision of these services, and adding strong support and guidance to patients [5]. Patient navigation involves collaboration between patients, providers, families, and caregivers. Their collaboration extends throughout the cancer continuum, from prevention and screening through treatment, survivorship, and palliative and end-of-life care. These programs employ a variety of individuals from laypeople to trained nurses and social workers to assist patients.

US emergency departments are an increasingly important site of care for patients with complex care needs. Specifically, ED visits for patients with cancer now exceed 4.5 million annually [6, 7]. ED visits for individuals aged 65 years and older now number nearly 30 million [8]. Many of these patients lack essential health knowledge including an understanding of the resources they need to optimize their health. Patient navigator systems help patients with complex care needs navigate the multifaceted and fragmented medical systems.

Case Study

Charlotte, North Carolina-based Atrium Health's Levine Cancer Institute developed a patient navigation program that featured 25 nurse navigators spread across seven locations. Patients who did not receive navigation services were 52% more likely to have unplanned hospital readmissions within 30 days when compared with patients who did. In a retrospective cohort study of approximately 2300 patients with poor prognosis (as defined by the American College of Surgeons [ACS]), the program found a significant survival benefit for patients who had received navigation services compared with those who had not. The greatest survival advantage was seen in patients who were either African American, were insured by Medicaid, or had lung or pancreatic cancer [9].

Background

Patient navigation is an intervention to reduce health disparities in cancer care. It is specifically aimed at vulnerable or medically underserved populations. The first patient navigator program was created by Harold Freeman in 1990 at Harlem Hospital in New York, NY. He focused on underserved women with breast cancer [10, 11]. The goals of the program were to expand access to cancer screening, improve

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_5

clinical follow-up among medically underserved women through community outreach, and reduce the time between an abnormal test result and diagnosis and/or treatment [12]. Eliminating barriers to health access, such as lack of insurance or cultural and communication barriers, was also critically important. The navigation program was remarkably successful with an increased 5-year survival of 31% [10, 11].

In the 30 years since Dr. Freeman's initial program, the use of patient navigator programs has spread to other cancer treatment programs as a means to decrease barriers to care and improve overall outcomes for disparate populations. Many of the current patient navigator programs were initially focused on providing guidance to the racial/ethnic minority or low-income populations. In 2001, the President's Cancer Panel was established with the National Cancer Act of 1971. It revealed that barriers limiting or preventing access to cancer care are not unique to poor Americans but were experienced by Americans across all socioeconomic levels [13, 14]. The panel found multiple reasons why people of all socioeconomic levels were not getting screened and treated. These were primarily related to fear, literacy, culture, and religion [15, 16]. In 2005, the Outreach and Chronic Disease Prevention Act was signed, providing financial grants for the development and operation of patient navigator services to improve healthcare outcomes across the entire country. Each approved hospital was to add a full-time navigator program [17]. In 2012, the ACS Commission on Cancer released standards that reflected the goal of "ensuring patient-centered care." One of the new standards (Standard 3.1) required all cancer programs seeking accreditation to have a patient navigation program [18, 19].

As the importance of patient navigation has been recognized, the role of nurse or patient navigators and the terms used to describe these individuals and their functions within the oncologic care team have evolved.

The National Cancer Institute (NCI) describes patient navigation as the support and guidance provided to persons with abnormal screenings or new cancer diagnoses, including overcoming challenges and barriers to accessing the healthcare system in a culturally competent manner [20–23]. They state that the role of a navigator is to help patients and their families assess the cancer care system and overcome barriers to receiving care. This includes facilitating the provision of timely, quality care in a culturally sensitive manner [15, 24]. Specific time points in the cancer continuum are the focus, and the goal is to reduce the complexity of the healthcare system for the patient [25].

Management

Patient navigation is provided to individual patients for a defined episode of cancer-related care. The goal of patient navigation is to provide an intervention that addresses barriers to quality standard care by providing individualized assistance to patients, survivors, and families [9, 26, 27]. Reducing time to access healthcare resources is critical for the patient. Oncologic navigators bridge the gap between health systems and the patient. An obvious byproduct of a successful cancer navigation program is decreased visits to the ED for these patients [28]. Navigators have the ability to effectively communicate with providers and other stakeholders within and across the institution while serving patients as knowledgeable, caring peers, and allies who have an inside track to the health system [29]. Patient navigators help patients address barriers ranging from communication to psychological or financial needs and health systems social support-related issues. Other common topics in oncologic navigation are [30]:

- Financial and economic issues
- Differences in language, which may prevent patients and family from understanding treatment recommendations
- Cultural and ethnic diversity requiring tailored interventions
- Communication among healthcare teams, patients, families, and other healthcare providers
- Transportation problems that impact patients' ability to receive healthcare
- Emotional concerns for patients including distress and fear, which may prolong decision-making and delay interventions

Oncologic patient navigators perform many roles. The navigators help reduce barriers to healthcare services through educating patients on their diagnosis/treatment and build partnerships in the community. Additionally, they help coordinate appointments, maintain communication, connect patients and families with support services, teach self-advocacy, and provide access to clinical trials. There are multiple roles in patient navigation yet no universally accepted definition. There is no consensus on necessary preparation and competencies for filling the role [31–33].

Oncologic Nurse Navigator

An oncologic nurse navigator (ONN) is a professional registered nurse with oncologic-specific clinical knowledge who offers individualized assistance to patients, families, and caregivers to help overcome healthcare system barriers and facilitate informed decisions [31, 32]. They ensure that the patient receives timely access to quality health and psychosocial care throughout all phases of the cancer continuum. In 2009, the National Coalition of Oncologic Nurse Navigators (NCONN) developed the first competencies that defined the role of the ONN [34–36]. Developed in consultation with

active professional oncologic nurse navigators throughout the United States, these core competencies cover five areas: (1) professional, legal, and ethical nursing practice; (2) health promotion and health education; (3) management and leadership; (4) negotiating the healthcare delivery system and advocacy; and (5) personal effectiveness and professional development [36, 37]. The first published guidelines establishing core competencies for ONNs were established by the Oncologic Nursing Society in 2013 [37, 38].

Oncologic Social Worker

Oncologic social workers are knowledgeable about cancer and the psychosocial and other effects of disease, treatment, and survivorship. They have advanced degrees and have additional experience and training in oncologic and other life-threatening illnesses. The oncologic social work navigator helps foster coping and adaption to cancer and its effects in order to help cancer survivors maintain or improve quality of life [38]. Their focus in clinical practice is to help complete a psychosocial assessment to determine survivor and family strengths and needs relative to coping effectively with cancer diagnosis, treatment, and follow-up care [39]. They work with other team members to develop a multidisciplinary care plan and help provide case management services. They also provide direct assistance to help meet financial, transportation, lodging, and other psychosocial needs, including end-of-life advance care planning [39]. Oncologic social workers also assist survivors in navigating through healthcare systems to help them achieve quality care. They help provide social and emotional support to cancer survivors by mobilizing new or existing family, system, and community resources [30]. In addition, oncologic social work navigators advocate with, or on behalf of, survivors, families, and caregivers to address their needs as well as advocate for policies and programs that will benefit them.

Lay Navigator

A lay navigator is a trained nonprofessional or volunteer who provides individualized assistance to patients, families, and caregivers [40]. They help overcome healthcare system barriers and facilitate timely access to quality healthcare and psychosocial care, from pre-diagnosis through all phases of cancer care. Interestingly, Dr. Freeman's original patient navigation program believed that the role of the navigator should be served by a layperson and not by a nurse or social worker [41].

Navigators can be disease, condition, or service specific, with many specializing in areas such as breast, prostate, or lung cancer. Some navigators focus primarily on the role of financial navigator. Others may provide assistance in the areas of screening and testing, as the original navigators did. Patient navigation in cancer care currently focuses on assisting patients in the coordination of care among providers, the community, and patients and their families [12, 42–44]. To move patient navigation forward, the cancer community will need to develop and agree upon a streamlined definition that can be promoted by all stakeholders and understood by patients and their families [45].

Patient-Centered Medical Home

The concept of a patient-centered medical home (PCMH) originated in pediatric literature dating to the late 1960s. Originally conceived as a way to integrate care for children with special needs, physicians soon realized that fragmented care was seen in the general pediatrics population as well. In 2007, the American College of Physicians, American Academy of Family Physicians, American Osteopathic Association, and American Academy of Pediatrics drafted the Joint Principles of the Patient-Centered Medical Home. This document defined the PCMH placing the relationship between the patient and their primary care physician at the center. While the primary physician maintains a longitudinal relationship with the patient, they also lead the team of other individuals integral to the overall care of the patient. Emphasis was placed on quality and safety leading to an overall reduction in cost with higher quality of care [46].

An additional positive outcome often mentioned when discussing the PCMH is a reduction in visits to the emergency department. The American College of Emergency Physicians (ACEP) released a policy on patient-centered medical homes in 2008 revising the policy in 2015. In this policy, ACEP fully supports the PCMH if it upholds the following principles:

1. Provide high-quality, safe, and efficient medical care
2. Provide patient access to a personal physician, the leader of a team of individuals who collectively take responsibility for ongoing care of their patients
3. Ensure patients have the freedom to select a specialist of their choosing and access emergency medical care when they feel they need it
4. Include the safety net of emergency care [47]

In 2012, the Michigan Oncologic Medical Home Demonstration Project was developed. It was one of the first multi-practice oncologic medical home projects in the country. Placing the oncologist and patient at the center of the design, this group standardized development of treatment regimens including deployment of enhanced triage and access protocols. The group also standardized advance care

planning across the groups. In addition, a medical home nurse line was established to help triage patients seeking unscheduled care. In the first year of the 85-patient pilot program, the overall cost savings was $550 per patient [48].

Health Services/Resource Utilization

Patient navigation programs and the backgrounds of those who serve as patient navigators are driven by local needs. There is no one type of patient navigation model that fits the needs of all medical settings or systems. Healthcare organizations that start patient navigation programs need to assess the needs of their populations and tailor the intervention to those needs. Patient navigation is typically a goal-oriented intervention that focuses on reducing the barriers to achieving a particular cancer healthcare goal, such as improvements in cancer screening rates, cancer treatment adherence, or patient satisfaction with care [12, 23]. Particular emphasis on implementing patient navigation interventions should focus on improvements in a particular outcome of interest. Although individual patients may benefit from actions taken by patient navigators across the cancer care continuum, current literature shows that interventions that target cancer screening outcomes have the greatest clinical benefit and most cost-effectiveness [49].

Patient navigation programs have had many successes. The Patient Navigation Research Program (PNRP) was designed to develop interventions to reduce the time to diagnosis and treatment of cancer after identifying an abnormal finding from a cancer detection procedure. The PNRP studies, enrolling over 10,000 patients, found that patient navigation reduced the time from abnormal findings to diagnosis in breast, cervical, colorectal, and prostate cancers [50]. Resolutions of cancer therapy at 180 days and at 270 days with navigation were 56.2% and 70.0%, respectively, compared with 53.8% and 68.2%, respectively, with usual care. The estimated cost of navigation in this study was $275 per patient.

Patient navigation services have proven to be effective at reducing the cost and improving the quality of care for patients with cancer. Patient navigation has been found in survey studies to increase patient and staff satisfaction while decreasing barriers to care. One study published by The Ralph Lauren Center for Cancer Care and Prevention in New York found improved cost-effectiveness for patients with breast and colorectal cancer [51]. Researchers found that patient navigation led to patients achieving diagnostic resolution with shorter treatment intervals. There were significant cost savings per patient at the end of treatment. A study at the George Washington Cancer Institute in Washington, D.C., found that the patient navigation program significantly reduced breast cancer diagnostic time. Use of patient navigation in the emergency department was found to decrease overall patient and hospital costs as well as reduce subsequent emergency department visits [4].

Adding care coordination to patient navigation has proven to have many benefits to physicians, patients, and their families. It enhances interaction among physicians, increases patient awareness and self-management, and improves patient education and satisfaction [52]. It also increases referrals for nutrition and physiological care as well as physical and social service needs [52, 53]. For the patient and the family, care coordination simplifies the process. Care coordination also facilitates access to ancillary and community services and resources. Other benefits include improved education of patient and family, increased collaboration and communication among the patient and the healthcare team, improved patient self-care and satisfaction, and increased multidisciplinary care [23].

ED visits have increased exponentially over the last three decades now topping 140 million per year [8]. Long recognized as a safety net provider, the ED is a usual source of care for those who are affected by barriers to continuity relationships with physicians as well as patients with complex medical problems requiring a coordinated care approach. Initial evidence suggests that patient navigators may help remove barriers to timely, effective patient care among vulnerable populations which may, in turn, influence ED utilization [54, 55]. In a survey of oncologic patient navigators, 91% indicated that lay navigation services would be either very helpful or moderately helpful for ED patients with cancer. Coordination of care, the provision of emotional support and educational resources, and providing companionship to older persons during the ED visits were identified as priorities for an ED-based lay navigation program. The three most common barriers that emergency department patient navigators help patients with include insurance and out-of-pocket expenses, transportation issues, and helping manage the feelings and fears associated with cancer [56]. Follow-up appointments and getting prescriptions filled were also important considerations. Funding for ED navigation programs came initially through small foundational grants for pilot programs. As the value and role of navigation programs have become more defined, hospitals have increasingly funded ED navigators who consist of teams of transitional care coordinators, case managers, and lay personnel.

There have been numerous emergency department studies on the use of patient navigation in patients who utilize the ED frequently. It has been reported that just 5% of ED patients comprise nearly 25% of all ED visits yearly [57, 58]. Though the reasons for this are multifactorial including low-income status, lack of insurance, severe chronic illnesses, and lack of primary care provider and familiarity, the cost to the patient and the community is exceedingly high [59, 60]. The cost to both the patient and community is not just monetary; care of these patients is inappropriately fragmented.

ED patients who frequently utilize the ED contribute to overcrowding affecting the community's emergency readiness. In one study, paid social work staff were trained to help patients navigate their healthcare options during their ED visit by educating the patient on their diagnosis, reviewing the associated treatment and follow-up plans including medications, and identifying proper primary care services and/or community resources that can aid with the patient's specific issues [58]. This study found that a patient navigator program reduced 1-year ED visits and costs by 9%. It was found that the majority of high utilizers had primary care providers as well as insurance. Lack of health literacy impacts their ability to navigate the health system. Lack of communication, lack of preventative care, referral options, and a cultural distrust led to poor outcomes and overutilization of the ED. Patient navigation has been shown to improve health outcomes and reduce costs [61, 62].

Another study by the Highmark Foundation found that patient navigators in three health systems were able to reduce excessive emergency department visits by 43% over 1 year [28]. In addition to the decrease in emergency department visits, one health system reported a 60% reduction in 30-day readmission, and another reported increased colonoscopy screening by 13%. The certified patient navigators in the study were laypersons who helped with nonclinical tasks such as picking up prescriptions, arranging transportation, connecting patients to community resources, and conducting post-discharge follow-ups [28].

A study at the Memorial Hermann Health System in Houston developed a patient navigation program designed to promote appropriate primary and oncologic care utilization and prevent or reduce ED use [63]. The navigators consisted of bilingual, state-certified community health workers who were trained in peer-to-peer counseling and connected medically underserved patients with medical homes and related support services. The navigators provided education about the importance of follow-up care, assisted with appointment scheduling, and followed up with patients to monitor and address additional care barriers. Over a 12-month period, ED visits declined as did medical costs [63].

Future Needs/Vision

Patient navigation needs to define the roles within the patient navigation team. Research has shown that there are similarities between the improvements in outcomes associated with patient navigation and those associated with care coordination [24]. One study reported that coordination and continuity of care were similarly important to the roles of patient navigator, nurse care manager or coordinator, and nurse navigator, for improving outcomes [33]. Another report suggested that professionally led models of patient navigation that were similar to comprehensive case management models—adding the supportive functions of advocacy, education, problem solving, and support to the standard model of assessment, outreach, and referrals—were favorable to other models [33, 64]. Coordination of care and ensuring continuity of care were described as overarching roles and responsibilities in an integrative review [64]. The future of patient navigation revolves around integrating the navigation team within the patient-centered medical home. Defining the roles within the navigation team will be essential to achieving specific clinical outcomes as well as creating efficiency and cost-effectiveness. In order to achieve their effectiveness, patient navigation programs will need to expand more to outpatient areas including the emergency department.

The new standard set by the ACS CoC in establishing patient navigation programs in all ACS CoC-accredited facilities has led to enhanced funding for navigation programs [64]. Further work is needed to demonstrate the value of the blended model patient navigation care coordination. Further studies will be needed to evaluate the economic impact of the patient navigation programs. Cost-effectiveness analysis and budget impact studies are needed to further refine these patient navigation programs in the patient-centered medical home. The Health Services Research (HSR) cost workgroup of the American Cancer Society National Patient Navigator Leadership Summit met to examine cost data relevant to assessing the economic impact of patient navigation and to propose common cost metrics. Five categories of core and optional cost measures were identified: program costs, human capital costs, direct medical costs, direct nonmedical costs, and indirect costs [64]. The researchers recommended adoption of these metrics to promote understanding of the economic impact of patient navigation and comparability across diverse patient navigation programs. Further funding opportunities will need to be explored to enhance the development of these patient navigator programs.

Conclusion

Models of patient navigation and care coordination must continue to evolve to meet the ever-changing needs of cancer patients and their families. New models must hold fast to the guiding principles of the original navigation program: improve access to the cancer care system and facilitate quality care. These programs will not only lead to more rapid diagnoses, improved patient outcomes, and increased cost savings, but they will also ensure greater patient adherence to treatment programs. With the increasing use of clinical pathways in oncologic, and the need to demonstrate the value of these pathways, navigation and care coordination programs can be effective tools for maximizing the quality of

care provided to patients. Expansion into the outpatient setting and emergency department may further increase the effectiveness and lead to both improved clinical outcomes and cost savings.

Emergency Nursing and Oncologic Emergencies

In 2011, the American Nurses Association recognized emergency nursing as a specialty practice. As a challenging and unique profession, this clinical practice area prepares nurses to provide prompt interventions to stabilize or prevent further patient deterioration. The fast-paced, high-acuity setting commands refined critical thinking, clinical assessment, communication, and prioritization skills. Additionally, emergency nurses (ENs) care for a diverse patient population with various medical conditions and acute care needs [1].

Of significance is the Emergency Nursing Association (ENA), founded in 1970 as the premier professional nursing association, devoted to illustrating the future of emergency nursing. The mission of ENA is to further excellence in emergency nursing [2].

Reflective of the diverse nature of healthcare, emergency medicine has multiple subspecialties. As such, different emergency departments (EDs) provide care to specific patient populations and health concerns. Some of the subtypes include trauma, stroke, cardiac, burn, neuro, disaster response, pediatric, and adult [3].

The same variations that exist in emergency medicine and EDs are also depicted among ENs. It is not surprising to find that most ENs assume multiple roles over the course of their career. Some of these roles include *trauma, triage, flight, critical care transport, pediatric, burn center, geriatric, and charge nurse* [3].

Professional advancement has also led to further specialization of ENs. This year, the Board of Certified Emergency Nursing recognized four different subspecialty professional certifications, including the *Certified Emergency Nurse*, *Certified Flight RN, Certified Pediatric Emergency Nurse, Certified Transport Registered Nurse, and Trauma Certified Registered Nurse* [3]. Notably, as professional advancement continues to detect emerging areas of subspecialty in emergency nursing, additional professional certifications, education, and targeted programs have been created to support quality care [3].

One emerging subspecialty is Oncologic Emergency Nursing (OEN), a clinical practice designed to provide care for patients presenting with cancer emergencies.

Consider this: the 5-year survival rate for all cancers increased from 39% in 1960 to nearly 70% in 2019 and thanks in part to new cancer treatment modalities, increased survival rates have led to approximately 15 million people in the United States with cancer. The majority of these individuals likely experience oncologic emergencies requiring an ED visit [4]. OEN is among the healthcare teams that assume multiple roles in the ED to provide quality care and ensure optimum health outcomes for the patients presenting with oncologic emergencies.

This chapter identifies high-frequency and high-risk conditions that an OEN may encounter when caring for an ED oncologic patient. For each condition, we then present a number of case studies to illustrate several medical diagnoses, associated risk factors, presenting signs and symptoms, potential causes, contributing factors, anticipated diagnostics, corresponding interventions, case dispositions, and specialty nursing considerations. We conclude with discussions of the impact of the pandemic (novel coronavirus) on cancer patients and an overview of regulatory bodies that guide ED practice in the oncologic setting.

Triage and General Assessment of Oncologic Emergencies

Triage

At triage, patients presenting to ED will encounter the triage nurse as the first medical professional. The role of the triage nurse is to identify patients needing immediate attention and then prioritize among those who do not require immediate life-saving interventions. Triage tools, such as the Emergency Severity Index (ESI), are used to standardize the approach and to predict patient disposition and ED resource use [5]. The ESI is a reliable and valid tool that is now in its fourth version [5], and is the most commonly used ED triage system in the United States [6]. The tool provides clinically relevant grading of patients into five groups from 1 (*most urgent*) to 5 (*least urgent*). This stratification is based on patients' acuity and resource needs [7].

Typically, patients with cancer have an ESI level of 1, 2, or 3 because of their potential to use multiple resources due to the complexity of their condition. Beyond the primary assessment is the need to screen for patients' cancer diagnoses, last treatment and modality, and any other significant surgeries or procedures [7].

General Assessment

ED nurses' ability to perform an accurate initial comprehensive patient assessment after triage is imperative in order to recognize the urgency and treatment needs of patients and to develop baseline data from which any changes in the condition of patients may be measured against [8].

Omission of accurate and timely patient assessments has been reported to result in adverse patient outcomes [9].

The EN can also expect the medical team to order laboratory tests. General labs should be assessed on almost all cancer patients, as treatment and disease processes may alter values from day to day and can likely provide additional insight into the underlying issue. Obtaining a complete blood count (CBC) with differential and comprehensive metabolic panel (CMP) is indicated for the vast majority of patients with a concurrent cancer diagnosis. Determining a patient's pancytopenia status, electrolyte levels and overall metabolic status are critical, as many abnormalities may not have associated symptoms in early stages. Early detection and correction of imbalances may prevent patients from incurring further injury or deterioration [10].

Although patients with cancer may present with an array of medical emergencies, this population is also at a high risk for infection. As such, sepsis should always be considered. Any signs or symptoms of infection should be promptly noted and addressed, as these patients are immunocompromised and have little physiological defense mechanisms. The presence of a central line also increases infection risk [11]. Timely collection of blood cultures and prompt administration of broad-spectrum antibiotics for any suspected infection can significantly improve the patient's prognosis [12].

Frequent ED encounters for patients with advanced cancer may also indicate a patient nearing end of life [13]. Patients with advanced cancer may benefit from conversations about advance care planning and code status to ensure their wishes are followed in the care trajectory. Although such conversations may be difficult, they can significantly improve the patient and family experience. Sending patients home with hospice from the ED is, at times, a feasible and appropriate option [14].

Chief Complaint: Chest Pain and Shortness of Breath

Patients presenting with chest pain and shortness of breath should be evaluated immediately for acute myocardial infarction via EKG. If EKG results do not suggest an acute MI, additional diagnostics should be employed to determine the underlying issue [15]. Chest pain and shortness of breath in cancer patients can be caused by various conditions that are common among cancer patients. These include pulmonary embolism, pleural effusion, pneumonia, spontaneous pneumothorax due to tumor burden, pericardial effusion, and cardiac tamponade [16]. See case studies in Table 6.1 illustrating a number of presentations involving these chief complaints [17–25]. Due to coagulopathies and bleeding tendencies, cancer patients may be at higher risk of cardiopulmonary-related adverse events [26]. As increasing numbers of patients receive immune checkpoint therapy, some cardiac presentation may represent immune-related adverse effects [27].

Tumors are known to cause collections of fluid proximal to tumor location. Depending on known lesions, tumors in the thoracic cavity may provide further insight into contributing conditions [28]. Pleural effusions are a high-frequency finding in lung cancer patients or patients with lung metastases. In recurrent pleural effusions, patients may have a Denver catheter drain placed to manage the fluid collection and reduce symptoms. If pleural effusion is identified, patients may require thoracentesis. This will likely alleviate any shortness of breath or chest pain symptoms almost immediately [29].

Table 6.1 Case studies: chest pain and shortness of breath

Vital signs	Signs and symptoms	Risk factors/contributing factors	Potential tests/ interventions	Nursing considerations
Pulmonary embolism. *A 37-year-old female with myosarcoma currently on treatment presents with sharp left-sided chest pain and SOB since 0800 today. She has a past medical history of right deep vein thrombosis. The pain worsened with motion and deep breathing. The pain has been progressively increasing in severity and she now has severe left back and shoulder pain. She complains of SOB and "feels like she is going to die." She denies cough, fever, sputum production, or hemoptysis*				
BP 121/84 HR 121 T 37.2 R 25 SpO_2 89%	Symptoms and clinical presentation may vary depending on the size of embolus & preexisting cardiopulmonary status, including asymptomatic/ incidental findings via outpatient diagnostic imaging studies Chest pain, often angina type onset and worsens with deep breathing. Chest pain will progress to pleuritic Dyspnea with sudden onset, tachypnea, crackles/wheezes, diminished breath sounds Tachycardia Low-grade fever (~40% of patients with PE) Cough/hemoptysis Syncope Back or abdominal pain Diaphoresis	Venous stasis Coagulopathies (may be induced by therapy or disease process) Atrial fibrillation Increased fatigue/ decreased activity Lung disease	General labs ECG Oxygen support CT with contrast to identify PE Arterial blood gases D-dimer (not as specific in cancer population) Initiation of thrombolytic therapy	Teach self-injection of low molecular weight heparin Monitor cardiopulmonary status for changes/ deterioration, may be rapid onset IV catheter = 18 g minimum for chest CT PE study protocol
Pleural effusion. *A 68-year-old man with lung cancer, congestive heart failure, and a 40-year history of cigarette smoking two packs a day. The patient reports that he has stopped smoking because of the lung cancer diagnosis. The patient presents to ED with shortness of breath and right-sided chest pain that worsens with deep breathing.*				
BP 150/70 HR 104 T 36.6 R 26 SpO_2 86%	Signs/symptoms dependent on amount and rate of fluid accumulation Dyspnea Cough Chest discomfort Abnormal breath sounds/ presence of pleural friction rub	CHF Pneumonia Malignancy Pulmonary embolism Pericardial constriction Obstruction of pulmonary vessels by tumor or stenosis Shedding of malignant cells into pleural space	General labs Chest X-ray and/or CT scan VQ scan ABG Thoracentesis provides symptomatic relief May be eligible for discharge if thoracentesis provides relief Cytological analysis of pleural fluid to determine if malignant cells are present	Information about procedure Treatment plan and possible placement of self-managed drainage system for recurrent pleural effusions Follow-up plan for early diagnosis and intervention for recurrent pleural effusion
Pneumonia [17, 18]. *A 68-year-old man with prostate cancer presenting to ED with a productive cough, fever × 3 days, shaking, and chills. He describes the sputum as thick and yellow. He also adds that a day ago, he developed pain in his right chest that is worsened with inspiration.*

Table 6.1 (continued)

Vital signs	Signs and symptoms	Risk factors/contributing factors	Potential tests/ interventions	Nursing considerations
BP 92/53 HR 120 T 39.0 R 26 SpO_2 90%	Fever, cough, sputum, hypoxemia, SOB Back pain, based on location of consolidation Vague, ill-defined symptoms Fatigue	Neutropenia Decreased activity Chronic obstructive pulmonary disease	General labs Blood cultures Lactic acid IV antimicrobial therapy Fluid resuscitation, ensure adequate cardiac status Sputum cultures Supplemental oxygen and use of noninvasive ventilation	Sepsis protocol Monitor changes in respiratory status, reposition as appropriate Maintain patent airway Promote normothermia Optimize fluid balance Encouraging coughing and deep breathing Promote adequate nutrition
Pneumothorax. *A 68-year-old female with a large tumor in the right lung presents with sudden onset shortness of breath. She is in acute distress and is breathing rapidly. Breath sounds are absent on the right.*				
BP 96/57 HR 119 T 38.6 R 27 SpO_2 88%	Signs/symptoms dependent on size/location of pneumothorax Respiratory distress/failure Dyspnea and chest pain Absent or decreased breath sounds on affected side Pneumothorax hyperresonant by percussion Deviation of trachea Unequal chest expansion Hypotension	Pulmonary malignancy Previous pneumothorax Procedures (i.e., central line insertion) Rupture of necrotic neoplastic tissue in pleural cavity [19] Tumor at lung periphery [20–22] Oncologic therapy [23]	Chest X-ray/CT scan Ultrasound Identification and treatment of underlying cause; may not require intervention Chest tube insertion	Monitor changes in respiratory status Assistance with chest tube insertion and management Pain management
Deep vein thrombosis. *A 54-year-old woman with uterine cancer and currently on treatment presents with left leg pain and swelling. She also reports that the swelling has been increasing over the course of 1 week. The affected leg is warm to touch, red, and edematous.*				
BP 152/74 HR 74 T 36.8 R 18 SpO_2 96%	Tight ache, tight feeling, or frank pain in calf or behind knee aggravated with standing or walking; alleviated with elevation Localized tenderness or pain over involved vein Tender, palpable venous cord of involved vein Swollen calf or thigh by measurement Calf swelling more than 3 cm in circumference in symptomatic leg Unilateral pitting edema in involved extremity Dilated superficial venous collateral vessels (non-varicose) Low-grade fever is possible	Procedures causing venous stasis (lengthy surgery) Active cancer (treatment or palliation within previous 6 months) Hypercoagulable state causing factors (physiological, environmental, iatrogenic) Presence of intravenous device (central venous access device) Coagulopathy induced by malignant cells Venous stasis (clot formation; pooling) Damage to blood vessel wall (endothelial)	General labs Laboratory: D-dimer Prothrombin/PTT Doppler ultrasonography Treatment: anticoagulants Surgical intervention: placement of vena cava filter to prevent PE in recurrent DVT Low-molecular-weight heparin (LMWH) may be self-administered	Minimize or prevent respiratory compromise Understand condition (signs & symptoms), risk factors, prevention and management Preventing further harm (adherence to treatment regimens, diet consistent with prescribed medication, health promotion) Safety measures: avoid contact sports, use of soft toothbrush for oral care and electric razor if there is a need to shave Monitor for changes and report leg pain, bleeding or signs of thrombophlebitis or PE
Pericardial effusion and cardiac tamponade [24, 25]. *A 55-year-old female with AML, currently on treatment, presents to the ED with complaints of a syncope episode with no injury. She endorses loss of consciousness for approximately "5 seconds" (verified by his adult son who was present at the time of fall). She reports that for the last 2 days, she has experienced increased fatigue associated with SOB. On assessment, her heart sounds are muffled on auscultation.*				

Table 6.1 (continued)

Vital signs	Signs and symptoms	Risk factors/contributing factors	Potential tests/ interventions	Nursing considerations
BP 108/60 HR 118 T 37.1 R 18 SpO_2 94%	Hoarseness, cough, hiccups, difficulty swallowing (compression of trachea, esophagus, vagal nerve) Muffled heart sounds Pericardial friction rub may be heard Increased jugular venous distension Kussmaul respirations Narrowing of pulse pressure – systolic blood pressure decreases and diastolic increases Paradoxical pulse (decline in systolic blood pressure on inspiration) Other signs of decreased cardiac output include tachycardia, anxiety, restless, peripheral cyanosis, oliguria, shock	Tumors most often associated with pericardial metastasis Some primary tumors (rare): sarcomas and mesotheliomas Lung and breast cancers can spread by direct extension of lymphatic metastasis Lymphomas and Leukemia routinely spread by hematogenous routes Radiation therapy of >4000 rad to the mediastinum Accumulation of excessive fluid within the pericardial sac (pericardial effusion) increasing pressure and compressing the heart	Primary goal to remove fluid and relieve/prevent impending cardiac collapse Chest X-ray, CT ECG Echocardiography Percutaneous pericardiocentesis Pharmacologic management to control heart rate	Patient teaching: early identification of signs/ symptoms Maximize safety with activities of daily life and ambulation Intervention to minimize severity: elevate head of bed; oxygenate; and manage pain and dyspnea Measures to enhance adaptation and rehabilitation

Patients undergoing cancer treatment may also reduce their activity, placing them at higher risk of developing thrombosis, leading to pulmonary emboli. The patient may be asymptomatic but should be treated with daily injections of anticoagulants. It is important to evaluate the patient's clotting times and platelet counts, as this may exclude them as candidates for anticoagulation therapies [30].

Chief Complaint: Altered Mental Status

Altered mental status (AMS) is a frequent chief complaint in oncologic patients presenting to the ED [31]. These mentation changes can result from metabolic disturbances, structural changes (such as metastatic disease or intracranial hemorrhage), or infection [32]. Ruling out the most life-threatening conditions is critical, as interventions are time-sensitive and require prompt identification to achieve desirable outcomes [33]. Table 6.2 illustrates presentations involving altered mental status [34–45].

Patients may present with varying degrees of AMS based on causative factors [32]. They may present as confused, somnolent, inattentive, or with seizure activity, both focal and widespread. Consider the type of cancer, risk factors associated with metabolic changes, infection risk, metastatic disease, and bleeding risk. Associated presenting symptoms and vital signs will also assist in identifying the underlying cause. Obtaining a thorough history from a family member or caregiver may also provide relevant information to AMS's cause, including the onset of mentation change, medications, medical history, and significant events. While the presence of malignancy creates an increased likelihood of atypical differential diagnoses, it is important to consider still acute ischemic stroke, hypoglycemia, and other common underlying conditions for patients presenting with changes in mentation.

Most oncologic patients presenting to the ED with AMS should receive a STAT head CT to determine if there is hemorrhage, as oncologic patients on active treatment are at higher risk for thrombocytopenia leading to bleeds [33]. Additionally, patients with known brain metastases are at risk due to the highly vascular nature of neoplasia. In addition to diagnostic imaging, a CBC and comprehensive metabolic panel (CMP) should be obtained. Platelets and white blood cell count may indicate additional causes, such as bleeding or infection. Many treatments cause pancytopenia and electrolyte disturbances that may be relevant to the patient's condition. Disturbances in electrolytes, bilirubin, and ammonia may cause changes in mentation. For example, hypo and hypernatremia can cause significant mental status changes and a common metabolic disturbance in certain lung cancer types. Ammonia can also cause AMS and may be present in cancers with hepatic involvement. All these components of the initial workup will assist in identifying the cause of AMS.

In the presence of new metastases identified in diagnostic imaging, corticosteroids can reduce edema around the lesion and subsequently diminish AMS symptoms [46]. If an acute ischemic stroke is suspected, it is critical to verify the platelet count to determine if the patient is an appropriate candidate for

Table 6.2 Case studies: altered mental status

Vital signs	Signs and symptoms	Risk factors/ contributing factors	Potential tests/ interventions	Nursing considerations
AMS related to metastatic disease [34]. *A 50-year-old female with history of breast cancer with bone/liver metastases presenting with altered mental status. Her boyfriend states she has increased confusion over last few days. He states she is not answering questions appropriately and has not been taking her medications as directed. Patient oriented to person and place but does not know what year it is. She is inattentive and takes a long time to respond to simple questions.*				
BP 117/68 HR 84 T 37.0 R 16 SpO_2 98%	Confusion (may be intermittent) Somnolence Seizures (may be focal)	Metastatic breast cancer Breast cancer has high metastatic risk in late stages	CT head Steroids (dexamethasone) Emergent neurosurgery to alleviate intracranial pressure if causing edema or ventricular obstruction	Frequent neuro vital signs Around the clock steroids to avoid additional edema Notify provider of any changes in mental status from initial baseline Elevate HOB and promote proper body alignment
AMS related to metabolic disturbances – sodium [35–40]. *A 56-year-old male with small-cell cancer of right lung, metastatic disease to bone/brain. He presents with altered mental status exhibiting delayed responses, confusion, and decreased concentration. Oriented to place/person but not time, GCS eye 3, verbal 4, and motor 6.*				
BP 117/68 HR 124 T 37.0 R 16 SpO_2 98%	Confusion Decreased PO intake Fatigue	Small cell lung cancer Most common electrolyte abnormality with small-cell lung cancer is hyponatremia Advanced disease increases likelihood of metabolic complications	General labs Head CT scan r/o bleed or metastatic progression Sodium replacement	Rebound cerebral edema with hypertonic solutions Seizure precaution Frequent neuro vital signs to identify subtle changes
AMS related to metabolic disturbances – ammonia [41–45]. *A 49-year-old female with metastatic colon cancer presents with altered mental status. Oriented to self only. GCS eye 4, GCS verbal 5, GCS motor 6. Patient has a history of hyponatremia, hyperkalemia, liver metastases. Finger stick glucose 105 mg/dL.*				
BP 93/58 HR 82 T 36.4 R 18 SpO_2 98%	Aggressive Confusion Lethargic Dehydration Hypotensive	Duodenum adenocarcinoma Cirrhosis of the liver Three cycles of chemotherapy Kidney damage and/or liver damage Drug, alcohol abuse Chemotherapy Colon cancer Liver failure	CBC, CMP, UA/C, PT/PTT, ammonia, liver enzymes CXR, EKG, CT head to r/o bleed Fluid resuscitation to flush Lactulose	Place on seizure precautions Monitor cognitive facilities May need restraints if aggressive If patient is unconscious, may have to administer lactulose through NG tube or rectal Lactulose will induce diarrhea and can contribute to falls

tissue plasminogen activator (tPA) [47]. If an infection is suspected, the patient should promptly receive broad-spectrum antibiotics. Timely administration of antibiotics can significantly improve patient prognosis in the presence of sepsis, with AMS being a frequent symptom indicating infection [48]. Patients with metabolic imbalances will improve upon the correction of the underlying disease process. Neurosurgery or neurology services may be consulted to address any neurological interventions based on ED findings [49].

Throughout the ED encounter, the EN should perform frequent neuro assessments to detect early deterioration signs. Placing the patient in semi-fowlers, elevating the head of the bed to 30 degrees or higher, and ensuring proper body alignment may also benefit patients with increased intracranial pressure [50]. Any changes in status should be immediately communicated with the provider. If steroids are ordered, they should be administered at scheduled times to reduce associated edema [49].

Chief Complaint: Back Pain

While back pain is a common chief complaint in EDs, the presence of back pain with cancer diagnoses can indicate metastatic spinal cord compression (MSCC), a time-sensitive emergency that requires prompt intervention. Although back pain is the most common complaint with MSCC, patients may also present with numbness, pain, or tingling in their extremities, bowel or bladder retention or incontinence, and even paralysis or gait disturbances. Patients with breast, lung, prostate, and renal cancer, as well as lymphomas and myelomas are at the highest risk, with men outnumbering women 2:1 [51]. See case study in Table 6.3 [51, 52].

Presenting symptoms will depend on the level of involvement and the degree to which the metastatic lesion is invading the spinal column. The degree of vertebral lesion invasiveness directly correlates with symptom severity. Symptoms may be alleviated with steroids by reducing the pressure on the spinal column [53]. Although symptoms may improve, these patients are at high risk for falls due to sudden sensory and motor function disturbances [54]. The patient's position may influence symptoms, activity level, level of involvement, and lesion location. Identifying a patient's position that reduces pain is important, and those with severe pain should be log rolled to avoid further injury. Range-of-motion assessments should also be conducted with caution, as they can cause additional injury in the presence of osteolytic lesions. These patients are at high risk for spinal instability, pathological fractures, and caudal equine syndrome.

Assessing for urinary retention and post-void residual are also necessary to determine if urinary catheter placement is necessary. Although patients may feel that they have fully emptied their bladder, there may be significant post-void residual, causing additional complications if not completely emptied. Patients may not state any bladder or bowel malfunctions due to loss of sensory perceptions, so assessment is necessary, regardless of patients' perceptions.

The radiological imaging modality of choice is magnetic resonance imaging (MRI) without contrast. If the patient cannot tolerate an MRI, a CT or X-ray may reveal findings but are not sensitive [55]. Treatments may include corticosteroids, radiation therapy, surgical intervention, and palliative chemotherapy [56]. Spinal cord metastases indicate late stages of cancer, and depending on patient functional status, treatment focus may be symptom management. Patients with MSCC may be candidates for advance care planning conversations, as this condition indicates advanced disease and poor prognosis [57].

Chief Complaint: Abdominal Symptoms

For patients with a concurrent cancer diagnosis, abdominal symptoms may indicate a variety of medical emergencies. Table 6.4 illustrates a number of presentations associated with these symptoms [58–80]. Oncologic patients are at high risk for bowel obstruction due to medication and antineoplastic treatments. Without prompt gastric decompression or surgical intervention, this can progress to perforation and severe infection. These patients may also present with nausea and vomiting due to the obstruction [81].

Table 6.3 Case study: back pain

Vital signs	Signs and symptoms	Risk factors/ contributing factors	Potential tests/ interventions	Nursing considerations
Metastatic spinal cord compression [52]. *A 67-year-old male with a history or metastatic prostate cancer presents to the emergency department with lower back pain 8/10 that has been progressing over the last week. He states he has some tingling in his legs and feels weak when he is ambulating.*				
BP 130/82 HR 77 T 36.8 R 16 SpO_2 97%	Primary complaint = back pain Weakness Paraplegia Sensory disturbances (numbness, neuropathy) Autonomic disturbances (incontinence, urinary retention)	Men out-number women 2:1 [51] Most prevalent in breast, lung, prostate, renal, lymphoma & myeloma Caused by vertebral body metastasis invading the spinal column Level of involvement directly reflects functional status and clinical presentation Symptoms may be affected by positioning (i.e., sitting vs. standing vs. laying down)	Diagnostics: radiological imaging of choice = MRI without contrast CT or X-ray if patient unable to tolerate MRI, not as sensitive Assessments: serial neurological evaluations, post-void bladder scan Treatments: corticosteroids, radiation therapy, surgical intervention, chemotherapy	Post-void bladder scan to evaluate for urinary retention Avoid range-of-motion testing if concern for spinal instability Best to immobilize patient as much as possible to prevent pathological fractures or additional pressure on the spinal cord High fall risk Strict bed rest for patients with poor performance status or spinal cord instability Indicates advanced disease = warrants advance care planning conversation

Table 6.4 Case study: abdominal symptom

Vital signs	Signs and symptoms	Risk factors/contributing factors	Potential tests/ interventions	Nursing considerations
Bowel obstruction [58–61]. *A 66-year-old female with a history of ovarian cancer presents with severe abdominal pain (9/10). Pain has progressed and began 4 days ago. She has a history of abdominal surgery, followed by radiation and chemotherapy treatment for her ovarian cancer. She has known metastatic peritoneal disease. Patient has not had a bowel movement in 5 days and feels nauseated. Chronic opioid use for pain related to cancer pain and radiation.*

Vital signs	Signs and symptoms	Risk factors/contributing factors	Potential tests/ interventions	Nursing considerations
Bile duct obstruction [78–80]. *A 72-year-old female with pancreatic cancer on active treatment presents to the ED with vomiting and fatigue for the past week. She is jaundiced and slightly confused. She states she has generalized pruritus and abdominal cramping.*				
BP 104/66 HR 76 T 36.9 R 16 SpO_2 99%	Projectile vomiting Upper right abdominal pain Lethargy, anorexia/decrease in appetite Severe heartburn/ reflux	Pancreatic cancer Female Increased age Diabetes mellitus Type II	General labs, bilirubin, alk phos, liver enzymes CT scan GI endoscopy consult for stent placement or G-tube placement	If undergoing biliary drainage patient should receive broad-spectrum antibiotics within 1 hour of start of procedure due to transit bacteremia during or after the procedure Monitor for bleeding, leakage around the tube and subsequent skin breakdown, catheter related pain, pancreatitis, sepsis

Cancer-related treatments may also cause acute kidney injuries (AKI) present as abdominal pain, oliguria, and flank pain. Depending on cancer location and gastrointestinal involvement, disease progression may be the primary factor causing pain or obstruction. Location of the pain, severity, onset, aggravating and alleviating factors, as well as medical and oncologic history is important in determining the cause of abdominal pain and necessary interventions. Due to pancytopenia caused by many treatments, bleeding and infection should also be considered if indicated in clinical presentation [81].

Unfortunately, cancer treatment frequently causes nausea and vomiting. Prevention of dehydration and symptom management are most important in chemotherapy-induced nausea and vomiting and depending on the severity, patients may require scheduled administration of multiple antiemetics. Sensations, including smell and taste, are also impacted with chemotherapies, and something as innocent as perfume may trigger emesis. Nurses should avoid wearing any creams, lotions or perfumes with strong scents that may trigger episodes of nausea and vomiting [82]. When attempting oral intake, small volumes of plain food and drink are best, as foods with strong flavors or smells may also increase the risk for emesis or even aspiration. Additionally, elevating the head of the bed to prevent aspiration is an important safety measure, as vomiting episodes may be sudden without warning [83].

In addition to upper GI symptoms, cancer treatments can cause lower GI symptoms such as constipation and diarrhea. Severe constipation can develop with both treatment and symptom management therapies, such as opioids for pain management. All cancer patients should be on a stool softener to prevent fecal impaction that can lead to additional complications. Before administering an enema, platelet levels should be verified to ensure no bleeding risk. In cases of diarrhea, dehydration can quickly progress and electrolyte imbalances may occur. Prompt replacement of fluids and electrolytes is necessary to prevent further complications related to electrolyte deficiency. While treatments can induce adverse events, patients with previous stem-cell transplants may experience similar symptoms due to graft-versus-host disease (GVHD). In these cases, tacrolimus levels should be monitored and steroids are generally the treatment of choice [84].

Ascites and abdominal distention are commonly seen in patients with metastatic peritoneal disease. Ascites may be recurrent and require frequent removal of peritoneal fluids via paracentesis. For patients with recurrent ascites due to metastatic disease, a peritoneal drain may be indicated to allow the patient to self-drain fluid build-up in the abdomen and prevent frequent ED visits. Patient education and discussion with the primary oncologist will help determine if the patient is an appropriate candidate for peritoneal catheter placement [85].

With cancer patients being at high risk for infection, the presence of colitis, gastritis, and diverticulitis should also be assessed to determine if a patient requires antibiotic therapy. Infection should always be addressed in any cancer patient presenting with abdominal symptoms to prevent further deterioration [81].

Abdominal symptoms are common for both general ED patients and cancer patients and are caused by various conditions. The patients' medical and oncological history can guide patient diagnoses, including cancer type and associated events leading up to the ED encounter. Evaluation of laboratory findings, including hepatic functions, pancreatic enzymes, CBC and CMP, is also essential in determining an appropriate treatment course.

Chief Complaint: Infection

Many cancer patients undergoing treatments experience pancytopenia, including neutropenia. This places them at significantly higher risk for developing an infection and becoming septic. Patients may present initially with a fever and neutropenia and otherwise stable vital signs. That said, these patients have a minimal metabolic reserve and no immune defense mechanisms, so they can quickly decline without the initiation of appropriate interventions. A central line is frequently standard in patients receiving chemotherapy regimens. This direct access to the bloodstream also places patients at higher risk for bacteremia and sepsis [86].

Development of a sepsis protocol and standing parameters for early interventions can help decrease the time from door to antibiotic administration, resulting in more favorable outcomes. Once the infection source is identified, antibiotic therapy should be tailored based on the organism's susceptibility to promote antibiotic stewardship [87].

Patients presenting with fever can be quickly identified as having a potential infection or sepsis. Some patients experience a condition called "tumor fever," which is the most frequent cause of pyrexia unrelated to infection. This is most commonly present in leukemias, lymphomas, sarcomas, renal cell carcinomas, and patients with liver metastases, but may present in any type of cancer. Although the cause may be unknown, patients should be treated as if an infection is present until otherwise ruled out [88].

There are some cases where patients are afebrile but exhibit tachycardia, tachypnea, or hypotension. These may indicate infection but are nonspecific in cancer patients. These could be caused by many other conditions common in cancer patients, including anemia, dehydration, or different physiological responses to malignancy. Infection is frequently the culprit in these cases, but does not rule out other diagnoses. Additionally, ED nurses should identify if the patient is taking any medications that could reduce the temperature before ED arrival, such as acetaminophen or ibuprofen. This may mask the fever and cause infection to be overlooked [88]. Table 6.5 illustrates typical presentations for neutropenic fever and sepsis [89–93].

Chief Complaint: Newly Diagnosed Cancer in the Emergency Department

Although less common, patients may present to EDs without a cancer diagnosis, only to be diagnosed during treatment in the ED [94]. These situations can be high acuity and high stress, as the patient's medical management may be complicated, and the emotional stress of the patient and family will likely be heightened. The initial presentation will vary based on underlying cancer diagnosis but may range from nonspecific complaints to a growing tumor site. Regardless of the final cancer diagnosis, the patient and family will need significant psychosocial support to begin their journey as cancer patients [95].

For patients without established primary care, the ED may be their only access to medical services. Unfortunately, patients presenting with an invasive solid tumor without

Table 6.5 Case studies: infection

prior cancer diagnosis tend to have a poor prognosis. Patients diagnosed with cancer in the ED are usually in late stages of the disease, with a 75% higher risk of being diagnosed as stage 4 cancer, versus stage 1 [96]. These patients may not have access to healthcare in a primary care setting, causing them to utilize the ED for access to treatment. Patients may not have symptoms severe enough to prompt an ED encounter until cancer has progressed. Delays in cancer diagnosis significantly increase the likelihood of metastatic disease being present upon initial diagnosis. Because of the poor prognosis, advance care planning should be discussed with the patient and family to ensure the quality care that supports the patient and family's wishes. Generally, solid tumor patients will not require immediate antineoplastic therapy in an emergency setting. ED nurses should focus on symptom management, oncologic plan of care post-ED visit, and appropriate supportive services such as social work, case managers, nutritionists, and pain management specialists [96].

In contrast with solid tumors, different types of acute leukemias may present as a medical emergency and require prompt cancer treatment and immediate antineoplastic therapies. These cancers are frequently diagnosed in the ED and are sometimes only identified via blood work. Patients with acute leukemias tend to have nonspecific symptoms of infections. The proliferation of immature white blood cells causes insufficient immune defense mechanisms required to fight an infection, and this may be the only indication of the underlying issue. An analysis of blood work and subsequent bone marrow biopsy will identify the specific cancer type and appropriate treatments. These patients are at high risk for sepsis due to an ineffective immune system and coagulopathies due to increased blood viscosity and thrombocytopenia secondary to leukemia [97].

Patients with newly diagnosed leukemia should be regularly monitored for status changes, as they can quickly deteriorate. Those with a white blood cell count of 50,000 or greater will require immediate therapy to reduce the number of immature blasts in circulation. The type of cancer will determine the induction phase of treatment, which the ED nurse will likely initiate. Due to the high-risk and time-sensitive nature of induction therapies, protocols should be developed by both emergency and oncologic departments to ensure there are no administrative barriers that may prevent the patients from receiving immediate induction therapy in the ED. This collaboration between these specialties can be a significant factor influencing the patient's care course and subsequent outcome [97].

The ED nurse's role in newly diagnosed cancer patients is essential for their quality-of-life trajectory. Ensuring adequate education and resources can completely alter the patient's experience in the presence of a life-changing diagnosis, such as cancer. Although not all patients will be candidates for curative therapies, providing patients with all potential treatment options and plans of care will ensure they are on track for course best suited to their medical and psychosocial needs. Along with coordinating the various services, including patients and families, the care team should be prioritized by the ED nurse once medically stabilized [97]. Table 6.6 illustrates presentations for newly diagnosed acute myeloid leukemia and acute promyelocytic leukemia [98–105].

Chief Complaint: Malignancy Progression, Antineoplastic Treatments, and General Medical Emergencies

Complications may arise with patients throughout the course of their cancer diagnosis. These may arise both from disease progression and impact on physiological processes and antineoplastic therapies and the associated adverse effects. These can range from mild to severe, and a thorough patient medical history can help determine the underlying cause. As previously mentioned, treatments can cause pancytopenia resulting in anemia, thrombocytopenia, and neutropenia. These can lead to more severe complications such as infection or bleeding if not promptly addressed with the appropriate replacement or supportive therapy [106].

Disease progression will generally be related to the tumor's location and associated symptoms. Patients with primary or metastatic osteolytic lesions may develop pathological fractures as the disease progresses. These osteolytic lesions may initially cause the patient mild-to-moderate pain at the tumor site with an acute event producing a pathological fracture [107]. Patients with large abdominal or thoracic tumors can develop superior vena cava syndrome as the tumor grows, placing pressure on blood's systemic return to the heart. Certain neuroendocrine tumors can cause significant disturbances in hormonal and metabolic function, possibly resulting in diabetes insipidus, acute adrenal crisis (Addisonian crisis) and hypophysitis [108]. The tumor location and associated symptoms will greatly assist with determining differential diagnosis and appropriate treatments.

While cancer itself can produce adverse events seen in an emergency setting, the treatments patients receive can also have severe therapy-related adverse events. Patients who have received a stem-cell transplant (SCT) may also present with graft-versus-host disease (GVHD) complications. These can affect all organs and systems and are frequently treated with high-dose steroids [109]. Along with pancytopenia and associated conditions, many chemotherapies are nephrotoxic and cardiotoxic. Depending on the patient's ability to tolerate the treatment and underlying comorbidities, some patients may have more severe reactions than others [110]. Reviewing the patient's wallet insert that identifies

Table 6.6 Case studies: newly diagnosed cancer in the ED

Vital signs	Signs and symptoms	Risk factors/ contributing factors	Potential tests/ interventions	Nursing considerations
Acute myeloid leukemia (AML) [98–102]*: A 32-year-old male presents with abnormal lab results from his primary care provider who instructed his to present to the ED. The patient had an upper respiratory infection for 2 weeks that prompted him to see her PCP. PCP prescribed PO antibiotics and obtained a CBC. The patient has no significant medical history. CBC results showed WBCs 173 k, Platelets 4 k, Hgb 6.1. The patient is a smoker (1/2 per day) and works at a chemical plant.*				
BP 117/76 HR 107 T 37.7 R 18 SpO_2 97%	Frequently present after unresolved infection and discover abnormal blood counts May have weight loss, bleeding/bruising and fatigue due to counts	AML more common in males than females Risk factors for AML are exposure to certain chemicals (work exposure), radiation and smoking	General labs Hydroxyurea for leukocytosis Bone marrow biopsy PRBC and platelet transfusions to replace counts Chest X-ray to evaluate for potential pulmonary infiltrates Antibiotic and antiviral therapy to prevent infectious complications	High-risk for bleeding with thrombocytopenia Disseminated intravascular coagulation Highly viscous blood due to increased WBCs At risk for tumor lysis syndrome due to systemic cancer involvement
Acute promyelocytic leukemia (APL) [103–105]*. A 48-year-old male presents with low-grade fever, weight loss, increased fatigue, and increased bruising. The patient has worked at a crude-oil processing plant for 22 years and has no significant health history. Lab results show severe neutropenia, anemia, and thrombocytopenia*				
BP 110/68 HR 96 T 37.2 R 20 SpO_2 99%	Anemia Thrombocytopenia Neutropenia	Middle aged Long-term exposure to petroleum products Unknown May be associated with work exposure	General labs All-trans-retinoic acid (ATRA) Bone marrow biopsy PRBC and platelet transfusions to replace counts Chest X-ray to evaluate for potential pulmonary infiltrates Antibiotic and antiviral therapy to prevent infectious complications	High-risk cancer, but highly curable if treated timely Extremely rare subtype of AML Requires pathology evaluation of cell morphology to determine if APL versus other types of acute leukemia

the antineoplastic agent they are receiving may be beneficial. Obtaining this information as early as triage can help determine the differential diagnosis as well as medical management [110].

Dedication of resources to cancer treatment research has led to new therapies, emerging as first-line treatments producing promising outcomes. One of these recent advances is the increase of immunotherapies. Although these generally have a lower risk of associated adverse events, immunotherapies such as chimeric antigen receptor (CAR) T-cell therapy can induce specific emergent conditions, most frequently being cytokine release syndrome (CRS) and CAR-related encephalopathy syndrome (CRES). These emergent conditions may develop after receiving immunotherapies and must be treated timely to prevent long-term deficits. CRS and CRES have specific grading systems that should guide medical management and determine the severity of the condition [111].

Patients with cancer may have comorbidities, such as diabetes, hypertension, psychiatric conditions, cardiac dysrhythmias, and other chronic illnesses, and patients may present with conditions completely unrelated to their cancer or treatment. General medical emergencies such as ischemic stroke, myocardial infarction, or diabetic ketoacidosis (DKA) should still be considered, even in the presence of concurrent cancer, if the clinical presentation is consistent with the noncancer-related condition [112]. Notwithstanding, precautions should be taken when determining therapy for the medical emergency and how the patient's cancer may impact the typical course of management. For example,

patients exhibiting signs of ischemic stroke may not be candidates for tissue plasminogen activator (tPA) based on platelet count, coagulation studies, and bleeding risk. All factors should be considered when determining medical management for the patient. The ED nurses' role is imperative to ensure a holistic approach to patient care [113]. Table 6.7 illustrates the wide variety of patient presentations discussed above [114–144].

Chief Complaint: End of Life in Advanced-Stage Cancer

Although advances in oncologic treatments have greatly improved the overall survival rate of cancer, end of life, patients with advanced cancer disproportionately represent cancer-related visits to emergency departments. The high-acuity and fast-paced environment in the ED has been conventionally felt to be incompatible with end-of-life (EOL) discussions. The delicate topic is rarely addressed in EDs and can increase the psychosocial burden on the patient and family, increased costs, and futile care initiation. By providing a holistic approach and initiating conversations to establish care goals, the ED can help enhance the value and quality of care for EOL cancer patients [13]. Table 6.8 describes a typical presentation for a cancer patient presenting to the ED at the end of life [145–147].

Although the ED is not typically a setting where EOL discussions occur, initiating a palliative care (PC) consultation to assist with determining care goals with the patient and family member can greatly assist ED personnel in navigating the complex sequelae of the dying process in all domains [13]. Patients and families will require substantial physical, emotional, and spiritual support to ensure a smooth transition to hospice care. The ED nurse plays a central role in coordinating this care by ensuring all necessary services can provide expertise and guidance for the multifaceted needs associated with dying. These will include palliative, pain, hospice, nutrition, social work, case management, chaplaincy, and other multidisciplinary services based on the patient and family's unique needs. This experience can be the difference between a traumatic and peaceful death for both the patient and their loved ones [13].

As a gateway to hospitalization, the ED plays a vital role in the quality and value of EOL cancer patients' care. It is the tendency of ED personnel to choose life-saving interventions over meaningful conversations about advance care planning (ACP). EDs should ensure proper training and education are provided to staff to provide quality care and ensure dignity, compassion, and comfort for EOL patients. Altered mental status, dyspnea on minor exertion, and poor performance status (ECOG 3 or 4) were found in previous studies to be the "Triple Threat" predictors of mortality in advanced cancer. Patients with two or more of these conditions had a predicted 30-day mortality of 49% (95% CI. 34%, 64%) [145]. This may be used as a triage screening tool to identify advanced cancer patients who may benefit from care goals conversation.

In 2014, the Institute of Medicine (IOM) released the report, "Dying in America," calling for significant reform of the healthcare system to improve the quality and value of EOL care in America. The report cited recommendations to improve EOL care, including patient-centered and family-oriented EOL discussions, professional education and development of palliative care, healthcare policies to support EOL initiatives, and public education and engagement [148].

The National Quality Forum endorses multiple ED visits within the last 30 days of life to indicate poor-quality cancer care. Additional indicators of poor-quality cancer care include admission to the intensive care unit (ICU) within the last 30 days of life, death in the ICU, curative chemotherapy treatment in the last 14 days of life, and hospice admission for less than 3 days before death. ED nurses should advocate for EOL cancer patients to avoid poor-quality outcomes, enhance care value, and provide a positive experience for patients and families [148].

Ideally, these conversations would be initiated in an outpatient setting allowing ample time for discussion between providers, patients, and families. However, this is not always the case, and patients may only find out they are dying upon presentation to the ED. Although it may be perceived as challenging or inopportune, initiating a discussion of care goals in the ED can be one of the greatest gifts a nurse can provide to a patient [149].

Pandemic Response: SARS CoV 2 – Novel Coronavirus

Novel coronavirus disease (COVID-19), also termed SARS-COV-2, has emerged as a global threat and healthcare concern [150]. The virus first cases were reported in Wuhan, China, and marked the beginning of a global pandemic that completely upended daily life and the world's healthcare system [151]. Human-to-human transmission of COVID-19 occurs via respiratory droplets (by coughing or sneezing) and through direct contact with infected individuals or indirect contact with fomites of the affected individuals' environment [150]. Since its outbreak in China at the end of 2019 and until the April 5, 2020, the pandemic has affected > a million persons and caused 62,773 deaths worldwide [152].

Table 6.7 Case studies: malignancy progression, antineoplastic treatments, and general medical emergencies

Vital signs	Signs and symptoms	Risk factors/ contributing factors	Potential tests/ interventions	Nursing considerations
Cytokine release syndrome (CRS) & CAR-related encephalopathy syndrome (CRES) [114]. *A 61-year-old male presents to triage with tachycardia, hypotension, and shortness of breath. He received a chimeric antigen receptor T-cell (CAR-T-cell) therapy infusion for treatment of lymphoma approximately 3 days ago and was instructed to present to the ED.*				
BP 88/54 HR 126 T 37.2 R 20 SpO_2 89%	Looks a lot like sepsis Fever, myalgias, anorexia, evidence of multiple organ involvement (dyspnea, hypotension, arrhythmias, confusion seizures)	Recent CAR-T cell therapy infusion Liquid tumor, potential high tumor burden can cause increased cytokine release A therapy-induced immune systemic reaction Release of IL-6 proteins causes systemic inflammatory process	Tocilizumab is first line treatment Supportive therapy Rule out infection	CRS & CRES grading system Assess for CRES in the presence of CRS, may be concurrent Maintain $SpO_2 > 92\%$
Pathological fractures [115–117]. *A 55-year-old female with metastatic breast cancer with known bone metastasis. She has been experiencing right groin pain that started approximately 3 months ago and got significantly worse over the last 3 days. The patient is experiencing severe pain and is unable to bear any weight on her right leg, prompting her to present to the ED. The patient is slightly tachycardia (112), all other vitals are WDL.*				
BP 130/88 HR 112 T 37.2 R 18 SpO_2 95%	Pain, sometimes chronic with acute exacerbation Acute change in functional abilities of affected limb	Metastatic breast cancer to the bones Weight bearing activities on a bone that has a metastatic lesion	X-ray to evaluate for acute pathological fractures Orthopedic consult to evaluate for possible surgical reconstruction if patient is a candidate Pain control	Log-roll patients to avoid further injury Premedicate with analgesia prior to movement Stabilize with pillows to avoid positional exacerbation Be aware of other bone lesions and take extra precautions as appropriate
Diabetic Ketoacidosis (DKA) [118–120]. *A 64-year-old male undergoing treatment for prostate cancer with Lupron and prednisone. He presented to the ED with chief complaints of progressive weakness, confusion, loss of appetite, and nausea. The patient was diagnosed with new onset diabetes presenting with DKA, hyperglycemia, and acute kidney injury. Glucose 520 mg/dL on serum chemistry, bicarb 17, and anion gap 2.*				
BP 114/74 HR 102 T 37.3 R 20 SpO_2 94%	Glucose greater than 250 mg/dL Dry mouth, dry skin Polyuria, polydipsia, polyphagia Changes in mentation Kussmaul respirations	Diabetes type 1 Diabetes type 2 Long-term steroid use Non-compliance with insulin therapy Infection Trauma	Urinalysis and culture Serum ketones Arterial blood gas Blood culture CBC and chemistry Cardiac monitoring Neuro assessments Critical care Insulin therapy, hydration, electrolyte replacement	Fluid volume status Increased risk for infection Knowledge deficit regarding glucose management
Addisonian crisis [121, 122]. *A 67-year-old undergoing treatment for recurrent metastatic uterine leiomyosarcoma. She presented with fatigue and altered mental status. The patient was diagnosed with adrenal insufficiency secondary to hypophysitis following immunotherapy.*				
BP 78/54 HR 116 T 36.2 R 22 SpO_2 96%	Tachycardia Altered mental status Dry skin Hypotension Low fasting blood glucose	Addison's disease Prolonged administration of glucocorticoids Infection Cancer Stress ACTH deficiency Hypopituitarism Hypothalamic-pituitary disease	Serum cortisol level Chemistries High-dose IV corticosteroid therapy Cardiac monitoring ACTH stimulation test (cosyntropin)	Fluid and electrolyte management Fall precautions

Table 6.7 (continued)

COVID 19: An Enhanced Threat to Cancer Patients

It is believed that patients with comorbid conditions, if infected, are at a heightened risk of manifesting complications associated with the virus [153]. Patients with cancer therefore remain at the forefront of this concern. Based on a recent Chinese cohort, patients with cancer had an increased risk of suffering severe events (intensive care unit admission, assisted ventilation or death) compared to those without cancer (39% vs. 8%, p = 0·0003) [154]. The threat the virus poses to medically compromised and noncompromised populations has therefore prompted extensive operational safety measures.

Table 6.8 Case study: end of life in advanced-stage cancer

Vital signs	Signs and symptoms	Risk factors/ contributing factors	Potential tests/ interventions	Nursing considerations
Triple threat [145–147]. *An 89-year-old male with stage 4 lung cancer on a clinical trial treatment regimen presents to triage with shortness of breath, altered mental status, and increased lethargy over the last couple of days. The patient presents with his adult son who is his primary caregiver and provides the history. He has visited the ED 3 times in the last 2 weeks for similar chief complaints resulting in admission to the hospital.*				
BP 101/56 HR 113 T 37.2 R 24 SpO_2 92% (on 3 liters/min via nasal cannula)	Delirium, altered mental status, or confusion in the last week Shortness of breath or difficulty breathing at rest or on minor exertion, such as toileting Spending more than 50% of their time in bed, or poor performance status with decreasing independence	Advanced stage cancer "Triple threat" symptoms at triage presentation Clinical trial, potentially indicating "Hail Mary" attempt to cure cancer Multiple ED visits may increase in the last weeks of life Patient may be nearing end of life Does the patient have advance care planning documents in place?	Discuss goals of care early in the encounter to prevent unwanted ICU admissions or invasive procedures Establish code status and provide realistic expectations of care to patient and family Ensure holistic approach and provide all necessary parties to produce a positive outcome	Provide support to patients and families to the best of your ability Use available resources to help provide patients/families with information. It takes a whole team to successfully have "goals of care" conversation in the ED You do not need to have all the answers as an ED nurse. Consult the experts in their specific areas (chaplaincy, social work, case management, palliative medicine, hospice, etc.) to assist in planning for those specific needs Ensure advance care planning documentation is available for all to see in the medical record to minimize confusion in an acute event regarding what the patient's wishes truly are Ensure the patient is comfortable – just because you are not providing curative treatment for the cancer does not mean they shouldn't receive treatment for infections, reversible conditions, and symptom management

Preventing Cancer Patients from COVID-19 Exposure from ED to Disposition

Notably, public safety measures in place are designed to reduce preventable hospital admissions and elective procedures [155]. These measures do not fully serve the interests of patients with cancer, who require continuous care inclusive of, but not limited to, diagnostic tests and therapeutic interventions. In this sense, both limitations in medical care and potential COVID-19 exposure could be risky, or even fatal [156].

It is for these reasons that remarkable efforts are taken by hospital personnel to screen for exposure to COVID 19 at hospital entry points. The oncologic ED is a main entry point for patients with cancer and as such, it adheres to the guidelines and recommendations put forth by the Center for Disease and Control (CDC) [157]. We share our adapted screening and preventative measures below.

Screening for COVID-19 and Safety Measures

- Staff member(s) are stationed near all ED and facility entrances (outdoors if weather and facility layout permit), or in the waiting room area, to ensure patients are screened for symptoms and fever before entering the treatment floor.
- Patients are provided with a face mask upon ED entry.
- Patients are screened for fever or symptoms consistent with COVID-19.
- Patients are directed to designated waiting areas which are divided to separate symptomatic from asymptomatic.
- Patients are separated by at least 6 feet; the area for symptomatic patients is at least 6 feet away from the area for patients without symptoms.
- For patients in need of urgent care, ED providers are notified immediately.
- Alerts and signs are posted in strategic places around the ED and the facility at large, with instructions for patients with fever or symptoms of respiratory infection.

Considerations for ED Staff

- Staff members in charge of screening patients remain 6 feet away from the patient until he or she is determined to be symptom-free and afebrile (temperature is determined by active temperature monitoring).

- Screening staff wear facemasks and shields (for source control) but do not need to wear PPE if they are separated from patients by a physical barrier such as glass or plastic window.
- Screening staff ensures these interactions as brief as possible by limiting the interaction to screening questions only.
- For staff members who must be within 6 feet of a patient, they are required to wear appropriate PPE, including an N95 or higher level respirator, gloves, and eye protection.

Post Patient Screening and Treatment Room Assignment

- Notification of direct patient care staff of the presence of a symptomatic patient.
- Safe and prompt transfer of symptomatic patients from triage to treatment rooms.
- Posting of appropriate isolation signs outside treatment rooms to communicate status.
- Immediate disinfection of waiting areas occupied by symptomatic/exposed patients and surfaces that were within 6 feet of the symptomatic patient; this is in addition to the regular (frequent) baseline cleaning and disinfection process that occurs for the entire waiting area.
- Items that cannot be disinfected remain with the patient or discarded.

Regulatory Standards for Oncologic Emergency Departments: Brief Introduction

Healthcare organizations that achieve accreditation through a Det Norske Veritas (DNV) or The Joint Commission (TJC) "deemed status" survey are determined to meet Medicare and Medicaid requirements and may receive payment from the Center for Medicare and Medicaid Services (CMS). Accreditation does not protect a hospital from an additional CMS survey. All healthcare organizations are still subject to a CMS survey based on a complaint or a validation survey [158]. Validation surveys usually occur within 60 days of the accreditation survey; however, TJC, in collaboration with CMS, has been working on redesigning the validation survey process. The objective of the redesign is to eliminate the validation survey and for CMS to oversee the accreditation process; thus, both may survey an organization at the same time [159].

CMS developed comprehensive Conditions of Participation (CoPs) and Condition for Coverage (CfC) that hospitals and other healthcare entities must meet to initiate or continue their participation in the Medicare and Medicaid programs [158]. All hospitals, including acute care, critical access, long-term care, children's, psychiatric, and cancer hospitals, are included. There are various key conditions of participation chapters for hospitals, and they all involve Emergency Services to varying degrees. Table 6.9 lists CMS subpart chapters applicable to an emergency setting but is not all-inclusive list of the regulatory standards [158].

Emergency services, one of the optional services that may be reviewed by CMS, are often an integral part of most hospital surveys. Thus, any organization with an ED will need to adhere to these standards. Table 6.10 displays additional subchapters that each hospital must examine to ensure compliance although some areas may not apply [158].

An emergency preparedness plan is required by all healthcare facilities. These guidelines will ensure compliance and demand a proactive approach to adequately plan for natural and man-made disasters. The CMS State Operations Manual, Appendix Z, Emergency Preparedness will guide the development of a comprehensive plan and will likely involve collaboration between the ED and the organization to meet the expectations or standards [160].

CMS is the single largest payer for healthcare in the United States, and the CoP health and safety standards are the foundation or *minimum* standards for its beneficiaries. There are other federal laws that all oncologic urgent or EDs or centers must follow. They include but are not limited to the Emergency Medical Treatment and Labor Act (EMTALA), originally part of the Consolidated Omnibus Budget Reconciliation Act (COBRA) passed in 1986 to address anti-dumping issues. Although motivated by the highly publicized anti-dumping incidents, EMTALA was intended to prevent inadequate care and delay or denial of

Table 6.11 Reporting violations of the Emergency Medical Treatment and Labor Act (EMTALA)

EMTALA violations are reported to:	Purpose
Office of Inspector General (OIG)	To issue and enforce civil monetary penalties
Office of Civil Rights	To evaluate if there are any civil rights violations
Justice Department	To evaluate for Hill-Burton Act violations
Internal Revenue Service	To evaluate of tax-exempt status
Joint Commission or Det Norske Veritas (DNV)	To review accreditation status, patterns and trends

treatment of an emergent condition for the uninsured person to include pregnant women seeking medical advice. EMTALA is a federally mandated social policy calling for access to healthcare that hospitals and physicians must address [160, 161]. EMTALA violations are also reported to other regulatory entities listed in Table 6.11. Of note, the most common violation is an inappropriate Medical Screening Examination [161].

The CMS State Operations Manual interpretive guidelines Appendix V is devoted to Emergency Services and EMTALA and provides direction with the EMTALA demands [162]. CMS is responsible for all investigations of EMTALA violations and is partially responsible for enforcements through citations, often designated as "Notice of Termination from Medicare," which gives a hospital 23 days to come into compliance. A plan of correction will need to be submitted with credible evidence of compliance beyond the date of reinspection. On day 19, a notice of termination is published in local newspapers, unless a plan has been submitted, accepted, and re-survey shows compliance within the 23 days [163].

Possible EMTALA violations need to be reported by the receiving hospital within 72 hours, and healthcare organizations have significant sanctions for failure to report, to include termination from Medicare participation. Some states require any healthcare employee with knowledge of a violation to report timely. CMS expects organizations to self-report violations. However, organizational practices vary. Blatant violations may go uncited, while minor or even marginal incongruities may receive punitive enforcement. Often, this variability is related to the interpretation of the law. The Government Accounting Office has reported the variability to Congress, calling for improved consistency. Currently, the inconsistencies continue [162].

Any EMTALA or CMS investigation or validation survey is very demanding for most hospitals. Every detail of hospital operation is often under intense scrutiny. The evaluation of compliance is very black and white, and there is no gray. Either you are compliant, or you are not. Also note, there are no pre-termination appeal rights under EMTALA [158].

COP investigations often lead to "lengthy citations for every dirt mark or dust covering found on any location in the facility. Inspectors are reported to literally surveyed facilities using magnifying glasses and flashlights" [163]. Oncologic hospital administration or nurse leaders do not expect CMS or EMTALA surveys to be as concrete as they are known to be and may struggle significantly. Even minutes are reviewed in detail. There is no gray, only black and white, when determining compliance during a CMS survey. Again, either you are compliant, or you are not [163].

There are two types of citations that CMS can issue. The "condition-level" is considered more serious and indicates that a hospital is not in substantial compliance. A "standard-level" deficiency is cited when a hospital is out of compliance with one aspect of the regulations and it is considered less severe than the condition-level citation. Most surveys have a mix of both types once the final report is released. The hospital has only 10 days to submit a correction plan once they receive the Form CMS-2567 report. If the plan of correction is not accepted as written, the hospital is asked to submit a revised plan [158].

When surveyors determine that the hospital's noncompliance from regulatory standards constitutes an immediate threat to patients' health and safety, they will issue an "Immediate Jeopardy" (IJ) [164]. An IJ determination forces a hospital to immediately stop and correct the underlying problems and is considered the most serious type of violation. Once a hospital or healthcare organization receives an IJ citation, it is given a short time frame to fix the deficiency. If the organization fails to address the IJ as CMS demands, CMS will terminate the facility's Medicare and Medicaid funding. Losing accreditation has a significant impact and can be devastating since the government is the largest payer, and loss of accreditation will affect hospital insurance rates, among other things. It may erode a hospital's infrastructure quickly; physicians stop sending patients, the staff starts leaving, and an organization quickly spirals downward [164].

Over the last few years, there have been several oncologic hospitals that have been surveyed by CMS. The plans of correction are considered public knowledge and are available for review online. They are an excellent source of information to strengthen your organization. Hospitals grow significantly after a survey, becoming stronger and more focused.

Interdisciplinary Collaboration

An essential aspect of providing high-quality care to cancer patients in the ED is the interdisciplinary team's collaboration and cohesion. As displayed in the case studies in this chapter, the cancer patient requires many different needs when presenting to the ED and will encounter many different teams. The collective plan must be centralized around the

patient and family and closed-loop communication is vital to preventing errors and for the administration of appropriate treatment.

The cancer patient population's needs require multidisciplinary care to address all aspects and provide holistic and comprehensive care. Communication between teams is essential for preventing errors and identifying issues in the plan of care. High-reliability organizations promote a just culture environment, seeking to improve systems and prevent human error. This means facilitating an environment where every healthcare team member feels supported to identify patient safety issues and speak up when advocating for the patient and family [164].

Recommendations to promote interdisciplinary collaboration include discussions from all stakeholders with practice changes and an opportunity to provide input, professional practice recognition from interdisciplinary members, and establish clear policies and procedures that clearly and concisely delineate role responsibilities. Another great tool for enhancing teamwork is interdisciplinary high-fidelity simulation exercises [165]. This can reveal strengths and opportunities for improvement without patient safety being jeopardized.

This textbook is an excellent example of interdisciplinary collaboration in action. The information can help physicians work more effectively with their nursing partners by providing information relevant to their scope of practice and how it applies to oncologic emergencies while adhering to the regulatory requirements. As the field of oncologic emergencies continues to evolve, the integration of multidisciplinary teams must continue to develop cohesively to create a useful model for patient-centered care.

Palliative Social Work

7

Robin Rudy Lawson and Alison Snow

Introduction

Cancer patients may require emergency department (ED) care as a result of symptoms or complications of the disease itself, from the side effects of cancer treatment, including chemotherapy or radiation therapy, or from intercurrent injury or illness unrelated to cancer. Sepsis, pain, neutropenia, fever, deep vein thrombosis, nausea/vomiting, and failure to thrive are common symptoms that prompt oncologic emergency care [1–3]. Despite the overall decrease in cancer death rates, ED visits for cancer-related emergencies are on the rise [4]. One Australian study showed that while the number of deaths in the ED for cancer and non-cancer-related presentations was similar, the number of inpatient deaths for patients with cancer was significantly higher than for non-cancer patients [5]. The impact of a new cancer diagnosis, worsening prognosis, or transition to end-of-life care exacts physical, emotional, financial, and psychosocial distress on patients and families. Medical social workers are key interdisciplinary team members within the inpatient, outpatient, and home care settings who intervene along the continuum of illness. They are specifically trained to assess the patient's adjustment to illness and treatment, as well as any social and financial concerns that may impact medical decision-making. Social workers also provide therapeutic interventions to enhance patient coping, reduce caregiver distress, and ensure continuity of care across settings [6].

When patients with oncologic emergencies and their families present to the ED, social workers may be called upon to intervene with issues involving the entire spectrum of cancer, from a new diagnosis to end-of-life care. In both inpatient and outpatient settings, oncologic social workers are trained to provide a variety of interventions to assist patients and families coping with cancer, including assessment of psychosocial needs, adjustment to illness and side effects of treatment, and linkage to community resources. Palliative social workers may also intervene to assist oncologic patients in crisis where primary attention may be placed on pain and symptom management, goals of care conversations, advance care planning, or education and counseling regarding end-of-life care. This chapter examines social work's involvement with oncologic patients in the ED, as well as the oncologic social work role in the outpatient setting, and suggests potential partnerships and collaboration among ED, oncologic, and palliative social work.

The Role of the ED Social Worker

The role of the ED social worker varies greatly, given the diversity of the patient population and the emergent nature of many social work referrals in this setting. ED social work consults are imperative for trauma victims and their families, victims of assault, homeless individuals, persons with substance use disorders, and minors [7]. Due to the time-intensive nature of these referrals, it may be difficult for the ED social worker to consult on less urgent referrals, including patients who, after a diagnostic evaluation, confront a newly diagnosed cancer. Despite these constraints, ED social workers may be the first psychosocial clinicians to see patients with life-limiting illnesses who present with distressing symptoms or who may be actively dying [8].

ED social workers strive to maintain a careful balance by blending their responsibility to provide concrete services such as community resource referrals, medical equipment/home health setup, and placement in short-term or long-term care facilities, with therapeutic interventions, including crisis intervention. ED social workers also conduct psychosocial assessments and provide bereavement counseling when deaths occur in the ED [9]. A 2016 study in a large, urban trauma ED identified that the most common ED social work

services provided were mental health services, followed by care coordination and then community resource information/referral [7].

Crisis Intervention

For ED social workers, priority referrals that require immediate intervention include domestic violence and sexual assault and elder or child abuse and neglect. In addition to providing support and crisis intervention, these referrals may also require consultation with law enforcement or state agencies as well as hospital security, as well as locating and supporting family members or friends, and maintaining constant communication with the ED physician and nurse. Given the sensitive and complicated nature of this work, the ED social worker may spend a great deal of time on such consultations. Crisis intervention skills utilized with victims of sexual assault and domestic violence include re-establishing coping skills, problem-solving to identify next steps, assessment for suicidality, provision of emotional support, and the resolution of concrete needs such as safety, housing, and financial support.

For patients who present with symptoms of depression, anxiety, suicidal ideation, or alcohol and drug abuse, but do not require inpatient admission, the ED social worker typically completes an assessment and provides brief counseling as well as linkage to community resources to ensure follow-up support. ED social workers with strong backgrounds in mental health may identify appropriate referrals to psychiatry or outpatient mental health agencies and provide brief interventions and education to interdisciplinary team members on strategies to help patients in this setting.

Complex Case Management

When a patient's ability to care for himself or herself is diminished but admission is not required, the ED social worker may be responsible for obtaining support through home-based health services. They also assist with applying for financial assistance to facilitate admission to a skilled nursing facility, as well as coordinating a plan for family and friends to support caregiving at home. For patients who need additional services, preventing a "social admission" by facilitating a safe discharge from the ED is important.

A Canadian study found that the ED social workers commonly assisted patients with financial concerns and discharge planning needs as well as adjusting to their illness and addiction [10]. Effective discharge planning reduces unnecessary hospital admissions and coordinates the outpatient services a patient needs to allow them to safely remain in their home environment. The expertise and range of skills implicit in crisis intervention, mental health assessment, and complex case management are essential to the care of oncologic patients and their families who present to the ED for help.

ED Social Work Role with Oncologic Patients

When oncologic patients present to the ED with complications from their disease or treatment, the ED social worker may be asked to see patients with concomitant symptoms of depression, anxiety, or suicidal ideation, while also evaluating caregivers who may be exhausted from providing care. Newly diagnosed cancer patients, as well as cancer patients who come to the ED in lieu of a visit with their primary physician or oncologist, may be referred to the ED social worker for assistance with medical follow-up, evaluation, and treatment, as well as provision of concrete services such as home health care or medical equipment.

When oncologic patients present to the ED at the end of life, the ED social worker provides emotional support to the patient and family, communicates with the hospital chaplain as requested by the family, and helps identify a private space for family members to gather and grieve. While there is no published research delineating the role of ED social work with oncologic patients, many of the skills outlined above are integral to assisting oncologic patients and their families.

Psychosocial Issues for Cancer Patients in the ED

Diagnosis of Cancer in the ED

A new diagnosis of cancer may elicit strong emotions and can induce a great deal of stress and anxiety for patients and families. It may cause the patient to experience feelings of loneliness, abandonment, and loss of control over their situation [11]. The ED social worker may be called upon to provide emotional support while identifying and clarifying, in consultation with the emergency physician, any real or perceived fears surrounding a new diagnosis, prognosis, or treatment. Providing patients and families with the necessary time to integrate a new diagnosis is essential to allowing them to consider decisions about appropriate treatment and continuing medical care [11]. For patients who decline further evaluation and treatment, it is essential that the patients understand the potential consequences of avoiding further care. An ED social work assessment of concerns and fears following a new diagnosis of cancer may provide the patient with an alternative plan of care aside from hospitalization,

such as follow-up with an oncologist to review and integrate medical options. Below is a case study of a newly diagnosed cancer patient in the ED that demonstrates the ED social worker's role with patients/families and the interdisciplinary team.

Case Discussion 1

Emergency Department Social Worker

The ED social worker receives a call from an emergency physician to see a 63-year-old Latina woman, who, with her three adult children, is anxiously awaiting the results of a CT scan of her pelvis and abdomen. Prior to this ED visit, her medical history includes diabetes and asthma. She presents with rectal bleeding, severe abdominal pain, and dizziness. The emergency physician informs the ED social worker that the patient has a new diagnosis of metastatic anal cancer and that he would like the social worker to assist as he provides this information to the patient and her family. The patient has no primary care physician and must be admitted to the hospital for further evaluation and consideration of treatment options.

The ED social worker had spoken with the patient earlier in the day while the patient was waiting. The patient confided, "I bleed every time I'm on the toilet, for the last few months." When the social worker inquires if she had told anyone, the patient states that she did not want to tell her family because she was scared. As the social worker begins to explore the patient's fears about telling family, the patient begins crying and pulls out rosary beads from her pocket. The patient explains that her youngest daughter is getting married in a few months and that the focus should be on the young, not the old. She goes on to say she has led a full and happy life and that it is up to God to decide her fate.

With the patient's permission, the ED social worker contacts the Catholic chaplain on call for the ED to be present at the family meeting. The ED social worker secures a private space for the patient and family to meet so that they can process this new diagnosis in a quiet setting. As the emergency physician explains the results of the tests done in the ED and describes the patient's diagnosis, prognosis, and treatment options, the patient and her children begin to cry. While the social worker and the chaplain comfort the patient/family, the emergency physician sits quietly, in order to allow them time to process this information.

After a few minutes, the emergency physician confirms with the patient that she has heard the words and is beginning to integrate the significance of her medical condition and the treatment options. Following this discussion, the ED social worker acknowledges the unique emotional responses of the patient and family and describes the oncologic and/or palliative services that can be provided concurrently with the chemotherapy or radiation that the patient may receive while in the hospital. The emergency physician concurs with the ED social worker, describing how the patient may benefit from specialized symptom management and the provision of psychosocial and spiritual services for both the patient and family. The patient is admitted to the hospital late that evening and is seen by oncologic and palliative consultants the next day. The ED social worker ensures a seamless transition by communicating with the inpatient unit social worker.

Communication in the ED

Due to an often chaotic and busy environment, ED clinicians are often unable to spend significant periods of time with patients/families. As most patients arrive to the ED in crisis and distress, it may be difficult for them to comprehend a complete picture of their medical problem and proposed treatment. The medical jargon and complex terms used by healthcare professionals may represent a foreign language to patients/families, regardless of their educational level. ED social workers can assess the patient's/family's health literacy and understanding of medical information and then work with the physician to clarify that the patient understands the care they are receiving. The essential role that social workers play as part of the healthcare system is evidenced by their frequent initiation, implementation, and support of end-of-life discussions with patients, families, and other caregivers [12]. Furthermore, social workers advocate on behalf of patients to physicians and nurses, increasing awareness of psychosocial issues along the continuum of illness and the benefits of early referrals to palliative care or hospice.

In addition to normalizing the challenge of integrating information when in crisis, the care taken to help patients and families to anticipate the next steps in resolving their medical crisis models a relationship that highlights both the emotional and informational needs of patients and families. Despite the often limited time that is spent with a patient, all clinicians who care for seriously ill patients contribute to the meaning making and processing of coping with illness. While ED interactions may be brief, they can forever impact patients and families.

ED as Primary Healthcare Site

Patients who typically use the ED as their primary healthcare site are more likely to learn of their cancer diagnosis in the ED. The fragmentary nature of emergency care may limit the possibility of establishing continuity of care and a predictable relationship with a provider after diagnosis [13]. For

patients with advanced cancer who present to the emergency department, one British study found that anxiety related to the disease related to patient interpretation of symptoms, feelings of comfort and safety within the hospital environment, difficulties accessing community healthcare services especially after hours or for urgent reasons, and previous patterns of health-seeking behavior are the major drivers of seeking care in this setting [14].

For those individuals without insurance, social work involvement can be pivotal to helping patients organize their medical care and access available financial assistance, without which, treatment for their disease can be delayed and suboptimal. In working with patients/families to identify alternative care plans, as well as available community resources to assist with integrating a new diagnosis, the ED social worker serves as the link between the community, primary care, and hospital settings.

Language/Cultural Barriers

In one Michigan study, those diagnosed with cancer in the ED were found to come from lower socioeconomic backgrounds, were older, and more often disabled [13]. A large number of these patients were found to be dually eligible for Medicaid and Medicare up to 12 months prior to diagnosis compared to those diagnosed with cancer in other settings. Racial differences were also found in this study, with African Americans being significantly more likely to receive a cancer diagnosis in the ED [13].

A small study of Spanish-speaking patients in New York City found that they were frustrated both due to their inability to comprehend their prognosis, as well as difficulty in accurately expressing to clinicians their feelings surrounding cancer diagnosis and prognosis [15]. Advocating for the use of an interpreter for patients/families whose first language is not English can enhance understanding of medical information and minimize the emotional distress and confusion that emanates from such misunderstandings. An ED social worker's assessment of specific cultural concerns related to hospitalization, caregiving, and in some cases, receipt of medical treatment, allows the ED team to practice more culturally sensitive care.

A key tenet of social work practice is cultural competence or the ability to work in the context of cultural differences. Health disparities in ED pain management have been demonstrated, with one study showing that Hispanics were twice as likely not to receive pain medication for bone fractures as compared to non-Hispanic whites [16]. ED social workers can take the lead role in educating their interdisciplinary team members about these and other disparities as well as specific cultural concerns and traditions that may impact medical decision-making.

Caregiver Distress

Whether driven by distressing symptoms that are unmanageable at home, exhaustion from the intensity and/or longevity of caring for a cancer patient, or feeling overwhelmed by the responsibilities of caregiving, caregiver distress may be the root cause of an ED visit. ED social workers who screen for caregiver distress can work to determine additional sources of support in the caregiver's life and ensure a link to these services. A case example of an oncologic social work intervention for a distressed caregiver is provided at the end of this chapter.

The Role of the Outpatient Oncologic Social Worker

In addition to the acute medical needs that prompt ED visits and invite the interventions of ED social workers, oncologic social workers serve to address the unique psychosocial stressors that accompany a cancer diagnosis. These may include adjustment to a new cancer diagnosis, alterations in role and identity, changes in caregiver needs and family roles, impact on work and finances, and goals of care planning. For cancer patients, these transitions can be markers of ambiguous loss, or the unclear, indeterminate losses that are less acknowledged than death, but can greatly impact coping, sense of control, and psychosocial functioning in both the patient and family [17, 18]. These losses can also trigger feelings of anticipatory bereavement, in which patients and families begin the process of mourning, coping with loss, and psychosocial reorganization in preparation for death. This process can trigger mixed emotions such as helplessness, denial, confusion, and guilt but, if managed effectively, may provide patients and their families with improved communication and meaningful interactions at the end of life [19].

Prior to a cancer diagnosis, patients may not have had needs that would necessitate an interaction with a social worker. The oncologic social worker may be their first introduction to such services. Once this connection is made, the oncologic social worker can link patients and their families to concrete resources in the community, as well as provide therapeutic interventions to address psychosocial needs. The oncologic social worker becomes the conduit of communication, linking the work done in the ED with the work of the outpatient oncologic team; thus avoiding a "new beginning" for patients and families and supporting continuity of care in the process. It is the author's experience that oncologic and ED social workers typically collaborate and communicate to ensure smooth transitions for patients in need between specialties and across outpatient and inpatient settings.

Social workers are the primary psychosocial professionals available to patients receiving medical treatment [20, 21].

While medical social workers have become more broadly available in healthcare settings, oncologic social workers have evolved as a subspecialty within the field [22]. The psychosocial needs of patients with cancer have become increasingly complex as treatment has shifted to the outpatient setting. The broader range of treatment options available to patients has complicated decision-making and increased both patients' and families' care management responsibilities [23–25].

Traditional social work interventions in outpatient oncologic settings include biopsychosocial assessments, psychoeducation, counseling, linking patients to community resources and coordinating the provision of concrete services including home care, hospice, durable medical equipment, and transportation. Social workers are highly skilled practitioners who are trained to provide screening, assessment, and therapeutic interventions across the cancer continuum including primary prevention, diagnosis, treatment, survivorship, palliative care, end of life, and bereavement [22]. Oncologic social workers are knowledgeable about cancer and its treatments as well as psychosocial aspects of illness, cultural and spiritual influences, pain and symptom management, finances, community resources, and research in the field of psycho-oncologic [22, 26].

Clinical Interventions

Oncologic social workers spend considerable time with patients and/or family members discussing their adjustment to a cancer diagnosis. Individual counseling can help the patient determine specific concerns and set priorities [26, 27]. The focus of clinical work in health care is on enhancement of coping rather than psychopathology [28]. The goals of clinical interventions are to reduce anxiety and assist in clarifying misconceptions and correct misinformation, as well as decrease feelings of isolation [22, 29]. Researchers have shown that psychological interventions can improve the emotional and physical health outcomes in patients with cancer [29, 30].

Cognitive Behavioral Interventions

Cognitive behavioral therapy (CBT) combines cognitive psychotherapy with behavioral interventions. It seeks to reduce emotional distress by identifying, challenging, and eliminating irrational beliefs, and encouraging patients to change their maladaptive preconceptions and behaviors [31, 32]. These techniques may include hypnosis, guided imagery, progressive muscle relaxation, and biofeedback, which are utilized during individual or group sessions [26, 29]. Social workers frequently obtain specialized training for this type of work [26]. Used either alone or in conjunction with medication, behavioral methods are effective for treating side effects associated with cancer. These include anticipatory nausea and vomiting associated with treatment, heightened anxiety, and pain [33, 34].

Relaxation Techniques

Relaxation techniques guide patients to achieve control over their muscles and thoughts, in order to reduce emotional distress [31]. Progressive muscle relaxation involves systematic tensing and relaxing of various body parts. The practitioner describes comfortable sensations in muscle groups usually progressing from head down to feet or from feet up to head. Patients are encouraged to practice these techniques at home to enhance competence and achieve mastery [31]. Visualization of restful scenes associated with pleasurable thoughts is another technique used to promote a sense of relaxation and calmness, allowing patients to feel more in control of their feelings. Social workers practicing these techniques should obtain specific training in these areas [26]. The growing use of complementary therapies (such as meditation, relaxation, hypnosis, and visualization) has resulted in their increasing availability in hospitals and oncologic centers [35–37].

Supportive Counseling

Counseling helps patients and their families manage the multiple problems associated with chronic illness [26]. Individual supportive counseling can decrease the distress and disruption experienced with a cancer diagnosis. While there is no clear definition for supportive psychotherapy, this approach is generally considered an intervention that can be used intermittently or continuously. This patient-centered flexible approach assists patients in dealing with distressing emotions by reinforcing strengths [31, 38]. Supportive counseling emphasizes the importance of compassion, empathy, and support in working with patients [29]. An important goal of counseling in oncologic social work is to help the patient and/or family maintain or redefine hope [26], moving beyond equating hope with cure to broader meanings, values, and intentions that are beyond the limits of an illness.

Crisis Intervention

A significant crisis can be triggered with the initial cancer diagnosis, throughout the course of treatment, when the disease recurs, and at the termination of curative therapy. Therefore, oncologic social workers may use crisis intervention techniques on a recurring basis throughout the illness trajectory. Oncologic social workers help the patient and family explore and clarify feelings, understand how to manage these

feelings, and teach new ways of coping, including solving problems [34, 39]. The oncologic social worker encourages familiar coping mechanisms, while also providing resources and support to patients experiencing a loss of stability [39].

Psychoeducation

Providing education to cancer patients serves to reduce the sense of helplessness that results from uncertainty and lack of knowledge. Psychoeducation can provide patients with a sense of mastery over their illness. It can involve disease-specific information and may also include information about coping, side effects, and wellness [29]. The goal of this intervention is to enhance coping skills and empower patients to become active participants in their care [29]. The information provided should be tailored to meet the patient's expectations, preferences, diagnosis, treatment, and prognosis. Information can also be related to maintenance of maximal health, coping, and financial/legal concerns.

A patient's educational needs change over time, such as during and after treatment [40]. A patient's primary language and reading comprehension level are also important factors for social workers to consider when adapting psychoeducational materials to cancer patients and their families. Oncologic social workers often provide patients with brochures, booklets, and materials from well-known sources, such as the Leukemia and Lymphoma Society, CancerCare, and the American Cancer Society, or refer patients to resource libraries and/or trusted websites. An understanding of patient health literacy is essential to effectively use these resources. Table 7.1 lists national resources that provide support, information, and/or financial assistance to those with cancer and their families.

Table 7.2 Description of psychosocial interventions that may be used with oncologic patients in the ED

Intervention	Description	Outcome
Cognitive behavioral therapy	Assists patients in identifying and changing maladaptive thinking and behaviors, in order to reduce negative emotions and facilitate psychological wellness	Reduces anxiety, increases problem-solving skills, increases understanding of maladaptive cognitions, and enhances coping
Relaxation techniques	Encompasses a variety of techniques to calm thoughts and muscles, in order to allow patients to feel more in control and at ease	Reduces anxiety, increases sense of control, enhances coping
Supportive counseling	Focuses on helping patients to cope with distressing emotions, reinforces pre-existing strengths, and promotes adaptive adjustment to illness	Enhances coping by establishing a therapeutic alliance, reduces anxiety
Crisis intervention	Time limited, used intermittently; focuses on symptom reduction; expression of feelings are encouraged and tangible support is provided	Reduces psychosocial symptoms, mobilizes social supports, increases sense of self-competency
Psychoeducation	Utilizes educational resources and provides information to reduce feelings of helplessness while increasing the patient's knowledge and sense of control	Prevents ED admissions (i.e., may increase compliance to medical recommendations), fosters improved decision-making, reduces anxiety, increases sense of control

Cancer patients may benefit from numerous intervention techniques and programs. Psychiatric interventions play a significant role in the comprehensive care of cancer patients. The list provided in Table 7.2 is not an exhaustive list of interventions but rather a compilation of interventions that are utilized by oncologic social workers in practice, which may also be applicable to oncologic patients in the ED.

Case Discussion 2

Oncologic Social Worker Interventions to Prevent an ED Visit

Charlotte was a 57-year-old African American female with metastatic triple-negative breast cancer. Charlotte was well

known to her outpatient oncologic social worker (OSW), who had been working with her since she was initially diagnosed with cancer a year before. The OSW assisted with referral to a home hospice program which had an inpatient unit affiliated with the cancer center. Several days later, the OSW received a call from her adult daughter, "Julie." She was upset because the hospice nurse told her that Charlotte was entering the dying stage and they were unwilling to transfer her to the inpatient unit. Julie had a 4-year-old daughter at home and had been explicit at enrollment that she did not want her mother to die at home. She was very frustrated that the hospice staff was not helping her to facilitate an inpatient admission as they believed her symptoms could be managed at home. Julie stated that she was going to call an ambulance to bring Charlotte to a hospital, if the hospice agency did not transfer her mother immediately. In order to avoid the crisis of an ED visit and added distress for Charlotte and her daughter, the OSW intervened and advocated for an immediate inpatient admission since Julie was going to call 911/ambulance if the agency did not act right away. The OSW also spoke to Julie and educated her about alternative options (other hospice programs with inpatient facilities), in order to avoid her calling 911/ambulance to have her mother brought to an ED. Within an hour, Charlotte was brought to the inpatient hospice unit. This case example demonstrates one way that continuity of relationship with an outpatient OSW, even in the setting of a hospice admission, assisted in preventing an ED visit/hospital admission and optimized the care of a dying patient, containing further risk of complicated bereavement for Julie and her 4-year-old child.

The Role of the Palliative Social Worker

Palliative social work developed as palliative care teams sought to increase patient and family-centered care for seriously ill patients and because of the need for the unique assessment and interventional skills provided by social workers. Building on the fields of hospice, oncologic, critical care, and other established areas of practice [41], early leaders in palliative social work helped identify specific competencies in palliative care, targeted psychosocial interventions, and areas of research [42]. Social workers are core interdisciplinary clinicians on palliative care teams whose multifaceted role includes education and counseling on one's adjustment to illness, with special attention to the multidimensional aspects of pain and other symptoms, including the impact of life-limiting illness on the patient's mood, goals, and relationships [43]. Palliative social workers also help facilitate patient/family decision-making regarding goals of care and advance care planning and provide therapeutic interventions to help reduce anxiety and distress in patients and families.

Palliative Social Work Initiative in the ED

As increasing numbers of ED's strive to integrate palliative care into their clinical setting with the goal of improving care for seriously ill patients and encouraging earlier palliative care consults and hospice referrals [44], there are opportunities for palliative social workers to provide consultation to patients, families, and clinicians in the ED. One study of ED utilization found that visits for palliative care, dehydration, and altered level of consciousness were higher during the final two-week period of life than during the last 6 months preceding death [45]. Palliative social workers may be called upon to consult in the ED to help patients and families integrate the meaning of the medical crises while attending to issues such as advance care planning, goals of care discussions and facilitating transitions in care.

The palliative social worker can obtain medical information, specify functional limitations in the patient, and complete symptom assessments [46], as well as discover the patient's narrative of the event that led them to the ED. The ability to ascertain unmet palliative care needs and communicate the benefits of a palliative consult or a hospice referral to the emergency physician encourages their initiation from the ED [47]. Early referral to palliative care in advanced cancer patients has shown to improve quality of life and does not appear to shorten survival [48]. The palliative social worker can be expected to communicate with the palliative care team regarding symptom management needs for seriously ill patients in the ED.

Visibility of the palliative care team is important in the eyes of emergency clinicians. The palliative social worker may become the "face" of palliative care by regularly consulting in the ED, through collaboration with the ED social worker to assist seriously ill patients, or by providing education on palliative care principles to ED clinicians. Whether helping to increase collaboration between emergency medicine and palliative care, identifying patients who are appropriate for palliative care consults and hospice referrals, or providing specific psychosocial interventions to patients in the ED [47], palliative social work can play a key role in assisting oncologic patients and families.

Goals of Care Conversations in the ED at End of Life

The ED is often where changes in the patient's illness trajectory are recognized, and new plans of care are established: thus identifying end-of-life patients who may be appropriate for a transition in care is appropriate in this setting. For oncologic patients who present to the ED and are actively dying, or for those whose prognosis is poor, facilitating goals of care discussions can help clarify options for ongoing disease-

modifying therapies. Within these discussions, it is important to understand the patient's or surrogate's wishes related to initiating, continuing, or foregoing potentially life-prolonging treatment (e.g., endotracheal intubation). With the assistance of the emergency physician, the palliative social worker can help guide goals of care conversation to enhance patient and family's understanding of diagnosis, prognosis, and treatment options at the end of life, including palliative care and hospice.

The nature of an oncologic patient's emergency may also invite a conversation about advance directives or MOLST/POLST to include decisions about resuscitation, treatment preferences, and goals of care [47]. Palliative social workers have the clinical skills and knowledge to work with the physician to obtain, interpret, and assist in completing these advance care-planning documents. ED social workers are also knowledgeable about advance care-planning documents as well as pertinent state laws that may pertain to this process.

Social Work Initiatives to Prevent ED Visits

Given the importance of ED social worker's role in care coordination, and other ED clinicians referral to them for assistance with illness adjustment [7], there is tremendous opportunity for them to be involved in improving care for cancer patients in the ED. Based on the acuity of cancer patients, initiatives will likely involve social workers who are most often responsible for making and following up on home care and hospice referrals. An initiative to assist in the prevention of ED visits requires screening, anticipatory guidance, and knowledge of resources. For example, caregivers experiencing distress and exhaustion might be connected to community resources that provide respite care. Below is a case example highlighting one such instance.

Case Discussion 3

OSW Connecting an Oncologic Patient's Caregiver to Community Resources

James is a 63-year-old, African American male with pancreatic cancer living in Tennessee. James's sister, Millie, his only caretaker, lives in New York City. When Millie found out about his diagnosis, she moved him to New York City, as he had no family in Tennessee. James sleeps on Millie's living room sofa and she assists him by coming to his medical appointments, chemotherapy appointments, making sure he eats properly, etc. *Millie met with the oncologic social worker (OSW) to discuss her feelings of being overwhelmed by the level of care that he required and she indicated that she felt she needed help. The OSW offered to make a home care referral and Millie agreed. After several weeks of home care, Millie reported that she was still feeling stressed and overwhelmed, and she requested that James be admitted to a nursing home. James has Medicaid, prompting the OSW to suggest that Millie try a day program at a nursing home close to where she lived. Millie agreed to the referral and James began attending the day program 4 days per week. The day program provided James with meals, activities, and transportation to and from Millie's apartment, all covered by his insurance. Millie was relieved by the referral, since the facility was one that she liked and was in her neighborhood. Millie had originally asked the oncologist for James to be admitted to the hospital in order to have him transferred to a skilled nursing facility. However, once the OSW suggested the day program, Millie no longer felt the need for James to stay full time at the nursing home. In this case, the OSW's involvement, recommendation, and referral to a community resource resulted in the avoidance of an ED admission.*

Psychiatry

One initiative to avoid ED visits and an additional crisis for patients and families is through partnering or making psychiatry services readily available. The accessibility to a psychiatrist can be helpful in avoiding ED visits for suicide assessment(s). In outpatient cancer centers, if a psychiatrist is not available and a social worker determines that a patient is at risk, the patient would likely be sent to the ED for further assessment. This is not a beneficial allocation of ED resources as it is a potentially avoidable visit that can be upsetting for the patient. If a psychiatrist is on staff at the outpatient cancer center, or psychiatric services are readily available in the community, then ED visits to assess for suicidality may be avoidable.

Health Home Initiative

As more cancer patients are living longer with the disease, cancer is increasingly viewed as a chronic illness [49]. Due to the ongoing evolution of the American healthcare system and changes in reimbursement for services, hospitals will no longer be reimbursed at the same rates for readmissions and ED visits [50]. Therefore, many hospitals are making efforts to lower and contain costs through initiatives that have the potential to decrease readmissions and ED visits. The "Independence at Home" (IAH) initiative for Medicare beneficiaries who have been hospitalized and received rehabilitative services in the past 12 months target those with two or more chronic conditions. This health home initiative offers home-based primary care services aimed at reducing repetitive ED visits and hospitalizations. Under a collaborative

care model of multidisciplinary team members, one IAH initiative utilizes nurses and social workers to do the majority of home visits with the support of physicians [51]. Health homes are one example of a program in which social workers can play a pivotal role to reduce ED visits and readmissions for oncologic patients.

Suggestions for Future Research

More research is needed to understand the optimal role of ED social work in caring for oncologic patients, as well as to identify therapeutic interventions and their effectiveness with patients/families in enhancing their ED experience. There is also a need to identify collaborations and initiatives between ED, oncologic, and palliative social work that have the potential to strengthen the psychosocial care of the patient, avoid duplication of services, and possibly prevent unnecessary ED visits and hospitalizations. As research continues to be done to integrate palliative care in the setting of the ED, social workers, in the fields of emergency medicine, palliative care, and oncologic social work have an opportunity to provide expertise and leadership in the coordination of patient care.

Conclusion

Clinical social workers are trained to conduct a comprehensive biopsychosocial-spiritual assessment of patients and their families, to better inform goals of care, enhance communication, and ensure smooth transitions in care [6, 52]. In working with cancer patients who present to the ED in crisis, the ED social worker can identify psychosocial, financial, and cultural concerns that may impact future medical care. ED, oncologic, and palliative social workers are in key positions to help identify and test new initiatives aimed at strengthening services for oncologic patients throughout the continuum of their illness. Collaboration among these social workers allows for earlier outreach to oncologic patients with unmet psychosocial and concrete needs and supports continuity of care across settings. Attention to the psychosocial needs of oncologic patients and their families can help patients, caregivers, and medical providers optimize the delivery and efficacy of healthcare services while managing the emotional and social aspects of illness [40]. Bridging biomedical and psychological well-being aids in the promotion of better health.

The current healthcare climate focuses on market-driven, cost-containment strategies for the provision of medical care. As such, social workers serve an essential function in the cost-efficient delivery of health care. Social workers are well positioned to contribute to the psychosocial care of oncologic patients in the ED and can identify and coordinate alternative plans of care that may reduce the number of unnecessary ED visits.

Acknowledgments The authors are very grateful to Terry Altilio, LCSW, and Halley Robinson, LMSW, for their constructive edits and assistance.

Part II

Prevention

Tobacco Control

8

Steven L. Bernstein

Background

Fifty years after Surgeon General Luther Terry's landmark report on smoking and lung cancer, tobacco use remains the leading cause of death in the United States and the leading cause of preventable death [1]. Worldwide, tobacco use is a growing cause of morbidity and mortality. In many developing countries, it is overtaking infectious diseases as a leading public health hazard. Although great progress has been made in curbing this man-made epidemic, the human and economic costs associated with smoking remain enormous.

In the United States, each year, about 437,000 Americans die from smoking [1]. An additional 41,000 die from exposure to secondhand smoke, largely as a result of living with a smoker. Although smoking prevalence has declined, in 2018, 13.8% of all Americans age 18 and older smoked [2]. The conditions associated with death from secondhand smoke exposure include lung cancer and coronary artery disease, residential fires, and prenatal and perinatal conditions such as sudden infant death syndrome [1]. Smoking is a causative agent in dozens of diseases, enumerated in Surgeon General reports dating back to 1964 and summarized in the most recent 2014 report [1]. These diseases are listed in Table 8.1. Of note, even half a century after publication of the first major Surgeon General's report on smoking, epidemiologic research continues to reveal new associations between smoking and certain cancers, such as renal cell carcinoma, pancreatic cancer, and acute myeloid leukemia.

Emergency departments, visited 138 million times by Americans in 2017 [3], are sites where ED clinicians may conduct opportunistic screening and intervention for tobacco use. ED-initiated tobacco control is effective as found by a 2017 meta-analysis [4] and can be done with a modicum of effort.

The terms "smoking" and "tobacco use" are often used interchangeably. They are not. "Smoking" refers to the consumption of combustible tobacco. In the United States, that is largely in the form of cigarettes. Other forms of combustible tobacco include cigars, cigarillos, and hookah. In developing countries, bidi and kretek are also popular forms of consuming combustible tobacco.

Smokeless tobacco may be consumed as well, in the form of snus (moist pouched tobacco placed between the lip and gum), chewing tobacco, dip, and snuff (dried, insufflated tobacco). Newer products include nicotine-containing water.

Electronic cigarettes, which consist of a heating element that vaporizes a nicotine-containing solution, which is then inhaled, constitute a new and rapidly growing product. E-cigarettes, as they are known, come in a variety of delivery devices. Most solutions contain nicotine; some do not. There is no uniformity in the design or manufacture of these products, which now come under the regulatory purview of the US Food and Drug Administration (FDA) Center for Tobacco Products. The potential for e-cigarettes to cause illness, including cancer, cardiovascular disease, and addiction, is not well understood. They are currently the subjects of intense study, as well as substantial marketing efforts by the traditional tobacco companies, many of which have acquired e-cigarette manufacturers. Because of the developing science surrounding the health effects of e-cigarettes, they will not be discussed at length.

Diagnosis of Tobacco Use

Tobacco-related illness is common in the ED. A complete listing would include diseases directly caused by smoking, such as chronic obstructive pulmonary disease (COPD), and conditions like asthma whose acuity or treatment is complicated by co-occurring tobacco use. Table 8.1 summarizes the list of tobacco-caused illnesses. An early paper found that about 5% of all ED visits, 7% of all admissions, and 10% of ED charges are attributable to smoking [5].

Chronic airways obstruction (J44)	10.58	6.80	13.08	6.78

From 2014 Surgeon General's report [1]
Note: ICD = International Classification of Diseases

Emergency physicians and nurses screen for smoking irregularly. Tobacco use is more likely to be solicited for patients with conditions that are clearly tobacco-related; less so for others.

There are various ways to screen for tobacco use. In research contexts, a two-question screener is often used. The screener is used by two large annual surveys, managed by the Centers for Disease Control and Prevention: the Behavioral Risk Factor Surveillance System (BRFSS) and the National Health Interview Survey (NHIS).

The two questions are:

1. Have you smoked at least than 100 cigarettes in your entire life?
   - ☐ No
   - ☐ Yes
   - ☐ Don't know/not sure
   - ☐ Refused
2. Do you now smoke cigarettes every day, some days, or not at all?
   - ☐ Every day
   - ☐ Some days
   - ☐ Not at all
   - ☐ Don't know/not sure
   - ☐ Refused

Individuals who endorse having smoked at least 100 cigarettes/lifetime, and are every- or some-day smokers, are considered to be current smokers. Individuals who endorse at least 100 cigarettes/lifetime, but do not currently smoke, are considered to be former smokers. Those smoking less than 100 cigarettes/lifetime are considered never-smokers.

Of note, these questions do not capture the use of other forms of combustible tobacco, or smokeless forms such as chew, snus, and the newer heat-not-burn cigarettes. Electronic cigarettes (e-cigarettes) and related products, known collectively as electronic nicotine delivery systems (ENDS), constitute a new and growing means of nicotine administration. The oncogenic and pathogenic potential of ENDS is only starting to be studied, although the market share of these products is growing rapidly.

However, in the context of routine clinical care, it is probably sufficient to ask patients if they currently smoke. In our experience, smokers tend to be forthcoming in disclosing

their tobacco use. In the current era of data capture via electronic health records (EHRs), there is typically a structured field in the social history (or elsewhere) to record smoking status. In that case, the provider's choices may be constrained by the responses offered in the "smoking box" of the EHR.

Diagnosis of Tobacco-Related Illness

The list of conditions in Table 8.1 is extensive but does not cover all clinical scenarios in which EM practitioners might discuss smoking with patients. For example, wound healing is often compromised in smokers, with higher risks of poor cosmesis and infection [6]. Injury comprises 18.9% of all ED visits [3], so smokers with injuries are common. Tobacco abstinence should be advised for all smokers with lacerations, fractures, abscesses, and other skin, soft tissue, and musculoskeletal injuries. Discharge summaries generated by electronic medical records should mention tobacco avoidance for patients with traumatic injury.

Illnesses Associated with Tobacco Use

The number of diseases associated with tobacco use is substantial, and Surgeon General reports since 1964 continue to identify new conditions associated with smoking. The list of tobacco-related illnesses, along with their associated relative risks for mortality, is summarized in Table 8.1.

Note that many of these conditions are commonly seen in the ED. These are largely the cardiovascular diseases, such as chest pain, acute coronary syndromes including myocardial infarction and unstable angina pectoris, and respiratory diseases including pneumonia, influenza, exacerbations of chronic bronchitis and emphysema, and asthma. Patients with cancer are, of course, seen in the ED. They generally present with a complication of treatment or the cancer itself.

Cancer is occasionally, albeit rarely, diagnosed de novo in the ED. It is important to note that these diagnoses are presumptive, because no tissue diagnosis has yet been made.

Some possible scenarios in which cancer may be presumptively diagnosed include:

- A heavy smoker who presents with a cough, dyspnea, or weight loss and has a new pulmonary mass seen on chest x-ray
- A heavy smoker who presents with marked weight loss, progressive difficulty swallowing, and a mediastinal mass contiguous with the esophagus seen on chest x-ray or CT scan
- A postmenopausal woman who presents with vaginal bleeding
- A person who presents with fever and generalized bleeding and is found to be thrombocytopenic with many blast cells in the peripheral blood smear

Of note, tobacco use also is relevant in the ED management of conditions not formally associated with smoking. For example, acute exacerbations of asthma are commonly treated in the ED [7]. Although asthma is not caused by smoking, tobacco use is common among ED asthmatics. It increases the frequency and severity of attacks and prolongs the duration of the exacerbation. Another example would be the management of cellulitis in the foot of a person with diabetes and concurrent smoking. Smoking contributes to the development of peripheral vascular disease and may impair wound healing.

Emergency Department Treatment of Tobacco Dependence

Because of tobacco's great burden of illness and death, its disproportionate use by individuals of low socioeconomic status (SES), and the heavy use of EDs by low SES individuals, the ED has been regarded as an opportune venue in which to initiate treatment for smoking. The accumulating evidence of tobacco's causative role in ED-managed illness and injury has led to its inclusion in the core curriculum of the specialty [8]. Much of the research in this area has entailed understanding provider facilitators and barriers to ED-initiated interventions for smoking.

The general approach to ED-initiated intervention for smoking is adapted from the model known as Screening, Brief Intervention, and Referral to Treatment (SBIRT) [9]. SBIRT entails using one or two questions to identify an individual with a risky health behavior, offering an abbreviated form of motivational interview [10] to promote behavior change and then referring to an appropriate source of aftercare. Initially developed to identify and intervene with persons with alcohol use disorders, SBIRT has been endorsed by the Substance Abuse and Mental Health Services Administration and other professional bodies for use in the ED [11]. ED-based studies with more intensive interventions have generally offered a combination of SBIRT (tailored for smokers) and motivational interviewing.

A newer approach to ED-initiated interventions known as Screening, Treatment Initiation, and Referral (STIR) [12] incorporates medication management into the ED intervention. In the case of smoking, a STIR-informed approach would include the initiation in the ED of nicotine replacement therapies such as patches and gum. Several studies have demonstrated the efficacy of STIR for tobacco dependence [13, 14] and buprenorphine for managing opioid

dependence [15]. STIR capitalizes on the teachable moment often found in the ED visit, when patients may be motivated to change an unhealthy behavior [16].

There are numerous evidence-based treatments for tobacco dependence. These may be divided into two broad categories: medication and counseling. Each is effective; used in combination, they provide even greater efficacy.

There are seven FDA-approved medications: nicotine patch, gum, lozenge, nasal spray, and inhaler, plus varenicline and bupropion. Counseling strategies with proven efficacy include one-on-one in-person sessions, group counseling, and telephone quitlines. The evidence base supporting these treatments is reviewed extensively in the 2008 Public Health Service's guideline on tobacco dependence treatment and in the 2014 Surgeon General's report on smoking.

Of note, quitlines are widely available in all 50 states. They can be accessed by a single phone number: 1-800-QUIT-NOW. Services vary somewhat from state to state, but as a rule include counseling by a trained provider, provision of written materials, starter doses of nicotine replacement, web-based services, and, increasingly, smartphone-based texting services. Quitlines are open 7 days a week, and languages other than English are available. Referrals can be made by providers or smokers. There is no cost to individuals or health systems, and insurance is not needed. Additional information is available at www.naquitline.org, the home page of the North American Quitline Consortium.

Most smoking cessation counseling uses principles of motivational interviewing or cognitive behavioral therapy. Of note, neither hypnosis nor acupuncture has demonstrated efficacy.

These treatments are summarized in Table 8.2.

The pharmacotherapy of nicotine dependence treatment is straightforward. Smokers who consume five or more cigarettes daily are good candidates for treatment. Medication is typically begun with a single agent, usually the nicotine patch or gum. A single cigarette contains 1–3 mg of nicotine, which can be used to guide dosing. In general, nicotine should be replaced milligram-for-milligram. A 21-mg patch, applied daily, would be a typical treatment for someone who smokes ten or more cigarettes daily. Higher dosing or additional forms of nicotine replacement therapy (NRT) may be added if the patient experiences cravings. Recent studies suggest combination therapy, using both long-acting and short-acting agents (e.g., patch and gum or nasal spray or inhaler), may be more effective than monotherapy. The reason is that transdermal nicotine generally does not replace enough nicotine to prevent cravings and other symptoms of withdrawal. NRT products that cross the blood-brain barrier quickly and easily can offer rapid relief for smokers with cravings.

Bupropion is a drug whose mechanism of action is incompletely understood. It was initially approved for treatment of mood disorders but also shows efficacy in smoking cessation. Varenicline is an interesting drug that blocks nicotinic receptors in the brain that mediate reward and craving. It is an agonist-antagonist. Varenicline prevents nicotine from binding to receptors but stimulates the release of a small amount of dopamine, generally sufficient to prevent symptoms of withdrawal. These drugs are beyond the scope of practitioners of emergency care and are not indicated for initiation in the ED.

The clinical trials of ED-initiated tobacco dependence treatment are summarized in Table 8.3 [13, 17–23, 25]. Most were single-institution studies with modest sample sizes and limited methodologic rigor. More recent studies from the 2010s used larger sample sizes, biochemical confirmation of tobacco abstinence at follow-up, and rigorous methods to minimize attrition and found various interventions to be efficacious.

A study from 2015 [13] found that a multicomponent intervention was able to produce a statistically significant higher rate of tobacco abstinence in subjects at the primary endpoint, 3 months, compared to controls. At 1 year, the effect attenuated but nearly reached statistical significance. The intervention consisted of provision of 6 weeks of nicotine patches and gum, initiation of the patch in the ED, a brief motivational interview (10–15 min) by a trained interventionist, a referral faxed to the state smokers' quitline, a phone call 2–3 days after enrollment, and a smoking cessation brochure. This study was the first to demonstrate the efficacy of ED-initiated tobacco dependence treatment. Although efficacious, the intervention has limited generalizability because of the use of nonclinical personnel to perform the motivational interview and the provision of a substantial supply of nicotine replacement medication.

An additional limitation of this study was the inability to disaggregate the effects of individual components, given the intervention was delivered as a package. To identify the efficacy of individual components, as well as interactions between components, the investigators conducted a $2 \times 2 \times 2 \times 2$ factorial trial using the multiphase optimization strategy (MOST) [27]. MOST studies use iterative approaches to identify packages of effective intervention components, subject to a cost constraint. In this study, 1056 adult smokers were enrolled and randomized to receive up to four interventions: a brief motivational interview, 6 weeks of nicotine gum and patches with the first dose applied in the ED, an active referral to a smokers' quitline, and enrollment in the SmokefreeTXT texting program of the National Cancer Institute. Each intervention was "on" or "off" for each participant, so the trial had 16 conditions.

At 3 months' follow-up, both the motivational interview and the nicotine replacement therapy were found to increase abstinence (motivational interview 13.5% vs. 8.9% [$P = 0.02$]; NRT, 14.4% vs. 8.0% [$P = 0.001$]) [14]. Neither

Table 8.2 Tobacco dependence treatment medications

Products OTC	Dosage	Duration	Precautions	Adverse effects	Patient education
Nicotine patch 21 mg 14 mg 7 mg	One patch per day. >10 cpd: 21 mg 4 weeks, 14 mg 2 weeks ≤10 cpd: 14 mg 4 weeks 7 mg 2 weeks	8–12 weeks	Do not use if patient has severe eczema or psoriasis Caution within 2 weeks of MI	Local skin reaction Insomnia	Apply each day to clean, dry, hairless skin Focal rash is common: Rotate site daily Available without prescription.
Nicotine gum 2 mg 4 mg	First cigarette ≤ 30 min after waking: 4 mg First cigarette > 30 min after waking: 2 mg 1 piece every 1–2 h	12 weeks	Caution with dentures Do not eat or drink 15 min before or during use Limit 24 in 24 h	Mouth soreness Stomachache Hiccups	*DO NOT CHEW LIKE ORDINARY GUM* Alternate chewing and "parking" between the cheek and gum (chew until mouth tingles and then park for 1 min, continue for 30 min) Nicotine absorbed across the buccal mucosa Avoid food and acidic drinks before and during use Available without prescription
Nicotine lozenge 2 mg 4 mg	First cigarette ≤ 30 min after waking: 4 mg First cigarette > 30 min after waking: 2 mg 1 piece every 1–2 h	12 weeks	Do not eat or drink 15 min before use One lozenge at a time Limit to 20 in 24 h	Heartburn Local irritation of the mouth and throat Coughing Hiccups	*DO NOT BITE, CHEW, or SWALLOW* Dissolve in mouth slowly Each lozenge takes 20–30 min to dissolve Avoid food and acidic drinks before and during use Available without prescription
Nicotine inhaler Nicotrol Inhaler®	6–16 cartridges/day Each cartridge = 2 cigs Use 1 cartridge q 1–2 h	6 months; taper	Reactive airway disease	Mouth and throat irritation Cough	Patient is not to puff like a cigarette. Gentle puffing recommended Absorption via the buccal mucosa Avoid food and acidic drinks before and during use
Nicotine nasal spray Nicotrol NS®	1–2 sprays each nostril/h 8–40 doses/day	3–6 months; taper	Not for patients with asthma	Nasal irritation Sneezing Cough Teary eyes	Instruct patient to tilt the head back and spray Tolerance to local adverse effects develops first week after use
Bupropion SR150 Zyban® or Wellbutrin®	Start 1–2 weeks before quit date Days 1–3: 150 mg each morning Days 4–end: 150 mg BID	2–6 months	Contraindications: Seizure disorder Current use of MAO inhibitor Eating disorder Alcohol dependence Head trauma	Insomnia Dry mouth Anxiety	Take second pill early evening to reduce insomnia Never double dose if miss a pill
Varenicline Chantix®	Start 1 week before quit date 0.5 mg/day for 3 days and then 0.5 mg BID for the next 4 days After first 7 days 1 mg/BID	3–6 months	Persons with kidney problems require dose adjustment Serious psychiatric illness	Nausea Insomnia Abnormal dreams	Take after eating and with water (full glass) Never double dose. Take missed dose as soon as remembered. If close to next dose wait and take at regular dose time Nausea is usually transient. If nausea persists, dose reduction is recommended

OTC over the counter, *MI* myocardial infarction, *MAO* monoamine oxidase

the quitline nor the texting program was efficacious. No interactions were noted. This study was the first to identify individually effective components of ED-initiated tobacco control. Future work for ED-based tobacco treatment should focus on the scalability of these interventions.

Table 8.4 reviews the components of an effective ED-initiated tobacco intervention. The individual components are all supported by evidence from high-grade clinical trials in various settings, with at least one high-quality ED trial to support their use.

Table 8.4 Components of an effective ED-initiated intervention for tobacco dependence

Component	Comments
Counseling	Brief counseling intervention employing principles of motivational interviewing; cognitive behavioral treatment may be efficacious
Medication	Provision of at least 4 weeks of nicotine replacement therapy. Combining short- and long-acting forms (e.g., patch and gum) likely to be more efficacious than monotherapy
Post-discharge treatment: quitline, texting	Aftercare should extend at least 30 days beyond visit. Active referral to state smokers' quitline, via fax or electronic health record, may achieve that. Newer interventions such as use of cellphone texting warrant further study
Interventionist	Ideally, a nonclinical individual, such as a health promotion advocate or health educator. Can be delivered by physicians, midlevel providers, and nurses, but constraints of time and clinical burden are substantial

Cost

Tobacco dependence treatment is among the most inexpensive, most cost-effective interventions in clinical medicine [28]. Integrating tobacco dependence screening, treatment, and referral into ED clinical workflows can be quite inexpensive. Several models of practice are available. The cheapest is to allow providers—physicians, nurses, and midlevel practitioners—to perform the screening as part of routine clinical care. Brochures advertising the state tobacco quitline, generally available from health departments in bulk at little to no cost, can be distributed to smokers. Advice to quit, call the quitline, or perhaps visit a locally available smoking cessation clinic can be templated and added to discharge summaries. Directed referrals to quitlines via fax can be made by clinical or clerical personnel. Some electronic medical records are integrating quitline referrals into their order sets for tobacco dependence [29].

A more intensive, and expensive, model of care entails placing lay educators or health promotion advocates in EDs to screen patients for tobacco use and other risky health behaviors [30]. These models are effective in identifying and referring patients, but their impact on long-term abstinence rates is unclear.

Conclusion

Tobacco use is widely prevalent in emergency department patients, and tobacco-related illness is a common reason for presentation. Recent evidence suggests that ED initiation of nicotine replacement therapy and behavioral counseling are independently effective in promoting sustained tobacco abstinence. As a result of the accumulating evidence regarding the efficacy of ED-initiated tobacco control, both the US Public Health Services' clinical practice guideline [31] and a report by the Institute of Medicine [32] recommend EDs as effective loci for tobacco screening and treatment. Tobacco use carries a sufficient burden of illness and death to warrant routine screening and intervention in ED patients. Future work should focus on finding ways to disseminate and implement these effective interventions.

Problem Drinking

9

Edouard Coupet Jr. and Federico E. Vaca

Case Study

Linda is a 52-year-old woman who presents to the emergency department (ED) with a chief complaint of a forehead laceration following a fall down a flight of stairs. While she was at home, she states that she had consumed a half a pint of vodka in the afternoon. While traveling down the stairs, she missed the last step, fell, struck her head, and sustained a small laceration to her forehead. She denies any other complaints and otherwise is nontoxic appearing. Her past medical history includes breast cancer, which was diagnosed 4 years ago, and hypertension. While in the ED, the physician orders a CT scan of her head which found no evidence of acute intracranial injury. The nurse administers tetanus prophylaxis and the physician repairs Linda's laceration. While repairing her laceration, the physician finds out that Linda drinks at least a pint of vodka every day. The physician soon determines that she appears clinically sober and almost ready for discharge. However, there is concern about Linda's heavy alcohol use. The physician notifies the social worker who comes to talk to Linda about her alcohol use and drinking pattern. A medical chart review reveals that Linda has presented to the ED three times in the last year for various falls. After further brief discussion and evaluation, it is determined that Linda meets the criteria for moderate alcohol use disorder (AUD). The social worker informs and educates Linda about unhealthy drinking and drinking patterns that are associated with AUDs. She further assesses her willingness to seek AUD treatment. Linda states she is not interested in seeking inpatient treatment at this time but is willing to accept a referral for outpatient treatment services. Linda is discharged from the ED and provided a follow-up appointment at a specialized treatment clinic that can help manage her AUD.

Background

Alcohol consumption plays a substantial role in human culture worldwide [1, 2]. It has been estimated to account for approximately 4% of the total global disease burden [3]. In 2016, it was the seventh leading risk factor for death, globally [4]. In the USA, similar to many other industrialized countries, alcohol use disorders (AUDs) remain among the most common, yet undertreated, behavioral health disorders [5]. This is particularly important because individuals with AUD contribute to nearly half of alcohol-related diseases, including various cancers and injuries [6].

Alcohol use most commonly begins during adolescence [7–10]. As youth progress from early to late adolescence, alcohol use typically increases. According to data from the Monitoring the Future National Survey Results on Drug Use, in 2018, 8% of 8th graders reported alcohol use, while 30% of 12th graders reported alcohol use in the past month [11]. Moreover, the earlier youth begin to use alcohol, the higher their risk is for alcohol-related adverse consequences. In one study of over 27,000 current and former individuals who have drank, an estimated 40% of individuals who started drinking at age 14 or younger developed alcohol dependence over their lifetime. The rate declined to nearly 10% when the individual started drinking at age 20 or older [12].

Previous literature has characterized four individual trajectory groups (i.e., low, high, increasing, and decreasing) of alcohol use based upon age at onset of drinking and drinking patterns [8, 13–15]. The "low" group consisted of individuals who either drank lightly or abstained completely across the entire adolescent-adult lifespan. The "high" group consisted of adolescents who drank heavily at a late-onset or chronically across the adolescent-adult lifespan. The

"increasing" group consisted of adolescents who began drinking heavily in their late adolescence or emerging adult years. Shortly after this developmental period, their alcohol use declined. The final group of "decreasing" individuals began drinking heavily early in their adolescence and declined as they transitioned into late adolescence.

In 2018, results from the National Survey on Drug Use and Health (NSDUH) showed that nearly 140 million Americans aged 12 or older drank and 67 million reported binge drinking alcohol in the past month. Among adolescents aged 12–17, 4.7% reported binge drinking in the past month. Among young adults aged 18–25 and adults aged 26 and older, 34.9% and 25.1% reported binge drinking alcohol in the past month, respectively. Approximately 15 million Americans aged 12 or older meet the criteria for AUD as defined by the *Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV)* criteria for abuse or dependence. An estimated 1.6% of adolescents aged 12–17 meet the criteria for AUD. Among adults, 10.1% of those aged 18–25 and 5.1% of those aged 26 and older meet the criteria for AUD [16].

A variety of public health problems are either directly or indirectly caused by excessive alcohol consumption, including hepatic and pancreatic diseases, cancers, diabetes, suicide, cardiovascular disease, infectious diseases, and both intentional and unintentional injuries [17]. Regulation of alcohol sales and taxes on alcoholic beverages has been instituted at both federal and state levels to mitigate excessive alcohol consumption and alcohol-related disease. There is strong evidence to support these efforts [18–23]. One study determined that alcoholic beverage tax increases in 1983 and 2002 in Alaska which reduced the rate of death from alcohol-related diseases by 29% and 11%, respectively [24]. A systematic review of literature that evaluated the effect of alcohol purchasing hours on several alcohol-related harms determined that regulation of these hours can reduce alcohol-related hospitalizations and injuries, such as motor vehicle collisions (MVCs) [25].

Research has informed a spectrum of drinking levels. According to the 2015–2020 Dietary Guidelines for Americans, a standard drink is defined as 1.5 oz (45 mL) of 80-proof spirits, 12 oz of beer, or 5 oz of table wine. Each of these contains approximately 14.5 g of absolute ethanol. For those of legal drinking age, moderate alcohol consumption is defined as one drink per day for women and up to two drinks per day for men. Binge drinking is defined as a pattern of alcohol consumption that increases the blood alcohol concentration (BAC) to 0.08% or greater. This usually happens after four drinks for women and five drinks for men within 2 h. Heavy alcohol use is defined as greater than four drinks a day for men or greater than three drinks a day for women. Both binge and heavy alcohol use increase an individual's risk of adverse and negative consequences [26].

In this chapter, we will review common emergency department (ED) encounters for alcohol-related diseases and injuries, the identification and diagnosis of AUD, the ED approach to prevention of AUD, and the role of ED-based alcohol screening, brief intervention, and referral to treatment (SBIRT) in preventing alcohol related-cancers.

ED Encounters for Alcohol-Related Disease and Injury

Acute Conditions Related to Alcohol Use

From 2006 to 2014, the number of alcohol-related ED encounters in the USA increased by nearly 62% [27]. The unhealthy consumption of alcohol is a substantial burden on EDs, causing both injury and disease. Injury is one of the most common causes of alcohol-related ED encounters, accounting for up to 50% of all alcohol-related ED encounters in one study [28]. Alcohol has a well-established link to many types of unintentional injuries, particularly because of its psychomotor impairing effects [6, 29]. A meta-analysis of 28 articles of acute alcohol consumption and injury demonstrated a strong dose-response relationship of acute alcohol consumption and both MVC and non-MVC injuries [30]. Moreover, drivers who drink alcohol, yet are not legally impaired, cause thousands of deaths as well [31]. In a multisite prospective cohort study of both intoxicated and non-intoxicated injured drivers, alcohol was found to be a significant predictor of morbidity post-injury [32]. Previous research shows that younger drivers who have consumed alcohol are at highest risk for a fatal MVC because of their lower alcohol tolerance and relative driving inexperience [24, 33, 34]. Prior consumption of alcohol is also highly associated with increased injury severity, longer hospitalization, and higher healthcare costs in bicycle-related injuries presenting to the ED [35].

Intentional injuries, which commonly present to the ED, have an even greater association with alcohol use [36–38]. Alcohol consumption is well-known to increase aggressive behaviors and decrease inhibition [39]. Existing literature shows a strong link between alcohol use and interpersonal violence [36–38, 40, 41]. In a meta-analysis of 37 EDs across 18 different countries, 44.1% assault-related injuries were attributed to alcohol use, the highest for all types of injuries [40]. Another ED-based study found higher rates of a positive BAC in those who suffered an assault-related injury compared to those who were injured due to other causes [42].

Although the relationship is not as strong as that for non-partner violence, there is evidence to support the link between alcohol and intimate partner violence [43, 44]. A meta-analysis determined a small to moderate effect size for the

link between alcohol use and male-to-female partner violence and a small effect size for female-to-male partner violence [43]. Previous literature also demonstrates an association between alcohol use and behavioral health disorders, which increase the risk for suicide [45, 46].

Chronic Conditions Related to Alcohol Use

In the USA, the number of ED encounters for chronic conditions related to alcohol use increased by nearly 76% between 2006 and 2014. Harmful alcohol use, as indicated by the World Health Organization (WHO), was associated with 48% of liver cirrhosis cases [39]. There is substantial evidence to support the deleterious effects of alcohol on liver function and its role in the development of liver diseases seen in the ED such as cirrhosis, hepatic encephalopathy, and hepatitis [47–49]. In a prospective study of middle-aged women in the UK, daily alcohol consumption, not paired with meals, was associated with a twofold increase in liver cirrhosis. Moreover, patients with alcohol-related liver disease who have refrained from alcohol use experienced an increase in their life expectancy [49]. Another prospective population-based study demonstrated that the relative risk of developing alcohol-related liver disease significantly increased when women drank 7–13 and men 14–27 alcoholic beverages per week [50]. Evidence shows that current recommendations for safe alcohol consumption thresholds may be too high, further contributing to the increased alcohol-related disease burden and harm [51, 52].

Since the turn of the century, there is increasing evidence that supports the casual link between alcohol consumption and cancer [53–56]. Alcohol consumption is linked to cancers of the head and neck, liver, gastrointestinal (GI) tract, and for women, breast [57]. Although the mechanism by which it causes cancer is not well understood, alcohol is believed to have several different carcinogenic mechanisms which likely differ by organ site. Acetaldehyde, the primary toxic metabolite of alcohol, is believed to alter deoxyribonucleic acid (DNA) strands [53, 57, 58]. Alcohol also reduces the blood concentration of important antioxidants including vitamins A and E, folic acid, thiamine, zinc, and iron. Additionally, it suppresses the immune system and can potentiate the effects of other carcinogenic agents [53]. Fortunately, evidence suggests stopping alcohol consumption can reduce the risks of developing certain types of cancers [59].

Along with tobacco use, alcohol consumption is one of the largest risk factors for cancers of the head and neck [60]. Previous research demonstrates that alcohol accounts for 26.4% of lip and oral cancers, 30.5% of all pharyngeal cancers, 21.6% of laryngeal cancers, and 16.9% of esophageal cancers [61]. Evidence also supports a dose-dependent relationship between alcohol use and head and neck cancers. In one study, participants who drank more than seven alcoholic beverages per day had four times the risk of developing cancers of the head and neck compared to those who abstained from drinking [62]. A meta-analysis of alcohol use and risk of head and neck cancers demonstrated that individuals who drank lightly, moderately, and heavily had relative risks of developing cancers of the head and neck of 1.13, 1.83, and 5.13, respectively [63]. There is also evidence to suggest that individuals who continue to drink, with a primary head and neck cancer diagnosis, are at increased risk of both primary cancer recurrence and development of a second primary cancer. A multisite study of more than 4000 individuals with head and neck cancer showed that participants who drank more than one alcoholic beverage per day had an increased risk of developing a second primary cancer [64]. A single-site retrospective study of individuals with a primary head and neck cancer diagnosis showed that consuming 8–14 drinks per week was associated with an elevated risk of recurrence.

Heavy alcohol use is among the strongest risk factors for developing hepatocellular carcinoma (HCC) [65, 66]. Alcohol is believed to be both directly responsible for HCC and indirectly by causing liver cirrhosis, a well-known risk factor for HCC [61]. Alcohol has been proposed to cause oxidative stress, leading to the generation of free oxygen radicals and consequently, DNA damage [61]. A previous epidemiological study suggests that drinking more than 80 g/day for at least 10 years substantially increases the risk of developing HCC [67]. Evidence also shows a synergistic effect when heavy alcohol consumption is paired with the hepatitis B or C virus infection. A case-control study of 115 patients with HCC demonstrated that those who report heavy alcohol use and have chronic hepatitis had an odds ratio (OR) of 53.9, compared to an OR of 2.4 with alcohol alone or 19.1 with the virus alone [68].

Although the evidence may not be as strong as that for other malignancies, there is evidence to support an association between alcohol use and cancer of parts of the GI tract, notably the esophagus, colon, and rectum. Up to 75% of cases of esophageal cancer can be attributed to alcohol use. Chronic alcohol consumption is understood to increase the esophageal mucosa's susceptibility to carcinogens [61]. Previous research shows a strong link between esophageal squamous cell carcinoma and alcohol consumption [69]. However, research does not support the same relationship for gastric cancer. A review of over 40 epidemiological studies of gastric cancer and chronic alcohol use did not find any association between the two [70]. Numerous studies suggest an increasing dose-dependent relationship between alcohol use and colorectal cancer [71]. A review of over 50 cohort and case-control studies found increased association between alcohol use and colorectal cancer by a factor of 2 [72].

The International Agency for Research on Cancer determined alcohol consumption to have a causal relationship to breast cancer, which exists in both premenopausal and postmenopausal women [69]. Existing literature suggests a 7–10% increase in risk for breast cancer for every 10 g (~1 drink) of alcohol/day consumed by an adult woman. This relationship has even been found in women who drink alcohol lightly [73–76]. A proposed mechanism behind this relationship appears to be the increased estrogen levels found in women who drink [75]. Alcohol has also been linked to recurrence of breast cancer and increased mortality from the disease. In a review, having more than 6 g of alcohol/day was associated with an increase in recurrence of and death from breast cancer. This relationship was determined to be even stronger in postmenopausal and obese women [77].

Special Considerations for Health Disparities

Existing data of alcohol consumption patterns demonstrate differences and disparities across ethnic and racial minority groups. According to the NSDUH, reported past month use of any alcohol in individuals aged 12 and older was highest in Whites (57.7%), followed by Blacks (43.6%), Latinos (43%), Native Hawaiians/Pacific Islanders (38.4%), American Indians/Alaska Native (37.3%), and Asians (34.5%). However, Native Hawaiians/Pacific Islander populations were most likely to report heavy alcohol use in the past month (8.9%), while Asian populations reported the lowest rates (2%) [16]. White and Native American populations have the highest risk for developing AUD [78].

Once alcohol dependence develops, Black and Latino populations have the highest rates of recurrent or persistent dependence [79]. A review of 19 studies of racial/ethnic disparities and alcohol-attributable injury determined that Native Americans had the highest rate of alcohol-attributable injuries such as MVCs, self-injury, and falls compared to other racial/ethnic groups [80]. Black and Latino populations are also at greatest risk for developing alcohol-related liver disease [81]. Previous research suggests that gaps in alcohol treatment utilization are highest in Latino populations, particularly among those primarily Spanish-speaking [82–85]. Evidence demonstrates that alcohol treatment programs should take these socioeconomic and cultural factors into consideration when addressing disparities among racial/ethnic groups [86–89].

Identification and Diagnosis of Alcohol Use Disorder

Alcohol-Related Conditions

There were over 138 million ED encounters in the USA in 2017. Alcohol use contributed to a substantial portion of these encounters. Over 4.2 million ED encounters were related to alcohol misuse, abuse, or dependence [90]. Furthermore, acute alcohol-related disorders, such as injury, are among the leading causes of alcohol-related ED encounters. The list of all of the International Classification of Diseases, Tenth Revision (ICD-10), alcohol-related conditions an ED clinician may encounter is provided in Table 9.1.

Diagnosis of Alcohol Use Disorder

Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), criteria for diagnosis of AUD has shifted to a broader spectrum based on severity as compared to the dual model of alcohol abuse and dependence within the DSM-IV. In the DSM-IV, there were four diagnostic criteria for alcohol abuse and seven for dependence. In the DSM-5, the diagnostic criteria, which highlight craving, loss of control, tolerance, and withdrawal, have increased to 11 (Box 9.1). Individuals with two to three criteria meet the diagnosis of mild AUD; individuals with four to five, moderate; and individuals with six or more,

Box 9.1 *Diagnostic and Statistical Manual of Mental Disorders*, **Fifth Edition (DSM-5): Alcohol Use Disorder**

1. Alcohol-related failure to fulfill obligations
2. Recurrent drinking in hazardous situations
3. Continued drinking despite problems
4. Tolerance
5. Withdrawal
6. Drinking more or more often than intended
7. Unable to quit/cut back drinking
8. Spent a lot of time drinking/recovering
9. Gave up important activities due to drinking
10. Continued drinking despite consequences
11. Craving
Mild alcohol use disorder (AUD): 2–3 criteria required
Moderate AUD: 4–5 criteria required
Severe AUD: ≥6 criteria required

Table 9.1 ICD-10 codes for alcohol-related conditions

Group	ICD-10 code	Disorder
Acute conditions	F10.0	Mental and behavioral disorders due to use of alcohol, acute intoxication
	R78.0	Finding of alcohol in blood
	T51.0	Toxic effects of ethanol
	V12–V14 (0.3–0.9), V19.4–V19.6, V19.9, V20–V28 (0.3–0.9), V29–V79 (0.4–0.9), V80.0–V86 (0.0–0.3), V87.0–V87.9, V89.2, V89.3, V89.9	Road traffic injuries-non-pedestrian
	V02–V04 (0.1,0.9), V06.1, V09.2, V09.3	Road traffic injuries-pedestrian
	W00–W19	Fall injuries
	W65–W74	Drowning
	W78–W79	Aspiration
	W24–W31, W45, W60	Occupational and machine injuries
	X00–X09	Fire injuries
	X78–X79, Y87.1	Assault
	X85–Y09, Y87.1	Child abuse
	X60–X84, Y87.0	Suicide
	X45	Accidental poisoning by and exposure to alcohol
	X65	Intentional self-poisoning by and exposure to alcohol
	Y15	Poisoning by and exposure to alcohol, undetermined intent
Chronic conditions	C01–C06, C09–C10, C12–C14	Oropharyngeal cancer
	C15	Esophageal cancer
	C22	Hepatocellular cancer
	C32	Laryngeal cancer
	C50	Female breast cancer
	E24.4	Alcohol-induced pseudo-Cushing's syndrome
	F10.1	Mental and behavioral disorders due to use of alcohol, harmful use
	F10.2	Dependence syndrome
	F10.3	Withdrawal state
	F10.4	Withdrawal state with delirium
	F10.5	Psychotic disorder
	F10.6	Amnesic syndrome
	F10.7	Residual and late-onset psychotic disorder
	F10.8	Other mental and behavioral disorders
	F10.9	Unspecified mental and behavioral disorder
	G31.2	Degeneration of nervous system due to alcohol
	G62.1	Alcohol polyneuropathy
	I42.6	Alcoholic cardiomyopathy
	K29.2	Alcoholic gastritis
	K70.0	Alcoholic fatty liver
	K70.1	Alcoholic hepatitis
	K70.2	Alcohol fibrosis and sclerosis of the liver
	K70.3	Alcoholic cirrhosis of the liver
	K70.4	Alcoholic hepatic failure
	K70.9	Alcoholic liver disease, unspecified
	K85.2	Alcohol-induced acute pancreatitis
	K86.0	Alcohol-induced chronic pancreatitis
	O03	Spontaneous abortion
	O36.5, P05, P07	Low birth weight

severe [91]. As a result of these changes in the DSM-5, some individuals may either have gained, lost, or changed in severity. The DSM-5 also removed alcohol-related legal problems and replaced it with the criteria of craving.

ED Approach to Prevention of Alcohol Use Disorder

Since many individuals seek emergency care for both acute and chronic alcohol-related concerns, the ED is the

ideal setting for the clinicians to approach and engage their patients regarding their alcohol use. With their patient's permission, ED clinicians should use this opportunity to discuss unhealthy alcohol use in an open, honest, nonconfrontational, nonjudgmental manner. To promote behavior change, ED clinicians should use health promotion, which is defined by WHO as "the process of enabling people to increase control over and to improve their health" [92]. For those who abstain or who are moderate alcohol consumers, this includes education about unhealthy/high-risk drinking and reinforcement of existing healthy behaviors. Individuals with high-risk drinking should be encouraged to reduce their drinking, ideally below the high-risk limits or less if possible. Federal dietary guidelines, endorsed by the National Institute on Alcohol Abuse and Alcoholism (NIAAA), clearly state that a person who does not drink alcohol should not start drinking for any reason [26].

Some individuals who report unhealthy or high-risk drinking may not be prepared to abstain from alcohol use completely. As an alternative to promoting abstinence, ED clinicians should provide harm reduction education. Harm reduction is a strategy to minimize the acute harms associated with alcohol intoxication [93–95]. It includes reducing alcohol consumption, avoiding drinking and driving, and changing drinking patterns. A systematic review of 63 studies of reduced alcohol use showed that harm reduction strategies can decrease alcohol-related injuries, slow progression of alcohol-related diseases such as cirrhosis and cardiomyopathy, and reduce withdrawal symptoms [96].

A substantial amount of literature has evaluated screening and providing an ED-based intervention for unhealthy alcohol use. Over two decades ago, a framework for intervention known as screening, brief intervention, and referral to treatment (SBIRT) was developed and tested in both acute and primary care settings for high-risk behaviors such as substance use. SBIRT involves a psychosocial intervention which utilizes principles of motivational interviewing to encourage individuals with unhealthy alcohol use to pursue treatment. The intervention, more specifically the brief negotiated interview (BNI), relies upon a patient-centered discussion that assesses their willingness to reduce their alcohol use toward healthier limits. It utilizes principles of both harm reduction and health promotion. The American College of Emergency Physicians, the Committee on Trauma of the American College of Surgeons, and the Emergency Nurses Association have all recommended SBIRT for addressing unhealthy alcohol use in their respective clinical settings [97–99].

There is modest evidence to support the effectiveness of ED alcohol SBIRT in reducing alcohol use and alcohol-related consequences in the ED [93, 100–103]. A 2007 systematic review of 13 studies found SBIRT did not have any effect on quantity/frequency of drinking at 12 months and was inconclusive at 3 months. However, it did find a 41% reduction in the odds of alcohol-related injury at 6 and 12 months following the initial ED encounter [104]. A more recent systematic review of 35 articles that evaluated the effect of a brief intervention on ED patients who were screened as high-risk for AUD showed a short-term effect in reducing alcohol consumption in those who drank low or moderately [101]. Previous research also shows that ED SBIRT for alcohol use is cost-effective [105].

The BNI of SBIRT has been developed and tested in numerous different modalities including in-person, computerized, and by smartphone (Box 9.2). A previous concern about SBIRT was that characteristics of the BNI and patient had not been evaluated. A 2019 clinical trial evaluated 750 ED patients with unhealthy alcohol use and randomly assigned them to receive either a computer-delivered BNI, therapist-delivered BNI with computer guidance, or enhanced usual care. The main outcome was alcohol use at 3, 6, and 12 months. Moderation of the intervention effect was also tested by gender, age, and severity of alcohol disorder. Overall, there was no difference in the main effects of either computer-delivered or therapist-delivered BNI compared to enhanced usual care. However, the therapist-delivered BNI group was more effective among patients with moderate to severe drinking patterns, while the computer-delivered BNI was more effective among younger participants [106]. Other benefits to computer-delivered SBIRT include its use in resource-limited EDs. There is also a reduction in time burden for care providers, enhanced fidelity of intervention delivery, and the potential for multilingual administration [86, 107, 108]. Overall, alcohol ED SBIRT represents a critical opportunity to identify patients with untreated AUD, particularly those who may not be seeking treatment. Once identified, these patients can receive a brief intervention or be linked to specialized treatment. Without this service, this precious opportunity is missed. Furthermore, both the NIAAA and Public Health Task Force recommend screening for unhealthy alcohol use; there appears to be no harm to the patients in doing so [109, 110].

Box 9.2 Modes of ED SBIRT for Alcohol Use Disorder

- Specialty-trained paraprofessionals
- Computerized interaction
- Computerized and human interaction
- Smartphone-based interaction

Potential Value of ED-Based Alcohol SBIRT for Alcohol-Related Cancers

The ED serves a unique opportunity to detect unhealthy alcohol use and render services to those who present with concerns related to at-risk and hazardous alcohol use. In addition to decreasing use, ED-based SBIRT has shown some promise in reducing alcohol-related consequences such as MVCs [101, 103, 104, 111]. However, to date, there have been no studies that evaluate the effect of ED SBIRT on alcohol-attributable cancers. Existing evidence shows that alcohol use has a strong link to several types of cancers including head and neck, liver, GI tract, and breast [55, 57, 60, 62, 63, 72–74, 112]. By decreasing alcohol use, ED SBIRT has the potential to reduce exposure to alcohol (i.e., physiologically) and the risks of developing alcohol-attributable malignancy and other diseases associated with it, such as cirrhosis. Previous evidence has also shown that ED SBIRT can increase treatment access, particularly for those with alcohol dependence and AUD. A 2015 systematic review found that 7 out of 15 studies evaluated whether or not participants pursued treatment. Four studies compared the referral to treatment rates in the group that received BNI to the control group. One study showed a higher referral to treatment rate, in favor of the group that received BNI [113].

Recognition and treatment of severe AUD and its sequelae in the ED are also important among those with terminally ill disease such as advanced-stage cancer and liver cirrhosis. Alcohol dependency affects up to 28% of palliative care inpatients [114]. As high as 87% of patients with severe AUD receiving palliative care would not have been diagnosed had they not been screened [115]. ED clinicians should consider ongoing or worsening AUD in their differential diagnosis, particularly when evaluating patients with advanced-stage cancer. They should also consider identifying what appears to be signs and symptoms of acute alcohol withdrawal albeit in a less familiar context. Although evidence of the management of alcohol dependency among terminally ill patients is limited, ED clinicians should be proactive in recognizing and treating symptoms of acute alcohol withdrawal in this population. Low-dose benzodiazepines, such as lorazepam, are recommended with careful attention to those with liver impairment. Terminally ill patients who are interested in receiving detoxification are most appropriate for referral to the inpatient setting [116]. Alcohol ED SBIRT may also provide additional benefits in identifying unhealthy alcohol use in patients who have either received a new diagnosis of cancer or may be terminally ill.

Conclusion

EDs across the world diagnose and treat acute conditions related to unhealthy alcohol use such as MVCs and more chronic conditions such as liver cirrhosis and breast cancer. Thus, the ED is the ideal setting to identify patients with unhealthy alcohol use and motivate them to pursue treatment using SBIRT. It has shown promise in reducing alcohol consumption and alcohol-related injuries. By reducing alcohol consumption, ED SBIRT has the potential to reduce the risk of developing alcohol-attributable cancers as well. Tobacco and alcohol ED SBIRT, when used in conjunction, have the potential to have synergistic effects in reducing the overall burden of cancer [117]. However, additional research is needed to evaluate the effects of alcohol SBIRT in the ED on alcohol-attributable cancer.

Ionizing Radiation

10

Richard T. Griffey

Case Study

A 28-year-old female with Crohn's disease presents with diffuse abdominal pain and low-grade fevers. She has had small-volume blood-tinged loose stools but no melena or vomiting. She was diagnosed with Crohn's disease at age 21 and has had several abdominopelvic CTs for staging and acute evaluations. She feels this may be a typical Crohn's flare but can't be sure. Knowing that as a young female at risk for repeat and multiple imaging with CT, which compounds an increased risk for luminal malignancies from her disease alone, the emergency physician discusses her care with her gastroenterologist and opts for imaging with magnetic resonance enterography (MRE) and admission, avoiding further ionizing radiation for non-obstructive symptoms.

Introduction

CT Is a Transformative Tool in Medicine

Computed tomography (CT) has numerous benefits that impact emergency care, including, but not limited to, decreasing negative appendectomy [1–5] and exploratory laparotomy rates, decreasing the need for hospitalization [6], allowing for safe discharge after exclusion of coronary disease [7], increasing provider [8] and patient [9, 10] confidence in diagnoses, and possibly even decreasing mortality [11] and increasing life expectancy [12]. Indeed, CT is fast, easy to obtain, relatively inexpensive, widely available, and highly sensitive, resulting in relatively low radiation exposure for the benefits obtained. The benefits of a CT *with appropriate indications* far outweigh the risks.

The Explosion in CT Utilization

In light of this, it is perhaps not surprising that CT use has skyrocketed over the last two decades, with a growth rate of 14% per year for about a 12-year period [13]. In 1981, 3 million CTs were performed, increasing to over 67 million exams by 2006 (Fig. 10.1) [14]. One in ten Americans undergoes a CT scan every year, and many undergo more than one [15].

Increasing awareness about cumulative radiation in addition to other policies and guidelines may have contributed to a plateauing of CT imaging rates observed in the years 2008–2010 onward [16, 17]. Though this trend is true for overall CT rates, utilization in the ED has continued to increase [18]. It is estimated that one in seven ED patients undergoes CT and that 25% of CTs in the USA are performed in the ED [7]. In one study, 70% of the nearly one million non-elderly adults underwent at least one imaging study that included ionizing radiation, resulting in mean effective doses that nearly doubled the cumulative radiation expected from natural sources alone [19]. Similar patterns of CT use have been observed in pediatric populations as well, though more so in non-pediatric EDs [20, 21].

CT Contribution to Cumulative Radiation

Because of the much higher exposures that are imparted by CT when compared to radiographs, discussion of this modality drives the discussion about concerns over cumulative radiation exposure as well as costs [22]. Though by volume, radiographs comprise the majority of imaging studies, on a population basis, these account for a relatively small amount of cumulative radiation exposure [23]. Interventional diagnostic studies and therapeutic procedures, such as thallium scans and radiotherapy, can impart much higher radiation doses than CT but are not as commonly performed. In 2006, CT comprised about 17% of imaging procedures but was the source for over half the medical radiation dose in the USA (Fig. 10.2) [1]. The delayed nature of the carcinogenic effects

of radiation exposure makes overutilization an insidious problem that fails to signal the usual alarms among patients or providers. Of concern, cumulative radiation from diagnostic imaging is projected to account for up to 5% of future cancers in the USA [15, 24, 25].

Reasons for Increased CT Utilization

Many reasons for the observed increases have been proposed, including but not limited to an aging population, the wide availability of CT, the replacement of older (X-rays)

with newer technology (CT), its speed and ease to obtain, concerns about malpractice and other factors, and for reasons that are surely multifactorial [18]. With hospital crowding, time pressures, the need to make decisions based on limited information, and a mandate to never miss life-threatening disease, the ED is fraught with the potential for error. This generally leads to a bias toward testing, including advanced imaging. It is important to appreciate that the increases in CT imaging in the ED have occurred in the context of a significant shift in the USA in the setting in which acute care is provided. The ED now accounts for nearly a third of the 354 million annual acute care visits in the USA, practically all acute care provided after hours and on weekends, more acute care for the uninsured than in all other settings combined, and nearly 50% of hospital admissions in the USA [26, 27]. To some degree, this shift in location of care explains some of the increases in volume of imaging performed in this setting, though early studies demonstrated that increases in CT utilization outpaced increases in ED visits [28]. Studies demonstrate that increased CT utilization far exceeds the amounts expected by replacement of technology [29] and that changes in tort law have had mixed findings as relates to CT utilization [30, 31].

Patterns of Repeat/Multiple CT Imaging in the ED

Though head and abdominopelvic CTs are the most commonly performed studies in the ED, it is known that certain indications for CT (e.g., kidney stones, suspected pulmonary embolus) predominate among patients who are repeatedly or multiply imaged [25, 32, 33]. It has been observed that significant proportions of CTs performed are unnecessary and/or could be replaced with other imaging modalities that do not impart radiation [34–37]. Studies identifying patients who are heavily imaged at a given point in time find that these patients tend to have multiple imaging generally and patients heavily imaged in the ED are also highly imaged in settings outside the ED [32, 33, 38].

Radiation and Its Effects

Radiation is the passage of an electromagnetic wave through space. At one end of the electromagnetic spectrum, lower-frequency and lower-energy waves, including radio waves, microwaves, infrared, visible and ultraviolet light, as well as ultrasound, comprise *non-ionizing radiation*. At the other end of the spectrum, the higher-energy, higher-frequency waves, including X-rays and gamma rays, are considered *ionizing radiation*. X-rays are produced when electrons are emitted from electron clouds as a result of electron excitation. Gamma rays are emitted from unstable nuclei as part of radioactive decay. Radiation is considered ionizing if it is of high enough energy to remove electrons from an atom. This is the basis for ionizing radiation causing cellular injury at the atomic and molecular level.

A displaced electron can cause direct injury if it hits and damages a strand of DNA or can indirectly damage DNA if the electron reacts with water, causing a hydroxyl radical that then interacts with DNA. When just a single strand of DNA is damaged, the cell is usually able to repair this, but when both strands are damaged, an abnormal reconnection of strands can occur, which is believed to account for the negative effects of radiation in humans. This may include a rejoining of strands incorrectly, leading to cell death or rejoining as a symmetrical translocation. This can result in oncogene expression during division and subsequent development of a malignancy or abnormal division in the gonads, potentially leading to hereditary disorders [39].

Deterministic Versus Stochastic Effects of Ionizing Radiation

At high doses, high-energy radiation causes direct cellular injury, resulting in what are called *deterministic effects*. These effects are dose related, occurring at threshold levels of radiation to cause sufficient cellular death within a tissue that then results in functional impairment of that organ or tissue (Fig. 10.3). Deterministic effects are discrete and specific, occurring within specific time frames following exposure. These effects are typically due to single large overdoses of radiation. Some examples include:

- Skin erythema, necrosis, and sloughing
- Cataract formation
- Sterility
- Radiation illness (GI tract, bone marrow, CNS)
- IUGR, teratogenesis, and fetal death

By comparison, so-called stochastic effects of radiation are due to DNA mutations whose effects become apparent after cell division. By definition, these are random, not guaranteed to occur, and they develop in an unclear time frame. Stochastic effect occurrence is thought to follow a linear, no-threshold (LNT) exposure where cumulative low doses result in increasing risk, not requiring some threshold level in order to cause these effects.

Organ	Effects	Thresholds (Sv)	
		Single absorption (Sv)	Prolonged absorption (Sv-year)
testis	permanent infertility	3.5 - 6.0	2
ovary	permanent infertility	2.5 - 6.0	> 0.2
lens	cataract	5.0	> 0.15
bone marrow	Blood forming deficiency	0.5	> 0.4

The Link Between Low-Dose Ionizing Radiation and Cancer

Without the benefit of direct observation to quantify amounts, considerable debate has existed about the nature of radiation exposure and the relationship to cancer. Questions about the relationship between radiation and cancer include whether cancer due to radiation results only from discrete exposures to some threshold amount, or whether the risk of cancer due to low levels of radiation increases in a linear (or other) fashion. Studies exploring this relationship have been based largely on data from observed vs. expected solid and liquid cancer rates among those in the blast zones of Hiroshima and Nagasaki, approximately 2000–3000 yards from ground zero receiving radiation in the 5–100 mSv range. Among 93,000 survivors followed over 55 years, 31,650 received a dose of 5–100 mSv. 44% of leukemia and 8% of solid tumor cases were attributable to radiation [40, 41]. Studies among survivors of the Chernobyl nuclear accident have also established the role of radiation as a precursor to malignancy. Other studies report increased all-cause mortality (primarily due to dose-related increases of cancer mortality) of nuclear workers related to cumulative low-dose exposure [42] and both projected cancers [43] and effects on cognition among infants exposed to low-dose radiation [44, 45]. In 2005, the US National Research Council's Seventh Biologic Effects of Ionizing Radiation Conference (BEIR VII) adopted the most widely used risk model for the effects of low levels of ionizing radiation [46]. The BEIR VII model, accepted by the International Commission on Radiological Protection and the UN Scientific Committee on the Effects of Atomic Radiation, holds that the risk of cancer from cumulative low-level radiation proceeds in a linear, no-threshold fashion so that low levels of radiation are cumulative and do not require a threshold level to increase the risk of cancer (Fig. 10.4)

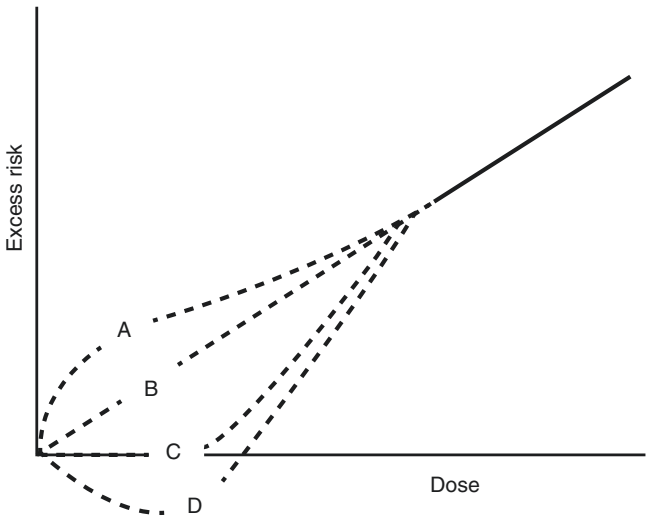

Fig. 10.4 Possible dose response curves for cancer induction at low doses. (**a**) Supralinear, (**b**) LNT (linear non-threshold), (**c**) threshold, (**d**) hermetic. Summing up the epidemiological data and biological findings, we are still unsure about the shape of the dose response curve in the low-dose range. While several dose response curves are possible as illustrated in the figure, the LNT model is usually adopted as a best estimate for low-dose risk. (From Anzai et al. [47], with permission Editorial Secretariat for JCBN)

[47]. Further, this risk model states that a 10 mSv exposure increases the risk of cancer by approximately 1/1000. In the USA, where the lifetime risk of cancer is approximately 42%, this means very crudely that a cumulative 10 mSv exposure increases this risk to 42.1%. Approximately half of cancers are fatal, and so by this risk model, a 10 mSv exposure translates to a risk of fatal cancer of approximately 1/2000 (Fig. 10.5) [46]. This model remains highly controversial, with major bodies, including the French Academy of Sciences, the American Nuclear Society, and the National Academy of Medicine suggesting that this model overesti-

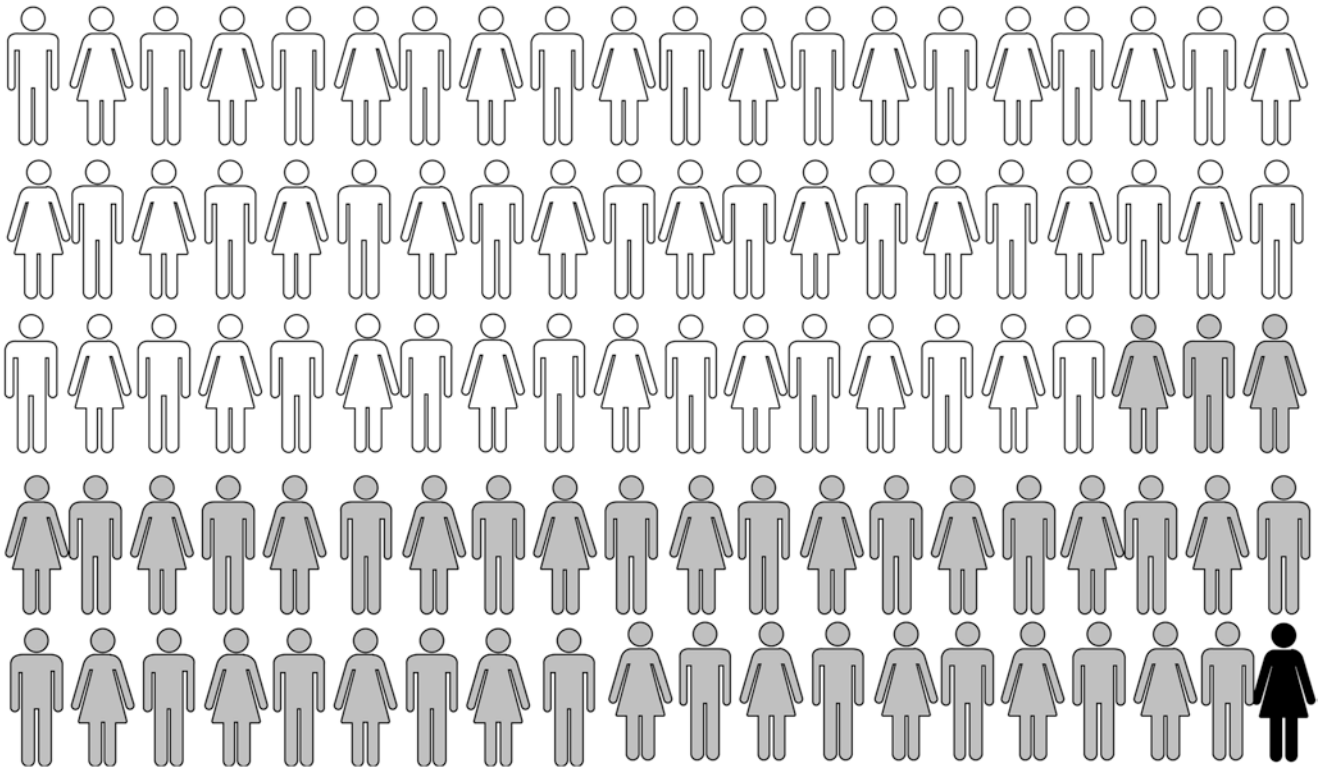

Fig. 10.5 In a lifetime, approximately 42 (solid circles) of 100 people will be diagnosed with cancer from causes unrelated to radiation. The calculation in this report suggests approximately 1 cancer in 100 people could result from a single exposure 100 mSv of low-LET radiation [46]

mates risk. It is important to appreciate that though this remains controversial, it is nonetheless the most widely accepted risk model. It is important to recognize that this model is unadjusted for gender and age at exposure. The American Association of Physicists in Medicine considers a cumulative dose in excess of 100 mSv to be of concern. The quantity of radiation that is considered to be "low dose" is generally in the range of 5–100 mSv.

Who Is Most at Risk?

It is known that age at exposure and gender are modifiers of risk. Women are scanned more frequently and are more sensitive to the effects of radiation, primarily due to increased radiosensitivity of female gonadal tissues [25]. Children have both a longer lag time to develop mutations or for mutations to result in malignancies, as well as increased radiosensitivity that declines with age [24]. However, recent models suggest that this decrease continues until middle age but that then cancer risks may then increase in a U-shaped distribution [15]. An additional risk factor is high cumulative radiation exposure due to multiple imaging. Certain conditions are known to be at increased risk for multiple imaging [32, 33, 48–53] including but not limited to inflammatory bowel disease (IBD) [51–55], kidney stones [20, 56, 57], and shunted hydrocephalus. This leads, in some patients, to very high cumulative doses and increases in lifetime attributable risk (LAR) of cancer. Patients who already have cancer may be at increased risk to develop second malignancies due to radiation. This is documented for radiotherapy, particularly for the lung, esophagus, luminal cancers [58], sarcoma, and breast cancer [59–61]. Cumulative low-dose radiation could represent another potential source of risk.

Measures of Radiation

There are many different units of radiation in use, and these can be difficult to remember for those who do not use them regularly. Measures of radiation relate to different aspects of radiation: exposure, absorption, biological effects, and for comparing effects and values of different exposures.

- *Exposure* to radiation can be measured in roentgens [R]. Exposure is the strength of a radiation field at some point in the air.
- *Absorption* is entry of radiation into body tissues and is measured in rads where 1 rad = 100 ergs/g or the International System of Units (SI) version and grays (Gy). A gray is defined as the absorption of 1 J (joule) of energy by 1 kg (kilogram) of matter. One gray = 100 rad.

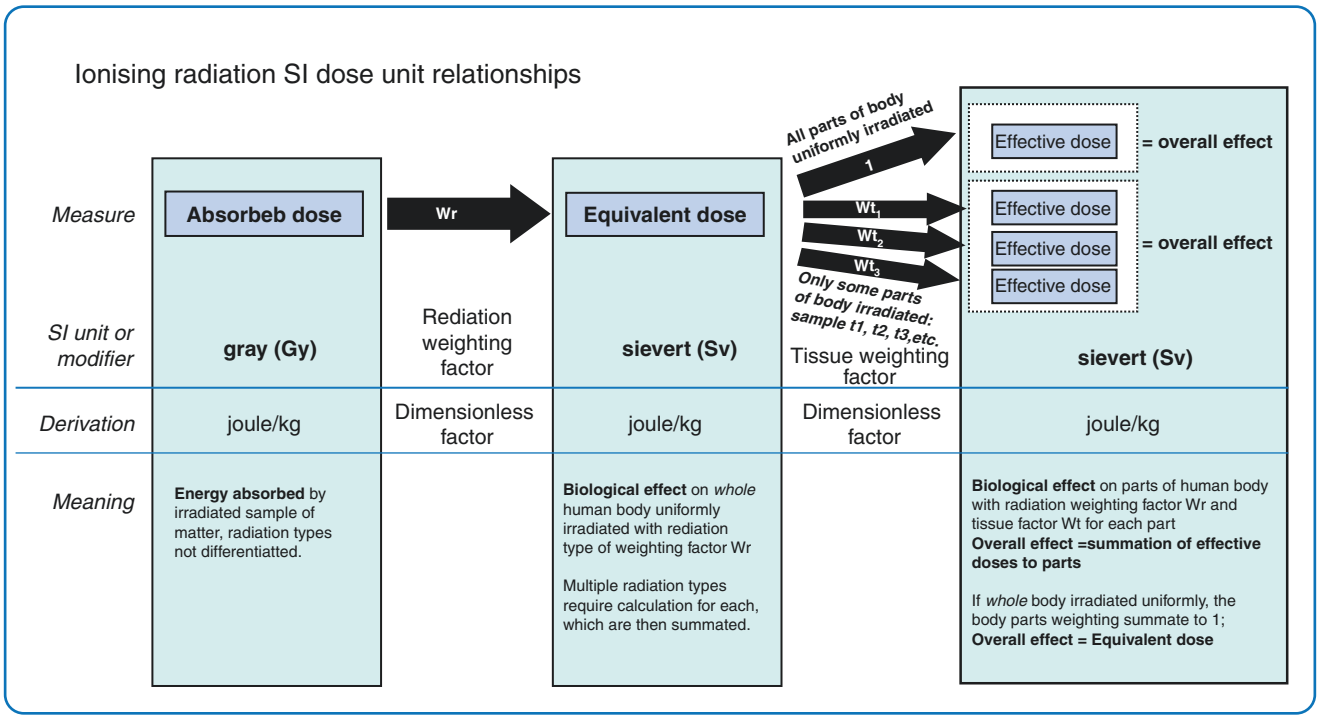

Fig. 10.6 Units and naming conventions for ionizing radiation. (From https://commons.wikimedia.org/wiki/File:SI_Radiation_dose_units.png with permission. Accessed: 8 Jul 2020 Courtesy of Doug Sim CC By-SA 3.0)

Absorbed dose is therefore expressed as a concentration, not an absolute amount. Absorption depends on the strength of the radiation, the distance from the source, and the duration of the exposure.

- The *biological effects* of absorbed radiation are measured in rems or sieverts (Sv), which is the SI unit.
- Important but sometimes confusing concept that is widely used and that can be somewhat controversial is that of *effective dose* (Fig. 10.6). This relates absorbed dose and biological effects. Effective dose is also used in comparing cancer risks and is not a dose but is rather a concept to reflect the risk of cancer from an exposure reflected over age and gender. It is expressed in millisieverts. Effective dose is determined by taking the sum of organ or tissue doses, multiplying these by the respective tissue weighting factors, based on an assumed uniform, whole body exposure. Because it is an average, unadjusted for age and gender, and mathematically derived using a standard body, it is not a true reflection of risk for an individual (Table 10.1).

Dose Estimates

Common units in estimating radiation dose include CT dose index (CTDI) and dose length product (DLP). Most current CT scanners generate these data based on the information provided in determining the protocol used, and these metrics can be reported with interpretations or in other lags. Reporting of CTDI and DLP may soon be required for all scans. CTDI can be thought of as the amount of radiation dose imparted in a single axial CT "slice" through the body with associated scatter and is measured by radiation detectors in a standardized acrylic "phantom" designed to detect doses to specific organs. Different variants of this measure exist, but the volume CTDI is most commonly used, measuring the amount of radiation delivered to the scan volume of a standardized phantom. DLP is the slice thickness multiplied by the number of slices acquired or length of the body scanned. When considering doses of radiation provided by a scanner, it should be remembered that these are not direct measurements for the patient on the gantry, but rather are estimates based on the protocol used as determined by detection in phantoms. In addition to age and gender, weight or body habitus also impacts the absorbed dose.

Efforts to Reduce Radiation and Optimize Imaging

Technological Improvements

At its most basic, CT is an X-ray tube that rotates around a patient. The X-rays passing through the patient are attenuated differently by different body tissues resulting in the detection of a pattern of photons by the detector opposite the tube. As a patient passes through the scanner, it acquires numerous "pic-

tures" in a 360-degree helical fashion that are then mathematically computed and joined to create an image that can be reconstructed in three dimensions. A number of technological improvements can greatly reduce dose per study:

- Standardizing the doses and protocols of CT studies so that for a given patient and a given study, the same dose is delivered. One study of four hospitals in the SF area found that for the same CT study in the same patient, doses varied by up to 13-fold. This sort of variability had significant implications as to projected cancer risk [65] and is unnecessary and wasteful.
- Optimizing aspects of data acquisition (e.g., speed with which the table passes through the scanner, length of body scanned, pitch at which patient passes through the scanner, minimizing amount of overlapped areas occurring due to the helical nature of the scan) may help reduce exposure.
- New detector technology, increasing detector number, and dual source imaging also offer the potential for lower doses [66].
- Accepting more noise in images where high resolution is unnecessary, such as for detecting ureteral stones, can decrease the radiation associated with this CT [67].
- Minimizing multiphase scanning, where patients are scanned, for example, first without, then again with, a contrast agent.
- Modulating tube current, where the amperage from the X-ray tube of a CT scanner is modified as it spins around the patient on the gantry such that a sufficient higher amperage is used in the plane in which the patient is wider and a lower mA setting is less used in the plane in which the patient is thinner.
- Use of shields, such as breast shields, may reduce dose to sensitive tissues. However, these also have limitations and can introduce noise and artifacts.
- Other technical features such as iterative reconstruction can provide high-quality images by eliminating sources of noise, for example, in the reconstruction of the data into images.

Though technological solutions hold promise to minimize the dose per scan, the biggest payoff in terms of radiation and certainly with respect to costs associated with imaging may come at the point of order entry and optimizing ordering to scan those who need it and avoid scanning those who do not. Changing provider behavior is difficult to do, however, as a number of different efforts have demonstrated.

Provider and Patient Awareness

Numerous studies have demonstrated lack of physician awareness of the risks of imaging, disbelief in risks of cancer related to radiation from imaging, and poor performance in estimating risks and equivalent doses of radiation between imaging modalities. This lack of knowledge crosses specialties, in some cases even including radiologists [68–73]. While these are mostly older studies that predate the current focus on this area, the few studies specific to EPs confirm these findings [68, 74, 75]. That said, it is not entirely clear what the right knowledge is: does it matter whether the EP knows the number of chest X-rays that are equivalent to an abdominal CT, or is it more important to know the increase in lifetime attributable risk imparted by an abdominal CT? What is the level of knowledge required for good decision-making? Raising awareness, though helpful, is likely insufficient on its own to make a difference. In one study, training house staff on radiation risks failed to change ordering behavior, though it made them more comfortable with discussing risks with patients [76].

Approaches to raising awareness have included a number of efforts providing information cards for physicians that outline radiation risk for patients, though studies of the effectiveness of these have not been published in the medical literature. One successful program in raising awareness is the Image Gently campaign, begun in 2007, and directed at improving the safety and effectiveness of the imaging of children. This includes "raising patient and provider awareness, providing education and advocacy on selection of appropriate imaging studies, and minimizing radiation dose to levels as low as reasonably achievable (ALARA) when imaging children" [77]. This successful campaign has subsequently led to the Image Wisely campaign directed at achieving similar goals for adults [78].

The few studies that have looked specifically at ED patient knowledge about radiation and their preferences found that patients generally prefer imaging and definitive diagnoses without concern for radiation or its risks [10, 11]. Studies among pediatric populations found that discussions of radiation risk with parents improved their understanding without causing them to decline necessary imaging studies [79]. In a survey of radiology department chairs at academic medical centers, two-thirds reported having guidelines at their institutions related to informed consent for non-emergent CT studies. And though informed decision-making related to imaging is recommended as a best practice [80, 81], only 15% included discussions about possible radiation risk of CT with their patients [82].

Clinical Decision Support

Appropriateness Criteria

A number of bodies have developed appropriateness criteria for imaging [83, 84], perhaps most notable of these is the American College of Radiology (ACR) Appropriateness Criteria, which consist of consensus-derived rankings of imaging studies and modalities for specific clinical indications for imaging. Particularly when radiologists are not available for consultation, rankings of appropriateness may help guide imaging selection and potentially curb overutilization. Providers board-certified in emergency medicine may find these criteria less useful in selecting appropriate imaging in the ED as this is part of their training and because daily practice and local resource availability inform selection of appropriate imaging modalities. In addition, rankings in the ACR Appropriateness Criteria are not impacted by the amount of radiation a study imparts, which is listed in a separate column called "relative radiation level."

Clinical Decision Rules

Clinical decision rules (CDRs) have been developed to help guide clinical practice in an evidence-based manner. Though this term is sometimes used casually, scientifically sound clinical decision rules require rigorous derivation and validation methods that are time-consuming and costly, requiring expertise to ensure their ultimate appropriate use. Moreover, it is unclear whether CDRs truly outperform clinical gestalt [85, 86]. CDRs relating to imaging have been developed to help determine whether patients require head CT imaging following minor traumatic brain injury, whether patients suspected for possible pulmonary embolus require chest CT, and whether patients with renal colic should undergo CT imaging [37, 87]. Even when a CDR is demonstrated to be effective, valid, and reliable, it is only useful if it is actually used. A number of studies describe how various imaging decision rules are underutilized [88–90]. One study estimated that use of a decision rule could prevent up to one-third of pulmonary embolus CTs [34].

Computerized Interventions

A common way to promote use of CDRs and appropriateness criteria is to embed them in computerized order entry systems. A limited number of studies have explored the

effectiveness of computerized decision support in the ED. There have been limited or no studies evaluating use of computerized decision support in providing information on the dose associated with commonly ordered CT studies, patients' individual CT study counts, associated cumulative radiation exposure, or lifetime attributable risks of cancer. One study described computer-assisted identification of patients who had accumulated certain threshold numbers of lifetime CTs, which then required a peer-to-peer conversation with a radiologist to proceed [91]. Though it has been proposed that patients might carry a card with them that specifies the amount of cumulative radiation they have had, it is unclear what providers should do with this information. One survey of EPs confirmed that though providers were interested in all forms of decision support and information described above, they were inadequately familiar with information on radiation dose to make use of such information clinically.

Shared Decision-Making with Patients

Emergency physicians want computerized tools to help guide decision-making and would like information that provides them with ways to discuss risks with their patients [75]. Data suggest that despite being recommended as best practice, discussions with patients regarding risks rarely occur [92]. A main limitation of shared decision-making as relates to CT imaging in the ED is that the decision to image is infrequently preference sensitive or at equipoise with some other diagnostic option. Conveyance of complex information is challenging enough in patients with adequate literacy and numeracy, let alone among those with lesser skills.

Quality Metrics and Regulatory Efforts

In addition to physician-initiated efforts to optimize imaging, a number of organizations and regulatory bodies have taken an interest in incentivizing improvements. Preauthorization is one approach taken by payers that has been successful in reducing imaging. However, it is frustrating for physicians to seek approval to care for their patients and would be highly impractical for use in the ED. Quality measures related to imaging have been advanced by various bodies, including proposals to report and track patient-specific dose information. Existing or proposed legislation in some states involves tracking CTDI and DLP. In addition, tracking and documentation of CTDI and DLP in each patient's record are required by the TJC for accreditation. Hospitals must compile and analyze data on patient CT radiation doses and compare these with external benchmarks when available.

The Centers for Medicare and Medicaid Services (CMS) have adopted imaging-related measures for the ED included as part of the Quality Payment Program. Other programs such as the Choosing Wisely campaign that focus on limiting avoidable imaging have also been championed in emergency medicine. One of these measures, directed at utilization of head CT in the ED for atraumatic headache, generated a fair amount of debate in the EM community. This measure, OP-15, was controversial because its derivation applied data obtained in a younger population to an older Medicare population, its exclusion criteria were felt to be insufficient, and it failed to include indications that were included in the American College of Emergency Physicians' clinical policies related to atraumatic headache and thus was felt to be invalid for public reporting. The Choosing Wisely initiative includes five recommendations directed at minimizing diagnostic radiation exposure: (1) avoiding head CT scans in patients with minor head injury who are at low risk based on validated decision rules; (2) avoiding head CT in asymptomatic adult patients with syncope, insignificant trauma, and a normal neurological evaluation; (3) avoiding CT pulmonary angiography for patients with low pretest probability of pulmonary embolism and either a negative Pulmonary Embolism Rule-Out Criteria (PERC) score or a negative D-dimer; (4) avoiding lumbar spine imaging for adults with non-traumatic back pain unless the patient has severe or progressive neurologic deficits or is suspected of having a serious underlying condition (such as vertebral infection, cauda equina syndrome, or cancer with bony metastasis); and (5) avoiding abdominopelvic CT in young otherwise healthy patients with known histories of kidney stones or ureterolithiasis, presenting with symptoms consistent with uncomplicated renal colic [93].

Summary

It is hard to imagine the practice of emergency medicine without the use of CT imaging. But it may be very important for the benefit of patients, to imagine practice with more judicious use of this tool, particularly for those at increased risk of cancer. Although the nature of the relationship of low-dose radiation and cancer remains controversial, it is accepted that radiation is a carcinogen and that high cumulative doses increase the risk of cancer. Awareness of the risks of CT imaging in young and female patients, particularly for those at repeat and multiple imaging, is a start toward appropriate use. A number of technological improvements are promising to reduce the dose per study. Decision support tools may be useful in helping risk-stratify patients to help in decision-making; however, more study is needed to evaluate their effectiveness. Quality measures and regulatory statutes related to tracking of cumulative doses may also help drive

improvement. Much work remains in order to make clinical use of this information. Finally, providing emergency physicians with options to CT imaging for high-risk patients, including alternate imaging modalities, is essential to help reduce utilization.

Cervical Cancer Screening

11

Natacha Phoolcharoen, Ellen S. Baker, and Mila Pontremoli Salcedo

Case Study

A 16-year-old girl received one dose of the human papillomavirus (HPV) quadrivalent vaccine when she was 14. The girl and her mother have come for vaccination counseling. They want to know if she can finish the HPV vaccination series and how many doses she will need. The nonavalent vaccine is available. Which vaccine should she receive, and how many doses are necessary to complete the series?

The only vaccine available now in the United States is a nonavalent vaccine, so she should receive another one dose of nonavalent vaccine. In the settings where a quadrivalent vaccine is still available, the clinician would recommend that she should receive another one dose of quadrivalent vaccine.

If providers do not know or do not have available the HPV vaccine product previously administered or are in settings transitioning to the nonavalent vaccine, any available HPV vaccine product may be used to continue or complete the series for females for protection against HPV 16 and 18.

Background

Cervical cancer is a leading cause of cancer death among women worldwide in spite of more than seven decades of effective prevention interventions. Cervical cancer is a preventable disease and its high mortality is unacceptable. In recognition of the morbidity and mortality associated with this preventable disease, in May 2018 the WHO Director General announced a global call for action toward the elimination of cervical cancer [1].

There were an estimated 569,847 new cases and 311,365 deaths from cervical cancer in 2018, and cervical cancer ranks as the fourth most commonly diagnosed cancer among women worldwide [2, 3]. The majority of cervical cancer cases occur in low- and middle-income countries (LMICs), where cervical cancer is often the most frequent cancer and the leading cause of cancer death among women. The global disparities in incidence and mortality of cervical cancer is due in part to the vast disparities in access to, and availability of, effective screening programs, including treatment of women who have precancerous lesions. Regions with the highest cervical cancer incidence rates are sub-Saharan Africa, Micronesia and Melanesia, Southeast Asia, Latin America, and the Caribbean [2].

Cervical cancer is a preventable disease. Primary prevention is available using one of the three available vaccines. If administered prior to sexual debut and exposure to HPV, generally in early adolescence, these vaccines will prevent 70–90% of cervical cancers. Furthermore, effective screening methods exist, including cytology and HPV testing. It takes many years for invasive cancer to develop following detection of a demonstrated persistent HPV infection and cervical dysplasia; thus there are many opportunities to intervene and treat a woman with abnormal screening test results. The main purpose of cervical cancer screening is to identify women with abnormal cervical lesions and treat precancerous lesions to prevent the progression to invasive cervical cancer.

Human Papillomavirus (HPV)

HPV is the most common sexually transmitted infection. Extensive evidence links HPV and development of cervical cancer, and virtually all cervical cancer is caused by persistent infection with high-risk HPV [4]. The average lifetime probability of acquiring HPV is 85% and 91% among women and men who have had at least one sexual partner, respectively. More than 80% of women and men acquire HPV by age 45 years [5]. The initial infection generally occurs during adolescence or early adulthood. Approximately 80% of individuals with HPV will clear the infection spontaneously within 18–24 months of infection [6]. In women with persistent HPV infection, 3–5% will develop significant preinvasive disease, and <1% will develop cancer [7]. HPV infection is also associated with other malignancies, including oropharyngeal, anal, penile, vulvar, and vaginal cancers [8]. Persistent infection with a high-risk HPV (hrHPV) type is required for the development of cervical cancer.

HPV is a double-stranded DNA virus. There are over 120 HPV types, and approximately 40 types are known to infect the anogenital tract [9]. The HPV type distribution varies by population and geographic region [10].

HPV types are grouped by the potential of the virus to cause malignancy. Low-risk (non-oncogenic) HPV types do not integrate into the host cell genome. They cause genital warts, and low-grade cervical dysplasia. HPV types 6 and 11 are associated with 90% of genital warts. High-risk (oncogenic) HPV types are associated with high-grade cervical dysplasia and invasive cancer and may also be associated with low-grade cervical dysplasia. HPV types 16 and 18 account for 70% of cervical cancers and 60% of high-grade cervical dysplasia [11]. The DNA of high-risk HPV integrates into the host cell genome and causes neoplastic cellular changes. In most women, the HPV infection is not persistent, the virus is cleared naturally, and the dysplasia regresses. In a small percentage of women, the infection is persistent, and the transformed cells can replicate and progress to cancer after several years [11–13].

Cervical Intraepithelial Neoplasia (CIN)

Cervical intraepithelial neoplasia (CIN) is a precancerous lesion of the cervical epithelium. It is a histologic diagnosis made from a cervical biopsy specimen. In the Bethesda system for reporting cervical cytologic diagnoses (cervical cytology), findings are described with the term "squamous intraepithelial lesion (SIL)" and histologic findings described with the term "cervical intraepithelial neoplasia (CIN)" [14]. More recently, the 2019 American Society for Colposcopy and Cervical Pathology (ASCCP) Risk-Based Management Consensus Guidelines for abnormal cervical cancer screening tests and cancer precursors recommended histopathology reporting based on Lower Anogenital Squamous Terminology (LAST) group classification scheme. Per these guidelines, histologic high-grade squamous intraepithelial lesions (HSIL) should be classified with CIN 2 or CIN 3 qualifiers, i.e., HSIL (CIN 2) and HSIL (CIN 3) as outlined below [14, 15].

CIN is graded into three degrees of severity depending on the how much of the epithelial layer contains atypical cells. The terminology of CIN is shown in Table 11.1. CIN 1 frequently spontaneously regresses, often within 6–12 months [16]. CIN 2 remains reversible, with approximately 40% regressing spontaneously without treatment [17]. CIN 3, once called severe dysplasia and carcinoma in situ (CIS), is a precursor of invasive cancer. Approximately one-third of CIN 3 lesions may spontaneously regress. However, treatment is recommended for CIN 3 [15, 18].

Risk Factors

The lifetime risk of developing cervical cancer is 0.9% and 1.6% in high-income countries (HICs) and in LMICs, respectively [19]. The most frequent age at diagnosis in the United States is 35–44 years [20]. Women who are immunocompromised from any cause (e.g., genetic disease, HIV infection, immunosuppressive therapy) have a higher risk of developing a persistent HPV infection [21].

The primary risk factor for cervical cancer is persistent hrHPV infection. The cofactors associated with developing cervical cancer include immunosuppression, smoking, parity, increased number of sexual partners, and oral contraceptive use [22].

Prevention

Primary Prevention: HPV Vaccination HPV vaccines protect against acquiring HPV infection and the development of subsequent HPV-associated disease. Three different vaccines are currently commercially available worldwide, although not in all countries (Table 11.2) [23–26]. All three vaccines are prophylactic vaccines. Randomized clinical trials have demonstrated 93–98% efficacy in the prevention of cervical dysplasia associated with the HPV types contained in the vaccine [27–31]. Once exposed and infected with a specific hrHPV type, the vaccine is not effective in preventing disease against that type. The vaccine should be given prior to HPV exposure to be effective and protective. Currently, the only vaccine available in the United States is the nonavalent vaccine. The availability of vaccines varies in different countries and regions.

Table 11.1 Terminology of cervical intraepithelial neoplasia

Bethesda classification	Cytology	LSIL	HSIL	
System	Histology	CIN 1	CIN 2	CIN 3
LAST Terminology	Cytology	LSIL	HSIL	
	Histology	LSIL (CIN 1)	HSIL (CIN 2)	HSIL (CIN 3)
Previous terminology		Mild dysplasia	Moderate dysplasia	Severe dysplasia/carcinoma in situ

CIN Cervical intraepithelial neoplasia, *LAST* lower anogenital squamous terminology, *LSIL* low-grade squamous intraepithelial lesion, *HSIL* high-grade squamous intraepithelial lesion

Table 11.2 Comparison of HPV vaccines [23–26]

	Bivalent	Quadrivalent	Nonavalent
Brand name	Cervarix™	Gardasil™	Gardasil-9™
Protection	HPV 16/18	HPV 6/11/16/18	HPV 6/11/16/18/31/33/45/52/58
Cross-protection	HPV 31/33/45	HPV 31	No data
Adjuvant	ASO4	Aluminum hydroxyphosphate sulfate	Aluminum hydroxyphosphate sulfate

Recommendation The Advisory Committee on Immunization Practices (ACIP) recommends routine HPV vaccination for all girls and boys at 11–12 years, though children can receive vaccines as early as 9 years of age. Catch-up vaccination is recommended for females and males aged 13–26 years who have not received the vaccine or who have not completed the vaccination series. The US Food and Drug Administration (FDA) recently approved the use of Gardasil-9™ up to age 45 years [32], and the ACIP suggests shared clinical decision-making between patient and doctor when considering vaccination in this age group (26–45 years) [33].

Schedule and Doses

- Individuals starting the vaccination series before age 15: two doses (0, 6–12 months)
- Individuals starting the vaccination series at age 15 or older: three doses (0, 1–2 months, and 6 months).
- Immunocompromised individuals: three doses (0, 1–2 months, and 6 months), regardless of age

If the vaccination series is interrupted or not given as scheduled, the ACIP recommends resuming at any time without restarting the series, regardless of the gaps in the vaccination schedule.

Efficacy Six landmark phase III studies demonstrated that HPV vaccines are highly immunogenic and effective in preventing the main oncogenic types of HPV infections. The data were from three studies of the quadrivalent vaccine [27, 28, 34], two studies of the bivalent vaccine [29, 30], and one study of the nonavalent vaccine [31]. The vaccine induced antibodies in all vaccinated individuals, and antibody titers in vaccinated individuals were higher than those produced by natural infection. Clinical trials of all three types of vaccines demonstrated an excellent humoral response with seroconversion rates near 95%.

The most recent evidence of HPV vaccine effectiveness is from large systemic reviews and meta-analyses, including data from 1702 articles with 60 million individuals and up to 8 years of follow-up. The data show the impact of HPV vaccines on HPV infections, CIN 2+, and anogenital warts. Among girls aged 13–19 years, the prevalence of HPV 16 and 18 decreased by 83%, and the incidence of anogenital warts decreased by 67%. In women aged 20–24 years, the prevalence of HPV 16 and 18 decreased by 66%, and the incidence of anogenital warts decreased by 54%. The incidence of CIN 2+ decreased significantly 5–9 years after vaccination by an estimated 50% among girls aged 15–19 years and 30% among women aged 20–24 years. In male participants, the incidence of anogenital warts decreased by 48% and 32% among boys aged 15–19 years and men aged 20–24 years, respectively [35].

The duration of immunity is not yet known, and so it is unclear if protection is life-long or whether a booster dose will be required. Because the vaccines do not provide protection against all cancer-associated HPV types, routine cervical screening is still recommended, including routine screening in vaccinated women.

Safety All HPV vaccines are made from virus-like particles (VLPs), which mimic the capsid of the virus but contain no genetic material [36]. These VLPs are not infectious and cannot cause an HPV infection. Several large clinical trials have documented all HPV vaccines to be safe, with no risks of serious adverse events. In addition, the World Health Organization (WHO) Global Advisory Committee on Vaccine Safety has stated that the benefit-risk profile is favorable [37].

Bivalent Vaccine Large placebo-controlled randomized trials data revealed the safety of the bivalent vaccine. There were no differences in serious adverse events between vaccine and placebo. In post-licensure data from the United States, there were 52 reports to the Vaccine Adverse Event Reporting System (VAERS) following administration of bivalent vaccine through September 2011, and 98% were considered nonserious [38].

Quadrivalent Vaccine The safety profile of the quadrivalent vaccine was evaluated in diverse populations of females from different resource settings in large licensing trials and post-licensure safety surveillance systems. Mild injection site reactions were the most commonly observed adverse events. The data showed that the vaccine is safe and well tolerated [27, 28].

There were 21,194 reports of adverse events following HPV immunization from 2006 to 2013, in which approximately 57 million doses of quadrivalent HPV vaccines were administered in the United States. Of reported adverse events, 92% were considered mild. Among serious events, headache, nausea, vomiting, fatigue, dizziness, syncope, and generalized weakness were the most frequently reported. There was no evidence of increased risk of Guillain-Barre syndrome compared with other vaccines [39].

Nonavalent Vaccine The nonavalent vaccine became available in 2014 and is currently the only vaccine used in the United States. There are less available post-licensure safety data of the nonavalent vaccine since it is relatively new. The overall safety profile appears similar to that of the quadrivalent vaccine with a slightly higher incidence of mild or moderate local reactions (pain, erythema, and swelling). The frequency of systemic adverse effects (e.g., headache, fever, nausea, dizziness) is similar to quadrivalent vaccines. Serious adverse effects occurred in less than 0.1% [40].

HPV Vaccination Challenges and Barriers In the United States, the uptake of HPV vaccination is relatively low, with only 50% of age-eligible children receiving the full series [41]. The acceptance of the vaccine in other high-income countries (HICs), e.g., Canada and Australia, is higher at approximately 70–80%, likely due to government-supported school-based programs [42–44]. The Global Alliance for Vaccination and Immunization (GAVI) has made the HPV vaccine available to low-income countries for US$4 to $5 per dose [45]. However, there are many remaining barriers limiting universal mass vaccination programs worldwide.

One of the barriers to HPV vaccination is cost, which is approximately $150 per dose in the United States. Significant progress has been made to improve the affordability of the HPV vaccine in LMICs through financing mechanisms, including the GAVI and the Pan American Health Organization (PAHO) revolving fund [46]. However, many LMICs are still ineligible for financial support offered through the GAVI.

In many countries, a government supported school-based vaccination approach serves as an effective method to deliver the vaccine to adolescents. If girls do not attend school, the primary health centers and clinics can reach girls who missed vaccination [47].

General public knowledge of the importance of HPV vaccination is poor universally. There is widespread misinformation about the vaccine and the safety of vaccination, and some parents have been reluctant to have their children vaccinated. This is true even among well-educated populations in countries with high-quality healthcare systems [48].

Secondary Prevention: Cervical Cancer Screening

Cervical cancer screening to detect precancerous lesions, or CIN, enables treatment of pre-invasive lesions prior to development of invasive cancer. Screening tools include cervical cytology (Pap test), HPV testing, or a combination of the two tests. Systematic reviews and meta-analyses show that screening is associated with a significantly decreased incidence and mortality of invasive cervical cancer. Previous cluster-randomized studies from India revealed that a single screening test in a lifetime among women age 30–59 years decreased the risk of developing cervical cancer (relative risk 0.56, 95% confidence interval 0.42–0.75) and mortality from cervical cancer (relative risk 0.65, 95% confidence interval 0.47–0.90) [49, 50]. In many LMICs, Pap and HPV testing are not available. In these low-resource settings, visual inspection with acetic acid (VIA) is used to identify precancerous lesions of the cervix.

Cervical Cytology Dr. Papanicolaou demonstrated in 1928 that cancer and its precursors could be identified by examining an adequately prepared and stained cellular sample scraped from the uterine cervix [51]. This method of screening for cervical cancer precursors was adopted in many HICs in the 1940s. Although cervical cytology has low sensitivity, regular and widespread screening with cervical cytology has reduced the incidence of cervical cancer by 50–70% over the past 60–70 years [52]. Invasive cancer takes 10–20 years to develop from persistent HPV infection and resultant dysplasia, so screening can be an effective prevention strategy. Generally, women who develop invasive cervical cancer are women who have never been screened, or have not been screened regularly, or women who were screened, had abnormal cervical cytology, but did not receive follow-up treatment.

The conventional Pap test is performed by scraping cervical cells using a spatula and endocervical brush and smearing the cells on a glass slide for later examination by a cytologist/pathologist. In many countries in recent years, this method has been replaced with a liquid-based approach where the cervical sample is placed in a liquid medium initially, and the cells are later examined microscopically. This method allows for better preservation of the cervical cells and a higher-quality microscopic examination. The liquid-based collection method allows for cytology and HPV testing from the same sample.

HPV Testing HPV testing is now part of the routine screening algorithm in the United States. Studies have demonstrated that HPV testing has much higher sensitivity in detecting CIN 2+ than cervical cytology (96% vs. 53%) with slightly lower specificity (91% vs. 96%) [53–55]. HPV DNA testing has been recommended in both high- and low-resource countries [56, 57]. While cervical cytology is still widely used in LMICs, co-testing (cervical cytology and high-risk HPV testing) is now also recommended.

Several studies have examined the effectiveness of cervical cancer screening with primary HPV testing alone. In a large randomized study in Canada, 19,009 women were screened with HPV testing vs. liquid-based cytology. The study demonstrated that a woman with a negative HPV test vs. negative cytology had a significantly lower likelihood of CIN 3 and cancer at 48 months [58]. The high sensitivity of HPV testing leads to a much higher negative predictive value, implying that the screening interval can be safely lengthened if HPV testing is used [55].

Guidelines for Screening The ASCCP guidelines recommend screening for cervical cancer between the ages of 21 and 65 [59]. Cervical cancer screening should not be performed in women younger than 21 years of age, regardless of the age of onset of sexual activity. The screening guidelines, stratified by age, are summarized in Table 11.3

The US Preventive Services Task Force (USPSTF) recommends the primary high-risk HPV screening test as an alternative screening in the United States for women age 30–65 years. The USPSTF recommends screening with cervical cytology alone every 3 years, high-risk HPV testing alone every 5 years, or co-testing every 5 years in this group of women [60].

Colposcopy Women with abnormal cytology may be examined with colposcopy. The colposcope is a low-power binocular microscope with a powerful light source that is used for examination of the cervix. Acetic acid (3 to 5%) is applied to the cervix during this examination to enhance the visualization of dysplastic lesions [61]. A colposcopist can identify lesions and tissue patterns associated with cervical dysplasia and determine whether a biopsy is indicated.

Treatment of CIN Observation is preferred to treatment for women with CIN 1 [62]. In general, women with CIN 2/3 are treated because of the higher risk of progression to invasive cancer. Treatment of women with CIN 2 or CIN 3 to remove abnormal areas of the cervix may be through ablation (with cryotherapy or thermal ablation) or excision of the precancerous area. Success rates of these treatments are greater than 90% in properly selected patients [62, 63]. Excisional

Table 11.3 The American Cancer Society (ACS), American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society for Clinical Pathology (ASCP) summary of recommendations [59]

Population	Recommended screening methods	Notes
<21 years	No screening	Regardless of the age of onset sexual activity
21–29 years	Cervical cytology every 3 years	No HPV testing
30–65 years	Co-testing with cervical cytology and HPV every 5 years (preferred) or cervical cytology alone every 3 years	
>65 years	Screening is not recommended for women with a history of negative screening	Negative prior screening is defined as 3 consecutive negative PAP tests or 2 consecutive negative HPV tests, provided there is no history of high-grade dysplasia (CIN 2/3) or cancer in the past 20 years. Women 65 years of age or older who have not had previous screening should undergo cervical cytology and HPV testing
After hysterectomy with removal of the cervix	No screening	Screening is not recommended for women who have had a hysterectomy with removal of the cervix and do not have a history of CIN 2+
HPV vaccinated	Same as unvaccinated women	

CIN Cervical intraepithelial neoplasia

procedures include loop electrosurgical excision procedure (LEEP), cold knife conization (CKC), and CO2 laser conization. The choice of treatment modality depends on the availability of equipment and experience and expertise of the clinicians. In the United States, excisional treatment is preferred to ablative treatment for histologic HSIL (CIN 2 or CIN 3) [15]. Excision is also recommended for adenocarcinoma in situ (AIS) [62]. For specific treatment details, ASCCP guidelines should be consulted, as recommendations can change.

Cervical Cancer Prevention in Low- and Middle-Income Countries (LMICs)

The majority of cervical cancer cases occur in low- and middle- income countries (LMICs), where cervical cancer is a leading cause of cancer among women. Moreover, the death rate of cervical cancer in LMICs is 18 times higher than in HICs [64].

Although the screening and diagnosis algorithms described above are effective, they are expensive and require high-level infrastructure and well-trained personnel. In low-resource settings, personnel and medical specialists to provide prevention, screening, and treatment services are lacking, and shortages of infrastructure and pathology services are common. In several LMICs there are no gynecologic oncologists and no formal training in gynecologic oncologic. The International Gynecologic Cancer Society (IGCS) provides a Gynecologic Oncologic Global Curriculum and Mentorship Program, a comprehensive 2-year education and training program to train gynecologists in gynecologic oncologic in countries with no formal training program in this specialty [65].

In many LMICs there are no organized, effective cervical cancer screening programs, and few women ever receive cervical cancer screening. Furthermore, many women with abnormal screening results may be lost to follow-up and fail to receive diagnostic and therapeutic care for precancerous lesions [66].

One approach to screening in low-resource settings is the one-visit screen-and-treat strategy employing visual inspection with acetic acid (VIA) and immediate treatment with ablation if VIA screening is positive. VIA is performed by applying acetic acid to the cervix. Precancerous lesions will turn white with the application of acetic acid, and the identified lesion can be removed through ablation. Both VIA and ablation therapy (cryotherapy or thermal ablation) can be performed by nurses or trained community health workers [56, 57]. In some studies, screening with VIA was shown to decrease cervical cancer mortality by more than 30% in unscreened communities in LMICs [67, 68]. WHO also recommends HPV DNA testing as a primary cervical screening option in LMICs [56, 57].

Cervical Cancer Prevention in the Emergency Department

The emergency department (ED) can serve as a valuable public health resource. In the United States, the ED provides medical care to an estimated 60 million women, and approximately 20% of adults visit the ED for medical services each year [69, 70]. For underserved populations and people who lack access to regular medical services, the ED may be the only place some individuals receive healthcare services [71, 72]. In particular, underserved, low-income women are at increased risk of developing cervical cancer due to a lack of access to regular cervical cancer screening. Visits to the ED present an opportunity to provide, refer, or counsel women for cervical cancer prevention and screening.

A previous retrospective cross-sectional study of a stratified random sampling weighted to represent more than 100,000 visits to 4600 EDs showed the estimated median ED waiting time to be 30 minutes. The study also revealed that the median ED length of visit was 4.3 hours for admitted patients and 2.3 hours for discharged patients [73]. Some hospitals use these wait times as an opportunity for patient education in preventive health. Some centers use medical students, nursing staff, or health advocates to provide education in the waiting room. Moreover, education offered in the waiting room can be shared with families or caregivers and all visitors [74, 75].

HPV Vaccination

Physician recommendation of the HPV vaccine is a strong predictor of HPV vaccination initiation [76]. Recommendation of HPV vaccine in the ED is a potential channel to improve vaccination rates among populations who do not have access to routine medical care.

A cross-sectional study assessed attitudes of emergency medicine physicians toward recommending the HPV vaccine in an ED setting. The study surveyed the willingness of physicians to recommend the vaccine and identified barriers to vaccination in the ED settings. Of 100 physicians, 9% stated they would not recommend the vaccine to patients in the ED. Twenty-four percent were neutral, and 67% would recommend the vaccine. The study revealed that a lack of proper reimbursement for vaccination was a significant barrier to immunization in this setting [77]. Support and encouragement of emergency medicine physicians to inquire about, and recommend, HPV vaccination could be a useful step to improve primary prevention of cervical cancer.

Screening

Self-sample HPV testing has been proposed as an alternative method for cervical cancer screening in several settings. Women insert a small brush into the vagina to collect cervical samples without requiring a clinician-provided speculum exam. Many studies have shown the advantage of self-sample HPV testing in increasing screening rates and coverage [78, 79]. A previous study evaluated an acceptability of self-sample HPV testing among medically underserved women visiting the ED and found that 85% of participants were willing to use this method for cervical cancer screening [80]. Although this collection method is not yet approved by the US FDA, self-sampling HPV testing could be a potential strategy to improve cervical cancer screening among high-risk women who do not attend regular screenings.

A pilot study conducted at an urban ED found that referral combined with text messages resulted in a 43% increased uptake of cervical cancer screening among nonadherent groups [81]. The ED is a potential resource for improving HPV vaccination rates and cervical cancer screening rates. Patients can benefit from education about vaccination and cervical cancer screening and can also receive a referral for screening during a visit to the ED.

Conclusion

Cervical cancer remains an important public health problem in many countries and regions, including underserved areas of the United States. It is a disease that is preventable with HPV vaccination, regular cervical cancer screening, and follow-up care. However, access to care is a significant barrier for underserved women. Research suggests that the ED has great potential to serve as a resource for cervical cancer prevention.

Lung Cancer Screening

12

Marcelo Sandoval

Introduction

Lung cancer (LC) is the most common and fatal cancer worldwide; in the USA incidence is decreasing, but it remains the deadliest cancer. Patients with LC come to the emergency department (ED) for disease or treatment complications. New LC will be discovered in some, and those with lung cancer diagnosed in the ED are more likely to have advanced disease refractory to treatment. Lesions that are likely benign with a small chance of representing early cancer are sometimes found in the course of ED evaluation. The current standard of care is to refer these patients for follow-up as recommended by various guidelines.

The historically grim prognosis for LC highlights the need for early detection. Lung cancer screening (LCS) of high-risk asymptomatic individuals with low-dose computed tomography (LDCT) has been shown to reduce mortality by finding LC at earlier stages but at the cost of false positives that can lead to unnecessary distress, radiation exposure, and invasive procedures. As the evidence base for screening grew, steps to minimize false positives and unintentional harm have been taken. Currently only a fraction of eligible patients are screened even though the Centers for Medicare and Medicaid Services (CMS) approved LDCT screening for LC as a preventative health service at 100% coverage in 2015. Currently, many patients at high risk for LC are likely coming to the ED for other reasons. We will review current evidence regarding LCS benefits and harms, barriers to screening, and how the new field of oncologic emergency medicine may help meet currently unmet LCS needs.

Case Studies

A 65-year-old woman presents with cough, chest pain, and shortness of breath. A CT pulmonary angiogram shows no evidence of pulmonary embolism; however, it reveals a left upper lobe infiltrate, left pleural effusion, enlarged hilar lymph nodes, and several lobulated lesions in the left lung of varying sizes; largest one is about 35 mm, in the area where her pneumonia is present. On further questioning she admits to weight loss and hemoptysis over the past 2 months. After full evaluation you judge she is stable to go home with oral antibiotics. However, you inform her that some of the findings on history and CT are highly suggestive of LC. "How can that be? I've never smoked in my life! What are my chances, doctor?" as she begins to cry. What can you tell her about how she might have developed this, and what is her prognosis?

A 45-year-old male with upper abdominal pain and vomiting and tenderness in the epigastrium (but no Murphy's or peritoneal signs) is found to have an elevated lipase, total and direct bilirubin, and alkaline phosphatase. He has a history of fatty food intolerance and denies drinking alcohol. CT abdomen confirms a dilated common bile duct and mild pancreatic inflammation due to a retained common bile duct gallstone. He feels much better after symptom relief and IV fluids. Given the absence of fever or WBC elevation, you decide to discharge him with GI follow-up the next day. Fifteen minutes later the radiologist calls you. "Hi there. I looked more closely, and he also has a right lower lobe lung nodule that's 10 mm in diameter, with subsolid/ground glass and part-solid features, minimal attenuation of surrounding structures, and no calcifications. I thought you should know." He hangs up and you ask yourself: "Hmm, do I even need to tell him about this? It doesn't sound so big and he has no chest symptoms. If it's nothing, I don't want to worry him. What should I do?"

A 65-year-old "frequent flyer" who you see several times a month for non-emergent problems approaches you. "Hey Doc. I just came by to tell you I just turned 65, and I actually

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_12

got my Medicare card yesterday, so now I don't have to come see you so often anymore! Maybe you can tell me how to get my hernia fixed I've been putting off, and seeing somebody for my knee pains and back pains instead of having to come see you all the time?" You smile because you like this patient, and after seeing him so often over the years, you've actually developed a rapport with him. You know he needs primary care. If only he would stop smoking! You tried to enroll him in smoking cessation a few times, but he wasn't interested. He told you "I feel good, I want to enjoy my life, and so what's the point of quitting? If I get the big C, there's nothing they can do anyway. My friend started coughing last year, he went to the doctor, and they found it in his lung. Two months later he was dead." Is he right? You know LC is very bad, and almost no one gets diagnosed early enough for surgical resection. So is there any point in looking for trouble since he feels well and looks pretty good for someone his age?

Background

LC is the most common and fatal cancer worldwide with 2.1 million new cases and 1.8 million deaths recorded in 2018 [1, 2]. The USA will see 229,000 new cases in 2020 [3]. Prostate and breast cancer are more common in men and women, respectively, but LC will claim 136,000 Americans, more than colon, prostate, and breast combined [3]. The National Cancer Institute (NCI) estimated LC expenditure has risen to $14.2 billion in 2018. In terms of lost productivity, $36.1 billion dollars are lost per year due to LC, more than for any other cancer [4].

Cigarettes and smoke exposure account for 90% of LC [5–7]. Pre-existing lung disease such as COPD and pulmonary fibrosis increases cancer risk and mortality. Smokers with COPD die from LC more than smokers without COPD [8, 9]. Cannabis-related risk is uncertain; pooled analysis in 2015 showed no specific links, but the investigators stated that they did not include enough heavy users [10]. More potent strains, medical and recreational use make further study warranted. Data on hookah smoking [5] and electronic cigarette-related LC risk [5, 7] are very sparse.

Never smokers (<100 cigarettes/lifetime) account for 15–25% of LC. Very common among Asian women [11, 12], it is rising in the USA [13] and affects women more than men for reasons that include lifestyle, genetic, and hormonal differences [14–16].

Environmental risk factors include uranium-derived radon in soil, homes [17], air pollution [18–21], and indoor coal burning [22]. Occupational risks include asbestos, arsenic, beryllium, cadmium, chromium, diesel fumes, nickel, and silica [5, 7, 11, 23]. Other known risk factors are age, HIV and family history, *Mycobacterium tuberculosis*, human papillomavirus, low socioeconomic status (SES), and Black, non-Hispanic White, or Native American status [5, 7, 11, 23].

Epidemiology and High-Risk Populations

Lung cancer occurs decades after smoking, so population-wide changes in incidence (new cases per 100,000 per year) and mortality (deaths per 100,000 per year) also lag by decades behind changes in smoking rates. Africa has the lowest rates of smoking [24], but use is increasing as disposable income grows [25]. Smoking peaked earliest among males (1970s) and females (1990s) in the USA, UK, Canada, and Australia; because men and women have been smoking less for decades, LC incidence and mortality have been declining for years in these countries [6, 7, 23, 26]. Higher-income northwestern European, South American, and Asian populations are experiencing more recent declines in incidence and mortality among males, due to decreases in male smoking over the last two decades [23]. At the same time, women's mortality is rising due to prior increases in smoking [6]. In low- and middle-income populations of southeast Europe, Asia, and South America, LC is rising sharply in men, less so in women, accounting for the recent global increases in cancer [6, 7, 26]. Air pollution also contributes to these rising rates, especially in China and Russia [27]. Among women, incidence and mortality rates have been declining in North America, Western Europe, Australia, and East Asia but remain the highest worldwide in these places [7, 28]. On a positive note, the World Health Organization's (WHO) Cancer Mortality Database showed tobacco cessation in North America, Europe, and South America has led to decreases in LC incidence and mortality in those under age 50 [29].

In the USA, despite incidence and mortality declines in both men and women, certain populations remain at high risk. 2019 American Cancer Society statistics show that Black Americans have long had the highest incidence and mortality of all ethnic/racial groups, despite declines in smoking among Black teens since the 1970s [30]. Incidence and mortality in Black individuals are followed closely by non-Hispanic Whites and Native Americans [31]; each group has about approximately 60–65 per 100,000 incidences and 35–45 per 100,000 mortalities. Black American male LC incidence (85.4) and mortality (63.9) are much higher than Black women (49.2 and 33.3, respectively). Men account for most of the burden among non-Hispanic whites and Native Americans as well [31]. Lower socioeconomic status [32] and education level also predict increased incidence and mortality [7]. A LC mortality belt across rural counties in Oklahoma, Arkansas, southern Missouri, southern Illinois, Kentucky, Tennessee, southern Ohio, West Virginia, and western Virginia is highly correlated with poverty, unemployment, lack of health insurance, obesity, and low air quality [21], as well as increased rates of smoking and decreased surgical treatment of stage I disease [33]. Asian and Hispanic Americans of both genders have the least incidence and mortality [6, 7, 31], and a 2019 meta-analysis showed that being

female (any group), Hispanic, or Asian American predicted increased survival from LC [34].

Others at risk for LC are lesbian, gay, bisexual, and transgender (LGBT) people; the disabled; mentally ill individuals; and low pay grade military personnel, due to disproportionate rates of smoking [35].

Pathology, Prognosis, and Treatment

80% of LCs are non-small cell (NSCLC), and 15% are small cell LCs (SCLCs); other carcinoid/neuroendocrine tumors account for the remainder [36–38].

The most common NSCLC is small-airway adenocarcinoma followed by central large-airway-based squamous cell carcinoma (SCC), which is almost always associated with smoking [39]. Traditionally, NSCLC referred to both as treatment was similar. However, since 2015 WHO guidelines emphasize biomarkers for individualized treatment with targeted and immunotherapy regimens [38, 40] making differentiation more important. In the early stage, both are amenable to resection.

Since the 1990s, adenocarcinoma is increasing, due to filtered cigarettes (allowing small carcinogens to penetrate deeper into the airways), while decreases in smoking have reduced SCC [23]. "Never smoker" LC is usually adenocarcinoma and is more common in women [15].

SCLC, also associated with smoking, is highly aggressive and classified as limited and extensive, with 20–25% 5-year survival and 10% 2-year survival, respectively [41]. There is hope combinations of chemotherapy and immunotherapy can improve this [42].

Early diagnosis and surgical cure has long been key to best prognosis [43–45], with stage I 5-year survival rates of 45–79% [46–48]. Efforts to improve outcomes from curative surgery have focused on techniques such as video-assisted thoracic surgery lobectomy (VATS), sublobar resection (SLR) [48], prognostic markers [49], and pre-surgical adjunctive treatments with immunotherapy [50]. For advanced LC, prognosis has changed little even with newer treatments [51, 52]. According to the NCI Surveillance, Epidemiology, and End Results Program (SEER), 5-year survival with localized disease is about 59% but only 5.8% in distant metastatic disease. Unfortunately, only 17% present with localized disease [3].

Lung Cancer in the Emergency Department

Data from the Nationwide Emergency Department Sample (NEDS) showed that of nearly 5 million US cancer-related ED visits in 2012, 10.3% were by known LC patients [53]. These patients most frequently went to EDs for pneumonia, COPD, and respiratory failure with 67% of visits resulting in admission. In a 2019 prospective observational cohort study of 1075 ED cancer patients, of whom 139 (12.9%) were diagnosed with LC, the most common symptoms were abdominal pain, fever, breathing abnormalities, nausea/vomiting, and throat/chest pain [54]. Major symptoms leading to ICU admission and short-term mortality were shortness of breath and altered mental status [55].

Diagnosis of cancer in the ED is summarized in a 2017 review by Zhou. Such patients are less likely to be curable, less likely to survive at 1 year, 3 months, and 1 month compared to those diagnosed electively, even when adjusting for staging [56]. It is relatively uncommon that emergency physicians expect to diagnose LC in a patient with cardiopulmonary symptoms. Serious illnesses such as pulmonary emboli, pericardial tamponade, acute coronary syndromes, pulmonary edema, anaphylaxis, pneumothorax, pneumonia, COPD exacerbations, and asthma are more commonly expected [57], and, of course, COPD and cardiovascular disease frequently co-exist with LC [58]. Common symptoms leading to LC diagnoses in the ED include cough, shortness of breath, chest pain, and/or hemoptysis [58–64]. Hemoptysis is the most predictive symptom [62–64], even more so if associated with cough, dyspnea, and weight loss [62].

A 2012 Michigan study compared patients diagnosed with LC in the ED to those diagnosed in other settings and found that ED patients had more co-morbidities, were older, more often female, more likely to be Black and more likely to present in advanced stages [65]. The authors noted the need for increased ED smoking cessation and cancer screening awareness.

Urban Black and Hispanic patients face disparities in health care, will go to the ED, and have worse outcomes for many conditions, including cancer [66]. In rural America, White individuals have twice the mortality from LC than their urban counterparts, even with similar staging distributions [33].

ED Imaging and Lung Cancer

Chest X-ray (CXR) has long been used for ED chest complaints [67, 68]. Since the late 1990s, however, computed tomography (CT) has replaced CXR for diagnosis of pulmonary emboli [69, 70], aortic dissection [71], coronary disease [72], and some pneumonias [73, 74] as it is more sensitive and more often changes management [73]. ED CT scanning also discovers more masses [75–77] and nodules [78, 79] than does plain CXR.

Lung masses (>30 mm) [80] are likely malignant; thus prompt referral to a pulmonologist is recommended. Other CT findings highly suggestive of cancer include pleural effusion, pleural nodules, enlarged hilar or tracheal nodes, endo-

bronchial lesions, post-obstructive pneumonia, spiculated or lobular borders, presence of a solid component within a ground glass lesion, and growth on serial imaging [81].

Nodules are rounded or irregular opacities (<30 mm) [80]. Attenuation can be solid (opaque) or subsolid, which can further be classified as ground glass (hazy) or part-solid (mixed features) [80]. Solid nodules are less likely to be malignant, especially if calcified or <6 mm in size, unless they are new or growing. Subsolid nodules are also unlikely to be malignant if smaller than 6 mm. Factors that increase the likelihood of malignancy include size >15 mm, spiculation, lobulation, upper lobe location, presence of COPD or pulmonary fibrosis, and a history of cancer or growth. Multiple (two to four) nodules are more likely malignant, but five or greater are less likely (unless there is history of cancer). The Fleischner Society makes recommendations for follow-up of incidental nodules found on CT. Unfortunately, discovery of these incidental nodules often happens after the patient has left the ED [82, 83], at which point the ED has responsibility for notifying the patient. Follow-up recommendations may vary from none to 3–12 months later, depending on the size, consistency, rate of growth, and patient factors. These guidelines do not apply to nodules found on CT screening for cancer (see Lung-RADS® below) or if the patient is < age 35 or immunocompromised or has a history of cancer [84]. For incidental nodules found in the ED, use of Fleischner Society Guidelines decreases the rate of follow-up scans and invasive procedures [85].

Lung Cancer Prevention

Smoking bans and cessation decrease LC incidence rates in a predictable fashion [86]. Cessation before age 40 reduces smoking-related mortality by 90%. Smoking cessation efforts in ED are fully discussed in another chapter of this book.

Fine particulate matter air pollution (PM2.5) is increasingly recognized as a risk factor for LC, disproportionately in the South and Midwest, among Black individuals and those living in socioeconomically deprived areas. Much of the risk associated with fine particulates occurs below current Environmental Protection Agency (EPA) standards for PM2.5, suggesting the need to reassess current clean air standards in the USA [87].

Although home radon testing is recommended by the CDC and EPA, it is infrequently performed as no state currently requires home testing. Some states mandate radon testing in public buildings or schools. Efforts to increase low testing rates include novel approaches such as smartphone apps [88]. Targeted public health efforts to increase radon testing in areas (Kentucky) where both smoking rates and radon levels are high [89] may be particularly effective given the known synergy of radon and smoking in causing LC.

Lung Cancer Screening with Chest X-Ray and the Problem of Overdiagnosis

LC screening (LCS) attempts early detection before symptoms appear, thus improving prognosis. The NCI-sponsored 1986 Mayo Lung Project randomized 2 groups of approximately 4600 male smokers to screening CXRs and sputum cytology every 4 months for 6 years against standard care (recommended annual CXR and sputum cytology). Twice as many early cancers were found, more surgery was done, and 5-year LC-specific survival was superior in the screening group; however, there was no benefit in overall mortality over 6 years [90]. Other contemporaneous NCI trials at Memorial Sloan Kettering [44] and Johns Hopkins [91] also confirmed lack of mortality benefit.

It is important to understand the difference between survival and mortality to interpret these seemingly contradictory results. Survival is measured as the percentage of those diagnosed with cancer alive after time, traditionally 5 years. It can be helpful when telling a patient how long they may have to live but is also used to identify improvements in treatment. Mortality is measured as those who die from a given disease per 100,000 of the general population per year. For a treatment to be deemed effective, both survival and mortality should improve [92]. Either can be increased by preventing death (screening or treatment) or preventing disease (smoking cessation), but survival can also be increased by diagnosing more people earlier, some of whom will not get sick. This phenomenon is intrinsic to cancer screening [93–95] and is termed overdiagnosis – i.e., finding early indolent (slowly progressive) cancers that will not progress to symptoms or death. The Mayo Lung Project found 206 cancers in the screening group and only 160 in the control group over 6 years; more early cancers were found by screening, but roughly equal numbers of late cancers were found in both groups [90]. If a randomized controlled trial is properly designed, and screening finds more early cancers, it should also find fewer late cancers (stage shift), keeping total incidence in the two groups approximately equal [94–96]. In addition, the smaller non-screening control group should eventually "catch up" to the screening group in numbers of cases, since two properly matched cohorts should have the same incidence of cancer over time. Too few subjects or too short a study period will not allow a stage shift or catch-up to be detected.

Technology that increases early detection will increase incidence (by finding more fledgling cases) and will also appear to improve survival because some of these will be slow-growing lesions that are not destined to harm over the follow-up period. Mortality, a static measure of deaths per year, is not affected by increases in detection of new cases, so it is not subject to overdiagnosis [92]. Over time, a relative reduction in mortality between the two groups is the best way to see if there is benefit to the treatment or screening.

The initial Mayo mortality rate over 6 years was equal – 122 deaths in the screening group and 115 deaths in the control group; 3.2 vs. 3.0 (deaths per 1000 person-years). When follow-up extended to 16 more years, there were still more cancers (585 vs. 500) in the screening group, but no difference in mortality (4.4 vs. 3.9 death/person-years). This strongly suggests overdiagnosis of indolent lesions in the screening arm that never progressed because these cancers did not result in more deaths [97]. The price of overdiagnosis is inappropriate testing and treatment of these indolent cancers.

Overdiagnosis has been long recognized in prostate and breast cancer [98]. The existence of indolent LCs was known for some time from autopsy studies [99] but was thought to be uncommon because most people who developed LC died. Formerly, these indolent cancers were known as bronchoalveolar carcinoma (BAL) but since 2015 have been reclassified by WHO and the American Joint Committee on Cancer (AJCC) [40, 100]. These lesions appear as malignancies on radiography and biopsy, and as there are no metastases, they are usually resected. However on resection they are found to have a lepidic growth pattern and are termed adenocarcinoma in situ (AIS) or minimally invasive adenocarcinoma (MIA). Both are very slow growing with almost 100% 5-year survival after resection compared to only 67% with other types on adenocarcinoma. They are so indolent that they may never manifest before a patient dies for other reasons, but identifying these prior to resection is not yet routine [100]. NCI is sponsoring research in genomic and molecular techniques to detect them, allowing for less invasive treatment or surveillance leading to similar good outcomes [101]. Since the advent of CT scanning, there is evidence that this occurs more frequently than previously thought, in up to 18% of cancers detected using low-dose computed tomography (LDCT) [102, 103].

The abovementioned CXR studies may have been underpowered to determine whether screening might have a small mortality benefit. The 2011 Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Trial was designed to detect smaller differences in mortality, randomizing 155,000 healthy smoking and non-smoking volunteers to annual CXR screening vs. usual care for 3 years. There was no mortality benefit [104], thus putting the question of CXR screening to rest.

Computed Tomography (CT) for Lung Cancer Screening

In the 1970s and 1980s, the potential of CT scanning for LCS led to a 1998 Japanese study by Sone et al. [105] and the 1999 Early Lung Cancer Action Project (ELCAP) study by Henschke et al. [106]. Both studies used LDCT protocols which had been developed and studied by Naidich [107] and Kaneko [108] with lower radiation doses than standard high-resolution scanning. Both found LDCT was vastly superior to CXR in finding earlier and smaller cancers; however, potential overdiagnosis, unnecessary testing, and invasive procedures made the value of CT screening less clear [94, 95, 109]. In 2006, Henschke et al. published a larger international multi-center study (I-ELCAP) evaluating annual screening CTs of smokers and non-smokers with other LC risks and incorporating 10- rather than standard 5-year follow-up. 412 of 484 detected cancers were in clinical stage I, with 88% 10-year survival with treatment; 92% if surgery was done within 1 month. The study concluded that CT screening could detect curable LCs as evidenced by long-term follow-up results [110]. Once more, the problem of overdiagnosis was cited [111] and the possibility that early AIS could regress due to innate defense mechanisms [112]. Also, as a one-arm observational case series without a control group, there could be no conclusion that early detection decreases mortality, despite the impressive 10-year survival rate. A randomized controlled study comparing CT screening with standard care was sorely needed [112].

National Lung Screening Trial

With this background, the NCI-funded National Lung Screening Trial (NLST) was initiated in 2002. Over 2 years, 53,454 current or former smokers aged 55–74 with 30 pack-years of smoking were recruited; if not currently smoking, participants had quit less than 15 years before. The subjects were randomized to undergo either three annual screening CXRs or low-dose CTs, and LC incidence and mortality were recorded for a mean of 6.5 years. The results were published in 2011. For the first time, screening showed a relative mortality reduction of 20% for LC and 6.7% in all-cause mortality. Unlike the CXR studies, "stage shift" was seen, more stage I (50% vs. 31%) but less stage IV (22% vs. 36%) cancers. Three hundred fifty-six deaths from LC occurred (247 per 100,000 person-years) compared with 443 deaths (309 per 100,000 person-years) in the chest radiography group. The number needed to screen (NNS) to save one life was 320. This was a landmark study demonstrating mortality reduction with LCS for the first time [113].

However, there were several concerns. Silvestri [114] and Bach et al. [115] noted that ~25% of CTs each year found "positive" nodules of which 96% were ultimately benign. Most follow-up for the "positive" nodules was radiographic, but approximately 6% had invasive testing (73% negative malignancy rate), and 10% had surgery (21% negative for cancer). Six patients without cancer died within 60 days due to workups. Furthermore, the study had well-trained radiologists and surgeons (surgical death rate was only 1%, much

better than average), motivated volunteer subjects, mostly ex-smokers, and only 8% were over age 70. Hospitals with less compliant, older patients with more co-morbidities and less experienced physicians would likely have worse benefit and harm rates. Screening benefits could be offset by increased smoking in those who became anxious from false positive results or falsely reassured by negative ones. Increased radiation and reduced quality of life due to anxiety were also cited [114, 115].

Overdiagnosis again became an issue. Finigan and Kern noted that of 119 additional cancers detected by CT, 75 were indolent bronchoalveolar carcinoma (BAL), now known as AIS and MIA [96]. Patz et al. analyzed NLST data and estimated an 18.5% overdiagnosis rate [102]. In 2013, the American Academy of Family Medicine (AAFP) concluded that insufficient evidence existed to recommend for or against LCS with low-dose CT [116].

The US Preventive Services Task Force (USPSTF) reported their assessment of LCS with low-dose CT in 2013. Humphrey et al. noted in a review written for the USPSTF that the NNS of 320 was better than those for mammography and sigmoidoscopy [117]. Because of concerns regarding overdiagnosis and harm, the Cancer Intervention and Surveillance Modeling Network (CISNET) developed screening simulation models incorporating age, frequency, and smoking history combinations predicting the most benefit for the least CT scans. The models predicted that by increasing age to 55–80 and keeping smoking requirements the same would result in superior outcomes than NLST criteria [118]. The USPSTF made a level B recommendation to Congress that all smokers aged 55–80 years and that have a 30 pack-year smoking history and currently smoke or quit within the past 15 years should get annual LDCT screening [119]; this led CMS (Centers for Medicare and Medicaid Services) to approve LCS as an annual preventative service benefit for all eligible Americans up to age 77 without copayment in 2015 [120].

There are strict requirements for federal LCS coverage and reimbursement [120, 121], including a documented shared decision-making conversation in the medical record that specifies the patient's eligibility by age and smoking history, the risks and harms of screening, and concurrent offers of smoking abstinence and cessation. LC CT screening programs must be accredited and use a central registry: the ACR Lung Cancer Screening Registry (LCSR), provided by the American College of Radiology [122]. In 2014 the ACR released Lung-RADS®, the Lung CT Screening Reporting & Data System [123] to better standardize reporting of findings among radiologists reading screening CT scans. Lung-RADS® increased nodule size threshold to 6 mm and incorporated other evidence-based criteria for nodule management. Applying the criteria to the NLST data, there was a 50–75% decrease in false positives which could lead to less invasive procedures [124]. Lung-RADS® is now the standardized method for radiologists to report on LCS nodules and make management recommendations. Version 1.1 was released in 2019 (Fig. 12.1).

Barriers to LDCT Screening

Jemal and Fedewa used the CDC National Health Interview Survey (NHIS) and found less than 4% of eligible Americans underwent LCS in 2015, and about 50% were uninsured or on Medicaid [125]. In comparison, screening rates among eligible candidates is 83% for Pap tests, 71.5% for mammography, and 62.4% for colorectal cancer screening tests [126].

Since 2012 the National Comprehensive Cancer Network (NCCN), comprised of 30 leading cancer centers dedicated to improving cancer care, has added a second group (group 2) to the population that should be eligible for LCS. NCCN consensus is that risk comparable to NLST criteria exists for patients age >50, 20+ pack-years of smoking, *and* one other risk factor (history of cancer, COPD/pulmonary fibrosis, family history of LC, radon exposure, or occupational exposure to carcinogens). Though initially a lower-level 2B recommendation in 2012 [127], the NCCN upgraded this to 2A in 2015 [128]. Pinsky had written in 2012 that strict adherence to NLST criteria would only find about 27% of lung cancers [129]; if criteria was expanded to those age 50–79, and any smoking history (current or quit <15 years), almost 50% of cancers could be found, though there would be much higher NNS and possible harm. By 2015 he found that the risk of current smokers with 20–29 pack-years was equivalent to that of former smokers with 30 or more pack-years; more women and minorities would be eligible for screening if the smoking requirement was reduced [130]. NCCN has recognized these and other studies by continuing to recommend group 2 LCS in their 2020 guidelines; they do acknowledge "true risks and benefits of screening these group 2 individuals are uncertain" and state a PLCO risk score [131] may help select the most appropriate group 2 individuals for LCS [132]. Two studies at single centers compared LCS in NCCN group 1 and 2 patients and found 1–2% rates of new cancer in both, but neither could not comment on mortality due to short follow-up or small sample size [133, 134]. The American Association for Thoracic Surgery has adopted similar LCS guidelines, advocating NCCN group 2 patients should be eligible for screening. They also added another group: those who have a history of LC and have been disease-free for 4 years [135].

Barriers to LCS in patients are awareness, cost, fear of cancer diagnosis, stigma of smoking, and radiation fears. Providers' barriers include unfamiliarity, lack of prompt access to accurate smoking history, time constraints for

Lung-RADS® Version 1.1

Assessment Categories Release date: 2019

Category Descriptor	Lung-RADS Score	Findings	Management	Risk of Malignancy	Est. Population Prevalence
Incomplete	**0**	Prior chest CT examination(s) being located for comparison Part or all of lungs cannot be evaluated	Additional lung cancer screening CT imaged and/or comparison to prior chest CT examinations is needed	n/a	1%
Negative No nodules and definitely benign nodules	**1**	No lung nodules Nodule(s) with specific calcifications: complete, central, popcorn, concentric rings and fat containing nodules	Coutinue annual screening with LDCT in 12 months	< 1%	90%
Benign Appearance or Behavior Nodules with a very low likelihood of becoming a clinically active cancer due to size or lack of growth	**2**	**Perifissural nodule(s)** (See Footnote 11) < 10 mm (524 mm^3) **Solid nodule(s):** < 6 mm (< 113 mm^3) new< 6 mm (< 34 mm^3) **Part solid nodule(s):** < 6 mm total diameter (< 113 mm^3) on baseline screening **Non solid nodule(s) (GGN):** < 30 mm (< 14137 mm^3) **OR** ≥ 30 mm (≥ 14137 mm^3) and unchanged or slowly growing **Category 3 or 4 nodules unchanged for ≥ 3 months**			
Probably Benign Probably Benign finding(s) - short term follow up suggested; includes noduless with a low likelihood of becoming a clinically active cancer	**3**	**Solid nodule(s):** ≥ 6 mm to < 8 mm (≥ 113 to < 268 mm^3) at baseline **OR** new 4 mm to < 6 mm (34 to < 113 mm^3) **Part solid nodule(s):** ≥ 6 mm total diameter (≥ 113 mm^3) with solid component < 6 mm (< 113 mm^3) **OR** new < 6 mm total diameter (< 113 mm^3) **Non solid nodule(s):** (GGN) ≥ 30 mm (≥ 14137 mm^3) on baseline CT or new	6 month LDCT	1-2%	5%
Suspicious Findings for which additional diagnostic testing is recommended	**4A**	**Solid nodule(s):** ≥ 8 to < 15 mm (≥ 268 to < 1767 mm^3) at baseline **OR** growing < 8 mm (< 268 mm^3) **OR** new 6 to < 8 mm (113 to < 268 mm^3) **Part solid nodule(s):** ≥ 6 mm (≥ 113 mm^3) with solid component ≥ 6 mm to < 8 mm (> 113 to < 268 mm^3) **OR** with a new or growing < 4 mm (< 34 mm^3) solid component **Endobronchial nodule**	3 month LDCT; PET/CT may be used when there is a ≥ 8 mm (≥ 268 mm^3) solid component	5-15%	2%
Very Suspicious Findings for which additional diagnostic testing and//or tissue sampling is recommended	**4B**	**Solid nodule(s):** ≥ 15 mm (≥ 1767 mm^3) **OR** new or growing, and ≥ 8 mm (≥ 268 mm^3) **Part solid nodule(s) with:** a solid component ≥ 8 mm (≥ 268 mm^3) **OR** a new or growing ≥ 4 mm (≥ 34 mm^3) solid component	Chest CT with or Without contrast, PET/CT and/or tissue sampling depending on the *probability of malignancy and comorbidities. PET/CT may be used when there is a ≥ 8 mm (≥ 268 mm^3) solid component. For new large nodules that develop on an annual repeat screening CT, a 1 month LDCT may be recommended to address potentially infectious or inflammatory conditions	> 15%	2%
	4X	Category 3 or 4 nodules with additional features or imaging findings that increases the suspicion of malignancy			
Other Clinically Significant or Potentially Clinically Significant Findings (non lung cancer)	**S**	**Modifier - may add on to category 0-4 coding**	As appropriate to the specific finding	n/a	10%

IMPORTANT NOTES FOR USE:

1) Negative screen: does not mean that an individual does not have lung cancer
2) Size: To calculate nodule mean diameter, measure both the long and short axis to one decimal point, and report mean nodule diameter to one decimal point
3) Size Thesholds:apply to nodules at first detection, and that grow and reach a higher size category
4) Growth : an increase in size of > 1.5 mm (> $2mm^3$)
5) Exam Category : each exam should be coded 0-4 based on the nodules(s) with the highest degree of suspicion
6) Exam MOdifiers: S modifier may be added to the 0-4 category
7) Lung Cancer Diagnosis: Once a patient is diagnosed with lung cancer, further management (including additional imaging such as PET/CT) may be performed for purposes of lung cancer staging; this is no longer screening
8) Practice audit definitions: a negative screen is defined as categories 1 and 2; a positive screen is defined as categories 3 and 4
9) Category 4B Management: this is predicated on the probability of malignancy based on patient evaluation, patient preference and risk of malignancy; radiologists are encouraged to use the McWilliams et al assessment tool when making recommendations
10) Category 4X: nodules with additional imaging findings that increase the suspicion of lung cancer, such as spiculation, GGN that doubles in size in 1 year, enlarged lymph nodes etc
11) Solid nodules with smooth margins, an oval, lentiform or triangular shape, and maximum diameter less than 10 mm or 524 mm3 (perifissural nodules) should be classified as category 2
12) Category 3 and 4A nodules that are unchanged on interval CT should be coded as category 2, and individuals returned to screening in 12 months
13) LDCT: low dose chesr CT

required shared decision-making, lack of support by specialists, and skepticism about benefit [136, 137].

Racial barriers to LCS were summarized by Borondy Kitts in 2019. Black individuals have higher rates of cancer and death than Whites but may be less likely to qualify for LCS due to lower smoking rates. She called for CMS to approve NCCN group 2 criteria and expand LCS for Black Americans. To date, however, LCS of NCCN group 2 is not covered by CMS or private insurance. Education, socioeconomic status, lack of primary care, mistrust of providers, and providers' implicit bias are additional barriers to LCS uptake among Blacks [138].

Annangi showed Black Americans have rates of early-onset LC (age 45–54) 73% higher than Whites [139]. A review of NLST data by Balekian et al. demonstrated ethnic disparities in rates of curative surgery for stage I LC. Black men had a 61% rate of curative surgery for stage I, whereas White men and women and Black women underwent curative surgery in 90% of cases. The reasons for these disparities are unclear [140].

Geographically, the South has 40% of screening-eligible patients, but has the lowest density of ACR-designated screening centers, and a 3.5% screening rate. In contrast, the Northeast has the lowest eligible percentage (15.5%) but the highest density and screening rate (10.1%) [141].

23% of the screening-eligible candidates live in rural areas [141]; however, most screening centers are in metropolitan areas; 28% of eligible patients have to drive 30 minutes or more to reach a screening center [142].

LCS barriers in the community hospital setting include low rates of screening by poorer eligible patients in favor of inappropriate screening of ineligible but affluent people, poor adherence to Lung-RADS® follow-up recommendations, poor patient compliance with follow-up, and inaccurate smoking data [143].

Huo et al. compared CDC NHIS data from 2010 and 2015, finding a trend toward increased CT LCS by people ineligible for screening and raising concerns regarding overuse of the modality in some settings [144].

While gays, lesbians and bisexuals have higher ratios of smoking, and thus higher percentages who are screening-eligible, they receive LCS ratios rates similar to their heterosexual counterparts [145]. One report from Japan demonstrated that screening-eligible schizophrenics, despite higher smoking rates, are less likely to receive screening [146].

Radiation risk from medical procedures is the subject of another chapter in this book, but perceptions of radiation risk among patients and providers bear discussion. Ionizing radiation is typically quantified as effective dose measured in millisieverts (mSv). LDCT in NLST delivered a mean effective dose of 1.4 mSv [147]. For perspective, the background radiation effective dose is 3 mSv per year, while a coast to coast flight is 0.035 mSv [148]. One CXR = 0.1 mSv per exam; a standard chest CT = 8 mSv; positron emission tomographic (PET) scans = 14 mSv; and a CT angiogram for pulmonary embolism = 10 mSv [149]. Bach in 2012 pointed out that NLST could lead to 1 radiation-related cancer death per 2500 people screened due to cumulative follow-up CT and PET-CT doses of 8 mSv over 3 years [115]. McCunney calculated that doses to smokers in annual LCS programs for 30 years would exceed that of nuclear plant workers [150]. The risk of developing cancer from LDCT was studied by the investigators of the Italian COSMOS; in their group of 5200 receiving annual CTs for 10 years plus PET-CTs for positive nodules, 1.5 LCs and 2.4 cancers could have occurred. They calculated 1 radiation-induced cancer for every 108 LCs found, but younger women 50–55 had a higher risk of radiation-induced cancer than other groups. They noted that all scans (including follow-up) were performed using low-dose technique, unlike NLST. They stated that Lung-RADS® would further reduce radiation and that technology would reduce CT dose even more; thus radiation-associated toxicity could decrease in time [151].

Proposed Solutions to LCS Barriers

Solutions to improve rates of LCS include provider incentives, use of dedicated navigators for patients and providers, further identification of barriers, and obtaining more accurate smoking histories [136, 137, 143]. Solutions addressing mistrust of the medical system include campaigns to engage patients, using testimonial success stories, avoiding scare tactics, and recruiting trusted community providers (rather than screening program representatives) to invite candidates to screening [136–138]. Racial and socioeconomic disparity solutions include expanding screening to Black Americans using NCCN group 2 criteria [138], seeking funding for free CT screening programs, providing free transportation, mobile CT screening centers, scheduling screening on evenings and weekends to minimize lost time at work [137], and developing culturally tailored educational and outreach programs in collaboration with community health centers and leaders [138].

Successful implementation of LCS program in non-academic community centers was demonstrated in two recent studies. Over the first 5 years of a community-based LCS program, 1241 patients underwent screening for 1 round, and 29 cancers were found, 72% in stage I. There was a 21.3% Lung-RADS® "positive" CT rate, with 20% of these false positive. An unfavorable finding was low adherence (37%) to repeat scanning in those with a negative scan, leading to speculation that this first negative result may falsely reassure some participants [152]. In another larger study, 3400 patients in a large community hospital network were screened over several years, 500 (14.6%) had "positive" CT, and of these 111 had cancer (95 lung, 16 others). Of the 95

LCs, 67 were stage I or II and they reported a 2.3% surgical mortality rate. The program had an 83% adherence rate to repeat screening. Diagnostic and complication rates were comparable to NLST, contradicting the belief that NLST results could not be generalized to the community setting [153]. Future studies may influence the AAFP to change their stance on LCS.

Ultra-low-dose CT (ULDCT) is a newer modality that provides comparable resolution to LDCT, with even lower doses of radiation (~0.13 mSv) almost equivalent to 1 CXR [154]. It is expected that this form of CT scanning will replace LDCT over time, further reducing radiation risk.

Management of nodules found through LCS has evolved since NLST. Lung-RADS® criteria raised the positive nodule threshold to 6 mm on initial scan or 4 mm for new nodules on subsequent scans. Growth is defined as an increase of 1.5 mm in size. Criteria were designed to decrease unnecessary repeat CTs, PET scans, or biopsies.

It is possible to reduce the need for repeat CT scans of nodules found on LCS by using software to calculate volumetric size rather than linear diameter to more accurately assess growth and increasing the interval for subsequent scans after the first two annual rounds in those with negative results to 2 years. These ideas were incorporated into subsequent large randomized control trials [155].

The Nederlands-Leuvens Longkanker Screenings Onderzoek (NELSON) Trial

The Dutch-Belgian NELSON study was initiated in 2003 and was designed to find a 25% reduction in mortality with 80% power over 10 years [156]. They recruited adults aged 50–75 with >15 cigarettes per day for >25 *years or* >10 cigarettes per day for >30 years, currently smoking or had quit <10 years previously. They were randomized to screening vs. standard care without screening. The protocol called for a baseline CT, subsequent scans at 1, 3, and 5.5 years and then follow-up for 10 years. The most obvious differences between NELSON and NLST were the lower age limit and less intense smoking history (mean 38 pack-years vs. 56 pack-years NLST) requirement. By including subjects with moderate risk, the investigators calculated that they be would be able to recruit the necessary number of people (16,000) to adequately power the study, as well as apply the results to a broader population [156].

The study used 16- and 64-detector MDCT scanners vs. four-detector scanners in NLST. Software allowed 3D volumetric rather than 2D linear measurements. Nodules would be classified as low, intermediate, or high risk based on size, newness, and other features. Low-risk nodules would be recorded and the patient would return for the next scheduled screening scan. High-risk nodules would be referred immediately to a pulmonologist for biopsy; if negative the patient would stay in the study for the next scheduled screening. Intermediate-sized nodules would receive a repeat CT after 1 ½ to 3 months per protocol to calculate growth by volume doubling time. Growth rates faster than specified cutoffs would be referred to a pulmonologist for further evaluation. If cancer was diagnosed, the patient would then leave the study. If negative, they would return for further screening rounds. NELSON 16-detector MDCTs emitted 2 mSv for all exams [157]. The protocol was designed to minimize repeat scanning of intermediate lesions to one CT, after which a decision to refer or not would be made.

The final results were published in *The New England Journal of Medicine* in 2020 [158]. After randomization of 13,195 men, 344 cancers in the screening group and 304 in controls were found. 203 of the 344 cancers in the screening group were actually detected by screening – 44 were diagnosed between screenings and 97 after cessation of screening. Almost 60% of cancers detected by screening were stage I vs. 14% in the control group. Mortality over 10 years was 24% lower in men and 33% lower in a separate analysis of women (only 2594 subjects were women, due to low smoking prevalence). Benefit was seen even with the longer 2-year intervals after the first two screenings, demonstrating that less frequent screening in those already proven "negative" twice was viable. Overdiagnosis was estimated at 10%, and the NNS to save one life was 132. They found that after the first round, approximately 20% of participants required a repeat CT within 3 months to assess intermediate nodules, similar to other studies. However, for rounds 2–4, only 1.9–6.7% required a short-term repeat CT, and over half of new nodules resolved. Only about 2% of the CTs were "positive" in each round, and about one-half of those had cancer, giving a false positive rate of about 1.2%. In NLST the false positive rate was almost 25%. All age and smoking sub-groups showed mortality benefit; examining only NLST-eligible NELSON patients, a trend towards mortality benefit exceeding NLST was seen. The *NEJM* editorial by Duffy stated: "With the NELSON results, the efficacy of low-dose CT screening for lung cancer is confirmed. Our job is no longer to assess whether low-dose CT screening for lung cancer works: it does. Our job is to identify the target population in which it will be acceptable and cost-effective" [159].

Future of Lung Cancer Screening

Of note, the authors of NLST published an extended 12-year update on their subjects in 2019. At 12 years there were 1701 LC cases in the LDCT arm vs. 1681 in the CXR arm, thus showing equal incidence due to catch-up. Stage shift was preserved, i.e., more stage I (39.6% vs. 27.5%) and less stage IV (27.5% vs. 35.5%), and was similar to the original.

Overdiagnosis was down to 3%. Relative reduction in LC mortality fell to 11% (previously 20%), and there was no benefit in all-cause mortality, which had been 6.7%. Likely long follow-up period in an older cohort allowed catch-up in mortality for other reasons. NNS remained stable at 303, which signified that the signal of LC deaths prevented by screening had lasted for a decade and was due to cure, not delay in death. The conclusion was that there was still benefit even more than a decade, further reinforcing the effectiveness of LCS.

The Microsimulation Screening Analysis Lung (MISCAN-Lung) model was used to project the ramifications of full-scale LCS, and it found that there would be less need for chemotherapy and radiotherapy but there would be major increase in demand for surgery above current capacity. Careful planning and increasing the number of thoracic surgeons as quickly as possible would be imperative [160].

There is likely benefit to screening patients who do not meet CMS criteria and defining this group is a current topic of debate. Some advocate criteria based on personal risk calculation [161], and others advocate selection of those who could live longer after screening [162].

Text messaging to increase colon, breast, and cervical cancer screening has had moderate success [163] and bears further study for LCS. There is currently a multi-center clinical trial randomizing LCS active smokers to three arms for smoking cessation: standard referral, digital-based education/reminders on phone, and computer and a tobacco treatment specialist/digital combination [164]. Creating similar clinical trials using electronic platforms for recruiting, educating, and reminding candidates of LCS may be viable.

The SARS-CoV-2 (COVID-19) pandemic has changed medical practice around the world and has affected LCS. In April 2020, the American College of Radiology and the American Thoracic Society jointly created expert consensus statements to delay the reassessment of incidental or LCS nodules with low/intermediate risk potential for at least 3–6 months and to delay LCS baseline exams for 3–6 months, to be re-examined as the situation unfolds. For high-risk nodules with 65–85% certainty of malignancy, PET-CT or biopsy to assess need for surgery or radiotherapy is recommended rather than proceeding directly to surgery as was recommended by prior guidelines. Only the highest-risk nodules with >85% certainty of malignancy, should proceed to empiric surgery or radiotherapy. The goal of the strategy was to decrease risk and conserving personal protective equipment (PPE) by reducing procedures [165]. Amit et al. wrote and editorial that questioned the postponement of LCS, pointing out that mortality for LC is higher than that for COVID-19 and warning of a "cancer boom" in the future. They advocate frequent reassessment of this policy, and upon reopening, using triage systems to prioritize those who might benefit the most. They also call for cross-disciplinary discussion, merging of programs and resources and collaboration to help decrease the coming backlog in a way that helps the most people for the lowest cost [166].

In these efforts, telemedicine can help to maintain social distancing while allowing shared decision-making sessions with a provider.

Health Economics

As stated previously, LC has very high costs in terms of expenditures and lost productivity [4]. Much of the cost occurs due to treatment and complications of late-stage disease. Cost-effectiveness studies are designed to convince insurers to pay for LCS by estimating the costs incurred for screening in return for quality life-years. A 2013 study found LCS was as cost-effective as cervical and colon screening and better than mammography, diabetes screening, HIV testing, cholesterol medication, and dialysis [167]. A 2019 CISNET computer modeling study compared cost-effectiveness and mortality benefits of LCS in NLST-, CMS-, and USPSTF-eligible groups and found the CMS criteria gave the best combination of cost-effectiveness, quality life-years, and mortality benefit [168]. Applying NLST criteria would cost less but have less benefit while USPTF criteria would give the most benefit but also be the most expensive. The cost to insurers of expanding screening to patients using NCCN or NELSON criteria was not estimated.

One of the centers using NCCN criteria to expand LCS reported on profitability analysis for the institution. They actually offered LCS CT for free, regardless of insurance status. As a result of this screening, 60 new patients entered their healthcare system, and profitability above the initial overhead was achieved after 2 years [169]. They also noted that 73% of the lesions found were stage I, and the cost of treatment was $10,000 to $20,000. Costs associated with treatment of stage III or IV LCs are $80,000 to $100,000. The argument that healthcare systems can profit from LCS may speed their dissemination.

Cancer Prevention and Screening in the ED

Smoking cessation counseling in the ED has been studied since the early 2000s and is discussed in detail elsewhere in this book. EDs have long been involved in public health initiatives such as accident prevention, domestic violence screening, and vaccinations, among others. The idea of using EDs to promote cancer prevention is also not new. A 1996 study screened 116 women for breast and 644 for cervical cancer in a busy New York City ED with an underserved population. Nine patients with cancers underwent treatment [170]. In 2006, Cummings et al. in Canada reported using ED surveys about cervical cancer screening and immunizations and finding 307 women overdue for Pap smears. One hundred fourteen were contacted in follow-up and 54

(47%) reported receiving an outpatient Pap smear. Four of the 54 had significant pathology requiring further intervention [171]. Zun and Downey in Chicago questioned ED patients (mainly Black and Hispanic) about colon, prostate, cervical, and breast cancer screenings; of the patients who accepted referrals, 33% (breast) to 53% (colon) had confirmed appointments on follow-up [172]. In contrast, a 2008 Boston-based survey conducted in three academic EDs found that most women and a majority of men were compliant with recommended cervical, breast, testicular, and prostate cancer screening compared to general population, regardless of race or ethnicity. This population was 65% non-Hispanic White and had higher average income than most urban ED populations [173]. A 2017 analysis of the National Health Interview Survey found that patients who used the ED for health care were far less likely to have had recommended cancer screening than those with a usual source of care [126]. An initiative to promote public health topics (not including cancer screening) in a busy Maryland ED used interactive computer kiosks, noting that self-selection of motivated individuals could potentially lead to more efficient delivery of health education and even follow-up without sacrificing ED time or staff [174].

Emergency medicine organizations such as the American College of Emergency Physicians, the Society for Academic Emergency Medicine, and the American Academy of Emergency Medicine all have sections and/or polices on public health, and SAEM has an interest group dedicated to oncologic emergencies.

Lung Cancer Screening in the ED: What Is Our Role?

General barriers to screening include poor access to health care, lack of awareness or skepticism by primary care providers about LCS, fears of radiation exposure, concerns about cost, concerns about adequate interpretation of LDCTs, concerns about unnecessary invasive procedures, and concerns about a positive diagnosis, to name a few. In addition, racial/ethnic minorities, rural residents, and sexual minorities who are at high risk but medically disenfranchised face additional barriers to this potentially lifesaving procedure.

EDs act as the nation's safety net and are integral to our healthcare system. Public health and cancer prevention initiatives are already part of our profession's infrastructure and mission. We could help to increase screening in different ways. Most EDs use electronic health record (EHR) systems that allow patients to be "flagged" for various conditions, including public health concerns. EHRs have been shown to improve colon and breast cancer screening rates in ambulatory settings [175]. It would not be difficult to adapt such tools to ED EHR systems to identify such patients when they present. The teachable moment during a health emergency is often mentioned and has been shown to increase patient's willingness to change behavior, particularly with regard to substance abuse [176, 177]. Existing ED smoking cessation programs are another avenue to recruit eligible patients as many of them are likely at higher risk for LC.

Education targeting high-risk patients as they come to EDs for any reason is a relatively low-cost opportunity to improve screening rates. Use of modern technology such as computer/kiosks or smartphones, texts, and social media platforms may help by giving patients preliminary information about LCS without need for a dedicated person to do so.

Navigators for LCS programs performing outreach and facilitation for patients and providers have had some success facilitating screening in other settings, and liaison between EDs and local LCS existing navigators may serve to increase recruitment without dedicating ED personnel to the task. Partnering of community hospitals or freestanding EDs in remote areas with distant LCS centers may be facilitated by the use of telemedicine, as this modality becomes more familiar.

Any initiative into public health and cancer screening by EDs will certainly require coordination between local and state government authorities, philanthropic programs, public health programs, large medical centers, and community stakeholders. Whatever solutions that EDs adopt should not detract real-time resources from the EDs' primary mission.

Shared Decision-Making

Ideally, the burden of formal shared decision-making conversations and documentation that are a CMS requirement for LCS reimbursement should be undertaken by primary care physicians, pulmonologists, or oncologists in the proper setting [178], rather than the ED. Even if not formally part of a referral network, any ED can direct eligible patients to publicly available decision aids regarding LCS to help patients with decision-making (Table 12.1).

Table 12.2 Key points/pearls

Lung cancer in the USA is the costliest cancer in terms of productivity and lives lost
COPD and coronary disease often co-exist with lung cancer, and COPD increases lung cancer mortality
Never smoker's lung cancer (LC) incidence is rising, and patients tend to be women. In East Asia, women have very high incidence of never smoker lung cancer, likely due to genetic variation. Air pollution is another cause of never smoker cancer, as is radon, as well as many other environmental exposures and medical conditions
Black men have the highest incidence and mortality from lung cancer, but non-Hispanic White and Native American men also have very high risk and mortality; there is correlation with geography, poverty, low air quality, and poor access to medical care. Others at risk include LGBT, disabled individuals, and enlisted military personnel. ED diagnosis of LC is associated with poor outcome
Shortness of breath and altered mental status correlate with ICU admission and short-term death
Adenocarcinoma and squamous cell LC are curable with early detection and surgical treatment but have poor prognosis if not resectable. Small-cell lung cancer remains highly deadly, even if found early
Incidental CT masses >3 cm are likely malignant and should be referred for further diagnosis. In adults 35 and older, lesions <6 mm in diameter are very unlikely to be malignant, unless the patient has history of cancer and immunosuppression or the lesions have irregular or spiculated morphology or are in the upper lobe location. Multiple nodules (2–4) are more likely malignant, but 5 or greater are less likely (unless there is history of cancer). Radiologists use Fleischner Society Guidelines for follow-up recommendations of suspicious lesions as part of the reading
Lung cancer screening is recommended by most medical organizations and approved by CMS for active or former smokers 55–77, with 30 pack-years of smoking, and those who have quit less than 15 years ago
Another high-risk group are those age >50 with 20+ pack-years ***plus*** history of cancer, COPD/pulmonary fibrosis, family history of LC, radon exposure, or occupational carcinogen exposure
Only 4% of eligible patients receive lung cancer screening (LCS) despite the test's approval by Centers for Medicare and Medicaid Services (CMS)
Overdiagnosis and false positives can lead to unnecessary distress, radiation, and procedures, but decreasing unintentional harm has been a priority in LCS research
Radiation dose from LDCT is about 10 times that of CXR, and one-fifth the dose of standard chest CT. As technology and protocols advance, the dose may soon approach that of 1–2 CXRs
Emergency physicians and departments can help increase LCS by "flagging" eligible patients using electronic medical records and then working with local LCS programs approved by the American College of Radiology. Many of these are developing outreach and navigator programs to increase recruitment and may be able to provide education and logistical support to interested patients. Use of telemedicine, cell phone, and social media platforms can be integrated. Coordination with local and state government authorities, philanthropic programs, public health programs, large medical centers, and community stakeholders is essential to maximize effectiveness and minimize dilution of ED resources

Conclusion (Table 12.2)

LC is the deadliest of all cancers in the USA and across the world. Despite advances in treatment, later-stage disease remains highly fatal. Early diagnosis at an early localized stage is the best chance for cure, and mass screening that had been unsuccessfully attempted for decades is only recently possible with LDCT. The potential for saving lives and costs makes increased screening for early LC a public health priority. Increasing the numbers of eligible patients who undergo screening should be approached on many different fronts.

As the safety net for society, the ED should certainly be able to assist with recruitment and referral. Real-time use of LDCT in eligible patients where CT scanners are not otherwise available may be another avenue worth exploring. However, this would only work if there is coordination with LCS programs and treatment centers. Partnerships with local community resources, advocacy in government circles at the regional and state level, and recruitment of philanthropic support are likely keys to success.

Colorectal Cancer Screening

13

Veronica Sikka, Raaj K. Popli, and Edward P. Cutolo Jr.

Case Study

Patient is a 68-year-old male presenting to the emergency department (ED) with hematemesis with a 30 pound unintentional weight loss in the last 2 months. His hemoglobin is 10 with associated lightheadedness. His previous hemoglobin last month was 14. He is also complaining of low back pain. He reports never having a colonoscopy.

Upon presentation, the patient is given IV fluids and an NG tube is placed. Additional labwork is pending. A CT of the abdomen reveals a large obstructing mass in the cecum with dilated small bowel. Multiple liver metastases are seen affecting most lobes as well as lytic lesions in the lumbar spine. What is this patient's prognosis?

If the patient had received his routine colonoscopy, this cancer could have been detected at the polyp stage. Treatment options include (1) resection of the primary lesion; (2) palliative radiotherapy to the vertebral metastasis; and/or (3) systemic chemotherapy with biological therapy. His expected prognosis is not promising with a median survival of 24 months with systemic treatment.

Background

Colorectal cancer (CRC) is the fourth most commonly diagnosed cancer in the United States and the third most common cause of death for both men and women after lung and prostate for men and lung and breast for women. The American Cancer Society estimates that in 2020, 104,610 people will be diagnosed with CRC and 53,200 people will die from the disease alone [1]. Fortunately, the incidence of CRC has declined steadily in recent years and is largely attributed to the detection and removal of precancerous polyps with CRC screening [2, 3].

Although the overall incidence is declining, incidence in patients under the age of 50 is still on the rise as screening is not as common [4]. Surgery is considered the first-line therapy for CRC and is generally elective. Chemotherapy and radiation are also treatment options in more advanced stages. Unfortunately, patients with CRC may present to the emergency department (ED) with complications such as perforation, hemorrhage, and obstruction, as well as general complications secondary to chemotherapy and radiation [5]. This chapter focuses on (1) the diagnosis of CRC in the ED and (2) the ED recognition and management of patients with CRC-related complications.

The lifetime risk of obtaining colorectal cancer is 1 in 23 (4.4%) for men and 1 in 25 (4.1%) for women, with a higher predominance in men compared to women. CRC incidence is 30% higher in men. Lifetime risk is similar in men and women despite higher incidences in men. This is attributed to higher life expectancies in women. In comparing 5-year age groups, the incidence rate almost doubles until age 50, after which it increases by approximately 30%. Interestingly, patients diagnosed with CRC are younger today than ever before. In the early 2000s, the median age at diagnosis was 72. Today it is 66 years old. This is due to an increase in CRC screening over the years [3, 6].

Diagnosis of CRC

The diagnosis of CRC is not straightforward. First, the cancer can be discovered at any stage during progression, from asymptomatic cancer identified by screening through consultation with a general practitioner or gastroenterologist to presentation as a surgical emergency (usually with bowel obstruction or perforation) [7, 8]. If diagnosis is delayed and surgery is emergent or palliative in nature, it is associated with a substantially elevated risk of mortality [9], especially among the elderly [10]. However, if detected early, the 5-year survival rate is 90% while still localized (i.e., confined to the bowel wall), 68% for regional disease (i.e., lymph node involvement), and only 10% if distant metastases are present [1, 11, 12].

Risk for CRC is increased by genetic mutations (i.e., familial adenomatous polyposis, Lynch syndrome, juvenile polyposis, and Peutz-Jeghers syndrome), personal history (i.e., irritable bowel syndrome, Crohn's disease, and ulcerative colitis), and lifestyle factors (i.e., smoking, alcohol consumption, and diets high in fat and low in fiber). Early-stage CRC does not usually present with symptoms. Therefore, screening is necessary to detect cancer at earlier stages. Patients with advanced disease may present with changes in bowel habits, blood in the stool, weakness, fatigue, shortness of breath, signs of intestinal obstruction (i.e., bloating, fullness, cramps, and pain), unexplained weight loss, pain with defecation, and thin stools. In addition to CRC, the differential diagnosis for these symptoms includes hemorrhoids, infection, and inflammatory bowel disease.

The American Cancer Society [13] provides recommendations for guideline CRC treatment by TNM (tumor, nodes, metastasized) stage. Specifically, resection is recommended for stage 0, I, II, and III CRC, and chemotherapy is guideline care for stages III and IV of CRC. Surgery is the most common treatment for CRC with the usual operation being either a segmental resection, partial colectomy, or diverting colostomy in the case of obstruction. Especially for CRCs that have not spread, surgical removal may be curative [14]. The choice of operation depends mainly on the site of the disease (left-sided versus right-sided), the patient's physical condition, nutritional status, and age. The treatment for right-sided lesions is a right hemicolectomy. However, treatment of left-sided lesions is still undecided. There are many therapeutic options such as primary or staged resections, Hartmann's procedure, subtotal colectomy, or colostomy. Other therapies involve nonoperative techniques such as laser therapy, colonic stenting, emergency endoscopy, and comfort measures.

Table 13.1 correlates the stages of CRC with the TNM categories and their associated management.

Trends in CRC incidence and mortality reveal overall declining rates, which have been attributed to reduced exposure to risk factors, early detection through screening, and prevention through polypectomy and improved treatment [15]. However, studies show a majority of US adults are not receiving age- and risk-appropriate screening or have never been screened [11, 16–19]. Among CRC patients, only 39% are actually diagnosed at an early stage, mostly due to these low screening rates [1]. Significant delays in screening translate into worse outcomes in terms of stage of cancer at diagnosis, ability for curative treatment, likelihood of recurrence, and survival, especially among the elderly [20].

Current recommendations for colorectal cancer screening from the US Preventive Services Task Force are presented in Table 13.2.

Table 13.1 Correlation between TNM categories and stage for CRC

Stage	TNM category	Interpretation	Colon cancer management	Rectal cancer management
0	Tis, N0, M0	Early-stage cancer where the cancer is limited to the mucosa of the colon or rectum (Tis). No lymph node involvement (N0) or distant spread (M0)	Surgery	Surgery
I	T1–T2, N0, M0	The cancer has grown through the mucosa into the submucosa (T1) or muscularis propria (T2). No lymph node involvement (N0) or distant spread (M0)	Surgery	Surgery ± radiation
II	T3–T4, N0, M0	T3–T4 stage with no spread to lymph nodes (N0) or distant sites (M0)	Surgery ± chemotherapy	Surgery + chemotherapy + radiation
III	Any T, N1–N2, M0	Any *T* stage with spread to 1–3 (N1) or four or more (N2) regional lymph nodes. No distant spread (M0)	Surgery + chemotherapy ± radiation	Surgery + chemotherapy + radiation
IV	Any T, any N, M1	The cancer can be any *T* stage and any *N* stage and has spread to distant sites such as the liver, lung, peritoneum, or ovary (M1)	Surgery + chemotherapy ± other treatments (RFA, cryosurgery)	Surgery + chemotherapy + radiation

Table 13.2 Summary of US Preventive Services Task Force recommendations

Population	Recommendation	Grade
Adults, beginning at age 50 years and continuing until age 75 years	The USPSTF recommends screening for colorectal cancer using fecal occult blood testing, sigmoidoscopy, or colonoscopy in adults, beginning at age 50 years and continuing until age 75 years. The risks and benefits of these screening methods vary	The USPSTF recommends the service. There is high certainty that the net benefit is substantial
Adults age 76–85 years	The USPSTF recommends against routine screening for colorectal cancer in adults 76–85 years of age. There may be considerations that support colorectal cancer screening in an individual patient	The USPSTF recommends against routinely providing the service. There may be considerations that support providing the service in an individual patient. There is at least moderate certainty that the net benefit is small
Adults older than age 85 years	The USPSTF recommends against screening for colorectal cancer in adults older than age 85 years	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits
Computed tomographic colonography and fecal DNA testing as screening modalities	The USPSTF concludes that the evidence is insufficient to assess the benefits and harms of computed tomographic colonography and fecal DNA testing as screening modalities for colorectal cancer	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined

The overall relative survival rate for CRC is 65% at 5 years following diagnosis and 58% at 10 years [6]. Forty percent of CRCs are diagnosed at a local stage, for which the 5-year survival rate is 90%. Thirty-six percent of CRCs are diagnosed at regional stage, for which the 5-year survival rate is 70%. Twenty percent of CRCs are diagnosed at a distant stage, for which the 5-year survival rate is 12%.

CRC Diagnosis in the ED

The number of patients presenting to the ED who are subsequently diagnosed with cancer in the ED has increased [21, 22]. In a comparison of patients diagnosed with cancer in the ED versus other settings, patients in the former category were found to be older, have Medicare or Medicaid, have stage IV cancer, and exhibit more symptoms [23]. A population-based study of 11,023 patients in Connecticut reported patients admitted from the ED with a CRC diagnosis were usually older (75+) and African American. An ED admission status was a significant predictor of distant stage in all patients [24]. A study of 151 patients in the United Kingdom examined the pathways to diagnosis of CRC. Despite considerable investment by the UK National Health Service in cancer diagnostic services for primary and specialty practices, 26% of patients had an emergency diagnosis [25].

Diggs et al. [26] focused on predictors and the associated burden of emergency CRC resection (E-CCR), which has been defined as the "clearest evidence on an individual level for a failure of screening" [27]. This cross-sectional study of over 120,000 discharges nationally focused on patients who underwent the procedure emergently, finding older patients dually eligible for Medicare and Medicaid were at higher risk for E-CCR. There was also a threefold increase in hospital mortality, longer lengths of stay, and more than $250 million in additional hospital charges associated with E-CCR. This study was limited in its focus on one type of cancer and a particular procedure associated with CRC.

Early CRC may present to the ED with vague to no symptoms, which further emphasizes the importance of screening. Symptoms that may suggest CRC and the need for additional screening if not already diagnosed with CRC are presented in Table 13.3.

Table 13.3 Emergent symptoms suggestive of colorectal cancer

Bleeding from the rectum
Blood in the stool or in the toilet after having a bowel movement
Dark or black stools
A change in the caliber or shape of the stool (i.e., narrow stools)
Cramping or discomfort in the lower abdomen
An urge to have a bowel movement when the bowel is empty
Constipation or diarrhea that lasts for more than a few days
Decreased appetite
Unintentional weight loss
Weakness and fatigue secondary to anemia

A positive family history of colon cancer should also raise suspicion for CRC on the differential. Findings on physical

exam include grossly positive or guaiac stools. It is important to get basic labs (i.e., CBC and BMP) since blood loss from the cancer leads to anemia, specifically iron deficiency anemia. In the ED, a CT of the abdomen with contrast can help locate and characterize a mass. Timely evaluation of symptoms consistent with CRC is essential, even for adults younger than age 50. If stable, the patient can be discharged with referral to a gastroenterologist for colonoscopy and/or surgeon if a mass is found.

Oncologic Emergencies Associated with CRC

More common is the management of the complications of patients already diagnosed with CRC, which include bowel obstructions, perforations, rectal bleeding, and complications secondary to chemotherapy and radiation. The sections below describe the relationship between CRC and the respective complications and associated history and clinical findings with the appropriate ED management [28].

Bowel Obstruction

As a tumor grows, it may bleed or cause obstruction of the colon. Intestinal obstruction can occur when tumor growth has invaded the lumen of the large intestine. Up to 20% of colon cancer in some series will present as bowel obstruction. This is more likely to occur in the left colon because it is narrower, with the splenic flexure particularly vulnerable [29].

Patients may present with diffuse, colicky abdominal pain, nausea, vomiting, and abdominal distension. They also may have decreased to no bowel movements and flatus. On physical exam, there will likely be diffuse abdominal tenderness and distension with high-pitched or absent bowel sounds. The patient may also be clinically dehydrated and, in advance stages, be hypotensive, tachycardic, and febrile. Labs such as a lactate, CBC, and BMP may be helpful and reveal a metabolic acidosis. Imaging includes an acute series that reveals multiple air-fluid levels, more than 3 cm of dilatation of the small bowel, and/or more than 3 mm thickening of the small bowel (Fig. 13.1).

An abdominal CT can also be very helpful in distinguishing between partial versus complete bowel obstructions as well as to assist in identifying the anatomic location of obstruction (Fig. 13.2). Intussusception primary or meta-

Fig. 13.2 Apple-core obstructing colon cancer following a barium enema demonstrated on an abdominal CT (axial). Note that the contrast material does not pass through the lesion retrograde and the upstream bowel appears to be distended

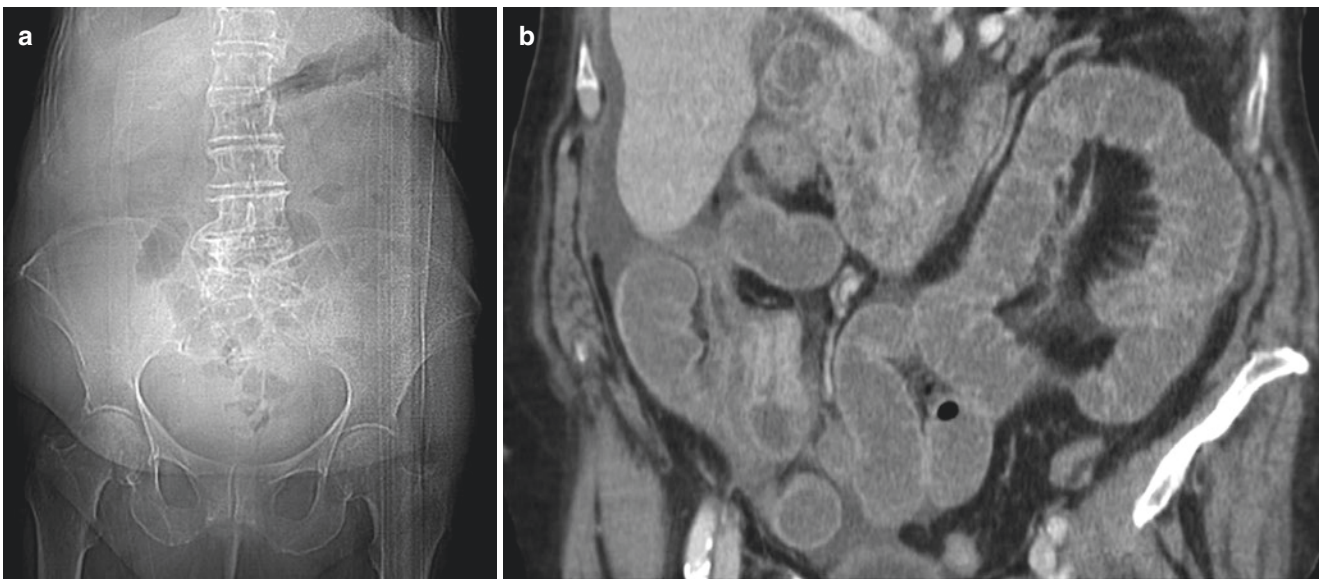

Fig. 13.1 (**a**) Small bowel obstruction on a KUB x-ray due to metastatic lobular breast cancer. (**b**) Coronal CT image revealing a segmental stricture in the right lower quadrant with thickened enhancement of the small bowel wall

static deposits to the bowel can contribute to obstruction (Figs. 13.3 and 13.4).

ED management includes symptomatic treatment with IV fluid boluses, antiemetics, and analgesia. An NG tube may be placed for a significant obstruction, especially if vomiting, and keeping the patient NPO for bowel rest. These patients require admission with gastroenterology and surgery consulting.

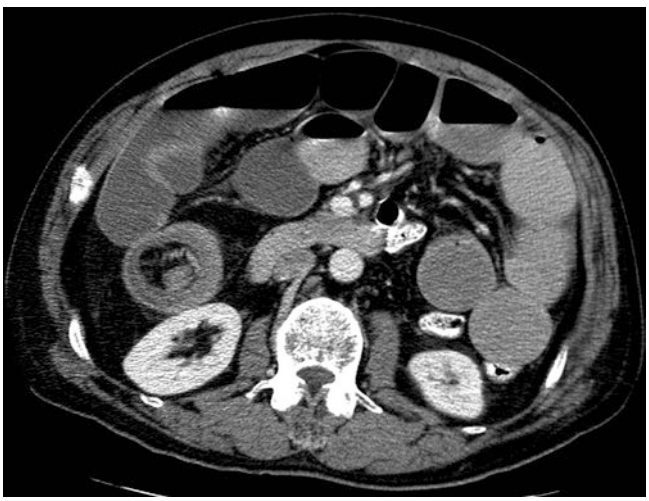

Fig. 13.3 Small bowel obstruction from intussusception secondary to melanoma metastasis, located in the right abdomen in front of the right kidney as demonstrated on an abdominal CT (axial)

Fig. 13.4 Intussusception from a primary cecal tumor as demonstrated by an abdominal CT (coronal)

Perforation

Patients with CRC may also present with bowel perforations as the CRC invades through the colon wall in more advanced stages. Patients may present with an acute onset of severe abdominal pain possibly associated with near or complete syncope. They are often unable to localize the pain but report worsening pain with any movement (parietal pain). Anorexia is common, but vomiting is often uncommon. On exam, the patient may have acute peritonitis with a rigid abdomen and rebound tenderness. Critical studies include an upright chest x-ray to ensure no air under the diaphragm. Free air can be seen in 70–94% of cases. A CT abdomen/pelvis would be the definitive study if the CXR is inconclusive.

ED management includes IV fluid resuscitation and antibiotics (i.e., 3.375 g of IV Zosyn). Immediate surgical consults are required with patients with perforation.

Rectal Bleeding

Patients with CRC can present with blood in their stools in the setting of recent changes in their bowel habits (i.e., constipation). In general, cancers of the ascending colon tend to be larger and more frequently bleed. Cancers of the descending colon tend to be smaller and more obstructive. Predominant constitutional symptoms include anorexia, fatigue, weight loss, and presyncope. Patients can present from asymptomatic rectal bleeding to ill-appearing with pale conjunctivae, hepatomegaly (secondary to liver metastasis), abdominal or rectal mass, and/or guaiac-positive stools.

Labs include a lactate, CBC, BMP, and coagulation studies. A CBC often reveals microcytic anemia. A BMP can be indicative of an anion gap (lactic) acidosis that is secondary to hypoperfusion. Coagulation studies should be ordered if the patient is anticoagulated or has liver disease.

The ED management depends on the severity of the rectal bleeding. With significant bleeding, two large bore IV lines should be established, and the patient should be volume-resuscitated with normal saline and cross-matched for 2–4 units of blood. If the patient is anticoagulated, FFP may be required to reduce the INR from 1.5 to 2.5. Vitamin K may be needed if bleeding continues despite FFP. General Surgery should be consulted if significant bleeding or obstructive symptoms exist. If stable with an occult lower GI bleed, outpatient oncologic work-up may be appropriate.

Complications Secondary to Chemotherapy and Radiation

Patients in stages 1 and above of CRC may require chemotherapy and radiation which can present to the ED as severe nausea and vomiting. Chemotherapy often causes symptoms

2–3 days after treatment. The emergency medicine approach is dependent on the patient's clinical status. If they appear significantly dehydrated, labs should be drawn to rule out any electrolyte abnormalities. The patient may require IV hydration and antiemetics. The final ED disposition is dependent on the patient's clinical status (i.e., orthostatic, able to tolerate PO, etc.), and the patient's gastroenterologist, hematologist, and/or surgeon should be consulted.

Conclusion

Despite the decreasing incidence of CRC, emergencies secondary to this deadly cancer still exist. It is important for the ED physician to be able to recognize the signs and symptoms that may hint at a new CRC diagnosis as well as how to manage complications in patients with pre-existing CRC. The approach is multidisciplinary with consultation of gastroenterology, hematology/oncologic, and surgery depending on the patient's presentation; however, most important is the emergent recognition and stabilization of these often complex patients.

Acknowledgments We are thankful for the images provided by Drs. Fergus Coakley and Elena Korngold, Department of Diagnostic Radiology, Oregon Health & Science University, Portland, Oregon.

We express additional thanks for Dr. Charles R. Thomas, Jr., for providing critical editorial assistance during the final stages of the chapter.

Melanoma Screening

14

Wei-Lynn Chong, Thomas M. Pitney, and Michael Sinnott

Case Study

A 23-year-old male is brought in by ambulance after having a syncopal episode on the beach. He is in Australia from the UK over the summer backpacking with friends. Collateral from the ambulance reports that he and his friends have spent the day on the beach and had consumed multiple beers. Temperatures outside have reached 38 degrees Celsius and there was no shade on the beach. He was playing volleyball and had a witnessed collapse where he lost consciousness. His friends placed him on his side and a bystander called the ambulance. There were no witnessed shaking movements or incontinence. After a couple of minutes, he regained consciousness and has Glasgow Coma Scale score of 15 since that time.

He reports a few days of heavy alcohol intake prior to today and has spent the weekend on the beach in the sun. He has no other medical conditions and denies any regular medications or recreational drug use. His examination reveals blistering sunburn to his face, trunk and upper limbs. His examination reveals normal vital signs except for a postural tachycardia, dry mucus membranes and an incidental finding of multiple melanocytic naevi with a large, irregular lesion on his lower back. Investigations of a bedside electrocardiogram, full blood count and biochemistry panel reveal a mild prerenal acute kidney injury consistent with dehydration. The impression is that the patient has had a syncopal event secondary to dehydration from sunburn, heat exhaustion and excess alcohol intake. The plan for his management in the emergency department includes IV fluid therapy, application of soothing gels to his sunburn, teledermatology referral for review of the lesion on his lower back and education on sun protection and alcohol consumption. On discharge his vitals have normalised and he is feeling much better. He has an appointment with dermatology in 3 days for consideration of excision of the lesion on his back. He was given written and verbal advice about sun protection, including wearing sunscreen, a hat, sunglasses and clothing to protect himself from the sun when outside, as well as to avoid being in direct sunlight between 10 am and 2 pm.

Introduction

In both the USA and Australia, skin cancer is the most commonly diagnosed malignancy. Importantly it is also the most easily preventable and most successfully treated when diagnosed early [1]. Although less common than basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), melanoma is more important to diagnose early due to its high metastatic potential and mortality risk. A melanoma is a malignant tumour arising from melanocytes. It is easily treatable if detected at an early stage. In situ lesions (confined to the epidermis) have a very low risk of metastatic spread. The main risk factor for metastasis and mortality is the depth of dermal invasion [2].

Given the importance of early detection, melanoma has been the focus of many primary prevention programmes in Australia, notably the "Slip, Slop, Slap" campaign of the 1980s, which encouraged the public to Slip on a shirt, Slop on sunscreen and Slap on a hat to limit excessive sun exposure [3]. There is evidence that this has been effective, with a noted age-specific decrease in incidence of melanoma in the 0–39 age group from a peak of 13 to 9.4 per 100,000. The same data reveal a decreased incidence of invasive melanomas in the under 55 group and a slower increase than prior in

the above 55 group [4]. Unfortunately, the proportion of thick melanomas at initial diagnosis has not changed over time. This is thought to reflect their highest incidence in older people, particularly men, to whom little specific advertising or primary prevention campaigns have been directed. This increasing incidence with age will become more relevant over time as populations age in the western world.

The burden of skin cancer in Australia is largely managed by public outpatient "general practitioner" physicians, with a smaller number being managed in public or private hospital outpatient clinics and very little being specifically managed by the urgent care or emergency physician. The importance of the emergency department (ED) in melanoma prevention and screening is in its valuable contact with people who may most benefit, such as those from lower socioeconomic groups. They may have poorer health literacy and have been shown to have poorer melanoma prognosis [5]. An unrelated ED visit for an emergency issue may be their sole point of contact with the medical profession for extended periods of time and an important opportunity to provide both primary prevention advice with sun protection, self-identification of suspicious lesion education and a secondary screening chance while addressing their primary presenting issue.

Opportunistic at-risk groups may include ED presentations for sunburn, or patients with melanoma risk factors such as a personal or family history of melanoma and other solar-related skin malignancies, solar damage, multiple naevi or immunosuppression. Other at-risk groups include young people without a primary healthcare physician. Identification of these groups with referral to specialist services when appropriate has demonstrated both improved outcomes for the patients and cost-effectiveness compared to standard community care. In a 2017 cost-effectiveness study, over a 10-year period, specialised surveillance services were estimated to result in a savings of $6828 (in 2013 Australian dollars) and a gain of 0.31 quality-adjusted life-years per patient when compared to standard care [6].

Epidemiology

Melanoma has an incidence rate of 49 per 100,000 in the Australian population and a mortality rate of 6.2 per 100,000 (standardised for age). Melanoma accounts for 10% of all cancers diagnosed in Australia and for 3.8% of cancer deaths [1].

Risk factors for melanoma are both environmental and genetic. Environmental ultraviolet (UV) radiation exposure from the sun with repeated significant sunburns appears to carry the greatest risk [7]. Sunbed (tanning bed) use is considered an independent risk factor, particularly if first exposure occurs before the age of 35 [8].

Genetic factors may increase risk of melanoma. Phenotypic features associated with this risk are skin types having poor ability to tan and higher risk of sunburn, including those with fair complexion, blond or red hair and pale eyes. Large numbers of melanocytic naevi are also associated with increased risk of melanoma. Other clinical features indicating higher risk include skin changes associated with solar damage, such as freckling, solar elastosis, solar lentigines and keratoses [8–11]. Conversely, darker-skinned groups have a lower incidence of melanoma primarily as a result of photoprotection provided by increased epidermal melanin, which filters twice as much UV radiation as does that in the epidermis of fair-skinned groups [9]. As such melanoma demonstrates greater variation in incidence rates across different ethnic groups than that of most cancers [10].

Although skin malignancies occur less frequently in those with dark skin types, they suffer from higher rates of mortality and morbidity. This is likely due to delayed diagnosis [9]. Though UV radiation exposure is not as significant compared to those with high-risk phenotypic features, sun protection is still advised to protect from basal cell carcinoma development.

A personal or family history of melanoma in parents or siblings is associated with increased risk. Having a parent with multiple melanomas is a particularly strong risk factor [12].

Pathophysiology

UV radiation (wavelength 100–400 nm) can be classified as UVC (100–280 nm), UVB (280–315 nm) and UVA (315–400 nm). All UVC and 90% of UVB are absorbed in the atmosphere. UV radiation has been implicated in the development of cutaneous melanoma. The precise mechanism of this pathogenesis is poorly understood; however, both UVB and UVA are implicated. UVB-induced mutations of the phosphatase and tensin homologue (PTEN) tumour suppressor gene, by direct DNA base pair damage, have been demonstrated in melanoma samples from patients with xeroderma pigmentosum [11]. UVA, which penetrates deeper into the dermis of the skin than UVB, can itself induce DNA damage through production of radical oxygen species and exerts an immunosuppressant effect which may also contribute to the development of melanoma [12].

Clinical Manifestations

Melanoma can present in a multitude of ways. Clinical features vary with melanoma subtype, tumour width and thickness, the anatomical site, the presence of regression or inflammation and even patient skin type (Table 14.1 [13, 14];

Table 14.1 Melanoma subtypes

Type	Incidence	Clinical features
Superficial spreading (Figs. 14.1 and 14.2)	Most common subtype in fair skin, rare before 4th decade	50% develop in a pre-existing naevus, and there may be clinically contrast between these two components [13]. Generally macular in early stages but can develop nodular components as it progresses
Nodular (Fig. 14.3)	Incidence peaks in 5th to 6th decade of life	Most common on the trunk region. Has rapid vertical growth pattern
Lentigo maligna (Fig. 14.4).	Elderly population	Often progress very slowly through an in situ phase from a pre-existing solar lentigo, usually on a sun-damaged skin background. Increase in size, depth of colour and irregularity of pigment are clues that suggest malignant change
Acral lentiginous (Fig. 14.5)	10% of melanoma on white skin but over 50% on darker skin types [14]	Appear as an irregular lentiginous pigmented area on the sole or palm of the hand
Subungual (Fig. 14.6)	Rare. Proportionally more frequent in darker skin types in 40–70 age group	Arise from the nail matrix and present as melanonychia (brown pigmentation of the nail). Extension of pigmentation onto the proximal nail fold (Hutchinson sign), heterogeneity of pigment colour, expansion of the width of pigment distribution and proximal growth are concerning features that separate from benign longitudinal melanonychia

Figs. 14.1, 14.2, 14.3, 14.4, 14.5 and 14.6). Lesions that are symptomatic, stand out from other naevi (the "ugly duckling" sign) or have a history of change should be examined closely. Dermoscopy is an essential tool to identify key features of malignant change but requires specific training in its use to be of benefit [15].

Commonly taught tools for both physicians and self-assessment of skin lesions (such as ABCDE mnemonic) are

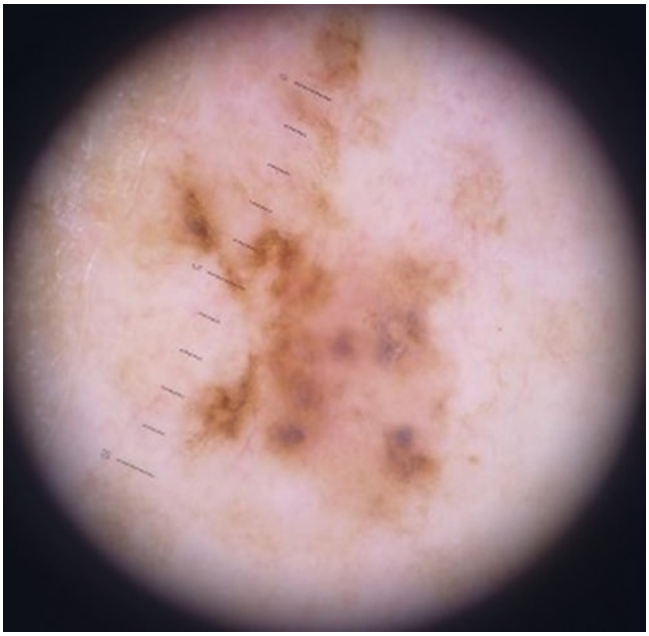

Fig. 14.1 Dermoscopy image of Fig. 14.2a (superficial spreading melanoma)

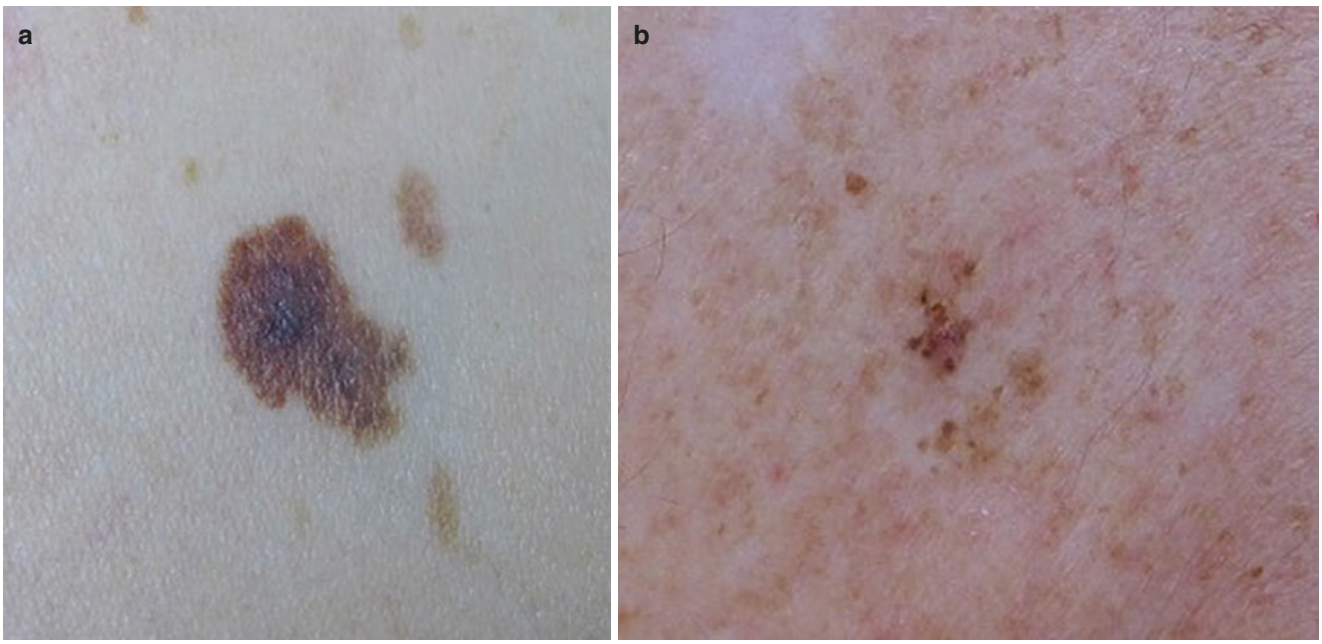

Fig. 14.2 (**a**, **b**) Superficial spreading melanoma

Fig. 14.3 Amelanotic nodular melanoma

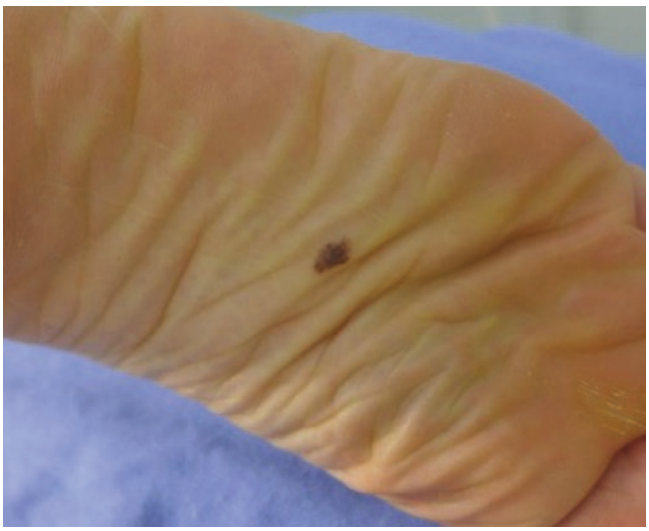

Fig. 14.5 Acral lentiginous

Fig. 14.4 Lentigo maligna

Fig. 14.6 Subungual melanoma

simple enough that patient education should be attempted in patients considered at risk [16]. This mnemonic reminds the patient to look for Asymmetry, Border Irregularity, Colour that is not uniform, Diameter (larger than a pea) and Evolving size, shape or colour.

Any of the above variants can also rarely be amelanotic, appearing as "skin coloured" or red, pink or purple discoloured areas with or without nodular components.

Teledermatology

Technological advancements in dermatology over the last two decades include the introduction of teledermatology into healthcare organisations worldwide to expand the availability of specialty services. Teledermatology is an innovative model of care and an alternative to traditional face-to-face specialist consultation. Primary referral physicians have greater and faster access to specialist dermatology opinion, and dermatologists are able to increase their work-flow efficiency through this method. There are two applications of teledermatology: (1) live interactive and (2) store and forward technologies; or a combination of both can be utilised [17]. Live interactive teledermatology involves live conferencing between the primary healthcare worker with the patient and specialist dermatologist. Store and forward technologies utilise still images and written clinical referral or over the phone referral to specialist dermatologists. Dermatology is a visual specialty and as such is highly suited to the use of digital images for diagnostic and disease management purposes [13].

The benefits of teledermatology are immense. Same-day access to dermatology opinion allows primary referral physicians, especially those in rural and regional areas, increased access to specialist services to improve their diagnosis, initiate treatment and reduce morbidity and mortality related to misdiagnoses or treatment delay [17, 18]. Successful programmes initiated in Queensland, Australia, revealed the highest number of external referrals came from a rural hospital, located 1200 km from the nearest dermatology clinic and that junior physicians represented the majority of referring clinicians [19]. Decreasing the number of second referrals to a dermatologist produces a reduction in cost burden with savings in patient travel times and wait times [18]. Teledermatology may also help address projected dermatology workforce shortages.

However, the limitations of teledermatology should be recognised. Live interactive teledermatology requires more initial financial investment compared to store and forward technology and is at the mercy of provider networks that may be unpredictable in rural areas and provide poor image quality [17]. Technological advances, increased consumer use of smart phones, increasing use of email, faster internet speeds and maturation of electronic health records may mitigate these downsides [20]. Medicolegal risks involving patient privacy and confidentiality are inherent in use of personal phones and emails as platforms to relay potentially sensitive patient information. Practitioners attempting to limit their legal liability in the event of a breach of privacy should demonstrate that reasonable measures were taken to protect patient information. This includes obtaining patient consent before using teledermatology, blocking auto-uploads of clinical images from clinician's devices, encrypting or password-protecting images before transmission, deleting any patient information from personal email accounts or devices after use and securely storing any video recording of consultations [13]. Use of hospital or hospital-approved camera devices, work emails and institution-approved messaging platforms is preferred over personal equipment.

Investigation and Diagnosis

Definitive diagnosis can be difficult to make clinically in some cases. Excisional biopsies of any suspicious lesions are necessary for definitive diagnosis. Often, biopsy is not logistically possible in a busy ED, and responsibility falls to the local general practitioner, dermatologist or surgeon. Clear communication between the ED and the local physician (ensuring precise documentation of the lesion so both physician and patient are aware of its location) and educating the patient on the importance of following up this appointment to have the lesion biopsied is essential. Disadvantaged groups may benefit from having these appointments organised for them to improve compliance. If admitted, seeking consultation from inpatient dermatology or surgical teams can expedite the investigation and management of suspected lesions.

If melanoma has been considered as a diagnosis, the patient should be examined for evidence of regional or systemic dissemination. This involves palpation of draining lymph nodes and exclusion of hepatosplenomegaly in the first instance. Urgent biopsy and appropriate investigation and treatment should occur.

Metastasis of melanoma occurs through regional lymph node disease in 63%, direct haematogenous spread in 24% and satellite deposits in 13% as their first site of metastasis [21].

Treatment

The recommended initial management of any suspected melanoma is complete excisional biopsy with 2 mm margin into the subcutis. Lesions that are small and appear minimally invasive may be amenable to techniques such as deep shave excision (saucerisation) or punch excisional biopsy; however, these may risk deep or lateral margin involvement and require skill and practice to perform reliably. Partial biopsy techniques should be avoided if possible.

The most important prognostic factor remains Breslow depth – the degree to which the lesion has penetrated into the skin. This is shown by diagram in Fig. 14.7.

The depth of subsequent wide local excision for melanoma is dependent on maximum Breslow thickness.

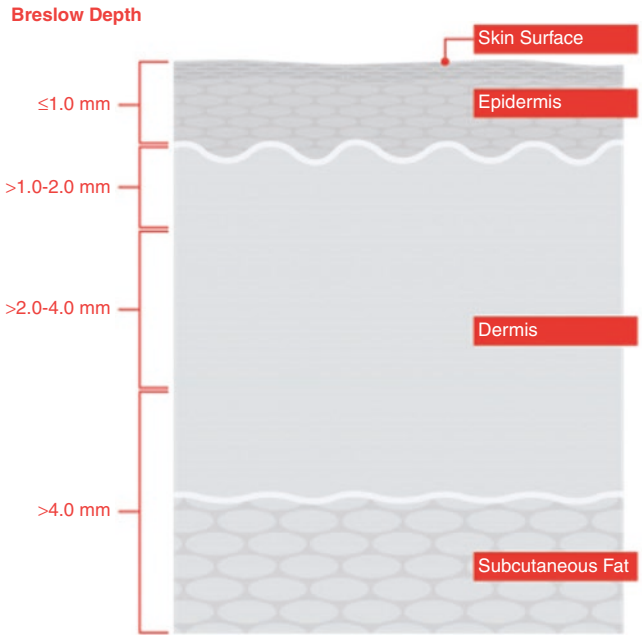

Fig. 14.7 Breslow thickness (Courtesy and with permission of the Melanoma Research Alliance, Washington, DC)

Table 14.2 Breslow thickness and 10-year survival [23]

Breslow thickness (mm)	Recommended clear surgical margin	10-year survival
In situ	5–10 mm	–
<1	1 cm	92%
1.01–2	1–2 cm	80%
2.01–4	1–2 cm (2 cm suggested when possible to achieve, particularly if concerning high-risk features)	63%
>4	2 cm	50%

Recommended clear margins for increasing depth are detailed in Table 14.2 [22, 23].

Metastatic risk and subsequent mortality are strongly linked to the Breslow depth. Those with in situ or very superficial melanoma (<0.78 mm) will have high (95–100%) 5-year survival rates. Thicker lesions or metastatic lesions predict poorer survival (see Table 14.2). The most recent classification guidelines also take into account other factors such as localised tumour characteristics (ulceration, mitotic rate), lymph node involvement, metastasis location and biochemical blood markers such as lactate dehydrogenase.

There is no uniform indication for performing a sentinel lymph node biopsy in patients diagnosed with cutaneous melanoma. Current Australian recommendations suggest that melanomas with >1 mm Breslow depth or >0.8 mm with high-risk features will benefit. High-risk features include presence of mitoses, ulceration or lymphovascular invasion or age <40 years old [24]. Sentinel node biopsy provides useful prognostic information, but is not recommended for all cases due to complications associated with the general anaesthesia and documented risks of seroma, infection, false negatives (higher in certain locations such as head and neck) and lymphedema.

The role of PET or CT scanning is dependent on stage of disease. Patients with asymptomatic Stages 1–2 (localised disease with no sentinel lymph node positivity if applicable for testing) are not recommended for further investigation, only routine follow-up with full skin checks every 6–12 months [25]. Patients with sentinel lymph node positivity or thick tumours with high-risk features should be considered for imaging on a case-by-case basis, or if specific symptoms suggestive of metastasis exist (in consultation with medical oncologic).

The Future of Diagnosis

Research involving artificial intelligence (AI) to develop algorithms that diagnose early melanoma as well (or better) than physicians has sparked much debate over the benefits and harm of incorporating this technology into clinical practice [26]. The potential benefits of AI are numerous; however, more research is needed, and governance needs to be established, prior to implementation of AI into clinical practice. Given the ethical and medicolegal issues involved, it will be important to maintain close clinical oversight when AI is employed. Its best current use may be as a supplement to clinician diagnosis. AI cannot substitute for the physician's ability to integrate historical data with physical examination findings in generating a differential diagnosis and management plan. Clinical assessment is a multifactorial, unpredictable and complicated process. However, with technological advancement this may change. The challenge of preventing diagnostic skill decay in AI-assisted dermatology must be recognised as well as the potential risk for layperson misuse of downloadable smartphone applications [27].

The diagnostic accuracy of AI is limited by the accuracy of histopathological diagnoses that feed into its algorithms and neural networks. While pathologist-interpreted diagnoses are considered the current gold standard, there is clear acknowledgement that interobserver variability exists, particularly with "borderline" lesions (Lallas, Elmore) [26, 28]. Further research is required before the integration of AI into mainstream clinical practice.

Primary Prevention

Numerous primary prevention strategies to reduce UV radiation exposure to the general population exist worldwide. From community awareness campaigns to workplace education, as well as legislation against tanning bed use, these policies have resulted in a higher early detection rates for melanoma.

Fig. 14.8 Can you spot a skin cancer? Community awareness campaign poster (Courtesy and with permission of SunSmart, Cancer Council Western Australia)

Sunscreen contains chemicals that absorb and reflect UV radiation. The sun protection factor (SPF) measures a sunscreen's effectiveness at protecting against sunburn [29]. Effective sun protection health campaigns target the population on an individual, workplace and community level. In Australia, one of the most successful health campaigns was launched by Cancer Council Australia, a non-government organisation, in 1981. Their "Slip, Slop, Slap" campaign has evolved into a multicomponent programme targeting both primary and secondary screening practices. It advocates regular skin checks at an individual level and provides advice and resources (e.g. factsheets and online courses) for schools, early childhood facilities, workplaces, sport groups, community events and health professionals, as well as local government. Figure 14.8 is of a poster targeting regular skin checks as part of the "Slip, Slop, Slap, Seek, Slide" sun protection campaign. In 2019, nearly 40 years after the launch of this health campaign, Australia achieved its highest rate of early melanoma detection, with over 90% of cases diagnosed as Stage 1 or 3 [1]. Melanoma has near 100% 5-year survival when diagnosed at Stage 1.

Sunbed (tanning bed) use is associated with a significant increase in melanoma risk. This risk increases with the number of tanning sessions and with initial exposure at a young age (<35 years) [30]. In 2003, the World Health Organisation published *Artificial Tanning Sunbeds: Risk and Guidance*, outlining the role of UV radiation from the sun and artificial sources in the development of skin cancer (https://www.who.int/uv/publications/sunbedpubl/en/). Subsequently, legislative changes in Brazil and Australia led to a ban on the commercial use of tanning beds.

Other sun protection regimes include municipal planning policies outlining the importance of access to services and facilities providing protection from solar UV radiation, such as shade provision in public places like bus stops, parks, playgrounds and sporting and recreational facilities. Signage at community events encouraging sun protection is also encouraged.

Health professionals prescribing medications known to cause photosensitivity such as certain antibiotics, antiarrhythmics and antihistamines should counsel patients to avoid direct sunlight while taking these medications as well as about the importance of SPF in sunblock choice. Similarly, care for patients presenting to the ED with UV radiation (i.e. sunburn) should include opportunistic counselling regarding sun protection in the future.

Secondary Screening

Secondary prevention or early detection by means of full skin examinations is recommended, especially for individuals at high risk of melanoma. A structured surveillance protocol with 6 to 12 monthly full skin examinations, supported by total body photography and dermoscopy, is proven to be beneficial both clinically and economically [6]. There is no general consensus on timing of first skin check and intervals between skin checks. Educating high-risk individuals to recognise and document suspicious lesions is recommended [31].

Full skin examinations in the ED are not routinely completed due to time constraints and lack of follow-up by the same physician. Identification of a suspicious lesion opportunistically in the ED warrants follow-up through referral to dermatology or to a general practitioner for consideration of biopsy. However, presentation to an ED by at-risk populations with poor health literacy may be the only opportunity to diagnose, educate and encourage urgent follow-up of high-risk individuals.

Part III

Evaluation and Treatment

Acute Airway Obstruction

15

Christopher H. Chang and Lakshmi Mudambi

Case Study

*A 65-year-old male presented with 2 months of large-volume hemoptysis. Prior medical history included Child-Pugh Class B cirrhosis with thrombocytopenia and hypothyroidism. He was an active smoker with a 110 pack-year smoking history. Computed tomography showed a right upper lobe mass extending into the right mainstem and post-obstructive pneumonitis of the right upper lobe (*Fig. 15.1*, arrow). A positron emission tomography (PET) scan showed no distant or nodal metastasis (*Fig. 15.2*). Rigid bronchoscopy was performed to debulk and cauterize the tumor (before and after therapeutic bronchoscopy pictures), which controlled the hemoptysis. The patient was not a candidate for surgical resection due to his poor functional capacity and advanced hepatic disease, so he underwent definitive radiotherapy for a cT2aN0M0 squamous cell carcinoma of the right upper lobe.*

Introduction

Malignant central airway obstruction (MCAO) is defined as a mechanical obstruction of the trachea or either mainstem bronchi impairing airflow to the lungs due to a malignant neoplasm.

Epidemiology

The most common cause of MCAO is a primary lung cancer with approximately 20–30% of patients with lung cancer developing symptoms related to central airway obstruction. MCAO can also occur due to metastasis from a solid organ malignancy, most commonly breast cancer, colorectal can-

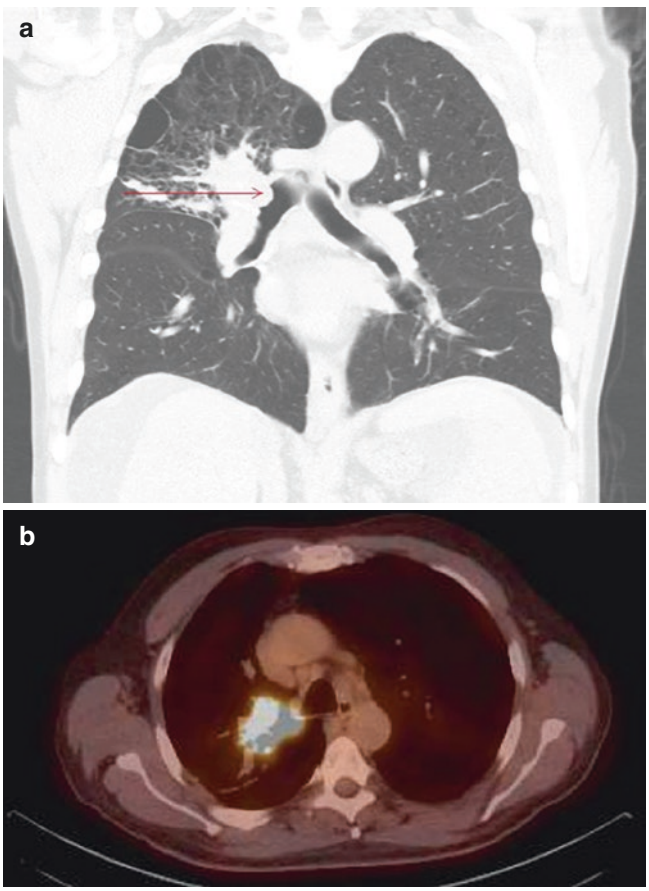

Fig. 15.1 (**a**) Computed tomography revealed a right upper lobe mass extending into the right mainstem (*arrow*) and post-obstructive pneumonitis of the right upper lobe. (**b**) A positron emission tomography scan showed no distant or nodal metastasis

cer, and renal cancer [1]. It can result from external compression or direct invasion from tumors of adjacent structures such as the esophagus, thyroid, and mediastinum [2]. Other causes of MCAO include carcinoid tumors, which account for the majority of primary tumors distal to the main carina, and primary malignancies of the trachea [3], such as squamous cell carcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma.

Classification

Bronchoscopy is used to characterize the appearance of the tumor and may be classified as an endoluminal (intrinsic), extraluminal (extrinsic), or mixed tumor. Endoluminal obstruction is caused by an exophytic lesion growing into the lumen of the airway. Extraluminal obstruction occurs when a tumor that is adjacent to an airway compresses the lumen. When both endoluminal and extraluminal obstruction occur from a tumor, it is classified as a mixed obstruction. The distinction between these types of obstructions is critical to developing a management strategy.

Presentation

The presentation of MCAO is variable, ranging from asymptomatic to catastrophic. Patients with MCAO present with a persistent dry or productive cough, dyspnea with exertion or at rest, wheezing, hemoptysis, or post-obstructive pneumonia. Stridor at rest suggests a tracheal diameter of less than 5 mm [4]. The diagnosis of MCAO can be elusive as many of these symptoms overlap with other diseases such as asthma, chronic obstructive airways disease, and pneumonia.

The development of dyspnea in an individual with MCAO is the result of an intricate interaction of multiple factors (Fig. 15.3). The sensation of dyspnea from a central airway obstruction is postulated to occur from the increased effort required to maintain airflow through a narrowed lumen [5]. Significant airway obstruction is defined as an endoluminal diameter of <50% of normal, but individuals who are otherwise healthy enough to generate sufficient negative intrathoracic pressure to overcome the increased airflow resistance are often able to tolerate much greater degrees of obstruction without symptoms. Factors such as the increased metabolic demand, cachexia from cancer, and the presence and severity of cardiac, pulmonary, and renal comorbidities also contribute to the sensation of dyspnea. Interestingly, some patients with significant MCAO and severe comorbidities may report being minimally symptomatic but only by limiting their activities.

Some symptoms may be dramatic and warrant urgent or emergent intervention. Hypoxemia that is refractory to supplementary oxygen or noninvasive ventilation can occur suddenly due to acute lobar atelectasis or after a period of slowly progressing dyspnea. Massive hemoptysis or hemoptysis associated with respiratory compromise creates urgent clinical situations that require immediate action. Post-obstructive pneumonias may not be responsive to antibiotics without relief of obstruction, can progress to sepsis, and preclude treatment with systemic chemotherapy.

Acute airway obstruction may also arise from complications related to prior treatment of MCAO. For example, radiotherapy is used extensively in the treatment of intrathoracic malignancies, and several reports of high-grade toxicities of the airways such as massive hemoptysis, airway necrosis, bronchial stenosis, and fistulas leading to central airway obstruction have been documented [6–9]. Airway stents can also lead to respiratory distress due to complications such as stent migration, stent fracture, and obstruction of the stent

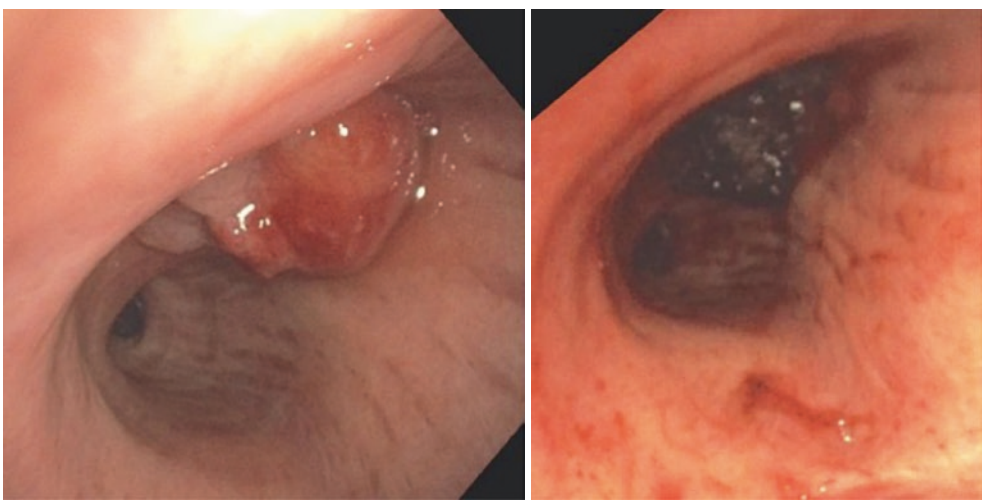

Fig. 15.2 Before (*left*) and after (*right*) images from therapeutic bronchoscopy in which the mass tumor was debulked and cauterized

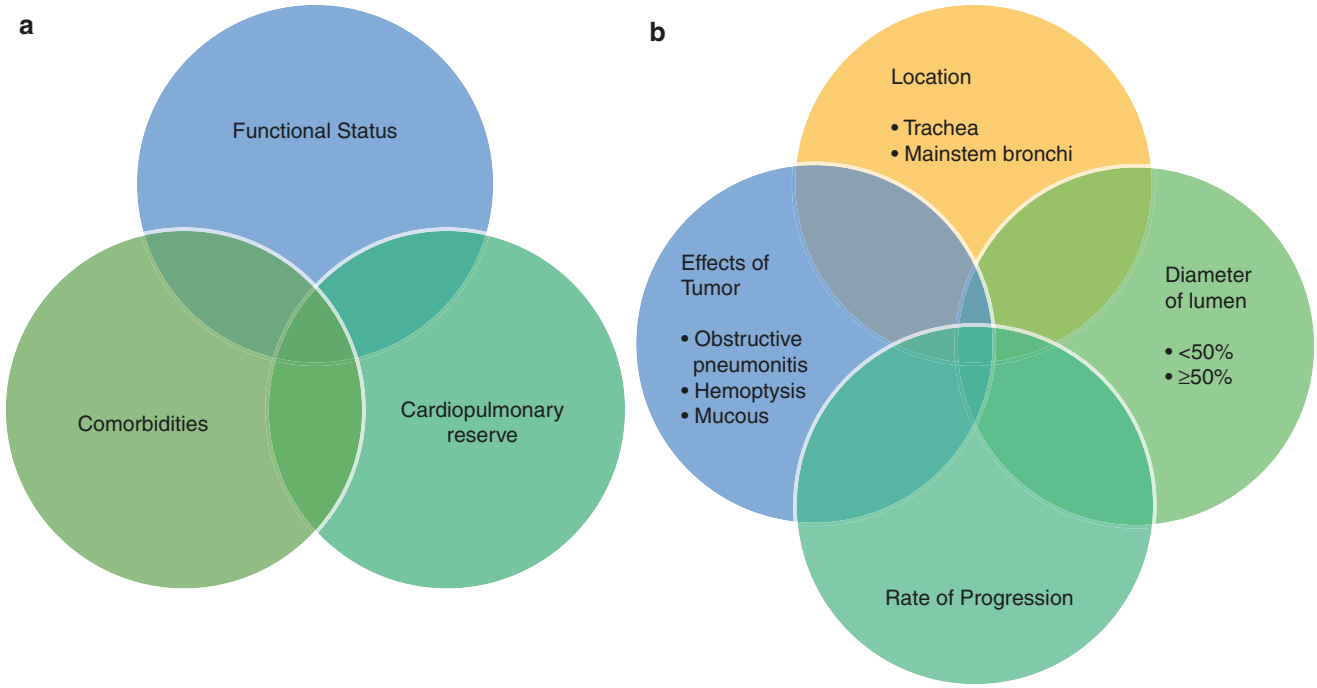

Fig.15.3 (**a**) Patient characteristics involved in the development of symptoms in malignant central airway obstruction (MCAO) (**b**) Tumor characteristics involved in the development of symptoms in MCAO

with mucous plugs or granulation tissue [10]. Although these situations cannot be purely designated as MCAO, it is reasonable to include them in this context since they present in the same patient population and can be life-threatening.

Evaluation

In addition to obtaining a complete history and performing a thorough clinical examination, radiographic imaging and bronchoscopy are useful tools to evaluate MCAO. Although plain radiographs are not very sensitive to detect MCAO, they may be the only imaging modality tolerated by a patient in respiratory distress. Plain radiographs can help determine laterality of the malignancy and show lobar or lung collapse, compression of the large airways, and lung masses. A computed tomography of the chest provides valuable information regarding the extent, location, morphology, and relationship of the tumor with surrounding structures, which is necessary for procedural planning [11, 12]. It is also useful to review prior imaging as the information obtained about the progression and rate of growth of a tumor can aid decision-making for both management and prognostication. Although flexible bronchoscopy is the gold standard diagnostic tool to assess MCAO, extreme caution must be employed as even gentle manipulation of a critical malignant airway obstruction can cause bleeding and edema resulting in an airway emergency, especially if immediate access to equipment and skilled personnel are unavailable to manage these compilations. In patients with large anterior mediastinal masses, the use of sedatives and paralytic agents for intubation, bronchosocpy or other procedures can cause complete airway collapse and respiratory arrest due to extrinsic compression of the airways [13]. In such situations, it is important to establish an airway that traverses the collapsed segment and can be secured either by an awake bronchoscopic intubation, rapid sequence intubation or rigid intubation.

Management Overview

The approach to the management of MCAO begins with an assessment of symptoms and the extent of disease. Interventional pulmonology, thoracic surgery, otorhinolaryngology, and interventional radiology play collaborative and complementary roles in the management of MCAO depending upon location and presenting symptoms. In a true emergency, resuscitation and stabilization are the primary aims. In impending or complete obstruction without access to specialized care, awake bronchoscopic intubation with a small-diameter, wire-reinforced endotracheal tube is an effective method to secure an airway in a critical malignant obstruction proximal to the main carina. Bronchoscopic guidance helps prevent excessive trauma to the tumor, thereby reducing the risk of hemorrhage while advancing the endotracheal tube past the obstruction. Rarely, in patients with dyspnea without significant hypoxemia, heliox can be used to reduce

resistance to airflow across the malignant obstruction as a bridge to therapeutic bronchoscopy.

It is paramount to objectively define goals of an intervention in MCAO. Aside from addressing urgent or emergent clinical situations, therapeutic bronchoscopy has been shown to improve dyspnea, spirometry, walk distances, survival, and, most importantly, quality of life [14–17]. Additionally, patients with greater dyspnea and poorer functional status derive the most benefit from therapeutic bronchoscopy [18]. A large, prospective review from the multicenter AQuIRE registry showed that complication rates of therapeutic bronchoscopy are low, averaging 3.9%; however, there is significant variability between institutions (0.9–11.7%) [19]. Although overall survival in MCAO is dependent upon the underlying malignancy, therapeutic bronchoscopy can bring significant relief and comfort as a palliative intervention [20].

In operable patients with MCAO and minimal symptoms, it may be reasonable to proceed to surgery as the first step with the goal of curative treatment (Fig. 15.4). Sometimes, symptoms like large-volume hemoptysis necessitate therapeutic bronchoscopy to prevent complications such as respiratory failure before considering treatment for the underlying malignancy (Fig. 15.5). The lobar airways distal to the central obstruction should be patent and spared from tumor infiltration when contemplating therapeutic interventions to alleviate dyspnea and recanalize the lumen. This can usually be identified on cross-sectional imaging and bronchoscopy, using thin scopes to explore past the central lesion (Fig. 15.6). Patency of distal airways, either on CT or bronchoscopy, has been identified as predictors of a successful therapeutic bronchoscopy to relieve MCAO [18, 21]. Control of hemoptysis

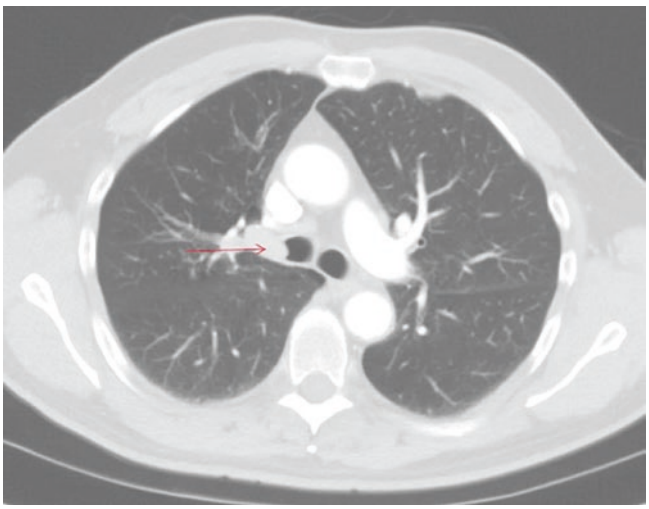

Fig. 15.5 61-year-old male with large-volume hemoptysis and respiratory distress. Computed tomography of the chest showed a well-circumscribed 2.5 cm nodule in the right upper lobe bronchus extending into the right mainstem (*arrow*). A rigid bronchoscopy was performed to debulk and cauterize the tumor. Two months later, he underwent a video-assisted thoracoscopic lobectomy for a pT1bN0M0 squamous cell carcinoma of the right upper lobe

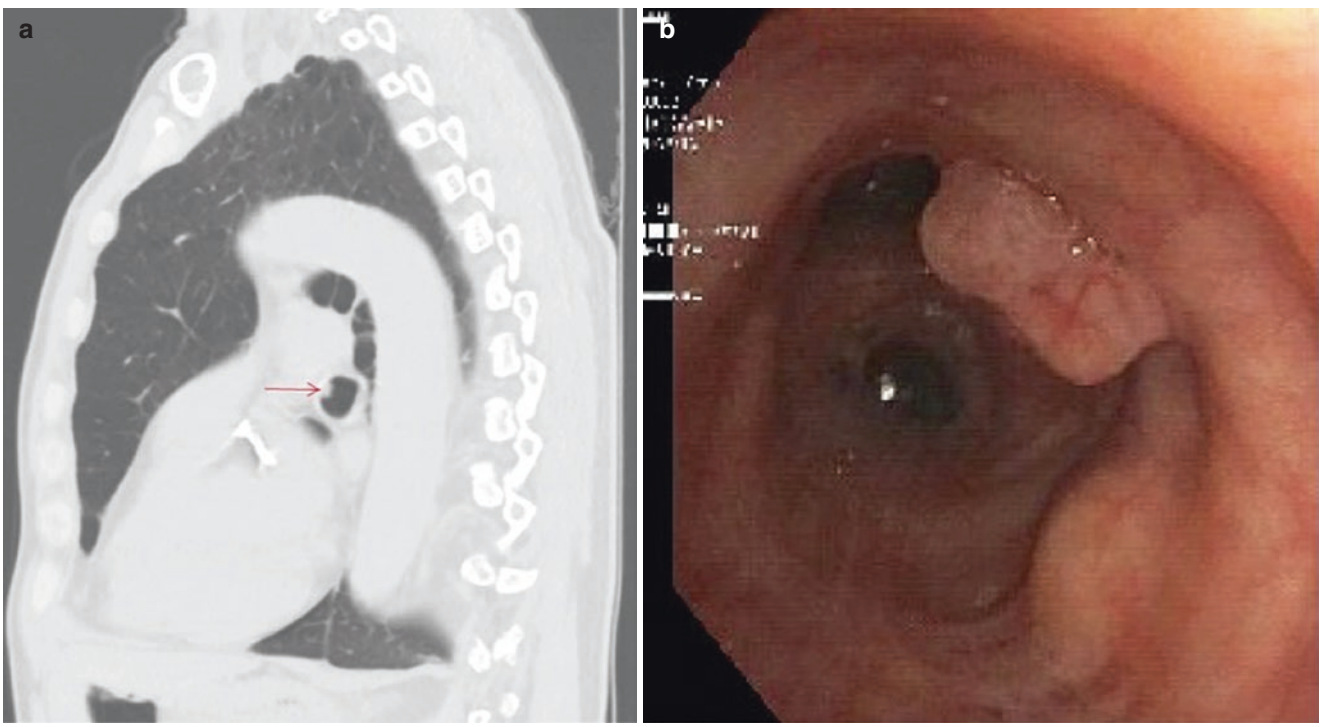

Fig. 15.4 61-year-old male with a new left mainstem sessile polyp on computed tomography of the chest (**a**, *arrow*). Prior history of pT1N1M0 squamous cell carcinoma of the oropharynx treated with surgery. Bronchoscopy revealed an endoluminal nodule and biopsy showed a non-small cell carcinoma with mucoepidermoid features (**b**). He underwent a thoracotomy with left mainstem sleeve resection

and an attempt to salvage contralateral lung are indications to intervene with therapeutic bronchoscopy, even when there is involvement of lobar bronchi (Fig. 15.7).

Management of massive or symptomatic hemoptysis is a harrowing clinical situation that can complicate MCAO. In symptomatic, alert patients maintaining their airway by coughing out blood, it is important to be completely prepared to assume control of the airway for intubation before paralyzing the patient as blood can quickly fill the trachea and mainstem bronchi leading to respiratory arrest. Visualization of the vocal cords can be difficult with direct laryngoscopy due to pooling of blood in the hypopharynx; video laryngoscopic and bronchoscopic visualization during intubation are useful adjuncts to secure an airway [22]. Tilting the patient toward the side of the bleed minimizes the blood flowing into the unaffected lung until the affected side can be isolated with an endobronchial blocker or contralateral mainstem intubation with a large endotracheal tube. If the cause of hemoptysis is known to be an endoluminal or mixed tumor and rigid bronchoscopy is readily available, the plan should be to proceed with rigid bronchoscopy as soon as possible. Bronchial artery embolization (BAE), a technique of selectively embolizing dilated or ecstatic bronchial arteries supplying tumors, must be considered if rigid bronchoscopy is not available, in cases of bleeding due to extraluminal

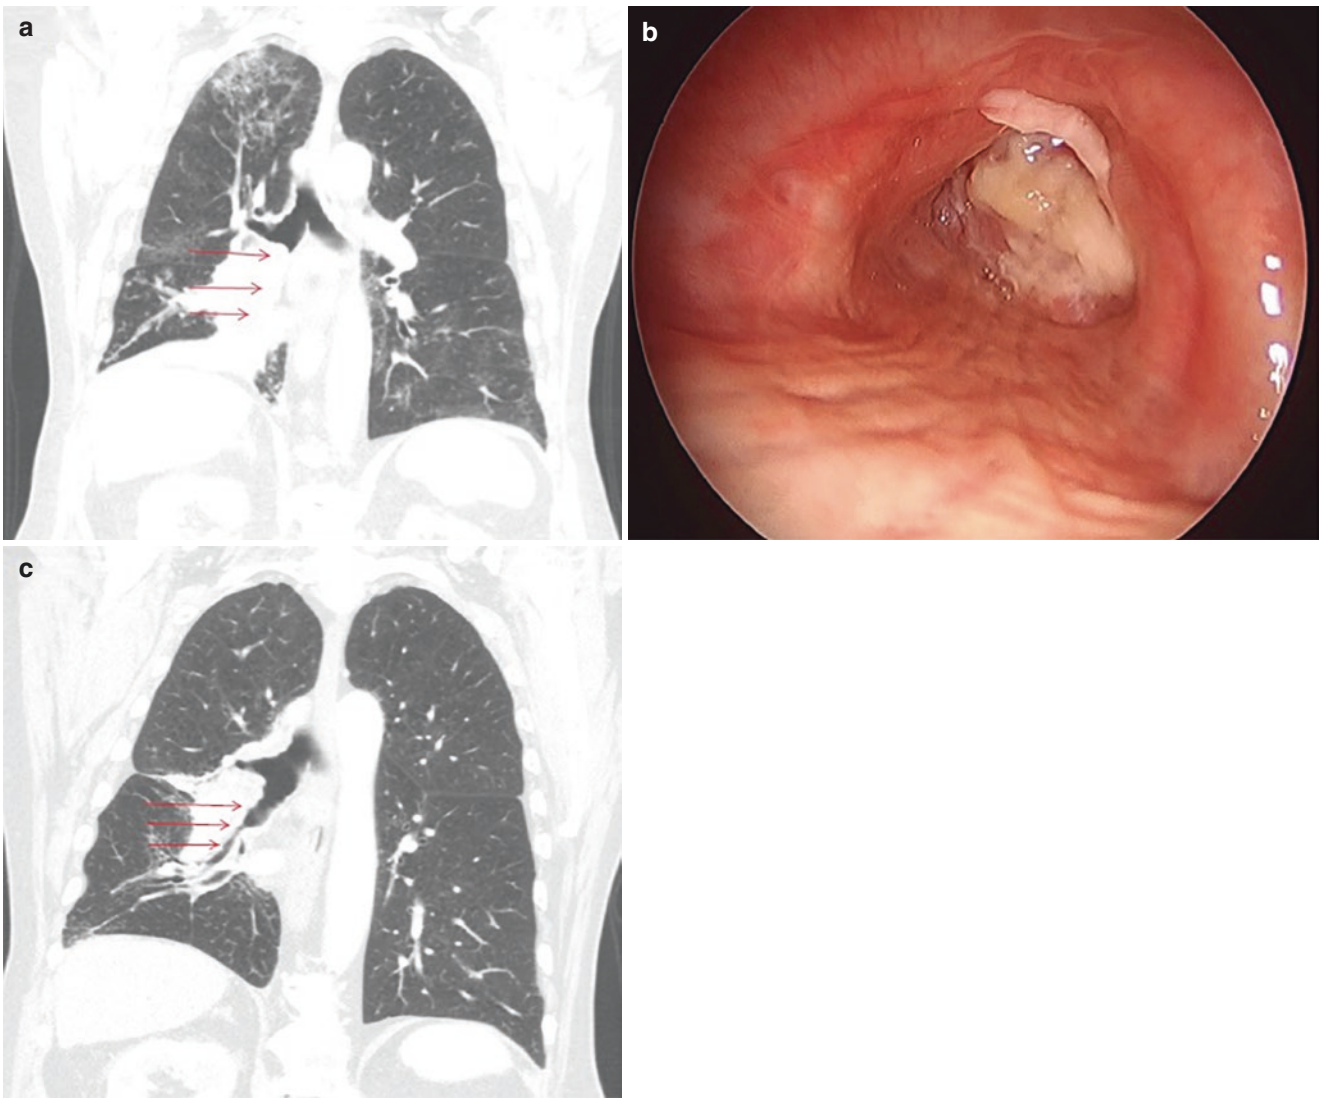

Fig. 15.6 73-year-old male with dyspnea and unresolving pneumonia of the right lower lobe. Computed tomography of the chest showed a mass in the right bronchus intermedius (**a**, *arrows*). Rigid bronchoscopy showed complete obstruction of the right bronchus intermedius with an endoluminal tumor (**b**). The right middle lobe and right lower lobe anterior segment were patent when the thin scope passed by the central tumor. The tumor was debulked with improvement in dyspnea and right lower lobe pneumonia, and he received definitive chemotherapy and radiotherapy to cT3N0M0 of the right bronchus intermedius. No evidence of recurrence 2 years after treatment on computed tomography of the chest (**c**; *arrows show patent right bronchus intermedius and radiation changes*)

MCAO or as a bridge to rigid bronchoscopy or surgery. BAE boasts high rates of immediate control of bleeding (>90%) [23, 24]. Recurrence after BAE occurs between 1% and 50% of cases and should be combined with definitive or palliative treatment of the underlying malignancy (surgery or radiation therapy) to prevent further episodes of hemoptysis [25]. Emergent surgical management of massive hemoptysis is associated with high mortality ranging from 15% to 25%. A single-center retrospective study of patients with massive hemoptysis showed that adopting BAE to control hemoptysis prior to surgery reduced mortality significantly [26]. Finally, the importance of correcting thrombocytopenia and coagulopathies as well as the reversal of antiplatelet agents and anticoagulants to control hemoptysis cannot be stressed enough.

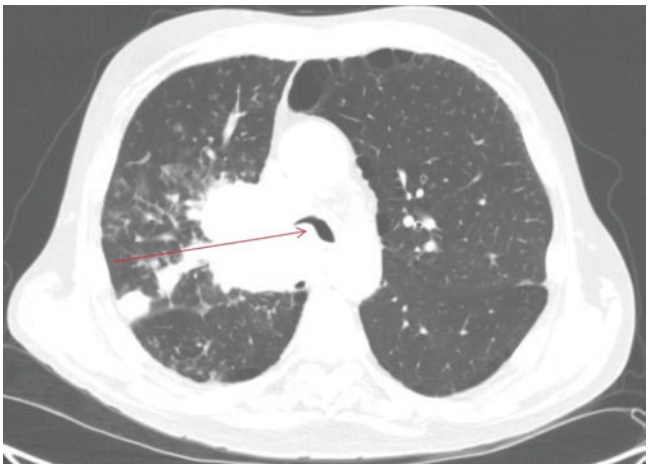

Fig. 15.7 Elderly male with an endoluminal squamous cell carcinoma, cT2aN2M0 of the right upper lobe extending slightly into the right mainstem presenting with large-volume hemoptysis. After rigid bronchoscopy, debulking, and cautery of the tumor, the patient declined all treatment options. He presented one year later with dyspnea due to tumor infiltration of right mainstem, right bronchus intermedius, and main carina with extension across the midline over the left mainstem. Post-obstructive pneumonitis seen in the right upper lobe distal to the large right hilar mass (shown in computed tomography of the chest). He underwent rigid bronchoscopy with successful recanalization of the right mainstem and right bronchus intermedius followed by palliation radiation to prevent obstruction of the left mainstem. He passed away one year later

Therapeutic Bronchoscopy: Tools

It is necessary to possess extensive knowledge about the unique characteristics of the tools used in therapeutic bronchoscopy to treat MCAO. Classic tools, such as the rigid bronchoscope, serve as foundational equipment through which interventions are performed safely. Other technologies have been adapted and customized for use in the airways from allied medical fields. The tools available can be classified into three broad categories: (i) mechanical tools, (ii) thermal tools, (iii) cold tools, and (iv) stents (Fig. 15.8).

Most MCAO require a variety of tools to reach the desired outcome of airway recanalization. To mitigate the perils of hemorrhage, endoluminal tumors are routinely cauterized prior to mechanical debulking or are debulked using tools that employ electrocautery. For extraluminal tumors, dilation followed by stenting is the only endoscopic method available to establish patency of the lumen.

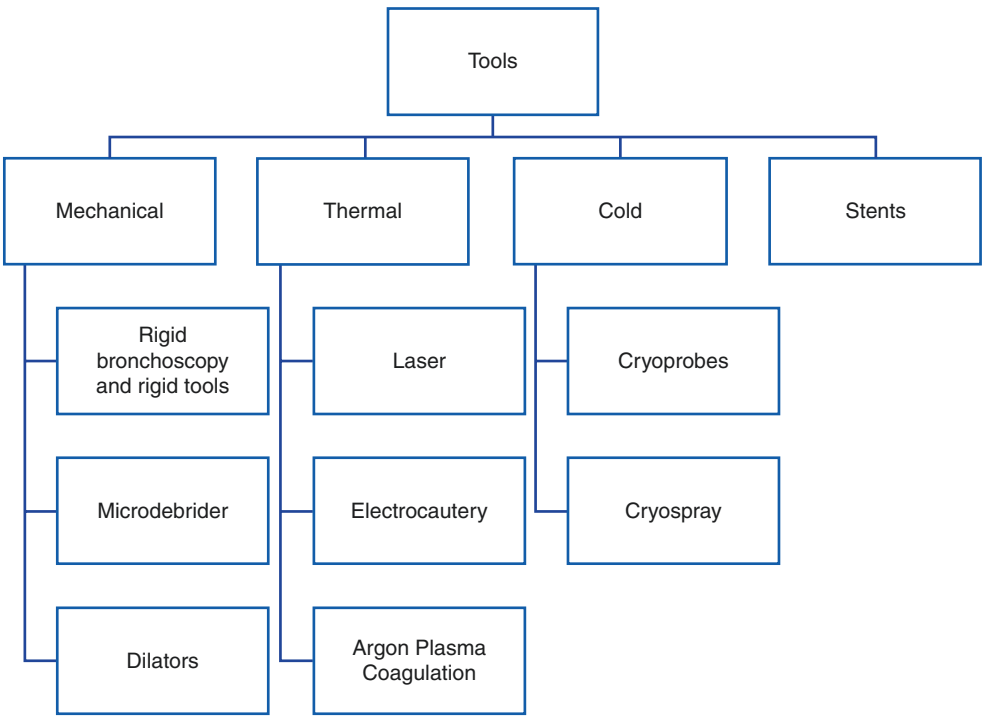

Fig. 15.8 Tools for therapeutic bronchoscopy

Mechanical Debulking

Mechanical debulking can be accomplished using a variety of rigid or flexible tools. The main advantage of this modality is that it allows rapid debulking without requiring a reduction in the fraction of inspired oxygen. This section will focus on a few prominent mechanical tools to address MCAO.

Rigid Bronchoscopy

Invented in the late 1800s to remove foreign bodies from airways, the rigid bronchoscope is now considered a fundamental tool for therapeutic airway interventions. The rigid bronchoscope has dual purposes. It is a straight, hollow, metal tube with a large lumen allowing the use of single or multiple, flexible, and rigid equipment. Additionally, the distal end of the bronchoscope has ventilatory side ports to allow ventilation while performing interventions. It is recommended to use the rigid bronchoscope for most therapeutic bronchoscopic interventions. The rigid bronchoscope is inserted into the airways under direct visualization with a rigid telescope. Some common methods of ventilation with the rigid bronchoscope include jet ventilation (manual or automatic, high or low frequency), spontaneous-assisted ventilation, and controlled mechanical ventilation [27]. The tip of the rigid bronchoscope is beveled and can also be used to "core" out endoluminal tumors. A variety of rigid instruments such as the rigid forceps, rigid electrocautery, rigid dilator, and high-volume suction catheter can be inserted through the rigid bronchoscope. The rigid scope also acts as the conduit for the microdebrider and insertion or removal of airway stents, which will be discussed later in this chapter.

Microdebrider

The microdebrider consists of a rotating cutting blade within a rigid metal suction catheter that is connected to a power console. The suction pulls tumor tissue into the rotating blade for resection and removes blood clots and debris out of the plane of view. The bronchial microdebrider blade can be used to resect tumors from the trachea and proximal mainstem bronchi with a high degree of success [28–33]. In skilled hands, complications are rare, but this device should be used cautiously as perforation of the airway walls and surrounding vascular structures could occur.

Dilators

Airway dilators can be rigid (used through a rigid bronchoscope) or flexible (disposable). Dilators are used to create a lumen in extrinsic compression (extraluminal or mixed airway obstruction) prior to deployment of a stent in MCAO. Radial expanding balloon dilators are available in many sizes and can be used with or without wire guidance through the working channel of a therapeutic flexible bronchoscope.

Thermal Tools

Thermal energy delivered through thermal tools, such as electrocautery, laser, and argon plasma coagulation, produce a variety of effects upon tissue based on the temperature generated by the instrument. Coagulation is useful both prior to debulking to devascularize tumors and after to control hemostasis at the base of the tumor. Temperatures must reach 60 °C at the tissue to produce a coagulation effect. For all thermal tools, there is a risk of an airway fire, so the fraction of inspired air should be less than 0.4 during application.

Laser

Lasers are used for their abilities to cut, coagulate, and vaporize tissue with each type of laser varying in its efficacy of these properties. The depth of penetration is determined by the laser beam's wavelength, distance from the tissue, and tissue absorbance. The neodymium-doped yttrium aluminum garnet (Nd:YAG) laser is most commonly used in MCAO management as it has excellent coagulation and ablative properties. Given the deeper penetration of lasers compared to other tools, there is an increased risk of airway perforation and fistula formation. A large retrospective case series reported success rates as high as 90% when recanalizing an obstructed airway using laser [34].

Electrocautery

Electrocautery utilizes heat that is generated when an electric current is met with resistance. A "coagulation current" is created when electricity is applied in alternating currents. This produces bursts of high-voltage peaks of energy resulting in thermal damage and coagulation. When a "cutting current" or

sinusoidal non-modulated waveform is used, it creates a higher average power that allows for smooth cutting and minimal thermal damage. A "blended current" alternates between cutting and coagulating currents. Given the heterogeneity of tissue composition – and subsequently its resistance – the effects of electrocautery can be unpredictable. Complications are rare but may include airway perforation, airway fire, airway stenosis, hemorrhage from damage to vascular structures and deprogramming of an implanted cardiac device. Newer high-frequency generators allow for more precise control of the power delivered and an automatic safety switch if temperatures reach 100 °C to prevent the formation of exploding steam pockets. A variety of electrocautery tools exist (e.g., rigid and flexible probes, snares, forceps). The tip of electrocautery tools must be cleaned frequently to maintain sufficient direct contact with tissue. Retrospective studies have shown good efficacy of electrocautery in the management of malignant and benign CAO, with the largest study reporting significant recanalization by bronchoscopic exam in 94% of cases and improved aeration on computed tomography in 63% of cases [35].

Argon Plasma Coagulation

Argon plasma coagulation (APC) is a type of noncontact monopolar electrosurgery used in the airways for over two decades [36, 37]. As argon gas passes by a high-frequency electrode, it is ionized into a plasma field between the electrode and nearby tissue leading to coagulation and desiccation. Different probe tips may direct the argon plasma flow forward, laterally or circumferentially. The effect on tissue can be modified by changing the gas flow rate, power, and mode of energy delivery. APC acts more superficially than other thermal therapies, and the resulting coagulated and desiccated tissue adds another layer of resistance in reaching the deeper, unaffected tissue. Although rare, APC can cause fatal gas embolisms particularly at higher flow rates and longer pulse durations [38].

Cold Tools

Cryotherapy: Cryoprobe and Cryospray

Certain gases (such as carbon dioxide and nitrous oxide) rapidly expand when moving from a high-pressure to low-pressure environment causing a drop in temperature. This is called the Joule-Thompson effect and is the basis of cryotherapy. Of the two modalities of cryotherapy available for bronchoscopy, the cryoprobe is the preferred method used to quickly reestablish patency of the lumen in acute symptomatic endoluminal or mixed MCAO. In cryo-recanalization, the tip of the cryoprobe is placed in contact with the tumor and activated to freeze the tissue until it is adherent to the probe. The tissue, probe, and bronchoscope are gently pulled away en bloc and removed from the airways without touching the airway walls. The advantage of this method is that it does not necessitate the reduction of fraction of inspired air in patients who are hypoxemic. Several prospective and observational studies have demonstrated a 77–94% success rate of relieving the obstruction by 50–100%. The most common complication seen in these studies was mild to moderate bleeding controlled with APC and/or electrocautery (4–10% of cases) [1, 39].

Cryospray or cryoprobe can be used to treat inoperable lung cancer of the airways or in situ lesions of the mucosa by applying repeat freeze-thaw cycles of extremely low temperatures (below −40 °C) to tissue, which results in direct cellular damage by the repeated intra- and extracellular crystallization of the water as well as dehydration of the tissue. The cold temperatures also cause tissue ischemia through vasoconstriction, formation of microthrombi, and increased blood viscosity. This method results in recanalization slowly and cannot be used to quickly relieve symptoms of acute MCAO.

Airway Stents

Airway stenting is a palliative procedure used to maintain patency of an obstructed airway. Airway stents are broadly classified as silastic/silicone stents or metallic stents, based on the composed material. Metallic stents (self-expanding metalic stent (SEMS) or balloon expanding) may be bare (no indication in MCAO) or covered (partially or completely with silicone or polyurethane to prevent tumor growth into the stent. Silicone stents are placed and removed through a rigid bronchoscope. Metallic stents can be placed through an endotracheal tube, but when doing so, the rigid bronchoscope should be easily available for removal if the stent is not deployed correctly. The optimal stent for MCAO fits perfectly along the airway wall and is neither too large (which can incite granulation tissue due to mucosal ischemia) nor too small (which increases the risk for migration). It completely covers the tumor and extends 0.5 cm proximal and distal to the obstruction [40].

There are only a few indications for airway stents in MCAO. Firstly, symptomatic extraluminal or mixed obstruction can be stented as a bridge to definitive or palliative therapy (Fig. 15.9). All forms of recurrent, symptomatic MCAO (endoluminal, extraluminal, or mixed) that have exhausted treatment options such as radiation or surgery can be considered for airway stenting. The benefit of airway stenting in asymptomatic patients with MCAO is not clear and should be assessed on an individual basis. Finally, placing an airway stent in tracheoesophageal fistulas with airway obstruction or excessive secretions can improve symptoms but should be performed only after considering esophageal stenting first.

Several large retrospective studies on the use of stents in malignant tracheobronchial central airway obstruction have

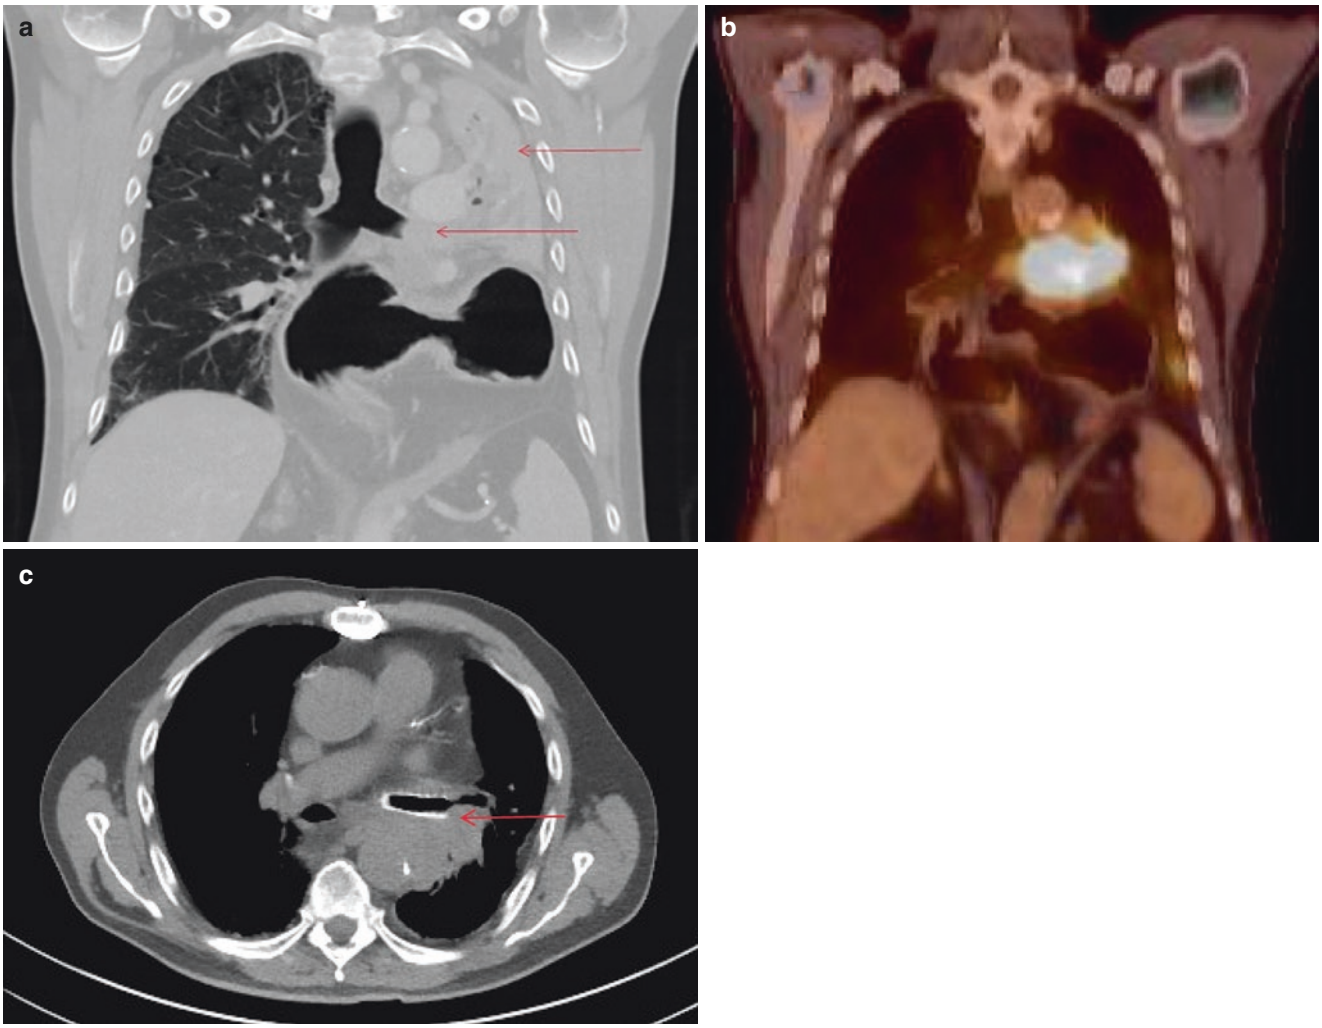

Fig. 15.9 70-year-old male with mild hemoptysis and dyspnea with exertion. Computed tomography and a positron emission tomography (PET) scan showed a large left infrahilar mass causing complete obstruction of left mainstem bronchus and collapse of the left upper and lower lobes (**a**, *arrows*), showing a large hiatal hernia that was chronic (**b**). Rigid bronchoscopy showed a mixed obstruction. The tumor was debulked, and a fully covered, self-expanding metallic stent was placed with resolution of dyspnea (**c**, *arrow*). Patient was treated with definitive chemotherapy and radiotherapy for a cT4N2M0 squamous cell carcinoma

reported on efficacy and safety of both silicone and self-expanding metallic stents but also focus on complications which include migration, obstruction from secretion, granulation, infections, and ulcerations [10, 41]. An absolute contraindication for airway stent placement is extrinsic compression from a vessel since the risk of erosion and development of a catastrophic fistula is extremely high. Overall, an airway stent is considered a useful adjunct for MCAO that must be used judiciously [42].

Conclusion

Malignant central airway obstruction can seriously impair quality of life and be life-threatening. Even in the most advanced malignancies, therapeutic bronchoscopy offers palliation of symptoms caused by MCAO. It is paramount to consider goals of intervention carefully, weighing risks and benefits with patient preferences for management. A multimodality and multidisciplinary approach to MCAO can both address the acute manifestations and provide long-term control.

Central Nervous System

16

Prashant Rai, Akhil Shivaprasad, Ivo W. Tremont-Lukats, and Sudhakar Tummala

Introduction

In this chapter, we describe central nervous system (CNS) complications of cancer commonly presenting to the emergency department (ED), including altered mental status, high intracranial pressure/brain herniation, status epilepticus (convulsive and nonconvulsive), acute ischemic stroke, intracranial hemorrhage, and cerebral venous sinus thrombosis. We also briefly discuss the effects of SARS-CoV-2 on the CNS. Many patients present with more than one problem and more than one cause. This multiplicity can make diagnosis and management difficult. The goal is to preserve life and function, achieved by early, correct diagnosis. Still, patients come late in the disease course, or these neurological emergencies unfold quickly and catastrophically. Acute mental status change is the top neurological symptom in cancer patients; it is the final common path to intracranial hypertension, epileptic seizures, infection, electrolyte abnormalities, intracranial hemorrhage, ischemic stroke, and adverse effects from drugs. The emergency physician should also be comfortable in starting discussions on goals of care and advance care planning before admission to other hospital areas.

Approach to the Patient with Altered Mental Status

Mental status is a state of wakefulness in alert persons. Changes in mental status can also affect cognition, including orientation to self, place, and time; the ability to register and recall objects (memory registration and recall after minutes); and the ability to understand and execute more complex commands, such as backward spelling or arithmetic operations (attention/concentration) and language.

Changes in mental status can occur in a patient with normal mental function or can appear against the backdrop of a chronic cognitive disorder such as dementia or mental retardation. In the medical literature, the terms altered mental status, changes in mental status, confusion, encephalopathy, and delirium are often used interchangeably. Encephalopathy and delirium are more relevant as diagnostic keywords. For simplicity, we will use delirium in this chapter for any acute change in arousal and mental function.

Frequency and Importance

In cancer, delirium is a life-threatening complication and a powerful driver of emergency services. Care providers in the ED frequently overlook delirium, with a reported misdiagnosis rate of 41% in the ED of an NCI-designated comprehensive cancer center [1, 2]. Its frequency ranges from 57 to 85% in cancer patients compared to 15–30% in medically ill hospitalized patients [3]. Among 352 cancer patients in the acute palliative care unit at The University of Texas MD Anderson Cancer Center, delirium was the most common diagnosis in 43% at admission, increasing to 70% during the entire stay [4]. At Memorial Sloan Kettering Cancer Center (MSKCC), delirium accounted for 27% of all inpatient neurology consults. This figure did not include psychiatry consults or unrecognized cases [3]. A review of 771 inpatient palliative care consults found that referring teams missed the

diagnosis in 61% of cases, of which 63% had hypoactive delirium [2].

Causes

Many patients with cancer have more than one reason for delirium [5, 6]. The most important causes in the ED are illustrated in Fig. 16.1. The first three suspects to investigate are drugs, sepsis, and organ failure [6]. Opioids and benzodiazepines are the most common drugs causing delirium in the ED, in surgical recovery rooms, and during hospitalization. It is impossible to quantify the relative weight of each drug in cases of polypharmacy, especially when accompanied by renal or liver impairment and advanced age [7].

The worldwide emergence of coronavirus disease (COVID-19) due to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is associated with higher mortality rates in cancer patients [8, 9]. A surveillance study in the UK reported AMS as the second most common neurologic complication in COVID-19, in 31% of 125 cases [10]. We currently do not have longitudinal data mature enough to estimate the frequency, course, and prognosis of delirium from COVID-19 in cancer, or whether it is from neuroinvasion, hypoxia, or both [11, 12]. The current view is that the COVID-19-related encephalopathy is the result of age, comorbidities, and the systemic inflammatory response to the infection, including adult respiratory distress syndrome (ARDS) resulting in cerebral hypoxia in postmortem examination [12, 13]. Preliminary evidence in non-cancer patients admitted to intensive care units with ARDS showed that, in addition to other neurologic findings, delirium was frequent (65%). Approximately 33% of survivors remained disoriented and inattentive after discharge [14].

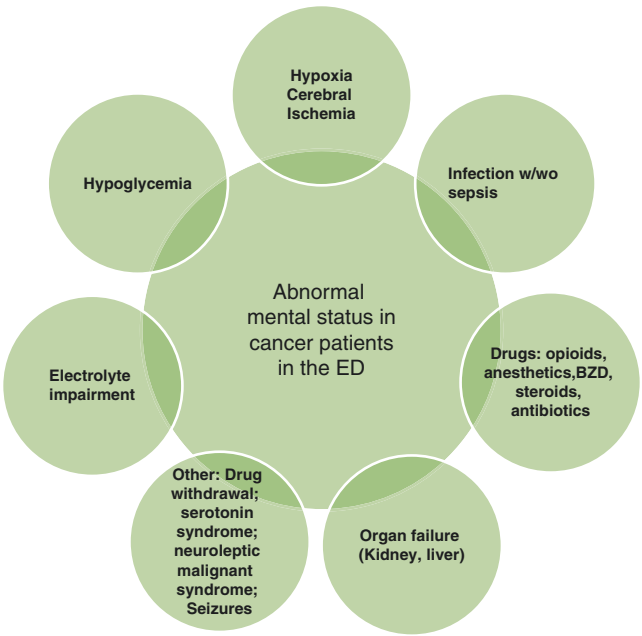

Fig. 16.1 Causes of abnormal mental status of patients in the emergency department. *BZD* Benzodiazepines; *ED* Emergency Department

A long list of chemotherapy agents, immune checkpoint inhibitors (ICI), and chimeric antigen receptor (CAR) T-cell therapies can also cause central neurotoxicity (Table 16.1) [15–17]. The immune-effector cell-associated neurological syndrome (ICANS) is a distinct, common complication of adoptive T-cell immunotherapy [18]. Some of these drugs have been linked to the posterior reversible encephalopathy syndrome (PRES). Physicians caring for cancer patients in the ED should consider PRES if symptoms and findings (confusion, headaches, cortical blindness, seizures, and hypertension) suggest the diagnosis and patients are on chemotherapy or immunosuppressive drugs [19, 20]. Another cause is progressive multifocal leukoencephalopathy (PML) among leukemia and lymphoma patients treated with monoclonal antibodies targeting B and T cells. Delirium is also one of the complications of allogeneic HSCT due to chronic immunosuppression for the prevention of graft versus host disease [21].

Diagnosis

Two elements are essential to the diagnosis of delirium: (1) acute or subacute onset in minutes, hours, or even a few days and (2) fluctuation in attention levels.

There are several instruments for the assessment of mental status in cancer patients [56]. The mini-mental state examination (MMSE) is easy to learn and use. It can detect encephalopathy within 1 minute, especially when assessing orientation, recall, and attention/concentration [57]. The language domain is generally unremarkable in mild or moderate delirium. The MMSE is useful to evaluate and diagnose delirium in patients with baseline dementia, but it is not adequate to screen for dementia itself. In the ED, pre-existing dementia is often based on information on prior cognitive function from relatives or friends.

Assessment and Management

Not every patient needs all the tests in Fig. 16.2. The essential laboratory data and procedures for adequate diagnosis of encephalopathy and its cause(s) are contained in the two upper bullets of the diagram. The treatment of delirium is supportive, and its resolution depends on control of the underlying problems; if these complications resolve, encephalopathy should improve. Figure 16.3 depicts the principles of treatment, as reviewed in detail elsewhere [7].

Table 16.1 Chemotherapy and other anticancer drugs associated with encephalopathy/delirium

Drug	Frequency	Comments
Bevacizumab	Unknown	Associated as monotherapy, or with other drugs in PRES [19, 22, 23]
Bortezomib and carfilzomib	Unknown	Well-known association with PRES [24, 25]
Blinatumomab	All grades: 36–53% ≥ grade 3: 7–14%	Pooled data [26, 27]
CAR T-cell therapy: Axicabtagene ciloleucel (YESCARTA®) Tisagenlecleucel (Kymriah®) Brexucabtagene autoleucel (Tecartus®)	ICANS (any grade): 68% [28] ≥ grade 3: 30–41% [28–30]	Stereotypical presentation, biphasic pattern. Early: tremor, dysgraphia, aphasia. Aphasia can be prominent later and is very specific for this class [18]. PRES in 2% [28]
Cisplatin	Unknown but rare	Described with PRES
Etoposide	Unknown but rare	Described with PRES
Fludarabine	Very rare but serious	
5-Fluorouracil	Very rare	Check for dihydropyrimidine dehydrogenase (DPD) deficiency
Gemcitabine		
Ifosfamide	15–21% [31, 32]	Risk is higher in ECOG PS 2–4, and increase in serum creatinine levels [33]
Interferons (**α** and **β**)	Rare, discrepant reports on severity [34, 35]	No association with PRES
Interleukin-2	Rare [36–38]	
Ipilimumab	<1% [39]	Described with PRES [40]
L-Asparaginase	Unknown, case reports [41]	Mostly during consolidation associated with PRES [42]
Methotrexate	With sporadic reports since the 1970s, frequency unknown	Described with parenteral [43–45] and intraventricular administration [46–48] associated with PRES [49]
Nitrosoureas	Unknown	Causality is difficult to demonstrate because the current use of these drugs is to treat CNS tumors
Procarbazine	Unknown; association is very weak	Described with CCNU and vincristine [50], not in PRES
Sunitinib	Unknown	Associated with PRES [51]
Tamoxifen	No firm association [52]	Not described in PRES
Thiotepa	18% with high-dose regimens [53]	Use of tramadol may increase the risk of neurotoxicity
Vincristine	Unknown	Causality unclear, associated with PRES [54, 55]

CAR T Chimeric antigen receptor T-cell therapy, *PRES* posterior reversible encephalopathy syndrome, *ICANS* immune-effector cell-associated neurological syndrome, *ECOG* Eastern Cooperative Oncologic Group, *PS* performance status

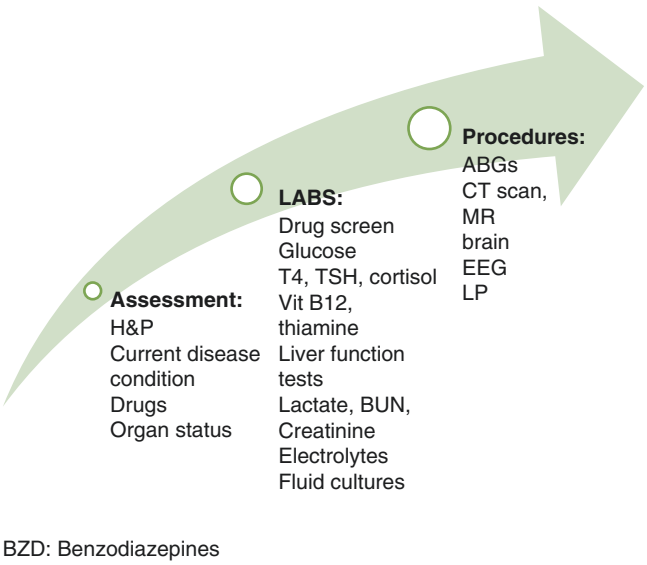

Fig. 16.2 Diagnostic sequence in the diagnosis of altered mental status (ABG arterial blood gases, EEG electroencephalogram, LP lumbar puncture)

Brain Herniation

Principles

Intracranial volume is the sum of the volumes of brain tissue, cerebrospinal fluid (CSF), and blood, within a rigid compartment (skull) [58]. This means that changes in relative volumes will not alter the total intracranial volume (Monro-Kellie doctrine). Figure 16.4 illustrates the interplay among these compartments and how an increase in intracranial pressure (ICP) can lead to brain herniation. High ICP triggers a compensatory shift of CSF into the spinal subarachnoid space and a reduction of blood volume by the cerebral venous system. If the cause of high ICP supersedes these homeostatic mechanisms, ICP will rise, and the brain parenchyma can herniate in three directions following a gradient pressure: under the falx (subfalcine herniation); past the tentorium cerebellum (uncal or transtentorial herniation); and past the foramen magnum (tonsillar herniation) [59]. Early recognition of impending

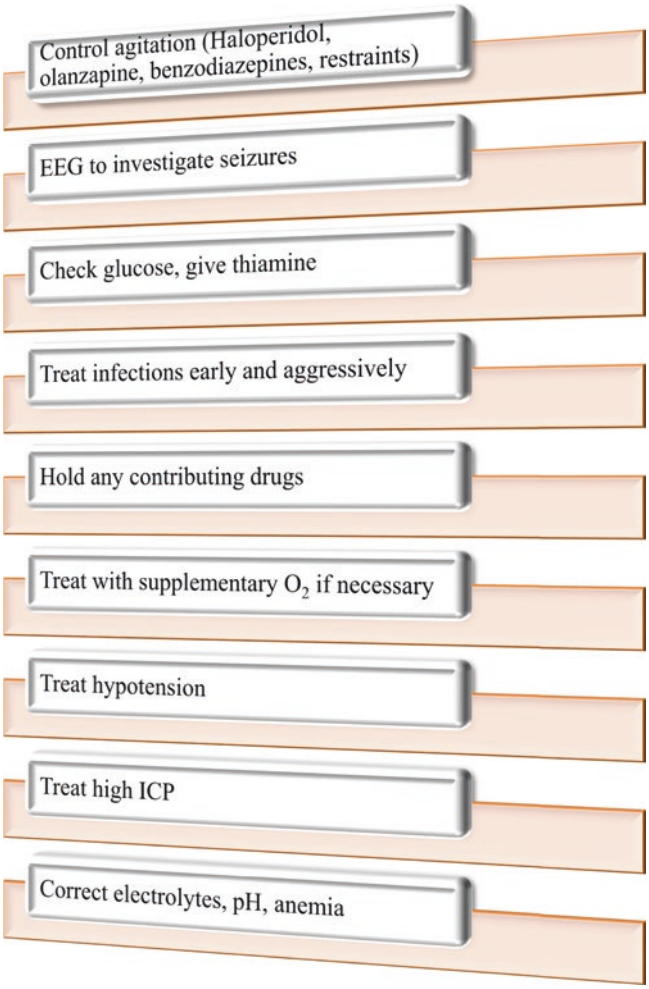

Fig. 16.3 Emergency department management of altered mental status in cancer patients

brain herniation will allow prompt treatment (Fig. 16.5). Miller Fisher argued that the crucial and irreversible injury are the events preceding herniation, such as displacement of midline structures against the tentorium or overcrowding of the posterior fossa [60], and this is supported by clinical observations [61].

Causes

In oncologic practice, cerebral edema and an intracranial mass are the most common causes of brain herniation syndromes. The intracranial mass can be (1) a primary tumor (e.g., glioblastoma, meningioma with brain invasion, or ependymomas); (2) a brain metastasis (single or multiple); and (3) radiation necrosis. In these cases, the perilesional edema is from BBB disruption (vasogenic) and can respond to corticosteroids.

Alternatively, nontumoral lesions with focal mass effects may cause intracellular (cytotoxic) edema unresponsive to steroids. Causes include (1) hypertensive hematomas; (2) traumatic or non-traumatic intracranial hemorrhage; (3) ischemic infarcts in the distribution of a large vessel such as the carotid artery or main trunk of the middle cerebral artery (MCA); and (4) vasculitis (if ischemia or hemorrhage predominates and the vasculitis is not due to an autoimmune process).

A third group has high ICP with diffuse cerebral cytotoxic edema from widespread cellular injury and includes the following: (1) hypoxia from cardiorespiratory arrest; (2) refractory convulsive epileptic status; (3) liver or renal failure; and (4) hydrocephalus (in neoplastic meningitis).

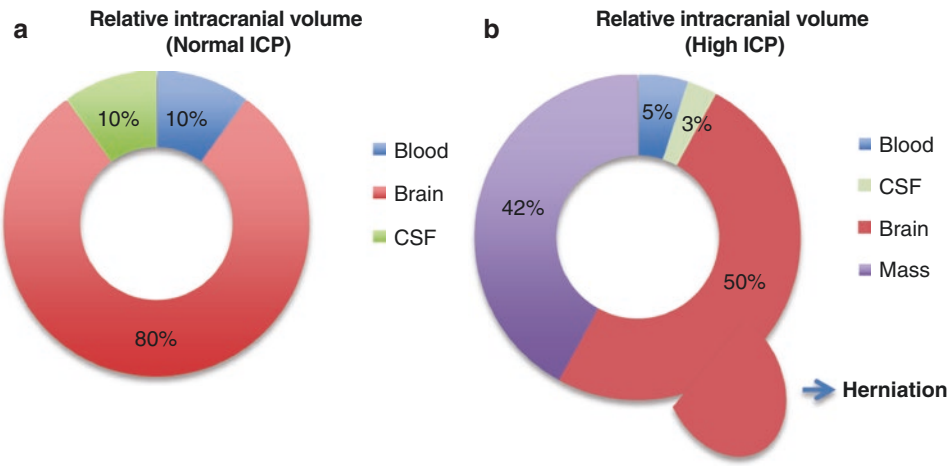

Fig. 16.4 Relative intracranial volume. (**a**) Normal intracranial volume pressure (ICP), (**b**) relative ICP (CSF, cerebrospinal fluid)

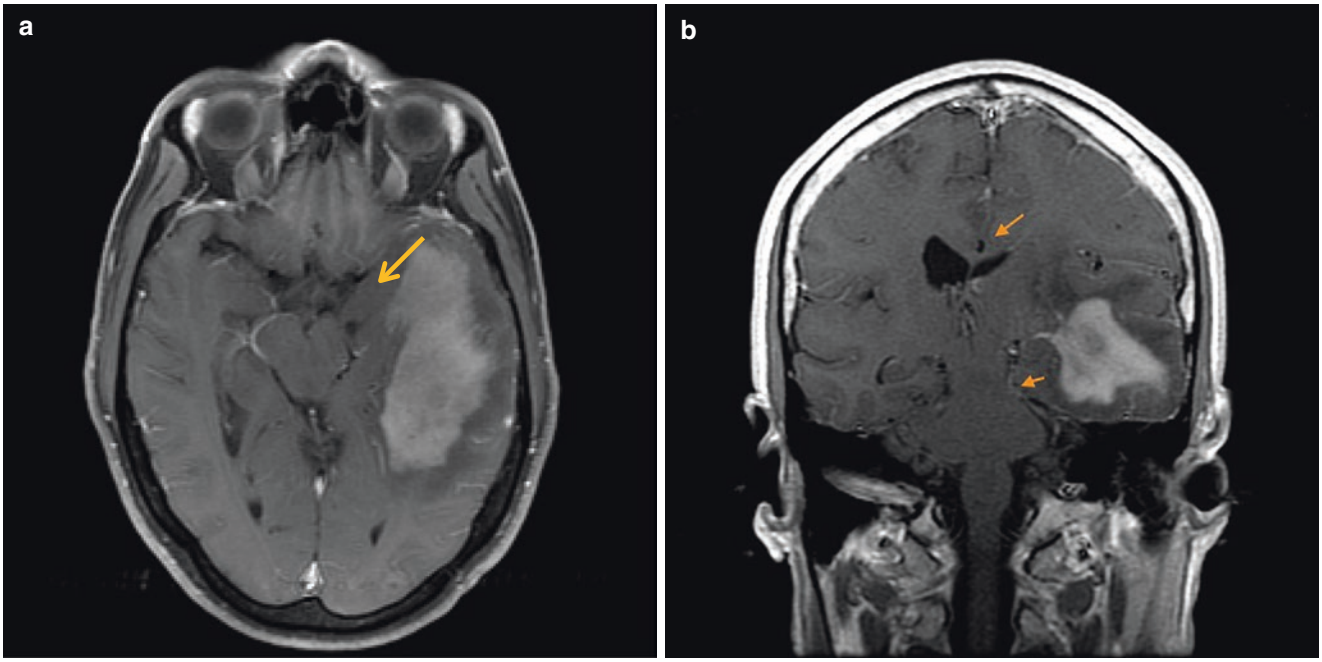

Fig. 16.5 Patient with metastatic B-cell lymphoma. (**a**) T1-gadolinium axial MRI. The left uncus is shifting against the cerebral peduncle (impending uncal herniation). (**b**) MRI of the brain, T1 with gadolinium, coronal section. Another view of the uncal displacement (*straight arrow*) and a simultaneous subfalcine herniation

Assessment

Not all patients with intracranial hypertension present with the same symptoms and findings; we have seen patients with radiographic evidence of impending herniation but a normal neurological examination, although they are rare (<5%) [62]. Many others do not have herniation but a mass effect, neurological deficits, and AMS. In general, headache, neck pain, AMS, or seizures can indicate high ICP. Papilledema is a useful sign with low sensitivity, and very few physicians in the ED have funduscopy skills to identify papilledema (Fig. 16.6). Point of care ultrasound may be a useful adjunct to fundoscopy in making the diagnosis of intracranial hypertension [63].

Other patients can present with acute bursts of neurologic dysfunction, often mistaken for epileptic seizures; many of them have mass lesions or hydrocephalus from leptomeningeal involvement. Such episodes are due to a sudden rise in intracranial pressure (plateau waves) and last from 1 to 20 min (Table 16.2). The EEG can sometimes show indirect clues of increased ICP with frontal intermittent rhythmic delta activity (FIRDA) patterns (Fig. 16.7).

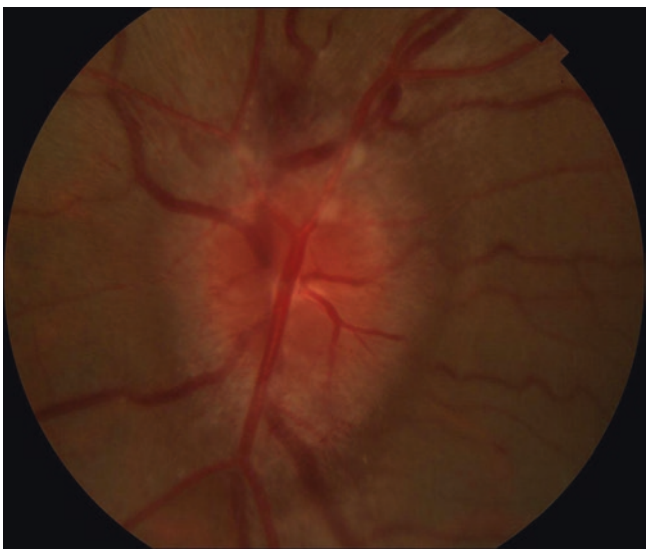

Fig. 16.6 Papilledema in a 53-year-old woman in the ED with new onset, daily headaches. Bedside fundoscopy quickly established a secondary headache. Opening cerebrospinal fluid pressure: 40 cm H20. Cytology: adenocarcinoma cells. Blurred optic disc contours, blurred retinal vessel walls, and soft exudates

Management and Prognosis

After an ED diagnosis of high ICP with or without evidence (clinical or radiographic) of brain herniation, the specific circumstance will dictate the urgency of treatment. The choice of medical interventions depends on the cause responsible for high ICP, and these include hyperventilation, osmotherapy, and corticosteroids (Table 16.3). Hyperventilation can be started in the ED,

with advanced airway management and mechanical ventilation before transfer to intensive care. Mannitol and corticosteroids can begin in the ED and continue on the hospital floor. Most hypertonic saline infusions, particularly 7.5%, 15%, and 23.4% sodium chloride, require ICU monitoring. The prognosis of symptomatic, acute brain herniation in cancer patients is dismal, with most dying in minutes or hours regardless of the cause. Even if they survive resuscitation efforts, they will remain unresponsive and comatose until death. Patients with metastatic or primary brain tumors and gradual elevation of ICP are more likely to respond to osmotherapy, steroids, and debulking surgery, if indicated.

Table 16.2 Signs and symptoms associated with plateau waves [5]

Altered consciousness (delirium, stupor, or coma)
"Spells" of blank stare (confused with partial complex seizures)
Spontaneous, wide oscillations of blood pressure, respiration, or heart rate
Headache, pain in neck or shoulders
Nasal pruritus
Nausea/vomiting
Facial flushing
Shivering, goosebumps, sweating
Temperature increase
Yawning or hiccups
Opisthotonus
Mydriasis
Weakness of cranial nerve III or VI
Nuchal rigidity
Clonic movements of extremities
Decorticate or decerebrate posturing
Bilateral extensor plantar signs

These episodes are paroxysmal, may last minutes, and may be triggered by touch, pain, suction, positioning, or noise

Status Epilepticus (SE)

Definition and Classification

Status epilepticus can be convulsive (CSE) or nonconvulsive (NCSE), and patients can evolve from one to another in the ED. CSE is easily recognizable, with partial (focal) tonic-clonic, generalized tonic-clonic, or predominant tonic posturing or clonic movements (rhythmic jerking), or mixed. Convulsive status epilepticus (CSE) is a life-threatening emergency [65].

Status epilepticus from some regions of the brain (temporal lobe, occipital and deep frontal) might not have overt motor manifestations and typify a complex partial status epilepticus. These events require observation of subtle movements or behavioral changes by observant witnesses or care providers:

- Licking behavior
- Lip-smacking
- Chewing, tooth grinding, spitting
- Grunting or guttural sounds
- Aversive or versive eye/head movements
- Nystagmus
- Myoclonus of eyelids, face, or perioral regions
- Picking/fumbling, facial grimacing, gesticulating activity
- Isolated focal facial, finger, or toe twitching

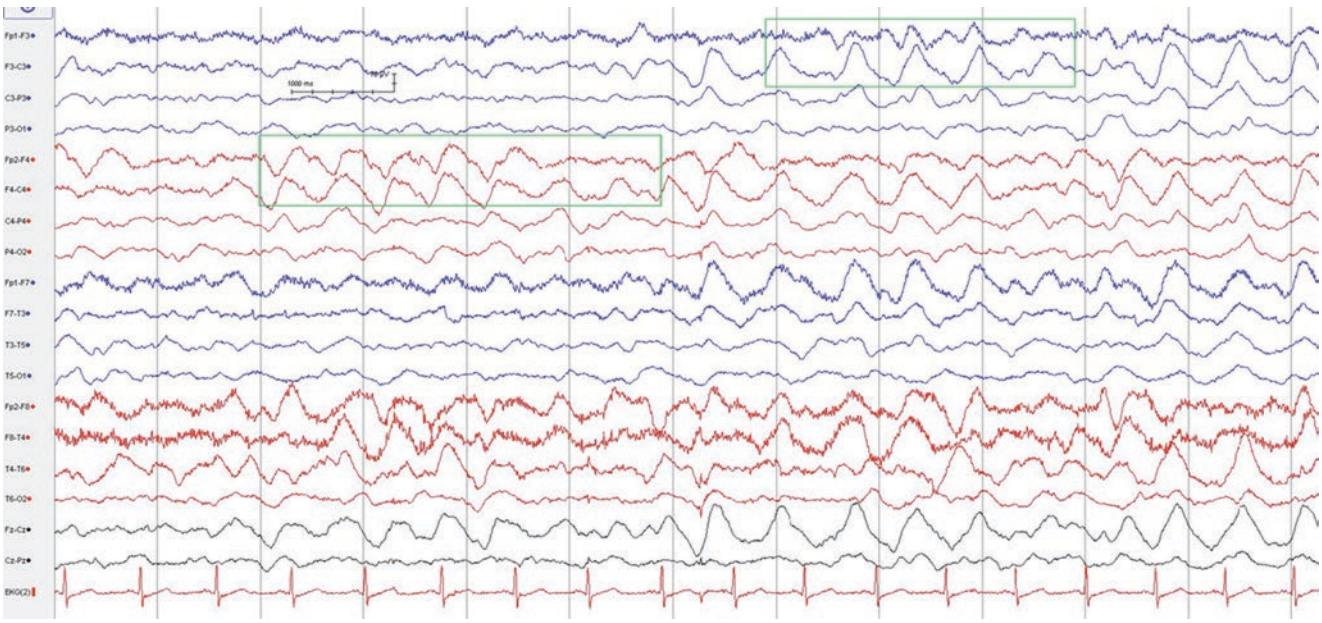

Fig. 16.7 Frontal dysfunction with delta (FIRDA, *boxes*). Opening cerebrospinal fluid pressure: 27 cm H2O. Patient with plateau waves

Table 16.3 Emergency medical treatment of patients with de facto or impending cerebral herniation [28]

Intervention	Dose	Onset/duration	Advantage(s)	Disadvantage(s)
Hyperventilation	Lower pCO2 to 25–30 mmHg by increasing respiratory rate with same tidal volume	Seconds/minutes	Fastest onset Effective for high ICP regardless of the cause	Very short duration, with effect lost after several hours Will require endotracheal intubation May be more harmful to an already injured brain
Osmotherapy (mannitol, 20% solution)	1 g/kg iv initial dose; next dose: 0.5 g/kg and 0.25 g/kg q6h	Within 15–20 min; max effect is in 1 h Keep osmolality between 210 and 320 mOsm/L	Longer duration Effective regardless of the cause Note: still is the standard of care in cancer patients	Rebound effect is possible Hyperosmolality and acute renal failure
Osmotherapy (hypertonic saline solutions)	3%: 250 mL 7.5%: 250 mL 23.4%: 30–60 mL	Onset: within min	Effective when mannitol is not Needs central line for administration – could be considered for rapidly evolving herniation	Minimal experience in brain tumors Safer than mannitol but it may have adverse effects: CHF, hyperchloremic acidemia, hypernatremia, seizures
Corticosteroids (dexamethasone most used)	Initial dose: 10 mg, then 4–6 mg iv q4–6 h. Decrease as soon as possible	24–36 h/days	Reliable and steady effect in vasogenic edema from metastatic or primary brain tumors	Not effective in anoxic-ischemic or toxic edema AE: hyperglycemia, mood changes, insomnia, immunosuppression, Cushing syndrome, skin frailty, accelerated bone resorption Myopathy can be disabling

ICP Intracranial pressure; *CHF* congestive heart failure; *AE* adverse effect

- Pelvic thrusting and bicycling movements
- Asymmetric tonic posturing ("sign of four")
- Dystonic limb posturing

These symptoms and signs require bedside EEG for prompt diagnosis. NCSE also presents with AMS and behavior changes from baseline, without overt motor manifestations. The list is diverse and includes:

- Altered consciousness
- Impairment of verbal skills
- Impairment of clock drawing
- Indifferent attitude
- Fear
- Rare hysteria
- Suicidal thoughts
- Hallucinations

Bedside EEG is essential for prompt diagnosis. Status epilepticus involves ongoing or recurrent seizures *without* recovery of sensory, motor, or cognitive function or consciousness to baseline. The duration of seizures in the definition of CSE has changed over time from 30 min to 5 min; we consider seizures lasting 2 minutes or longer in cancer patients as an emergency requiring prompt treatment and workup. There is no consensus on how soon to intervene; other experts recommend treatment after 5 min [64].

Unlike CSE, NCSE requires timely recognition without overly aggressive treatments. NCSE has a prevalence of 15% among critically ill cancer patients and seems associated with lower mortality, normal kidney function, and hematologic malignancies receiving chemotherapy [66]. Postictal deficits (Todd paralysis) include temporary limb weakness or hemiplegia after a seizure, with new or worsening of prior known weakness, and clinically masquerade as an ongoing seizure. The EEG is necessary to identify surreptitious seizure activity.

Causes

Epileptic seizures are a frequent symptom of CNS metastases (leptomeningeal, dural, or parenchymal), primary brain tumors (meningiomas, astrocytomas, and oligodendrogliomas, with oligodendrogliomas having the highest seizure rate), metabolic disorders (hyponatremia, hypoglycemia, hypoxia, and hypercalcemia), CNS infections (herpesvirus), intracranial hemorrhage (spontaneous or traumatic), ischemic infarctions, and treatment-related factors, as well as paraneoplastic limbic encephalitis.

In the era of immunotherapy, we increasingly recognize autoimmune encephalitis, meningitis, and demyelinating brain lesions. We also see seizures associated with blinatumomab and CAR T-cell therapy. If these patients return to the ED with AMS, it is necessary to perform a complete workup (sepsis workup, MR brain, EEG, lumbar puncture).

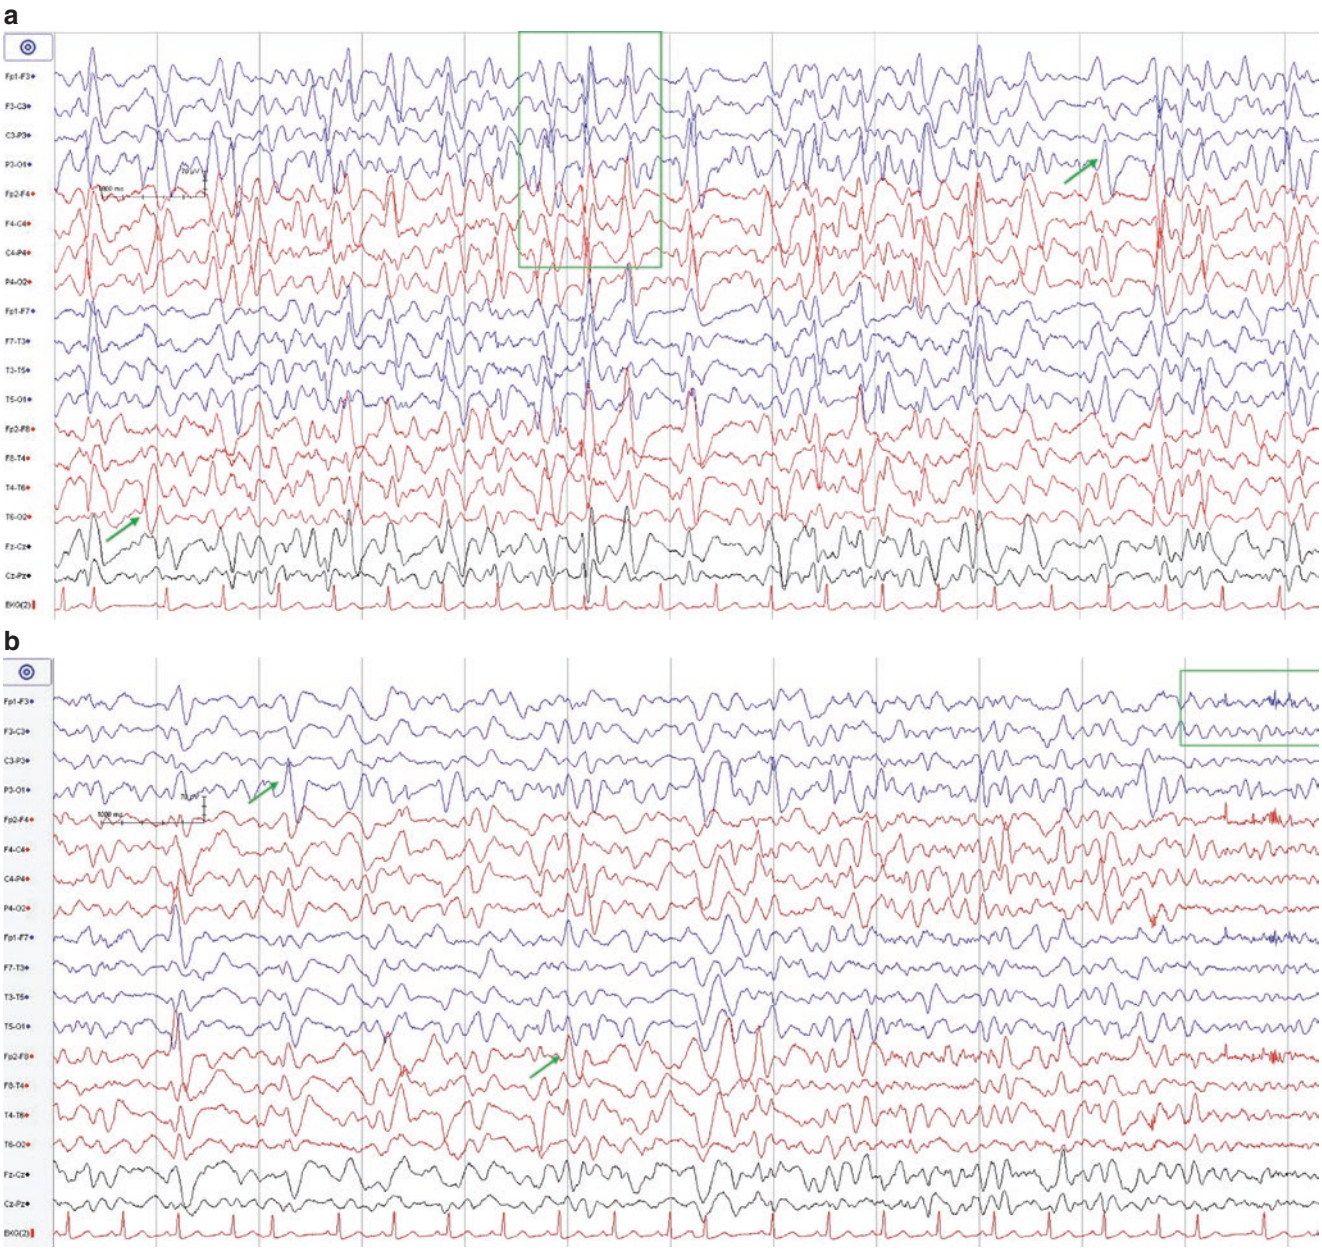

Fig. 16.8 (**a**) Nonconvulsive convulsive status epilepticus with ifosfamide toxicity: disorganized background with generalized and multifocal periodic complexes that are isolated (*arrow*) and at 2.5 Hz (*box*). (**b**) After 1.5 mg lorazepam: organized background (*box*) with attenuation of the periodic complexes (*arrow*). Patient able to state her name and follow one-step commands. Normal MR brain

Assessment

ED providers should observe or inquire for behavior changes, subtle movements, and AMS. Manifestations of NCSE can range from being awake, able to count from 1 to 20 but not backward, to confusion and overt coma. Clinical and EEG improvement to a benzodiazepine challenge (Fig. 16.8) can facilitate the diagnosis. The EEG has limitations, especially with intermittent seizures. Prolonged EEG or repeat EEG can increase the detection level, and a nondiagnostic EEG does *not* rule out a seizure. Clinical judgment should prevail, acknowledging the limits of diagnostic tests, and with high suspicion it is clinically and ethically justified to start benzodiazepines and anticonvulsant drugs [67], and we recommend upfront treatment if EEG is not readily available. An EEG should be performed following resolution of CSE if the patient's mental status and focal neurological deficits have not recovered to baseline. The aim is to rule out subclinical electrographic seizures.

Management and Prognosis

The initial assessment and treatment of CSE is detailed in Fig. 16.9. After securing ventilatory and circulatory support, the early and rapid use of benzodiazepines, phenytoin, levetiracetam, lacosamide, sodium valproate, phenobarbital, propofol, midazolam, and, in some cases, pentobarbital may prevent progression to refractory and super-refractory status epilepticus. Any seizure longer than 2 minutes should be treated aggressively. If the duration is uncertain, treatment has to be equally aggressive, even though the probability of success ("breaking" the SE) is less if the patient has been in status for hours or days. The prognosis is complicated and depends on the duration of status, underlying causes, and presence of additional complications. CSE and partial status epilepticus can contribute to further neurological injury in cancer patients due to cytotoxic edema and intracranial hypertension.

NCSE generally requires 1 to 4 mg lorazepam in different doses and sequences, for example, 1 mg doses as needed with reassessments in between or 2 mg plus additional doses as needed. Drugs with little or no sedating effects (levetiracetam or lacosamide) are preferred.

Following the resolution of NCSE, we recommend lower-dose intermittent lorazepam 0.5 mg iv q4–8 hrs x 24 hrs. Follow-up EEGs can often be indeterminate with trials of benzodiazepine and antiepileptic drugs.

NCSE and CSE share similar etiologies, and it is essential to address the root cause quickly. In our experience, leptomeningeal disease, drugs (ifosfamide, cephalosporins), and acute or acute-on-chronic renal injury are among the most common reasons. For both conditions, clinical improvement and EEG (Fig. 16.8b) are therapeutic endpoints.

Intracranial Hemorrhage (ICH)

Importance and Causes

Although the overall incidence is unknown, ICH is a frequent ED diagnosis in any institution caring for patients with cancer. ICH is a generic term that includes parenchymal, subarachnoid, subdural, and epidural hemorrhage. Although non-traumatic, ICH can occur as an adverse effect of supratherapeutic anticoagulation (but not therapeutic anticoagulation for venous thromboembolic disease [68]) or due to profound or prolonged

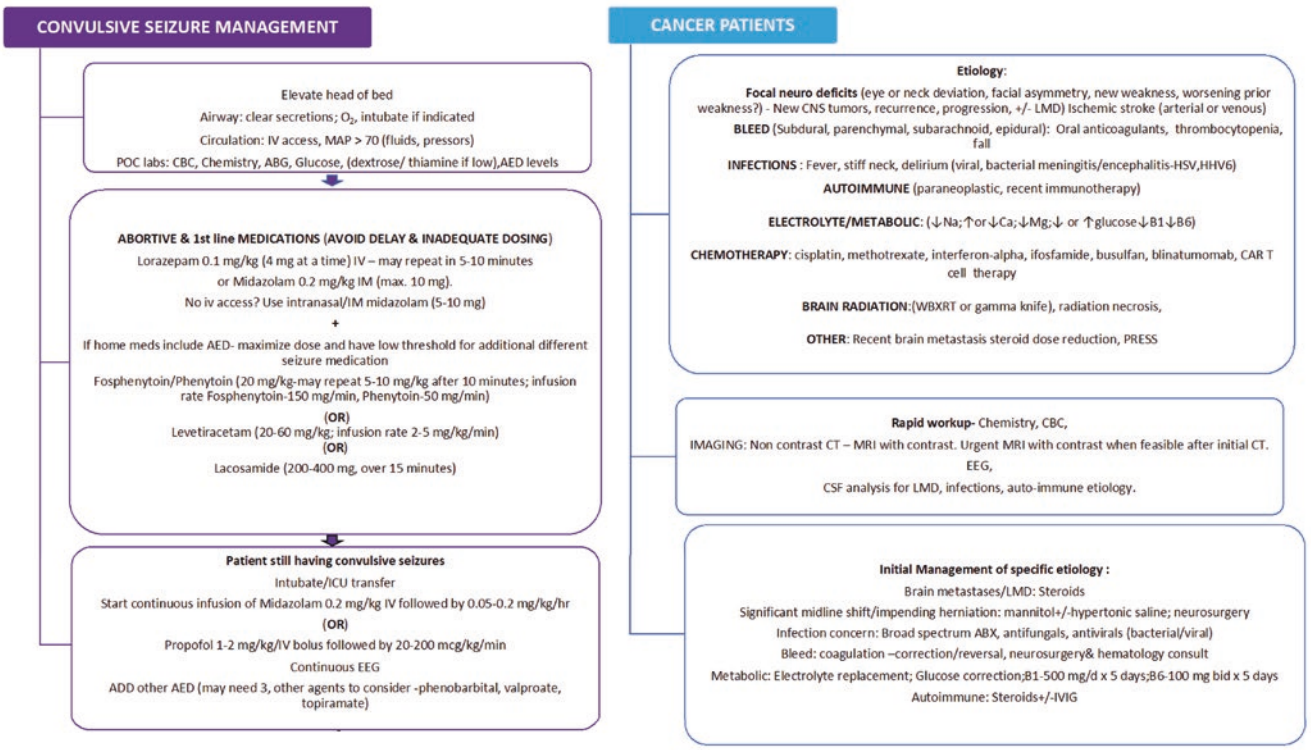

Fig. 16.9 Management guidelines for convulsive status epilepticus in cancer patients at the University of Texas MD Anderson Cancer Center. MAP Mean arterial pressure, POC point-of-care, CBC complete blood count, ABG arterial blood gases, AED antiepileptic drugs, LMD leptomeningeal disease, WBXRT whole brain radiation therapy, SRT stereotactic radiotherapy, ABX antibiotics, IVIG intravenous immunoglobulin

thrombocytopenia caused by drugs, disseminated intravascular coagulation (DIC) [69], or sepsis.

In solid tumors, bleeding can be spontaneous because of neovascularization (melanoma, lung cancer, renal cell carcinoma, or glioblastoma). ICH is an adverse effect with bevacizumab, but there is no evidence of additional risk in these patients [70]. The 72 h mortality rate of ICH in leukemia ranges between 12% and 19%. After 30 days, it climbs up to 40% [71]. Old age and high disease burden increase the risk of death [69].

Presentation

Patients with ICH can present with symptoms ranging from an incidental finding on CT scan of the brain to the classic picture of sudden headache, AMS (including stupor and coma), focal deficits, and epileptic seizures. Incidental or mildly asymptomatic presentations are more frequent in patients with intratumoral bleeding. Patients without a history of cancer may present with an ICH as the initial manifestation of neoplasm.

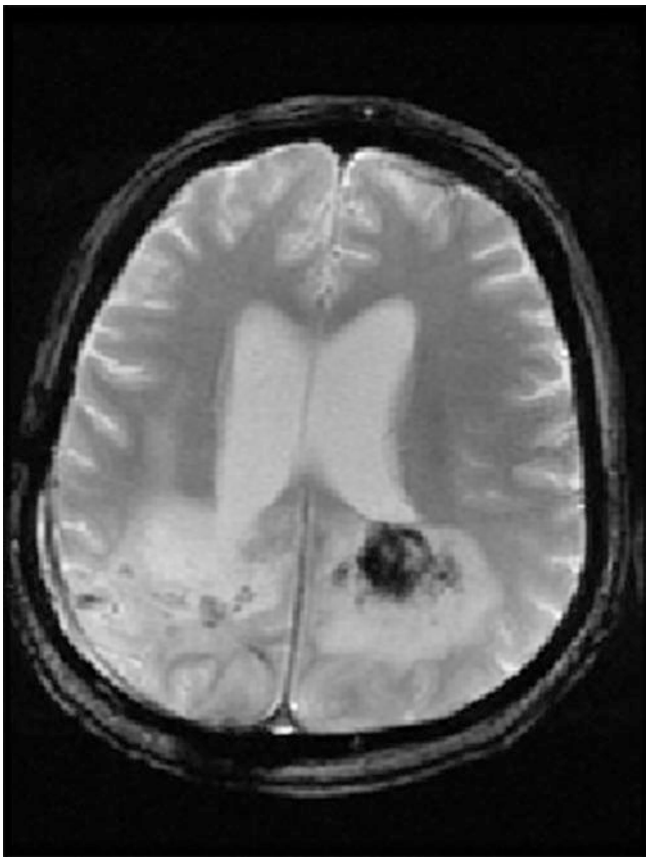

Fig. 16.10 Intratumoral hemorrhage in glioblastoma. Axial T2* MRI of the brain of a 49-year-old man presenting with a 7-day history of confusion. Fluent (Wernicke-type) aphasia on exam. No headaches

Diagnosis

A CT scan confirms ICH in most cases. In doubt, the MR brain with T1 with/without gadolinium and gradient echo or T2* (star) sequences are most helpful (Fig. 16.10). Bleeding in venous angiomas, cavernomas, incidental aneurysms, and elderly patients with amyloid angiopathy can sometimes pose a problem of differential diagnosis. In most cases, a careful analysis of the MRI sequences correctly identifies the cause.

Treatment and Prognosis (Fig. 16.11)

The treatment of ICH depends on the location of bleeding and cancer status. For prognosis, see section "Importance and Causes" above. Aggressive platelet and factor transfusion is indicated with the goals to keep fibrinogen >150 mg/dl and platelets >50 × 10^9 L^{-1}. Most patients with solid tumors and ICH that are symptomatic but stable can be managed conservatively. Critically ill patients usually arrive after cardiac arrest or are stuporous or comatose. These patients, if they survive, have severe and irreversible neurological deficits that will exclude them from further oncologic interventions, and supportive care is the best option.

Acute Ischemic Stroke

Importance and Causes

Patients with cancer have a high risk of arterial cerebrovascular ischemia, twice as high as the general population [72, 73]. The risk is highest before primary tumor treatment, in gastrointestinal adenocarcinomas, in brain tumors, in patients who have had neck irradiation to treat head/neck neoplasms, and in advanced stages [74].

In a large population-based study, brain and GI tract tumors (colorectal, pancreas, and liver) had the highest mortality rates; stroke clustered in patients treated for brain

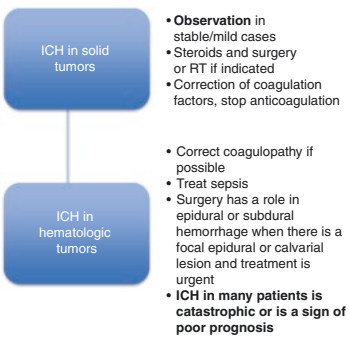

Fig. 16.11 Treatment alternatives in intracranial hemorrhage

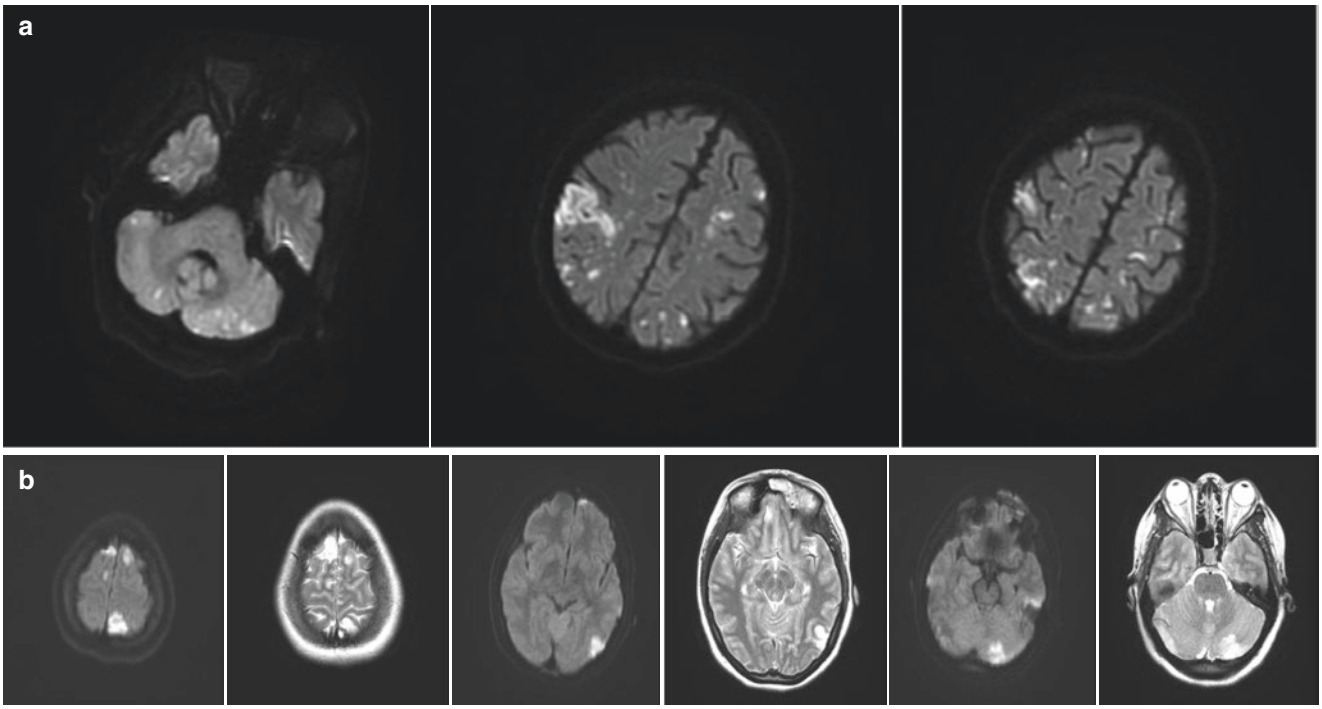

Fig. 16.12 (**a**) Axial, diffusion-weighted imaging (DWI) sequence. Cortical infarcts in multiple vessel distributions in a 26-year-old patient with sarcoma. MRA/MRV/2D echocardiograms were normal. These cortical strokes are due to meningeal pial penetrating arteries infiltrated by carcinomatosis meningitis or bacteria. In this case, bacterial meningitis. Source: an intravenous pain pump

tumors and lymphomas if younger than 40 years and in prostate, breast, and colon if older than 40 years of age [73]. The classical, conventional stroke risk factors so prevalent in the US population compound the risk even more: age; hypertension; atrial fibrillation; obesity; diabetes; and hypercholesterolemia. Other powerful stroke triggers in cancer patients, ranked from more to less common [5, 74], include (1) hypercoagulability and disseminated intravascular coagulation (DIC); (2) nonbacterial thrombotic endocarditis (NBTE) (Fig. 16.12a); (3) septic emboli (bacterial or fungal) (Fig. 16.12b); (4) tumor emboli; and (5) accelerated atherosclerosis after radiation therapy (Fig. 16.13).

Diagnosis

Most cancer patients in the ED present with three well-defined stroke syndromes [74, 75]. Those with *focal neurological deficits* (e.g., aphasia, hemiparesis, hemi-inattention, or homonymous temporal hemianopsia) are the most straightforward. Postictal deficit (Todd paralysis) should be included in the differential diagnosis, as it is a notorious stroke mimic among cancer patients. *Delirium* without focal signs is a more significant diagnostic challenge. Encephalopathic patients may present without lateral signs (focal deficits). ED providers *must* include ischemic stroke in the differential diagnosis of patients with delirium and no other apparent neurological deficits. Multiple, bilateral embolic infarcts in the carotid and vertebrobasilar territories are common in this group [74, 76]. Finally, patients may present with *both focal deficits and delirium*.

Assessment, Treatment, and Prognosis

The diagnostic sequence is similar to the diagnosis of stroke in the general population. An initial CT head without contrast screens for hemorrhage. The best tool to confirm the diagnosis is brain MR with diffusion-weighted imaging (DWI). Apparent diffusion coefficient (ADC) values may indicate areas of ischemic penumbra, and if there is no description of ADC changes in the radiology report, the emergency physician should ask about them. Fluid-attenuated inversion recovery (FLAIR) will help determine the approximate age of the ischemic lesion, and T1 without gadolinium and gradient echo (GRE) will assist in the diagnosis of hemorrhagic transformation from reperfusion injury, a spontaneous event in ischemic strokes or after thromboly-

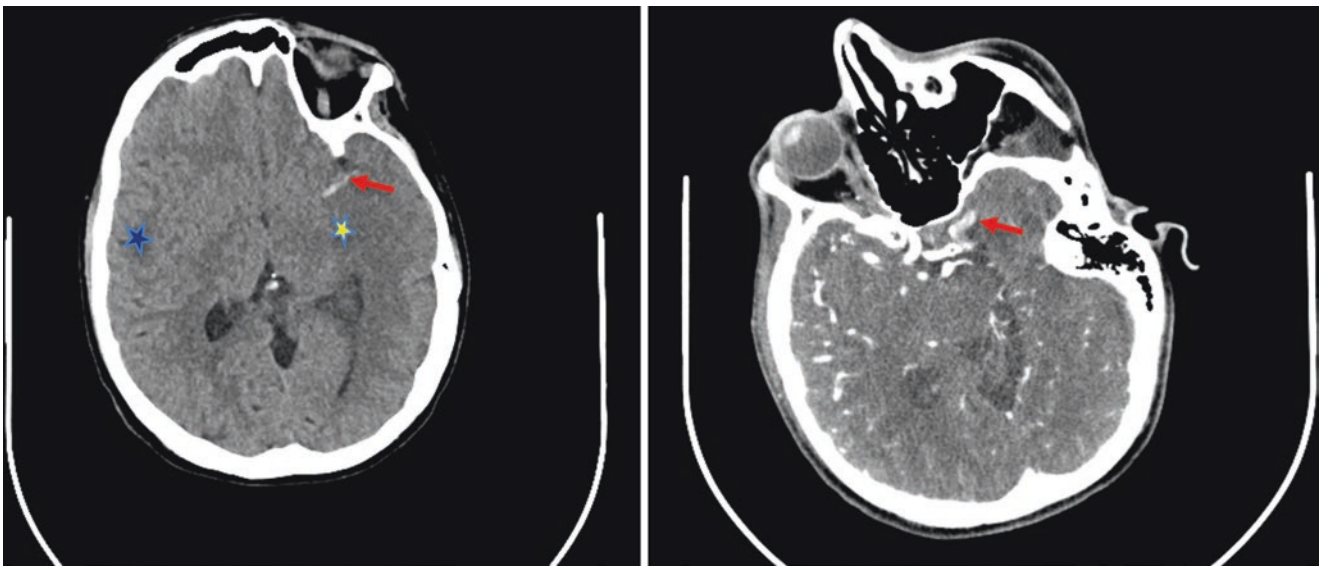

Fig. 16.13 47-year-old woman with history of left oral cancer, treated with radiation and chemotherapy 7 years before. She came to the ED with acute onset aphasia, right hemiparesis, and fall. National Institutes of Health (NIH) Stroke Scale score: 20. CT of head (*left panel*, *arrow*): classic hyperdense middle cerebral artery (MCA) sign from acute thromboembolic occlusion. Also: loss of left insular ribbon from cytotoxic edema, suggesting onset longer than 6 h (*yellow star, compared to blue star on the right*). *Right panel:* CT angiogram. Thrombus in the left internal carotid artery

sis. Finally, an MR angiogram of head and neck and MR venogram can assess for extra- or intracranial stenosis, vasculitis, and venous or sinus thrombosis.

The treatment of acute stroke is conditional to the status of underlying cancer or intercurrent complications derived from the tumor or its treatment. It is obviously more straightforward to treat patients in remission and not on active therapy than patients with complications of chemotherapy, sepsis, or active DIC.

In principle, all patients should have control of hypertension, diabetes, and hypercholesterolemia. If no contraindications exist, aspirin 325 mg daily for secondary prevention and oral anticoagulation for patients with atrial fibrillation are appropriate. Aspirin 100 mg daily for primary prevention of cardiovascular or cerebrovascular events in cancer patients has no evidence for widespread use yet and requires a thoughtful benefit-harm discussion based on patient preference [77]. Patients within 4.5 h of stroke onset are candidates for iv thrombolytics, as long as there is no absolute contraindication [78, 79]. A brain tumor is not in itself a contraindication, but a recent hemorrhagic metastasis poses additional risk, and most patients arrive past the therapeutic window, are too unstable, or have contraindications to thrombolytic therapy. Only 1.6% of patients with cancer and acute stroke receive iv thrombolytics or endovascular therapy [78].

The prognosis of acute ischemic stroke in patients with cancer is generally poor [80]. In patients after thrombolytics, the 3-month mortality is about 50%, and among survivors, 50% had a poor functional outcome. Patients with solid tumors and metastases have worse outcomes than patients with hematologic malignancies. In those undergoing antineoplastic therapy, a stroke resulting in worse functional outcome means poor performance. This consequence has relevance for goals of care, quality of life, and eligibility for clinical trials, among other issues.

Cerebral Venous Sinus Thrombosis

Frequency

Venous sinus thrombosis occurs in 9% of adults with hematologic malignancies or solid tumors. It affects more women than men and tends to happen within the first year of cancer diagnosis [81].

Presentation

Headache, confusion, and seizures are common presentations. As in other emergencies, the severity of symptoms varies from an incidental finding to coma. Younger patients tend to present with headache and papilledema (increased ICP), whereas older patients (>50 years) have more AMS [82].

Diagnosis

A venogram by CT or MRI is the most direct means of non-invasive diagnosis [83]. The regular MRI of the brain can point to the suspect area before the angiogram.

Treatment and Prognosis

If asymptomatic, we tend to treat with anticoagulation, with admittedly little evidence that this approach is better than observation. For symptomatic, stable patients, supportive measures are the first steps, followed by anticoagulation with subcutaneous low-molecular-weight heparin (LMWH). The optimal duration is unclear, but many patients receive treatment for 3 to 6 months, and some permanently, reflecting how little we know and the need for well-controlled studies. Thrombectomy and thrombolysis with the tissue plasminogen activator (tPA) are effective interventions in selected cases. We have no experience with these agents as most of our patients have contraindications, or their prognosis is poor. For stable and symptomatic patients, the prognosis for survival and neurologic function is good. For patients with an acute presentation with brain herniation and CSE, the outlook is poor with a high mortality rate. Predictably, the prognosis for survival or recovery in cancer patients is worse than in non-cancer patients [75].

Case Studies

Case Study 1: Pembrolizumab-Associated Myopathy

A 73-year-old man with renal cell carcinoma, bone, and lung metastases began treatment with pembrolizumab (ICI) every 21 days and axitinib (a tyrosine kinase inhibitor). After cycle 4, patient came to the ED with diffuse bilateral muscle tenderness and weakness, ascending to involve neck and bulbar muscles. On examination, he exhibited severe neck ptosis (antecollis), eye ptosis, dysarthria, and dysphagia (requiring a feeding tube). He had acceptable respiratory function, without need for supplemental oxygen. Before arrival, he had received IVIG and high-dose prednisolone at another institution with partial improvement.

Our initial clinical diagnosis was acute inflammatory myopathy. There is a clear association between ICI, myositis, and myasthenia gravis. His CK levels rose from 49 U/L on admission to 545 U/L on day 19 (72 h after admission) and 343 U/L on day 21. EMG was consistent with myositis in the cervical paraspinals and trapezii. A muscle biopsy was nondiagnostic twice and anti-titin and striatal antibodies were negative.

He was treated with plasma exchange and rituximab 375 mg/m2 BSA days 1 and 15, plus infliximab 5 mg/kg days 1 and 15. Steroids were tapered over 6 weeks. Mild neurological disability persisted, and although the patient is ambulatory, he still speaks in a low voice and has slurred speech and dysphagia for solids.

Case Study 2: Atezolizumab-Associated Meningoencephalitis [50]

A 53-year-old woman with metastatic squamous cell carcinoma of the cervix was referred to the ED by her gynecologic oncologist for evaluation of headache and AMS for 24 h. Thirteen days earlier she had received her first doses of atezolizumab and bevacizumab.

She was found to be delirious, with nuchal rigidity. Laboratory evaluation revealed a normal absolute neutrophil count (ANC), lymphopenia, and a white blood cell count of 3.4 10^9/L. Brain MRI suggested diffuse leptomeningeal enhancement along the cerebral sulci and cerebellar foliae (Fig. 16.14). *Supportive care was initiated in the ED. She was transferred to the ICU and treated with dexamethasone* (Fig. 16.15).

On day 6 after admission, her mental status deteriorated. A routine EEG showed a pattern of nonconvulsive status that responded readily to lorazepam (Fig. 16.16). *After this event, the patient steadily recovered, and corticosteroids were tapered after 21 days of therapy. She had no residual neurological disability and became fully independent.*

Case Study 3: CAR T-Cell Neurotoxicity

A 58-year-old man with diffuse large B-cell lymphoma was in relapse after multiple lines of treatment. He had received axicabtagene ciloleucel (YESCARTA®) on day 0 and on day 3, and he exhibited cytokine release syndrome (CRS) grade 2 with fever, fatigue, nausea, and malaise. He was managed accordingly, with symptomatic treatment and observation in the fast-track clinic as an outpatient. This mild CRS was resolved by day 8 when his family brought him to the ED for acute onset confusion. He was alternating between moments of combativeness with sleepiness, and this was a departure from his normal behavior.

On examination the emergency physician found that patient was disoriented, with no attention span, and mostly uncooperative. He could not speak in complete sentences, and could not write when his relative gave him a paper and pen to help him communicate. There was no evidence of concurrent CRS, and the ED physician diagnosed neurotoxicity grade 2 related to YESCARTA®. He was treated immediately with dexamethasone 10 mg iv q6h and admitted. He also began levetiracetam, a bolus of 20 mg/kg and maintenance dose of 1000 mg iv q12h. Besides sinus tachycardia, all vitals were normal, and laboratory values, including liver and

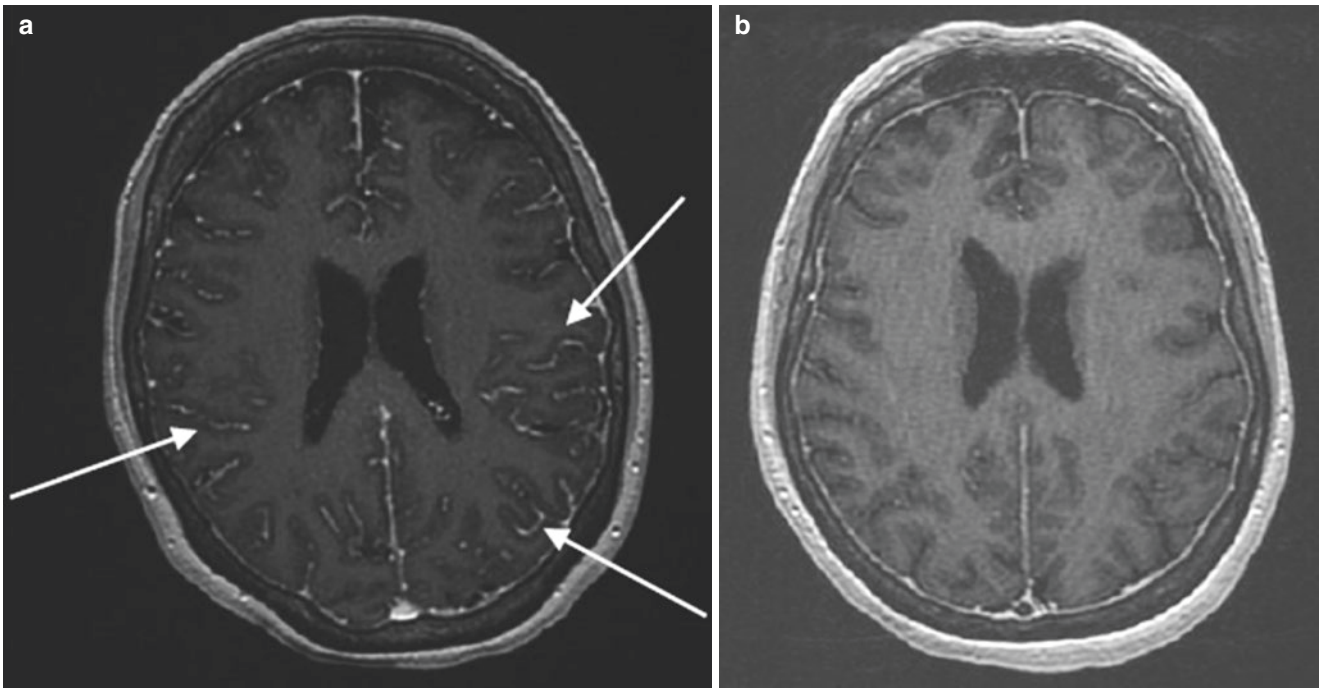

Fig. 16.14 *Case study 2*: (**a**) axial MR brain, T1 with contrast, leptomeningeal enhancement (*arrows*) in case study 2, on day 2 of symptom onset. (**b**) At day 8, after high-dose iv steroids

Dexamethasone 4mg/day ↑24 mg/day

Opens eyes, follows commands

Fig. 16.15 *Case study 2*: Treatment course, with serial cerebrospinal fluid (CSF) findings revealing high CSF white blood cells, protein, beta-2-microglobulin, and basic myelin protein levels

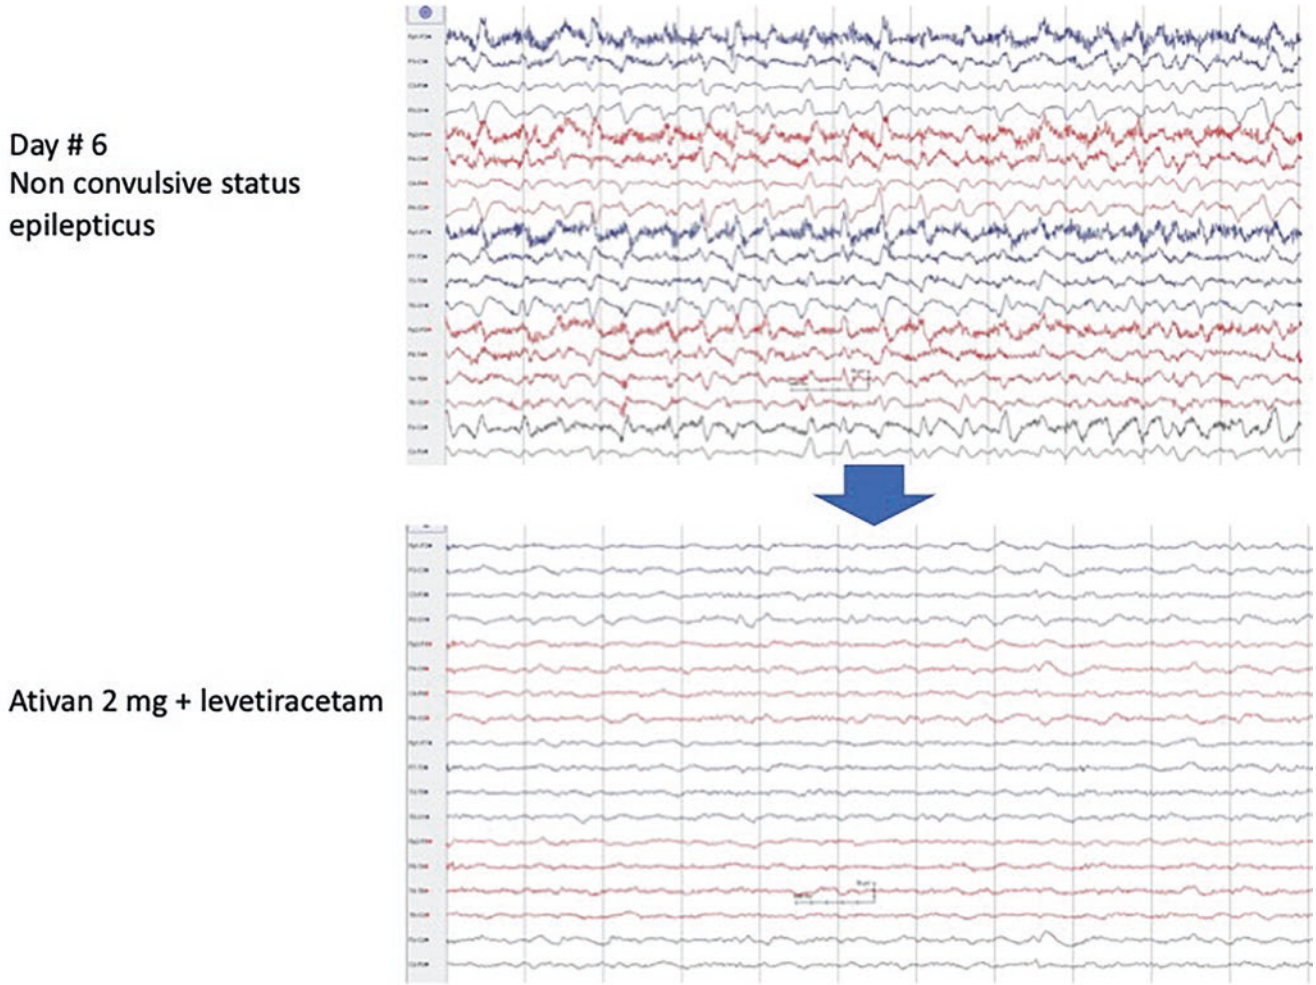

Fig. 16.16 *Case study 2:* acute altered mental status on day 6, with EEG diagnostic of nonconvulsive status before (*upper panel*) and after treatment with antiepileptic drugs (*lower panel*)

renal parameters, were normal. Urine analysis and chest x-ray were unremarkable.

The patient went to the regular floor where dexamethasone continued for 4 more days (day 12). He improved steadily within 72 h and was at baseline by day 14. His treating team stopped dexamethasone and the patient was discharged.

Comment: In the trials leading to the FDA approval of YESCARTA®, 85% of patients had neurotoxicity, 31% of them grade 3 or higher. Most cases (98%) happened within 8 weeks of the infusion day (day 0), with a median onset at 4 days (range: 1–43 days). Our patient began neurological symptoms on day 8. The median duration of neurotoxicity is 15–17 days, with rare cases having encephalopathy for almost 6 months. For grade 2 toxicity and no concurrent CRS, dexamethasone, AED, and hemodynamic monitoring in a regular floor are appropriate.

Pituitary Apoplexy

17

Daria Krivosheya and Ian E. McCutcheon

Case Study

A 78-year-old woman had an intense headache and nausea, both of sudden onset, and consulted her family physician. Noting hypertension to 189/96, he treated her with clonidine and morphine. She presented with unrelieved headache to her local emergency department (ED) the following day, where an MRI showed a sellar and suprasellar mass, the heterogeneity of which suggested hemorrhage within a pituitary macroadenoma (Fig. 17.1). *This hemorrhagic component was not, however, recognized at that time. The tumor did not reach the optic chiasm. Cerebral atrophy and chronic ischemic demyelination were also seen, consistent with her age. No endocrine workup was undertaken. Her analgesic was changed to hydromorphone 2 mg by mouth, four times daily. Nonetheless, her headache persisted, and she became forgetful and was excessively sleepy. Her family sought a second opinion 5 days after the ED visit. At that time she was somnolent but had clear mental status when aroused. She said she felt "tipsy" much of the time. She showed no cranial neuropathies, and no visual field deficit. She had tenderness and swelling on the dorsolateral aspect of her right foot but had no recollection of the fall that had caused this local contusion. Her endocrinological history included diabetes mellitus controlled by metformin and Graves' disease with hypothyroidism after 131I treatment of that condition. She also took methotrexate for rheumatoid arthritis.*

On laboratory workup, the following values were obtained: sodium, 119 mEq/L; serum osmolality, 253 mOsm/kg of water; urine osmolality, 217 mOsm/kg of water; magnesium, 1.4 mg/dL; and glucose, 148 mg/dL. Hormonal assessment showed the following: cortisol, 3.9 mcg/dL (normal, 4.4–12.4); ACTH, <5 pg/mL; prolactin, 11 ng/mL; luteinizing hormone, 1.6 mIU/mL; follicle-stimulating hormone, 12.8 mIU/mL; free T4, 1.20 ng/dL; and thyroid-stimulating hormone, 0.49 μIU/mL. She also had a possible urinary tract infection with 19 WBC/hpf and 7 hyaline casts/hpf; cultures of urine and blood were negative.

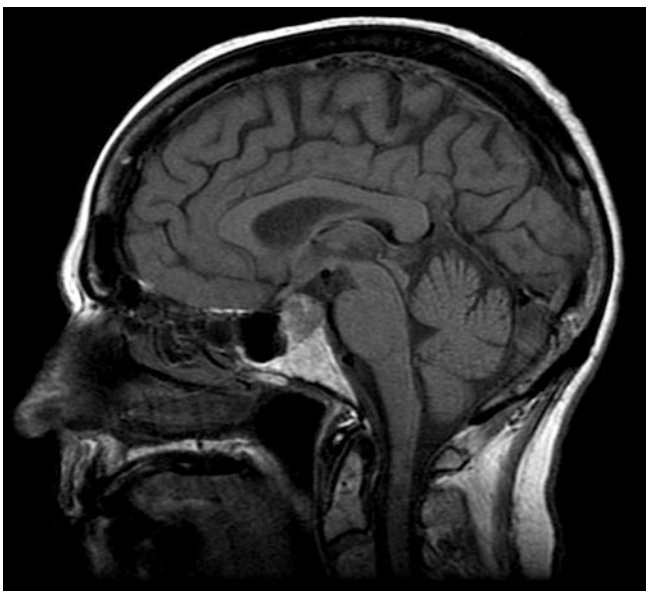

Fig. 17.1 Pituitary macroadenoma with heterogeneity (areas of both hyperintensity and hypointensity) on pre-contrast MRI, sagittal view

She was admitted to hospital for the following diagnoses: clinically nonfunctional pituitary macroadenoma with pituitary apoplexy; syndrome of inappropriate ADH secretion causing severe hyponatremia; diabetes mellitus, poorly controlled; hypertension; central hypogonadism; cellulitis of the right foot; and headache. Her treatment included transsphenoidal removal of pituitary tumor and associated hemorrhage; fluid restriction; glyburide; adjustment of clonidine; Levaquin x 5 days; discontinuation of hydromorphone; and initiation of hydrocodone/acetaminophen.

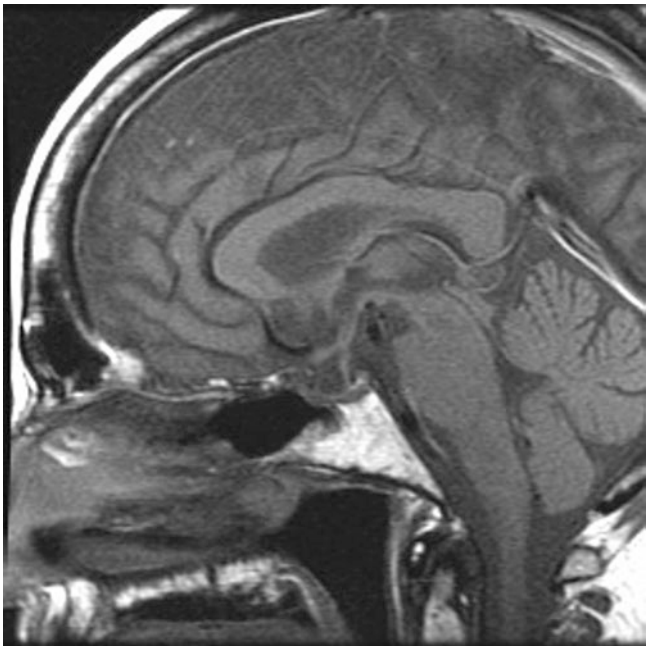

Fig. 17.2 Sella (MRI, pre-contrast, sagittal view) showing preservation of pituitary gland after complete removal of pituitary macroadenoma and associated hemorrhage

Transsphenoidal removal of the pituitary tumor was done 10 days after her admission (Fig. 17.2). *The tumor was removed in gross total fashion, and in the 6 years since, it has not recurred. Although some cases of pituitary apoplexy demand more immediate surgical intervention, in this patient the tumor was not producing visual loss, and her obtundation was provoked by the unhappy combination of profound hyponatremia and over-medication with a powerful narcotic analgesic. The presence of an unrelated cellulitis required treatment prior to surgery, and time was needed for correction of her hyponatremia, hyperglycemia, and hypocortisolemia in order to reduce surgical risk. Thus, a delayed surgical approach was chosen. Her headaches diminished as serum sodium returned to normal levels and disappeared once the tumor had been removed.*

This case offers several important lessons in the management of pituitary apoplexy. It is essential to recognize the MRI signature of hemorrhage in a pituitary adenoma, as the presence of apoplexy raises significantly both the urgency of treating it, and the concomitant risk of pituitary hypofunction. When any pituitary tumor is found, measuring hormone levels and serum electrolytes is essential. Severe headaches caused by a pituitary tumor are best treated by eliminating the tumor, and opioids should not be used at such a high dose in an elderly patient, in whom adverse effects are achieved at lower dose levels than in younger people. It is important to treat any potential inciting causes of pituitary apoplexy (e.g., hypertension or coagulopathy) present when a diagnosis of pituitary apoplexy is made, but treatment is only sufficient when the tumor itself is also treated. Hyponatremia is an important consequence of pituitary apoplexy and should be treated before surgery is undertaken. The same is true for low levels of serum cortisol, which must be corrected with steroid supplementation prior to an operation. Finally, even a complex medical situation in a sick patient with pituitary apoplexy can be managed effectively and safely if a deliberate, thoughtful, careful approach is used, so that surgery can be done effectively and safely.

Definition

Pituitary tumor apoplexy is a clinical syndrome, the hallmarks of which include headache, ophthalmoplegia, and altered level of consciousness. Hemorrhagic infarction of a pituitary tumor leading to rapid expansion of the contents of the sellar region and subsequent acute pituitary gland dysfunction is the underlying basis for this syndrome. The first case of pituitary apoplexy was described by Pierce Bailey in 1898 [1]. However, the term "pituitary apoplexy" was first introduced by Brougham et al. in 1950 in a case report describing five cases of hemorrhagic infarction of pituitary adenomas [2]. The word apoplexy derives from Greek (*apoplēssein* = to strike down, disable) and means in modern parlance the sudden onset of a neurological deficit, as when a stroke, in a setting of bleeding, results in abrupt loss of function. While nowadays we refer to such bleeding as hemorrhagic stroke, the term apoplexy has remained in use to describe hemorrhage in the pituitary region. Such hemorrhage in most cases occurs when a pituitary tumor is present, and as such, some authors argue that this condition would be more accurately described as pituitary tumor apoplexy [3].

Hemorrhage into a pituitary adenoma with resulting clinical symptoms is also called classical pituitary apoplexy. Spontaneous silent hemorrhage can occur in up to 25% of pituitary adenomas, and when discovered incidentally during routine imaging or histopathologic examinations, it is referred to as subclinical pituitary apoplexy [4, 5]. Pituitary apoplexy has to be distinguished from hemorrhage into a Rathke's cleft cyst, a very rare event whose clinical presentation is identical to pituitary tumor apoplexy syndrome [6–8]. Furthermore, infarction of the pituitary gland during a prolonged or severe period of hypotension is well described in pregnancy and post-partum and is referred to as Sheehan's syndrome [8–10]. The following discussion is dedicated to the diagnosis, management, and outcomes of classical pituitary apoplexy caused by bleeding in a pituitary adenoma.

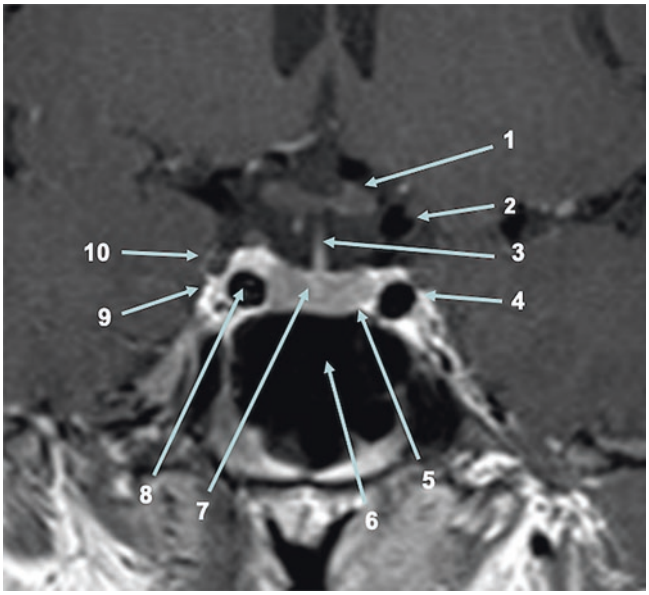

Fig. 17.3 Post-contrast MRI (coronal, T1-weighted image) showing the anatomical structures in the sella and parasellar region. (1) Optic nerve; (2) suprasellar internal carotid artery; (3) pituitary stalk; (4) lateral wall of cavernous sinus; (5) medial wall of cavernous sinus; (6) sphenoid sinus; (7) pituitary gland; (8) intracavernous carotid artery; (9) abducens nerve (nerve VI); and (10) oculomotor nerve (III nerve)

Anatomy and Physiology Review

To understand the clinical presentation of pituitary apoplexy, it is essential to review the contents of the sellar region and how the apoplectic event disturbs them (Fig. 17.3). Its clinical symptoms can be associated with the sudden onset of one (or more) of four events: presence of intracranial blood; acute onset of pituitary gland dysfunction; loss of vision; and cranial nerve dysfunction, usually manifesting as diplopia.

The presence of acute intracranial blood is a major source of headache. While in most cases of pituitary apoplexy the blood is contained within the tumor, there can be subarachnoid extension of the hemorrhage. Thus, ancillary tests are necessary to rule out a vascular cause of subarachnoid blood such as an aneurysm or a vascular malformation.

The pituitary gland is located within the sella turcica of the sphenoid bone. The gland comprises two parts: an anterior lobe that produces six hormones, including growth hormone (GH), adrenocorticotropic hormone (ACTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and prolactin, and a posterior lobe, the site of delivery and release of oxytocin and vasopressin produced in the hypothalamus. Acute hemorrhage into the anterior pituitary can result in sudden cessation of secretion of one or more of these hormones. Of the above hormones, acute deficiency of ACTH is of upmost importance as it results in a blunted cortisol response to stress, which if severe enough can be associated with profound hypotension and hyponatremia. Although dysfunction of the posterior pituitary causes alteration of vasopressin secretion leading to central diabetes insipidus and associated hypernatremia, it is rarely observed clinically. Since almost all pituitary adenomas arise in the anterior lobe, they mainly affect the function of that part of the gland. Prolactin, on the other hand, is secreted by the anterior lobe and rises in response to pituitary stalk compression, or when the adenoma itself secretes prolactin. While acute alterations of serum prolactin level do not affect the clinical picture, initial and subsequent prolactin levels have diagnostic significance and thus should be measured.

The two cavernous sinuses are located on either side of the pituitary gland. These venous structures enclose the internal carotid arteries as well as cranial nerves III, IV, and VI. The latter control eye movements, and dysfunction of any of these nerves results in abnormal eye movements on directed gaze with the subjective report of diplopia. Profound compromise of cranial nerve III can also cause eyelid closure. Finally, the optic nerves and chiasm are located in the suprasellar region, and with sufficiently large lesions, compromise of visual acuity and/or fields may occur.

Clinical Presentation

Familiarity with the anatomical structures of the sellar region allows one to understand the symptoms that patients may experience after hemorrhage in that area. The spectrum of presentation of pituitary apoplexy correlates with the size of the hemorrhage and degree of injury to the surrounding structures. While small hemorrhages may be detected radiographically in otherwise asymptomatic patients, a condition referred to as subclinical apoplexy, large hemorrhages can present with an acute alteration of consciousness, cardiovascular collapse, and obtundation, and they can be life-threatening. Between these two extremes lies a spectrum or constellation of clinical signs that can include headache, changes in vision including diplopia, and various degree of pituitary hypofunction (Fig. 17.4). A given presentation may include one or many of the above signs and symptoms. The most common presenting clinical symptoms are summarized in Table 17.1. The typical ranges of demographics and predisposing or associated factors are shown in Table 17.2 [11].

Headache

Headache is the most common symptom observed in pituitary apoplexy, occurring in 95% of patients [9, 12]. The etiology of headache is likely multifactorial. The rapid increase in pressure within the intrasellar compartment as a result of the hemorrhage causes stretching of the dura lin-

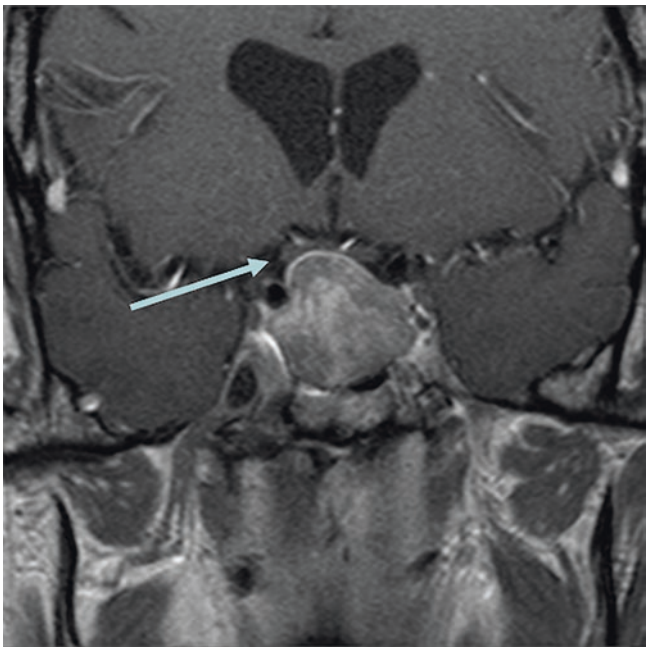

Fig. 17.4 Pituitary macroadenoma with intratumoral hemorrhage (= pituitary apoplexy). This tumor has expanded into the suprasellar space and compresses the optic nerve and chiasm, with resulting onset of severe headache and a temporal visual field deficit. The patient also has profound hypopituitarism. Surgical removal of this hormonally nonfunctional tumor is indicated

Table 17.1 Common presenting clinical features of pituitary apoplexy

Clinical symptom
Headache
Nausea and vomiting
Decreased visual acuity

Diplopia
Cranial nerve palsy (III, IV, or VI)
Altered mental status
Seizure
Collapse/shock
Coma

ing the sella and produces the resulting headache. Leakage of blood from the hemorrhagic tumor into the subarachnoid space can contribute as well. Vomiting is observed in 70% of patients presenting with a headache and can stem from increased intracranial pressure or from pituitary hypofunction [14]. Headache associated with pituitary apoplexy is most commonly "thunderclap" in nature and tends to respond to resection of the underlying hemorrhagic tumor. When a conservative (non-operative) strategy is chosen, drugs that inhibit platelet aggregation should be avoided and opioid usage limited to prevent clouding of the patient's sensorium [13].

Table 17.2 Clinical correlates of pituitary apoplexy [11]

Gender (male/female) (no.)	48/52
Demographics	(%)
Patients with apoplexy as first presentation of pituitary disease	73
Patients with apoplexy and prior known pituitary disease	27
Predisposing/associated factors[a]	
Prior diagnosis of hypertension	33
Pregnant or post-partum	13
Diabetes mellitus	8

Dopamine agonist	4
Radiotherapy	4
None	46
Secretory status of associated adenoma	
Nonfunctional or gonadotroph adenoma	90
Prolactin-secreting adenoma	10

[a]Some patients had more than one predisposing factor

Visual Disturbance

Visual symptoms observed in cases of pituitary apoplexy include either optic nerve dysfunction or diplopia. The optic apparatus, which includes optic nerves, optic chiasm, and optic tracts, is located in the suprasellar compartment and can be subject to direct pressure from the expanding hematoma. Such pressure most commonly provokes bitemporal visual field restriction due to pressure against the undersurface of the chiasm. Direct pressure on one or both nerves or tracts could also result in changes in visual acuity, culminating in a central or junctional scotoma. The latter results in the superior temporal defect in one eye and decreased central vision in the other eye as a result of compression of anterior chiasm, the site of anteriorly looping fibers from the contralateral nasal retina (Fig. 17.5).

Diplopia is another very sensitive presenting symptom of pituitary apoplexy. Cranial nerves that control eye movements, namely III, IV, and VI, run within the cavernous sinus on either side of the sella and are highly susceptible to compression (see Fig. 17.3). Cranial nerve III dysfunction is observed most frequently and can present as ptosis, a dilated pupil and an eye that looks down and out with inability to adduct. Cranial nerve VI innervates the lateral rectus muscle of the eye and controls eye abduction; thus, dysfunction results in inability of the eye to look outward.

Pituitary Dysfunction

Up to 80% of patients with pituitary apoplexy present with pituitary dysfunction [12, 15–17]. While any of the pituitary hormones can be affected, acute decrease in ACTH secretion with subsequent hypocortisolism is the most clinically sig-

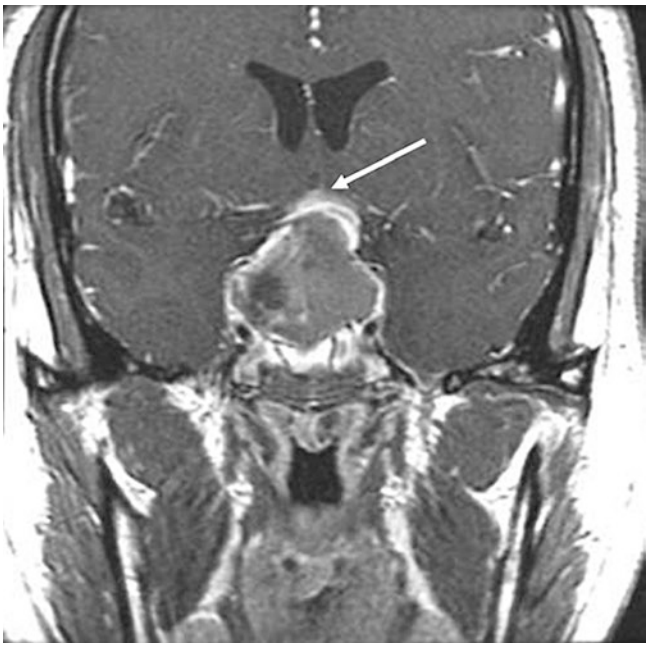

Fig. 17.5 Nonfunctional pituitary macroadenoma expanded by hemorrhage and causing a bitemporal visual field deficit. The arrow points to the area of impaction on the optic chiasm. Note the fuzzy, ill-defined hyperintensity present; this is subarachnoid blood that leaked through a disrupted diaphragm sellae. This patient's vision returned to normal after transsphenoidal removal of the tumor and associated hemorrhage

nificant endocrinopathy. Acute adrenal insufficiency can precipitate hypotension (shock) but may also present with hyponatremia, hypoglycemia, nausea, vomiting, obtundation, and coma [18].

Serum prolactin levels at presentation may reflect the degree of pituitary compression and thus give an indirect, albeit imperfect, indication of intrasellar pressure. Low prolactin levels indicate a high degree of pituitary compression and less chance of recovery from hormone impairment after a decompressive procedure [19].

While other pituitary hormones may be affected as a result of pituitary hemorrhage, the reported incidence of these abnormalities varies greatly. Although ACTH dysfunction is most clinically important, it is crucial to identify dysfunction in other hormonal axes as well. GH deficit is seen in 88% of cases, ACTH dysfunction in 66%, TSH abnormality in 42%, and loss of FSH and LH in 85% of cases of pituitary apoplexy [20, 21].

On rare occasions apoplexy causing global infarction of a functional adenoma can cause spontaneous remission of the patient's clinical symptoms of hormonal excess, as well as correction of the relevant hormone levels. This phenomenon has been reported in patients with moderately sized adenomas causing acromegaly or Cushing's disease [22].

Incidence and Predisposing Factors

The true incidence of pituitary apoplexy is difficult to estimate, as many cases are asymptomatic. The reported incidence for symptomatic hemorrhage ranges from 2% to 7% of all pituitary adenomas [12, 15, 16]. In 80% of patients with pituitary apoplexy, the initial diagnosis of hemorrhage is made at the time the tumor is first discovered [23]. There is a slight male predominance for hemorrhage into a pituitary tumor, and most patients present in their fifth or sixth decade [17, 24, 25].

It has been estimated that pituitary adenomas are five times more likely to bleed compared to other tumors [26]. Several characteristics of pituitary adenoma have been identified that put patients at this increased risk of apoplexy. Gender, age, and specific hormonal subtypes carry no increased risk of apoplexy compared to matched controls [21]. An increased risk of hemorrhage is, however, observed in patients with a history of hypertension [12, 17]; usage of anticoagulants or antithrombotic medications [27, 28], estrogen therapy [29], or dopamine agonists [16, 30]; or dynamic testing of pituitary function (see Fig. 17.5) [31, 32]. Rarely, a patient with a pituitary adenoma sustains a head injury that provokes apoplexy [33]. One factor more consistently associated with a higher incidence of apoplexy is tumor size; macroadenomas are much more likely to present with intratumoral hemorrhage than are microadenomas [15, 34–37]. Furthermore, some series have shown that in many cases there is an associated area of infarction within the tumor; thus it is not clear whether the initial event is infarction or hemorrhage [38, 39].

Several hypotheses have been put forward to explain what causes ischemia and hemorrhage in pituitary adenomas. One theory postulates that as a tumor enlarges, it compresses its own blood supply, eventually leading to ischemia and hemorrhage. On the other hand, tumor enlargement may be associated with the tumor's outstripping its own blood supply, thus leading to ischemic necrosis. The higher incidence of hemorrhage into an ischemic or necrotic area within a pituitary adenoma may relate to the unique vascular supply of these tumors [34].

The unique blood supply to the pituitary gland has been implicated in predisposing these tumors to hemorrhage. The pituitary gland is supplied by the hypophyseal portal system. The blood supply to the anterior pituitary comes from the superior hypophyseal arteries, branches of the internal carotid artery that travel along the pituitary stalk and form a rich vascular portal system. The posterior pituitary receives its blood supply from the inferior hypophyseal arteries, which are terminal branches of the meningohypophyseal trunk of the internal carotid artery. There are many anasto-

moses between the hypophyseal network on and in the pituitary gland and the portal vascular on the pituitary stalk [40]. Pituitary adenomas receive their blood supply from the portal system, as well as directly from the hypophyseal vessels. This exposes the pituitary adenoma to systemic blood pressures. The presence of hypertension with the rich and complex network of the portal system increases the risk of bleeding by fivefold compared to other tumors [13].

Inherent tumor characteristics have also been implicated in predisposing pituitary adenomas to ischemia and apoplexy [41]. Pituitary adenomas are metabolically active tumors that require a continuous supply of glucose and demonstrate a high glucose uptake in 18F-fluorodeoxyglucose-PET studies [42]. Interruption of glucose supply results in rapid adenoma cell death and may lead to infarction [41]. Furthermore, pituitary adenomas have a low level of secretion of such angiogenic factors as vascular endothelial growth factor (VEGF) [43]; thus it is not surprising that they have a reduced vessel density on histological examination which clinically translates into decreased contrast uptake on imaging studies [44]. Finally, perfusion studies have demonstrated very low blood flow in pituitary adenomas [45], likely as a consequence of the high intratumoral pressure that is typical for these tumors [46], factors that predispose pituitary adenomas to a higher risk of developing ischemia. In summary, the combination of the microvascular architecture of pituitary adenomas with the resultant low blood flow and the inherently high metabolic demand of adenoma cells make these tumors very susceptible to ischemic injury during times of systemic blood pressure fluctuation and thus to development of intratumoral pituitary hemorrhage and clinical apoplexy.

Pituitary Apoplexy Workup

Differential Diagnosis

In a patient presenting with a severe headache, a number of other conditions should be considered and ruled out besides pituitary apoplexy. The differential diagnosis includes subarachnoid hemorrhage secondary to a ruptured aneurysm, meningitis, and hydrocephalus, among others. When visual loss and ophthalmoplegia point to pathology in the sellar region, cavernous sinus thrombosis, brain abscess, or a growing cerebral aneurysm should be considered. Other clinical conditions to be considered as part of the differential diagnosis for pituitary apoplexy include temporal arteritis, ophthalmoplegic migraine, hypertensive encephalopathy, basilar artery occlusion, and brainstem stroke or hemorrhage [21, 34].

Diagnostic Imaging

Visualization of the hemorrhage within the sellar region is necessary to make the definitive diagnosis of pituitary apoplexy. Computed tomography (CT) of the brain is a good initial study for detecting acute blood in the sellar region (Fig. 17.6) [47]. A hyperdense lesion in the sellar region on a non-contrast CT scan is highly suggestive of hemorrhage within the first 3 days after the event. Although this modality of imaging is sensitive for hemorrhage, it is not necessarily specific. As intracranial aneurysms and calcifications associated with the craniopharyngioma are also hyperdense on CT scans, it may be difficult to make a definitive diagnosis [35]. To characterize the lesion as well as the underlying pathology, magnetic resonance imaging (MRI) should be obtained [48].

The MRI T2-weighted gradient echo sequence is most sensitive for blood products and may detect even small hemorrhages. It is not, however, accurate at estimating the size or age of the hemorrhage. By surveying the corresponding T1- and T2-weighted sequences, it is possible to determine the age of the hemorrhage. The changes in signal intensity of the hemorrhage over time on T1- and T2-weighted MRI scans are summarized in Table 17.3. Furthermore, MRI allows better anatomical visualization of the pituitary gland and may help delineate the underlying tumor, as well as define the relationship of the tumor and the hemorrhage to the optic apparatus. It can also identify extension into either cavernous sinus and rule in or rule out an aneurysm [48–50].

Laboratory Investigations

Fluid and electrolyte disturbances are frequently observed in patients with pituitary apoplexy. Hemorrhage into the pituitary adenoma may affect the function of the pituitary gland itself. In fact, reduced ACTH secretion and resulting hypocortisolemia are observed in 80% of cases [12, 17, 51]. Acute adrenal insufficiency may lead to hyponatremia and, in severe cases, to cardiovascular collapse. Therefore, determination of serum electrolyte levels and fluid balance status is critical to avoid missing adrenal crisis in patients with pituitary apoplexy. Symptoms of acute adrenal insufficiency include vomiting, abdominal pain, myalgia, joint pains, and severe hypotension, leading to hypovolemic shock [18].

Other pituitary hormones can also be affected. TSH deficiency is noted in 50% of cases, and if pre-existing, it may lead to increased morbidity and mortality of pituitary apoplexy in the context of concurrent ACTH deficiency. Disturbance of the gonadotropin axis is observed in 75% of cases [12, 17, 51]. Prolactin levels should be measured, as

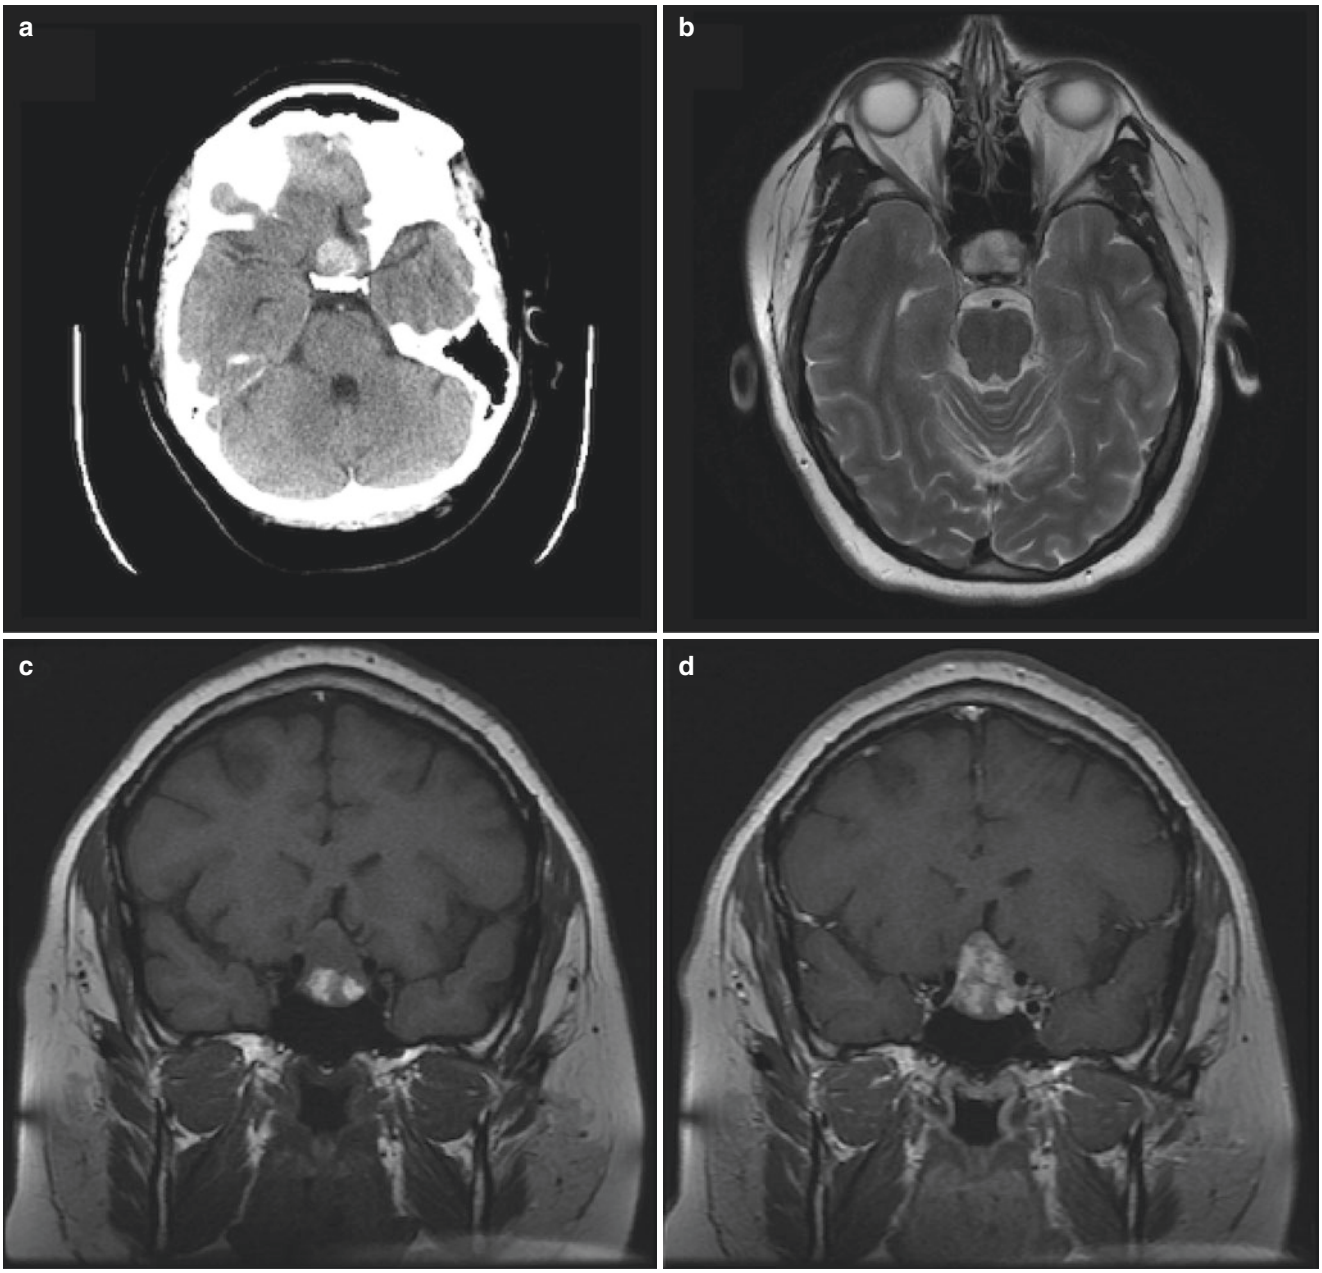

Fig. 17.6 Representative images for a patient with pituitary apoplexy. Non-contrast CT axial image (**a**) demonstrates a hyperdense lesion in the sellar region consistent with recent hemorrhage. The T2-weighted axial MRI image (**b**) demonstrates an expansile hyperintense lesion in the sellar region. The T1-weighted coronal slices through the sellar region (**c**, **d**) demonstrate a 2.5 cm lesion with an inferior hyperintense component consistent with subacute blood (**c**). The superior component of the tumor heterogeneously enhances with contrast administration, giving an appearance consistent with an underlying pituitary adenoma (**d**)

Table 17.3 Typical appearance of blood on T1- and T2-weighted MRI images

Stage of hemorrhage	Time	T1	T2
Hyperacute	<24 hours	Isointense	Hyperintense
Acute	1–3 days	Isointense	Hypointense
Early subacute	3–7 days	Hyperintense	Hypointense
Late subacute	7–14 days	Hyperintense	Hyperintense
Chronic	>14 days	Hypointense	Hypointense

lower levels of this hormone are predictive of the degree of pituitary compromise and of a higher likelihood of need for pituitary hormone replacement in the future [19].

Alteration of anterior pituitary function is often observed in cases of pituitary apoplexy. In contrast, function of the posterior pituitary gland is rarely affected. While transient hyponatremia in the acute period is frequently attributed to

SIADH, permanent central diabetes insipidus is observed in only 3% of cases [52, 53].

In summary, a patient with suspected pituitary apoplexy requires careful assessment of fluid and electrolyte balance. In addition, a complete blood cell count with differential should be obtained to assess for meningitis and for states of coagulopathy secondary to platelet dysfunction. Finally, a panel of hormone studies should be obtained to diagnose and monitor pituitary dysfunction. These should include random serum cortisol, free T4, TSH, IGF-1, and prolactin levels.

Emergency Department Management

Initial management of pituitary apoplexy in the emergency department should focus on supporting the patient's hemodynamic status and treating adrenal insufficiency (Fig. 17.7). The major source of morbidity and mortality associated with pituitary apoplexy is acute adrenal insufficiency from which early series of patients reported mortality close to 50% [2, 34]. However, in recent years there has been quite an improvement in outcomes associated with treatment of this condition largely attributed to improved ability to diagnose pituitary apoplexy with better imaging technology and to recognition and appropriate management of adrenal insufficiency.

The most important initial treatment of pituitary apoplexy and the associated cortisol deficiency is administration of glucocorticoids. After drawing blood for a baseline measurement of serum cortisol, a "stress" dose of 100 mg of hydrocortisone is administered intravenously in patients with suspected adrenal insufficiency. This is followed by a short course of high-dose hydrocortisone (50 mg intravenously at 6-hour intervals) with a subsequent slow taper based on the patient's clinical response. Patients are typically discharged on a maintenance dose of hydrocortisone (15–20 mg daily in divided doses) [18]. In addition to treating the adrenal insufficiency, in the acute setting, glucocorticoids reduce the swelling associated with the underlying tumor and hemorrhage. Thus they minimize the pressure in the sellar region and may lead to symptom improvement.

Intravenous fluid administration to maintain euvolemia and support blood pressure should be instituted. To minimize the amount of edema associated with the hemorrhage, normal saline or Ringer's lactate should be used. If the patient presents with hyponatremia, attention should be paid to the rate of sodium correction to ensure that it increases by 12 mEq/L or less in 24 hours [18]. Gradual correction helps to minimize the risk of central pontine myelinolysis, a devastating complication of sudden large shifts in serum sodium levels.

In patients with pituitary apoplexy who are hypertensive or who take anticoagulants or antithrombotic medications, the blood pressure should be controlled medically and the anticoagulant effects reversed [54]. This is relatively straightforward for patients on heparin or warfarin but more chal-

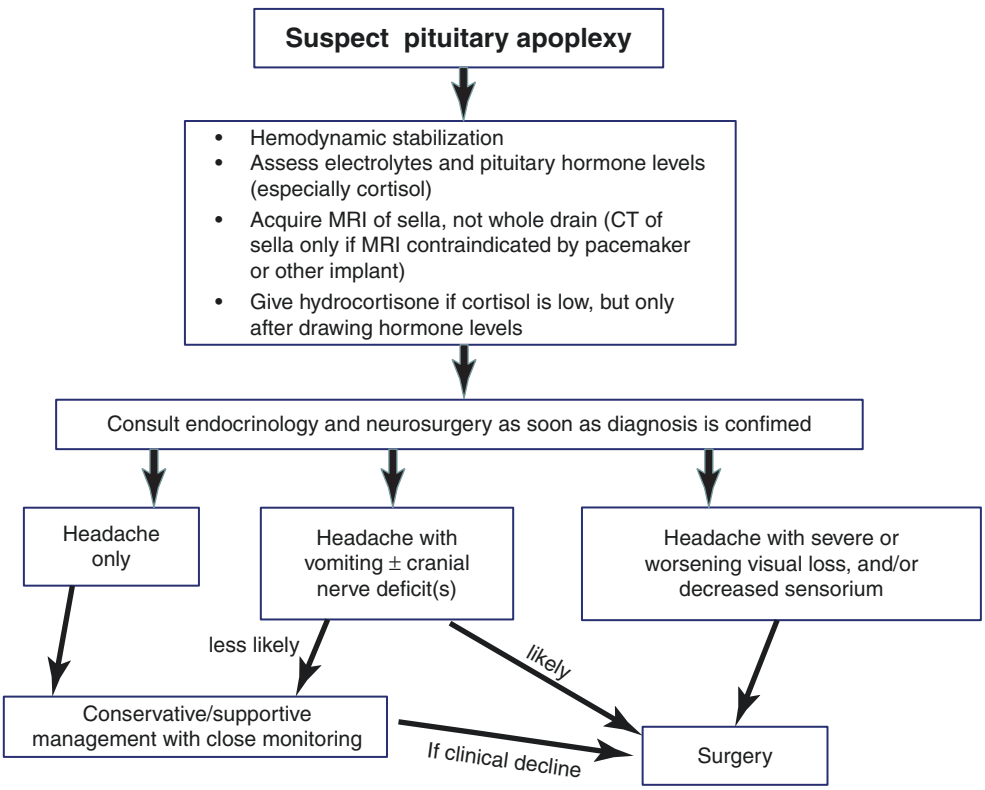

Fig. 17.7 Algorithm for decision-making when treating a patient for possible pituitary apoplexy

lenging for those on one of the direct oral anticoagulants now widely used for treating venous thromboembolism and for stroke prevention. These include the direct thrombin inhibitor dabigatran and the Xa inhibitors apixaban, rivaroxaban, and edoxaban. Reversal of the latter group requires either administration of prothrombin complex concentrate or andexanet alfa; dabigatran can be abrogated by idarucizumab (5 gm i.v. over 5 minutes), which binds it with high affinity [55].

Neurosurgical Management

There are no clear guidelines for definitive management of pituitary apoplexy. In a subset of patients managed conservatively, it is difficult to predict who will ultimately require a surgical intervention. No randomized controlled studies are available to provide evidence of differences in outcomes in conservative versus surgically treated patients. Although the question remains unanswered whether operative or nonoperative management is best, patients usually undergo surgery unless their symptoms are minor and no neurological deficits are present (see Fig. 17.7).

Traditionally, pituitary apoplexy has been treated surgically. In patients presenting with acute vision loss, worsening visual field deficit, or ophthalmoplegia, surgical intervention is indicated (see Figs. 17.4 and 17.5) [12, 50, 56]. The "pituitary apoplexy score" (PAS) introduced in 2011 can be used for monitoring patients for signs of deterioration [50]. It incorporates assessment of level of consciousness, visual acuity, visual field deficits, and presence of ocular nerve palsies. A PAS of 4 or greater, or an increasing score while the patient is under observation, may indicate the need for a surgical intervention [50, 57]. Furthermore, surgery should be offered to patients who have no improvement in their symptoms after 1 week of steroid administration [15, 58]. Recent surgical series show that endonasal transsphenoidal surgery for tumor removal and evacuation of hemorrhage provides prompt, effective, and safe decompression of sellar and parasellar structures and is associated with good recovery of vision and clearance of headache [59–61].

Recent retrospective case series demonstrate no difference in the visual and endocrine outcomes between patients treated conservatively and those who underwent surgery and thus make a case for conservative management of pituitary apoplexy [17, 51, 62, 63]. Indeed, some degree of slow shrinkage of tumor has been reported in 76% of patients followed without surgery [59]. These studies, however, suffer from a significant selection bias and do not have appropriately matched controls, since in most studies patients with larger tumors or more severe symptomatology undergo surgical decompression. One study examined the imaging characteristics of pituitary adenoma, including ischemic and hemorrhagic tissue, in an attempt to predict the likelihood of success of conservative management [58]. The presence of a single larger hypodense area within the tumor on a CT scan and early radiographic evidence of tumor involution may be associated with a higher likelihood of clinical resolution of pituitary apoplexy [58]. Regardless of the management strategy chosen, the outcome after treating pituitary apoplexy is excellent, as demonstrated in a recent retrospective cases series of 87 patients [56]. While 20% of patients were treated conservatively, there were no significant differences in outcome metrics between the two groups. Moreover, among those patients, one third presented with a significant alteration of level of consciousness but had an excellent recovery with conservative management [56].

One strong argument for conservative treatment can be made for hemorrhage into a prolactinoma given that medical treatment is the standard of care for that tumor subtype at present. Dopamine agonists are effective at reducing prolactin levels and at reducing the size of the tumor [64]. However, if such a patient presents with worsening vision caused more by the hemorrhage than the tumor volume per se, it is reasonable to consider prompt transsphenoidal decompression of the optic apparatus.

The endoscopic or microsurgical transsphenoidal approach is used most often for decompression of hemorrhage into a pituitary adenoma [34, 61, 65]. This surgery confers low morbidity and mortality for the patient and provides adequate decompression of the neurological structures of the sellar region. Furthermore, because this approach for the most part allows access to the adenoma itself, it allows the surgeon to address the primary lesion in addition to the hemorrhage.

Rarely, subarachnoid bleeding associated with pituitary apoplexy can provoke arterial vasospasm, which may lead to cerebral infarction if not controlled. Vasospasm can be diagnosed by transcranial Doppler or cerebral angiography and reversed by angioplasty directed at the affected vascular segment(s) [66]. As a patient with apoplexy severe enough to cause subarachnoid hemorrhage generally has a concomitant visual and hormonal loss, urgent transsphenoidal decompression is indicated with avoidance of hypotension, in conjunction with angioplasty.

In summary, no clear guidelines exist to determine the optimal management strategy for pituitary apoplexy. A multidisciplinary team involving an endocrinologist, neurosurgeon, and ophthalmologist is necessary to determine the optimal direction of care. Patients with minor symptoms of pituitary apoplexy, or those who have clinical improvement after the apoplectic episode, can be treated conservatively with excellent recovery. On the other hand, patients with visual compromise, significant visual field deficits, and ophthalmoplegia require surgical decompression of the sellar lesion via a transsphenoidal approach.

Outcomes and Follow-Up

The goal of treatment of pituitary apoplexy is to improve compromised visual acuity, reduce visual field defect, and enhance pituitary function. Loss of vision resulting from pressure on the optic nerves has traditionally been thought to be difficult to restore. Nevertheless, if surgical decompression is undertaken within 1 week of the event, there is significant improvement in visual acuity [12, 67]. The success rate is much lower when the surgical intervention is delayed, implying that prolonged compression of optic nerves ultimately results in permanent nerve damage.

In patients who present with minor visual symptoms such as a small field cut, conservative management demonstrated a comparable rate of symptom improvement, thus suggesting that conservative management with glucocorticoids is an alternative strategy [51]. The direct comparison of surgical versus medical management in pituitary apoplexy is complicated due to lack of appropriately matched controls in the studies.

In contrast to the improvement in the visual symptoms, pituitary function does not recover as well after apoplexy. Nevertheless, 50% of patients will have some improvement in pituitary function [19, 68], but 80% of patients will require long-term supplementation of at least one hormone, usually cortisol or thyroxine [12, 51, 62]. Overall, testosterone replacement is needed in 64% of patients [15]. On the other hand, central diabetes insipidus is relatively uncommon, and DDAVP replacement is required only in 20% of patients. Interestingly, the incidence of a need for DDAVP in the conservatively managed group of patients is low, while surgical decompression is associated with a higher rate of diabetes insipidus, observed in 23% of patients treated surgically [56]. Recovery from anterior pituitary insufficiency does seem to correlate somewhat with the prolactin level prior to surgery, with the best outcome in this regard seen when prolactin is ≥8.8 ng/mL [69]. That correlation makes sense as a low prolactin indicates a more profoundly damaged anterior lobe.

The pace and likelihood of improvement after resection of an apoplectic pituitary adenoma was nicely demonstrated by Zaidi et al. [70]. In their large surgical series, headache and loss of vision showed consistent resolution, whereas complete correction of ophthalmoplegia occurred in 83%; hormonal deficits recovered infrequently and typically required long-term supplementation. Ophthalmoplegia was the slowest to improve, with a mean time to recovery of 2.4 months, in contrast to the much faster mean times for recovery found with visual field deficits (8 days) and headache (2 days).

Summary

Pituitary apoplexy is a clinical syndrome associated with pituitary tumor hemorrhage that may result in visual acuity and field compromise, ophthalmoplegia, and pituitary dysfunction. Initial investigations should include a CT scan to detect the presence of acute blood, formal visual field testing, and an MRI scan to delineate further the size and extent of the adenoma and hemorrhage. A complete endocrine workup should be performed on admission, and acute cortisol deficiency should be corrected if present. Further management of a patient with pituitary apoplexy should include a multidisciplinary team consisting of a neurosurgeon, endocrinologist, and ophthalmologist, and a decision with respect to surgical versus conservative management should be made in a careful and nuanced fashion driven by the severity of the patient's symptoms, the degree of compression of the optic nerves and chiasm, and the size of the pituitary adenoma. Overall the outcomes of pituitary apoplexy are excellent.

Spinal Cord Compression

18

Jayne M. Viets-Upchurch and Sorayah S. Bourenane

Case Study

A 73-year-old woman with a history of breast cancer presented to the emergency department (ED) for evaluation of bilateral lower extremity weakness and shaking. She was diagnosed with locally invasive, nonmetastatic breast cancer 6 months prior to her presentation. Treatment has been delayed due to endemic health concerns. In the interval, she received hormonal therapy in anticipation of surgical resection which was scheduled to take place in 2 days.

She reported a 3-week history of bilateral lower extremity weakness with a sensation that her knees were about to give out. Symptoms were intermittently and without warning. Although she has not fallen, her symptoms occur frequently enough that she quit taking her routine morning walks. Two weeks prior to her presentation, she developed bilateral hip pain that was sharp and shooting. It occurred at night and was described as nonradiating and 8/10 in severity. Three days prior to her presentation, she had a near-miss fall in her kitchen and now feels weak enough that she ambulates with a cane. For the past 2 days, her calf muscles felt tight bilaterally. She denies fecal or urinary incontinence and has no numbness or paresthesias. She has a headache she describes as "not bad." She has taken no medications for her symptoms, electing to treat them with breathing exercises, meditation, and rest.

She was evaluated at an urgent care facility in her hometown. The physician suggested she might have Guillain-Barre syndrome and offered no further evaluation or therapy. She traveled 1500 miles yesterday to arrive at your facility for her surgery day after tomorrow.

Aside from lower extremity ankle edema after air travel yesterday, her review of systems is otherwise negative. Her past history is notable for venous thromboembolism managed with IVC filter placement.

Her physical exam reveals a well-appearing woman. Her neurologic exam revealed normal strength and patellar reflexes with intact sensation, with no saddle anesthesia or clonus. Her gait is not tested due to the patient's sensation of instability. The remainder of her examination is unremarkable, with the exception of a firm tumor mass in the upper outer quadrant of the left breast. There is no apparent lymphadenopathy and only mild ankle edema.

Her laboratory evaluation reveals a normal CBC, metabolic profile, and no evidence of coagulopathy. A CT of the head is normal; however, an MRI of the cervical thoracic and lumbar spines shows evidence of metastases at T9 with circumferential epidural tumor burden compressing and deforming the cord. She has further osseous metastases at L5 with circumferential epidural tumor burden narrowing the canal and crowding the roots of the cauda equina.

Neurosurgery evaluated the patient in the ED. She had no bony impingement upon the spinal cord or thecal sac, and recommendations were given for radiation therapy. Radiation oncologic evaluated the patient and deemed her a suitable candidate for therapy.

The patient was admitted to the hospital and treated with steroids and analgesics. On restaging, a CT of the chest showed the known primary tumor with new invasion of the chest wall musculature as well as scattered pulmonary nodules too small to characterize. There was no lymphadenopathy. CT of the abdomen and pelvis revealed no clear-cut evidence of visceral metastases. Multiple bony lesions were noted. Nuclear medicine bone scan was notable for multifocal skeletal uptake consistent with metastases at T9, L5, left acetabulum, left femur, and left ischium.

Physical therapy was consulted. She was discharged home on hospital day 3 with improved symptoms. Outpatient

follow-up was scheduled with physical therapy, relation oncologic, and breast medical oncologic.

Introduction

Traumatic spinal cord injury is a well-documented, devastating injury leading to sensory loss, paralysis, sphincter dysfunction, and protracted pain. The Centers for Disease Control and Prevention estimates that there are 12,000–20,000 such cases annually [1]. Malignant spinal cord compression (MSCC) is equally devastating and occurs at a similar rate to traumatic spinal cord injury [2]. Curative and life-prolonging treatments in cancer patients are expected to yield an increased incidence of the condition.

Cancer is the most common systemic disease affecting the spine [3]. MSCC presents as a true oncologic emergency resulting from tumor-related compression of the thecal sac and spinal cord [2, 4]. As with traumatic injury, untreated MSCC leads to paraplegia, incontinence, and permanent disability. It presents clinically in approximately 3–10% of cancer patients prior to death [5, 6]. Cancer patients have a median survival of 3–6 months from diagnosis of MSCC [5, 7, 8]. Once treated, 8–20% of patients experience recurrent compression either locally or at another vertebral level [9, 10].

The past several years have yielded significant advances in the diagnosis and treatment of this condition. Prompt recognition and treatment is essential to maintain mobility and neurological function. Any former or active cancer patient presenting with new or worsening back pain, even in the absence of neurological deficit, merits evaluation for spinal cord compression [11]. Individual risk assessment is necessary [12].

Epidemiology

Postmortem studies suggest that MSCC is present in up to 36% of cancer patients [13, 14]. In a US nationwide study of 15,367 cases of MSCC, the mean age at hospitalization was 62 years [6]. Men outnumber women nearly two to one, with only 37.5% of cases occurring in women. In approximately 20% of cases, MSCC is the initial presentation of cancer [8, 15]. Increasing cancer prevalence, coupled with prolonged life expectancy of diagnosed patients, is anticipated to drive the incidence upward.

Prevalence of MSCC varies depending on tumor type. Cancers of the breast, lung, and prostate each account for 15–20% of cases. Renal cell carcinoma accounts for an additional 5–10%. Multiple myeloma and lymphoma are the most frequent liquid tumors associated with MSCC, each contributing 5–10% of cases [2, 6, 16]. MSCC affects up to 15% of myelomas [5, 6] and 13% of lymphomas [6]. In patients with prostate cancer, 5.5% develop MSCC [6]. In contrast, it occurs in only 0.2% of pancreatic cancers [5]. In children, the most commonly associated malignancies are sarcoma, neuroblastoma, germ-cell tumor, and Hodgkin lymphoma [2, 16].

The most common location of MSCC is the thoracic spine (70% of cases); 20% of cases occur at the lumbosacral level and 10% in the cervical region [2]. It is hypothesized that this pattern represents the primary tumor's lymphatic drainage. Accordingly, metastases from breast and lung cancers tend to be found in the thoracic spine. Pelvic and intra-abdominal malignancies most commonly migrate to the lumbar spine. Multiple, noncontiguous spinal epidural metastases were noted in 32% of patients who underwent complete imaging of the spine [17]. Among those, two-thirds have multicentric disease affecting more than one region (cervical, thoracic, and lumbar) of the spine [18].

Historical factors that predispose the patient to MSCC include known metastatic disease at the time of cancer diagnosis and known vertebral metastases.

Pathophysiology

Most cases of MSCC are epidural in origin, arising from the vertebral column in 85% of patients [2]. The marrow of the vertebral body provides fertile ground for circulating tumor cells. Their growth eventually replaces the marrow and invades into the canal through thrombosed venous plexuses. These events appear to occur independently of bony destruction [19]. Epidural spread may also occur by direct tumor extension or by direct deposition of tumor cells into the epidural space [16].

Ultimately, neuronal injury is thought to involve vasogenic edema [20] leading to ischemia [19], presumably through venous infarction, but there has been debate regarding this last phenomenon [21]. In cases of paralysis, demyelination is evident [21].

Clinical Presentation

History

Presenting symptoms of MSCC can be motor (weakness, paraplegia), sensory (pain, numbness, neuropathy), and/or autonomic (incontinence). Symptoms vary based on the location of the metastatic lesion; however, they are a poor indicator of the level of involvement [18].

Although it is nonspecific, pain is the primary complaint in 83–96% of those with MSCC [22, 23]. Pain can be referred, local, radicular, or a combination of all three [24].

Misdiagnosis is a common issue in the ED setting. In an interesting retrospective study of 63 patients with spinal cord compression from a variety of causes (only 10 were due to cancer), 18 (29%) were misdiagnosed [25]. Consequently, there was a significant delay in diagnosis despite obvious neurological deficits at presentation. Highlighting this historical delay, back pain is present for a median of 62 days prior to treatment of MSCC [26].

Patients may report pain in a band-like distribution. It is generally described as sharp, shooting, or deep [11]. As with mechanical causes of back pain, the pain associated with MSCC may worsen with weight-bearing loads, which bring pressure to bear on the vertebral column [27]. Other common precipitating factors include coughing, bending, and sneezing [11]. Twenty percent of patients report that rest in a supine position exacerbates symptoms and often disrupts sleep [3, 11]. These patients frequently sleep in an upright position.

Weakness follows pain with an estimated 35–85% of patients endorsing the symptom [28]. Patients presenting with radiculopathy are symptomatic an average of 9 weeks prior to diagnosis [29].

Early studies showed ataxia in up to 67% of patients with nearly 65% of those having profound motor deficits that prevented walking [22]. Perhaps as a result of heightened awareness, a more recent study of patients receiving radiation therapy showed 67% of patients were ambulatory (although 28% required assistance) [30]. Loss of sensation, dense paraplegia, and incontinence are late findings and signal some degree of permanent disability [22].

Because of its high specificity (98%), any cancer patient with new back pain should be considered to have metastasis until proven otherwise [3]. Because cord compression is an evolving condition, a patient with previously stable back pain may present with recently worsening symptoms.

Physical Examination

Spinal tenderness may be present overlying the level of metastatic deposit. Nonetheless, it is difficult to thoroughly assess the location of MSCC lesion on the basis of examination alone. Pain in the thoracic spine and abnormal gait are suggestive of cord compression [31]. However, the absence of these findings is not sufficient to rule out the disease.

Documentation of a detailed physical examination is essential. Serial exams are frequently required, and a thorough neurologic exam, including sensation, strength, and reflexes, should be carefully recorded upon presentation.

Patients with cervical spine tenderness or symptomatology should be immobilized and placed in a Philadelphia collar until stability of the area can be assessed. Likewise, if spinal instability is suspected, range-of-motion testing is contraindicated, and the patient should be immobilized.

Table 18.1 Levels of disability according to Frankel et al. [32]

Frankel grade	Motor	Sensory
A	Complete paresis	Insensate
B	Complete paresis	Sensation preserved
C	Incomplete but nonfunctional	Sensation preserved
D	Functional but symptomatic	Sensation preserved
E	Normal	Normal

Hyperreflexia and an upward-going Babinski reflex are common findings [31]. Weakness and paraplegia are late findings. Decreased rectal sphincter tone and urinary incontinence are indicators of poor outcome. A bedside bladder scan may be useful for documenting post-void residual to assess for evidence of urinary retention.

Degree of disability is typically described using the Frankel grading scale [32]. This scale, established in 1969, classifies patients according to five levels (A through E) with A being complete loss of both motor and sensory function and E being normal (Table 18.1).

Imaging

Advanced imaging is essential to delineate the extent of disease. By themselves, plain films of the spine are of little value in diagnosing the condition. Approximately 26–29% of metastatic deposits are occult on plain film X-ray [8, 14]. Furthermore, given the prevalence of osteoarthritic changes of the spine in adult patients, such plain films may offer false reassurance as to the etiology of the pain.

Prior to the 1990s, spinal cord compression was diagnosed by myelography [33]. Fortunately, this invasive and uncomfortable procedure has largely been supplanted by magnetic resonance imaging (MRI) (Fig. 18.1) [18].

While gadolinium-enhanced MRI can help to determine intradural tumor or leptomeningeal disease, it is not required for cord compression studies. Unenhanced MRI is equal to myelography in detecting epidural disease and is more sensitive at detecting vertebral metastasis [34], justifying its use and reducing procedure time compared to gadolinium-enhanced studies.

Computed tomography (CT)-guided myelography is of value for patients unable to tolerate MRI [35]. If both CT and MRI are unavailable, bone scintigraphy in combination with plain films may be of use [33].

Imaging studies should include the entire spine, not just the perceived area of pain. Up to 31% of patients have multilevel disease [17]. Sensory deficits and mechanical pain may be present 2–4 vertebral levels away from the actual lesion [31].

If MRI suggests cord compression, severity can be graded using the Epidural Spinal Cord Compression scale described by Bilsky [36]. This 6-point scale rates the degree of cord compression between 1 and 3 (with 3 being the most severe) based on the level of cord impingement (Fig. 18.2) [37]. A recent trial confirmed its continued utility for enhancing agreement and clarity of communication among clinicians [38].

Fig. 18.1 A 16-year-old female with ovarian cancer and spinal cord compression at the level of the third thoracic vertebra

Management

The goal of therapy is symptom control and preservation of function. This requires a multidisciplinary approach involving nursing, medical oncologic, neurosurgery, and radiation oncologic services.

Nursing Efforts

Upon diagnosis and initiation of therapy, serial neurological evaluations should be undertaken. Neuro-vital signs should be scheduled to coincide with other nursing efforts to minimize patient discomfort and ease the burden of care. Patients with involvement of the cervical spine should have a Philadelphia collar placed until spinal stability has been confirmed. Strict bed rest (including logroll and bedpan use) should be instituted if there is suspicion of spinal cord instability.

In the United Kingdom, the National Institutes for Health Care Excellence guidelines recommend that all patients with suspected cord compression be maintained in a flat position [29]. Other authors do not believe that strict bed rest is necessary. Proponents of this theory believe that MSCC is inherently different from that caused by trauma. Authors supporting this position contend that the increased incidence of deep vein thrombosis, infection (particularly from the respiratory and urinary tracts), and decubitus ulcers outweigh the benefit of bed rest.

There is a lack of data or randomized controlled trials to strongly support either position [39]. A recent systematic review of non-pharmacological interventions in spinal cord

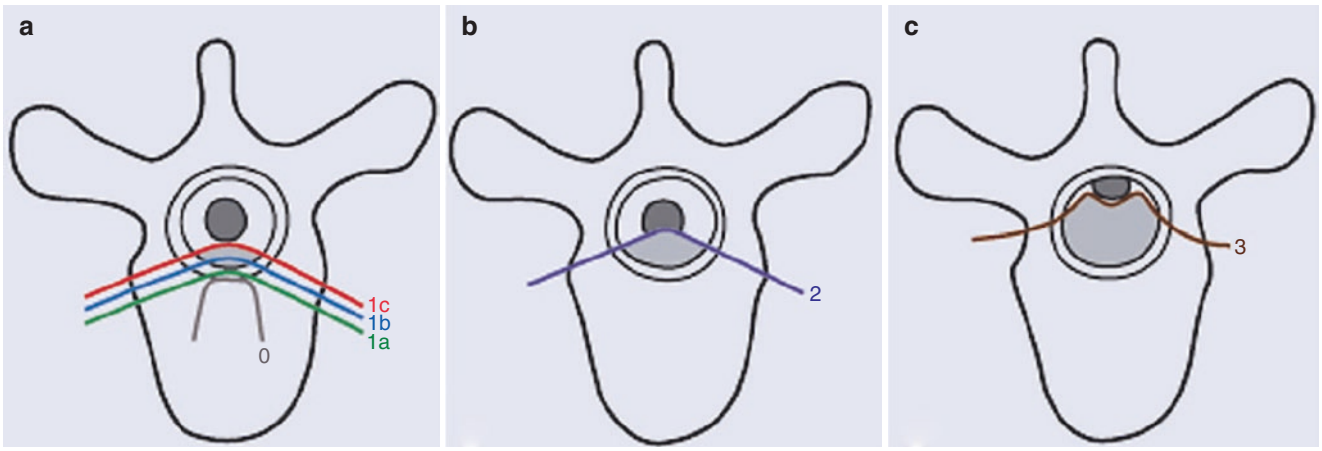

Fig. 18.2 Schematic representation of the 6-point ESCC grading scale. A grade of 0 indicates bone-only disease; 1a, epidural impingement, without deformation of the thecal sac; 1b, deformation of the thecal sac, without spinal cord abutment; 1c, deformation of the thecal sac with spinal cord abutment but without cord compression; 2, spinal cord compression but with CSF visible around the cord; and 3, spinal cord compression, no CSF visible around the cord. (From Bilsky et al. [37], with permission Elsevier)

compression found that while supine positioning is extremely important in other causes of spinal cord compression, it seemed excessive in MSCC patients, although again, the quality of the data was poor [40]. Patient performance status and preference should be taken into consideration as those with good functional status may be quite resistant to bed rest, particularly if it worsens their symptoms.

Medical Therapy

The mainstay of medical therapy is treatment with corticosteroids [4]. Unless contraindicated, they are recommended for all patients, particularly those with neurological deficits. Initial trials demonstrated that corticosteroids improve functional status, as well as symptoms, in MSCC.

Controversy exists regarding the effective dose. A randomized, controlled trial by Sorensen et al. evaluated functional outcomes in 57 patients who received radiotherapy in conjunction with high-dose versus no corticosteroids as adjunctive therapy. Fifty-nine percent of patients in the dexamethasone group were ambulatory 6 months after treatment compared to 39% in the group who did not receive steroids [41].

More recent studies have shown similar results with lower-dose corticosteroids [42]. A recent systematic review by Kumar suggests a loading dose of 10 mg of intravenous dexamethasone followed by 16 mg per day orally in two to four divided doses [4, 5, 43, 44]. In patients with recent-onset neurological deficits, higher doses may be considered [4]. National guidelines in both Canada and England now recommend more moderate dosing.

Corticosteroids are associated with psychosis, gastric ulceration/perforation, rectal bleeding, and hyperglycemia. Care should be taken to mitigate against these effects. Steroids should be weaned as early as tolerated and gastrointestinal prophylaxis should be initiated. Special attention should be given to glucose control (particularly in patients with preexisting diabetes). While not typically of use in the ED, chemotherapy is of value in longer-term management. In particular, seminomas, myeloma, and lymphomas may show a dramatic response to treatment [45–47].

Surgical Therapy

Overall, decompressive surgery is indicated in 10–15% of MSCC cases [48]. Surgical evaluation is required in cases of spinal instability, direct cord compression due to a bony fragment, and impending sphincter dysfunction. Unknown primary tumors will require biopsy even if full resection is not possible. Patients not responding to radiotherapy or those who have previously received radiotherapy may benefit from surgical intervention [20]. Radoresistant tuores, including sarcoma, melanoma, GI tumors, lung, renal and thyroid, are more likely to require surgical intervention [49].

The Spinal Instability Neoplastic Score (SINS) developed by Fisher et al. is the most frequently used tool to determine patients that will require surgical stabilization. The scale assigns a score between 0 and 18 to metastatic deposits. Six elements are considered, including lesion location, the degree of pain, type of lesion, radiographic spinal alignment, degree of vertebral body collapse, and the presence of involvement of the posterolateral spinal elements. Scores of less than 6 are generally considered stable. Those greater than 13 are deemed unstable and likely to require surgical intervention. Indeterminate lesions graded 7–12 require further evaluation [50] (Table 18.2).

Patients with good functional status, limited disease, and a life expectancy greater than 3–6 months may benefit from surgery [51]. Those with paraplegia of less than 48 hours duration may experience a degree of functional restoration. In a recent study, 101 patients presenting with neurologic symptoms underwent decompressive laminectomy. 74% showed improved motor function and 51% had regained the ability to walk at discharge [52].

Previously, laminectomy was the primary surgical option available. In many cases, it provided suboptimal results. Over

Table 18.2 Spinal Instability Neoplastic Score (SINS) System (From Fisher et al. [50], with permission Wolters Kluwer Health)

Component	Score
Location	
Junctional (occiput–C2, C7–T2, T11–L1, L5–S1)	3
Mobile spine (C3–6, L2–4)	2
Semi-rigid (T3–10)	1
Rigid (S2–S5)	0
Pain relief with recumbency and/or pain with movement/loading of the spine	
Yes	3
No (occasional pain but not mechanical)	1
Pain-free lesion	0
Bone lesion	
Lytic	2
Mixed (lytic/blastic)	1
Blastic	0
Radiographic spinal alignment	
Subluxation/translation present	4
De novo deformity (kyphosis/scoliosis)	2
Normal alignment	0
Vertebral body collapse	
>50% collapse	3
<50% collapse	2
No collapse with >50% body involved	1
None of the above	0
Posterolateral involvement of the spinal elements (facet, pedicle, or CV joint fracture or replacement with tumor)	
Bilateral	3
Unilateral	1
None of the above	0

the past two decades, significant improvements have been made. New surgical techniques including circumferential decompression of the spine with anterior posterior surgery stabilization have advanced the care of these patients [53].

Minimally invasive procedures, in conjunction with stereotactic body radiation therapy, have shown promise in the management of MSCC [54]. Although not routinely used, vertebroplasty or kyphoplasty has been shown to be effective for management of pain associated with pathologic compression fractures. Some authors have recommended kyphoplasty with stabilization. Chen reported excellent results in a study of 282 patients undergoing percutaneous kyphoplasty for metastatic disease. Patients were followed as far out as 15 months and reported decreased use of analgesia as well as improved quality of life and Karnofsky performance scores [55]. Similarly, in a study of 50 patients with spinal metastasis, Kwan found minimally invasive stabilization with percutaneous screws provided adequate relief of symptoms, with an associated improvement in Frankel score [56]. In a study specific to patients with MSCC, Chen found kyphoplasty with short instrumentation provided equivalent results to more traditional long stabilization. Moreover, there was less blood loss and fewer complications [57].

Prior to any surgical procedure, any coagulopathy should be corrected, and thrombocytopenic patients should receive platelet infusion. A recent review found post-operative complications are common. These include wound infection/dehiscence, pneumonia, pleural effusion, respiratory failure, pulmonary embolism, venous thrombosis, cerebral spinal fluid leak, urinary tract infection, and instrument failure [58].

Radiotherapy

The combination of surgery with radiotherapy has been shown to improve outcomes [59]. Whether for therapeutic or palliative intent, radiotherapy is provided to virtually all patients.

Tumors such as leukemia, lymphoma, and germ-cell tumors are particularly responsive to radiotherapy. Breast, prostate, and ovarian cancers have intermediate sensitivity [49].

Issues regarding duration and dosing depend on intent of therapy and must be individualized to the patient. While guidelines have been recommended, there are few randomized, controlled trials to clarify specific regimens [60].

Generally speaking, patients with a favorable prognosis will benefit from longer courses of therapy [61, 62]. End-of-life patients with a poor prognosis are typically treated with a single-dose regimen [61, 63]. These regimens provide similar symptom control as fractionated regimens but with an increased incidence of local recurrence [63–65]. A recent systematic review and meta-analysis showed no difference in survival or motor function between patients receiving short- versus long-course radiotherapy [66]. Patients experiencing local recurrence may be candidates for re-irradiation [48, 67].

While standard of care currently involves a combination of medical, surgical, and radiation therapies, recent advances in radiation oncologic underscore the increased impact of the specialty. Rades et al. showed promising results with radiation alone in treatment of myeloma [68]. Another study suggested that radiotherapy alone constitutes sufficient therapy in neurologically intact patients [69].

Stereotactic body radiation therapy (SBRT) has shown potential for treating metastatic bone disease in the spine. It has the ability to provide large doses of radiation to a highly select area providing local control of even radioresistant tumors. However its use in metastatic spinal cord compression remains limited at this time [70]. While a recent consensus study suggests that SBRT is contraindicated in cord compression [71], a new study by Ghia et al. found that it may be beneficial in select, inoperable patients [72].

Special Considerations

In spite of improved surveillance and diagnostic practices, 20% of MSCC occurs in patients without a known malignancy. A patient without a biopsy-confirmed cancer diagnosis in need of corticosteroid treatment presents a dilemma. If there is any question regarding the nature of the lesion, tissue diagnosis must be obtained without delay.

Steroids are used with curative intent in treatment of plasmacytomas, thymomas, lymphomas, multiple myeloma, and germ-cell tumors [45]. In these circumstances, corticosteroids given before tissue samples are obtained may cause regression of disease, hindering diagnosis and complicating delivery of definitive chemotherapy [73, 74]. In the absence of neurological deficit, corticosteroids may be withheld pending consultation with neurosurgery and oncologic.

Cancer patients are at increased risk of recurrent malignancy. Overall, cancer survivors have a 14% higher risk of developing a new malignancy than the general population [75]. In fact, second primary malignancies accounts for 16% of new cancer diagnoses [76].

The etiology of second primary malignancy varies. Treatment-related secondary cancers are well-documented complications of chemotherapeutic, hormonal, and radiation modalities. Familial cancer syndromes result in multiple primary cancer sites. Shared risk factors and lifestyle choices such as tobacco and alcohol use and sun exposure contribute to development of second primaries. Cancer survivors who are thought to have no evidence of disease may be experiencing either recurrent disease or the initial manifestations of a second primary process.

Prevention

Patient education is of primary importance. Lu et al. found that only 54% of patients were aware that back pain should be reported to their physician [31]. Delays in diagnosis and treatment are common and well described in the literature [26]. Patients should be instructed to call their physician within 24 hours of the development of any new or worsening back pain and should be advised to seek immediate care if they develop any neurologic symptoms.

Bisphosphonates have been shown to be effective in controlling symptoms from and prevention of skeletal metastases in breast cancer. However, they were not shown to delay development of MSCC [77, 78].

To facilitate appropriate and prompt management of MSCC, hospitals and treating physicians should develop diagnostic algorithms to minimize delays in referral to a comprehensive center for further treatment.

Prognosis

MSCC can be treated successfully; nonetheless it is associated with a poor outcome in most patients. It is evidence of an uncontrolled and aggressive disease process. Although lymphoma and myeloma patients fare better than other patients, the average lifespan after development of MSCC is less than 6 months [5, 7, 8]. Patients with limited disease and good functional status may survive for years [53].

A consensus study including 60 international experts included metastatic spinal cord compression among 11 major criteria for referral to palliative care [79]. Certainly, patients with poor functional status and those with end- or late-stage disease should be referred to palliative care for the management of symptoms [80].

Given the poor prognosis of MSCC in general, end-of-life discussions are warranted. In a retrospective study of 88 patients with MSCC, "do not resuscitate" orders were in place in only 9% of the patients during their hospital admission [81]. Improved doctor-patient communication in the ED setting will facilitate the patient's coping with future losses.

Conclusion

Metastatic spinal cord compression is an uncommon but well-established consequence of advanced cancer. It affects both survivors and patients with active disease. Patient education is a key factor in early diagnosis. It may represent the first manifestation of cancer (or a second primary cancer in the case of long-term survivors). The primary complaint is typically back pain. Neurological deficits are associated with a poor outcome. The diagnosis requires a high index of suspicion and MRI is the imaging modality of choice. Definitive treatment requires cooperative efforts by medical, surgical, and radiotherapeutic disciplines. Symptom control and maintaining (or regaining) functional status are of paramount importance. While the best predictors of outcome are ambulatory and functional status at the time of diagnosis, MSCC is generally associated with a poor prognosis. Palliative care and end-of-life issues should be considered with all patients who develop the condition.

Head and Neck

19

Ray Y. Wang, Eugene L. Son, Clifton D. Fuller, and Neil D. Gross

Introduction

Head and neck cancer is the fifth most common cancer worldwide with almost 53,000 people diagnosed each year in the United States [1]. These include malignancies of the upper aerodigestive tract (UADT), which begins at the lips and nose and extends to the mucosal surfaces of the cervical trachea and esophagus. The UADT includes the oral cavity, oropharynx, hypopharynx, larynx, nasal cavities, and paranasal sinuses. The most common malignancy of the UADT is squamous cell carcinoma of the head and neck (SCCHN), making up over 97% [2]. For simplicity, SCCHN will be the primary focus of this chapter. Other pathologies in the head and neck including carcinoma of the major and minor salivary glands, thyroid, and skin will not be covered.

Patients with SCCHN may present to the emergency department (ED) with a variety of complaints at any point in the course of their disease, from initial diagnosis to years after completion of therapy. Patients presenting on an emergency basis represent 7% of all referrals with dysphagia, stridor, and neck mass being the most common chief complaints [3]. Also typical, pain and gastrointestinal complaints were the most common presenting symptoms among patients with SCCHN in a population-based study from Taiwan [4]. The symptom profile of patients presenting may vary over their treatment course, although pain is a consistent symptom [5]. In one prospective cohort study, patients presenting during or soon after treatment presented most frequently with gastrointestinal complaints while those presenting >6 months after treatment initiation were most likely to present with pain [5].

Uncontrolled SCCHN can result in life-threatening emergencies, principally from compromise of the airway and/or bleeding. Patients with undiagnosed SCCHN may present to the ED in distress because the SCC of the base of tongue and larynx can grow to be large with relatively few symptoms [6]. In this chapter, we discuss acute management of the airway in patients with SCCHN including in the context of COVID-19. We also review the management of emergent bleeding in patients with SCCHN. Finally, we cover common complications from the treatment of SCCHN and end with clinical pearls for acute management of SCCHN in the ED.

Case Discussion

A 59-year-old man with a history of recurrent oropharyngeal squamous cell carcinoma presented to the ED for evaluation of bleeding from his neck and mouth. A few hours prior to presentation, he suddenly developed severe bleeding ("several cupsful") externally from his tumor as well as from his oral and nasal cavity. This resolved spontaneously prior to arrival in the emergency room.

He has a complex oncologic history including squamous cell carcinoma of the base of tongue initially treated with concurrent chemoradiation approximately 2 years prior to the presentation followed by partial glossectomy, neck dissection, and free flap reconstruction for recurrence a few months later. He again was noted to have recurrence with extensive progression involving the neck soft tissues with multiple pharyngocutaneous fistulae.

On examination, he was afebrile, tachycardic (HR 110s) but normotensive. He was breathing well on room air without stridor though with audible pharyngeal secretions. He had extensive tumor involvement of the anterior neck with

multiple fistulae with dark clot but no active bleeding. He also had post-treatment sequelae including radiation fibrosis with limited neck range of motion and trismus from his prior surgery and reconstruction. Flexible fiberoptic nasopharyngoscopy demonstrated a large blood clot at the left base of tongue at the site of his recurrence with marked supraglottic edema.

Given the potential for acute airway compromise due to bleeding from his pharyngeal tumor, he was taken emergently to the operating room where he underwent awake transoral fiberoptic intubation followed by tracheostomy. After securing the airway, a CT angiogram of the head and neck was obtained which did not demonstrate obvious extravasation. He was then taken by interventional radiology for angiography and a pseudoaneurysm of the left facial artery was noted. This was managed via selective arterial embolization. The patient demonstrated no additional bleeding after the procedure.

Airway Management

Airway obstruction due to SCCHN affects up to 80,000 patients annually, with most patients presenting to the ED for acute care [7]. Ideally, planning for airway management in patients with SCCHN should occur well before an emergency. This may include prophylactic tracheostomy. In addition to acute airway obstruction, SCCHN patients have increased rates of aspiration pneumonia because of dysphagia and difficulty handling even normal oral secretions [8]. The 1-year and 5-year incidence of clinically meaningful aspiration in SCCHN patients is 15.8% and 23.8%, respectively, with 84% of these patients requiring hospitalization [9]. For the purposes of this chapter, we have divided the airway into *unsecure* and *secure*.

Unsecured Airway

Undiagnosed SCCHN can lead to signs of obstruction before causing other symptoms such as pain [10]. Metastatic cervical adenopathy can also cause obstructive lymphedema and direct extrinsic compression of the airway. Patients with undiagnosed SCCHN may present with orthopnea, hoarseness, dysphagia, odynophagia, and hemoptysis [10]. Stridor and/or drooling can be signs of an unsecured airway.

In stable patients, a contrasted computed tomography (CT) of the head, neck, and chest can be performed quickly to assess the location and extent of the obstruction [10]. This imaging study provides important staging information if malignancy is confirmed. Flexible fiberoptic laryngoscopy (FFL) is a critical tool for assessing the airway and is the most direct method to evaluate for impending obstruction

Fig. 19.1 Flexible fiberoptic laryngoscopy demonstrating normal larynx

[10] (Fig. 19.1). Skilled management of the FFL is important for evaluating a potentially tenuous airway. Topical administration of local anesthetic such as lidocaine and topical decongestants (oxymetazoline or phenylephrine) to the nasal cavities may make FFL more tolerable and potentially safer (see Fig. 19.1). Management of a suspected unsecure airway starts with optimal positioning to make the patient as comfortable as possible. Administration of supplemental oxygen may be helpful but should be used with caution in patients with uncompensated chronic obstructive pulmonary disease (COPD). Administrating nebulizers and steroids are unlikely to improve the airway but may be useful in temporizing the patient. The use of Heliox, a mixture of helium and oxygen, has been described in the acute management of patients with an unsecure airway. The decreased viscosity of Heliox can temporarily improve airflow and reduce stridor. Because it is an inert gas, it can assist in temporizing an unsecure airway, but it may not be readily available in the ED [11].

SCCHN patients with acute respiratory failure from an unsecure airway should be managed expeditiously. Transoral intubation is preferred if FFL predicts that direct visualization of the endolarynx can be achieved safely. The use of laryngeal mask anesthesia (LMA) is not recommended in these cases because of likely distortion of the normal anatomy. In cases where oral intubation is not possible (e.g., obstructing mass, trismus), awake fiberoptic transoral or nasotracheal intubation is usually the next best option. Nasotracheal intubation is preferred over awake fiberoptic oral intubation to decrease patient gagging but requires a unique skill set and is probably best performed by experienced anesthesiologists or otolaryngologists. Successful intubation can avoid an emergent surgical airway and allow a controlled environment for formal tracheostomy [6]. SCCHN involving the larynx is most likely to result in an unsecured airway (Fig. 19.2). Intubation of a patient with

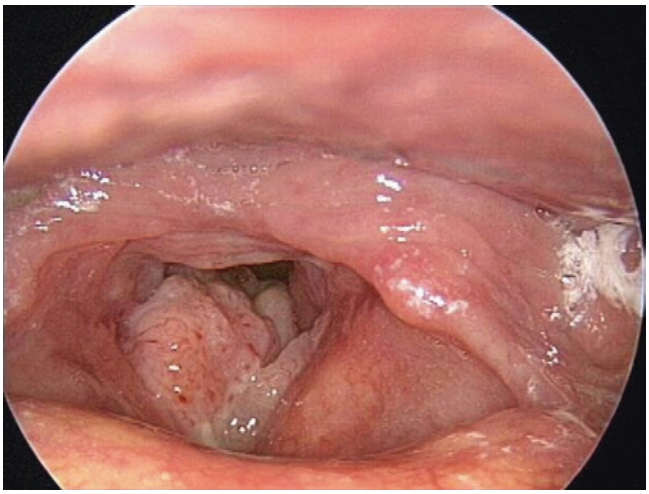

Fig. 19.2 Flexible fiberoptic laryngoscopy demonstrating obstructing mass of the larynx. Note loss of visualization of the vocal cords and the markedly decreased diameter of the airway

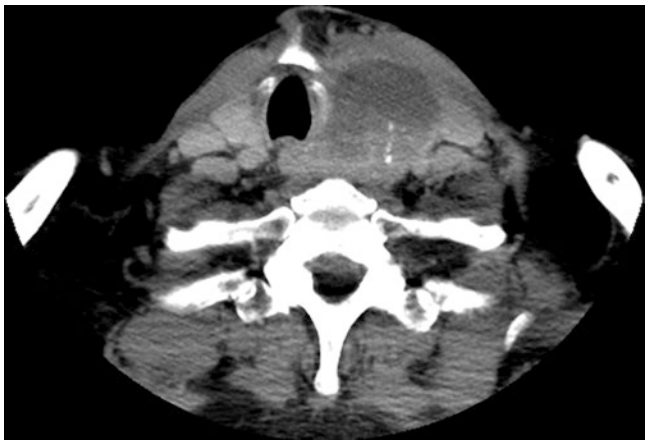

Fig. 19.3 Axial computed tomography (CT) of the neck demonstrating a left-sided thyroid mass with invasion into the cricoid cartilage. This patient presented with a paralyzed ipsilateral vocal cord secondary to involvement of the recurrent laryngeal nerve

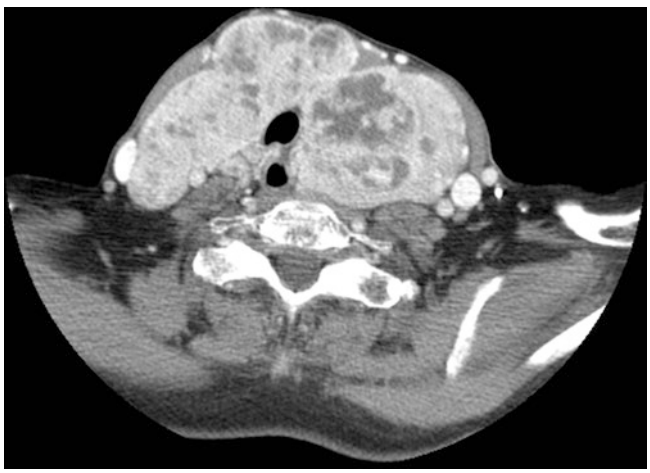

Fig. 19.4 Axial computed tomography (CT) of the neck demonstrating a large goiter with narrowing of the airway but no obstruction

locally advanced SCC of the larynx can be hazardous because of the distorted anatomy and risk of bleeding during laryngoscopy. In these cases, the airway is best managed in the operating room by an experienced anesthesiologist and/or otolaryngologist.

If attempted intubation is deemed unsafe or unsuccessful, then a surgical airway via cricothyroidotomy or tracheostomy should be performed. Awake tracheostomy can be performed under local anesthesia in select SCCHN patients with an unsecure airway. This is best performed in the operating room. If an urgent airway is needed (e.g., acute obstruction) then a "slash" cricothyroidotomy should be performed. A vertical incision is usually advised in this setting, as a midline dissection is critical to minimize bleeding from the paired paramedian anterior jugular veins and allowing for identification of the airway across a vertical range. In cases where the trachea is deviated, a needle on a saline-filled syringe with negative pressure can be used to locate the trachea by visualization of air bubbles [12]. Transtracheal catheterization has also been described if cricothyroidotomy or tracheostomy cannot be performed [13].

Some head and neck cancers, particularly thyroid cancers, can cause paralysis to one or both of the vocal cords via direct involvement of the recurrent laryngeal nerves (Fig. 19.3). This is in contrast to large goiters that can distort the airway over time but rarely cause respiratory distress (Fig. 19.4). Acute bilateral vocal fold paralysis, either by direct tumor involvement or iatrogenic after thyroid surgery, can cause respiratory distress marked by stridor. These patients typically require intubation and subsequent tracheostomy if possible. Anaplastic thyroid cancer is the prototypic malignancy to cause acute airway obstruction by direct tracheal involvement, recurrent laryngeal nerve involvement, or both. Fortunately, anaplastic thyroid carcinoma comprises only 1.7% of all thyroid cancers [14]. Management of the airway in patients with anaplastic thyroid cancer is complex and controversial particularly given the dismal prognosis associated with the disease [15]. For this reason, current American Thyroid Association guidelines recommend against elective tracheostomy [14].

Secured Airway

The airway management of SCCHN patients with a tracheostomy or laryngectomy stoma requires some familiarity with changes to the anatomy with these procedures. Most clinicians are familiar with tracheostomy patients whereby the oral cavity, oropharynx, and larynx are bypassed by a tube directly into the trachea. In contrast, laryngectomy

patients are obligate "neck breathers" with no remaining connection between the mouth and trachea.

As with all patients presenting with respiratory distress, conservative measures should always be initiated including oxygen administration. However, nasal cannula or facemask administration may be ineffective if the patient breathes through a surgically created stoma in the neck. Oxygen can be applied to both the face and stoma for tracheostomy patients but only the stoma for laryngectomy patients. Fiberoptic tracheoscopy can be a valuable tool to rule out a proximal obstruction or false passage of the tracheostomy tube. The scope can be introduced inside the stoma or tube in place to visualize the carina and proximal mainstem bronchi.

SCCHN patients with a tracheostomy are at risk of life-threatening complications, including bleeding and tube dislodgement with airway obstruction and death [16]. There are known late complications of tracheostomy in up to 65% of patients including possible granulation tissue formation, tracheomalacia, tracheoinnominate fistula (TIF), tracheoesophageal fistula, pneumonia, and aspiration [17]. These potential complications from tracheostomy tubes are important to recognize in the acute setting.

Patients can present to the ED with airway obstruction despite having a tracheostomy tube. If a tracheostomy tube becomes dislodged, then every effort should be made to replace the tube as the stoma can close substantially in a matter of hours. If the original tracheostomy tube is too large for the tracheostomy stoma at the time of replacement, then the tract can be dilated with a nasal speculum or a smaller tube can be inserted. An endotracheal tube can even be used temporarily to secure the airway if needed. However, it is important to keep the cuff visible near the stoma to avoid a mainstem bronchus intubation.

Mucous plugging of a tracheostomy tube can cause acute airway obstruction and death. For this reason, most commercially available tracheostomy tubes have an interchangeable inner cannula. Patients need appropriate humidification of air and frequent suctioning of the tube to prevent mucous build-up. Applying small amounts of saline and suctioning with a soft flexible catheter can soften and remove hardened mucous.

There are special considerations regarding the emergency management of laryngectomy patients. A survey of members of the National Association of Laryngectomy Clubs in the United Kingdom underscored concerns regarding the quality of care they receive in the emergency setting [18]. It is incumbent upon emergency physicians to be familiar with the anatomy of patients after laryngectomy and the common complications that can occur. For example, it is important to realize that either a standard tracheostomy tube or more customized laryngectomy tube may be used for comfort or to stent the stoma. In the superior posterior wall of the trachea, a tracheoesophageal puncture (TEP) device may be present which provides a one-way valve for air to flow from the trachea into the esophagus for speech (Fig. 19.5). If a patient requires mask ventilation, then the laryngectomy patient should be intubated through the stoma either with a cuffed endotracheal or tracheostomy tube past the TEP, if present. The rate of 30-day unplanned readmission independent of complications following laryngectomy ranges from 26.5% to 42% [19]. Most of these patients present for stomal or TEP complications [19]. Non-humidified air entering the proximal trachea can cause thickened respiratory secretions that are difficult to clear. These secretions can dry into dense circumferentially crusts which can obstruct the airway. Post-laryngectomy patients also frequently come to the ED for TEP dislodgement. When this happens, a chest film must be taken to rule out aspiration of the device as aspiration has been reported to occur in up to 13% of patients [20]. If the patient comes with a dislodged TEP device in hand, replacement can be difficult without extensive experience and specialized tools. Replacement of the TEP is usually done by a speech and language pathologist or otolaryngologist. If replacement is not an immediate option, then placement of a temporary red rubber catheter through the TEP site can help prevent aspiration and closure of the puncture itself.

Considerations During the SARS-CoV-2 (COVID-19) Pandemic

The SARS-CoV-2 (COVID-19) pandemic introduced significant new challenges for providers caring for head and neck cancer patients. Given the anatomic location of SCCHN, care for these patients places providers at high risk for transmission due to the need to examine the UADT. Furthermore, cancer patients may be at increased risk for severe complications related to COVID-19, including ICU admission, need for mechanical ventilation, or death [21].

Emergency airway management in head and neck cancer patients presents several unique challenges as concerns for COVID-19 transmission disrupt the typical workflow of care. Ideally, all patients undergoing aerosol-generating procedures would have pre-procedure testing for COVID-19, but in emergency circumstances, this may not be possible. As such, these patients must be treated as persons under investigation (PUI) for COVID-19. Precautions taken to reduce potential exposure of healthcare providers must be balanced with the need to provide expeditious care for these critically ill patients. FFL, a mainstay of airway evaluation in head and neck patients, is considered an aerosol-generating procedure and appropriate personal protective equipment (PPE) including an N95 mask or powered air purifying respiratory (PAPR), eye protection, and gloves is recommended by the American Academy of Otolaryngology-Head and Neck Surgery [22]. Steps should be taken to reduce the number of providers exposed during the procedure, such as recording the exam or having a senior member of the team perform the exam alone. Airway support measures, such as high-flow nasal cannula or non-invasive positive pressure ventilation, are also at high risk for aerosolization of respiratory secretions and should be used with caution [23].

Awake tracheostomy is particularly high risk for transmission of COVID-19 given the high likelihood of coughing during the procedure, inability to control ventilation when entering the airway, and respiratory distress of the patient during the procedure [24]. All personnel involved in these procedures should wear full PPE including N95 masks or PAPRs. Protocols for emergency airway management during the COVID-19 pandemic are not standardized and may not be tailored specifically for the head and neck cancer population. When possible, fiberoptic intubation after application of sufficient topical anesthetic should be performed as it allows for controlled entry of the airway and the ability to hold ventilation, thus reducing the aerosolization of respiratory secretions. In patients with difficult anatomy or in emergent circumstances this algorithm may not be feasible. In these cases, the providers should proceed directly to awake tracheostomy and take all possible precautions to avoid unnecessary exposure of healthcare personnel to respiratory secretions. General recommendations from the New York Head and Neck Society regarding tracheostomy for COVID-19 patients included performing tracheostomy in a negative pressure room (e.g., in the intensive care unit or a designated pod within the operating room), preoxygenation and holding ventilation when entering the airway, avoiding monopolar cautery or harmonic technology and use of cold instrumentation, minimizing the use of suction, and potentially utilizing percutaneous tracheostomy when feasible [25]. Alternative measures such as securing a face mask with a seal around the mouth and nose rather than the standard nasal cannula may reduce aerosolization during awake tracheostomy [24].

Bleeding Management

Patients with head and neck cancer, most notably SCCHN, can develop life-threatening bleeding. There is a rich vascular supply to the head and neck region. Bleeding can occur from direct tumor involvement and/or as a side effect of therapy [26]. The most common cause of bleeding is poor wound healing after surgery or radiation. The initial management of bleeding in head and neck cancer patients is no different than the general population. The patient must first be stabilized. The ABCs (Airway, Breathing, and Circulation) of shock trauma should be addressed. Two large-bore intravenous lines should be obtained. Warmed isotonic electrolyte solutions such as lactated Ringer's solution or normal saline should be administered in a bolus fashion. Transfusion of packed red blood cells (pRBC) should be considered. When administering large amounts of pRBC, calcium supplementation should be considered as there are chelating agents of calcium in these blood products [27]. Laboratory studies including complete blood count (CBC), prothrombin time (PT), activated partial thromboplastin time (aPTT), and other coagulation labs should be performed and corrected as needed to assist in hemostasis.

Acute Arterial Bleeding

Acute arterial bleeding from the mouth or neck can occur after treatment of SCCHN. Surgery can strip the vascular supply of the arterial wall. Radiation therapy can cause obliteration of the vasa vasorum, premature atherosclerosis, adventitial fibrosis, and fragmentation of tunica media elastic fibers leading to weakening of the arterial wall [28]. Patients with head and neck cancer have other factors that contribute to poor wound healing including nutritional compromise, poor tissue perfusion, soft tissue exposure to salivary enzymes, and infections [29].

Major arterial bleeding is often preceded by a sentinel bleed, usually from a pseudoaneurysm, that can be profuse but self-limited [29]. A spontaneous cessation of brisk bleeding in a patient with SCCHN can give the emergency physician a false sense of safety. Immediate diagnostic workup followed by treatment should be obtained to prevent a catastrophic bleed. CT imaging may show irregular thickening of the arterial wall of major vessels [30]. If the patient is stabilized, CT angiography (CTA) can be an effective screening tool for locating the site of hemorrhage and can also assist in

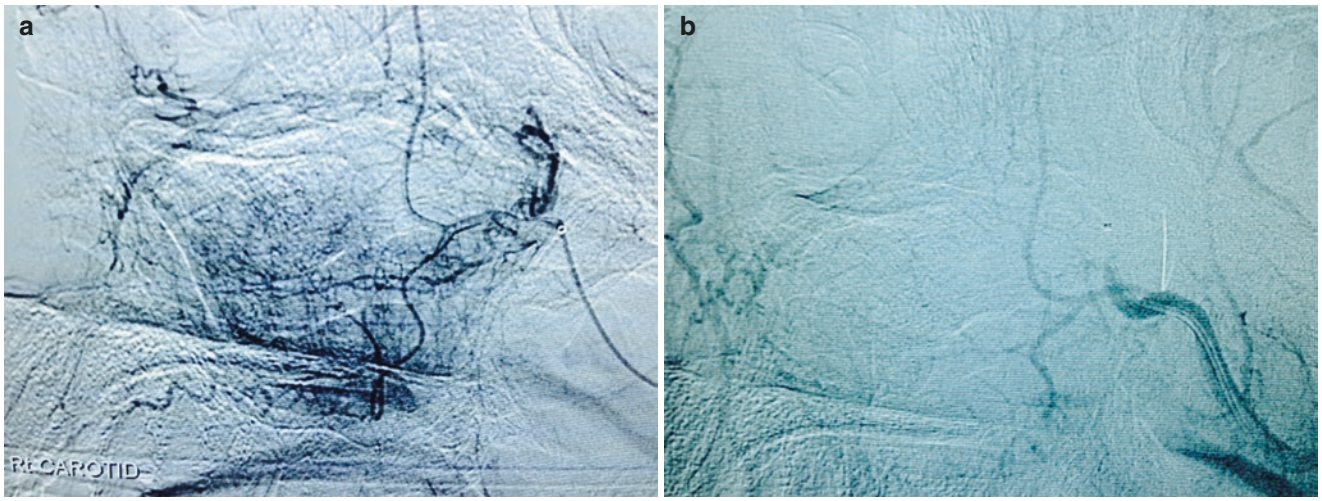

Fig. 19.6 Angiogram of the right internal maxillary artery in a patient with epistaxis from a sinonasal cancer before (**a**) and after (**b**) embolization

procedures performed by the intervention neuroradiologist [29]. Prophylactic treatment of the diseased vessel can prevent catastrophic events (Fig. 19.6).

Direct pressure is key to temporarily controlling any acute bleeding. In the head and neck, there is the additional challenge of managing the airway. If the bleeding is origination from the oral cavity or oropharynx, then the airway must be secured before effective pressure can be applied. With the airway secured, bleeding from the mouth can generally be temporized with a throat pack. If a tracheostomy tube is present, the cuff should be immediately inflated to prevent aspiration of blood into the lower airway and lungs. If the tracheostomy tube does not have a cuff, then it should be replaced with a cuffed tracheostomy tube. If a significant amount of blood becomes static in the trachea and the bronchial tree, then clots will cause total obstruction of the airway. This risk is much lower in laryngectomy patients since the oral cavity and oropharynx have no connection to the airway. Even so, it is advisable to intubate the trachea for protection in these patients during any significant bleeding episode. Once the airway is secure, the underlying cause of bleeding can be investigated and managed by a head and neck surgeon and/or interventional neuroradiologist.

Carotid Blowout

The most feared bleeding complication from SCCHN is carotid rupture (aka carotid blowout). Without immediate, aggressive intervention, carotid blowout is uniformly fatal. Before interventional angiography, hemostasis for carotid artery rupture was obtained via an open surgical approach. This was associated with 60% neurological morbidity and 40% mortality. More recently, endovascular stenting of a carotid artery rupture has shown >80% survival and far fewer neurological events. However, endovascular stent placement without further treatment has a recurrent bleeding up to 26% [29]. So, the patients who are successfully resuscitated and stented should undergo subsequent definitive surgical management (e.g., overlying soft tissue flap reconstruction) to prevent further bleeding episodes [31]. In dire cases, the ipsilateral carotid artery can be permanently occluded, albeit with at least a 15–20% risk of delayed cerebral complications [32].

Internal Jugular Vein Bleeding

Internal jugular vein bleeding, although rarer than carotid artery bleeding, can occur after treatment of SCCHN. These are typically less severe, characterized by multiple episodes, and aggravated by coughing [32]. Internal jugular vein bleeding is almost uniformly associated with a pharyngocutaneous fistula [32]. The treatment is a surgical exploration of the wound and ligation.

Tracheoinnominate Fistula

A tracheoinnominate fistula (TIF) is a connection from the trachea to the innominate artery. It is a rare complication after tracheostomy placement ranging from 0.1% to 1% in incidence and usually occurring between postoperative days 7 and 14 [31]. There are a number of factors that can predispose a tracheostomy patient to this complication including lower placed tracheotomies, over-inflated cuffs causing ero-

sion of the trachea, and anomalies of the innominate or other large caliber arteries [33]. Before this catastrophic event, there may be an ominous sign of milder pulsating bleeding from the tracheostomy (sentinel bleed) [33].

TIF has a high rate of mortality as it causes rapid exsanguination in combination with aspiration of large amounts of blood. The mortality rate approaches 100%, even when surgical intervention is taken [34]. Definitive management of a TIF requires a sternotomy and vascular repair in the operating room. Placing direct pressure against the anterior tracheal wall can temporize the bleeding. This can be done either digitally with a finger or by placing a cuffed tube, creating a temporary tamponade [33]. Endovascular embolization or placement of a stent graft of the innominate artery has also been reported [31].

Epistaxis

Epistaxis is a common reason for presentation to the ED. Management of epistaxis from head and neck malignancy or after surgery is different from ordinary epistaxis and merits special considerations. A typical case of epistaxis can usually be watched and stopped with external digital pressure and lubrication of the nasal mucosa with nasal saline spray and antibiotic ointment. Epistaxis in the setting of a sinonasal cancer can be more serious and should be handled more aggressively.

With active epistaxis, visualization with anterior rhinoscopy or endoscopy may not be possible depending on the volume of bleeding. The patient should be sitting up and positioned leaning forward to allow the bleeding to exit the nares rather than into the pharynx, where it may cause airway compromise. If the bleeding is severe, the airway may need to be secured with intubation. Packing is often required to tamponade uncontrolled epistaxis. There are dissolvable packing materials, such as cellulose polymers (Surgicel®) and porcine skin gelatin (Gelfoam®), and non-dissolvable packing materials, such as cross-linked polyvinyl alcohol (Merocel®) and balloon packs (Rapid Rhino®). A headlight, nasal speculum, and bayonet forceps should be used for placement of packing. Other products such as topical thrombin components (Floseal®) can be topically placed inside the nose to aid in hemostasis.

Given the high viral load of SARS-CoV-2 in the nasal cavity and nasopharynx, providers should proceed with caution when managing patients with known COVID-19 or unknown infection status [35]. When possible, testing for COVID-19 should be obtained prior to intervention for epistaxis. Nasal packing and other procedures to manage epistaxis are high-risk aerosol-generating procedures and appropriate PPE should be utilized, including N95 masks or PAPRs, eye protection, gown, and gloves. Noninvasive measures such as digital compression or medical management should be attempted for mild epistaxis before more invasive measures are undertaken. Absorbable packing should be considered to reduce the need for further procedures to remove packing.

Management of Treatment Complications

Surgical Complications

There are risks of complications after surgery for SCCHN beyond those already covered in this chapter (airway and bleeding). The most common complications after surgery are edema and seroma formation.

After neck dissection (cervical lymphadenectomy), it is common for patients to develop lymphedema of the lower face and neck. Patients who receive adjuvant treatment including radiation therapy and chemotherapy often have lymphedema after treatment. This most commonly presents in the neck and submental region with pitting and non-pitting edema [36]. Seroma is a collection of sterile, straw-colored serous fluid in a dead space of the surgical field and most commonly happens after neck dissection and thyroidectomy. A seroma can easily be mistaken for an abscess if the skin is red and tender. A white blood cell (WBC) may not be helpful as this can be elevated after surgery without infection. A key difference is that there are typically no clinical signs of severe infection (e.g., fever, sepsis) with seroma. If there is uncertainty, then sterile needle aspiration of the fluid can be diagnostic. Seromas typically do not require emergent treatment.

In contrast to seroma, a hematoma is a collection of blood within the surgical bed and can occur in up to 4% of all major head and neck cancer surgeries [37]. A hematoma can be distinguished from seroma by the presence of bruising and turgor of the overlying skin (Fig. 19.7). An expanding hematoma of the neck should be recognized as an emergency because of the potential for airway compression. The treatment of an expanding hematoma is evacuation of the hematoma and control of any bleeding vessels. This is best performed sterilely in the operating room to reduce the risk of infection but may be necessary at the bedside if the patient develops an unstable airway.

A chyle leak is an uncommon complication that can occur after surgery in the low neck. A chyle leak can present in a similar manner to a seroma. The defining difference is that chyle has a characteristic milky color with normal dietary intake and can have inflammatory effects. Chyle leaks present soon after major neck surgery often when drains are still in place. Most chyle leaks occur on the left due to the pres-

Fig. 19.7 Hematoma of the upper neck 24 h after neck dissection. Note ecchymosis of the overlying skin

ence of the thoracic duct emptying in the left subclavian vein near the internal jugular vein. Needle aspiration of a suspected chyle leak will be unproductive. Most chyle leaks can be managed conservatively with a no-fat diet and continuation of a drain.

Salivary fistula is a complication distinct to surgery of the head and neck involving the parotid gland. A salivary fistula can present like a seroma but is treated differently. There may be other signs of infection including erythema, turbid fluid in the drain, purulence, or wound breakdown. Diagnostic needle aspiration can be performed but the fluid should be tested for amylase which would be unique to saliva. Pharyngocutaneous fistula, a connection from the pharynx to the skin, can occur after major head and neck surgery, particularly in patients who have had prior treatment with radiation [38]. Treatment typically includes incision, drainage, and packing of the wound.

Radiation Therapy Complications

Radiation therapy (RT) is a commonly used method of treatment for head and neck cancer, particularly SCCHN. RT-related toxicities in the head and neck include erythema, ulceration, xerostomia, lymphedema, fibrosis, and osteoradionecrosis (ORN) of the jaw or temporal bone. RT has early and late effects on normal tissue. The early effects are caused by DNA damage and reactive oxygen species formation with resultant cell death to ciliated epithelium, blood vessels, and secretory glands [39]. The late effects are caused by ischemia from microvascular damage and fibrosis, which cause tissue edema, erythema, hemorrhage, and thickened secretions [39]. The combination of chemotherapy and radiation therapy (CRT) in the head and neck causes a synergistic effect on cancer cells but also has a more intensified impact on normal cells causing increased and more severe toxicities [40]. A large population-based study showed that 62% of head and neck cancer patients receiving CRT and 46% of patients receiving RT alone had a hospitalization or ER visit for an acute adverse effect [1]. The most prominent side effect of RT or CRT is dysphagia. Dysphagia is the result of tissue fibrosis, mucositis, laryngopharyngeal dysmotility, and xerostomia [41]. Severe dysphagia can lead to malnutrition, aspiration, and pneumonia.

A complication unique to RT of the head and neck is ORN of the jaw. ORN of the jaw is a result of direct and indirect (loss of saliva) tissue effects that culminate in poor bone healing [42]. The patient can present with recurrent or chronic pain, mandible fracture, and exposed bone in the oral cavity. ORN of the jaw after RT is often precipitated by a dental procedure. Radiation-induced necrosis of cartilage is also a well-known complication of RT. For example, radiation-induced necrosis of the larynx can occur even years after treatment [43]. Differentiating radionecrosis of the larynx from recurrent cancer can be difficult. Diagnosis is based on examination and clinical suspicion.

Chemotherapy Complications

Patients receiving chemotherapy can manifest complications in the head and neck. For primary SCCHN, chemotherapy is often used in combination with RT for definitive treatment or alone a palliative therapy. Some common agents used for SCCHN include cisplatin, carboplatin, 5-fluorouracil, docetaxel, and cetuximab. These drugs can cause nausea and vomiting, renal failure, myelosuppression, thrombocytopenia, mucositis, and neuropathy. The majority of patients treated with CRT experience severe mucositis [44]. This can lead to decreased quality of life, weight loss, gastrostomy dependence, and increased ED visits and hospitalizations [45]. When symptoms are severe enough, up to one-third of SCCHN patients will require hospitalization [46]. The most common reason for presentation to the ED during or after CRT is dehydration and malnutrition. Symptoms can be ameliorated with topical lidocaine or "magic mouthwash," which usually includes topical lidocaine, steroid, antifungal,

and antibiotic. Finally, acute hearing loss can occur from the administration of chemotherapy, most notably cisplatin. Sudden-onset tinnitus may be an early sign of acute hearing loss. Steroids and discontinuation of cisplatin may limit the loss of hearing; however, cisplatin-induced hearing loss is generally permanent.

Common Pitfalls

Neck Abscess Versus Occult SCCHN Cystic Cervical Lymph Node Metastasis

The workup of a patient presenting to the ED with a neck mass often includes a contrast-enhanced CT of the neck. It is common that the only abnormality observed is a fluid-filled collection with peripheral rim enhancement (Fig. 19.8a, b). In an adult, this almost invariably represents occult SCCHN metastatic to a cystic or necrotic lymph node in the neck. It can unfortunately be misinterpreted as an abscess, particularly if there is redness of the skin and tenderness [47]. Unlike an abscess, these patients will usually lack the cardinal findings of infection, fever, and elevated WBC. Fine needle aspiration (FNA) biopsy is the most appropriate diagnostic test of any persistent neck mass >2 cm in an adult patient. Incision and drainage are strongly discouraged without a definitive diagnosis of abscess as it can substantially alter the management of a patient with occult SCCHN metastatic to a cervical lymph node.

Sinusitis Versus Occult Sinonasal Malignancy

Acute bacterial sinusitis is a common diagnosis for patients presenting to the ED. Sinonasal malignancies, on the other hand, are very rare. However, patients with cancer involving the sinuses are often treated unsuccessfully for sinusitis for weeks or months before an alternative diagnosis is entertained. The result is a delay in diagnosis that can impact the stage of disease, treatment options, and prognosis.

There are a few key differences between patients with sinusitis and sinonasal malignancy. First, the clinical presentation is strikingly different. Patients with sinonasal cancer most often present with unilateral, rather than bilateral symptoms. Unilateral nasal obstruction, persistent nasal bleeding, facial pain or pressure, facial numbness, visual changes, and/or epiphora should be carefully evaluated for a possible sinonasal malignancy. This could most readily be accomplished with a sinus CT. Any unilateral opacification of the sinuses should prompt timely referral to an otolaryngologist (Fig. 19.9).

Ear Infection Versus Occult SCCHN of the Oropharynx

Unilateral otalgia is a common presenting symptom of SCCHN involving the oropharynx, including the tonsil or base of tongue. Other common causes of ear pain are infection and temporal mandibular joint (TMJ) disorder. It is

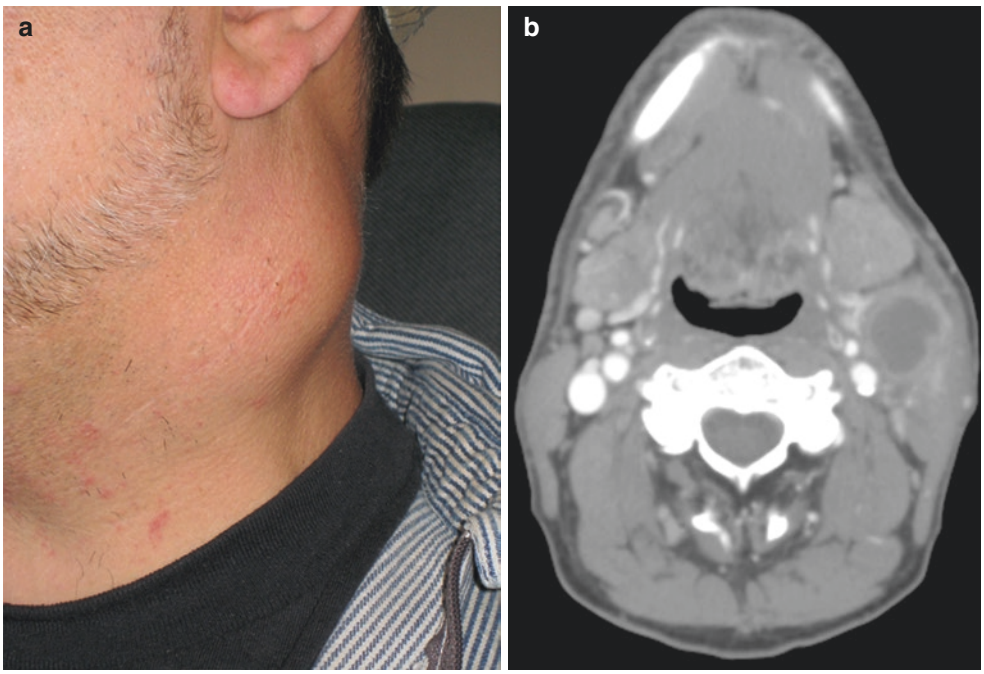

Fig. 19.8 Patient presenting with a non-tender left-sided neck mass (**a**) which appears cystic on axial computed tomography (CT) imaging (**b**). Any lateral neck mass in an adult should be considered cancer until proven otherwise, regardless of smoking status or other risk factors

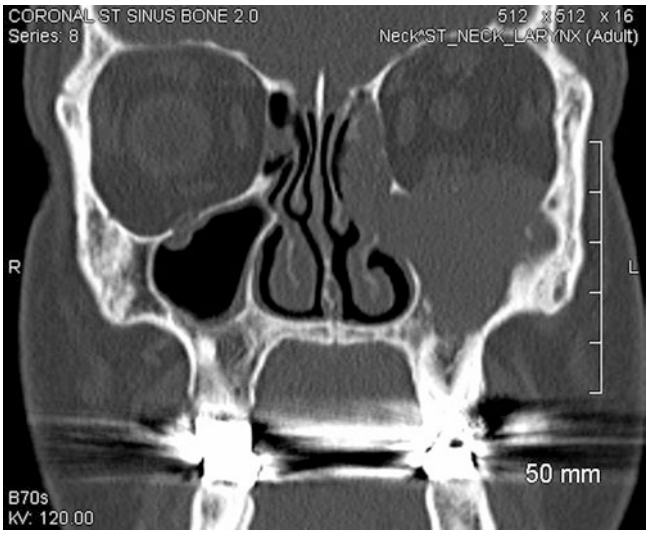

Fig. 19.9 Coronal computed tomography (CT) of the sinuses demonstrating a left-sided nasal cavity mass with opacification of the left maxillary sinus and ethmoid sinuses and invasion into the ipsilateral orbit. Any unilateral opacification of the sinuses is concerning for malignancy

important for medical practitioners in the ED to be able to distinguish between benign and malignant causes of ear pain. As with occult sinonasal malignancies, a delay in diagnosis is common for patients with SCCHN of the oropharynx.

The incidence of SCCHN involving the oropharynx (tonsil or base of tongue) continues to increase dramatically [48]. This has been attributed to the human papillomavirus (HPV) which is now associated with >70% of these cases. Patients with HPV-associated SCCHN tend to be younger and are more often non-smokers and are often not thought to be at risk of head and neck cancer [49]. However, unilateral otalgia without clinical findings of an ear infection (e.g., ear drainage, middle ear effusion, painful ear canal) should prompt a thorough evaluation of the oropharynx by a specialist to rule out occult malignancy.

Summary

The UADT is a complex area where functions of breathing and eating take place in a highly vascularized area. Patients with SCCHN frequently present to the ED with a difficult airway. Frontline physicians in the ED must have a plan for airway control in these patients. An understanding of anatomy and physiology of the surgically altered airway in patients after tracheostomy and laryngectomy, so-called neck breathers, is essential. Bleeding related to the treatment of SCCHN can be catastrophic. Therefore, control of the airway along with methods to stabilize the patient is important. The use of direct pressure to tamponade bleeding and shock trauma principles can be employed before definitive management by a head and neck surgeon. There are other treatment-related complications related to surgery, radiation therapy, and chemotherapy that must be recognized to prevent further sequelae. To avoid common pitfalls in SCCHN management, ED medical personnel must also be aware of distinctions between signs of malignancy and common otolaryngologic symptoms.

Ophthalmic Emergencies in Cancer Patients

20

Diana Chao, Mathieu F. Bakhoum, and Bita Esmaeli

Introduction

While there are a few ophthalmological emergencies that are life-threatening, there are a number of ocular conditions in cancer patients that require immediate diagnosis and management. This chapter reviews the differential diagnosis and management of common ocular or visual symptoms encountered in a cancer hospital-based emergency department (ED). It is organized based on the symptoms that patients may present with to the ED, including acute visual loss, diplopia, red eye, proptosis, epiphora, ptosis, flashes, and floaters. A review of trauma-related ocular emergencies is outside the scope of this textbook, and the reader is referred to other texts for a detailed discussion of noncancer-related ocular emergencies [1, 2].

Acute Visual Loss

One of the most distressing ophthalmologic symptoms is the sudden loss of vision. The causes of sudden acute visual loss may be classified as those affecting the optic nerve, those affecting the retina, and those affecting the retinal vasculature.

The primary symptoms associated with optic nerve disease may include decreased visual acuity associated with a central visual field defect, decreased color vision and contrast sensitivity, and ocular pain on eye movement. A sensitive clinical sign for the presence of asymmetric optic nerve disease is a relative afferent pupillary defect (Marcus Gunn pupil) on the affected side using the swinging-light test [3]. On ophthalmoscopy, the optic nerve head may appear swollen or pale. A red desaturation test may also be performed; when there is damage to the optic nerve, the affected eye sees the color red as a blanched orange-pink color.

Acute visual loss secondary to optic nerve disease in cancer patients can be due to a mass effect, either from a primary orbital tumor process (Fig. 20.1), secondary to an orbital metastatic process (Fig. 20.2), or from secondary extension

of tumor from paranasal sinuses (Fig. 20.3), from nasal cavity, or from the brain or skull base. Primary malignancies of the optic nerve include optic nerve glioma (Fig. 20.4), meningioma, craniopharyngioma, and medulloblastoma [4].

Fig. 20.4 Axial T2 image demonstrates left optic nerve glioma in a 61-year-old female who presented with visual loss in the left eye

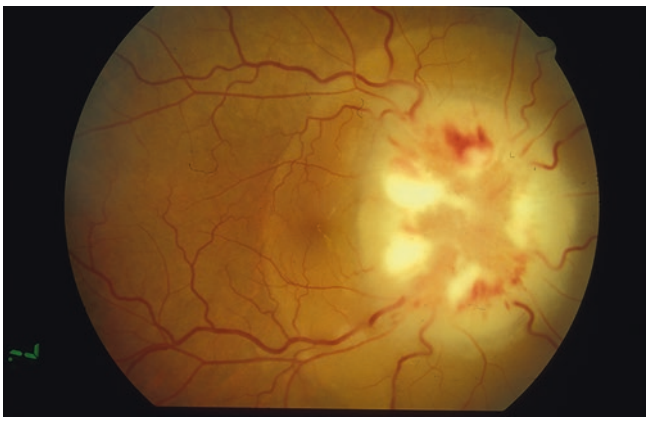

Fig. 20.5 Fundus photograph demonstrates infiltration of the optic nerve by leukemic cells, causing progressive visual loss

Infiltration of the optic nerve by leukemic or lymphomatous cells may also occur (Fig. 20.5) [5]. In addition, the optic nerve may be infiltrated by leptomeningeal disease from solid or liquid tumors. Invasive aspergillosis of the paranasal sinuses and/or orbit should also be considered in immunocompromised patients, as it is most prevalent among leukemic patients with granulocytopenia and is associated with a high mortality rate [6]. Optic nerve toxicity secondary to chemotherapeutic agents is another possible cause of optic neuropathy in cancer patients.

The most common noncancer-related cause of optic neuritis (optic nerve swelling) is multiple sclerosis; however, optic neuritis may also result from inflammatory conditions,

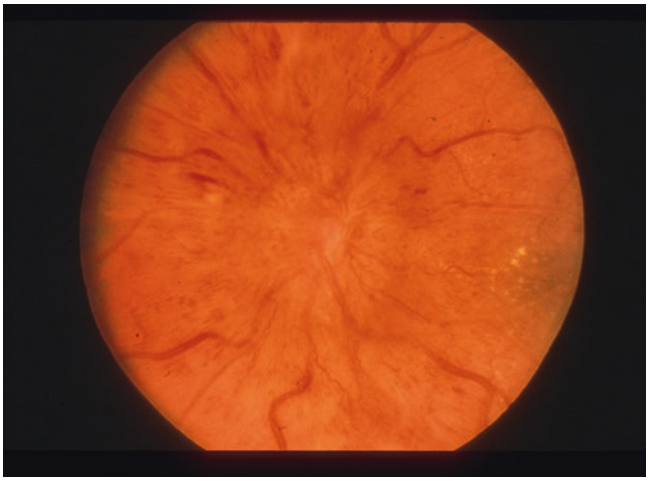

Fig. 20.6 Fundus photograph demonstrates ischemic optic neuropathy in a patient with diabetes mellitus who experienced acute painless loss of vision

such as Wegener's granulomatosis (granulomatosis with polyangiitis), systemic lupus erythematosus, and sarcoidosis, or it may be idiopathic. Infectious etiologies (including syphilis and Lyme disease) may also produce similar findings. In the elderly population or in patients with atherosclerosis, hypertension, and/or diabetes, the most common cause of acute visual loss of optic nerve origin is an ischemic optic neuropathy (Fig. 20.6). In the older population, giant cell arteritis is an important form of ischemic optic neuropathy that is sometimes associated with polymyalgia rheumatica [7]. Giant cell arteritis requires prompt diagnosis and treatment with high-dose systemic steroids to prevent progressive and sometimes bilateral visual loss. In diabetic patients or in the immunocompromised cancer patients, the possibility of orbital cellulitis or fungal infections such as mucormycosis or aspergillosis of the sinus with extension into the orbit should also be considered as a cause of optic nerve swelling and compression.

The preferred diagnostic test to evaluate optic nerve disease is magnetic resonance imaging (MRI) of the brain and orbit, with and without gadolinium, fat suppressed. MRI can usually demonstrate the extent of optic nerve disease, although may be normal in the early stages of leptomeningeal disease [8].

The management of optic nerve disease depends on the etiology. In cancer patients, the initial management may include systemic antibiotics or antifungals, chemotherapy, external beam radiation therapy, high-dose steroids, or surgery [9–11].

Retinal disease (particularly if it involves the macula, where visual acuity is most sensitive) may cause acute visual loss. Symptoms associated with retinal disease include decreased vision, metamorphopsia, flashes of light, new floaters, and a "curtain" over the visual field. A dilated fundus examination is necessary to correctly diagnose the retinal causes of acute visual loss.

Rhegmatogenous retinal detachment is the most common type of detachment, and it occurs when there is a tear or break in the retina, allowing fluid to accumulate in the subretinal space, separating the neurosensory retina from the underlying retinal pigment epithelium. In cancer patients, serous and exudative retinal detachments may result from leukemic or lymphomatous infiltration of the choroid and/or subretinal space, choroidal metastatic lesions (Fig. 20.7), or, less commonly, primary intraocular tumors such as uveal melanoma. Serous and exudative detachments occur despite the absence of a hole, tear, or break. Opportunistic infections such as those with *Cytomegalovirus* (CMV) (Fig. 20.8), herpes simplex virus (HSV), herpes zoster virus (HZV), and *Candida* may cause retinitis in immunocompromised patients. Retinitis due to HSV or HZV may cause rapid

Fig. 20.7 Fundus photograph demonstrates a choroidal metastatic lesion causing elevation of the choroid and metamorphopsia

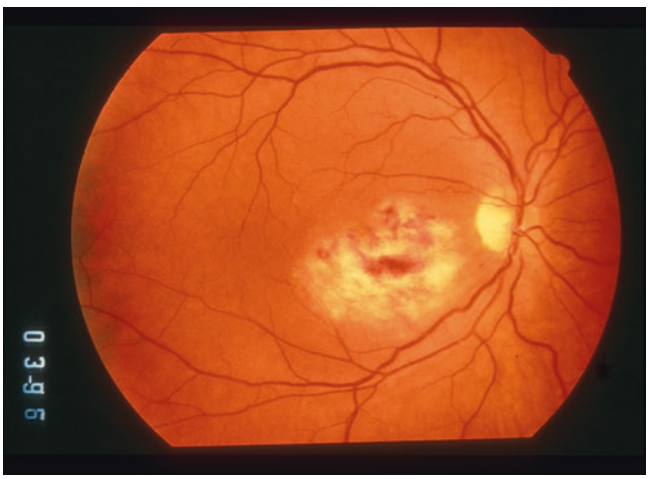

Fig. 20.8 Fundus photograph demonstrates CMV retinitis, characterized by necrosis and hemorrhage often in the posterior pole

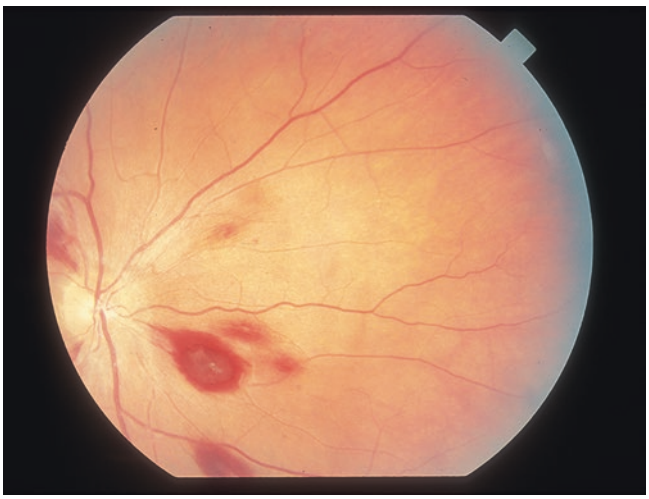

Fig. 20.9 Fundus photograph demonstrates spontaneous retinal hemorrhage in a patient with acute myeloid leukemia and thrombocytopenia

visual loss to "no light perception" within 24 h [12]. It is important to diagnose the infectious forms of retinitis in a timely fashion so that the appropriate systemic therapy can be initiated as soon as possible.

Another very common cause of visual loss among cancer patients is retinal hemorrhage secondary to thrombocytopenia (Fig. 20.9) [13]. Prompt referral to an ophthalmologist is necessary for appropriate diagnosis and management. Treatment for rhegmatogenous detachments includes urgent laser photocoagulation or surgical management. For all other etiologies, timely treatment of underlying disease including chemotherapy and/or radiation for metastatic lesions and intravenous and/or intravitreal antiviral and antifungal therapy for opportunistic viral infections is necessary.

Obstruction of the retinal vasculature can also cause acute visual loss. Retinal vascular obstruction usually results from thrombi or emboli and is more likely to occur in patients with hypertension, atherosclerosis, or diabetes. However, cancer patients have the added risk of neoplasm-associated hypercoagulability [14]. Central retinal artery occlusion (CRAO) or central retinal vein occlusion (CRVO) may lead to devastating visual loss. Involvement of the smaller vessels may lead to partial visual acuity or visual field loss. Most occlusive vascular events are not reversible although they require prompt diagnosis and follow-up to address the underlying medical problems and to prevent future ocular complications from ischemic retinopathy. The visual prognosis depends on the extent of retinal ischemia. Particularly, the ischemic variety of CRVO can be complicated by secondary neovascular glaucoma and may require panretinal photocoagulation and intravitreal anti-VEGF inhibitors [15]. Prompt referral to an ophthalmologist is recommended when a retinal vascular event is suspected.

Diplopia

Diplopia (double vision) is a common symptom in cancer patients. The first thing to establish is whether diplopia is monocular or binocular and whether it is horizontal or vertical. In addition, true diplopia must be distinguished from blurred vision, in which the image is blurred, but is not in fact double. If diplopia persists after one eye is covered, the patient has monocular diplopia, which is almost certainly not a neurologic problem. The usual causes of monocular diplopia include refractive error or media opacity (i.e., cataract). In contrast, if diplopia is present only when both eyes are open, it is binocular in nature, and there is usually an underlying neurologic or extraocular motility problem. Binocular diplopia can be horizontal, vertical, or torsional [16]. Extraocular motility exam should be performed to assess whether only one or multiple cranial nerves are affected and for any signs of ptosis.

Specific neurologic causes of binocular diplopia include cranial nerve III, IV, or VI palsies, or a mechanical process that may limit the function of the extraocular muscles. If only one cranial nerve or extraocular muscle is affected, then a simple noncomitant diplopia may develop. In contrast, leptomeningeal disease or any space-occupying lesion in the orbital apex, superior orbital fissure, or the cavernous sinus may affect multiple cranial nerves at the same time, resulting in a more complex pattern of diplopia.

While cranial nerve palsies can be secondary to an ischemic event (particularly in patients with hypertension, diabetes, or atherosclerosis), in cancer patients, the most common etiology is tumor extension in the orbital apex or cavernous sinus. Extraocular muscles may also be compressed or entrapped by a mass, or they may be infiltrated by inflammatory or neoplastic processes. Opportunistic infections, particularly fungal infections secondary to mucormycosis or aspergillosis, may extend into the orbit from the paranasal sinuses. A high index of suspicion for fungal cellulitis or pansinusitis is necessary to make the correct diagnosis and initiate therapy for these potentially fatal infections in immunocompromised patients [17].

Another important but less common cause of third cranial nerve palsy, particularly if pupillary fibers are involved, is a cerebral aneurysm. This is not unique to cancer patients but should be considered on the differential diagnosis of a patient with an acute onset of third cranial nerve palsy.

In the emergency evaluation of a patient with an acute onset of diplopia, an imaging study (ideally, an MRI of the brain and orbit with and without gadolinium, fat suppressed) is often necessary to rule out or establish the diagnosis and extent of orbital or cavernous sinus involvement if any.

If a cerebral aneurysm is suspected, magnetic resonance angiogram (MRA) or computed tomography angiography (CTA) of the brain is indicated.

The treatment of diplopia depends on the underlying cause and (usually in cancer patients) entails treatment of the underlying tumor or infectious etiology. The patching of one eye or temporary Fresnel prisms may help the patient symptomatically until the exact cause and treatment for diplopia is determined.

Red Eye

There are many possible causes of a red eye in cancer patients. It is helpful to classify the causes of a red eye on the basis of intraocular structures that may be the cause of inflammation on the surface of the globe. Any disease process that can cause inflammation in the conjunctiva, cornea, iris, anterior chamber, ciliary body, or sclera can present as a red eye. Therefore, it is important to perform a comprehensive ophthalmologic examination to identify the correct cause.

Conjunctivitis is probably the most common cause of a red eye. Conjunctivitis can be due to infectious etiology such as bacteria (*Staphylococcus aureus*, *Streptococcus pneumoniae*, *Pseudomonas aeruginosa*, *Chlamydia*, *Neisseria gonococcus*) or viruses (adenovirus, herpes simplex virus [HSV]) [18]. However, occasionally, the cause is not infectious. The inflammatory causes of conjunctivitis include toxic conjunctivitis secondary to the excessive or inappropriate use of topical antibiotics (medicamentosa), allergic conjunctivitis, and acute or chronic ocular graft-versus-host disease.

Subconjunctival hemorrhage and hemorrhagic chemosis are benign conditions that may cause asymptomatic, sudden, painless red eye (Fig. 20.10). Conservative management with lubrication of the eye and observation for spontaneous resolution over several weeks is appropriate.

Fig. 20.10 Subconjunctival hemorrhage, causing painless red eye, in a 57-year-old patient who has a history of acute lymphoblastic leukemia and low platelet count (30,000/μL)

Superficial keratopathy secondary to ocular graft-versus-host disease (GVHD) or as a side effect of cancer chemotherapeutic agents such as arabinosylcytosine (ara-C) can cause ocular surface irritation, corneal epithelial defects, and, possibly, a red eye [19, 20]. Many other chemotherapeutic agents such as docetaxel and 5-fluorouracil are secreted in the tear film and may lead to conjunctivitis. Slit-lamp examination of the cornea using topical fluorescein dye and cobalt-blue light to assess for decreased tear film, punctate epithelial erosions, pseudomembranes, serosanguinous exudates, and corneal epithelial defects is performed to evaluate for most forms of superficial keratopathy. The management of conjunctival or corneal problems secondary to ocular GVHD entails the use of topical lubricants, cyclosporine drops, punctal plugs, and topical and/or systemic administration of immunosuppressive agents, such as steroids and tacrolimus [21]. Superficial keratopathy secondary to ara-C use is treated with topical steroids, lubricating artificial tears, and ophthalmic ointment, and in refractory cases by lowering the dose of ara-C.

Another common cause of superficial keratopathy in cancer patients is exposure keratopathy secondary to facial palsy. Facial paralysis secondary to the compressive effects of a parotid mass or due to ablative surgery for malignancies in the parotid area can result in inadequate eyelid closure and chronic corneal exposure [22]. The immediate treatment of exposure keratopathy entails the use of lubricating artificial tears and ophthalmic ointments. If facial paralysis is expected to last longer than a few weeks, periocular surgery, such as placement of a gold weight in the upper eyelid, repair of paralytic lower eyelid, and a lateral tarsorrhaphy, should be considered [23].

Infectious keratitis is another important cause of red eye and can be caused by bacterial (*S. aureus*, *S. pneumoniae*, *N. gonococcus*, *Moraxella*, *P. aeruginosa*), viral (adenovirus, HSV, HZV), or fungal (*Candida*, *Aspergillus*) organisms [24]. Herpes zoster ophthalmicus occurs when varicella-zoster virus is reactivated in the ophthalmic (V1) division of the trigeminal nerve and is associated with immunosuppression, and it may be a harbinger of increased risk of cancer [25] or other immunocompromised states. It may present with periorbital vesicle formation in a unilateral, V1 dermatomal distribution with associated red eye and pseudodendritic fluorescein-staining pattern under cobalt light. Prompt diagnosis and treatment of HZV with systemic antiviral agents like acyclovir and topical agents is appropriate. The diagnosis and management of infectious keratitis requires the direct involvement of an ophthalmologist. Management often involves obtaining corneal cultures and instituting topical fortified antibacterial, antiviral, or antifungal agents.

Acute angle-closure glaucoma may also cause a painful red eye. It occurs in patients who have narrow angles that become blocked by the iris. Symptoms and signs of acute angle-closure glaucoma are pain, redness, blurred, or "steamy" vision from corneal edema, halos around lights, and a mid-dilated pupil. The intraocular pressure can rise to 50–60 mmHg, and urgent medical treatment to lower the pressure is necessary to avoid permanent vision loss. There are many causes of acute angle-closure glaucoma, and prompt diagnosis is necessary for appropriate treatment. Anticholinergic or sympathomimetic medications dilate the iris and lead to crowding of the anterior chamber angle peripherally [26]. A mass in the ciliary body or choroid can also push the iris forward and cause angle closure [27]. Primary intraocular tumors such as uveal melanomas or medulloepitheliomas may be present in the angle and may obstruct the aqueous outflow. The medical management of angle-closure glaucoma in the ED includes the immediate use of topical antiglaucoma medications, and systemic carbonic anhydrase inhibitors are often necessary to bring the intraocular pressure down to a safe level. For primary acute angle-closure glaucoma, the patient should be referred to an ophthalmologist for consideration of a laser peripheral iridotomy after the intraocular pressure has been brought down to a safer level with medications [28].

Inflammation of the iris, ciliary body, or choroid is referred to as uveitis. In addition to red eye, uveitis can present with pain, photophobia, blurred vision, and miosis. Anterior chamber cells and flare noted during slit-lamp biomicroscopy are the hallmarks of iritis or uveitis. Uveitis is thought to be idiopathic in about 50% of cases or can be associated with various autoimmune processes such as rheumatoid arthritis, lupus, ankylosing spondylitis, and Wegener's granulomatosis (granulomatous polyangiitis) [29]. In immunocompromised patients, infectious causes of uveitis must be considered. The most severe form of intraocular infection, endogenous endophthalmitis, can initially present as mild but progressively worsening uveitis [30]. Once the diagnosis of endogenous endophthalmitis is suspected, blood culture and vitreous biopsy are often necessary to identify the causative infectious organism. Prompt referral to an ophthalmologist is necessary for diagnosis and management. Treatment for uveitis due to noninfectious causes includes the judicious use of topical steroids and cycloplegic drops to decrease the inflammation in the anterior chamber and prevent ciliary body spasm. For suspected endogenous endophthalmitis, broad-spectrum intravenous antimicrobial therapy is administered until sensitivity results are available from the vitreous biopsy cultures. Intravitreal injection of antibiotics or antifungal drugs is the treatment for endogenous endophthalmitis, and in some cases, a surgical vitrectomy may be necessary both for diagnostic and for therapeutic purposes [31, 32].

Epiphora

True epiphora (excessive tearing) results from an obstruction of the tear drainage apparatus. Epiphora must be differentiated from pseudoepiphora, which may be caused by ocular surface irritation due to conditions such as dry eye syndrome, ocular graft-versus-host disease, and exposure keratopathy. The most common cause of epiphora in the general population is primary nasolacrimal duct blockage which is due to obstruction of the nasolacrimal duct at its junction with the lacrimal sac [33]. Primary idiopathic nasolacrimal duct blockage occurs more frequently in women and is involutional in nature. In cancer patients, however, the most common etiology for epiphora is likely to be (a) mechanical blockage of the tear drainage pathway secondary to either primary lacrimal sac or nasolacrimal duct cancers or from extension of tumors from the paranasal sinus or nasal cavity [34], (b) canalicular and nasolacrimal duct stenosis secondary to chemotherapy [35, 36], or (c) canalicular or nasolacrimal duct obstruction secondary to radiation therapy [37, 38]. Common chemotherapeutic agents that are known to cause canalicular stenosis include S-1, 5-fluorouracil, mitomycin C, and docetaxel (Taxotere) [39–42]. Nasolacrimal duct obstruction may also occur secondary to local toxicity or active uptake of radioactive iodine used in the treatment of thyroid carcinoma [43–45]. Because timely diagnosis of early canalicular stenosis in patients receiving these agents can lead to early insertion of silicone tubing in the nasolacrimal duct and therefore prevention of further narrowing of the canaliculi, appropriate referral to an ophthalmologist early in the course of therapy with these agents is crucial.

Acute dacryocystitis is another important cause of epiphora. The infectious causes for acute or chronic dacryocystitis include *S. aureus*, *S. pneumoniae*, and *Haemophilus influenzae* [46]. Clinical signs associated with dacryocystitis are epiphora, mucopurulent discharge upon pressure over the lacrimal sac, and erythema and edema over the lacrimal sac. Initial treatment for infectious dacryocystitis involves systemic antibiotics and warm compresses. A dacryocystorhinostomy may be necessary to prevent future episodes of dacryocystitis, particularly in immunocompromised patients [47].

Proptosis

Proptosis (outward protrusion of the eye) may be caused by an orbital mass or a diffuse inflammatory or infiltrative process involving the retrobulbar space. Other possible associated symptoms and signs may include diplopia, decreased vision, and multiple cranial neuropathies secondary to involvement of the orbital apex.

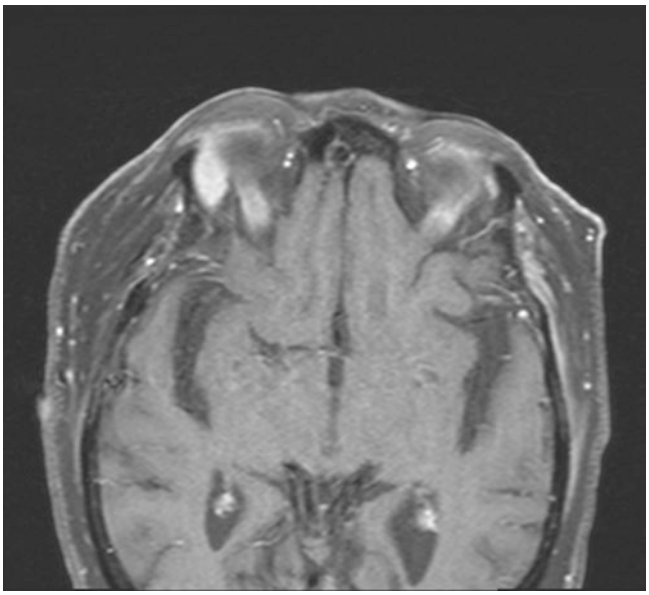

Fig. 20.11 Axial T1 image demonstrates a right lacrimal gland lymphoma in a 75-year-old female who presented with a slow-growing painless mass and mild proptosis

The most common primary cancer affecting the orbit in adults is lymphoma (Fig. 20.11) [48, 49]. Orbital lymphoma can be the extranodal manifestation of systemic lymphoma or may be the only site of lymphomatous involvement [50, 51]. Other benign or malignant tumors that can cause proptosis include optic nerve glioma, meningioma, orbital hemangioma, sarcoma, and metastatic lesions [52]. The most important cause of sudden and progressive proptosis in children is orbital rhabdomyosarcoma [53]. Another important cause of proptosis, particularly if associated with pain and inflammatory signs, is orbital pseudotumor. The diagnosis of orbital inflammatory syndrome (orbital pseudotumor) is a diagnosis of exclusion and should be made only after an orbital biopsy specimen proves to be negative for malignancy [54]. Timely diagnosis with diagnostic imaging (preferably MRI of the brain and orbit with and without gadolinium, fat suppressed) and orbital biopsy is important for institution of appropriate therapy. Management of proptosis consists of treatment of the underlying cause. It is important to avoid the administration of systemic steroids until the diagnosis is clearly established, ideally on the basis of an orbital biopsy in addition to MRI to rule out lymphoma, orbital metastasis, or rhabdomyosarcoma as the underlying cause of proptosis. The use of anti-inflammatory agents can mask the clinical signs and symptoms, delay diagnosis, and lead to a lower yield for an orbital biopsy. Prompt referral to an orbital and oculoplastic surgeon is appropriate when a patient presents with acute proptosis. An experienced orbital specialist may be able to recognize common radiographic features of common orbital lesions and sometime avoid a biopsy, but in most instances, if radiographic features are not classic for a benign vascular lesion such as hemangioma, the most appropriate next step after an imaging study is an orbital biopsy or complete excision of the mass depending on the radiographic features.

Orbital cellulitis may also present as proptosis, and it is associated with visual loss, decreased and painful extraocular movements, and general orbital congestion. Orbital cellulitis usually results from the direct extension of infection from the paranasal sinuses, especially the ethmoidal sinus [55]. However, direct inoculation from trauma, extension of an eyelid infection, and septicemia may also cause orbital cellulitis [56]. The causative infectious organisms are typically *S. aureus*, *H. influenzae*, *S. pneumoniae*, or fungi, such as *Aspergillus* [57]. Orbital cellulitis may be complicated by the formation of an orbital abscess or by direct extension of infection into the cavernous sinus and the brain, a complication with a high risk of mortality [58]. Immediate treatment with systemic antibiotics and antifungals is prudent when orbital cellulitis or an orbital abscess is suspected. An orbital abscess can be diagnosed by computed tomography (CT) or MRI and usually requires immediate surgical drainage, particularly if it is associated with progressive visual loss or proptosis [59].

Proptosis can also be caused by orbital hemorrhage. Possible causes include postoperative hemorrhage, trauma, and hematologic disorders [60]. The patient's vision and intraocular pressure (IOP) should be immediately assessed because retrobulbar hemorrhage may cause a compressive optic neuropathy that may lead to permanent visual loss. If the vision is decreased or the IOP is elevated above 30–35 mmHg, a lateral canthotomy and cantholysis should be considered in the ED to expand the orbital volume and relieve orbital pressure [61]. In the pancytopenic cancer patients who are often pancytopenic due to chemotherapy, more conservative measures such as the use of pressure-lowering glaucoma drops may be more appropriate and should be tried first as a canthotomy may lead to continuous oozing and bleeding from the orbit. Orbital emphysema can rarely yield findings similar to those of orbital hemorrhage, and a lateral canthotomy and cantholysis or needle decompression may also be indicated if symptoms and signs of compartment syndrome of the orbit occur [62, 63]. The usual cause of orbital emphysema is trauma or a history of tracheal or thoracic surgery [64].

Ptosis

Ptosis (droopiness of the upper eyelid) can be gradual or sudden in onset. As with other symptoms discussed in this chapter, determining the underlying cause is the most important

aspect of the management of ptosis in the ED. The most common cause of ptosis in adults in the general population is involutional ptosis. In children, a congenital abnormality of the levator muscle is the most common cause of ptosis. In cancer patients, the most common cause of ptosis is neurologic. A palsy of the third cranial nerve due to primary or metastatic tumors of the base of the skull can cause ptosis, decreased extraocular muscle movement, and a dilated pupil. Perineural invasion secondary to cutaneous carcinomas of the facial skin can also cause multiple cranial neuropathies, including a third nerve palsy [65].

Another neurologic cause of ptosis is Horner syndrome. Horner syndrome refers to the triad of ipsilateral mild ptosis (≤2 mm), miosis of the pupil, and anhidrosis [66]. A mass effect anywhere along the path of sympathetic fibers can cause Horner syndrome. This three-neuron chain originates in the hypothalamus. The second-order neurons originate in Budge's center (C8–T2) and wind over the lung apex. The third-order neurons originate in the superior cervical ganglion, where they follow the carotid artery and then the fifth and sixth cranial nerves before they accompany the third cranial nerve to the eye. When ipsilateral miosis is associated with ptosis, Horner syndrome must be ruled out. Associated signs and symptoms may be helpful in determining the location of the lesion causing Horner syndrome. For example, ataxia, nystagmus, and weakness may indicate a first-order Horner syndrome from a brain tumor, whereas coughing, hemoptysis, or shoulder pain may indicate a lung process (the so-called Pancoast tumor) and thus a second-order Horner syndrome. Other common causes of Horner syndrome among cancer patients are iatrogenic causes, such as surgery or radiation in the cervical and neck area. Heterochromia in children usually indicates congenital Horner syndrome and does not require extensive work-up or treatment. Pharmacologic testing with cocaine or apraclonidine may result in reversal of anisocoria in patients with Horner syndrome and can help in confirming the diagnosis; hydroxyamphetamine drops may also help localize the lesion [67].

Another cause of ptosis may be mechanical. For example, inflammatory changes in the upper eyelid due to orbital or paranasal sinus infection, surgical trauma, or external beam radiation therapy may cause temporary ptosis. An isolated tumor in the upper eyelid, such as a lacrimal gland carcinoma or lymphoma, plexiform neurofibroma, or any other tumor that extends to the superior orbit, may also lead to mechanical ptosis of the upper eyelid.

Flashes and Floaters

Flashes of light, "showers of new floaters," and a "curtain" coming down over the visual field can be ominous symptoms of vitreoretinal traction, possible retinal tear, or retinal detachment (please refer to "acute vision loss" section mentioned earlier in the chapter). A thorough dilated funduscopic examination by an ophthalmologist is necessary to determine the exact nature of vitreoretinal pathology and to rule out retinal tears or retinal detachment in patients who complain of an acute onset of flashes and floaters, particularly if these symptoms are associated with a loss of vision.

Vitritis (inflammation of the vitreous gel) can be caused by intraocular neoplasms, most commonly leukemia and lymphoma, and it can present with the onset of floaters and gradual loss of vision [68]. In patients whom intraocular leukemia or lymphoma is suspected, a MRI of the brain/orbit with and without contrast is necessary to evaluate for central nervous system (CNS) involvement as the CNS is frequently involved [69]. A vitrectomy and vitreal biopsy may be required to make a definitive diagnosis [70].

A common benign condition that can also cause the acute onset of flashes and floaters is acute posterior vitreous detachment, which is mostly secondary to senescence or trauma [71, 72]. Various forms of retinitis, endogenous endophthalmitis, and posterior uveitis may also present with the same initial symptoms. Management of endophthalmitis includes blood cultures, possible vitreous biopsy to determine the causative organism, and immediate intravenous antibiotics.

Conclusion

Ophthalmological emergencies in cancer patients are multifaceted. In most instances, consultation with an ophthalmologist is necessary to insure the timely diagnosis and management of these conditions. A general understanding of the different components of an eye examination and the differential diagnosis for common ocular presentations may help the oncologist or emergency physician with triaging, work-up, and initial treatment of these conditions until the patient can be examined by an ophthalmologist.

Cardiovascular Oncologic Emergencies

21

Tarek Nafee, Dany Debs, Maria Isabel Camara Planek, Allison Zimmerman, Tawanna Charlton, Michelle Dimza, Alexandra Murphy, Stephen Dobbin, Ninian N. Lang, Sara Tyebally, Tarek Barbar, Syed S. Mahmood, Evelyn Horn, Umberto Campia, Arjun K. Ghosh, Ki Park, Michael G. Fradley, Rhian M. Touyz, Tochukwu M. Okwuosa, and Sherry-Ann Brown

Introduction

Cancer and its treatment are associated with an enormous burden for patients [1]. Cancer itself may be life-threatening, and cancer therapies are often associated with cardiovascular toxicities (Fig. 21.1) [2]. An overview of various cardiovascular toxicities will be presented, including ischemic manifestations, non-ischemic vascular conditions, pericardial diseases, cardiomyopathies, myocarditis, conduction disturbances, and valvular heart disease. We will also address the utility of imaging modalities and strategies in the prevention, diagnosis, and management of many of these emergent cardiovascular oncologic toxicities. Finally, we end the chapter with brief comments on cardio-oncologic in the COVID-19 era.

Ischemic Cardiovascular Manifestations

Case Study

A 63-year-old postmenopausal female with a past medical history of untreated hyperlipidemia and obesity was diagnosed with invasive ductal carcinoma following screening mammogram. Approximately 18 months prior to this diagnosis, she presented with substernal chest pain and a computed

tomography angiography (CTA) revealed proximal left anterior descending (LAD) coronary artery disease without flow-limiting stenosis, calcification, and possible flow-limiting stenosis within a diminutive diagonal branch with a calcium score of 45 and a Coronary Artery Disease-Reporting and Data System (CAD-RAS) score of 3. Initiation of aspirin and statin therapy were discussed at length; however, the patient declined. She underwent right breast mastectomy with pathology consistent with low-risk stage 1A ER+ HER2- RS2 oncotype. Per her primary oncologist, a plan was made to initiate aromatase inhibitor (AI) therapy without additional chemotherapy; however, initiation was delayed due to infection of the breast expander after reconstructive surgery.

On post-op day 1 of removal of the infected breast expander, and now 2 months from initial cancer diagnosis, the patient experienced sudden-onset chest pain and shortness of breath at home. EMS arrived within 30 minutes and administered 325 mg aspirin. En route, she went into ventricular fibrillation requiring cardiopulmonary resuscitation for approximately 1 minute and one dose of epinephrine after which return of spontaneous circulation was achieved. On arrival to the emergency department, she was hemodynamically stable, but in mild respiratory distress. Electrocardiogram demonstrated acute ST segment elevations in the anterior leads (Fig. 21.2)*. Bilevel positive airway pressure was started promptly, as well as a nitroglycerin infusion and administration of intravenous furosemide 80 mg. She was given 180 mg ticagrelor and taken emergently for cardiac catheterization.*

Coronary angiography revealed 100% occluded proximal LAD without other significant coronary artery disease. Percutaneous coronary intervention (PCI) of the LAD was performed, and drug-eluting stent was deployed resulting in TIMI 3 flow. Transthoracic echocardiogram showed diffuse apical and mid septal left ventricular segment akinesis with mild reduction in ejection fraction of 40–45%. She was continued on dual antiplatelet therapy (DAPT) with aspirin and ticagrelor, initiated on guideline-directed medical therapy for heart failure and referred to cardiopulmonary rehabilitation with aggressive lifestyle modifications.

At outpatient follow-up, patient was doing well without cardiac symptoms. Prior to the myocardial infarction, the original plan from oncologic was to initiate letrozole, an AI, for adjuvant therapy. Alternative treatment with tamoxifen was considered, however felt to be suboptimal secondary to thrombotic risk and inferiority to letrozole for recurrence of breast cancer. After discussion with the patient's primary oncologist, the decision was made to defer initiation of letrozole for 12 months, while the risk of recurrent cardiovascular events was highest. Additionally, the decision was made to continue DAPT for an additional year following the initiation of letrozole. Atorvastatin was initiated, but hepatic enzymes became abnormal and thus the therapy was discontinued. This posed a significant challenge as it is well known

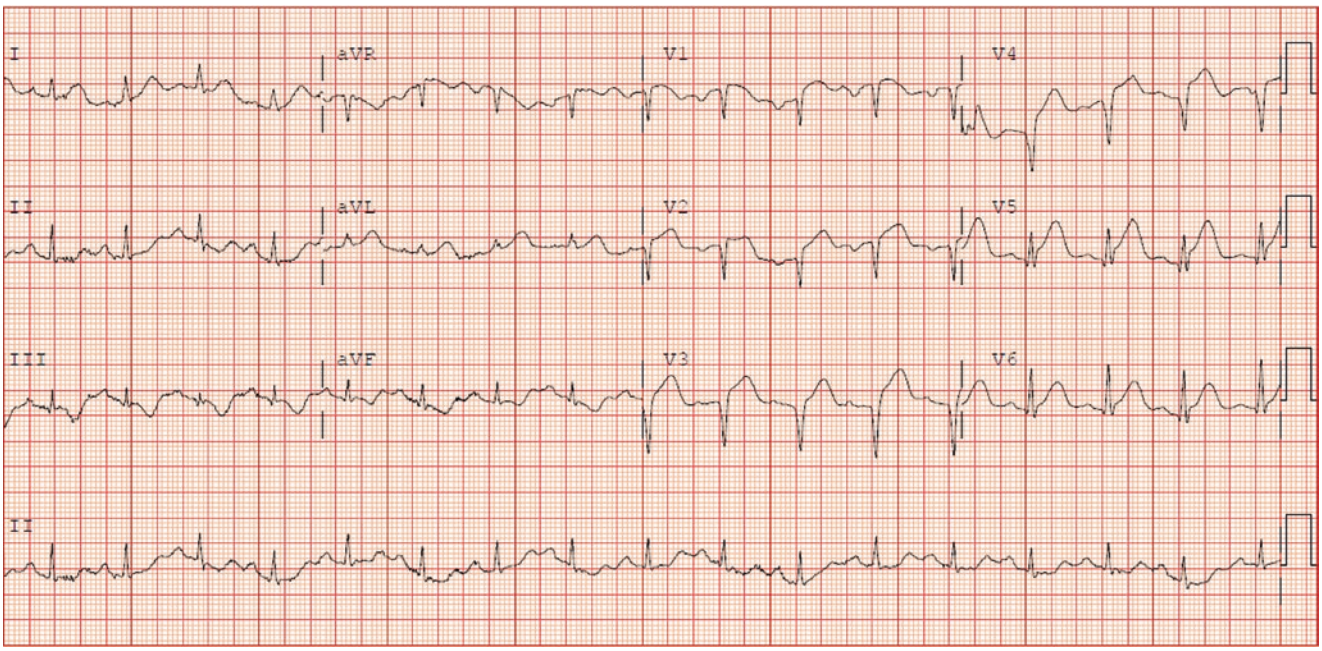

Fig. 21.2 12-lead ECG on presentation revealing anterior ST elevations

that letrozole (as well as other AIs) impacts lipid profiles. Alternative therapies such as evolocumab are being considered.

Case Discussion

We describe the case of a postmenopausal woman with recent diagnosis of ER+ HER2- breast cancer presenting with anterior STEMI and underwent PCI with drug-eluting stent placement. This is a patient with known nonobstructive coronary disease by CTA within a year prior to her MI event. Whether pre-existing atherosclerotic coronary disease contributed to this patient's presentation in the setting of heightened inflammation secondary to cancer is unclear. However, it is known that patients with cancer are at elevated risk of arterial thromboembolic (ATE) events manifesting as ischemic heart disease and stroke within the first several months after cancer diagnosis.

Following the management of her acute coronary syndrome, her treatment teams then needed to address long-term management of cancer and cardiovascular disease. Unfortunately, there are no current guidelines that address the vast majority of management decisions for a cancer patient experiencing an ATE event. There are infinite variables requiring risk and benefit analysis. For example, a large meta-analysis suggested the lack of survival benefit for AI over tamoxifen in breast cancer, even with longer cancer-free periods, may be secondary to the increased risk of cardiovascular events with AI. This elevated risk was amplified in women with pre-existing cardiovascular disease [3]. *Furthermore, several studies have found an association of unfavorable changes in lipid profile for patients on letrozole* vs *tamoxifen* [4, 5]. *This data would suggest consideration of switching letrozole to tamoxifen for patients with elevated cardiovascular risk. However, others would argue that the overall risk of cardiovascular events in both letrozole and tamoxifen is consistently low in both trial arms, and this must be weighed against the elevated risk of venous thrombosis with tamoxifen as well as the established superiority of AI in decreasing cancer recurrence* [3, 4, 6].

A common dilemma in the setting of myocardial infarction or thromboembolic stroke is selection of antiplatelet or anticoagulation regimen. The risk of thrombosis must be weighed against the propensity for bleeding in the setting of thrombocytopenia, platelet dysfunction, and anemia. The Society for Cardiovascular Angiography and Interventions published a consensus statement for cancer patients undergoing PCI, focusing mostly on thrombocytopenic patients with elevated bleeding risk. Recommendations included platelet cutoff values for each antiplatelet agent and dosing, as well as reduced duration for DAPT when platelet count <50,000 [7].

However, it is important to note that cancer patients have an increased risk of stent thrombosis, even on DAPT [8, 9]. *Furthermore, several chemotherapy agents can negatively affect stent endothelialization secondary to the cytostatic and cytotoxic properties* [10]. *Vascular endothelial growth factor (VEGF) is an important molecule in negating restenosis, and therefore VEGF inhibitor therapies have been hypothesized to also increase risk of stent restenosis, although adequate data is lacking* [10].

Ultimately, without large randomized controlled trials and data that can be easily extrapolated to a specific patient, management for acute ATE events in cancer patients will continue to require an individualized approach. For our patient, interdisciplinary discussion between cardiology, oncologic, and the patient was critical in complex decision-making. In this patient, given her low risk of cancer recurrence and low bleeding risk, a cautious approach of delaying AI for 12 months post-MI and extending DAPT for an additional 12 months was pursued.

Arterial Thrombosis

As described in the case, patients with underlying malignancies are at increased risk for arterial thrombosis. This risk is related to the frequent presence of a prothrombotic milieu in patients with cancer and/or to the direct adverse vascular and thrombogenic effects of various cancer treatments. Several mechanisms have been postulated to account for the occurrence of arterial thrombotic events, but the pathophysiology remains incompletely understood. However, it is appropriate to conceptually frame the discussion by separating the causes of arterial thrombosis secondary to the cancer itself from those associated with cancer treatment.

Secondary to Cancer

While the association between cancer and venous thromboembolism has been recognized for over a century, the increased risk of arterial thrombosis has been more recently appreciated. In particular, recent data from the Surveillance, Epidemiology, and End Results-Medicare database indicate a significant increase in arterial thromboembolism, including myocardial infarction [11]. These authors compared 279,719 patients with the most common types of malignancies in the United States (breast, lung, prostate, bladder, pancreatic, gastric, and colorectal cancer and non-Hodgkin lymphoma) with age- and sex-matched controls. At 6-month follow-up, patients with cancer had a substantially increased risk of arterial thromboembolism (composite of myocardial infarction and stroke) compared to controls: 4.7% (95% confidence interval [CI], 4.6% to 4.8%) versus 2.2% (95% CI, 2.1–2.2%) (hazard ratio, 2.2; 95% CI, 2.1–2.3), respectively. The risk was greatest in patients with lung cancer compared to other types of cancer and in patients with more advanced stages of cancer [12]. The hypercoagulable state observed in patients with cancer is likely mediated by a diverse array of mechanisms rather than a single common pathway. Cancer-related factors include elevated neutrophil and platelet count, enhanced tissue factor expression, release of microparticles, and increased inflammatory mediators. Neutrophils can contribute to thrombus formation by extruding neutrophil extracellular traps (NETs), which consist of strands of nuclear chromatin, granular proteins, and proteases. NETs have been shown to directly activate the contact pathway, inhibit thrombomodulin, and promote red blood cell and platelet adhesion. In addition to high neutrophil count, patients with cancer frequently present with elevated platelet count, a known risk factor for VTE. Circulating microparticles are small spherical cellular fragments released from the plasma membrane of various cells. They may trigger thrombosis secondary to their high levels of tissue factor and by providing negatively charged phospholipids [13, 14].

Secondary to Cancer Therapy

Various cancer treatments are associated with an increased risk of venous and arterial thrombosis [14]. The mechanisms underlying this risk are complex and involve effects on the vascular endothelium, on the coagulation pathways, and on metabolic risk factors. Direct endothelial cell injury, such as from platinum-based agents, antimetabolites (5-FU), antimicrotubule agents (paclitaxel and vinblastine), and antitumor antibiotics (bleomycin), is likely the main mechanism whereby these agents increase thrombotic risk. In addition, VEGF inhibitors such as bevacizumab and VEGF-signaling pathway inhibitors such as sorafenib and sunitinib have also been associated with arterial thrombosis, probably related to their effects on endothelial function [15].

Premature Coronary Artery Disease

Secondary to Pharmacologic Therapy

While there is scant evidence that cancer therapy is directly a cause of atherosclerosis, several treatments have long-lasting endothelial and metabolic effects that may predispose to the development of premature atherothrombosis. For example, patients who previously received cisplatin-based chemotherapy for testicular cancer had increased risk of developing lipid disorders, obesity, and hypertension [16].

As mentioned previously, AI therapy has been associated with adverse cardiovascular events, likely secondary to the impact on serum cholesterol. It is proposed that the decreased levels of estrogen during adjuvant hormonal therapy have downstream effects on HDL and LDL levels. Not all AI agents have the same effect, which may be explained by varying modes of action. Anastrozole and letrozole are non-steroidal reversibly binding AIs. Letrozole has been associated with adverse effects on lipids, including increased LDL and total cholesterol. Anastrozole has little to no effect on lipids. By contrast, exemestane, a steroidal irreversibly binding AI, demonstrated a slight positive impact on lipids in clinical trials [17]. Of note, tamoxifen has estrogenic agonist effects on lipid profiles, with several studies showing a decrease in total and LDL cholesterol and mild increase in HDL [17, 18]. A recent large cohort-based retrospective

analysis found an association of increased risk of myocardial infarction (HR = 2.08; 95% CI, 1.02, 4.27) but not cardiovascular mortality (HR = 0.87; 95% CI, 0.49, 1.54) when comparing patients switching from tamoxifen to AI vs continuing tamoxifen therapy [19]. Although there are no specific guidelines for management of hypercholesterolemia in this context, close lipid monitoring and identification of high-risk patients are crucial. Adherence to ACC/AHA guidelines is advisable for patients undergoing hormonal therapy to optimize cardiovascular risk management [20]. In special cases consideration of alternative hormonal therapy is reasonable.

Secondary to Radiation Therapy

Radiation therapy is an integral part of treatment in over 50% of patients with cancer and should be readily queried in the history obtained in the ED. Unfortunately, the effects of radiation are nonselective, and vessels within the field of radiation are vulnerable to acute injury, leading to endothelial dysfunction, inflammation, and thrombosis, as well as to long-term damage, with premature atherosclerosis and extensive calcification [21]. The clinical manifestations of radiation-induced vascular damage depend on the area of exposure. Radiation to the chest, such as for Hodgkin's lymphoma and breast cancer, has been associated with increased risk of premature CAD, whereas head and neck radiation confers a higher risk of carotid disease, transient ischemic attack, and ischemic stroke [22–26]. In support of this evidence, in 5-year survivors of childhood cancer, an average radiation dose exceeding 5 Gy is associated with a significant increase of risk of dying from cardiac disease [27]. Furthermore, patients who received mediastinal irradiation for Hodgkin's lymphoma had a 3.2-fold increased risk of requiring surgical coronary revascularization, a 1.6-fold risk of needing endovascular coronary procedure, and a 9.2-fold risk of requiring valve surgery [28]. Most modern radiotherapy programs have been able to deliberately exclude cardiac substructures from direct beam paths as part of the computer-based and image-guided treatment planning process.

Coronary Artery Vasospasm

The fluoropyrimidines antimetabolite 5-fluorouracil (5-FU) and its oral prodrug capecitabine are first-line agents for the treatment of head and neck, breast, and gastrointestinal cancers. One of the most concerning toxicities of 5-FU and capecitabine is the occurrence of coronary vasospasm, leading to ischemia, angina, myocardial infarction, arrhythmias, or sudden death. Postulated mechanisms of fluoropyrimidine-mediated vasospasm include endothelial dysfunction, with increased bioactivity of the potent vasoconstrictor endothelin-1, cytolysis with denudation of the intima, and enhanced smooth muscle cell contractility [14]. Coronary vasospasm is a medical emergency and requires prompt medical attention and treatment. Given the primary role of fluoropyrimidines in the treatment of various malignancies, in patients who develop vasospasm, rechallenge may be considered with the use of cardioprotective pretreatment [29].

Vasculitis

The introduction of immunotherapies, which harness the body's own defense system to attack malignant cells, has represented an unprecedented leap forward in the treatment of a growing number of cancers. In particular, immune checkpoint inhibitors (ICIs) have shown high rates of sustained response in various malignancies and are now considered also as first-line therapy. However, the enhancement of immune responses has been associated with the occurrence of a wide range of autoimmune phenomena, with reported involvement of most organs. While less common than other manifestations, the involvement of the cardiovascular system has been of significant concern, as mortality in patients with ICI-mediated myocarditis is as high as 50%. In addition to myocarditis and pericarditis, vasculitides have also been reported in association with ICI. Any vascular bed can potentially be affected, but large vessel vasculitis of the aorta and temporal arteries are most commonly reported. As such, the ED practitioner should consider this as a possible etiology when evaluating known cancer patients for an acute presentation consistent with systemic vascular inflammation. Importantly, patients with temporal arteritis are at risk of permanent visual loss and require prompt treatment with high-dose steroids [30].

Peripheral Artery Disease

Secondary to Pharmacologic Therapy

Tyrosine kinase and VEGF-signaling pathway inhibitors represent important therapeutic classes and have revolutionized management of several cancers. However, their use has been associated with unpredictable and at times severe vascular toxicity including hypertension, stroke, arterial thrombosis, and aortic dissection [14, 31]. Dasatinib has been linked to the development of pulmonary arterial hypertension, whereas nilotinib and ponatinib have been associated with an increased risk of myocardial ischemia, cerebrovascular accidents, and peripheral artery disease, in some cases requiring revascularization or leading to amputation. Of note, while the vascular toxicity of nilotinib may be related, at least in part, to its adverse effects on body weight and on glucose and lipid metabolism, the vascular toxicity of ponatinib appears to be a new form of microvascular angiopathy [32].

Table 21.1 Chemotherapeutic agents associated with HTN and VTE and the incidence of each

Drug class	Chemotherapeutic agent	Clinical use	Hypertension incidence (%)	VTE incidence (%)
Alkylating agents	Cisplatin	Bladder, breast, head and neck, lung, ovarian, testicular	14–53	8.5–12.9 (74% cases within first 2 cycles)
Histone deacetylase inhibitors	Vorinostat	Cutaneous T-cell lymphoma	–	4.7–8
Immunomodulators	Thalidomide	Multiple myeloma	–	<5–58
	Lenalidomide		–	3–75
VEGF-signaling pathway inhibitors	Bevacizumab	Colon, ovarian, cervical, lung, renal cell, hepatocellular, thyroid, sarcoma	26–55	8–14
	Axitinib		40	3
	Cabozantinib		22–37	4–6
	Lenvatinib		41–68	–
	Pazopanib		35–57	2–5
	Sorafenib		17–48	5.5
	Sunitinib		16–47	0.5–3
Tyrosine kinase inhibitors Bcr-Abl	Bosutinib	Chronic myeloid leukemia, sarcoma	7.8	–
	Dasatinib		<10	–
	Imatinib		4	–
	Ponatinib		67	5–27
	Nilotinib		8–10	–
EGFR	Erlotinib	Lung	–	1.2–11

Secondary to Radiation Therapy

As introduced above, radiation therapy induces extensive vascular wall injury. The biological consequences of this damage extend beyond the acute phase and lead to progressive abnormal remodeling, increased susceptibility to atherosclerosis (also in the absence of traditional risk atherosclerotic risk factors), and extensive calcific degeneration. The clinical manifestations usually reflect the occurrence of hemodynamically significant stenoses in various arteries (e.g., brachiocephalic, subclavian, renal, iliac) and the presence of severe calcifications (e.g., porcelain aorta with inability to perform coronary bypass surgery). Of note, the risk of radiation-induced vascular injury increases with young age at time of exposure, higher total cumulative dose, higher dose of radiation fractions, concomitant cancer treatment, and superficial location of the vessels [23–25].

Non-ischemic Vascular Conditions

Of the non-ischemic vascular disorders, hypertension and venous thromboembolism (VTE) are especially important, because (i) many antiangiogenic drugs, especially vascular endothelial growth factor inhibitors (VEGFIs), induce development of hypertension; (ii) some anticancer treatments promote thrombogenesis and coagulation; and (iii) the underlying cancer itself is a prothrombotic condition. VEGFI-induced hypertension develops rapidly, is often severe, and may be associated with posterior reversible leukoencephalopathy, a medical emergency [33]. Cancer-associated VTE is especially prevalent in metastatic disease and is often associated with comorbidities such as atrial fibrillation. An overview of classes of chemotherapy agents most commonly associated with the non-ischemic cardiovascular toxicity emergencies – hypertension and VTE – will be highlighted, including alkylating agents (e.g., cisplatin), histone deacetylase inhibitors (e.g., vorinostat), immunomodulators (e.g., thalidomide), and tyrosine kinase inhibitors (TKIs), which include inhibitors of Bcr-Abl, endothelial growth factor receptor (EGFR), and VEGF (Table 21.1). We will also address strategies in the prevention, diagnosis, and management of these conditions in the emergency setting.

Hypertension

Hypertension (HTN) is a common comorbidity in cancer patients (37%) [34]. Newer more-targeted cancer therapies such as VEGFI have been associated with an increased risk of HTN. Almost every clinical trial of VEGFI reports a treatment-associated rise in blood pressure. Furthermore, up to 80% of patients develop HTN, either de novo or worsening of previously controlled disease [35].

The clinical consequences of VEGFI-associated HTN can be severe. The rapid onset of HTN in patients not previously "conditioned" to high blood pressure can lead to end-organ complications, such as stroke, myocardial ischemia, heart failure, and acute kidney injury, and proteinuria. Furthermore, VEGFIs have been associated with the development of posterior reversible encephalopathy syndrome (PRES), charac-

terized by headaches, confusion, visual impairment, and seizures [33]. These manifestations, however, may be reversible with prompt recognition and treatment of the severe hypertension.

Mechanisms underlying VEGFI-induced HTN are incompletely understood. However, VEGF inhibition leads to a reduction of vasodilator, nitric oxide (NO), and is associated with increased production of the vasoconstrictor, endothelin-1 [36, 37]. Other hypotheses include oxidative stress, capillary rarefaction, and activation of the renin-angiotensin-aldosterone system (RAAS) [38]. Oxidative stress and excessive reactive oxygen species (ROS) production can lead to a reduction in NO bioavailability. Rarefaction is a reduction in density of arterioles and capillaries, and marked reductions in capillary density have been demonstrated with VEGF inhibition, although it is uncertain if this is a cause or effect of VEGFI-associated HTN. The role of RAAS activation is unclear as VEGFIs have been associated with a decrease in renin levels and angiotensin-converting enzyme (ACE) inhibition has a limited impact on VEGFI-associated HTN.

Diagnosis

The Cardiovascular Toxicities Panel of the National Cancer Institute recommends frequent monitoring of blood pressure, particularly during the first cycle of treatment. Home blood pressure monitoring and 24-hour ambulatory blood pressure monitoring should be pursued, where feasible, to diagnose and monitor HTN, with blood pressure ≥140/90 mmHg defined as HTN [34].

Treatment

Prior to commencing cancer treatment, adequate blood pressure control (<140/90 mmHg) should be achieved in patients with pre-existing HTN. Patients with blood pressure ≥140/90 mmHg should be treated with antihypertensive therapy. VEGFI-induced HTN can be difficult to treat and may require multiple agents to achieve blood pressure control. The choice of antihypertensive agents generally follows national guidelines for first-line treatment of HTN, and there is no evidence of superiority of one agent over another. However, non-dihydropyridine calcium channel antagonists such as verapamil and diltiazem inhibit cytochrome P450 3A4 and should be avoided secondary to the potential for consequent VEGFI toxicity. ACE inhibitors or angiotensin receptor blockers (ARBs) may be of benefit in patients with left ventricular dysfunction or proteinuria. Other agents such as dihydropyridine calcium channel antagonists, beta-blockers, and diuretics can also be used. There is some evidence that phosphodiesterase inhibitors, NO donors, and endothelin-1 receptor antagonists may be effective; however, these have not been studied extensively in clinical trials. End-organ complications of VEGFI-induced HTN should be managed as per existing guidelines. PRES is diagnosed with magnetic resonance imaging of the brain revealing characteristic posterior fossa changes on T2-weighted imaging reflecting edema. Treatment is largely supportive, with blood pressure control and withdrawal of VEGFI therapy and antiepileptic therapy to treat seizures.

Venous Thromboembolism

Cancer is a prothrombotic condition, and VTE risk appears to be greatest in those with distant metastases and established VTE risk factors. Independent risk factors include central venous catheters, immobility, heart failure, and chemotherapy [39].

The pathophysiological processes associated with VTE in cancer include secretion of inflammatory cytokines and interaction with endothelial cells and platelets with activation of clotting cascade, particularly via increased TF expression. Additionally, there is inhibition of anticoagulant factors such as activated protein C and thrombomodulin, as well as reduced fibrinolysis [40].

Cancer therapies can further contribute to the prothrombotic state from direct damage to the endothelium and cancer cells, inducing apoptosis and releasing inflammatory cytokines. Additionally, they increase the activity of procoagulants such as TF and reduce the production of anticoagulants such as protein C and antithrombin from direct hepatotoxicity [39]. Cisplatin-associated VTE may be induced by direct endothelial injury, vascular inflammation, hypomagnesemia-induced vasospasm, increased procoagulant activity, and reduced anticoagulation formation [41]. Thalidomide and its analogues increase levels of von Willebrand factor and, when used in combination with anthracyclines, have been shown to induce endothelial dysfunction and increase levels of TF [42]. TKIs have also been shown to increase levels of von Willebrand factor and TF reflecting activation of endothelial cells [43].

Diagnosis

DVT is diagnosed by compression Doppler ultrasonography which can readily be acquired in the ED, while the gold standard for PE diagnosis is spiral CTA of pulmonary vessels. Nuclear medicine techniques such as ventilation/perfusion scans and magnetic resonance imaging angiography are alternative options for those with contraindications to computed tomography (CT).

Prevention

Generally, thromboprophylaxis should not be offered to ambulant patients with cancer. However, it may be consid-

ered in high-risk patients and those with other risk factors for VTE such as obesity, previous VTE, central venous catheters, and immobility. The Khorana risk score is used to stratify the risk of VTE in cancer patients. This takes into consideration the type of cancer, platelet count, hemoglobin, and body mass index (BMI), with a score ≥3 classified as high risk [44]. Thromboprophylaxis with low molecular weight heparin (LMWH) or direct oral anticoagulants (DOACs) should be offered, taking bleeding risk and drug interactions into consideration. DOAC therapy has been associated with increased risk of bleeding with gastrointestinal and genitourinary malignancies. Patients treated with thalidomide and dexamethasone or anthracycline chemotherapy should also be considered for prophylaxis with aspirin (75–150 mg), low molecular weight heparin (LMWH), or direct oral anticoagulants (DOACs) [45].

Treatment

The American Society of Clinical Oncologic guidelines recommend treatment of cancer-associated VTE with LMWH or DOAC therapy. These are preferred over vitamin K antagonists secondary to improved efficacy. The American College of Emergency Physicians recommends treatment of VTE with vitamin K antagonists or LMWH, and the use of DOAC therapy as an alternative. However, no recommendations have been made specifically for cancer patients [46]. Anticoagulation treatment should continue for at least 6 months, with duration of treatment beyond this dependent on risks and benefits for individual patients.

Pericardial Diseases

Malignant involvement of the pericardium is detected in 1–20% of autopsy studies of cancer patients, and the spectrum of the acute clinical presentation can include acute pericarditis, pericardial effusion with or without cardiac tamponade, or effects of local cancer invasion (primary or secondary). Additionally, pericardial disease in cancer patients can be as a result of their cancer treatment, such as cytotoxic chemotherapy and/or radiotherapy. Determining the etiology and providing effective treatment can often be challenging. The natural history of pericardial diseases in the oncologic setting can be complicated with pericardial emergencies requiring prompt diagnosis, procedural intervention, intensive care with hemodynamic monitoring, and early aggressive management.

Pericarditis

Pericarditis is the commonest form of pericardial disease and is responsible for around 5% of presentations to emergency departments with non-ischemic cardiac pain [47, 48]. Mortality rates can reach 1% [49].

Acute Pericarditis

Acute pericarditis can present a medical emergency manifesting with symptoms such as intense sharp chest pain, alongside other diagnostic signs such as pericardial friction rub, and widespread saddle-shaped or concave ST segment elevation on the electrocardiogram (ECG), with or without a pericardial effusion. At least two of the four aforementioned features should be present to make the diagnosis [50]. In an unselected cohort of pericarditis patients, approximately 5% of cases were attributable to underlying cancer [48]. This may develop via direct infiltration of malignant cancer cells via adjacent structures, pericardial hemorrhage, or hematogenous dissemination of cancer cells [51]. In addition, pericarditis may occur as part of the paraneoplastic syndrome. In some instances, it can be caused as an acute side effect of radiation therapy. This acute phase is mediated, in part, by tumor necrosis factor (TNF) and interleukins (IL) IL-1, IL-6, and IL-8, further leading to neutrophil infiltration [24].

Alongside markers of inflammation such as C-reactive protein and erythrocyte sedimentation rate (ESR), diagnosis of cancer as the cause of pericarditis requires imaging (e.g., CT scan or cardiac magnetic resonance (CMR) imaging), cytology of pericardial fluid, and, ultimately, biopsies confirming malignant infiltration within the pericardial tissue.

The treatment of acute pericarditis is usually as per recommended guidelines in the general population. However, it is to be recognized that many cancer patients may have a predisposition to bleeding due to abnormal blood counts or coagulation abnormalities secondary to their disease or treatment. It can thus be challenging to introduce routine therapy such as nonsteroidal anti-inflammatory agents in this context. As a result, there is often a greater and earlier use of other agents, e.g., colchicine and steroids, although this may not alter outcomes [49]. In the case of radiotherapy-induced acute pericarditis, treatment of primary malignancy should not be withheld because of this.

Immunotherapy-Induced Pericarditis

Adverse effects of ICIs are distinct from conventional cytotoxic chemotherapy and can be life-threatening if left unrecognized. Pericarditis is an infrequent cardiac toxicity of ICIs and can occur with coexisting myocarditis. A total of seven cases of ICI-associated pericardial disease have been described, two involved ipilimumab and five involved nivolumab [52]. The exact mechanisms underlying ICI-mediated pericardial disease remain unknown; however, they might include pericardial inflammation by ICI-stimulated cytotoxic T-cells.

The treatment regimens for ICI-associated pericarditis vary depending on the case; however, the principal strategy

concentrates on targeting the hyperactive T-cell response with steroids often used as first-line agents.

Pericardial Effusion

Cardiac tamponade is the ultimate emergent complication of pericardial effusion, and is an absolute indication for urgent drainage, either by pericardiocentesis, a surgical pleuropericardial window, or by surgical pericardiotomy. Tamponade develops when the pericardial fluid pressure is greater than the intracardiac filling pressures, compromising the cardiac filling and leading to reduced cardiac output and cardiogenic shock. Patients may present acutely unwell with presyncopal symptoms, dyspnea, orthopnea, chest pain, and/or arrhythmias. Clinical findings include sinus tachycardia, jugular venous distention, pulsus paradoxus (>10 mmHg drop in systolic blood pressure during inspiration), lower extremity edema, hypotension, and, eventually, circulatory collapse. ECG findings include low-voltage QRS complexes, electrical alternans (alternating amplitude or axis of the QRS complexes between each cardiac cycle), PR segment depression, and sinus tachycardia. Echocardiography is the diagnostic test of choice since it can help with establishing the diagnosis and also guide management.

Although malignant pericardial effusion can occur as an early manifestation, they are usually a late finding in patients with metastases. This condition usually occurs because of obstruction of lymphatic drainage or an excess of fluid secretion from tumor nodules on the pericardial surface. The majority of patients are asymptomatic, and the effusion is discovered incidentally on echocardiography ordered for other reasons during their treatment. The mainstay of treatment is to allow sufficient drainage of the pericardial fluid to relieve the symptoms and prevent recurrence. Pericardiocentesis is an easier and less invasive procedure than pericardial window surgery, allowing prompt treatment at the time of diagnosis. However, pericardiocentesis leads to a recurrence rate of up to 20% at 30 days, which is higher than recurrence after surgical drainage (1–10% of recurrence) [53]. Rarely, malignant pericardial effusions are managed with intrapericardial injection of chemotherapeutic agents.

Cytotoxic chemotherapy agents themselves are also associated with pericardial diseases. Traditional chemotherapy agents such as fludarabine, cytarabine, doxorubicin, docetaxel, and cyclophosphamide have been associated with acute pericarditis and pericardial effusion [54, 55]. Dasatinib, a TKI targeting BCR-ABL, has also been linked to an increased incidence of pericardial effusions.

In rarer cases, primary neoplasms of the pericardium such as malignant mesotheliomas and angiosarcomas can cause primary pericardial effusions via direct invasion and are associated with a poor prognosis. Specific to angiosarcomas, patients often present with pericardial effusions and/or in cardiac tamponade in about 56% of cases. Angiosarcomas are mostly resistant to chemotherapy and radiotherapy and necessitate surgical therapy.

Cardiomyopathies

Systolic Cardiomyopathy

Systolic cardiomyopathy (CM) has long been associated with traditional cytotoxic chemotherapeutic agent toxicity. In addition, thoracic radiation therapy (XRT), newer molecular-targeted agents, and immune checkpoint inhibitors (ICI) have been shown to produce left ventricular (LV) systolic CM (traditionally defined as reduction in LV ejection fraction [LVEF] by at least 10%, even if LVEF is >50%) in recent years. Systolic CM is divided into four stages: stage A is defined as exposure to a known cardiotoxin, stage B is asymptomatic LV dysfunction, and stages C and D are defined as symptomatic heart failure (HF) to end-stage HF [56]. The main agents causing systolic CM are summarized in Table 21.2 [25, 58–64]. Risk factors common to all classes include age (>65 or < 10 years old), uncontrolled hypertension, smoking exposure, pre-existing diabetes, and baseline systolic LV dysfunction (LVEF <50%) [56].

Stress Cardiomyopathy

Of the agents in Table 21.2, some have been shown to cause acute stress CM related to initial dose [58, 60]. This has especially been studied in anthracyclines. The incidence of stress CM in all cancer patients is up to 10%, which may be related to chemotherapy and XRT use [61]. Cyclophosphamide >140 mg/kg or >1.55 g/m^2/day is known to cause acute systolic CM by mechanism of acute myopericarditis, which can be hemorrhagic. Rituximab has been shown to cause acute infusion-related cardiogenic shock [61]. Sunitinib and sorafenib can cause stress CM with stress-induced angiogenesis [64]. Antimetabolites such as 5-fluorouracil; clofarabine and capecitabine; lomustine + bevacizumab + cyclophosphamide + etoposide; rapamycin; interferon alpha; and trastuzumab have demonstrated an ability to cause cardiogenic shock secondary to stress CM, requiring ionotropic agents in up to 20% of patients [61].

Immune Checkpoint Inhibitor-Induced Cardiomyopathy

Adverse cardiac events associated with ICI therapy are rare (less than 1% of patients) but can be potentially life-threatening. The most common and well characterized is

Table 21.2 Systolic cardiomyopathies

Class	Agents and incidence [58, 61]	Mechanism [58–61, 63]	Class-specific risk factors[a] [25, 57, 60, 62, 64]
Anthracyclines and analogues	Doxorubicin Epirubicin Idarubicin Mitoxantrone Class Inc: 3–48%	Multiple-stress theory: ROS via iron chelation Nucleus topoisomerase IIB activation Iron overload Inhibition of DNA repair	Cumulative dose: Doxorubicin >360 mg/m^2 Daunorubicin >800 mg/m^2 Epirubicin >720 mg/m^2 Idarubicin >150 mg/m^2 Mitoxantrone >160 mg/m^2 Concomitant XRT Renal dysfunction, female sex
Monoclonal antibodies	Trastuzumab (HER2 target): 1–20%	Interruption of ErbB signaling, upregulated by ROS	Concomitant or prior anthracycline use
Alkylating agents	Cisplatin Cyclophosphamide Ifosfamide Class Inc: 7–38%	Direct endothelial and DNA injury Lipid peroxidation ROS Hemorrhagic myopericarditis	Usually during initial dose Dose-related (>140 mg/kg), irreversible in up to 25% at dose >1.55 g/m^2/day
Antimetabolites	5-Fluorouracil: 1–68% Capecitabine: 5.5%	Apoptosis of myocardial and endocardial cells Myocarditis Angiogenesis inhibitors Coronary vasospasm Cardiac arrhythmias	Usually during drug infusion Concomitant cisplatin use
Antimicrotubules	Paclitaxel Docetaxel Class Inc: 2–13%	NCS-1 activation → calcium overload	Concomitant anthracycline use
Proteasome inhibitors	Bortezomib: 25–% Carfilzomib: 42–8%	NF-κβ suppression	Baseline subclinical heart disease, measured by GLS
Protein kinase inhibitors, with tyrosine kinase inhibitors	Dasatinib: 3–29% Lapatinib, imatinib mesylate, cobimetinib, vemurafenib, trametinib, ibrutinib Inc: <1%	Mitochondrial damage Intrinsic apoptotic pathway	a
Vascular endothelial growth factor receptor inhibitors (VEGFR TKIs)	Sorafenib Sunitinib Lenvatinib Pazopanib Regorafenib Class Inc: 1.5–14%	Inhibits platelet-derived growth factor Inhibits nitric oxide generation → myocardial stress	Direct myocardial toxicity amplified by hypertension
Monoclonal antibody VEGFR	Bevacizumab Class Inc: 2–4%	Activated tissue factor release Prevention of endothelial regeneration	History of arterial thrombotic events
Immune checkpoint inhibitors	Nivolumab Pembrolizumab Ipilimumab Atezolizumab Durvalumab Class Inc of myocarditis 0.27%–1.14%	Out of those who develop myocarditis, ~50% present with systolic cardiomyopathy	Combination of ICIs[b]
Radiation therapy	N/A	Endothelial damage Acceleration of CAD ROS Fibrosis Sustained inflammation via NF-κβ	Age at XRT (>50 y); anterior or left chest XRT; concomitant chemotherapy with anthracyclines; high cumulative dose of XRT fractions (>2 Gy/day) or total dose >30 Gy; pre-existing CAD

CAD coronary artery disease, *ErbB/HER2* human epidermal growth factor receptor 2, *GLS* global longitudinal strain, *Gy* Gray, *ICIs* immune checkpoint inhibitors, *Inc* incidence, *NCS-1* neuronal calcium sensor 1, *NF-κβ* nuclear factor j-light-chain-enhancer of activated B-cells, *ROS* reactive oxygen species, *TKIs* tyrosine kinase inhibitors, *VEGFR* vascular endothelial growth factor receptor, *XRT* radiation therapy

[a]Risk factors common to all classes include age (>65 or <10-year-old), uncontrolled hypertension, smoking exposure, pre-existing diabetes, and baseline systolic LV dysfunction (LVEF <50%) [56]

[b]Note early versus late ICI toxicity described in text

ICI-induced acute fulminant myocarditis which typically occurs within 90 days of initiation of therapy, and is often associated with acute hemodynamic failure and death in up to 50% of patients [63]. The most commonly used and studied are nivolumab, pembrolizumab, and ipilimumab. Animal models suggest cardiac dysfunction may occur secondary to autoimmune response to cardiac troponin-I in PD-1-deficient mice via stimulation of calcium ion influx [65]. Fulminant myocarditis is more common in those receiving combination therapy ICI compared to monotherapy and is also associated with higher mortality rates [63].

Late ICI cardiac adverse effects have just begun to be examined. In a recent retrospective cohort study, late ICI cases (defined as >90 days after therapy initiation) revealed significantly more LV systolic dysfunction in 73.7% of cases (described as LVEF drop of >10% or LVEF <50%, with or without HF symptoms) than early ICI cases, and significantly higher rates of symptomatic HF (47% versus 21%, respectively; p = 0.01) [66]. Though overall mortality rates were not different between the two groups, it is important to be aware of the two clinically separate entities of ICI-induced cardiotoxicity.

Diastolic and Restrictive Cardiomyopathy

Radiation Therapy

XRT may cause systolic or diastolic dysfunction, with diastolic dysfunction being more common [25]. One single-institution study found that of 294 asymptomatic patients with Hodgkin's lymphoma treated with mediastinal XRT, 14% developed some form of diastolic dysfunction during the mean follow-up period of 3.4 years [67]. Factors that increase the risk of XRT-induced injury are shown in Table 21.2.

Acutely, XRT-induced inflammation results in mild myocardial dysfunction. Between 5 and 30 years post XRT, myocardial edema and inflammation directly lead to non-ischemic myocardial fibrosis [26]. The rate of ischemic heart disease, including myocardial infarction, is known to increase after mediastinal XRT [59, 68]. Myocardial ischemia can compound concurrent myocardial dysfunction secondary to XRT-induced myocardial fibrosis, potentiating the risk for flash pulmonary edema and acute progression to advanced HF [67]. XRT may lead to restrictive CM several years to decades after exposure [61].

In the Framingham study, systolic and diastolic dysfunctions after XRT were found in 13%, 18%, and 29% of patients with latency periods of 2–10, 11–20, and >20 years, respectively, compared to age-matched controls without XRT [60]. Authors did not assess for prior anthracycline use [21].

Anthracyclines and Monoclonal Antibodies

The effects of chemotherapy on diastolic dysfunction remain incompletely defined. In a recent longitudinal cohort study of 364 breast cancer patients, doxorubicin or doxorubicin followed by trastuzumab therapy was shown to produce diastolic dysfunction at 60% in 1 year, 70% by 2 years, and 80% by 3 years, with diastolic dysfunction shown to correlate with reduction in LVEF (2.1%; $p < 0.001$), and global longitudinal strain (GLS) (0.6%; p 0.013) [69]. Trastuzumab alone was not associated with diastolic dysfunction. Further studies are needed to determine long-term risk of HF in this population [69].

Cardiomyopathy Diagnosis

Cardiac dysfunction in oncologic patients and survivors is diagnosed by careful monitoring of the LV. Baseline LVEF and quantitative evaluation of diastolic dysfunction should be measured before treatment [56]. GLS should be measured in those with baseline GLS monitoring [56, 62]. Though routine use of cardiac biomarkers to detect CM is not well-established, some biomarkers such as troponin levels have been shown to predict CM in high-risk patients, such as those with pre-existing cardiovascular disease and those receiving high-dose anthracyclines [56]. In the most recent largest prospective study of patients treated with anthracyclines and/or trastuzumab, high sensitivity cardiac troponin T >14 ng/L at completion was associated with a twofold risk of CM, N-terminal pro-B-type natriuretic peptide (NT-proBNP) was shown to predict CM in sequential anthracycline-trastuzumab therapy, and myeloperoxidase was shown to be a promising new biomarker for anthracycline-induced CM [70].

For CM associated with ICI, early recognition and diagnosis of ICI-related myocarditis are critical secondary to its life-threatening potential. Shortness of breath is the most common presenting symptom [63]. Cardiac troponin appears to be a valid marker with a sensitivity of 94–100% [71]. Elevated NT-proBNP, peripheral edema, angina, and electrocardiogram abnormalities are common findings [63]. Severe conduction diseases including ventricular tachycardia and complete heart block are frequently seen.

Early detection in cardiogenic shock can be difficult as most patients have preserved LVEF, which can make diagnosis challenging. Whereas reduced LVEF may be a late finding, abnormal GLS may detect early evidence of cardiotoxicity not readily diagnosed by 2D echocardiography and can be a useful screening tool [62].

Cardiomyopathy Treatment

Patients who develop systolic LV dysfunction (LVEF <50%) or in stage B during anthracycline treatment should be treated with HF goal-directed medical therapy, including beta-blockers, angiotensin-converting enzyme inhibitors, or angiotensin II receptor blockers [56, 57]. The most studied agents are carvedilol, metoprolol, and bisoprolol, with notable recent trials showing significant reduction of mean change in LVEF using candesartan versus metoprolol and placebo. Statins, aspirin, enoxaparin, and rivaroxaban/apixaban have some clinical trial data to suggest cardioprotection as well [56]. Other cardioprotective strategies for anthracyclines include choosing liposomal formulations, using less cardiotoxic ones – epirubicin, idarubicin, and mitoxantrone – and continuous rather than bolus administration [56, 57]. Dexrazoxane, a cardioprotective agent via iron chelation and topoisomerase II inhibition, may be used if cumulative doxorubicin is >300 mg/m^2 and/or the disease is metastatic [72]. In stage C and D HF, critical decision on withholding further chemotherapy, implantable cardioverter-defibrillator placement, cardiac resynchronization therapy, and more advanced measures of inotropic support to transplant are considered [56, 60].

For ICI, by recent guidelines, it is recommended to discontinue ICI therapy with any sign of cardiotoxicity [56, 73]. In patients with severe disease with hemodynamic compromise, intravenous prednisone 1–2 mg/kg, or methylprednisolone 500–1000 mg/kg, is recommended as first-line therapy. Addition of mycophenolate or infliximab can be considered in patients with suboptimal response to corticosteroids [74]. In corticosteroid-refractory cases, the use of antithymocyte globulin (ATG) and the combination of alemtuzumab and abatacept have been found to be effective [75, 76].

In cases of cardiogenic shock, treatment overall does not differ from that of the general population [61]. Ensuring hemodynamic stability is the first priority, and advanced mechanical circulatory support with extracorporeal membrane oxygenation or ventricular assist devices can be considered for patients with refractory cardiogenic shock and good life expectancy [61]. Treatment options for cardiogenic shock in the setting of fulminant XRT-induced myocarditis include immunoglobulin, ATG, tacrolimus, mycophenolate, and infliximab [61].

Ultimately, prevention of cardiotoxicity at the non-pharmacologic level should start before cancer treatment begins (before stage A), and with the help of a multidisciplinary team involving oncologic, cardiology, and immunology.

Myocarditis

ICIs are antibodies that enhance antitumor immunity by increasing the activation of T-cells [63, 77, 78]. Since the US Food and Drug Administration (FDA) approved the first ICI in 2011, the application of this immunotherapy has increased from late-stage malignancy to adjuvant and even first-line settings in early malignancy [77, 78]. The number of ICI therapies continues to grow. Nivolumab, pembrolizumab, and cemiplimab target the programmed cell death receptor-1 (PD-1); ipilimumab and tremelimumab target the cytotoxic T-lymphocyte antigen-4 (CTLA-4); and atezolizumab, avelumab, and durvalumab target the programmed cell death ligand-1 (PDL-1) [77]. Consequences of increased immune system activity include disrupted immunological homeostasis and resultant inflammatory disease of nearly every organ system, e.g., the gastrointestinal tract, endocrine glands, skin, muscle, and liver, with complications termed immune-related adverse events (irAEs) [77]. The severity of irAEs varies, based on the organ system involved. The spectrum of cardiovascular toxicity can include myocarditis, pericarditis, and vasculitis, among other conditions. Myocarditis in particular is associated with an elevated case fatality rate of up to 30–50% [63, 79].

Presentation

Data on myocarditis following ICI therapy are limited by their retrospective nature, given the relatively low prevalence of this irAE at up to 1.14% [63, 80]. Awareness of myocarditis as an irAE has been rising, with an increase in reporting incidence over time [81]. The median time from ICI initiation to myocarditis admission is 51 days [82], with 4 out of 5 patients presenting within the first 3 months [63]. Symptoms include chest pain, shortness of breath, fatigue, orthopnea, and paroxysmal nocturnal dyspnea [63]. Myocarditis can often occur with concomitant myositis, hepatitis, and myasthenia gravis [81]. In our experience, electrocardiographic changes include PR interval prolongation, QRS interval prolongation in a right bundle branch pattern progressing to high-grade atrioventricular conduction block and ventricular tachycardia. Troponin has been elevated in nearly 90% of cases and fourth-generation troponin T assay ≥1.5 ng/mL is associated with a fourfold increase in major adverse cardiovascular events (MACE; defined as a composite of cardiovascular death, cardiogenic shock, cardiac arrest, and hemodynamically significant complete heart block) [63]. LVEF measured by transthoracic echocardiogram (TTE) or cardiac magnetic resonance (CMR) is preserved in over one half of cases at presentation [63, 78]. However, subclinical left ventricular dysfunction in myocarditis patients is evident in the form of reduced GLS on TTE, such that myocarditis patients have a median 14% GLS, compared to normal GLS among controls without myocarditis. Furthermore, each percentage decrease in GLS is associated with a 1.5-fold increase in MACE among patients with a reduced EF and a 4.4-fold increase in MACE among patients with normal LVEF; GLS ≤14% is associ-

ated with the highest major adverse cardiovascular event (MACE) rate. GLS has been predictive of a nearly twofold increase rate of MACE in a multivariable model adjusted for EF [82].

Diagnosis

Suspected myocarditis patients with rising troponin should undergo emergent left heart cardiac catheterization, with left ventriculogram if possible, to rule out acute coronary syndrome and stress cardiomyopathy. If cardiac catheterization demonstrates nonobstructive coronary artery disease, we favor right ventricular endomyocardial biopsy as the gold standard for diagnosis of myocarditis, as a diagnosis of ICI-associated myocarditis could preclude further possibly life-prolonging ICI cancer therapy. Endomyocardial biopsy in myocarditis demonstrates a relatively distinctive diffuse lymphohistiocytic infiltration characterized by a predominant CD163-positive histiocytic infiltrate, with an associated CD8+ and PD-1+ T-lymphocytic infiltrate, some of which is granzyme B-positive [83]. In the acute setting, use of CMR for myocarditis diagnosis appears limited, as only one in five myocarditis cases demonstrates late gadolinium enhancement (LGE) when the CMR is performed at <4 days from myocarditis presentation; it may take some time for myocardial fibrosis to develop and accumulate before becoming detectable on CMR [78]. On the other hand, when CMR is performed later in the clinical course of myocarditis (≥4 days), nearly three out of four myocarditis patients have LGE [78]. Nevertheless, even among patients with myocarditis diagnosed with histopathology showing lymphocytic infiltration, only 38% have LGE and only 26% have an elevated T2-weighted STIR signal on CMR [78]. MACE does not necessarily associate with the presence of an LGE pattern or elevated T2-weighted STIR signal. Overall, as earlier treatment of myocarditis is associated with a lower rate of MACE, endomyocardial biopsy should still be considered among patients with a negative CMR, if there is a strong clinical suspicion for myocarditis.

Treatment

Myocarditis resulting from ICI cancer therapy should warrant rapid assessment, similar to acute coronary syndrome, as a delay is associated with a higher rate of MACE [63]. In suspected myocarditis cases, early initiation of corticosteroids in <24 hours from presentation has been associated with a 7% MACE rate, whereas corticosteroid initiation at >72 hours has associated with an 85% MACE rate [84]. There was an inverse relationship between initial dose of corticosteroids (measured in methylprednisolone equivalents) and the occurrence of MACE where <60 mg/day recipients experienced a 62% MACE rate, while 501–1000 mg/day recipients experienced a MACE rate of only 22% [84]. Overall, initiation time of corticosteroids appears to play an important role such that using a higher dose of corticosteroids may not overcome the late effect of delayed corticosteroids [84]. We favor treating suspected myocarditis cases, including those with pending endomyocardial histopathology results, with 1000 mg/day of methylprednisolone, which in our experience is associated with decreasing troponin levels and improvement in cardiomyopathy and tachybrady arrhythmias within 24 hours of corticosteroid initiation.

When needed, we utilize mechanical circulatory support, such as intra-aortic balloon pump or Impella, a micro-axial flow pump placed across the aortic valve, in myocarditis patients experiencing cardiogenic shock, with concurrent initiation of immunosuppressive therapy. Whether to start extracorporeal membrane oxygenation should involve shared decision-making among the providers and the patient or patient surrogates while keeping in mind long-term cancer-related prognosis.

We dose 1000 mg/day of methylprednisolone for 3–5 days [85], followed by prednisone taper starting at 1 mg/kg/day, provided troponin assays show a downward trend, and any complete heart block, ventricular arrhythmias, or cardiogenic shock has resolved [63]. Clinicians can also consider starting mycophenolate as a steroid-sparing agent to facilitate a more rapid taper off corticosteroids, although robust data on use of mycophenolate in this clinical context is lacking.

There is limited data on second-line immunosuppressive agents for patients refractory to corticosteroids with most case report-based data available for ATG therapy [75]. In a single-patient case report, the CTLA-4 agonist abatacept has been reported to be effective for steroid-refractory myocarditis [86]. However, cancer outcomes after CTLA-4 agonist therapy remain unknown. In another single-patient case report, alemtuzumab, which is an anti-CD52 monoclonal antibody, has also been shown to treat steroid-refractory myocarditis; the safety of alemtuzumab use in this population warrants further investigation [87]. There is paucity of non-case report-based data on the use of other therapies such as infliximab, intravenous immunoglobulin, and plasma exchange.

Conduction Disturbances

Arrhythmias are an increasingly recognized issue for cancer patients. Heart rhythm disturbances can be a consequence of various cancer therapeutics and can significantly impact optimal delivery of care. The majority of observed arrhythmias are supraventricular, particularly atrial fibrillation, and can lead to significant morbidity but are rarely life-threatening

[88]. If atrial fibrillation or other supraventricular tachycardia is accompanied by severe hypotension, then emergent cardioversion is necessary; however, most cases can be managed conservatively [89]. Less commonly observed arrhythmic complications include ventricular tachyarrhythmias and conduction disorders such as complete heart block. These can be either a direct consequence of the cancer therapy or a result of another cardiotoxicity such as cardiomyopathy or ischemia. Regardless, when these occur, expeditious intervention is necessary to avoid potentially serious and life-threatening consequences.

The risk of ventricular arrhythmias in cancer patients is primarily related to QT prolongation, which is frequently encountered in this population. The QT interval is an ECG measure of ventricular depolarization and repolarization, and significant prolongation is a marker of increased risk of *torsades de pointes* (TdP), a specific type of polymorphic ventricular tachycardia (VT) [90]. The likelihood of developing TdP increases with QT intervals greater than 500 milliseconds (ms) or with a change in the QT interval of more than 60 ms from baseline [91]. Among cancer patients, various factors contribute to QT prolongation. Specifically, electrolyte abnormalities such as hypokalemia and hypomagnesemia are well known to prolong the QT interval and lead to TdP, and these frequently occur secondary to cancer-associated nausea, vomiting, and diarrhea. Moreover, QT prolongation is more common in older individuals, women, as well as patients with underlying renal and cardiovascular disease [91].Additionally, various pharmaceuticals frequently prescribed to cancer patients have QT-prolonging potential which can be augmented in the setting of the aforementioned conditions. Specifically, certain antibiotics, antifungals, antidepressants, and anti-nausea medications are well known to increase the QT interval [91]. Additionally, various cancer therapeutics from traditional cytotoxic chemotherapy to targeted therapies are associated with QT prolongation [92]. Despite significant attention paid to the QT interval in oncologic drug development and monitoring, the actual risk of arrhythmia remains quite low. A study by MD Anderson evaluating patients enrolled in various phase 1 clinical trials reported a 20% incidence of QT prolongation with rates of TdP well below 1% [93]. Electrolyte repletion, avoidance of multiple QT-prolonging agents, and routine ECG monitoring are common strategies to mitigate the risk.

Among cytotoxic chemotherapeutics, QT prolongation is most frequently observed with arsenic trioxide, which is used primarily in the treatment of acute promyelocytic leukemia. In one study of over 3000 ECGs, 26% had a QT interval of more than 500 ms though no clinically significant arrhythmias were reported [94]. Implementation of aggressive risk mitigation strategies including electrolyte repletion and discontinuation of therapy when the QT interval is >500 ms, with resumption of the drug once the QT interval is <460 ms, has led to low TdP event rates [94]. Nevertheless, this drug carries a FDA black box warning for QT prolongation and sudden cardiac death [95].

QT interval prolongation is also an issue with certain targeted therapeutics including TKIs and cyclin-dependent kinase (CDK) 4/6 inhibitors. Among the TKIs, at least ten have standard or black box warnings for QT prolongation and sudden cardiac death. TKIs most commonly associated with QT prolongation include sunitinib, nilotinib, and vandetanib, with the latter two having an FDA black box warning. Sunitinib is a small molecule TKI used in the treatment of various solid tumors including renal cell carcinoma and gastrointestinal stromal tumors (GIST). There was a 2.3% incidence of QT prolongation greater than 500 ms with sunitinib though malignant arrhythmias occurred in less than 0.1% of treated patients [96]. Nilotinib is a second-generation BCR-ABL TKI used in the treatment of chronic myeloid leukemia. In the ENESTnd trial, a phase 3, randomized, open-label study, no patients developed a Fridericia-corrected QT interval of more than 500 ms [97]; however, sudden cardiac death occurred in 0.3% of patients [98]. Although preceding QT prolongation was not documented in any of these cases, the drug still carries a black box warning [98]. Vandetanib is a TKI used for medullary thyroid cancer also which carries a black block warning; however, QT interval prolongation is substantial (up to 18%) and arrhythmic complications have been observed [99]. Nevertheless, while a recent meta-analysis confirmed the QT-prolonging potential of these drugs, it was not predictive of TdP or other life-threating arrhythmias [100]. Finally, QT prolongation is also a significant cardiotoxicity of ribociclib, a CDK 4/6 inhibitor used to treat metastatic hormone receptor-positive, HER2-negative breast cancer. In the MONALEESA-2 trial, 3% of participants had an increase in their baseline QT interval by >60 ms, with 3.6% having an average QT interval of >480 ms [101]. Although no episodes of TdP have been definitely proven, it is recommended to avoid using ribociclib if the baseline QT interval is >450 ms and hold the drug if the QTc prolongs to a value >480 ms [102]. Interestingly, this does not appear to be a class-related effect as other CDK 4/6 inhibitors do not demonstrate similar QT-prolonging potential.

Several cancer therapeutics are directly arrhythmogenic, leading to malignant ventricular arrhythmias in the absence of other cardiovascular abnormalities or QT prolongation. Ibrutinib is a small molecule inhibitor of the Bruton's tyrosine kinase used to treat various B-cell malignancies. While ibrutinib is most associated with atrial arrhythmias [103], there is also an increased risk for ventricular arrhythmias with an incidence of 596 per 100,000 person years [104]. The mechanism of ibrutinib's arrhythmogenesis remains unclear; however, there is increased mortality in the setting of ibrutinib-associated arrhythmias [105].

Life-threatening ventricular arrhythmias can also occur as a consequence of another cardiotoxicity. They are frequent complication ICIs, which harness the body's immune system to target cancer cells. Ventricular arrhythmias most commonly occur in the setting of myocarditis; however, they can also occur in the absence of documented myocardial inflammation and may be the first manifestation of ICI cardiotoxicity [106]. Overall incidence of ICI-induced ventricular arrhythmias is reported at 27%, with an incidence of 7% in the setting of normal EF [107]. In addition, ventricular arrhythmias also occur in the setting of anthracycline-induced cardiomyopathy. Several studies have demonstrated rates of ventricular arrhythmias similar to other non-ischemic cardiomyopathy etiologies. In a study by Mazur and colleagues, incidence of non-sustained VT was 73.9%, with sustained VT or ventricular fibrillation (VF) at 30.4% [108]. In a related study, the incidence of non-sustained VT, sustained VT, or VF was reported at 44.4% [109]. Ventricular arrhythmias may also occur as a result of myocardial ischemia/infarction which can be seen in the setting of 5-fluorouracil (5-FU)-induced coronary vasospasm [110].

If patients develop hemodynamically unstable ventricular arrhythmias associated with cancer therapeutics, treatment should be initiated using standard advanced cardiac life support (ACLS) algorithms, with prompt CPR and defibrillation if the patient is unconscious and without pulse or cardiovascular perfusion [111]. If the drug is actively being delivered via infusion, as is the case with ICIs or 5-FU, the treatment should be immediately stopped. For patients experiencing TdP, electrolytes should be promptly repleted, with intravenous magnesium given regardless of plasma concentrations [111]. Cardiac pacing is also an option since the QT interval shortens at higher heart rates (generally greater than 100 beats per minute) [112]. For patients with chemotherapy-induced cardiomyopathy and persistent systolic dysfunction, implantable cardioverter-defibrillators (ICDs) can be considered depending on the patient's oncologist prognosis and overall goals of care [112]. In fact, the MADIT-CHIC study demonstrated significant improvement in EF and LV volume in patients with chemotherapy-induced cardiomyopathy (EF <35%) and concomitant left bundle branch block [112]. In general, future administration of the offending cancer therapeutic should be avoided in patients that have developed a life-threatening ventricular arrhythmia except in rare and individualized circumstances.

Bradyarrhythmias are associated with various cancer therapeutics including the taxanes and crizotinib, an ALK-inhibitor TKI for non-small lung cancer; however, they are generally asymptomatic and inconsequential [113, 114]. Rarely, severe symptomatic bradycardia or advanced conduction system disease including complete heart block can occur with certain treatments. High-degree atrioventricular block is a known manifestation of ICI cardiotoxicity [80]. In a large multicenter ICI myocarditis registry, complete heart block was part of the composite major adverse cardiac events that occurred in 46% of cases [63]. In fact, complete heart block is often the first indication of ICI myocarditis and can be fatal [80].

Treatment of advanced conduction disease and/or bradycardia first involves cessation of the offending agent. In the case of hemodynamic instability and/or serious symptoms, temporary transvenous pacing should be considered [115]. In many situations, recovery of conduction is possible, but if heart block persists more than 3–5 days, then a permanent pacemaker should be implanted [116]. In the case of myocarditis, there should be a low threshold to also implant an ICD if ventricular arrhythmias and left ventricular systolic dysfunction coexist with heart block [116].

Arrhythmic complications of cancer therapeutics are an emerging area of recognition and concern. In most cases, arrhythmias can be managed without significant sequelae. Rarely however, arrhythmias can present as life-threatening emergencies that require prompt medical attention. Specific cancer treatments can lead to sustained symptomatic ventricular tachyarrhythmias or advanced conduction system disease, often necessitating resuscitative efforts. In particular, various targeted therapies are associated with QT prolongation, which can lead to TdP, and certain treatments are directly arrhythmogenic to the ventricular myocardium. Advanced conduction system disease is most commonly associated with ICI myocarditis. Given the severity of these toxicities, improved screening and monitoring strategies must be developed to minimize patient risk while allowing them to continue receiving necessary and potentially life-saving cancer treatment.

Valvular Heart Disease

Therapeutic advances in chest radiotherapy have improved survival in patients with thoracic malignancy. As a result, patients are living long enough to unveil latent cardiac toxicity [117]. Although radiation-induced heart disease (RIHD) can manifest in a variety of pathologies, valvular disease imposes a high cardiovascular burden in cancer survivors and is associated with significant therapeutic challenges [117].

Pathophysiology

RIHD is largely attributed to direct endothelial damage caused by transient increases in oxidative stress and a resultant pro-inflammatory state. This leads to the upregulation of matrix metalloproteinase, adhesion molecules, cytokines, and collagen and is the hallmark of radiation-induced fibro-

sis [118]. Further to this, direct deposition of collagen on the heart valves leads to leaflet thickening and ultimately calcification resulting in regurgitation and/or stenosis [118]. The aortomitral curtain is classically affected and can mimic rheumatic heart disease, although is distinguished by the commissural fissure which is characteristically lost in rheumatic heart disease but not RIHD [119]. This cellular damage may be further confounded by the atherosclerotic contribution of traditional cardiac risk factors such as hyperlipidemia and smoking [118]. Additionally, the combination of anthracycline chemotherapy and mediastinal radiation as seen in common cancers such as breast, Hodgkin's lymphoma, and non-Hodgkin's lymphoma can further amplify RIHD [120].

Management of Valvular Heart Disease

Patients presenting with an acute valvular emergency require urgent stabilization, irrespective of their malignancy status. Symptoms and signs of acute valvular emergency may include dyspnea, tachycardia, pulmonary edema, and cardiogenic shock; patients can also present with angina or syncope, particularly with exercise. Accurate diagnosis of the underlying etiology of these findings may be confounded in oncologic patients with concomitant bleeding or anemia. Additionally, treatment-related factors including tumor lysis syndrome with hemodynamically significant fluid shifts and chemotherapy-related left ventricular dysfunction can contribute to acute decompensation of otherwise stable valvular disease [121].

Radiation-induced valvular disease may manifest as any valvular abnormality; however, left-sided valves are more commonly affected, most frequently the aortic valve [122]. Symptomatic severe aortic stenosis is associated with a high mortality without intervention, irrespective of cancer status [123]. This is particularly apparent in studies from the pre-transcatheter aortic valve replacement (TAVR) era which demonstrates a significant survival advantage in oncologic patients undergoing surgical aortic valve replacement (SAVR), regardless of cancer stage [124]. Despite this, current heart team risk assessment using the Society of Thoracic Surgeons (STS) score incorporates a history of cancer and chest radiation as covariates secondary to the greater burden of periprocedural complications in this group.

Modern Techniques

The innovation of TAVR has provided a platform to treat patients at increased surgical risk. Recent studies have demonstrated favorable results in patients with a history of chest irradiation undergoing TAVR with less adjusted 30-day mortality, less postoperative atrial fibrillation, and shorter hospitalization compared with SAVR, despite older age, higher STS score, and more baseline comorbidities [125–127]. However, patient selection for TAVR in the oncologic population must involve careful consideration of disease prognosis, both from the perspective of the oncologist and the cardiologist. The outcomes of patients with active cancer undergoing TAVR in a large registry study were recently described [128]. Although effective and safe in the short term, the use of TAVR in patients with active cancer was found to carry a worse intermediate prognosis compared with patients without cancer. This was largely attributed to cancer-related death and highlights the importance of individualized assessment regarding the appropriateness or futility of invasive valvular intervention.

Cardiovascular Imaging

With rapid increase in new therapeutics that leads to improved survival in cancer patients, we observe a concomitant increase in the morbidity and mortality attributed to their side effects. While cancer remains the second most common cause of death, worldwide, after heart disease, indeed, cardiovascular disease is the most common cause of death among cancer survivors. This may result from shared risk factors by cancer and CV disease, and/or due to toxic effects of therapeutics. As we begin to recognize trends and disentangle associations of cardiovascular outcomes with certain therapies, cardiovascular oncologic programs have relied on cardiac imaging for surveillance, early recognition, and management of treatment-related cardiotoxicities in cancer patients. Advanced imaging modalities can shed light onto pathophysiologic mechanisms and often recognize sub- or preclinical manifestations.

In this section, we will describe the role and utility of various imaging modalities in the evaluation of the cardiac emergencies discussed in this chapter, including myocardial dysfunction, ischemic heart disease, valvular heart disease, pericardial disease, myocarditis, amyloid, and non-ischemic vascular dysfunction. Importantly, we address the role of multimodality imaging in assessing various components of the cardiovascular system to paint a comprehensive snapshot of a patient's cardiovascular health. Indications for serial imaging and surveillance, in accordance with current guidelines, will also be discussed in the context of the underlying neoplasia and the presumed offending chemotherapy, immunotherapy, or radiation therapy. This section focuses on echocardiography, CMR, and cardiac CT. Yet it should be noted that *single-photon emission computed tomography* (*SPECT*) and positron emission tomography (PET) are also being explored in the preclinical and clinical setting for imaging patients in cardio-oncologic, particularly for myocardial perfusion and molecular imaging to detect subclinical cardiovascular dysfunction [129].

Echocardiogram

Widespread availability of echocardiography makes it the most utilized imaging modality for assessing myocardial dysfunction. Global longitudinal strain (GLS) is a particularly valuable tool in this setting. Guideline committees recommend performing echocardiogram with a GLS speckle-tracking technique at baseline, and at clinically reasonable intervals during treatment with anthracyclines, ICIs, and TKIs. Additionally, LVEF should be assessed at least annually after the end of treatment. Similarly, echocardiography for monitoring of LVEF and strain imaging are recommended at baseline and with every three cycles (or every 3 months) of trastuzumab, VEGF inhibitors, and every 6 months in the immediate post treatment period. Importantly, in emergent situations where patients undergoing treatment present with clinical symptoms of heart failure or those with a significant drop in LVEF on routine follow-up, echocardiography is a particularly useful tool to monitor the extent of damage and response to intervention. In addition to assessment of systolic function, echocardiogram is the modality of choice for evaluation of radiation-induced valvular heart disease and diastolic dysfunction commonly associated with cardiac remodeling [130, 131].

Initial changes in GLS often precede clinical manifestations of heart failure that would require emergent action. This provides an opportunity for the clinicians to assess and discuss the benefit-risk of continuing with the current cancer treatment plan. Such discussion may result in temporary or permanent change in the treatment plan, continuation of the plan with closer monitoring, or in some cases, the addition of cardioprotective agents to alter the progression of cardiac adverse effects.

Echocardiography with strain imaging should be strongly considered when suspicion of ICI toxicity exists. A recent study has shown that GLS is reduced in these cases, independently of the LVEF being reduced or preserved [82]. The definitions of "definite," "probable," or "possible" myocarditis all involve new wall motion abnormalities on echocardiogram, combined with a clinical syndrome consistent with myocarditis, biomarker evidence of myonecrosis, EKG evidence of myopericarditis, and/or negative angiography excluding obstructive coronary disease [132]. In cases where the pericardium is involved, echocardiography is, again, the first-line modality as it can assess for effusion and provide hemodynamic data suggestive of tamponade or constrictive physiology. Stress echocardiography is valuable for the assessment of wall motion abnormality secondary to ischemic cardiomyopathy in patients undergoing radiation or endocrine therapy in patients presenting with signs of stable or unstable coronary artery disease.

Cardiac Magnetic Resonance Imaging

In recent years, the use of CMR has grown exponentially due to its accurate evaluation of chamber quantification and function. Intracellular and interstitial myocardial tissue changes are more directly visualized with T2 and T1 mapping sequences. These changes, when detected early, can provide a valuable insight to the pathophysiologic mechanisms of cancer treatment associated-myocardial dysfunction. Early detection of edema and fibrosis, measured as extracellular volume fraction (ECV), and their surveillance during treatment could inform mitigation strategies to avoid progression to a cardiac emergency. As for now, guideline committees recommend CMR instead of echocardiogram only if echo is technically unfeasible, or where echo results are discrepant or suboptimal [130, 131].

In cases of new-onset heart failure where the etiology is unclear, CMR provides volumetric and mass data that can accurately assess fibrosis burden in the setting of patients undergoing radiation therapy or to confirm noninvasively a diagnosis of cardiac amyloidosis. Similarly, it may be used for hemodynamic assessment and evaluation of pericardial inflammation. Using T2-weighted imaging (representing free water and edema), one can assess for myocardial edema, to assess for myocarditis, which is useful in acute heart failure emergencies in those receiving ICI therapy [132]. Stress perfusion by CMR is an effective and noninvasive method of quantifying myocardial perfusion reserve when an ischemic insult is suspected. This imaging modality may be considered during evaluation of suspected TKI-related ischemia.

While no specific recommendations are provided for its use in these settings, CMR is a powerful diagnostic tool that may provide more granular data than traditional echocardiograms and may serve in lieu of more invasive methods (e.g., biopsy, angiography) in the right clinical setting.

Cardiac Computed Tomography

CT scans can also play a vital role in diagnosis and prevention of cardiovascular emergencies. Cardiac CT scans with contrast can identify stenosis to assist with ischemic cardiovascular disease diagnosis or intervention decisions or calcification to aid prevention planning. While coronary gating is important for assessing stenosis, calcification can be noted on chest CTs performed during lung cancer screening or follow-up. Aortic valve calcium score can also be assessed on CT, which can be particularly helpful when considering severity in the context of patients being considered for valve procedures such as TAVR. Pericardial calcification and effusion, as well as subepicardial delayed gadolinium enhancement suggestive of myocarditis, can also be assessed on

chest CT. Non-gated chest CTA is most often used to diagnose pulmonary embolism.

Cardio-Oncologic in the COVID-19 Era

The coronavirus disease 2019 (COVID-19) pandemic primarily spanning 2019–2020 posed unprecedented challenges for cardio-oncologic. The emergence of this new field of medicine coincided with a once-in-a-lifetime experience. Most clinicians and scientists will serve in at most one pandemic in their lifetimes. For some during this pandemic, their lifetimes were cut short. Healthcare workers across the globe sacrificed their lives, health, mental well-being, and time with their families in order to present daily at the frontlines and save lives. In cardio-oncologic, management decisions needed to be balanced between anticipated cardiovascular toxicities from cancer therapies and observed cardiotoxicities from COVID-19. Rapid implementation of innovative technologies related to telemedicine, artificial intelligence, and digital health paved the way for continued transformation in precision cardio-oncologic. Precision cardio-oncologic knows no bounds and has a tremendous potential to revolutionize our care for patients, using various "omics" in partnership with imaging, machine learning, computational simulation, *ex vivo* modeling, and mobile health [129, 133]. Combining biotechnological advances integrated in electronic health records with informatics tools for patient care in real time will likely herald a new era. The pandemic taught us how to raise the standard of emergency care, leading to a new outlook on care delivery.

Superior Vena Cava Syndrome

22

Thomas C. Williamson, David E. Manthey, and Leslie R. Ellis

Case Study

A 65-year-old man with a 40-pack year smoking history presents to the emergency department complaining of shortness of breath and facial swelling that has acutely worsened over the last 24 hours. His vital signs are significant for O_2 saturation of 92% on 3 liters nasal cannula, respirations of 14/minute, blood pressure of 132/60, and heart rate of 100. Physical exam is significant for facial plethora, temporal wasting, decreased breath sounds over the right upper lung field, 1.5 cm left supraclavicular lymph node, ascites, and bilateral lower extremity edema. CT angiogram is significant for near complete occlusion of the superior vena cava without collateralization, a right upper lobe mass, and mediastinal and supraclavicular lymphadenopathy. The patient is admitted to the hospital and a bedside fine needle aspirate of the supraclavicular node is consistent with small cell carcinoma of lung origin. Further staging imaging, including MRI brain, does not reveal metastases. Treatment with chemotherapy (carboplatin/etoposide) is initiated.

Etiology/Epidemiology

Superior vena cava syndrome (SVCS) was first described by the Scottish physician William Hunter in 1757 in a case involving syphilitic infection of the aorta [1]. SVCS affects at least 15,000 people in the United States annually, occurring most commonly in patients between the ages 50 and 70 years [2]. Historically, the etiology of SVCS was predominantly infectious (syphilis, tuberculosis); however, at present, the majority of cases are due to malignancy. A review of 78 patients with SVC syndrome identified malignancy as the etiology in 60% of cases [3]. When malignancy is the cause, it is most commonly associated with non-small-cell lung cancer (50%), small-cell lung cancer (25%), lymphoma (10%), and metastatic lesions (10%), typically from breast cancer (Fig. 22.1). SVCS is actually found in a greater percentage of patients who have small-cell lung cancer (10%) versus non-small-cell lung cancer (less than 2%), but because of the greater incidence of non-small-cell lung cancer, the majority of cases of SVCS seen will be in this population [4]. Lymphomas associated with SVCS are overwhelmingly non-Hodgkin lymphomas, despite the fact that Hodgkin lymphoma typically presents with mediastinal lymphadenopathy. Common subtypes of non-Hodgkin lymphoma associated with SVCS include the diffuse large B-cell and lymphoblastic lymphoma subtypes. A type of lymphoma called primary mediastinal large B-cell lymphoma with sclerosis, although rarer, has a greater likelihood of being associated with SVCS when present, with up to 57% of patients having SVCS as presentation and over 80% having some radiographic evidence for the potential for SVCS [5, 6]. Obstruction of the superior vena cava in these situations is typically due to external compression from either the primary mass or an involved lymph node, although tumors less likely to be associated with SVCS can cause SVCS via intravascular extension and occlusion, such as intravascular large cell lymphoma or thymoma, among others [7, 8]. Approximately 2% of all cancer patients will develop some degree of SVCS [2, 9].

Surprisingly, up to 40% of the cases are now caused by indwelling lines secondary to an intrinsic thrombus associated with the line. In nonmalignant SVCS, it is estimated that intravascular devices account for up to 70% of cases [3]. This is felt to be due to not only compromised intraluminal laminar flow due to the presence of the indwelling line but also from alteration of the integrity of the vessel wall due to irritation of the endothelium by the catheter tip or wire lead [10]. However, only 1–3% of patients with central venous

catheters will become symptomatic [11]. This is commonly referred to as "benign" SVCS as it is not due to malignancy or alternatively because it is caused by intrinsic clot rather than external compression. A patient with benign SVCS is more often in the 30–40-year age range. Approximately 25% of pacemaker insertions are associated with obstruction or stenosis of the central venous system. It is reportedly less in patients with implanted pacemakers at an incidence of 0.2–3.3% [12]. Other nonmalignant causes of SVCS include mediastinal fibrosis, vascular diseases (atherosclerotic), infection (histoplasmosis, tuberculosis, syphilis, and actinomycosis), goiter, benign mediastinal tumors (cystic hygroma, thymoma, and teratoma), pericardial constriction, and nephritic syndrome. In pediatric patients, the cause of SVCS is most commonly iatrogenic secondary to indwelling central lines, ventriculoperitoneal shunts, or due to complications of cardiovascular surgery rather than caused by a cancer.

Anatomy

To fully understand the signs and symptoms of SVCS, the corresponding anatomy should be reviewed. The superior vena cava is 4–6 cm in length and 1.5–2 cm in width in an adult. It originates from the left and right innominate veins and terminates into the right atrium. The SVC does not contain any venous valves. The vein itself is thin walled and therefore easily compressible. It is surrounded by lymph nodes that may become enlarged and cause external compression. It is joined just above the right atrium by the azygos vein, which drains the veins from posterior aspect of the abdominal to chest cavities. The azygos vein can become an alternative drainage system for the upper extremity through collateral veins if it is not obstructed (Fig. 22.2). An obstruction of the SVC above the azygos vein, and therefore not involving the azygos vein, may present with less severe and more insidious onset of symptoms. Other potential sites for collateral development include the internal mammary veins, lateral thoracic veins, paraspinal veins, and esophageal veins, although the ability of these systems to fully compensate for SVC obstruction is more limited than the azygos vein system. The development of these collaterals usually occurs over a period of weeks; therefore, SVCS due to rapid tumor growth may not be associated with sufficient collateral development and symptoms may be more severe. When the vena cava is obstructed, the venous pressure in the cervical veins increases to 20–40 mmHg, significantly higher than the normal range of 2–10 mmHg [13]. Development of collaterals and the rapidity of the obstruction will affect the actual values.

Clinical Features (Signs/Symptoms)

The clinical features of SVCS align with what you would expect to encounter due to obstruction of the major venous drainage of the head, neck, and upper extremities (Fig. 22.3 panel a). The most common sign of SVCS is facial edema (82%), which may be most noticeable in the morning after being in a recumbent position or with bending forward. Even in the presence of marked physical changes due to facial edema, this is rarely of clinical consequence [15]. Additional signs include distended neck veins (63%), distended chest veins (53%), arm edema (46%), and facial plethora, also referred to as a red ruddy complexion (20%) [16]. An interesting sign is the Pemberton sign, which is the exaggeration of the edema and flushing of the face due to the placement of the patient's arms over the head [17].

Most patients have symptoms for 2–4 weeks before a diagnosis is made. As discussed earlier, the development of collateral vessels may delay the onset of symptoms and signs. The most common symptoms of SVCS are cough (54%) and dyspnea (54%). The latter is commonly due to an associated pleural effusion and is seen more often in malignancy-associated SVCS. Additional symptoms include hoarseness (17%), syncope (10%), headaches (9%), and dizziness (6%). Stridor may occur in 4% of patients due to swelling around the trachea. Confusion (4%) and obtundation (2%) may also be present if cerebral edema is occurring but are unlikely to be the only complaint. Visual symptoms (2%) are also rarely encountered. It is important to note that improvement in these symptoms does not necessarily represent resolution of SVCS but instead may reflect the development of an adequate venous collateral system. Additionally, symptoms may not be due solely to SVCS but due to direct compression of additional structures by the primary or metastatic mass. This pearl is especially important when considering altered mental status or neurological findings, which may be due to increased venous pressure in the cranial vault or due to brain metastases from the primary tumor [18]. The

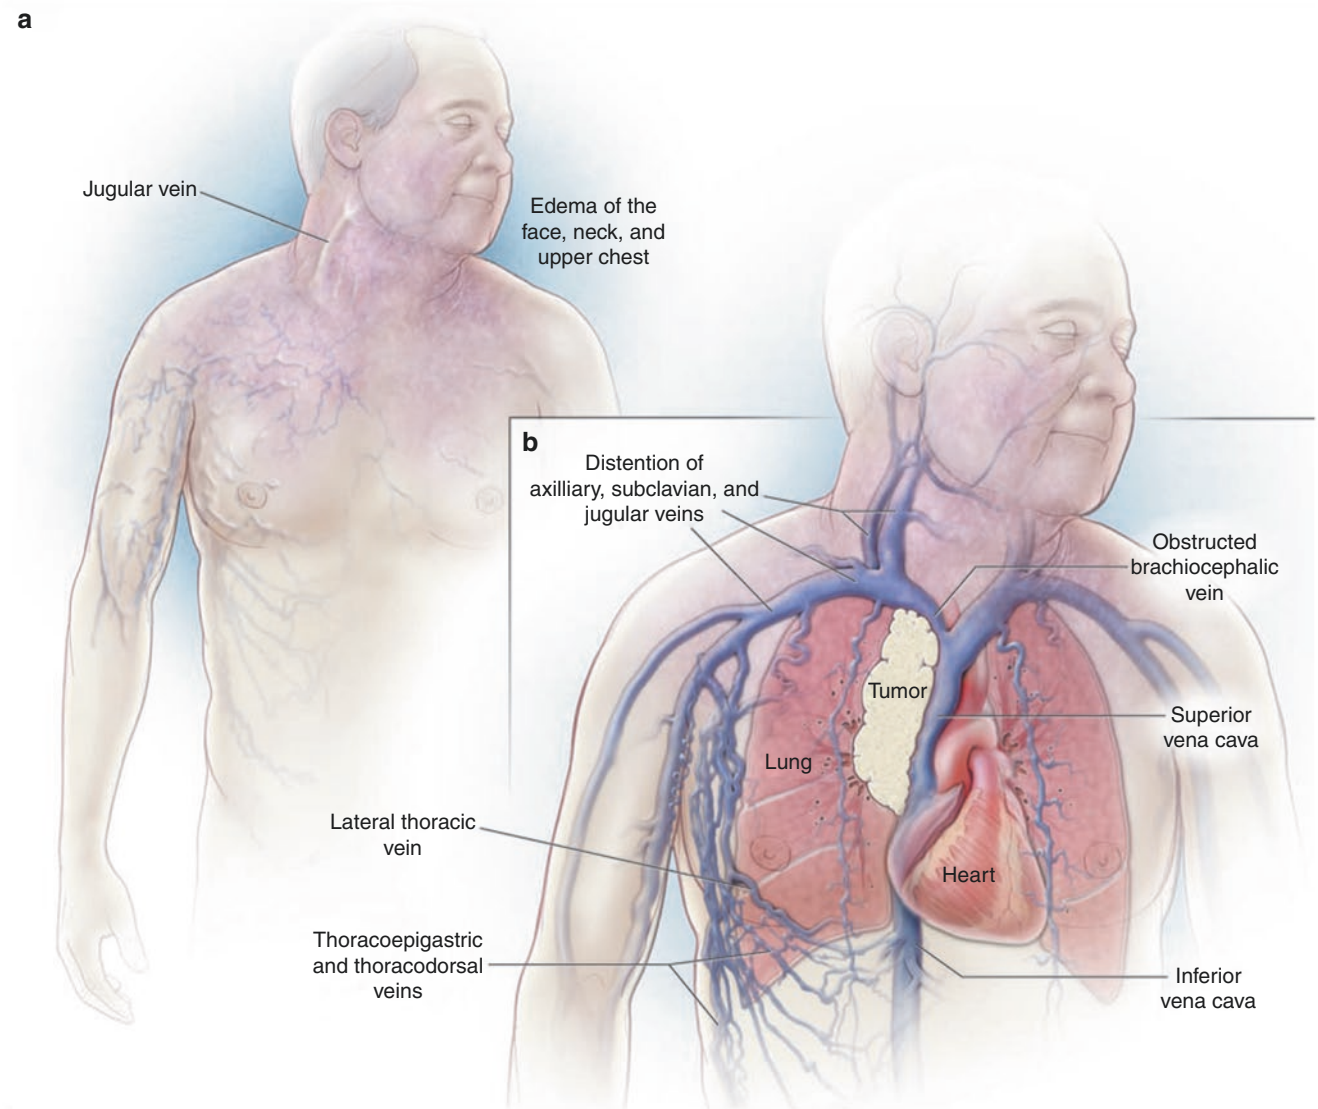

Fig. 22.3 Clinical findings in a patient with superior vena cava syndrome, including facial edema, plethora, jugular venous distention, and prominent superficial vascularity of the upper chest and neck, are shown in panel (**a**). The vascular anatomy of the upper chest, including the heart, superior vena cava, inferior vena cava, and subclavian vessels, is shown in panel (**b**). The tumor is shown compressing the superior vena cava. (From Wilson et al. [2]. ©2007 Massachusetts Medical Society, with permission)

most concerning signs and symptoms are those suggesting respiratory compromise or cerebral edema, as this may be life threatening. Because over 70% of malignancies associated with SVCS are either small-cell or non-small-cell lung cancer, an accurate history as to tobacco use is important. A thorough lymph node exam may identify palpable supraclavicular lymphadenopathy or multiple areas of lymphadenopathy, both of which have a high likelihood of being associated with malignancy [19]. Additionally, a thorough physical exam may identify targets that are easily amenable to tissue biopsy in order to establish a diagnosis, as illustrated in the case study.

Radiographic Evaluation

Although the diagnosis is suspected on a clinical basis, it is confirmed by radiologic studies. The chest radiograph (CXR) is abnormal in 84% of patients with SVCS, reflecting the malignancy that is causing the obstruction [2]. Findings on CXR include mediastinal widening (64%) and a superior mediastinal mass, 75% of which occur on the right side, consistent with SVC anatomy (Fig. 22.4). Pleural effusions are found in 25% of patients and, in older radiologic literature, are purported to be found mostly on the right side.

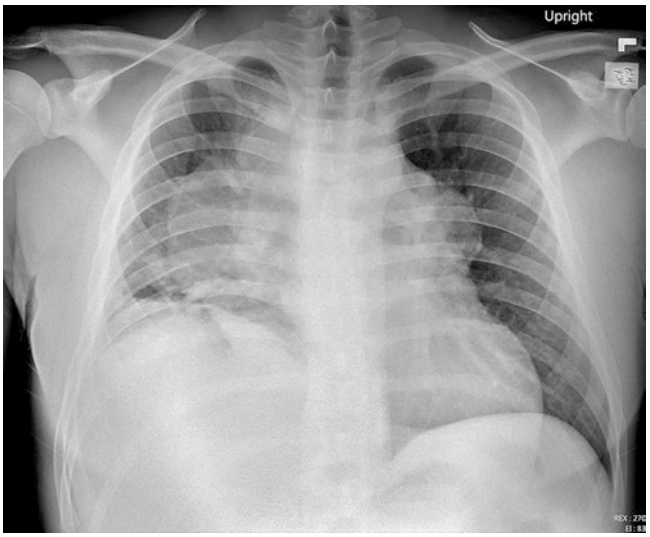

Fig. 22.4 Radiographic evidence of mediastinal mass (lymphoma) with right-sided pleural effusion

Fig. 22.5 Superior vena cava syndrome with blood returning via collaterals draining to the azygos vein. *White open arrows* pointing to collaterals. *White solid arrow* pointing to azygos vein

For definitive diagnosis, computed tomography (CT) of the chest with intravenous contrast is the modality of choice. CT angiography (CTA) can identify the location of the obstruction as above or below the azygos vein. At the same time, it will identify the development of collateral vessels (Fig. 22.5). It can differentiate between intrinsic clot and mass versus extrinsic compression of the superior vena cava with or without a superimposed thrombus [20] (Fig. 22.6). In addition, a chest CT may give information about structures such as the vocal cords/airway, as well as where best to perform a biopsy (via mediastinoscopy, bronchoscopy, or percutaneous fine needle aspirate). CTAs have sensitivities of 96% [21]. However, CT imaging and magnetic resonance angiography (MRA) both require the patient to lie flat, which may increase dyspnea and therefore cause movement artifact on images, making interpretation more difficult.

One epidemiologic study found pleural effusions on CT, which occurred in 70% of cases when associated with malignant causes and in only 58% of cases associated with benign causes [22]. Most effusions are small, with the majority filling less than 25% of the hemithorax. Contrary to the expected, pleural effusions occur on either side with equal incidence. The effusions, when sampled, were found to be either chylous in origin or exudative. This differs from the classic thinking that the fluid was transudative due to hydrostatic pressure differences. The chylous origin may be due to obstruction of the thoracic duct or due to impedance of lymphatic flow.

As indwelling devices are a common cause of SVCS, those patients presenting with unilateral arm swelling and an indwelling device will often undergo a Doppler ultrasound of the upper extremity to rule out a thrombus in the subclavian, axillary, and brachiocephalic veins. It is important to note, however, that the SVC cannot be directly imaged by Doppler ultrasound (due to its encasement by the ribs) and therefore additional imaging such as CT is required. Some texts suggest that patency of the SVC can be indirectly determined by normal waveforms in distal veins such as the subclavian or brachiocephalic, but there is no definitive evidence to back this approach. Transesophageal echocardiography would allow for imaging of the SVC and the right atrium but is more invasive.

Contrast venography can also diagnose SVCS, but it requires a significant load of iodinated contrast and radiation

exposure. Venous cannulation of the affected arm may be difficult as well, and if completely obstructed, limited visualization will occur. Finally, extrinsic compression versus internal clot cannot be distinguished. Venography is commonly done before stenting by interventional radiology and will provide information about the patency of the vena cava, as well as the extent of collateral circulation.

Magnetic resonance angiography (MRA) is also relatively sensitive (92–96%) and may be used in those patients with allergy to contrast dye. However, MRA carries the risk of gadolinium-induced nephrogenic systemic fibrosis in patients with renal failure. It provides much greater detailed imaging of the mediastinal structures and can be viewed in multiple planes. Disadvantages include cost and duration of scanning in a dyspneic patient.

Positron emission tomography (PET) scans, either with or without CT scans, are commonly used to assist in the staging of malignant disease both before and after treatment. However, the benefit to diagnosing SVCS with a PET scan is still dependent upon the CT portion of the scan. Specifically, a PET scan without a CT scan will have the ability to show a PET-avid mass in the area of the SVC but will not be able to provide a clear picture of SVC compression or obstruction. Similarly, a PET/CT, with the CT scan performed without IV contrast, will provide better images of the mediastinal area, but diagnosis of SVCS will still be limited. The only way to definitively diagnose SVCS with a PET scan would be to obtain a PET scan followed by a CT scan with IV contrast. Due to the increased costs associated with PET scans and the relative decreased availability, PET scans remain a method of staging prior to initiation of treatment as opposed to a fast or accurate way to diagnose a patient with SVCS.

Histologic Diagnosis

Malignancies remain the most common etiology of SVCS. Malignancy must be confirmed by a tissue diagnosis, although this does not necessarily require a biopsy of the mass that is causing the SVCS. An individualized approach is needed to decide whether less-invasive means can be utilized to obtain a tissue diagnosis before proceeding to mediastinoscopy. Less invasive means of obtaining tissue diagnosis, such as bronchoscopy, transthoracic needle aspiration, palpable lymph node needle aspiration, sputum cytology, or thoracentesis with pleural fluid cytology, are often sufficient for diagnosis. The ideal diagnostic approach is based on underlying patient factors such as ability to tolerate procedure(s), location of disease, and risk of biopsy. For example, if a patient has a palpable supraclavicular or axillary lymph node, needle aspiration biopsy would be preferred as there is high pretest probability and low complication rate. If minimally invasive testing is not diagnostic and a high suspicion for malignancy remains, a mediastinoscopy or mediastinotomy can provide a diagnosis in greater than 90% of the cases, with little increase in complications, as only 3% of patients developed significant hemorrhage with the procedure [23, 24]. Whenever lymphoma is on the differential, an excisional biopsy is preferred in order to allow the pathologist to determine tumor architecture and have sufficient tissue to perform immunohistochemical staining, both of which aid in an accurate diagnosis of the particular subtype of lymphoma. As will be discussed below, most treatments for SVCS are directed toward the causative malignancy, and thus tissue diagnosis is of utmost importance.

Treatment

Historically, treatment for SVCS consisted of emergent radiation, steroids, and diuretics. Importantly, SVCS is described in many textbooks as an oncologic emergency; however, few cases require emergent therapy [25]. In order to attempt to distinguish which patients with SVCS would require aggressive therapy, a proposed staging system has been developed [15]. This algorithm proposes a different treatment approach based on the severity of disease as graded (Table 22.1).

As seen in the treatment algorithm (Fig. 22.7), emergent treatment is indicated only if altered mental status, respiratory distress, or hemodynamic instability is present. The emergent treatment in these cases would be either thrombolytic for thrombus or stent placement for extrinsic compression and/or thrombus. It is important to note that the majority of patients will not present in extremis requiring emergent intervention, allowing for expedited evaluation of the underlying etiology. If not emergent, therapy is supportive or directed at the underlying cause.

Table 22.1 Grading of symptoms associated with SVCS

Grade	Definition	Estimated incidence (%)
0	Asymptomatic; radiographic evidence	10
1	Edema in head/neck, plethora	25
2	Functional impairment of voice, facial muscle by edema (dysphagia, cough, visual disturbance)	50
3	Mild/moderate cerebral edema Mild/moderate laryngeal edema Poor venous return with orthostatic syncope	10
4	Confusion, obtundation Stridor Significant hemodynamic compromise	5
5	Fatal	<1

Supportive Therapy

In the recent past, glucocorticoids have been utilized based on case reports suggesting benefit. However, there is no good evidence to support their use outside of patients for whom lymphoma or thymoma is the cause of SVCS [4]. In a previously undiagnosed patient, this potential benefit should be weighed against the potential risk of eliminating a tissue diagnosis, especially in cases of suspected lymphoma. Diuretics have been used, again based on anecdotal evidence. Since the disease is based on limited flow return to the heart and not on volume overload, it makes little intrinsic sense to utilize diuretics.

Elevation of the head of the bed to theoretically decrease the hydrostatic pressure increase in the brain secondary to the elevated cervical venous pressures has been suggested and has little to no downside.

Treatment of Malignant Causes of SVCS

For patients with SVCS due to malignancy, treatment goals are twofold: (1) relieving the obstruction; and (2) treating the underlying malignancy. Initiation of treatment with chemotherapy and/or radiation therapy before a diagnosis is obtained not only exposes the patient to the side effects of the treatment without guarantee of response but also decreases the yield for an exact tissue diagnosis, with one study reporting only one of six patients (16.7%) having a histologic diagnosis obtained after chemoradiation therapy was initiated [26].

Chemotherapy

Chemotherapy is often the initial treatment of choice for SVCS if the tumor is felt to be chemotherapy sensitive. Small-cell lung cancer, non-Hodgkin lymphomas, and germ cell tumors are all considered chemosensitive, and even symptomatic patients with SVCS will have chemotherapy initiated first. This is in contrast to non-small-cell lung cancer, which traditionally is felt to be less chemosensitive and for whom radiation therapy is often the initial treatment of choice, with or without concurrent chemotherapy [27]. Multiple studies have shown that prompt initiation of chemotherapy in patients with small-cell lung cancer is effective (77% response rate) in alleviating SVCS symptoms within 1–2 weeks of treatment, although a small percentage of patients will experience recurrent obstructive symptoms (17%) [4, 28–32]. Similarly, for lymphomas, prompt initiation of treatment with chemotherapy is usually sufficient to prevent worsening of symptoms and alleviate obstruction (Fig. 22.8).

With greater understanding of the molecular pathways involved in malignancy, targeted therapies are more commonly employed either alone or in combination with cytotoxic chemotherapy. For example, the BRAF inhibitor, vemurafenib, has been shown to successfully treat SVCS in a patient with melanoma, with resolution of his symptoms by 72 hours [33]. In lung cancer, PD1 or PDL1 inhibitors (pembrolizumab, nivolumab, durvalumab, etc.) are most often given in conjunction with cytotoxic chemotherapy, although monotherapy could be considered in rare situations in which PD1 or PDL1 expression is high and/or the patient has poor functional status.

Radiotherapy

Again, almost 50% of malignancies causing SVCS are non-small-cell lung cancer. This tumor is more radiosensitive than chemosensitive; therefore, radiation therapy is the modality of choice for a patient presenting with symptomatic SVCS. In patients receiving radiation, either as monotherapy or in combination with chemotherapy, symptom improvement may begin as soon as 72 hours after initiation of treatment with the majority of responses occurring within 3 weeks. Relapse of SCVS after radiotherapy, chemotherapy, or combined therapy occurred in 16.7% of those with small-cell lung cancer and 20.8% with non-small-cell lung cancer [4]. It should be noted that radiation therapy can paradoxically worsen patients' symptoms with the development of edema associated with treatment. In the long term, radiation-

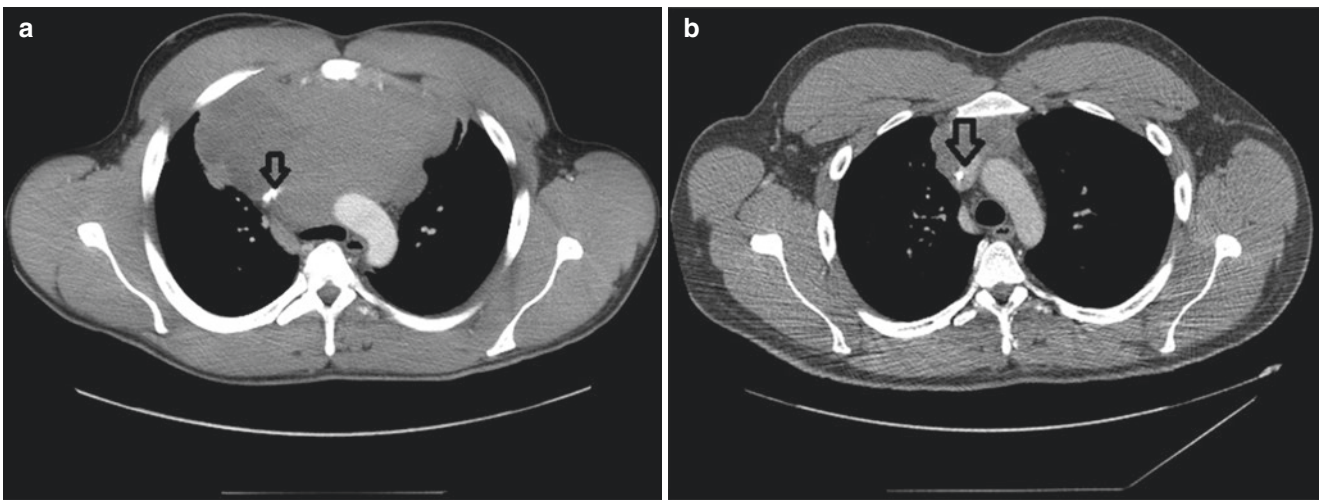

Fig. 22.8 (**a**) Superior vena cava syndrome caused by mediastinal tumor (lymphoma). *Black open arrow* pointing to collapsed vena cava with central line in place. (**b**) Same patient s/p induction chemotherapy with marked reduction in tumor burden. *Black open arrow* pointing to open vena cava with central line in place

induced fibrosis can result in recurrence of SVC obstruction, although the exact incidence is unknown [34].

However, it is difficult to discern how much of the improvement in symptoms is from the radiation therapy alone versus the development of a collateral vasculature sufficient to compensate for the obstruction. In an interesting study evaluating patients being treated with radiation therapy for SVCS, 85% of the patients reported improvement in symptoms, yet consecutive venograms showed that only 31% of patients had complete resolution of their SVC obstruction, and only 23% had partial resolution of the SVC obstruction. Evaluation during autopsy revealed even lower numbers, with only 24% of patients with either complete or partial resolution of the SVC obstruction [18].

Intravascular Therapy (Stents)

Stents are indicated as an emergent treatment or for cancer that is not responsive to treatment. Intravascular stents can provide symptomatic relief secondary to edema within 48–72 hours. However, one study found that only 17% of patients had complete relief with the stent, suggesting that the edema is multifactorial beyond the vena cava obstruction [35]. Tissue diagnosis will not be adversely affected by stent placement. Stents do not interfere with treatment of the cancer with either radio or chemotherapy and, most importantly, remain an additional treatment option for those patients who have recurrence of their SVCS after initially responding to either chemotherapy or radiation therapy [35].

Intravascular stents can be placed across the occlusive lesion, thus recanalizing the vein. Catheters are introduced from above via the internal jugular vein or below the diaphragm via the common femoral vein (Fig. 22.9). A femoral approach is beneficial in that it allows for assessment of the brachiocephalic veins and determination of the length of the SVC obstruction [36]. A wire is placed across the obstructive lesion. If recombinant tissue plasminogen activator is to be used, it is often delivered via a catheter with multiple side ports. Then a percutaneous balloon angioplasty is performed with a 10–16 mm angioplasty balloon. After the angioplasty, a stent is placed. The incidence of early re-intervention for thrombus in one study was 4%. Patency at 30 days was 96% [38].

In a study of patients with malignancy-associated SVCS, the treatment was clinically successful in 95% of cases (156 out of 164 patients) with an early mortality rate of 2.4%. Relapse occurred in 22% (36 patients), but re-stenting was successful in 75% of these patients. Recurrence was associated with occlusion, initial associated thrombosis, or the use of steel stents. Complications occurred more commonly if the stent was >16 mm in diameter [37]. Some have suggested using stents for indwelling catheters or primary treatment of benign SVCS [38].

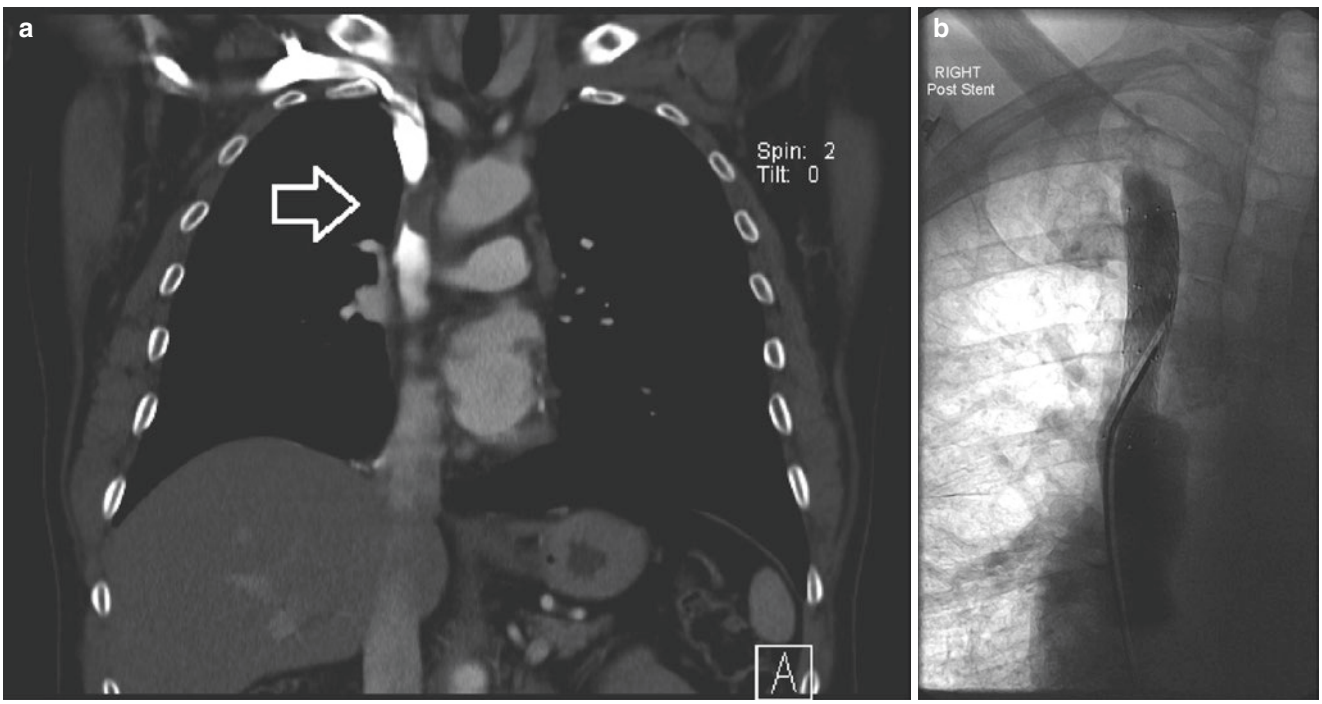

Fig. 22.9 (**a**) CT coronal view of superior vena cava syndrome. *White open arrow* indicates area of narrowing on contrasted study. (**b**) Deployment of a stent across the superior vena cava

Complications of stent placement include migration of the stent, hematoma at the site, perforation of the SVC, bleeding, infection, and pulmonary embolism. These have been reported in 3–7% of patients treated with stent placement [2].

Anticoagulation is often recommended after stent placement, but there are no evidence-based protocols to support this practice. Treatment is based upon the use of other stents and the treatment of other venous clotting. Typical practice is to use anticoagulation for 3–4 days post procedure with consideration for long-term anticoagulation based on an individualized assessment of risk factors for rethrombosis [36].

Treatment of Benign (Nonmalignant Causes) of SVCS

Medical treatment with steroids or diuretics has not been shown to be useful, especially in treating SVCS of benign origin. If an indwelling line is present, and the SVC was due to a clot, then anticoagulation is often utilized, although the effectiveness of this approach has not been shown either in the short- or long-term setting.

Thrombolytics

Patients who have developed SVCS due to intraluminal thrombus may benefit from thrombolysis, often in combination with stent placement. The use of thrombolytics (typically tissue plasminogen activator or urokinase) before stents are placed has been shown to decrease the length of blockage due to thrombus and therefore the number of stents placed [35, 39–43]. It is also felt that thrombolysis prior to stent placement decreases the burden of material that has the potential to embolize during stent placement. Adverse events, however, are increased as well when thrombolytics are used, including complications such as gastrointestinal hemorrhage, hemoptysis, and intracranial hemorrhage. This does have to be balanced with the relative success rate of thrombolysis, which has been reported to be as high as 88% [44]. Although typically thrombolysis occurs by pharmacological means, new advances in technology have provided additional methods of clot dissolution, primarily through the use of ultrasound-accelerated catheter-directed thrombolysis, which utilizes high-frequency sound waves in combination with tissue plasminogen activator [45]. This relatively new technology will require additional research to determine its efficacy relative to traditional chemical thrombolysis.

Prognosis

The outcomes of patients with malignant SVCS are directly related to the underlying malignancy and do not necessarily portend a lower overall survival compared to patients with similar tumor types who do not have SVCS [2]. Within the literature for small-cell lung cancer alone, studies have shown either no change or an improvement in overall survival for those patients who presented with SVCS when compared to patients who did not develop SVCS [28, 30–32, 46]. This may be due to patients with SVCS symptoms presenting to medical care earlier in the course of disease.

While many studies report the median life expectancy for a patient with SVCS as only 6 months, patients may survive over 2 years after treatment [15]. In some patients, treatment of the underlying malignant disease will result in cure of the disease and resolution of the SVCS.

In addition to the underlying etiology, poor prognostic factors for SVCS in patients with malignant cause include advanced age (>50), history of smoking, and use of steroids [47].

Recurrence (Durability of Treatment)

Almost 32% of patients with SVCS secondary to small-cell lung cancer, after treatment with chemotherapy, radiotherapy, or indeed both, have a recurrence of SVCS; however, these data are from 1983 and treatment advances may have improved this prognosis [29]. Relapse after placement of an SVC stent is approximately 11% (reported values of 9–20%). Most of these undergo a successful second stent placement, although a small percentage of patients will have recurrent obstructive symptoms (17%) [4, 28–32].

Palliative Care Discussions

As with any potentially life-threatening illness, palliative care considerations are a must. There are many definitions of palliative care, but most involve the concepts of preventing and minimizing suffering, optimizing one's quality of life, and aligning healthcare with patient goals and values. Many organizations, including the Institute of Medicine and the World Health Organization, recognize that palliative care specialists are integral to superior cancer care [48]. One widely quoted study identified an improved quality of life for patients with metastatic non-small-cell lung cancer who received early palliative care interventions while also receiving standard oncologic care [49]. The American Society of Clinical Oncologic clinic practice guidelines also recom-

mends involving palliative care specialists early in the disease course of patients with advanced cancer, in combination with chemotherapy and/or radiation therapy [50].

Many have used the concept of estimated life expectancy as a surrogate marker for when to more fully involve the palliative care team in a patient's care. In fact, the National Comprehensive Cancer Network's Guidelines for Palliative Care references a life expectancy of less than 6 months as a trigger to more actively engage palliative care, for which SVCS is one indicator [51]. However, additional factors must be taken into account, including the underlying malignancy, the patient's performance status, and patient goals of care. It is crucial that an oncologic specialist be involved in the conversations with the patient and other members of the healthcare team in order to provide an overall perspective of the disease course and potential outcomes.

Pulmonary

23

Nagendra Y. Madisi and Wissam Abouzgheib

Case Study

A 73-year-old male with a remote history of smoking presented with complaints of worsening shortness of breath and dry cough. His imaging studies showed a large right pleural effusion, and a PET scan revealed extensive pleural hypermetabolism throughout the right hemithorax, suspicious for malignancy. Bronchoscopy and transbronchial needle aspiration were nondiagnostic. Pathological results of a pleural biopsy and pleural fluid were positive for Ber-EP4, MOC31, p53, and CK7 consistent with adenocarcinoma with lung primary. The patient was treated with one cycle of combination chemotherapy following which immunohistochemical staining indicated that 70% of the patient's tumor cells expressed PD-L1. The patient began a 3-week cycle of pembrolizumab. Initially, pembrolizumab was tolerated fairly well, but after completing four cycles of single-agent therapy the patient developed increasing dyspnea and CT chest showed patchy areas of ground-glass opacity throughout both lungs. Based on these imaging findings, the clinical course, as well as negative results of cultures and viral antibody tests, the patient was diagnosed with pembrolizumab-induced pneumonitis. Thereafter, immune checkpoint inhibitor was held and prednisone 40 mg per day with a slow taper begun. This regimen resulted in the regression of both the pulmonary opacities and symptoms.

Introduction

The worldwide surveillance of cancer survival during a 15-year period (2000–2014) was recently reported from 71 countries, including data on 18 cancer types. While cancer incidence is increasing, survival trends are reported to be increasing, even for some of the more lethal cancers [1]. This is directly linked to an aging population, improved diagnostics and screening tools for cancer, high population awareness, and more advanced therapeutic options. The incidence rate of new cancer cases in the United States is 436 per 100,000 population [2]. In 2019, there were an estimated 1.7 million new cancer cases diagnosed and 606,880 cancer deaths in the United States [2]. Intensive chemotherapy regimens and the use of new and more targeted therapeutic drugs have resulted in higher cancer cure rates. However, the treatment often leads to repeated invasive procedures, drug-related organ toxicities, and increased susceptibility to infection. As a consequence, emergency physicians and intensivists are increasingly managing cancer patients presenting with single- or multi-organ dysfunction. Pulmonary complications include respiratory failure, including acute respiratory distress syndrome (ARDS); pleural diseases (such as pleural effusion or pneumothorax); chemotherapy or radiation-induced pulmonary toxicity; hemoptysis; and pulmonary embolism.

Respiratory Failure, ARDS, and Ventilator Management

Respiratory Failure

Acute respiratory failure (ARF) is common in cancer patients, occurring in up to 50% of hematological malignancies and 15% of solid tumors or solid organ transplantation. It is associated with high mortality rate. Risk factors include invasive mechanical ventilation, organ dysfunction, advanced age, poor performance status, delayed intensive care unit admission, and invasive fungal infection [3]. Etiologies of respiratory failure in cancer patients are numerous. The most frequent etiologies include pneumonia, cardiogenic pulmonary edema, ARDS, chemotherapy or radiation-induced lung injury, pneumothorax and bronchopleural fistula, large pleural effusions, hemoptysis, and thrombotic/nonthrombotic embolus [4–6].

Acute Respiratory Distress Syndrome (ARDS)

ARDS represents an acute and diffuse inflammatory lung injury. It leads to increased pulmonary vascular permeability, acute inflammation of the alveolar walls, and diffuse alveolar damage [3, 7]. Clinical hallmarks of ARDS are hypoxemia and bilateral radiographic opacities in the absence of heart failure. The hypoxemia is profound as defined by a ratio of arterial oxygen to fraction of inspired oxygen (PaO_2/FiO_2) of 300 or less. ARDS is further subdivided into mild (300–201 ratio), moderate (200–100 ratio), and severe (≤100 ratio) [8].

ARDS in patients with malignancies is not well studied, as these patients are often excluded from ARDS trials; however, a few studies are available [9, 10]. ARDS incidence is reported around 12% in all cancer patients in the ICU and 18% among those on mechanical ventilation. ARDS is more common in hematologic malignancies. Higher mortality was noted overall in retrospective assessment of ARDS network trials and was attributed to a more severe presentation and advanced age [11–13]. The mortality of cancer patients with ARDS in these trials was 54% compared to 24% among non-cancer patients [13]. In a more recent prospective study [10], the main factors associated with higher severity and mortality were the duration of mechanical ventilation and ICU stay prior to ARDS onset. Later onset was associated with higher mortality. Other risk factors included excessive positive fluid balance before ARDS onset and acute kidney injury. The presence of neutropenia is also an important contributing factor, whether a manifestation of the underlying cancer or secondary to chemotherapy. The course of ARDS in patients with neutropenia was different from that of the general population. In general, the outcome of ARDS is determined in the first 10 days, by which time half of the patients either have died or weaned off treatments. In patients with neutropenia, more than 85% of ICU survivors were still hospitalized after 10 days [14]. One recent study evaluated the various etiologies of ARDS in patients with malignancies; infectious etiologies were found in almost 90% of patients [15, 16].

In the same study [15], noninvasive positive-pressure ventilation (NIPPV) was used in more than a third of cancer patients with ARDS. Ultimately, the majority (71%) of patients on NIPPV required endotracheal intubation in correlation with severity of ARDS. Failure of NIPPV ventilation was associated with worse outcome. This study also examined potential prognostic indicators and found that two factors are associated with lower hospital mortality: solid tumor and primary ARDS (caused by direct lung insult, including infectious or noninfectious causes). Factors associated with higher mortality are allogenic bone marrow transplant, higher admission Sequential Organ Failure Assessment scores (SOFA) [17], presence of invasive fungal infection, and failure of NIPPV [4, 13].

Ventilator Management

Early recognition in the emergency department (ED) and initiation of supportive therapy, including mechanical ventilation, are mainstays in the management of ARDS patients.

ED length of stay for patients requiring admission to intensive care units has increased gradually in recent years [18]. Mechanical ventilation is an integral part of critical care and mechanically ventilated patients are commonly managed and monitored by emergency physicians. With the increasing demand for ED care as well as ICU beds [19], emergency physicians are expected to manage many patients on mechanical ventilation for prolonged periods of time. When invasive mechanical ventilation is initiated and managed in the ED, the emergency physician should have an understanding of open-lung ventilation and associated low tidal volume ventilation (LTVV) or lung-protective positive-pressure ventilation.

NIPPV delivered to selected patients obviates the need for an endotracheal tube. The ventilator is connected to the patient via a facemask. The mask is attached firmly to the patient's face using straps in order to prevent air leak. Most clinicians prefer the use of invasive intermittent positive-pressure ventilation (IPPV) over NIPPV in patients with ARDS considering the potential for hypoxemia to worsen in these patients and the risk for rapid deterioration. Other non-invasive ventilation strategies include high-flow nasal cannula (HFNC) oxygen therapy that delivers a high flow of heated and humidified gas. In a recent post hoc analysis including 82 immunocompromised patients, those treated with HFNC alone had a lower intubation rate than the NIPPV group (31% with HFNC vs. 65% with NIPPV). Similarly, the mortality rate at day 90 was lower with HFNC compared to NIPPV [20]. These differences were not observed between HFNC and the standard oxygen group. A prospective randomized study evaluated the early use of NIPPV versus high concentration of oxygen in a less severe group of patients with mild ARDS [21]. Despite a historical high rate of intubation in patients with ARDS initiated on NIPPV, this study showed a significant decrease in the respiratory rate, improved PaO_2/FiO_2 ratio, and lower incidence of subsequent organ failure. However, this study had a very selective young group of patients who were able to tolerate and cooperate with this mode of ventilation.

When using IPPV, it is very important to consider the following issues: (a) alveolar involvement in ARDS is heterogeneous; and (b) damage caused by adjustments in ventilation to maintain adequate blood gases may result in delayed additive iatrogenic lung injury. Therefore, LTVV (low tidal volume ventilation) is the preferred mode of ventilation for patients with ARDS. The rationale for this mode is that overdistension of the alveoli is a major reason for ventilator-induced lung

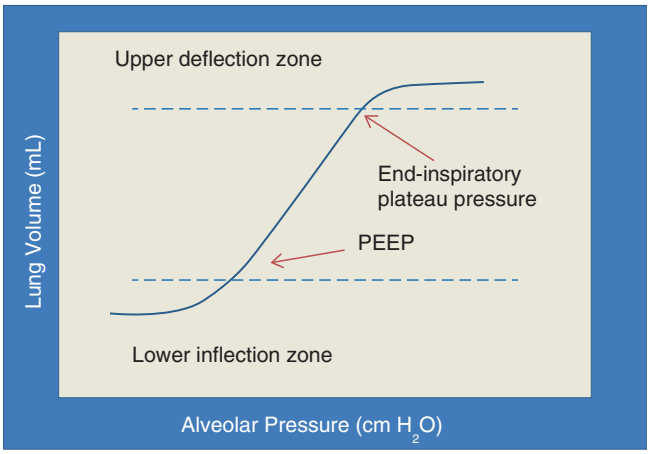

Fig. 23.1 The inspiration limb of a pressure–volume curve in an ARDS patient without PEEP application. Initial pressure application produces very little lung inflation as the pressure is applied against wet boggy lung. As lung begins to inflate, compliance improves and the curve assumes a steeper slope. As tidal volumes become too large for a lung that is questionable for ventilation (overinflation), the curve flattens. Low tidal volume strategy in ARDS should target avoiding moving into the flattening portion of curve (upper deflection zone, *upper arrow*). The goal of PEEP application is to avoid lung collapse at end inspiration and a repeated cycle of lung collapse and reopening with each delivered ventilation breath (with production of shear force injury or atelectrauma). Therefore, optimal PEEP would be applied at the lower end of the upslope of the curve (lower arrow, lower inflation point)

Table 23.1 ARDSnet PEEP table

Lower PEEP/higher FiO_2								
FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
FiO_2	0.7	0.8	0.9	0.9	0.9	1.0		
PEEP	14	14	14	16	18	18–24		
Higher PEEP/lower FiO_2								
FiO_2	0.3	0.3	0.3	0.3	0.3	0.4	0.4	0.5
PEEP	5	8	10	12	14	14	16	16
$FFiO_2$	0.5	0.5–0.8	0.8	0.9	1.0	1.0		
PEEP	18	20	22	22	22	24		

From NIH NHLBI ARDS Clinical Network Mechanical Ventilation Protocol Summary. http://www.ardsnet.org/files/ventilator_protocol_2008-07.pdf

Use a minimum PEEP of 5 cmH_2O. Consider use of incremental FiO_2/PEEP combinations such as shown below to achieve goal. Consider the higher PEEP table in the presence of more severe hypoxemia

PEEP Positive end-expiratory pressure, *FiO_2* Fraction of inspired oxygen

injury (Fig. 23.1). The majority of evidence suggests that LTVV improves mortality as well as other meaningful outcomes in patients with ARDS. The multicenter ARMA trial [22] compared LTVV (initial tidal volume 6 ml/kg predicted body weight, PBW) versus conventional ventilation (initial tidal volume 12 ml/kg/PBW). The benefits of LTVV were lower mortality rates (31 vs. 40%) and more ventilator-free days (12 vs. 10 days). As expected, LTVV may be associated with hypercapnia, which is generally well tolerated and may be associated with beneficial effects not directly related to LTVV [23, 24]. In permissive hypercapnia, the accepted and managed rise of $PaCO_2$ and subsequent acidosis increases arterial and tissue oxygenation by a right shift of the oxygen–hemoglobin dissociation curve and possibly by increasing cardiac output and circulating catecholamines. Hypercapnic acidosis reduces cyclic mechanical stretch-induced nuclear factor-κB activation, reduces interleukin-8 production, and decreases epithelial injury and cell death compared to normocapnia [24, 25]. However, the rise of $PaCO_2$ should occur gradually. Rapid rise should be avoided as the negative effects may exceed the beneficial ones (increased heart rate/blood pressure, arrhythmias, and pulmonary vasoconstriction/worsening hypoxemia). A typical approach for enacting a low tidal volume strategy in ARDS is as follows: (a) set tidal volume initially to 8 ml/kg/PBW; (b) titrate down to 7 and then 6 ml/kg/ PBW; (c) measure the airway plateau pressure (Pplat), if ≤30 cmH_2O, no other adjustment is required; and (d) if Pplat is >30 cmH_2O, then further decrease the tidal volume to as low as 4 ml/kg/PBW to achieve target. Higher Pplat may be allowed in the presence of obesity or anasarca ng volume (mL)

Open-lung ventilation represents the addition of positive end-expiratory pressure (PEEP) to the LTVV strategy, targeting to prevent collapse of edematous lung at end expiration. PEEP is believed to maximize alveolar recruitment and prevent cyclic atelectasis. According to several meta-analyses, the use of open-lung ventilation is associated with improved oxygenation; however, the effect on mortality has not been well established. The ARMA trial used a type of open-lung strategy in both arms, increasing PEEP levels with increasing severity of hypoxemia. Open-lung strategies have repeatedly shown improved oxygenation and perhaps more importantly, improved lung compliance. The titration of PEEP is typically based on oxygenation deficit or pressure–volume curves (see discussion below). When guided by oxygenation, start with the lowest PEEP possible to maintain an adequate PaO_2 of 55–80 mmHg with a FiO_2 of less than 60% and then titrate PEEP according to the ARDS net PEEP/FiO_2 protocol (Table 23.1) (http://www.ardsnet.org/files/ventilator_protocol_2008-07.pdf). When pressure–volume curves are used, it is important to calculate lung compliance and use a PEEP level that moves the end-expiratory P/V point onto the steep part of the pressure–volume curve (see Fig. 23.1).

One additional, nonventilation-related strategy is worthy of mention in the early management of ARDS patients, that is, the use of neuromuscular blockade. There is some evidence that early use of neuromuscular blockade agents in patients with ARDS is associated with better outcomes, including mortality [26, 27]. The recent Reevaluation of Systemic Early Neuromuscular Blockade (ROSE) trial involved patients with ARDS who were treated with a strategy involving a high PEEP and who showed no signifi-

cant difference in mortality at 90 days between the cisatracurium group and the control group [28]. This finding is contrary to the results of the *ARDS et Curarisation Systématique* (ACURASYS) trial published in 2010, in which the adjusted 90-day mortality was lower in the cisatracurium group than in the placebo group [20, 26, 27, 29].

In the paralyzed patient, both the Pplat, as an estimate of end-inspiratory pressure, and the pleural pressure Ppl are positive; therefore, the TP pressure estimate is Pplat − Ppl. In the spontaneous breathing patient, the pleural pressure may be negative at end inspiration, and this negative pressure will increase transpulmonary pressure with the delivery of the same tidal volume. Paralysis, by eliminating inspiratory effort, would be expected to decrease TP pressure in the presence of overinflation, thereby decreasing the risk of ventilator-induced lung injury.

Summary

Acute respiratory failure and ARDS are common in patients with malignancies. Infectious etiologies are most common. Early recognition and intervention are crucial and should be initiated in the ED upon presentation. A trial of NIPPV/HFNC is acceptable initially in stable and cooperative patients. Lung-protective and open-lung ventilation strategies are keys to improve outcomes and survival. Given the limited treatment options for ARDS, and the early onset after admission, measures to prevent onset and mitigate severity should be instituted in the ED.

Pneumothorax and Pleural Effusion

Pleural manifestations are not uncommon in patients with malignancies. The pleura is often a metastasis site from local or distant cancers, presenting more commonly as pleural effusions rather than solid masses. Also, the pleura can be involved with spontaneous or iatrogenic pneumothoraces in patients with malignancies.

Pneumothorax

Definitions, Etiologies, and Diagnostic Modalities

Pneumothorax refers to the presence of air in the pleural space. The classification of pneumothorax includes spontaneous, traumatic, or iatrogenic. Spontaneous pneumothorax occurs without obvious cause, either primary without evidence of underlying lung disease, or secondary with apparent underlying lung disease, often COPD. Traumatic pneumothorax occurs after blunt or penetrating trauma to the chest. Iatrogenic pneumothorax occurs after a diagnostic or therapeutic intervention, such as transthoracic lung biopsy, central line placement, or barotrauma, due to mechanical ventilation. The incidence of pneumothorax in patients receiving mechanical ventilation ranges between 7% and 14% [30]. Patients with acute lung injury or ARDS are at increased risk.

Clinical manifestations are widely variable, ranging from asymptomatic to respiratory failure to prolonged bronchopleural fistulas (BPFs). Prompt diagnosis and management are crucial especially in symptomatic patients with underlying lung diseases or critically ill patients requiring mechanical ventilation.

Sometimes found incidentally on routine chest imaging, the presence of a pneumothorax is clinically suspected in the appropriate clinical setting. A small pneumothorax can be asymptomatic and self-limited, whereas a large pneumothorax can cause hypoventilation, hypoxemia, and/or hemodynamic instability.

Tension pneumothorax represents a surgical emergency and requires emergent intervention. It may lead to respiratory failure requiring mechanical ventilation. It may also complicate preexisting respiratory failure on positive-pressure ventilation.

In intubated and sedated patients, a pneumothorax should be suspected with sudden and unexplained worsening respiratory failure, increased oxygen requirements, hemodynamic instability, and a sudden rise in peak and plateau pressures. It is frequently diagnosed based on clinical presentation, risk factors, and physical exam (not by imaging) and should be treated by immediate emergent decompression in hemodynamically unstable patients. However, the increasing availability of bedside ultrasonography has made emergent imaging confirmation of pneumothoraces possible prior to emergent decompression.

The current first-line imaging modality used to identify a pneumothorax is chest radiography, although bedside ultrasonography has great potential to compete as the diagnostic method of choice in the future. The typical finding is displacement of the white visceral pleural line from the chest wall on an upright chest radiograph. The underlying lung parenchyma should be examined for the presence of lung disease that might suggest a cause for the pneumothorax. In bedridden or ICU patients, care should be exercised in order to differentiate the visceral pleural line from skin folds. Skin folds frequently extend beyond the rib cage; blood vessels and lung parenchyma often extend beyond the skin fold. Their attenuation profile is also different, forming a negative black Mach band instead of the white visceral pleural line (Fig. 23.2).

Computed tomography (CT) diagnosis is best utilized for complicated or unclear situations. CT scans are more accurate in determining size of pneumothorax when compared to chest radiography [31].

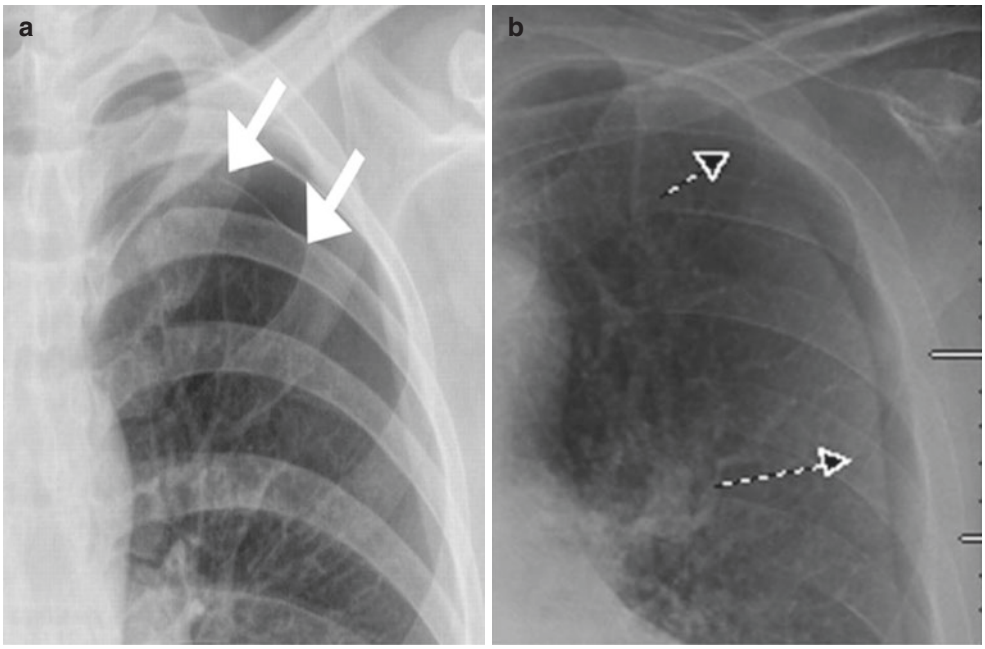

Fig. 23.2 (**a**) White visceral pleural line in pneumothorax. (**b**) Black Mach band in skin fold

Point-of-care ultrasound is increasingly used at the bedside and is the modality of choice in the ICU and ED to integrate the clinical assessment of the critically ill; in particular, lung ultrasound has advanced significantly in the last decade. Lung ultrasound can be used for early detection and management of respiratory complications under mechanical ventilation, such as pneumothorax, ventilator-associated pneumonia, atelectasis, and pleural effusions [31, 32]. Beside ultrasonography offers several advantages over chest radiography or CT scans including rapid availability, lack of radiation, real-time interpretation, and lower cost. It also offers the ability to immediately rule out a pneumothorax after an invasive procedure or in the midst of a clinical deterioration.

Clinical Scenarios in Cancer Patients

The common ED clinical scenarios involving a cancer patient presenting with a pneumothorax include the following:

1. *Secondary spontaneous pneumothorax in patients with underlying lung disease (e.g., emphysema) and a concomitant cancer diagnosis:* In fact, most cancer patients presenting with a secondary spontaneous pneumothorax had lung cancer (20%) or underlying chronic obstructive pulmonary disease (COPD or emphysema) (52%) [33]. The mechanisms could be due to bronchopleural fistula within a necrotic tumor, tumor-induced rupture of a subpleural bleb, or direct invasion of the pleura. These patients require hospitalization for observation, and potentially, chest tube insertion. Definitive surgical interventions, such as pleurodesis or wedge resection, may be required. As would be expected, patients with active cancer have a significantly worse survival compared to those without active cancer (3 vs. 113 months) [33].
2. *Iatrogenic pneumothorax following diagnostic procedures:* CT-guided or bronchoscopic lung biopsies, as well as therapeutic procedures, such as thoracentesis, bronchoscopic endobronchial tumor ablations, or percutaneous radiofrequency ablation, may produce pneumothorax. CT-guided biopsy is often considered when the abnormality is not easily accessible with a bronchoscope but the procedure is associated with higher rate of complications. For CT-guided core biopsy, the pooled rate of pneumothorax was 25.3%, pulmonary hemorrhage 18.0%, and hemoptysis 4.1%. For FNA procedures, these rates were lower, 18.8%, 6.4%, and 1.7%, respectively [34]. A high level of suspicion should exist in patients who undergo CT-guided biopsy and present with worsening dyspnea, cough, chest pressure, or pain. Usually symptoms occur within 3 h after the procedure; however, onset can be delayed in a small percentage (<4%) of patients [35]. Approximately 20% of patients with this complication require chest tube insertion, depending on the size of the pneumothorax and associated symptoms. Predisposing factors include distance of the target to the pleura, number of needle passes traversing normal lung, and presence of underlying lung diseases [36].
3. *Treatment-related pneumothorax secondary to thoracentesis, bronchoscopic ablation of central airway obstruction, percutaneous radiofrequency ablation, or chemo-induced tumor necrosis:* With the use of ultrasound, the rate of pneumothorax post-thoracentesis has dropped to less than 0.63% [35]. When a pneumothorax occurs, it is usually small and only a third of patients

require chest tube insertion. A chest tube should be considered if the pneumothorax is large or progressive and the patient is symptomatic or requires mechanical ventilation.

Central airway malignant obstruction is currently aggressively treated with several minimally invasive bronchoscopic interventions. One third of patients with advanced lung cancer develop central airway obstruction, and several other malignancies may metastasize to the airway. Pneumothorax after an ablative bronchoscopy, although rare, is usually immediate and treated in the bronchoscopy suite. It is most often related to supportive care, such as jet ventilation during rigid bronchoscopy. Nevertheless, pneumothorax must be ruled out in symptomatic patients presenting after any ablative bronchoscopy.

Image-guided percutaneous therapies became popular over the last two decades for the treatment of pulmonary malignancies, especially in nonsurgical candidate patients. They include radiofrequency or microwave ablation. Pneumothorax, pleural effusion, and subcutaneous emphysema were observed after radiofrequency ablation, respectively, in 15.9%, 20%, and 5% of patients in a recent study by Picchi et al. [37].

Pneumothorax is the most common peri-procedural complication after microwave ablation with an incidence of 33.9% and only 11% of these patients require intervention [37, 38]. Risk factors are similar to CT-guided biopsies. In addition, the number of tumor ablations during a single procedure and lack of prior lung surgery are risk factors as well. Patients with underlying emphysema are at increased risk of pneumothorax [39].

Treatment

Simple manual aspiration using an intercostal needle or small catheter is indicated in noncomplicated patients presenting with the first episode of a large or symptomatic secondary spontaneous pneumothorax. The most recent Cochrane review concluded higher immediate success rates in the needle aspiration (NA) group compared to chest tube drainage and shorter hospital length of stay in the NA group [40]. Treatment consists of inserting a needle or catheter in the pleural space, aspirating the pleural air, followed by removal of the needle or catheter. The resolution rate is high [41]. When simple aspiration is unsuccessful to keep the lung inflated or when air leak is large or persistent, a tube thoracostomy is indicated. There is no evidence that large tubes (20–24 F) are any better than small tubes (10–16 F) in the management of pneumothoraces. The initial use of large (20–24 F) intercostal tubes is not recommended, although it may become necessary to replace a small chest tube with a larger one if there is a large air leak preventing complete reinflation of the lung [42].

The most common position for chest tube insertion is in the mid-axillary line. This position minimizes the risk of injury to underlying structures, such as the viscera and internal mammary artery. For apical and large pneumothoraces extending to the apex, an antero-apical approach is favored. It requires minimal positioning and rotation of a critically ill patient. The second intercostal space in the mid-clavicular line is often chosen: two fingerbreadths from the lateral sternal border. The internal mammary vessels are at risk and bedside ultrasound may be very helpful in choosing the optimal location while avoiding vascular structures. In patients with persistent air leaks, one-way endobronchial valves are an alternative to surgical intervention [43].

Pleural Effusion

Patients with cancer frequently develop pleural effusions. Of 5888 pleural effusions collected from consecutive patients and analyzed in a single laboratory over a 14-year period, Johnston, et al. reported that 584 (9.9%) samples taken from 472 patients contained malignant cells. Leading etiologies of malignant pleural effusions (MPE) in both sexes were lung cancer (35.6%), lymphoma/leukemia (15.9%), breast cancer (14.8%), female genital cancer (8.1%), and gastrointestinal malignancies (5.9%). The incidence of cancer with unknown primary was 10.2% [44]. Fifteen to 40% of patients with MPE are asymptomatic at the time of diagnosis [45]. On chest imaging, a majority of MPE present as ipsilateral effusions, and approximately 10–13% are bilateral [46]. A quarter of all pleural effusions in a general hospital are due to cancer, and up to 50% of patients with a variety of metastatic malignancies develop a paramalignant or malignant pleural effusion. In addition, 30–70% of all exudative pleural effusions are malignant [47, 48]. Paramalignant pleural effusions are caused by tumor effects on surrounding structures; pleural fluid cytology and pleural biopsy are usually free of cancer cells. Malignant pleural effusions are caused by direct invasion of the pleura, and fluid cytology or pleural biopsies may be positive for malignant cells.

Nearly all malignant or paramalignant pleural effusions become symptomatic. It is advisable to treat these effusions upon presentation, especially if moderate to large in size, since their recurrence may hinder and delay therapy for underlying malignancy. Several important questions face the emergency physician when evaluating patients with malignant pleural effusions. Does the effusion need to be drained? What is the volume of fluid that can be drained safely at one time? What is the appropriate size of the chest tube?

Drainage

Since symptoms are frequent in patients with cancer and pleural effusion, drainage is recommended. For patients who

do not require admission after drainage, a simple therapeutic thoracentesis is recommended. We advocate the use of an 8-French pleural drainage catheter, inserted in the posterior axillary line under ultrasound guidance with gravity drainage. We prefer gravity drainage to repeated manual aspirations as it avoids steep fluctuations in negative pleural pressure, results in slower re-expansion of the lung, and allows for pleural pressure monitoring when indicated [49].

Amount of Drainage

Initial thoracentesis is a simple procedure providing symptomatic relief after acute presentation, as well as allowing assessment of the degree of lung re-expansion, which may be important to determine future management strategies. It has been advocated to drain only 1.5 liters during therapeutic thoracentesis, the rationale being to minimize the risk of re-expansion pulmonary edema (REPE) [50]. We believe in draining the majority of the pleural effusion as much as tolerated by the patient for several reasons: One, the incidence of REPE is extremely rare and typically patients develop early mild symptoms (cough and chest pressure) allowing termination of the procedure [50]. Two, in order to assess whether the patient is a candidate for future pleurodesis with a post-thoracentesis chest radiograph, one needs to document the juxtaposition of visceral and parietal pleura. Three, draining the majority of pleural effusion provides the optimal and longest symptomatic relief in between recurrences. The common side effects from large-volume thoracentesis are cough and chest discomfort, believed to be secondary to the sharp drop of intrapleural pressure [50]. Therapeutic thoracentesis should be interrupted in case of development of symptoms, as they may precede more severe complications, such as REPE, if drainage continues. Once symptoms develop, patients should limit deep breathing and refrain from talking in long sentences as further stretching the lung may lead to worsening symptoms. These symptoms typically resolve spontaneously. There is evidence that application of noninvasive positive-pressure ventilation lessens the degree of intrapleural pressure drop during large volume thoracentesis [51].

Chest Tube Size

Small-bore chest drains (defined as size < 16 Fr) are now used extensively in MPE drainage and are recommended in major guidelines (e.g., 2010 British Thoracic Society guidelines) [52]. However, the optimal chest tube size for pleurodesis has not been identified. Older case/comparative studies and one RCT suggested that small bore drains are effective for pleurodesis; unexpectedly, a higher complication rate has also been reported. If presenting with recurrent large malignant pleural effusion, we recommend small-bore (8–16 Fr) chest tube insertion in the posterior axillary line, with connection to a Pleur-evac® system (Teleflex, Morrisville, NC) without wall suction or gravity drainage bag. We also advocate early pulmonary consultation in order to plan for long-term fluid management strategies. We do not see any advantages to large-bore chest tube insertion, as documented in previous studies [53].

Indwelling pleural catheters (IPCs) should be considered first-line management of MPEs, in conjunction with standard talc pleurodesis. Recognition of the advantages and disadvantages of each approach allows patients to choose an option. It is acknowledged that the use of IPCs without pleurodesis agents can lead to spontaneous pleurodesis [42, 54], allowing removal of the catheter. In patients who desire faster removal of the catheter, a more aggressive drainage regime or instillation of talc via the IPC is a judicious option [55]. Some special situations may face emergency physicians with patients carrying tunneled pleural catheters who present for worsening symptoms due to inability to drain fluid or clogged catheters. Pulmonary consultation is suggested in these situations, as an evaluation of the pleural space with chest radiograph or thoracic ultrasound is required to evaluate for residual pleural fluid. In cases of clogged tunneled pleural catheters with significant residual pleural fluid, intrapleural catheter instillation of alteplase may be indicated to unclog the tube [55].

Summary

Pleural effusion and pneumothorax are common pulmonary manifestations in patients with cancer, most commonly occurring after required interventions treating the primary malignancy. Early recognition and intervention are indicated as delays may interfere with cancer treatment. Small-bore chest tubes are as good as large bores tubes and should be used primarily. Talc pleurodesis and indwelling pleural catheters effectively manage the symptoms of MPE. The use of bedside ultrasound has improved diagnostic accuracy and minimized complications.

Hemoptysis

Etiologies

One of the most common causes of hemoptysis is lung cancer, along with inflammatory and infectious etiologies, such as bronchiectasis, bronchitis, and tuberculosis [56]. During their lifespan, 20% of patients with lung cancer develop hemoptysis. Non-small-cell lung cancer patients have a higher incidence than small cell. Other malignant causes include endobronchial metastatic carcinoma (melanoma, breast, colon, or renal cancer), bronchial carcinoid in young patients, and Kaposi sarcomas in AIDS patients. Hemoptysis can also be chemotherapy induced, caused by necrosis of large tumors or potential medication side effects. With the

development of several antiangiogenic agents inhibiting vascular endothelial growth factor for the treatment of advanced lung cancer, more patients are started on those agents as they progress with their disease. One of the reported side effects of these agents, for example, bevacizumab, is hemoptysis. When hemoptysis from bevacizumab occurs, it is often massive. In fact, life-threatening hemoptysis has been reported in up to 9% in patients receiving bevacizumab [57] and most of the hemorrhages were fatal, occurring during the initial cycles of treatment [58]. It is therefore important to recognize and attribute hemoptysis in patients receiving bevacizumab and realize that it is often fatal. Early critical care and interventional pulmonary or radiology consults are crucial in patients receiving bevacizumab presenting with hemoptysis, even if mild.

Massive Hemoptysis

The definition of massive hemoptysis remains poorly defined in the literature because terms used to describe the amount of hemoptysis are inconsistently utilized. Life-threatening or massive hemoptysis is characterized by a larger volume of blood, while clinical instability is considered to be a better indication of poorer outcome. Reported thresholds for massive hemoptysis in the literature range from 100 to 1000 mL in a 24-h period [59]. In our opinion, massive hemoptysis is present when a patient is coughing more than 100 ml/24 h and raises concerns as to airway protection issues or gas exchange impairment. Massive hemoptysis is the cause of death in 3% of patients with lung cancer. Urgent diagnostic and therapeutic interventions are advised in patients with massive hemoptysis. Several initial steps are important upon presentation: localize the source, protect the airway, optimize gas exchange, and then control the bleeding. A multidisciplinary team approach (pulmonology, interventional pulmonology, interventional radiology, and surgery) should be undertaken as soon as the condition is identified [60].

Clinical suspicion, previous history, and available previous imaging are important in localizing or estimating the location of the bleeding. The suspected bleeding site should be placed in a dependent position in order to prevent spillage or formation of large blood clots into the nonbleeding lung. If massive bleeding is associated with significant symptoms, endotracheal intubation should be performed using at least an 8.0 mm endotracheal tube (ETT). A large ETT tube facilitates access for the therapeutic bronchoscope and provides a route for laser coagulation or cryoprobe-assisted removal of large blood clots. Additionally, the tip of the ETT can be pushed deep into the nonbleeding main bronchus to further protect the nonbleeding side from blood contamination. This maneuver obviously requires bronchoscopic guidance. After intubation, mechanical ventilation may be initiated with optimized settings to achieve adequate oxygenation and ventilation. Also, correction of any underlying coagulopathy is warranted.

Bronchoscopy with instillation of epinephrine or ice-cold saline is a temporary measure to potentially control bleeding until laser ablation equipment is available for more permanent control. Use of iced saline has become common practice. Endobronchial epinephrine and norepinephrine are also commonly used; however, recommendations for safe dosage and concentration vary quite widely in the literature. In contrast to iced saline, the safety of endobronchial epinephrine has been questioned, given reports of coronary vasospasm and arrhythmia [61].

Bronchoscopic measures are effective only for bleeding sites within the reach of the bronchoscope. Otherwise, arteriographic localization of a bleeding site and embolization is the method of choice to control bleeding from peripheral sites not easily reached through the airway [62]. Surgical evaluation and possible intervention are indicated in case of an uncontrollable bleeding site [63]. Surgical intervention in bleeding patients is associated with significant morbidity and mortality [64]. Tranexamic acid (TXA), an antifibrinolytic medication that competitively inhibits plasminogen activation, has been prospectively studied in groups of submassive hemoptysis in both IV and nebulized form. TXA was associated with a decrease in hemoptysis and need for interventional procedures [65]. Additionally, recombinant activated factor VII and recombinant thrombin have also been used in cases of hemoptysis due to diffuse alveolar hemorrhage with moderate hemoptysis [66–68]. One-way endobronchial valves have also been used in a small study of patients with moderate hemoptysis [69]. Most available literature on massive hemoptysis is limited.

Summary

Hemoptysis in cancer patients is a serious manifestation of airway involvement or chemotherapy side effect. Hemoptysis is often massive and potentially fatal in patients receiving bevacizumab. Early intervention and consultation of specialized services are crucial steps in the management of massive hemoptysis.

Chemotherapy and Radiation-Related Pulmonary Toxicities

Chemotherapy-Related Pulmonary Toxicity

Acute Complications

Immune Checkpoint Inhibitor-Related Pulmonary Toxicity Immune checkpoint inhibitors (ICIs) have revolutionized cancer treatment and are now a standard of

care for a variety of cancers in both metastatic and adjuvant settings. Despite the clinical benefits of the ICI therapy, they are not without complications and can affect multiple organs. ICI-associated pneumonitis is an uncommon, but potentially serious, adverse event.

Lung Toxicity ICI-associated pneumonitis is defined as focal or diffuse immune-related inflammation of lung parenchymal cells and ICI-induced pneumonia is defined as the infection of lungs after ICI treatment. The incidence of pneumonitis is variable in clinical trials, ranging between 3% and 5% [70]. The overall mortality rate associated with all PD-1/PD-L1 inhibitors is about 0.45% but ICI-induced pneumonitis is the most common reason for death among patients treated with ICIs [71].

The duration from ICI administration to onset of pneumonitis is variable (2–24 months). Early onset of ICI pneumonitis was found to be more severe in one study [72]. No definite clinical symptoms, characteristic CT manifestations, or serological markers are available to establish a diagnosis of ICI-induced pneumonitis. It is usually a diagnosis of exclusion after an extensive evaluation for potential infectious etiologies. Computed tomography (CT) usually displays reticular infiltrates with ground-glass opacities and consolidation in patients receiving PD-1 inhibitors [73]. Supportive care and empiric antibiotics are recommended during the initial treatment. Most ICI-associated pneumonitis cases are corticosteroid therapy responsive; however, 15–30% of cases can show a poor response to therapy, leading to a poor prognosis for these patients. High-dose steroids are advised with a taper over 6 weeks or longer.

Conclusion

Treatment with immune checkpoint inhibitors induces a variety of adverse events, which can sometimes be serious or fatal, albeit infrequent. Among them, pneumonitis is one of the most life-threatening adverse events. Currently, no optimal management guideline exists for the management of pneumonitis, but it usually responds to immunosuppressive medications.

Conventional Chemotherapy-Related Pulmonary Toxicity

Pulmonary toxicity from antineoplastic agents is common. The exact incidence of lung toxicity remains unclear; this is related to confounding factors, including pulmonary comorbidities and prior or concurrent use of other treatment modalities, such as radiation and antineoplastic drugs. It is estimated that approximately 10–20% of patients receiving chemotherapy develop some form of lung toxicity [74, 75]. Pulmonary injury can vary from mild to severe and is divided into acute and delayed onset [76]. The acute onset syndromes include inflammatory interstitial pneumonitis, pulmonary edema, bronchospasm, and pleurisy or pleural effusion, typically presenting after the first one or two cycles of the administered agent.

The inflammatory interstitial pneumonitis syndrome is a hypersensitivity-like reaction. It is the most common chemotherapy-associated lung injury [76]. It has an acute to subacute presentation with productive cough and worsening dyspnea, associated with low-grade fevers and fine crackles on physical exam. A chest radiograph shows either an interstitial or mixed interstitial and alveolar pattern. The most common agents associated with this syndrome are methotrexate, bleomycin, procarbazine, and carmustine. It can mimic an atypical pneumonia or hypersensitivity pneumonitis. The prognosis is generally favorable with simple discontinuation of the offending agent and treatment with corticosteroids for more severe cases.

The pulmonary edema syndrome, less common than interstitial pneumonitis syndrome, has a more acute presentation. Caused by endothelial inflammation and vascular leak, it leads to noncardiogenic pulmonary edema (NCPE). Patients may present with severe dyspnea. Cough, fatigue, and increased work of breathing may also be present, sometimes associated with profound hypoxemia and crackles on physical exam [77]. Chest radiograph shows similar findings to those found in patients with pulmonary edema but with a normal size heart. It is typically a diagnosis of exclusion after establishing normal cardiac function in a clinical picture of congestive heart failure. Chemotherapeutic agents most commonly associated with NCPE are (by order of frequency) cytarabine, interleukin 2, trans-retinoic acids, and gemcitabine. A higher incidence of NCPE has been reported in patients undergoing allogenic and autologous bone marrow transplant, beginning with induction chemotherapy [78, 79].

Bronchospasm and asthmatic-like reactions can also occur with chemotherapy agents. They have been reported upon exposure to the first cycle. Two mechanisms are responsible: IgE and non-IgE related. The chemotherapy agents causing IgE-related bronchospasm are platinum compounds, such as cisplatin, carboplatin, and oxaliplatin. Those causing non-IgE-related bronchospasm are taxanes (paclitaxel and docetaxel), asparaginase, and epipodophyllotoxins (etoposide and teniposide). In the acute setting, anaphylactoid reactions in the absence of hypotension should be treated with intramuscular injections of epinephrine 1:1000, 0.5 mg per single dose. In the presence of severe hypotension or shock, continuous intravenous infusion of epinephrine is recommended. Antihistamines and corticosteroids, as well as bronchodilators and supplemental oxygen, are also indicated.

Pleurisy or pleural effusion can be a manifestation of chemotherapy-induced side effects with methotrexate. When administered in high doses, it may cause chest pain, sometimes 2–5 days later, in 2–4% of patients. Thirty percent of those may progress and develop pleural effusion [80]. Pain typically subsides 3–5 days after discontinuation of the drug and may relapse if the offending agent is restarted [81].

Late Complications

Late-onset chemotherapy-related pulmonary complications usually present 2 months after completion of therapy. The most common manifestation is pulmonary fibrosis. The agents most commonly associated with this complication are bleomycin, busulfan, carmustine, and mitomycin-C. Common risk factors for this toxicity are advanced age, concomitant radiation treatment, or combination chemotherapy. The use of supplemental oxygen, even at low flow rates, amplifies bleomycin toxicity and may play a role in the development of pulmonary fibrosis, even years after treatment [82].

Patients typically present with the insidious onset of dyspnea associated with nonproductive cough. Physical examination reveals crackles and chest radiograph shows bibasilar reticular interstitial markings. Pulmonary function tests may be consistent with restrictive disease. History and physical examination with elimination of other underlying issues, such as congestive heart failure, are essential to the diagnosis. Bronchoscopy may be useful in ruling out lymphangitic spread as well as infectious etiologies. Definitive diagnosis may require video-assisted thoracoscopic surgery. Supportive treatments and a trial of corticosteroids are mainstays of therapy; however, use of oxygen in patients who have bleomycin lung toxicity should only be used in those with severe hypoxemia.

Radiation-Related Pulmonary Toxicity Radiation-induced lung injury (RILI) encompasses any lung toxicity induced by radiation therapy (RT) and manifests acutely as radiation pneumonitis and chronically as radiation pulmonary fibrosis [83]. Radiation-induced lung injury results from the combination of direct radiation cytotoxicity in addition to radiation-induced cellular signal transduction. This cellular activation initiates a repair process that involves cytokines and growth factors, such as basic fibroblast growth factor, interleukin-1, and transforming growth factor-beta, leading to the development of fibrosis. The incidence of serious pulmonary complications from radiation therapy has decreased secondary to advances in radiation delivery techniques. More recent data suggest RILI incidence is highest for lung cancer (5–25%), followed by mediastinal lymphoma (5–10%) and breast cancer (1–5%) [84].

Several risk factors have been described, including volume of lung irradiated, total dose of radiation >60 Gy, number of fractions delivered, concomitant chemotherapy, previous radiation treatment, and weaning of systemic steroids. Age is not a risk factor but radiation pneumonitis seems to be worse in elderly patients. Radiation pneumonitis occurs within 6 months of therapy (most often within 12 weeks), whereas radiation pulmonary fibrosis occurs >1 year following therapy [85]. If symptoms begin earlier, patients tend to suffer a more severe course. The severity of radiation pneumonitis varies from radiographic findings with no clinical symptoms to life-threatening disease requiring hospitalization [86]. The most common symptom is dyspnea, which may be associated with a pinkish productive cough. The diagnosis is usually clinical and based on the timing of radiation treatment and typical chest radiograph findings corresponding to the field of radiation. Clinically significant radiation-induced pulmonary fibrosis typically occurs months to years following therapy and is described as progressive dyspnea associated with lung scarring. Tachypnea and cyanosis are both signs of advanced disease.

Bronchoscopy is rarely helpful and serves only to rule out an infectious or recurrent malignant process. Corticosteroid therapy is commonly used, although its efficacy is controversial. Prednisone (1 mg/kg or equivalent doses of other corticosteroids) is indicated for acute radiation pneumonitis, but not in fibrosis. Therapy should be continued for 2–4 weeks, followed by a slow tapering of the medication for an additional 6–12 weeks [87]. The only two drugs that have shown efficacy in reducing rates of pneumonitis in humans are amifostine and pentoxifylline in combination with tocopherol. Amifostine is the only FDA-approved drug, but its use is limited because of adverse effects [88].

Another reported and more acute form of radiation-induced lung injury is radiation-related bronchiolitis obliterans with organizing pneumonia (BOOP) [89]. Most reported cases occur among patients irradiated for breast cancer. Common manifestations include cough and fever and, to a lesser degree, dyspnea. The radiographic findings begin in the radiation field but may progress even to the contralateral lung in 40% of cases. Patients respond dramatically to corticosteroids but also carry the risk of significant relapse if tapered in a short period of time.

Summary

Radiation pneumonitis often progresses to lung fibrosis and is typically limited to the radiation field. Clinical and radiographic suspicions are important in establishing the diagnosis. Radiation-induced BOOP is a more acute form that often involves the contralateral lung. Treatment with corticosteroids should be tapered slowly in order to avoid the risk of a relapse.

Nonthrombotic Pulmonary Embolism (NTPE)

NTPE is the embolization of nonthrombotic tumor material into the pulmonary circulation, blocking it either entirely or partially. The nonthrombotic tumor material in patients with cancer includes macro- or microembolism. It is called pulmonary tumor embolism (PTE). These emboli are distinct from true metastases as they remain intravascular and rarely invade the pulmonary parenchyma. With complete occlusion, necrosis of the dependent pulmonary parenchyma similar to a thrombotic event follows. When partially occluding the vascular lumen, inflammatory reaction, vascular intimal proliferation, and activation of the coagulation cascade may develop. The reported incidence of this complication is difficult to assess and is reported at 2.4–26% based on postmortem examination [90, 91]. This variability reflects the difficulty in diagnosing this syndrome. There is predominance of digestive system and liver tumors associated with PTE; breast cancer and cardiac lymphomas have also been reported, but at a lesser rate. The risk of tumor embolization is increased among patients undergoing chemotherapy, radiation, or surgical intervention (fragmentation and embolization of tumor fragments or cells). The presentation is often insidious, progressing over several weeks to months. In rare instances, it can be acute (10–20%) [92]. In patients with proximal and large tumor emboli, the presentation can be dramatic and acute with signs of right heart failure. Patients typically present with worsening dyspnea, cough, and increased work of breathing, sometimes associated with ascites and peripheral edema, reflecting increased right heart pressure. The gold standard test is pulmonary artery blood cytology, obtained through a pulmonary artery catheter. Though PTE is not considered to be metastasis, the prognosis is still poor. Treatment is supportive and should be directed to the primary tumor. Chemotherapy does not generally affect the prognosis of patients with PTE unless the primary tumor is very chemotherapy responsive (e.g., trophoblastic or Wilms tumors).

Summary

PTE syndrome is often the result of tumor destruction, whether with medications or surgical intervention. Symptoms are insidious, however, may mimic thrombotic events. Diagnosis is often clinical but occasionally can be made with pulmonary artery blood cytology. Prognosis is generally poor.

Venous Thromboembolism

24

Nicholas R. Pettit and Jeffrey A. Kline

Case Study

A 55-year-old male presents to the emergency department (ED) with chest pain. It started about 1 day ago, constant in nature, substernal, nonexertional, and pleuritic. He took some acetaminophen without any relief. He has had some dyspnea on exertion for the past week, but no fever, chills, myalgias, leg pain, or swelling. He has had some anorexia because he is undergoing chemotherapy, and last received gemcitabine 2 weeks ago. His vital signs are blood pressure of 145/85, heart rate of 75 beats per minute, SpO_2 99% on room air, and a temperature of 37.4 °C. He is comfortable in the bed and otherwise is well appearing in no acute distress. You suspect pulmonary embolism, order troponin and pro-BNP which return normal, and the ECG is sinus rhythm unchanged from his previous. Remainder of labs including BMP and CBC are within normal limits. CT scan of his chest demonstrates several small subsegmental pulmonary emboli without any evidence of right heard strain. As the treating practitioner in the ED, you are responsible for this patient's disposition, and ultimately decide to discharge this patient after communication with the patient's oncologist. Application of the Hestia criteria determines that the patient is low risk for outpatient management of his pulmonary emboli, so you prescribe rivaroxaban and discharge the patient home after arranging follow-up with his oncologist in 2 days.

Pathophysiology of Thromboembolism in Cancer

Annually, 1.5 million patients will receive a new diagnosis of cancer in the United States, of whom 5% or 75,000 patients will receive an additional diagnosis of venous thromboembolic disease (VTE). VTE is a direct complication of cancer and is known to be influenced by tumor type, stage, and active treatment [1]. The risk of VTE is 53-fold higher than baseline in the first 3 months after diagnosis of cancer and remains approximately fourfold higher until 15 years after initial cancer diagnosis [2]. Carrying a dual diagnosis of both cancer and pulmonary embolism (PE) is associated with worsened prognosis, increased recurrence rates, longer duration of anticoagulation, and worsened bleeding risks.

In healthy patients, the vessel endothelium prevents thrombus formation by acting as a barrier to the underlying subendothelium, which contains tissue factor (TF). When TF is exposed through vessel wall damage, it complexes with circulating Factor VIIa and initiates the extrinsic pathway, the primary driver behind the entire coagulation cascade. To initiate a clot, TF must bind with circulating Factor VIIa. This results in a complex capable of converting Factor X to Xa, which cleaves prothrombin to thrombin, in turn cleaving fibrinogen to fibrin, leading to a cross-linked fibrin clot after the action of Factor 13, itself activated by thrombin. Cancer increases the exposure of TF to the blood by several mechanisms, including the surface characteristics of cancer cells, their production of TF-bearing microparticles, and by direct vascular damage as a result of tumor spread. As an example, pancreatic cancer, a highly thrombogenic malignancy, causes significant elevations in microparticle-associated TF, leading to rates of VTE as high as 45% in some series [3, 4]. In addition to increased production of TF, cancers can also release various proinflammatory cytokines, interleukins, and procoagulants [5].

Cancer patients undergo a variety of procedures and treatments that further increase their risk for thrombosis. Surgery, chemotherapy, and radiation therapy cause a proinflammatory

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_24

state, and some chemotherapeutic agents produce a prothrombotic state that independently increases clotting risk, notably fluoropyrimidines, L-asparaginase, and thalidomide derivatives [6, 7]. The chemotherapeutic agents Ara C and 5-fluorocytosine alter the metabolism of coumarins and complicate the ability to achieve stable anticoagulation. In addition, interrupting anticoagulation for procedures in patients with active VTE has been associated with increasing rates of postoperative thrombotic and bleeding complications [8]. Cancer patients frequently have other risk factors for VTE including indwelling catheters, immobility, and folate deficiency [9].

Thrombogenic Cancers

Emergency physicians will often consider the need to test for VTE while treating patients with cancer. However, thrombogenicity varies with host factors, tumor stage, and type. In general, the more undifferentiated the cell type and the larger the tumor burden, the higher the risk. The incidence of VTE in a large study population demonstrated a rate of 2% of all cancer patients, with increased rates seen among patients with metastatic disease, pancreatic cancer, and colon cancer [10]. Cancers that appear to confer no or minimal risk of VTE include localized breast, cervical, prostate, and nonmelanomatous skin cancers, such as squamous cell carcinoma and basal cell carcinoma. However, advanced stage breast cancer or breast cancer patients undergoing chemotherapy may have a thrombosis risk of up to 10% during treatment [11, 12]. Similarly, treatment of leukemias, particularly acute lymphocytic leukemia treated with L-asparaginase and acute promyelocytic leukemias treated with all-trans-retinoic acid have each been associated with an approximate 10% incidence of VTE throughout the course of therapy. Other cancers that are particularly thrombogenic include adenocarcinoma, glioblastoma, melanoma (in contrast to other skin cancers), lymphoma, and multiple myeloma [13]. Pancreatic, gastric, ovarian, and renal cell cancers carry notoriously high risks. Finally, in addition to different risks based on malignancy types, within the California Cancer Registry (CCR), racial disparities exist with non-Hispanic whites and African Americans having an incidence of VTE almost twice that of Hispanic and Asian patients. This may be due in part to variable expression patterns in different ethnic groups, but the basis for these disparities are mostly undefined [14, 15].

Clinicians should be especially vigilant for VTE during the induction phase of chemotherapy, as this is the most thrombogenic period [16]. L-asparaginase and bolus fluorouracil treatment confer particularly high thrombosis risks, probably by reducing antithrombin concentrations [17]. While localized breast cancer has a relatively low thrombogenic potential, risk approximately doubles with tamoxifen treatment, whereas aromatase inhibitors do not appear to increase risk. Concomitant treatment with red cell growth factors such as erythropoietin clearly increases risk of thrombosis, regardless of tumor type or stage [18]. Any patient who presents with extremity swelling or chest pain during the initial treatment phase with these drugs should undergo diagnostic studies outlined in Table 24.1 to exclude thromboembolism. Similarly, multiple myeloma patients treated with lenalidomide or thalidomide are at risk, although one large Japanese cohort study found this to be 1.4% and at baseline for their cancer [19, 20]. Bevacizumab presents a complex picture, with some studies suggesting a high risk and a more recent systematic review showing no increase compared with matched patients receiving other forms of chemotherapy for similar tumors [21]. A clinical prediction rule has been developed [18] to determine which cancer patients are at highest risk for future thrombosis. In this model, patients with ≥3 points are found to have VTE risks of approximately 7%. Lastly, a recent systematic review and meta-analysis reports a pooled VTE rate of approximately 7% among cancer patients receiving neoadjuvant therapy, with highest rates among those with bladder and esophageal cancers [22].

Table 24.1 Diagnostic criteria required to exclude venous thromboembolism in cancer patients

Deep vein thrombosis	Pulmonary embolism
Negative full leg duplex ultrasonography[a]	Adequate quality negative CTPA
Negative (<500 ng/μL) d-dimer plus negative proximal ultrasound	Negative homogenous perfusion scan
Two negative proximal ultrasounds 2–7 days apart[b]	Low probability V/Q scan and a single negative bilateral whole-leg lower extremity duplex ultrasonography or two negative proximal ultrasounds 2–7 days apart

CTPA Computed tomography pulmonary angiography, *V/Q* A ventilation–perfusion scan

[a]Full leg ultrasound includes spectral and B-mode compression imaging of the proximal and distal femoral vein, the popliteal, posterior tibial, peroneal and greater saphenous veins

[b]Proximal ultrasound includes spectral and B-mode compression imaging of the proximal and distal femoral vein and the popliteal vein

What Does VTE Mean for the Cancer Patient?

Cancer patients who develop VTE have higher morbidity and mortality risks. This risk represents the synergistic effect between the two disease entities. Diagnosis of VTE in cancer confers several independent, negative consequences, including a reduced overall probability of survival, indication of more aggressive cancer, and a higher risk of bleeding from anticoagulation than noncancer patients that suffer from VTE [23]. In addition, cancer-associated nausea impairs oral anticoagulant administration and absorption. Pill fatigue can impair anticoagulation therapy compliance, as these patients

are often on multiple medications. For those receiving vitamin K antagonists (VKAs) such as warfarin, the additional needle sticks for INR checks can be onerous. Finally, cancer patients tend to experience higher severity of clot burden than patients without cancer. In the authors' experience, these thrombi are larger and more extensive in both the extremities and in the lung, leading to a larger disease burden and increased incidence of postthrombotic syndrome.

Special Considerations for Diagnosis

The diagnostic approach to a cancer patient with suspected VTE mirrors that of other moderate- to high-risk patients with suspected PE (see Table 24.1). Unfortunately, while being at higher risk for thrombosis, cancer patients are also at higher risk for complications from diagnosis. One such currently debated topic is that of contrast-induced nephropathy (CIN), as older literature illustrates an increased risk of CIN in all outpatients receiving contrast-enhanced computed tomography, as well as in active cancer patients receiving contrast-enhanced CTs [24, 25]. More recently, however, in a retrospective cohort comparing contrasted to noncontrasted CT scans in a cancer cohort, the rate of acute kidney injury (AKI) was independent of the administration of contrast, but instead was more associated with preexisting congestive heart failure and prior AKIs [26].

The D-dimer, which normally can be used to reliably exclude VTE because of its high sensitivity, becomes markedly less specific in the cancer population. Many cancer patients will have positive D-dimer results in the absence of clot, meaning that the test is less useful in patients with active cancer. Active malignancy induces a system-wide activation of the clotting network, and elevated D-dimer levels may herald a poor cancer prognosis without indicating thrombosis [27]. This phenomenon likely reflects important interactions between hemostatic mechanisms and tumor-associated angiogenesis and inflammatory mediators. D-dimer levels confer additional prognostic value to tumor stage and predict decreased survival for breast cancer patients, and is a marker of decreased survival in colorectal, cervical, pancreas, prostate, brain, and melanoma cancers [1]. While a negative D-dimer still helps rule out VTE, it does so in a smaller proportion of patients with active cancer.

Risk Stratification and Management

In the era of target-specific anticoagulants (TSAs, formerly referred to as direct oral anticoagulants or DOACs) such as rivaroxaban, apixaban, and dabigatran, the need to hospitalize all patients with thromboembolic event, including PE, is being called into question. It has been long held that many patients with DVT can be safely discharged home [28]. However, several caveats to this practice exist, chief among them is a low-risk status. In practice, low-risk status among those with cancer refers to the lack of a reason why the patient would need hospital care in the next 30 days. The primary determinant of success of outpatient treatment will be access to anticoagulant and ability to administer it. While the preferred method of treatment for both DVT and PE in active cancer remained injected low-molecular-weight heparin (LMWH), rivaroxaban is now an acceptable primary therapy for VTE according to The National Comprehensive Cancer Network Guidelines [29, 30]. Thus, the first objective with home treatment is to determine if the patient and caretakers have the capacity and competence to administer twice daily subcutaneous injections. Other predictors of return to the hospital are inadequate pain control, decompensation of other disease processes, need for oxygen, or hemodynamic and respiratory effects of concomitant PE, which occur in over 1/3 of patients [31]. Patients with significant iliofemoral clot burden may require admission for catheter-based therapy in view of evidence that this approach significantly decreases postthrombotic syndrome and leg ulceration, which are the major complications of these proximal, occlusive DVTs [32].

Patients with PE are increasingly treated at home, starting the same day of diagnosis, provided that these patients meet low-risk criteria [32–34]. Several criteria have been validated, including the Hestia criteria, the PESI, and sPESI scores [35–38]. However, the sPESI score excludes discharge of patients with cancer. The Hestia criteria do not exclude patients with cancer, but we suggest that cancer patients with VTE must also meet a separate set of rules, of which two have currently been published: POMPE-C and criteria derived from the Registro Informazitado Enfermo TromboEmbolica (RIETE) database by den Exter et al. [39]. These criteria include additional predictors such as metastases, immobilization, and low body weight while they also stratify cancer patients based on perceived risk of thrombosis [39, 40].

Thus, to deem a patient with either DVT or PE and with active cancer (defined as under the current care of an oncologist or receiving palliative therapy, or any patient with metastasis) as low risk for home treatment, we recommend a two-step approach. First, apply the Hestia criteria (Table 24.2) and second, for patients with confirmed PE or patients with DVT and strongly suspected PE, apply either the POMPE-C criteria (Table 24.3) or the den Exter criteria [35, 41–43]. The POMPE-C criteria predicts mortality for cancer patients with PE; however, for safe outpatient management, the Hestia criteria account for several other variables that may particularly impact cancer patients (e.g., renal dysfunction, liver disease, medical/social reasons for admission). The EPIPHANY index has been derived and validated for pre-

Table 24.2 The Hestia criteria

Patient fails criteria if any of the below are true
Hemodynamically unstable
Requires thrombolysis or embolectomy
Active bleeding or high risk for bleeding
More than 24 h supplemental O_2 required to maintain O_2 saturation >90%
PE diagnosed while currently under active anticoagulant therapy
Severe pain requiring >24 h intravenous analgesic therapy
Medical or social reason for hospitalization >24 h (infection, malignancy, no support system, etc.)
Creatinine clearance <30 mL/min
Severe liver impairment
Pregnancy
Documented history of heparin-induced thrombocytopenia

Table 24.3 The POMPE-C criteria (used in an online calculator for overall risk of death at 30 days)

If all criteria shown are absent, the patient's risk of death is sufficiently low to justify home treatment for the patient with active cancer
Absence of a *Do Not Resuscitate* order
No respiratory distress (defined by the patient showing fear, anxiety, or dyspnea)
No unilateral leg swelling
No altered mental status
Heart rate <100 beats/min
Respiratory rate <28 breaths/min
Pulse oximetry >94% on room air
Weight >140 pounds

dicting risk of serious complications from incidental PEs in cancer patients but has not been used to demonstrate safe ED-discharge among acute DVT/PE in cancer patients [44].

Treatment

At present, the recommended treatment for VTE in cancer is daily injections of 200 IU/kg bodyweight of dalteparin, a LMWH, as opposed to warfarin. The CLOT trial in 2003 demonstrated that dalteparin was superior to warfarin with a 52% risk reduction profile for recurrence of clot [45]. It is important to recognize that there is a widespread assumption that enoxaparin 1 mg/kg bodyweight (Lovenox®) is equivalent to dalteparin (Fragmin®), although this has never been demonstrated in a clinical trial.

Despite the knowledge of a risk reduction from dalteparin, patients often request oral therapy, as injections are expensive, onerous, and painful, as well as causing bruises and disfigurement [37]. While limited data suggest that patients prefer efficacy and safety over convenience [46], it is the authors' opinion that physicians underestimate the negative perceptions that patients have toward injections. Given the difficulty of self-injection and cost of the injectable LMWHs, many EDs utilize case managers or social workers to assist with the transition to outpatient therapy.

FDA-approved drugs, specifically target-specific anticoagulants (TSA), include apixaban (Eliquis®), betrixaban (Bevyxxa®), dabigatran (Pradaxa®), edoxaban (Savaysa®), and rivaroxaban (Xarelto®). These drugs offer alternative to therapies more inconvenient injectable LMWHs and VKAs as they are easier to take and less invasive for patients [47]. Furthermore, they don't require weight-based dosing, facilitating outpatient compliance and management.

Available data support a shift toward the use of orally available TSAs for treatment of patients with active cancer and VTE. The basis for this statement comes from a pooled subgroup analysis of patients with cancer at the time of enrollment in the EINSTEIN DVT and PE studies [38]. Together, these studies randomized 597 patients with either active cancer at baseline (n = 430) or cancer diagnosed during the study (n = 167) and found statistically insignificant reductions in risk of both VTE and bleeding for rivaroxaban versus standard therapy (LMWH + VKA) while producing a net clinical benefit for the composite outcome of recurrent VTE and major bleeding (hazard ratio, 0.60; 95% CI, 0.36–0.99) favoring rivaroxaban. This is reinforced by a Cochrane review suggesting that LMWHs compared to VKAs produce a reduction in VTE and in comparing TSAs to LMWHs finding a reduction in VTE but an increased risk of major bleeding [48]. Results from a trial dedicated to treating patients with VTE and active cancer suggest equal efficacy of rivaroxaban to LMWH but with a slightly higher rate of clinically relevant bleeding [49]. Lastly, comparing oral rivaroxaban to LMWH and VKA in the treatment of symptomatic VTE in cancer patients, rivaroxaban had similar efficacy and reduced number of major bleeding events as compared to LMWH/VKA but had no difference in clinically relevant bleeding [50]. It is reasonable to assume equipoise between injectable LMWH and the direct-acting anticoagulants. Figure 24.1 highlights a summary of randomized trials on TSAs in patients with cancer, both in terms of completed work and ongoing trials [51].

Deciding on which therapy to initiate in the ED should include patient preferences that might influence adherence (some patients hate injections; others with nausea may want to avoid swallowing pills) [48]. The Anti-Clot Treatment Scale is a 15-item patient report scale developed and validated for use in measuring patient-reported satisfaction with anticoagulation treatment [52]. This scale has been utilized in several trials to demonstrate that treatment with oral TSAs results in improved treatment satisfaction as compared to enoxaparin/VKA, as well as improved psychological impacts as compared to VKAs [53, 54]. Similarly, in a systemic review of patient-reported outcomes associated with TSAs, patients prefer TSAs to VKA with higher quality of life scores and increased adherence

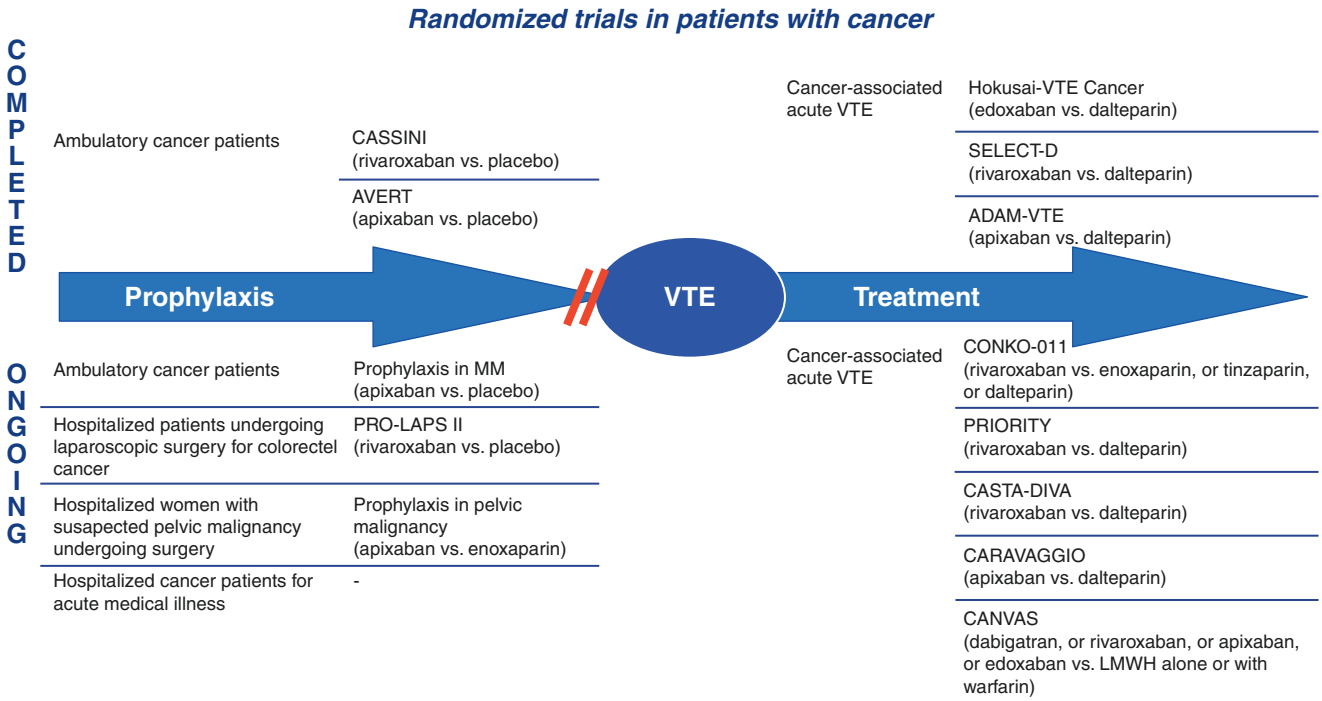

Fig. 24.1 Summary of randomized trials on target-specific anticoagulants in patients with cancer. (From Vedovati et al. [51], with permission from Elsevier)

[55]. Lastly, twice daily dosing with LMWH in cancer patients was nonsignificantly associated with a trend toward worsening perceptions of the 6-month VTE LMHW treatment, further suggesting that daily dosing is preferred, or additionally suggesting that TSAs may be more tolerable in the long term [56].

Duration of need for anticoagulation sometimes emerges as a concern in the ED, particularly for patients who present with bleeding. Although several stopping criteria have been derived [57], none are adequately validated to provide clear, binary decision-making for cancer patients. A general rule of thumb is to anticoagulate for the duration of cancer treatment and then for several months thereafter. At a minimum, cancer patients with any venous thrombosis, even if distal or superficial, should be treated with anticoagulants for 3 months and patients with proximal DVT or any PE for 6 months [57]. There is some evidence that men who develop PE during cancer should remain on lifelong anticoagulation. Thus, the prudent emergency practitioner would be wise to consider thrombosis as a cause for disease in patients recently in remission. Patients with a history of cancer that is inactive and who develop thrombosis should be treated in accordance with guidelines recommended for a patient with unprovoked DVT (3–6 months) and PE (minimum of 6 months).

Table 24.4 Risk tool of Khorana for prediction of which patients undergoing chemotherapy will develop venous thromboembolism

Site of cancer	Risk score
Very high risk (stomach, pancreas)	2
High risk (lung, lymphoma, gynecological, bladder, testicular)	1
Prechemotherapy platelet count >350,000/μL	1
Hemoglobin <10 g/dL or red cell growth factors	1
Prechemotherapy white blood count >11,000/μL	1
Body mass index >35 kg/m^2	1

Thromboembolism Prophylaxis

Some malignancies confer an extraordinarily high risk of VTE, prompting the consideration to prescribe a prophylactic dose of anticoagulant [14]. Rivaroxaban was utilized in a double-blind, randomized trial of 841 high-risk, ambulatory, cancer patients, which demonstrated rivaroxaban did not significantly reduce the incidence of VTE or death from VTE over 180 days [58]. Conversely, several other studies have demonstrated some utility in VTE prophylaxis, such as in a study with 563 intermediate-to-high risk for VTE cancer patients (Khorana score ≥ 2, Table 24.4), using apixaban for VTE prophylaxis during chemotherapy. Primary outcomes were incidence of VTE in 180 days and major bleeding, and

Table 24.5 Contraindications to anticoagulation in the cancer patient [62]

Absolute contraindications
Active, major, serious, or potentially life-threatening bleeding that is not immediately reversible with medical or surgical therapies
Malignant hypertension, severe and uncontrolled
Liver failure leading to uncompensated coagulopathy (cirrhosis)
Severe platelet dysfunction, known bleeding diathesis, inherited bleeding disorder
Persistent thrombocytopenia (<20,000/μL)
High-risk invasive procedure needed (lumbar puncture)
TSA specific: concurrent use of P-glycoprotein or CYP3A4 inhibitor
Relative contraindications
Intracranial or spinal lesion at risk for bleeding
Active gastrointestinal bleed or risk for bleeding (ulceration)
Active but non-life-threatening bleeding (hematuria)
CNS bleeding in past 4 weeks
Recent high-risk procedure/intervention
Persistent thrombocytopenia (<50,000/μL)
Consider not starting anticoagulation
End of life, hospice patient
Asymptomatic thrombosis at high risk for bleeding
Patient refusal or against their wishes
Risk for nonadherence

apixaban was found to significantly reduce the rate of VTE compared to placebo, however, at an expense of increased major bleeding [59]. Similar other trials utilizing nadroparin and semuloparin have demonstrated reduction in thromboembolic events in cancer patients actively receiving chemotherapy [60, 61].

Given numerous recent studies exploring the efficacy and utility of VTE prophylaxis, a meta-analysis was completed of randomized controlled trials published over a 4-year period (2014–2018) [62]. The American Society of Clinical Oncologic (ASCO) recommends thromboprophylaxis with apixaban, rivaroxaban or LMWH for high-risk outpatients with cancer. Rivaroxaban and edoxaban have added as options for VTE treatment. Lastly, other recommendations have been made regarding VTE treatment in the setting of brain metastases, hospitalization prophylaxis, and prophylaxis in the setting of major cancer surgery. Concurrently, the emergency medicine physician must be aware of contraindications to therapy and these are listed in Table 24.5 [62]. Decisions to alter or discontinue VTE prophylaxis should occur in consultation with the patient's oncologist.

Incidental Diagnosis and Thrombophilia Workup

Patients will occasionally be diagnosed with PE discovered incidentally during routine imaging. This is often because of a CT scan of the chest performed with iodinated contrast for other reasons, such as staging of lung cancer or routine surveillance. The prognosis and treatment for these emboli are unchanged and confer the same risk to the patient as does symptomatic embolism [36]. All cancer patients with any confirmed venous thrombosis require systemic anticoagulation if they have no contraindications. Further, risk of recurrent VTE is significant despite anticoagulant treatment [63].

The thrombophilia workup adds only unnecessary cost to the care of the cancer patient [64]. In terms of treatment choices and duration, cancer dominates as the driver of decision-making regarding type and duration of anticoagulation, regardless of the patient's other genetic predisposition to thrombosis. Current guidelines do not support the testing of patients or their families for thrombophilia in the setting of a cancer-associated thrombus, including the "Choose Wisely" points issued by the American Society of Hematology [65]. Overtesting for inherited risk factors for VTE when not indicated lead to excess costs for patients and the health care system, and reductions in unnecessary testing can ultimately reduce health care costs [66].

Catheter-Associated Thrombosis

In 18 published studies of cancer patients with peripherally inserted central catheters, 6.8% (234/3430) were reported to experience deep venous thrombosis [67]. Intraluminal occlusions are best treated by interventional radiology or other specialists with access to and experience using fibrinolytic agents (e.g., Cathflo®) for this purpose. Extraluminal venous thrombosis (a form of DVT) can be treated by either removal of the catheter or anticoagulation with the catheter in place. In contrast to other sites of deep venous thrombosis, symptomatic PE occurs <5% of patients, but more than half experience total venous obstruction, which can lead to post-thrombotic syndrome and venous scarring with permanent stenosis [68]. Moreover, peripherally inserted central catheters (PICC lines) have a higher risk of thrombosis in cancer patients than central venous catheters [67]. PICC line-related DVT is highest within the first 2 weeks of placement, and smoking and high BMI significantly contribute to the rate of DVT; meanwhile, in a similar cohort, anticoagulation did not prevent thrombotic events [69, 70]. The decision to leave or remove the thrombosed catheter should be based primarily on the degree of swelling and pain, balanced against the need for the catheter and availability of alternative source of venous access, preferably determined in conjunction with the patient's oncologist. Regardless, PICCs can be safely and successfully utilized in nonhospitalized cancer patients for both chemotherapy and parental nutrition [71].

For indwelling lines used for active chemotherapy or other ongoing treatment, anticoagulation is often the best route. If the catheter can be removed, and the patient has trivial swelling and no pain, the author's preference for sub-

sequent treatment is a 7-day course of anticoagulation. Patients with visible swelling or pain should have 3 months of anticoagulation [29]. Prophylactic anticoagulation has shown disappointing results in both adults and children for prevention of catheter-associated thrombosis [72, 73].

Advanced Treatment

For all patients with massive PE, defined by either hypotension (systolic blood pressure <90 mmHg) or a 40 mmHg drop in systolic blood pressure (observed in the ED), clinical guidelines are aligned to recommend systemic fibrinolysis in the absence of contraindications [74, 75]. We recommend infusion of 15 mg of alteplase followed by 85 mg over 2 h. All patients should receive full-dose heparin anticoagulation (e.g., 5000 U unfractionated heparin bolus, followed by 16–18 U/kg/h infusion and PTT monitoring).

Patients with cancer have higher bleeding risk with standard anticoagulation and likely have higher bleeding risks with administration of fibrinolytic agents [76, 77]. Recent work suggests that a subpopulation of patients with DVT and PE will benefit from advanced therapies such as thrombolytics or catheter-based treatment [78, 79]. These patients fall primarily into two categories: DVT patients with large iliofemoral clot burden causing pain and leg swelling, and PE patients with right ventricular dysfunction, evidenced by an elevated troponin measurement (>99 percentile at a precision of 10% coefficient of variability), elevated brain natriuretic peptide (BNP >90 pg/mL), elevated pro-BNP (>900 pg/mL), or an echocardiogram demonstrating right ventricular hypokinesis or dilation, often defined as the right ventricular diameter larger than the left ventricular diameter (Table 24.6) [74]. Limited retrospective data exists for catheter-based treatment of either PE or DVT in cancer patients [80]. Regarding inferior vena caval filters in patients with PE who can be anticoagulated, no evidence has shown a clinically important net benefit for their insertion, and we do not recommend their use in any patient with PE who can be anticoagulated [81].

Table 24.6 Findings that suggest a worsened prognosis and may serve as indications for thrombolysis

Vital sign and physical examination abnormalities	Lab and imaging abnormalities
Systolic blood pressure <90 mmHg or a 40 mmHg drop from a known baseline blood pressure	Elevated cardiac BNP (>90 pg/mL) or pro-BNP (>900 pg/mL)
Hypoxemia (<92% at or near sea level) with respiratory distress	Elevated troponin or CK-MB
Altered mental status or delirium, usually seen as agitation, panic, and inattention	Right ventricular dilation with or without hypokinesis on echocardiography; a tricuspid annular plane systolic excursion (TAPSE) distance <16 mm; lobar or larger clot burden on CT together with RV > LV and evidence of contrast reflux

BNP brain natriuretic peptide, *CK* creatine kinase, *CT* computed tomography, *RV* right ventricle, *LV* Left ventricle

Patients with Absolute Contraindications to Anticoagulation

The treatment options are limited. An important intervention for these patients is to insert a vena caval filter as soon as possible [82]. With limited options for the patient in the presence of a strong contraindication to anticoagulation, such as active gastrointestinal bleeding, or recent glioblastoma surgery, physicians may be forced to consider treatments based upon case reports or hypothetical reasoning. These include inhaled nitric oxide (35 ppm by face mask or 50 ppm by nasal cannula) to reduce pulmonary vascular resistance and inhaled heparin localize anticoagulation in the lung vasculature [83]. Under fluoroscopic guidance, an interventional radiologist can place an infusion catheter through the body of the thrombus lodged in a proximal pulmonary artery and infuse 0.5 mg/h of alteplase with or without adjunctive ultrasonic (e.g., Ekosonic®), hydraulic (e.g., Angiojet®), or mechanical (e.g., rotating pigtail) thrombus disruption. No clinical trials have tested this method and the risk of hemorrhage remains unknown. Methods of clot extraction, including the use of the large bore Angiovac® device or open surgical thrombectomy, require that the patient be placed on an extracorporeal perfusion circuit with systemic anticoagulation.

Discontinuation of Treatment

One of the primary challenges of treating VTE in the cancer population is choosing a stop date for the desired therapy. In noncancer patients, anticoagulation may be continued for 3–6 months [84]. Given the prothrombic nature of cancer, the exact duration of anticoagulation treatment has no well-defined criteria. Instead, knowing that the risk of recurrence of thrombosis after discontinuation of anticoagulation exists, physicians must use their best judgment as to when to discuss discontinuation. Whenever possible, patients and families should be involved in the decision-making process, as at some point continuation of anticoagulation may offer no symptomatic benefit or improvement in the qualities of life [85, 86]. Ultimately, the decision to discontinue is best made through shared decision among all involved parties, especially as performance status declines and as death approaches.

VTE as First Manifestation of Cancer

Again, VTE in the setting of known cancer will not benefit from additional thrombophilia workup; however, a newly diagnosed, unprovoked VTE may be associated with underlying cancer [87]. One prospective study found that 3.3% of newly diagnosed VTE were the result of an underlying, undiagnosed malignancy, as compared to 0% of the provoked VTE. Furthermore, the presence of residual vein thrombosis in patients with unprovoked DVT who do not develop cancer within 3 months of the diagnosis of VTE is an independent predictor of subsequent overt malignancy [88]. Several other studies have demonstrated an association between idiopathic VTE and underlying undiagnosed cancer [89, 90].

Follow-Up

Discharge of patients for outpatient follow-up must be done in conjunction with an outpatient physician. This may either be the patient's primary care physician or oncologist. Determining if the VTE is primary or secondary may provoke physicians to perform additional testing to see if an underlying malignancy is present. As stated earlier, with the development of the target specific anticoagulants, routine anticoagulation monitoring in the form of "coumadin clinics" will become less prevalent, especially in view of the fact that warfarin is not recommended to treat active cancer. Thus, the role of the physician in evaluating and caring for the patient with blood clots will shift away from simple INR management and dosage adjustment, and instead focus on duration of therapy, prognosis, and quality of life. These skills are well within the purview of primary care physicians. Stopping criteria, while imperfect, can be used in a shared decision-making model to determine individual duration of anticoagulation [57].

Case Study

A 65-year-old male with 2-year history of diabetes presents to his local emergency department with a history of progressive anorexia, early satiety, and 2 days of jaundice. Work up revealed a bilirubin of 5.3 (high) and a CAT scan of the abdomen and pelvis showed a markedly dilated stomach that was fluid and food filled. A 3-cm solid enhancing mass was seen in the head of the pancreas resulting in upstream biliary obstruction, duodenal invasion, and pancreatic duct dilation. A nasogastric tube was placed in the emergency room to suction with prompt evacuation of 2.5 L of dark brown murky fluid and relief of many of his symptoms. Gastroenterology was consulted.

The following day, upper endoscopy revealed a high-grade ulcerated duodenal stricture at the apex of the duodenal bulb. The endoscope was unable to be advanced to the second portion of the duodenum due to the stricture. Endoscopic ultrasound was performed, and fine needle aspiration of the pancreatic mass was positive for malignancy per the rapid on site cytopathologist. A duodenal stent was placed traversing the stricture. After the enteral stent was allowed to expand over the next 2 days to facilitate endoscopic access to the major papilla, ERCP was performed with placement of a biliary stent across the malignant biliary stricture. Staging CT scans of the chest, abdomen, and pelvis were performed and demonstrated locally advanced pancreatic cancer. A multidisciplinary pancreatic oncologic team met and offered the patient neoadjuvant chemotherapy and staging CT scans to follow to assess for surgical resectability.

This case illustrates the use of advanced endoscopic techniques to diagnose and palliate symptoms of duodenal and biliary obstruction due to a new tumor diagnosis.

Introduction

In the past, gastroenterology's involvement in oncologic care centered on endoscopic tissue acquisition for malignant diagnoses. With technological advances in gastroenterology (GI), the field of interventional endoscopy has increasingly become married to cancer care from staging to surveillance to management of tumor or treatment-related emergencies. Oncologic emergencies in gastroenterology, much like that of other body systems, are related to the presence of cancer (the tumor itself or metastatic growth) or occur as a consequence of the treatments undertaken for cancer. In the GI tract, these include both structural derangements such as luminal or biliary obstruction as well as metabolic emergencies such as hepatic failure. In general, GI-related emergencies represent a minority of all oncologic emergencies, which are more often metabolic or hematologic. Many GI-related oncologic events require timely evaluation; however, for the most part, they are not imminently life threatening. These events will be the focus of this chapter. Some types of GI oncologic emergencies are insidious and develop gradually over time until a clinical threshold is achieved (e.g., gastric outlet obstruction, jaundice), whereas others may manifest over hours (e.g., cholangitis related to biliary obstruction).

In some patients, the devastating emergency is the first presentation of cancer itself. Given the increase in outpatient oncologic care in modern-day practice, early signs and symptoms of an evolving gastrointestinal emergency or urgency may be overlooked by patients and families. As with any emergency, early recognition and diagnosis are paramount to effective management. Early consultation with a gastroenterologist to help in diagnosis and management may

impact patient outcome, and thus, multidisciplinary care for complex oncologic patients serves the patient best. This chapter will examine the most common cancer-related gastrointestinal emergencies, discuss their diagnosis, and review their treatment (Table 25.1). Specifically, we will address gastrointestinal hemorrhage, enteral and biliary obstruction, acute pancreatitis, hepatic decompensation, and urgent issues related to enteral feeding.

Gastrointestinal Hemorrhage

Bleeding Related to Tumors

Neoplasia is considered an infrequent cause of upper gastrointestinal bleeding (UGIB), accounting for approximately 5% of all UGIB cases [1–4]. While oncologic patients are at risk for common causes of gastrointestinal bleeding (peptic ulcer disease, gastroduodenal erosions, esophagitis, etc.), those patients that have solid tumors of the gastrointestinal tract, or metastatic lesions that involve the GI mucosa, pose a bleeding threat from the esophagus to the anus. This risk is further compounded by the presence of neutropenia and thrombocytopenia, as well as the use of anticoagulation in the setting of tumor-related thromboembolic disease. These factors, as well as the innate characteristics of the tumor, can make endoscopic treatment of bleeding a significant management challenge. Additionally, cancer-related bleeding overall is a poor prognostic sign.

A large prospective study of over 3200 patients admitted with acute nonvariceal upper GI bleeding demonstrated that those patients with neoplasia had 2.5 times (95% CI, 1.32–4.46; $P < 0.0001$) the risk of death when compared to those who bled from benign conditions [1]. Of those with cancer ($n = 153$), the mortality rate was significantly higher in those with esophageal compared to cancer of the gastric cardia or gastric body (33% vs. 23.5% and 7.2%, respectively) [1].

Lesions in the esophagus (squamous cell carcinoma and adenocarcinoma), stomach (adenocarcinoma, gastrointestinal stromal tumors [GIST], lymphoma, carcinoid tumors, etc.), and proximal small bowel (adenocarcinoma, lymphoma, GIST, carcinoid tumors, etc.) are typically reached with a standard upper endoscope, while tumors in the jejunum and ileum often require the use of device-assisted enteroscopy, mainly in the form of single- and double-balloon enteroscopy or spiral enteroscopy. Colonic (adenocarcinoma, neuroendocrine [including carcinoid] tumors, etc.) and terminal ileal (adenocarcinoma, lymphoma) lesions are accessed via standard colonoscopy. Irrespective of the direction of endoscopic approach or the specific endoscope utilized, catheter-based devices (clips, injection needles, cautery devices) used to treat bleeding are advanced down the working channel of the endoscope and directed at the target lesion.

A variety of endoscopic techniques are available for the treatment of GI bleeding, and these modalities may also be applied to bleeding tumors although overall success rates of hemostasis are inferior compared to the endoscopic treatment of benign bleeding pathology. The main reason for the limited success of endoscopic therapy for tumor-related bleeding is that bleeding in such cases is not generally from a single exposed vessel (for which the majority of current endoscopic treatments are designed). Malignant bleeding tends to be diffuse mucosal oozing from numerous small microvessels, and therefore focal targeting of therapy is less effective due to the generally larger surface area involved.

The literature on the efficacy of endoscopic therapy for bleeding directly due to the primary or metastatic malignancy is sparse and is mainly based on case reports and series [5, 6]. Thermal therapies, including heater probe, bipolar electrocautery, and argon plasma coagulation (APC), are perhaps the most widely used modalities for tumor bleeding [7]. There have been a few case reports in the literature, but no trials comparing the efficacy of bipolar electrocautery and heater probe. A 1996 study by Savides and colleagues reported on the use of heater probe or bipolar electrocautery with or without epinephrine injection, in seven patients with focally oozing tumors. Initial hemostasis was achieved in all, but the 30-day rebleeding rate was 29%, similar to those not treated endoscopically [8]. Several studies have evaluated the use of neodymium-yttrium aluminum garnet (Nd:YAG) laser for tumor palliation in the GI tract [9–13]. Immediate hemostasis rates of 94% were achieved with the Nd:YAG laser for the emergent treatment of 18 patients with massive bleeding from esophageal and gastric cancer; however, rebleeding occurred in three of 17 patients with initial success, making laser therapy less suitable for definitive therapy [10].

Argon plasma coagulation (APC) is widely accepted as an effective modality for hemostasis as well as tissue fulguration and is readily available in most endoscopy suites and hospitals. It has generally replaced laser therapy due to its ease of use, low cost, and portability. The specific use of APC for palliation of upper GI tumor has not been well studied, with very few small case series [14–16] related to its use in esophagogastric or rectosigmoid cancers. Much of the lit-

erature related to APC in the setting of malignancy focuses on its use as a curative therapy for early-stage cancers (i.e., treatment of high-grade dysplasia in the setting of Barrett's esophagus, which has now been largely replaced by radiofrequency ablation or cryotherapy) or for decreasing tumor bulk to maintain luminal patency for palliation of dysphagia in esophageal cancer, which is discussed separately.

Spray cryotherapy is a newer endoscopic therapy that has been mainly used for the ablation of dysplasia associated with Barrett's esophagus (BE). Cryotherapy is a noncontact, targeted application of a cryogen (liquefied nitrogen or carbon dioxide) to destroy tissue through repeated freeze/thaw cycles [17]. Cryotherapy has been shown to completely eradicate high-grade dysplasia associated with BE in 97% of treated subjects [18]. This technology has also been applied to bleeding tumors with a single case report demonstrating hemostasis achieved in locally unresectable hemorrhagic esophageal cancer [19]. A major advantage of cryotherapy over other catheter-based endoscopic therapies for the treatment of bleeding from cancer is the surface area of coverage with cryotherapy treatment (several square centimeters) compared to the focal treatment effect (several square millimeters) of other probe-based endoscopic therapies (such as heater probe, bipolar electrocoagulation, hemostatic clips). It is expected that more literature will be published on its use in malignancy given its ease of use and wide surface area coverage.

A novel modality for the treatment of gastrointestinal bleeding is the use of hemostatic powders. These inorganic powders are designed to control active bleeding by two mechanisms: (1) adhering to the bleeding site and forming a mechanical barrier when in contact with blood, tissue, and the extracellular matrix; and (2) increasing local concentration of clotting factors while enhancing clot formation [20, 21]. Many of these products have been utilized in the military for temporizing battlefield-related injuries and show great hemostatic promise. There are currently three hemostatic powders available for endoscopic use, though only the TC-325 (Hemospray™, Cook Medical Inc., Winston-Salem, NC, USA) has FDA approval. Of all GI endoscopic therapies, hemostatic powders have thus far demonstrated the greatest potential for sustained hemostasis in malignancy. Several small case series demonstrate successful immediate and sustained hemostasis with hemostatic powders [22–25]. A recent pilot randomized control study also noted 90% immediate hemostasis rates and significantly lower rebleed rates compared to controls [26].

Mechanical methods of endoscopic hemostasis are in the form of hemoclips and are currently in use, with overall relatively poor results due to their focal targeted area of therapy. Once again, most tumor-related bleeding is diffuse mucosal hemorrhage rather than from a single exposed blood vessel. Hemostatic clips have most commonly been used for prevention of bleeding following endoscopic mucosal resection, but can be applied to neoplastic lesions. Cheng et al., reported two cases of hemostasis achieved by hemoclip placement on bleeding gastrointestinal stromal tumors [27]. Oftentimes, the bleeding tumor has several areas of active oozing, and mechanical disruption of the friable tumor with the use of a hemoclip may potentially worsen bleeding. Hemoclips are generally avoided in bleeding from tumors unless there is a focal targeted area of hemorrhage.

If endoscopic therapy fails to achieve hemostasis, angiographic evaluation by interventional radiology (IR) is generally the next step. While data on angiographic treatment of bleeding tumors is limited, angiography should be attempted as second-line therapy [28]. Access to the bleeding vessel may be achieved by selective catheterization in the distribution of the culprit vessel as evidenced by active contrast extravasation. Superselective embolization using microcoils or Gelfoam is highly successful in achieving hemostasis when the anatomy is favorable. However, given the nature of cancer-related bleeding, that is, diffuse mucosal hemorrhage from multiple microvessels, embolization of the feeding blood vessel may place the patient at risk for ischemia from collateral damage.

In those instances when both endoscopic and interventional radiology interventions are not successful in achieving hemostasis or not possible, targeted radiation therapy (RT) should be considered. Overall, RT plays a crucial role in the treatment of gastrointestinal malignancies and in the management of hemostasis. The effects of RT bleeding can be realized within a matter of days and a few fractions of treatment. In general, even though bleeding ceases, further treatment is undertaken to sustain a more durable response. RT causes damage to the intima of the blood vessels that supply the tumor, leading to capillary necrosis and thrombosis, and consequently hemostasis. This effect on tumor blood vessels as well as destruction of the tumor is the main mechanism by which RT is effective for hemostasis. Several retrospective studies on the role of RT on bleeding gastric cancers have demonstrated that palliative short-course RT is effective in hemostasis in 50–95% of cases [29].

In general, palliative surgical resection is the last option for definitive care of GI bleeding related to cancers and is associated with a poor prognosis [30, 31]. A comparison of elective and emergency presentation of gastric cancer in 291 patients reported that overall 2-year survival was less in those that presented with emergency complications requiring operative intervention (25% in emergency group versus 67% who presented electively) [31]. Surgical resection is only appropriate for surgically fit patients, and prior literature has suggested a mortality rate of 10% and morbidity rate of up to 30% in cancer patients [32–34]. Surgery indeed is effective in hemostasis; however, improvement in survival is extremely low at 6%, and the impact on the quality of life after palliative resection is not clear [33].

To date, there have been no prospective trials comparing endoscopic therapy, surgery or RT in the treatment of bleeding related to luminal tumor. Therefore, there is no clear answer as to which is the most effective treatment option. In general, the management approach is to enlist the least invasive method of hemostasis first, which may include the following sequence: endoscopy, then interventional radiology, then radiation therapy, then ultimately, surgery if necessary.

Bleeding as a Consequence of Treatment

Mallory-Weiss Tear. In patients receiving chemotherapy, nausea, vomiting, and retching are common. These symptoms place patients at risk for an upper GI bleeding related to a Mallory-Weiss tear, a mucosal injury at the gastroesophageal junction area that exposes a bleeding arterial vessel. Patients often present with hematemesis that may be clinically significant. This type of injury can produce significant bleeding especially in the setting of chemotherapy-induced thrombocytopenia. This condition can often be managed with endoscopic therapy alone with the use of electrocautery, epinephrine injection (for vasoconstriction and tamponade), or mechanical clips for hemostasis via upper endoscopy. If endoscopic therapy is unsuccessful in establishing hemostasis, IR-angiography is the next step for arterial embolization.

Radiation Proctitis. Radiation injury to the rectum and sigmoid may result from treatment of cancers of the prostate, cervix, rectum, anus, urinary bladder, and testes, occurring in up to 20% of these treated cancer patients. Endoscopic findings are mucosal ulceration, edema, erythema, bleeding, and telangiectasia from neovascularization (Fig. 25.1). It presents as persistent or intermittent hematochezia that may be associated with tenesmus or abdominal cramping and can be a significant source of GI blood loss. Acute radiation proctitis occurs either during or within 6 weeks of RT and is usually self-limited, while chronic radiation proctitis often occurs several months to years following RT [35]. Risk factors include the total surface area of exposure, method of delivery and cumulative radiation dose, with doses above 70 Gy resulting in long-term injury to the rectal mucosa [36]. Additional factors associated with the development of RT proctitis include prior GI or genitourinary surgery, endometriosis, diabetes, hypertension, collagen vascular disorders, and inflammatory bowel disease, all of which contribute to vascular compromise in the area [37]. Most cases of radiation proctitis are self-limiting and respond to medical therapy. In general, rates of radiation proctitis may be decreasing as RT techniques are improving to allow more targeted delivery of higher doses of radiation. While supportive care is typically offered for mild cases, patients who develop persistent outlet-type bleeding may benefit from targeted therapy. There is a paucity of well-designed trials comparing medical and endoscopic therapy, making it impossible to identify the most effective approach for the management of chronic radiation proctitis.

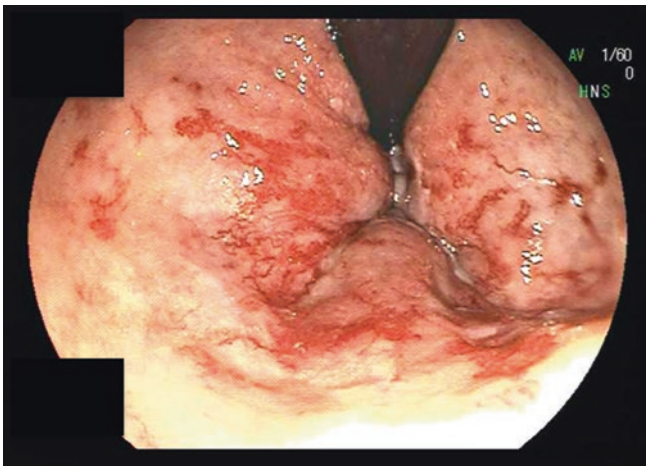

Fig. 25.1 Radiation proctitis. Endoscopic appearance of radiation proctitis, characterized by multiple telangiectasias in the rectum as seen on retroflexion in sigmoidoscopy. (Courtesy of Jeffrey L. Tokar, MD, Fox Chase Cancer Center, Philadelphia, Pennsylvania)

Treatment for radiation proctitis is medical therapy or endoscopic therapy. Medical therapy options include anti-inflammatory agents such as 5-aminosalicylic acid containing medications; antioxidants such as vitamin A, E, and C; sucralfate and short chain fatty acid enemas; and metronidazole and formalin therapy [38]. Kochhar and colleagues reported the use of sucralfate enemas in 26 patients, with durable remission of symptoms in a majority of patients with moderate-to-severe bleeding [39]. Several other reports have also demonstrated efficacy in improving symptoms of proctitis or proctosigmoiditis [39–41]. Given its overall low cost, minimal side-effect profile, and ease of administration, sucralfate topical therapy is a reasonable first step.

Endoscopic therapy with argon plasma coagulation (APC) is currently the first-line endoscopic modality for treatment of bleeding associated with radiation proctitis. It is easy to use, effective, widely available, safe, and relatively inexpensive. The goal of endoscopic therapy to is obliterate the telangiectasias. APC provides a predictable, noncontact, uniform, limited depth of coagulation (0.5–3 mm) to the target tissue, resulting in lower risks of perforation, stricture, and fistula formation [42, 43]. Studies have also demonstrated sustained remission of bleeding in patients with severe radiation proctitis (90% in a mean follow-up of 18 months) [44]. Typically, more than one session of APC

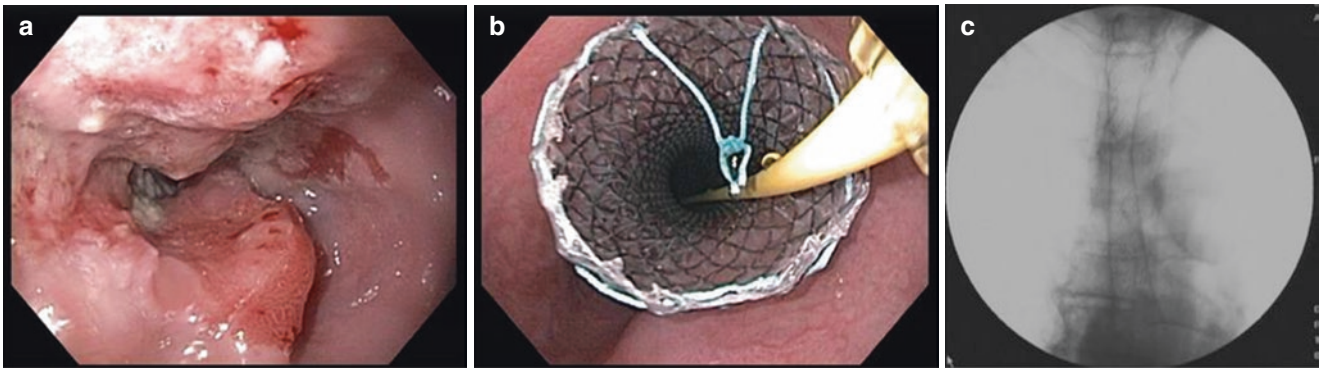

Fig. 25.2 Palliation of duodenal (**a**) and biliary obstruction (**a**, **b**) from pancreatic cancer. (Courtesy of Vinay Chandrasekhara, MD, University of Pennsylvania, Philadelphia, PA, and Kaveh Sharzehi, MD, Oregon Health & Science University). Two example fluoroscopic images of dual duodenal and biliary stenting (**a**, **b**)

therapy is required, with durable hemostasis achieved after three sessions [38, 45].

Other endoscopic treatments include radio-frequency ablation and cryotherapy [46]. Both these therapies have the advantage of allowing a broader field of treatment than the focal therapy of APC. Initial studies have demonstrated high rates of hemostasis (>90%) as well as minimal to no side effects (up to 19 months of follow-up) with both RFA and cryotherapy [47–49], though all studies are small. RFA has the benefit of inducing neosquamous epithelialization that may prevent recurrence of symptoms, but this has yet to be studied formally [43]. Hyperbaric oxygen therapy (HBOT) is currently utilized for the treatment of radiation proctitis in those patients who have failed more conventional medical or endoscopic techniques. It involves inhalation of 100% oxygen, delivered daily for weeks in a full body chamber with increased atmospheric pressure. It has been shown to be 89% effective with minimal morbidity with overall good compliance with treatment [50]. However, this therapy is not widely available and is often associated with wound care centers.

Luminal Obstruction

Patients with GI malignancies are at risk for obstruction of the GI tract, which is the most common surgical emergency encountered in the cancer patient [51]. Obstruction is characterized by poor oral intake due to nausea, vomiting, abdominal pain, and paucity of stool or flatus passage. Abdominal X-rays or CT scans may reveal air-fluid levels and a transition point indicating the site of obstruction. Initial management is conservative, with bowel rest, intravenous fluids, antiemetics, electrolyte repletion, and nasogastric (NG) tube placement for decompression. In general, the majority of noncancer-related bowel obstructions related to adhesions resolve in this conservative approach.

Malignant obstructions of the esophagus, stomach, duodenum, and colon can be alleviated by placing a self-expanding metal stent (SEMS) via endoscopy. Stents are placed with endoscopic and fluoroscopic guidance and are generally effective at maintaining patency in this setting (Fig. 25.2). SEMS has been shown to be a safe and effective means of maintaining esophageal patency in the setting of malignancy and the procedure has a very high technical success rate. Stent migration is the most common complication, with widely varying rates. While patients should be made aware of this potential in the informed consent process, the advent of stents with antimigration struts and endoscopic suturing devices, this risk has been reduced significantly [52, 53]. Post-procedure pain can be quite significant and is common, but often resolves after 48–72 h, with oral analgesia as support. Other considerations are the management of the induced acid reflux of the gastroesophageal junction that is bridged with the stent. As such, patients with esophageal stents are generally provided with a twice daily proton pump inhibitor (PPI) as well as instructed to sleep at a 45° angle indefinitely. The decision to place a SEMS for esophageal cancer is institution dependent and best made in a multidisciplinary setting. In some cases, surgeons prefer not to have an esophageal stent in situ if the patient is a candidate for an esophagectomy and instead prefer to provide nutrition via a surgically placed jejunostomy tube (at which time, surgical ischemic conditioning of the future gastric conduit can be performed). Esophageal stents, in this instance, are reserved for palliative cases only. Alternatively, some practices routinely place SEMS for obstructing esophageal cancer to aid in nutritional improvement prior to neoadjuvant therapy and surgery.

Gastroduodenal stenting for malignant obstruction of gastric, duodenal, or pancreatobiliary cancers has technical success rates of 90–95% according to multicenter retrospective studies [54], resulting in the ability to tolerate an enteral diet. Reintervention rates are low (only 5%), providing evidence

that enteral stents achieve excellent palliation. Overall prognosis should be considered prior to palliative luminal stenting. If patient life expectancy is anticipated to exceed 6 months, a more durable approach such as a surgical bypass (gastrojejunostomy) should be employed. While generally well tolerated, the main complications of gastroduodenal stenting include stent migration, perforation, and stent obstruction by tumor or food. These obstructions can typically be resolved endoscopically by placing a stent within the originally placed stent [55–57]. GI has witnessed multiple endoscopic advances with the use of endoscopic ultrasound and one of them has been the endoscopic gastrojejunostomy in which a lumen apposing metal stent is used to create a stable fistula between the stomach and jejunum. This novel technique is being refined currently but shows promise to potentially avoid surgeries in patients with advanced cancers [58–60].

Simultaneous biliary and gastroduodenal stenting is performed relatively commonly and has been shown to be a safe and effective means of palliation [61, 62] (Fig. 25.3). An additional consideration is that luminal stenting may not be effective for infiltrative-type gastric cancers in which motility is significantly compromised due to tumor (i.e., linitis plastica), rather than a true obstruction.

Finally, colonic stents have been used in the setting of colonic obstruction for palliation and also for colonic decompression prior to surgical intervention (so-called bridge to surgery). Once again, similar to other luminal stenting, technical (>92%) and clinical success rates (>89%) are high, and adverse rates are generally low, although some studies raise concerns about perforation [63–65]. There are multiple studies evaluating the role of colonic stents with respect to bridge to surgery or allowing for a one-step surgery (i.e., primary anastomosis versus an ostomy with subsequent takedown and anastomosis). Overall, results from the available literature are highly variable largely due to multiple small studies, lack of homogeneity in patient populations, as well as definitions of success and treatments. The most recent meta-analysis of eight RCTs and 497 patients in the surgical literature shows that stent as a bridge to surgery over emergency surgery for left-sided malignant colonic obstruction was associated with lower 60-day morbidity and lower rates of stoma formation; however, 30-day mortality rates are no different than surgery [66].

For surgically unresectable disease, with a life expectancy <6 months, colonic stenting is the treatment of choice [67, 68]. In potentially curable disease, colonic stents should only be considered when surgical intervention is anticipated to shortly follow stent placement. A multidisciplinary discussion between the performing gastroenterologist, the colorectal surgeon, and oncologist is warranted to optimize patient outcomes, given the lack of clear data in this area [69].

Two example fluoroscopic images of dual duodenal and biliary stenting (**a**, **b**)

Acute Pancreatitis

In patients with cancer, acute pancreatitis may occur as a result of pancreatic duct obstruction from tumor or as a result of chemotherapeutic agents. The diagnosis of acute pancreatitis is established by two of the following: clinical symptoms of abdominal pain; elevation of serum pancreatic enzymes greater than three times the upper limit of normal; and imaging studies documenting active pancreatic inflammation (CT or MRI with or without intravenous contrast). Mechanical obstruction of the main pancreatic duct or its branches is one of the etiologies of acute pancreatitis. While the most common reason for such an obstruction is gallstone disease, pancreatic neoplasms are recognized as an important, albeit more rare, cause of acute pancreatitis [70]. The risk of pancreatic adenocarcinoma after a single episode of acute pancreatitis is increased, with diagnosis that is often delayed for up to 2 years [71]. Age greater than 50 years, a history of smoking, weight loss of 10 lb or greater, serum bilirubin of 2 mg/dL, or alkaline phosphatase level greater than 165 U/mL, as well as radiologic findings of distal pancreatic atrophy or mass had statistically significant association with the subsequent diagnosis of pancreatic adenocarcinoma on follow-up [72]. Pancreatic neuroendocrine tumors are an uncommon cause of acute pancreatitis, but also should be included in the differential diagnosis of acute pancreatitis, especially in patients older than 40 years in whom the etiology of acute pancreatitis is not clear [73].

Acute pancreatitis can sometimes be the first presentation of primary pancreatic or ampullary neoplasms or metastatic disease to the pancreas [74, 75], the latter of which has been described in patients with cancers of the lung, kidney, bile duct, and melanoma [76]. Malignancy-associated hypercalcemia may also be the cause of acute pancreatitis [77]. The risk of primary pancreatic cancer is significantly increased in patients with hereditary pancreatitis due to genetic mutations; the risk of pancreatic adenocarcinoma in these individuals is as high as 54% by age of 75 years [78].

Acute pancreatitis may also develop in patients undergoing antineoplastic chemotherapy. While in general, less than 2% of acute pancreatitis is drug induced, the development of acute pancreatitis has been infrequently associated with antineoplastic chemotherapy. While it is often impossible to definitively conclude that a particular drug is the etiology of pancreatitis without rechallenge, multiple cases of chemotherapy-induced pancreatitis have been reported, including with capecitabine, paclitaxel, bortezomib, vinorelbine, and ifosfamide. Rechallenge was not attempted in many of the reported cases [79]. Tamoxifen may act through induction of hypertriglyceridemia to induce pancreatitis [80]. It is important to recognize that patients receiving chemotherapy can develop acute pancreatitis independent of their tumor or therapy for malignancy due to common etiologies such as gallstone disease or alcohol.

The management of patients with acute pancreatitis involves administration of aggressive intravenous fluid hydration, analgesia, and bowel rest. Aggressive hydration is defined as 250–500 mL/h (unless cardiovascular or renal indications dictate otherwise), with close observation of urine output and adjustment of hydration as needed, with the goals of decreasing blood urea nitrogen [81]. Early effective management of acute pancreatitis is critical to prevent multiorgan failure (renal failure, hypotension, respiratory compromise, and cardiovascular collapse) that can ensue as a result of the systemic inflammatory response syndrome [82, 83].

Inadequate early hydration may lead to any of these devastating consequences and is one of the most common clinical pitfalls in the management of acute pancreatitis. Furthermore, strict bowel rest (nil per os status, NPO) until patients are pain-free to limit pancreatic stimulation is a hallmark of initial management. The vast majority of patients have a mild course with inpatient admission for <5–7 days. In those cases in which the patient's clinical course dictates prolonged NPO status for more than 3–5 days, supplemental nutrition is indicated, preferably by enteral route with NG or nasojejunal (NJ) feeding. The optimal strategy is usually to allow the patient to consume nutrition per os; however, many patients are unable to meet the metabolic demands via only PO intake, and thus enteral nutritional supplementation should be instituted. In patients with acute pancreatitis, enteral nutrition significantly reduced mortality, multiple organ failure, systemic infections, and the need for operative interventions compared to those who received TPN. This was demonstrated in a meta-analysis of eight randomized controlled trials [84].

Patients who develop complications as a result of acute pancreatitis such as acute pancreatic fluid collections, pancreatic necrosis, or pseudocyst warrant a multidisciplinary discussion with gastroenterologists, including interventional endoscopists and pancreatic surgeons to optimize management of such complications.

Biliary Obstruction

Malignant obstruction of the biliary tree can arise from primary tumors of the bile duct (intrahepatic or extrahepatic cholangiocarcinomas) or from extrinsic compression and/or invasion of the bile duct by pancreatic, ampullary, or duodenal cancers and lymphadenopathy (peripancreatic or portal lymph nodes), or from metastatic spread to the biliary tree or liver. Biliary obstruction manifests as jaundice, acholic stool, dark urine, pruritus, abdominal pain, nausea, and weight loss. Cholangitis may occur as a result of biliary stasis and

subsequent infection; however, in general, in the absence of prior biliary intervention or choledocholithiasis, ascending bacterial cholangitis is uncommon in patients with malignant biliary obstruction.

Biliary obstruction is diagnosed by abnormalities in serum bilirubin, alkaline phosphatase, and liver transaminases, as well as imaging (ultrasound, CT, MRI) showing evidence of obstruction such as biliary dilation proximal to the site of obstruction. Once established, it is important to triage the urgency of biliary decompression. Patients with asymptomatic jaundice do not require biliary decompression unless their hyperbilirubinemia interferes with chemotherapy (i.e., some chemotherapeutic regimens require a normal bilirubin). Patients with intolerable jaundice or pruritus or poor nutritional status as a result of hyperbilirubinemia should have elective biliary decompression. Pruritus associated with hyperbilirubinemia can be debilitating and has been managed with antihistamines, corticosteroids, cholestyramine, and other medications with only limited success, thus relief of obstruction is the mainstay of treatment. Those patients with signs and symptoms of acute cholangitis require urgent drainage and intravenous antibiotics.

Biliary decompression can be accomplished by endoscopic (endoscopic retrograde cholangiopancreatography, [ERCP]) (Fig. 25.4), percutaneous (interventional radiology), or surgical means. With the development and advances in endoscopic and percutaneous drainage procedures, surgical decompression is rarely utilized in modern clinical practice.

Endoscopic and percutaneous biliary drainage procedures have their individual risks and benefits. Common risks to both procedures include infection, stent occlusion, or migration. Endoscopic drainage via ERCP is considered relatively noninvasive, highly successful, and well tolerated. However, it carries risks associated with bleeding specifically from the biliary sphincterotomy site, intestinal perforation, and procedure-related pancreatitis (generally 3–10%) [85]. Percutaneous transhepatic cholangiography (PTC) eliminates the potential for acute pancreatitis and intestinal perforation and requires less sedation than ERCP. It is highly successful especially in high-volume centers through, may be challenging in cases where there is no significant intrahepatic biliary dilation to serve as a target. This means biliary drainage may be necessary in the setting of gastroduodenal obstruction, although new endoscopic ultrasound-guided adjunct techniques allow for biliary drainage in this setting (i.e., choledochoduodenostomy). Percutaneous biliary drains can be replaced and exchanged with relative ease. Nevertheless, percutaneous biliary drainage does leave the patient with an external drain which may impact their quality of life, while endoscopic drainage obviates the need for external catheter drainage.

ERCP-placed stents can be plastic or metal (self-expandable metal stents, SEMSs). The advantage of plastic stents is their low cost and relative ease of removal, if needed, at the time of surgery. Plastic stents, however, have shorter life span due to their smaller diameter (maximum diameter of plastic stent is 12 French, 4 mm) and may not maintain patency long enough to allow for neoadjuvant chemoradiotherapy in cases of pancreatic adenocarcinoma. Up to 55% of patients with ERCP-placed biliary plastic stents for malignant obstruction from pancreatic cancer require additional ERCP intervention for biliary obstruction or cholangitis related to stent occlusion [86]. Biliary SEMS do not adversely affect surgical outcomes and are preferable for more durable stenting, however are more expensive upfront. Decision analysis studies have not shown plastic stents to be more cost effective for pancreatic cancer [87, 88].

While biliary metal stents have been shown to be superior to plastic stents for decompression caused by pancreatic adenocarcinoma by maintaining patency longer, stent occlusion may still develop. In a multicenter study of 241 patients treated with metal stents as part of preoperative protocol, 5.8% of patients developed stent occlusion with a median time to occlusion of 6.6 months (range 1–20 months) [89]. Mechanisms of metal and plastic stent malfunction differ.

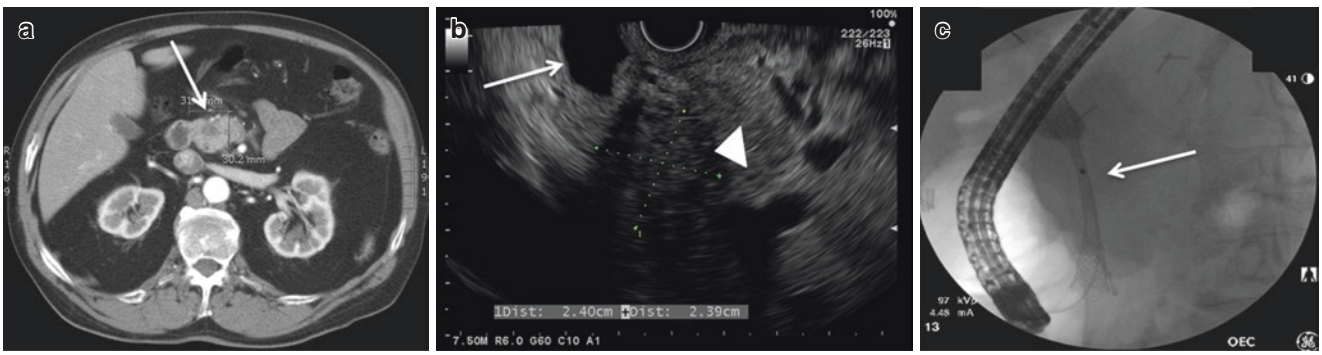

Fig. 25.4 Obstructing pancreatic adenocarcinoma. (**a**) A 2.5-cm ill-defined lesion in the pancreatic head on CT scan; (**b**) pancreatic head mass (*arrowhead*) resulting in biliary obstruction and dilated common bile duct (*arrow*) on endoscopic ultrasound; and (**c**) tight fluoroscopic waist within ERCP-placed self-expanding biliary metal stent for obstructing pancreatic head mass

Plastic stent may occlude due to formation of bacterial biofilm and sludge formation, or they may migrate proximally or distally and no longer span the obstructing biliary stricture. There may be tumor overgrowth covering the proximal end of the stent. Covered metal stents may have similar mechanisms for occlusion. Uncovered metal stents are less likely to migrate; however, there may be tumor or benign reactive tissue ingrowth, in addition to biofilm and sludge formation.

Patients with occluded biliary stents or percutaneous catheters may present with recurrence of their original symptoms that led to interventions, as well as jaundice, fever, chills, and abdominal pain. Intermittent obstruction due to sludge and stones is possible. Imaging studies may show biliary dilation. Lack of pneumobilia (an expected finding in patients with patent biliary stents) may be a radiologic clue to biliary obstruction, but it is neither a specific nor sensitive finding.

The acute management of biliary obstruction with cholangitis in patients with malignancy is not different from patients with benign disease and involves management of sepsis with intravenous fluids, broad-spectrum antibiotics, and prompt establishment of biliary drainage via endoscopic or percutaneous methods. Endoscopic management options of occluded stents include removal of the occluded stent and placement of new covered or uncovered metal stent or plastic stent. Percutaneous catheter exchange in patients with prior PTC is the treatment of choice for acute cholangitis.

Management of these complicated patients necessitates a multidisciplinary team with input from medical, radiation, and surgical oncologists, the patient's primary care physician, interventional radiologists, and gastroenterologists to determine the optimal management strategy.

Hepatic Decompensation

Fulminant Hepatic Failure

Fulminant hepatic failure due to malignant infiltration of the liver is rare, but has been reported in case studies in the literature [90, 91]. These case reports have centered on diffuse infiltration by tumor cells (lymphoma and infiltrative carcinoma) rather than numerous hepatic metastases and could not be distinguished on cross-sectional imaging. Though it is a rare complication of metastatic liver disease, it carries a high mortality. Many chemotherapeutic agents may have hepatotoxic manifestations and thus the selection of the appropriate antineoplastic regimen must take into account the patient's baseline liver chemistries and associated comorbidities. Polypharmacy which many oncologic patients are the victims of is also an additional cause of abnormal liver chemistries. Most often, drug induced liver injury is self-limited (possibly limited to abnormal liver chemistries) and can be reversed with removal of the offending agent; however in rare cases, it may lead to fulminant hepatic failure with a decline in synthetic liver function.

In the setting of fulminant hepatic failure, patients usually present with jaundice, altered mental status or bleeding. The etiology is due to replacement or destruction of hepatocytes with tumor resulting in the compromised liver synthetic function. As a result, there is decreased synthesis of albumin and oncotic proteins which promote the development of ascites, decreased conjugation of bilirubin resulting in jaundice, or obstruction of intrahepatic ducts from tumor resulting in jaundice, bleeding due to elevations in the prothrombin/international normalized ratio (INR) due to derangements in the synthesis of key clotting factors, and eventually decreased ability of the liver to process toxins resulting in encephalopathy. Cerebral edema may develop in patients with acute liver failure leading to increased intracranial pressure and risk of subsequent herniation. The early recognition of acute liver failure is critical given its overall dismal prognosis if left untreated. In cases in which the etiology is nonmalignant, lifesaving measures such as orthotopic liver transplantation should be considered. Clearly, when malignancy is the underlying etiology, recognition of hepatic decompensation is a sign of terminal prognosis.

Laboratory evaluation initially should include liver enzymes including AST, ALT, alkaline phosphatase, GGT, total and direct bilirubin, albumin, prothrombin time/INR, serum chemistries, ammonia level, and viral serological tests. Cross-sectional imaging may show diffuse hepatic involvement by tumor resulting in loss of hepatic reserve (Fig. 25.5). It is important to exclude a secondary etiology to liver dysfunction that may be at play and cause the sudden

Fig. 25.5 Innumerable intrahepatic masses due to metastatic colorectal cancer resulting in jaundice and compromised synthetic liver function. (Courtesy of Alice Fung, MD, Oregon Health & Science University)

imbalance in liver synthetic function. Thus, formal hepatology consultation is appropriate. Additionally, it is important to exclude extrahepatic biliary obstruction as an underlying etiology for jaundice as therapy for biliary obstruction may lower the patient's bilirubin enough to allow for further oncologic treatment. In this vein, cross-sectional imaging (CAT scan of the abdomen or preferably MRI/MRCP) and consultation with gastroenterology and interventional radiology may benefit the patient. In general, progressive malignant liver dysfunction leads to hospice. Nonetheless, it is important to exclude reversible contributing illness to a patient's declining hepatic function.

Ascites

Ascites, defined as free intra-abdominal fluid accumulation, may be a result of malignancy with and without liver involvement. Ascites may be detected due to the presence of bloating, abdominal distention, and dullness to abdominal percussion. Abdominal ultrasound may be required to determine with certainty that fluid is present within the abdomen. Breast, lung, colon, and pancreatic primary malignancies are most commonly complicated by ascites [92]. In addition, significant intrahepatic tumor burden may result in liver dysfunction and subsequent ascites.

While there are many possible etiologies of ascites including cirrhosis, Budd-Chiari syndrome, pancreatitis, congestive heart failure, etc., we will focus on malignancy-related ascites. The serum-ascites albumin gradient (SAAG) has been used to categorize ascites; it is able to differentiate portal hypertensive ascites vs. nonportal hypertension-related ascites with a diagnostic accuracy of 97% [93, 94]. In a patient with new ascites, a diagnostic paracentesis is performed in order to calculate this gradient and help identify the etiology. The pathophysiology of malignant ascites is not related to portal hypertension, and thus these patients have a SAAG <1.1 g/dL. There are several pathophysiologic mechanisms of malignant ascites including lymphatic obstruction by lymphoma or mass, low serum oncotic pressure due to various causes (including massive liver metastases with liver dysfunction), and exudation of proteinaceous fluid from tumor cells that line the peritoneum in patients with peritoneal carcinomatosis [92].

Unlike portal hypertension-related ascites in which the underlying pathophysiology involves a complex interplay of splanchnic and systemic vascular resistance coupled with sodium and water retention which in general responds to dietary sodium restriction, diuretics (such as furosemide or spironolactone), or intravascular volume expansion (intravenous albumin), the mainstay of the management of malignant ascites is large-volume paracentesis for symptomatic relief. This can be arranged as an outpatient via ultrasound guidance with interventional radiology or with gastroenterology. The timing and frequency of paracenteses are dictated by patient symptoms. In general, peritoneal catheters are avoided in these patients given the potential for loss of protein and hydration as well as potential to seed the catheter track. In patients with malignancy ascites related to ovarian cancer, tumor debulking and chemotherapy may be effective in ascites management (Sugarbaker technique).

Urgent Issues Related to Enteral Feeding Devices

Many patients with cancer battle with issues related to malnutrition. This is due to the prolonged negative balance of protein and energy below metabolic requirements that result from the tumor itself or intensity of treatments. As such, cancer patients may require supplemental enteral feeding via nasoenteral tubes, gastrostomy, or jejunostomy feeding devices. The type of enteral access is usually decided upon based on the length of anticipated need. Nasoenteric tubes are commonly used and have the benefit of relative ease of placement. Such tubes are utilized when the feeding is predicted to be approximately less than 30–45 days. Dislodgement of nasoenteric tubes is usually not of major concern as they are easily replaced and dislodgement can be prevented by the use of a nasal bridle device [95–97].

When long-term enteral access devices are needed, gastrostomy or jejunostomy tubes are the most common methods. Such devices may be placed by endoscopic (gastroenterology), percutaneous (interventional radiology), or surgical means. Once placed, it is recommended that these devices should not be removed for at least 6 weeks to allow the enterocutaneous fistula to mature prior to intentional removal. The patient should be made aware that once removed, the track can take up to 2 weeks to close and to expect some leakage during this time frame.

Enteral access replacement may be urgently needed in cases of unintentional dislodgement in order to prevent closure of the enterocutaneous fistula. If dislodgement occurs within 14 days of insertion, this track may not be mature, and "blind" reinsertion of a tube via the fistula should not be attempted to avoid erroneous placement of the enteral device into the peritoneal cavity [98]. The patient should be advised to call the provider who initially inserted the enteral device to arrange for reinsertion or present to the emergency department. In cases where the track is mature (>6 weeks from placement) and the device is dislodged, a temporary tube

such as a Foley balloon catheter can be inserted in the track to maintain patency until the appropriate replacement device can be inserted and secured. This can be done at the bedside in any emergency. By directly addressing the dislodged tube in a timely manner, the clinician may be able to avoid the need for an endoscopic, interventional radiology, or surgical replacement procedure.

Summary

GI-related oncologic emergencies represent a small proportion of all oncologic emergencies and those herein discussed include GI bleeding, luminal and biliary obstruction, acute pancreatitis, hepatic decompensation, and dislodgement of enteral devices. These disorders require early recognition allowing clinicians, patients, and families to be aware of these possibilities and aid in early identification of such emergencies. A multidisciplinary approach to such patients and conditions, including consultation with oncologic, radiation oncologic, surgery, primary care, and gastroenterology to assist in management (which may include a therapeutic GI procedure), is likely to lead to optimal patient outcomes.

The Acute Abdomen

26

Linda Ferrari and Alessandro Fichera

Case Study

History present illness: A 57-year-old woman presenting to the emergency department for persistent left upper quadrant pain, nausea, and weight loss. Pain is constant in nature over the past 5 days. She has been having regular bowel movements, formed stools without blood or mucus.

Laboratory values: Hb 107 g/L (120–150 g/L), CRP 272 mg/L (0–4 mg/L).

Abdominal radiograph: No features of intestinal obstruction or perforation

CT chest, abdomen, and pelvis: Highly suspicious wall thickening involving the distal transverse colon/splenic flexure with extramural involvement of the left colic and inferior mesenteric vein. Regional lymph nodes are enlarged. There is an associated collection measuring approximately 4.8 × 4.1 cm which is suggestive of focal tumor perforation. There is surrounding inflammatory changes and it is difficult to exclude associated peritoneal involvement. Such collection is abutting the gastric wall with edematous wall thickening and a likely perforation into the gastric lumen. No definite distant metastatic disease.

Past medical history: Seven years before, patient had right breast invasive cancer. She underwent mastectomy with implant-based reconstruction, axillary clearance, chemoradiation therapy, and adjuvant endocrine treatment with Letrozole (aromatase inhibitor).

Hospital course: The patient underwent upper endoscopy which showed a lesion within the stomach, biopsy showing inflammatory tissue and a colonoscopy which showed a transverse colon lesion consistent with invasive adenocarcinoma. The patient was then discharged awaiting colorectal multidisciplinary team discussion and readmitted 2 days later for nausea and inability to tolerate oral intake. An extended right hemicolectomy and en-block partial gastrectomy was recommended and performed as a combined procedure involving an upper and lower gastrointestinal surgeons. The anastomosis was protected with a diverting loop ileostomy.

Key message: Patients with cancer involvement of multiple organs should be management in the context of a multidisciplinary team to optimize outcome.

Small Bowel Obstruction

Small bowel obstruction (SBO) is a common condition responsible for over 300,000 annual hospital admissions in the United States [1], associated with 10% of mortality rate and significant morbidities among survivors [2]. Small bowel obstruction occurs when the flow of contents through the intestines is interrupted. Simple SBO may lead to intestinal dilation, hypersecretion, bacterial overgrowth, and vascular impairment. Closed loop obstruction may immediately compromise mesenteric blood supply leading to ischemia, necrosis, and perforation with subsequent peritonitis.

Patients with SBO are often unable to tolerate oral intake for several days and they should be considered as patients having acute intestinal failure, which has been defined by the European Society of Coloproctology as "the reduction of function below the minimum necessary for the absorption of macronutrients and/or fluids and electrolytes, such that intravenous supplementation is required to maintain health and/or growth" [3].

The most frequent cause of small bowel obstruction is abdominal adhesions following previous surgeries which account for approximately 60–70%, followed by hernia in approximately 15% of the cases, including incisional, inguinal, and parastomal [4]. Cancer has been estimated to be the third cause of small bowel obstruction, with approximately 8–10% cases. In the National Audit for Small Bowel Obstruction (NASBO) [5], 205 (8.4%) out of 2431 patients had cancer as the primary cause of small bowel obstruction. Of those, disseminated intra-abdominal malignancies are the most common cause responsible for 70% of cancer cases, followed by right colon cancer (24.4%), while primary tumors of the small bowel represent only 4.9%.

Malignant bowel obstruction (MaSBO) has been defined "as definitive diagnosis of intestinal obstruction distal to the ligament of Treitz and the presence of incurable intra-abdominal malignancy or extraabdominal primary (melanoma, breast, and lung) with known intraperitoneal metastases" [6]. MaSBO is a life-threatening complication of intraabdominal cancer, with an incidence between 5% and 51% in patients with ovarian carcinoma and between 10% and 28% in patients with gastrointestinal malignancies [7]. Different mechanisms are responsible for the occlusion, such as a cancer obstructing the lumen, impaired intestinal motility, medication-related (i.e., opioid analgesics) and radiation therapy complications or sequelae [8].

Obstruction in a patient with previous history of cancer or with a recent diagnosis may also be secondary to benign causes including fibrosis or stricture, postoperative adhesions or ileus, medication-related dysmotility or treatment-related edema. Generally, MaSBO of the small bowel is more likely to be multifocal and extrinsic; the most common cancers leading to this are metastatic ovarian and colorectal adenocarcinoma with peritoneal implants, direct invasion, or carcinomatosis [8]. Other causes of SBO may include an obstructing mass which can be extrinsic and compressing the bowel (e.g., carcinomatosis with implants) or less frequently intrinsic (e.g., small bowel adenocarcinoma, lymphoma).

Goals of therapy for SBO include relieving symptoms of nausea, vomiting, and pain, allowing oral intake. These goals, in the case of MaSBO or primary small bowel cancer, should be weighed against the high morbidity and mortality rate in this cohort of patients [5, 9–11] and palliative care considerations should be entertained. The goals for treatment should be individualized for each patient especially for those facing end-of-life decisions.

A palliative, nonoperative approach should be offered for patients with poor performance status, multiple sites of obstruction, carcinomatosis, or ascites. Recurrent obstruction may be as high as 50% in these patients. Patients not suitable for surgical intervention or who refuse surgical care, should receive pharmacological therapy with the aim to reduce bowel edema and inflammation and improve symptoms such as pain, nausea, and vomiting. Combination of medications including antiemetics, drugs to reduce gastrointestinal secretions, anticholinergic medications to reduce peristalsis and secretions, opioids for pain control, and corticosteroids to decrease the tumor-associated edema (and act as antiemetics) are also widely utilized. Patients who are not operative candidates and do not respond to medical management may still benefit from endoscopic stenting or gastrostomy tube placement. The goals of medical management should be aimed at limiting pain and improving quality of life. In cases of overwhelming cancer burden or transition to comfort care, artificial nutrition and hydration may be discontinued. The focus of care should be shifted to symptom relief and hospice care.

Clinical Presentation and Initial Assessment

Patients often initially present with nausea, emesis, and abdominal pain. Depending on the location of the obstruction as well as whether the obstruction is partial or complete, patients may or may not initially present with abdominal bloating and distention. A patient with a proximal obstruction or tumor encasing the proximal small bowel may not present with distention, but rather severe nausea and emesis, often projectile in nature.

Clinical evaluation of SBO should begin with identifying the where, when and how of the patient symptoms—where the obstruction is (proximal or mid-small bowel versus large bowel), when symptoms started and their duration, and how complete (or partial) obstruction appears to be. A clinical estimate of the level of obstruction may be made from the frequency of the pain (short intervals tend to correlate with SBO versus longer intervals typical of large bowel obstruction) and distention. The duration of symptoms should include any gradual or sudden changes in bowel habits, flatus, or bowel movements. Complete vs. partial obstruction may be inferred from current bowel activity.

Pain from SBO tends to be periumbilical and colicky initially. The colicky nature of pain is secondary to compensatory increased intestinal motility that initially occurs to counter the obstruction. However, such intestinal activity eventually subsides, and there are fewer contractions especially with the use of opioid analgesics. As hypoactivity ensues and intraluminal pressure increases, microvascular perfusion may be compromised. Obstipation may follow with complete bowel obstruction.

Differential diagnosis should include adhesive disease and hernias (including abdominal wall and internal hernias) as well as constipation, volvulus, stricture, and ileus, due to chronic narcotic use, are not uncommon scenario in cancer

patients. Additionally, neurogenic and metabolic etiologies should be entertained. History of surgeries, radiation, and any anticholinergic medications should be elicited.

A complete physical exam includes evaluation for hernias and a rectal exam to evaluate for the presence of stool in the rectal vault, obstructing rectal lesions, fecal impaction or occult bleeding. If the patient has an ileostomy or colostomy, the stoma should also be digitally examined to ensure no obstruction at the level of the fascia. Abdominal distention may lead to dyspnea. Jaundice should raise concern for involvement of the hepatobiliary tree including lymphadenopathy at the porta hepatis or liver metastases.

The most important task in the emergency department (ED) assessment is to determine whether the patient requires immediate operative intervention. Indications for immediate operative intervention include incarcerated abdominal hernia, frank peritonitis, sepsis, or other findings concerning ischemic bowel disease. Fever, tachycardia, increased fluid requirement, leukocytosis, and certainly signs of sepsis should raise concern for abscess or perforation in the setting of obstruction.

Diagnostic Workup

The diagnosis of SBO is often based on clinical findings. Predictors of small bowel obstruction are: previous history of abdominal surgery, obstipation, and abnormal distension on examination [12]. Minimum laboratory tests include blood count, lactate level, and a metabolic panel.

Abdominal X-ray should be the first imaging modality for most patients with suspected SBO coming from the emergency department due to widespread availability, easy interpretation, and low cost. A single upright chest X-ray may exclude subdiaphragmatic free air, and it is a simple and quick test to determine the need for an emergency exploration, especially in patients whose exam is unreliable (unresponsive, immunosuppressed, chronic opioid users, or elderly patients). A plain abdominal film might be used initially to localize the level of obstruction (proximal vs. distal) and also as baseline for patients' undergoing nonoperative management. It is the authors' preference to initially evaluate patients with SBO with plain abdominal films unless there is a clear indication for emergency exploration. Air-fluid levels and bowel loops in the same place on supine and upright films indicate fixed adhesions.

Computed tomography (CT) scan with IV contrast is an important tool in diagnosis and preoperative planning in stable patients without indication for emergency exploration. CT may delineate a lesion, level of obstruction, and the severity of obstruction including any transition point (Fig. 26.1) or closed loop obstruction, and other radiographic evidence of ischemia. CT should be taken with intravenous contrast while enteral contrast is not necessary. In high-grade SBO, oral contrast may delay diagnosis and cause patients discomfort and possibly even complications such as aspiration.

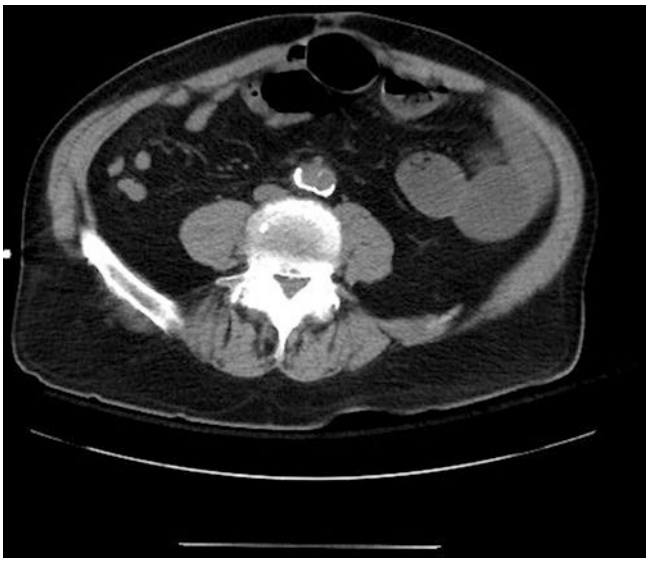

Fig. 26.1 CT—transition point in setting of complete mechanical small bowel obstruction

The most common cause of bowel obstruction is postoperative adhesions as previously mentioned. The diagnosis of adhesions is made by locating the point of obstruction (transition between dilated and decompressed bowel) without identifiable cause of obstruction, such as neoplasm, hernia, or inflammatory condition. The ability of CT scan to identify a transition zone ranges from 63–93% [12, 13].

CT imaging features in small bowel obstruction indicating the need for surgical intervention include small bowel ischemia, closed loop obstruction, and perforation. Contrast-enhanced CT has a sensitivity of 75–100% and specificity of 61–93% in the identification of ischemic SBO [12, 13]. Radiographic signs of ischemia in bowel obstruction include decreased enhancement, mucosal thumbprinting, bowel wall thickening, mesenteric edema, and pneumatosis intestinalis. Closed loop obstruction results from obstruction of a segment of bowel at two different points, and, as a consequence, this obstructed segment of small bowel is isolated from remainder of the gastrointestinal tract. CT scan might differentiate between complete and partial bowel obstruction. Complete SBO is characterized by an abrupt cutoff with air-fluid levels that suggests complete obstruction, while the presence of gas throughout the colon suggests ileus versus partial obstruction. CT is also particularly important for those patients with past medical history of cancer, to assess potential recurrence and/or progression and allow proper cancer staging in the setting of SBO.

Although CT is considered a first-line test in diagnosis, it exposes patients to radiation and it is an expensive modality. Abdominal ultrasound (US) has been investigated as a possible option for diagnosing SBO. The advantages of US include rapid diagnosis and serial assessments without radiation exposure. However, it is operator-dependent. Comprehensive and bedside US have sensitivity ranging between 83% and 97.7%, and specificities between 84% and 100% [14]. US has potential limitations such as if the presence of air limits visualization of underlying structures in the presence of dilated loops of bowel. Further testing then becomes necessary when US fails to identify the cause of the SBO. Diagnostic US findings for SBO include distended and collapsed bowel segments in close proximity, free peritoneal fluid, inspissated intestinal content, paradoxical peristalsis, highly reflective fluid within the bowel lumen, bowel wall edema between serosa and mucosa, or a fixed aperistaltic loop concerning ischemia.

Treatment and Operative Intervention

All patients should have initial management with volume resuscitation, bowel decompression, and rest with correction of metabolic abnormalities (Fig. 26.2). Unless there is indication for immediate intervention, initial pharmacologic management should be centered on antiemetics, analgesics, and antisecretory medications. Prospective trials have evaluated the use of somatostatin with decreased distention and nausea, allowing for effective nasogastric tube decompression and symptom management in poor surgical candidates [15, 16]. After the initial conservative management, different treatments options are available depending on the etiology of SBO.

Adhesive Disease Current guidelines for the management of adhesive SBO recommend that in the absence of signs of bowel ischemia, non-operative management should be tried for up to 3 days as long as the patient does not deteriorate with symptoms suggesting intestinal ischemia [17, 18]. Nonoperative management consists on bowel rest and decompression using nasogastric tube or long intestinal tube, analgesics, and antiemetics if necessary. Conservative management is effective in approximately 70–90% cases [16].

Possible adjunct to nonoperative management is the use of water-soluble contrast agent (WSCA). WSCA creates an osmotic gradient, which then increases bowel transit. A recent systematic review and meta-analysis [19] has shown that WSCA has a sensitivity of 92% and a specificity of 93% in predicting resolution of bowel surgery and that diagnostic accuracy increased significantly if abdominal X-ray is taken after 8 h from the administration. The administration of WSCA reduces the need for surgery (OR 0.55, $p = 0.003$), length of stay (−2.18 days, $p < 0.00001$), and time to resolution (−28.25 h, $p < 0.00001$), without adding morbidity and mortality.

If conservative approach fails after 3 days and/or patients deteriorates, the next step is surgical management, which includes adhesiolysis and small bowel resection if necessary. Although laparoscopic approach might be considered as first option, especially in patients with previous minimally invasive approach, the feasibility of a laparoscopic procedure in the setting of an abdomen with distended loops of bowel and potential complex adhesions could increase the risk for patients' complications. Some authors have reported an increased risk of bowel injury and need for bowel resection in laparoscopic adhesiolysis compared to open approach (53.3% lap vs. 43.3% open). Predictors for a successful laparoscopic adhesiolysis are the following: ≤2 previous laparotomies, appendectomy as past operation, no previous median laparotomy and single adhesive band [20]. Laparoscopic approach should be carefully evaluated in patients with previous oncologic abdominal procedure, where extensive procedure might have created adhesions too extensive to be treated with a minimally invasive approach.

Small Bowel Intussusception In patients with a small bowel intussusception indications to proceed immediately to the operating room include clinical or radiographic evidence of bowel compromise and peritonitis. In patients with no prior history of operation, cancer should be suspected and a low threshold for prompt surgical exploration is indicated. It is a rare cause of SBO in adults (1–5%) but is secondary to a malignant disease in up to 50% of patients [21] (Figs. 26.3 and 26.4). Strangulation is associated with high mortality rates and conventional signs of vascular compromise may not always be present [22]. Bowel telescoping will then lead to venous and lymphatic congestion, edema, and potentially ischemia and perforation.

Intussusception in the adult necessitates surgical intervention with resection of the involved bowel segment and identification of lead point after thorough evaluation of bowel and peritoneal cavity. Based on fact that half of adult patients with intussusception were noted to have a malignant neoplasm [21], appropriate oncologic workup should be completed.

Intraoperatively, bowel viability may be determined by observation of peristalsis and color, Doppler ultrasound, and occasionally IV fluorescein and Wood lamp. Tumor debulking or even an oncologic resection may be indicated. Operative decision will include whether or not to restore bowel continuity, fashion a stoma, or leave the operating room and come back for a second look laparotomy in the unstable patient. If the lesion is felt to be a primary and resectable neoplasm in a stable patient, the tumor should be resected with a wide margin proximal and distal to the lesion of normal bowel including the lymph node basin for the involved segment.

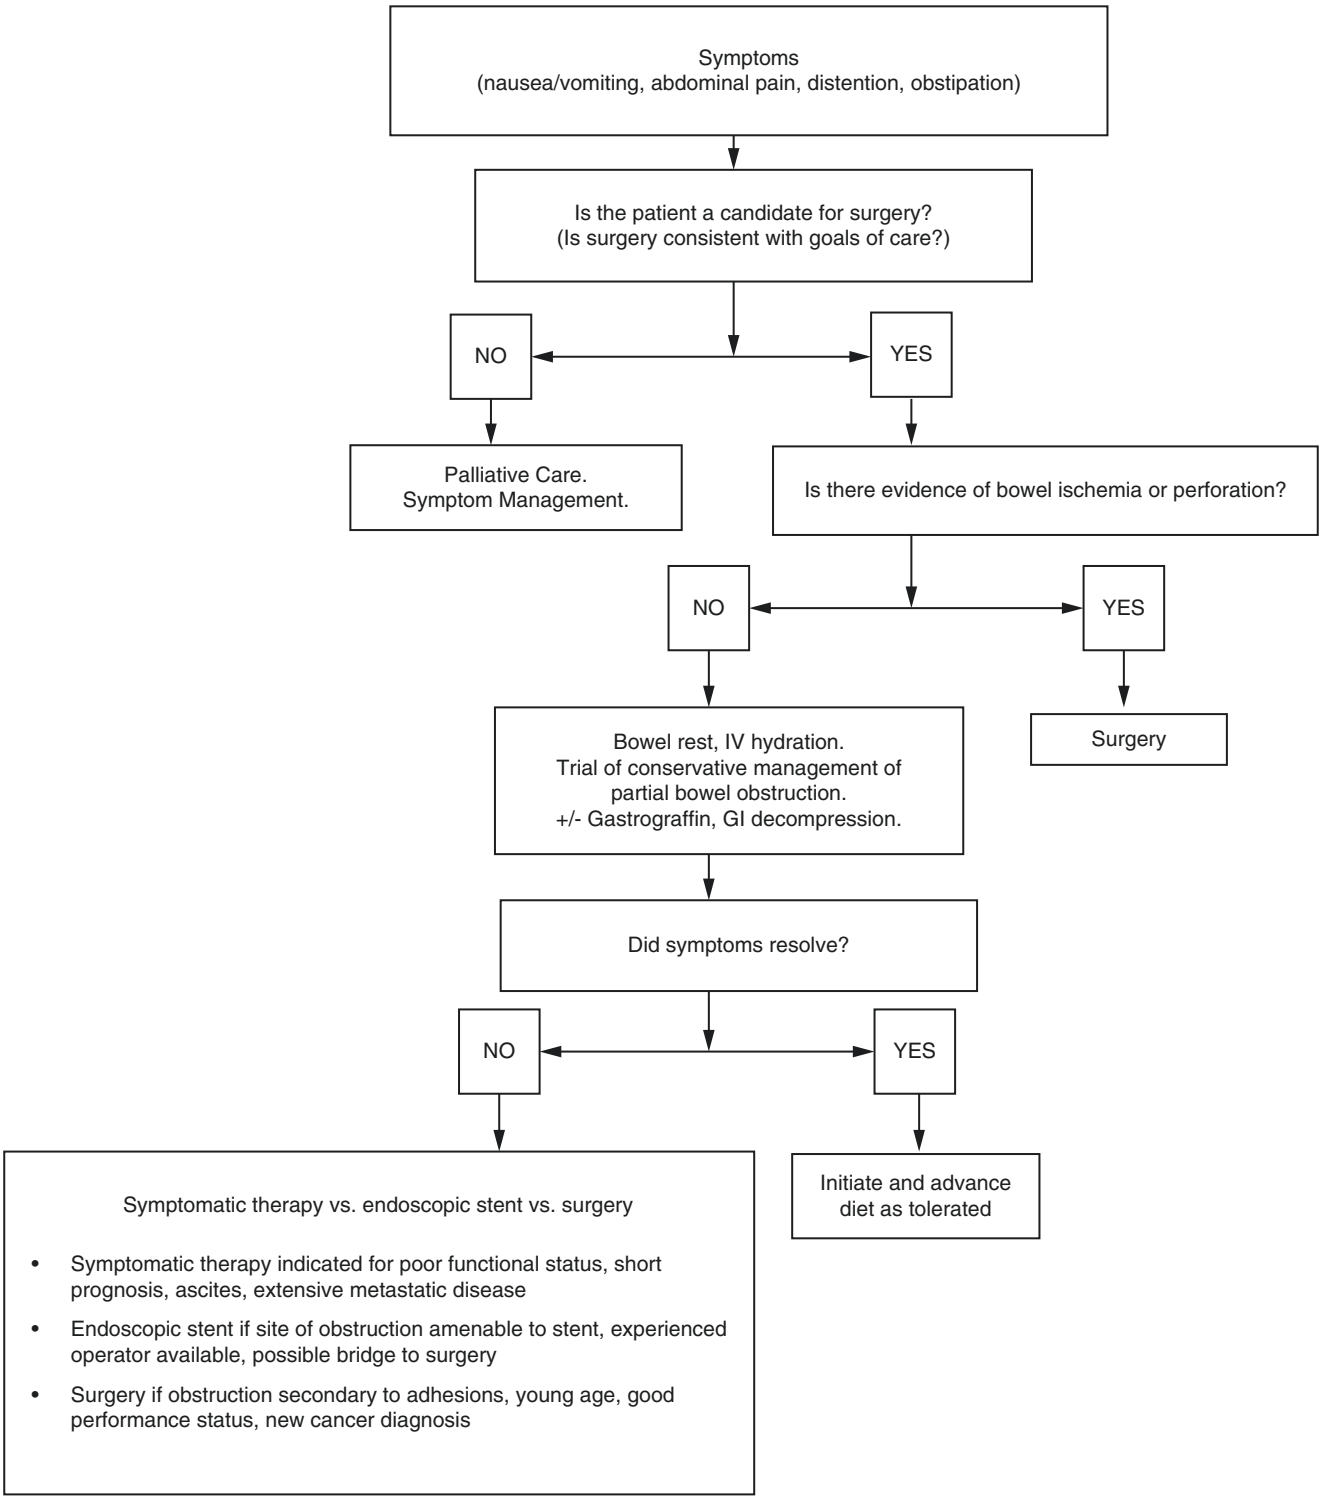

Fig. 26.2 Small bowel instruction intervention algorithm

Fig. 26.3 Intraoperative intussusception with bowel telescoping

Fig. 26.4 Intraoperative intussusception with malignant lead point

Malignant Small Bowel Obstruction (MaSBO) MaSBO is usually caused by locally advanced or metastatic cancer and management is still controversial. Song et al. [9] looked at patients with MasBO from the National Surgical Quality Improvement Program between 2005 and 2017 and compared them to patients with SBO from nonmalignant causes. Of 46,706 patients studied, 1612 (3.5%) had MaSBO. The oncologic patients were more likely to have recent weight loss (22% vs. 4.0%, $p < 0.001$), severe hypoalbuminemia (18.6% vs. 5.2%, $p < 0.001$) and pancytopenia (with anemia defined as hematocrit <30%, thrombocytopenia defined as $<150 \times 10^9$ cells/L and white blood cell count $<4 \times 109$ cells/L). The risk of mortality for the oncologic patients was higher (OR 3.3, $p < 0.001$). Factors associated with 30-day postoperative mortality are advanced age (over 70), wound status, impaired functional status, low body mass index, low album level (<2.5 g/dL) as a surrogate of nutritional status, smoking history, thrombocytopenia ($<150 \times 10^9$ cells/L) and elevated WBC count ($\geq 11 \times 10^9$ cells).

Considering the high morbidity and mortality, small bowel obstruction in the setting of suspected or known malignancy should include consideration and discussion of goals of care and quality of life in view of life expectancy and overall disease burden. Efforts should be made early in the hospital course to work collaboratively for a treatment plan incorporating patient and family values with a clear discussion regarding the limitations of surgery. A comprehensive and multidisciplinary treatment plan should include consultation with medical oncologists, palliative care specialists, gastroenterologists, radiologists, and dieticians. Considering all factors, up to 50% of patients with MaSBO are deemed inoperable [10]. Surgery might increase overall survival, but morbidity (7–44%), mortality (6–32%), readmission (38–74%) and recurrent obstruction (6–47%) are frequent [23]. In case of surgery, bowel resection when feasible provides the best outcome. Otherwise, bypass should also be considered as well as fecal diversion and gastrostomy tubes for decompression [10].

A palliative, nonoperative approach should be offered for patients with poor performance status, multiple sites of obstruction, carcinomatosis, or ascites. Further details about palliative management of malignant small bowel obstruction can be found in the chapter dedicated to palliative treatment.

Large Bowel Obstruction Large bowel obstruction (LBO), while less common overall than SBO, is more likely to be secondary to malignancy. While SBO can be managed conservatively in approximately 70% cases, LBO requires surgical intervention in 70% of cases. In Western countries, colorectal cancer represents the most common cause of mechanical obstruction and is responsible for 50% of LBO. LBO occurs at initial presentation in 10% of patients with colorectal cancer [24]. The second most common cause for LBO is diverticular strictures accounting for 10–20% of cases. Colonic volvulus, generally cecal or sigmoid, is the third most common cause and it is responsible for 10–17% of cases. Among sites for colonic obstruction, the sigmoid colon is the most common followed by descending colon, splenic flexure, transverse colon, rectum, and ascending colon.

Clinical Presentation and Initial Assessment

Patients with LBO may present similarly to patients with SBO with abdominal distention, absence of flatus and/or bowel movements, and crampy abdominal pain. Physical examination should again pay special attention to evidence of dehydration and hypovolemia as well as hernias with a rectal exam performed to evaluate for the presence of stool in the vault, an obstructing rectal mass or bleeding.

Diagnostic Evaluation

Large bowel obstruction should be worked up similar to SBO. Plain abdominal X-ray has 84% sensitivity and 72% specificity and might be able to reveal the degree of bowel distension and sometimes it is able to localize the presence of transition point. CT abdomen-pelvis with venous contrast is the modality of choice to evaluate the extent and level of obstruction (Fig. 26.5). CT is estimated to have 95% sensitivity and 93% specificity for the diagnosis of LBO.

Treatment and Operative Intervention

All patients should be placed on bowel rest with fluid resuscitation. If the ileocecal valve is incompetent and there is also small bowel distention, nasogastric decompression may be indicated. Partial colonic obstruction should be attempted to be treated conservatively with the hope that a patient can undergo a single-staged planned oncologic resection in an elective situation.

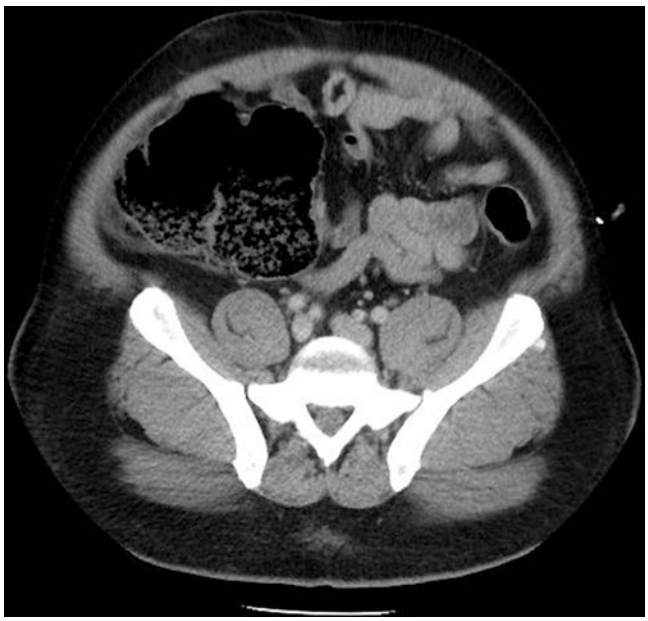

Fig. 26.5 CT—right colon/cecal dilatation in setting of partial large bowel obstruction

For primary right- sided obstructive colon cancer, general consensus is for primary resection with ileocolonic anastomosis [25, 26]. For unresectable right-sided colon cancer, a side-to-side anastomosis between terminal ileum and transverse colon as an internal bypass can be performed. Alternatively, in the presence of small bowel distension, a loop ileostomy for palliation should be considered. Optimal management of left-sided malignant bowel obstruction is controversial and it is dictated by patient and disease-related factors and available resources and technical skills. Recommendation and guidelines in the literature are at best conflicting [27]. Different surgical options have been explored for left-sided malignant bowel obstruction including primary resection, with or without anastomosis, subtotal colectomy, with or without anastomosis, or diverting stoma. Emergency surgery is associated with mortality rates three times higher than elective resection [28]. Primary resection with/without anastomosis is the most frequent recommended procedure [27]. A Hartmann's resection is an option when the anastomosis is associated with prohibitive risks.

An additional option to bridge to definitive surgery is the use of self-expanding metallic stents (Fig. 26.6) and therefore a gastroenterology consultation may be indicated in the ED. Stent placement can be followed by elective colonic resection (Fig. 26.7) after medical optimization, bowel preparation cancer staging [29, 30]. Self-expanding colonic stents as a bridge to surgery have resulted in high rates of primary anastomosis, less permanent stomas, and lower wound infection rates, without increasing the rate of mortality compared to emergency surgery. In one study, nearly three quarters of patients in the stented left-sided large bowel obstruction group underwent successful one-stage operation versus closer to one quarter with emergency surgery. Initial technical success rates have been quoted as high as 90% with prompt colonic decompression and overall 30-day mortality of less than 2% [31]. Another important advantage of stenting is that it allows a complete cancer staging and discussion at the multidisciplinary meeting, with consensus about the most appropriate treatment and a definitive procedure performed by the appropriate surgeon. Despite all these theoretical advantages, a recently published phase III randomized controlled trial comparing stenting as a bridge to surgery with emergency surgery for left-sided malignant bowel obstruction did not show a difference in mortality at 1 year [32].

Palliative Treatment At present, majority of guidelines recommend stenting as treatment of choice in case of need for palliative management of left-sided malignant bowel obstruction. In the palliative setting, colonic stenting results in faster resumption of oral intake and shorter hospital stay.

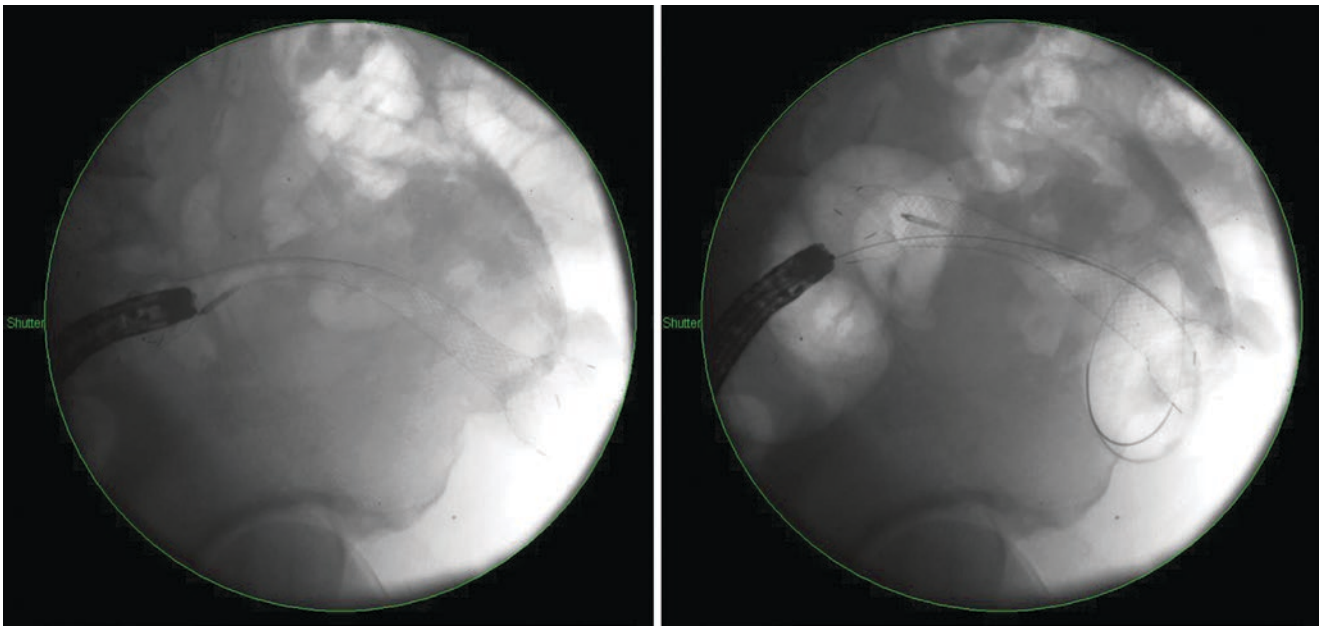

Fig. 26.6 CT—stent deployed in malignant bowel obstruction

Fig. 26.7 Large bowel specimen with stent in place

Complication rates are relatively low and include stent migration, perforation, and re-obstruction [27, 31].

Main reason to prefer stent is that as previously mentioned, emergent colonic surgery is associated with a significantly higher morbidity and mortality than elective surgery. The bowel is often friable and distended with significant stool burden, and the patients are often malnourished. Postoperative complications, re-obstruction rates, and readmission rates are high for palliative malignant bowel obstruction surgery [27]. Should the decision be made to proceed with operative intervention without colonic stenting, patients should be selected based on favorable prognostic features.

Gastric Outlet Obstruction

Advanced malignant disease in the upper gastrointestinal tract might result in gastric outlet obstruction (GOO). The most common malignancies that result in GOO are pancreatic cancer, which accounts for 15–20% cases, periampullary cancer, advanced gastric cancer, duodenal/jejunal cancer, and lymphoma. Less commonly, GOO is seen in cases of gallstone impaction, gastric polyp prolapse, PEG tube migration, or gastric volvulus.

Clinical Presentation and Initial Assessment

Patients will present with progressive symptoms, predominantly nausea and vomiting, often projectile, weight loss, abdominal discomfort, cachexia, poor nutritional status, and severe dehydration. Early symptoms may include early satiety and bloating. Patients with malignant disease may have a fairly short duration of symptoms, and symptoms may be intermittent until obstruction is complete.

Median survival in the palliative setting is usually only 7–20 weeks, and for this reason, it is important to reestablish oral intake quickly to improve quality of life.

Diagnostic Evaluation

Initial evaluation should begin with an abdominal X-ray film. Patients with gastric outlet obstruction will have a gastric bubble if no nasogastric tube has been placed, with little or no air in the small bowel or the colon on radiographic imaging. CT imaging offers the advantage of identifying the obstruction and underlying lesion(s).

Barium swallow is a dynamic study and may distinguish GOO from delayed gastric emptying, anastomotic leak, or gastric fistula in the postoperative setting. Evaluation will generally proceed to EGD for both diagnosis and potential treatment with balloon dilation or self-expanding metallic stenting to improve gastric emptying. Differential diagnosis should include gastric dysmotility as well as dysphagia secondary to chemoradiation and anastomotic leak or gastric fistula in the postoperative setting.

Treatment and Operative Intervention

Therapy for GOO should begin with nasogastric decompression and fluid resuscitation and correction of the metabolic sequelae are often seen. Surgical and GI consultation should be sought for treatment planning.

Surgical gastrojejunostomy, often with a concomitant biliary bypass, is currently performed by a laparoscopic or open approach. Patients who are not considered surgical candidates are referred for endoscopic stent placement. For this reason, majority of the studies that have compared surgical jejunostomy and endoscopic stenting have been biased based on patients' selection. Self-expanding stent is inserted under combined endoscopic and fluoroscopic guidance to restore the patency of the stomach and/or duodenum and allows patients to receive nutrition and hydration via the oral route. Stents have the advantages of a short hospital stay compared to palliative surgery but they are also associated with complications such as bleeding, migration, obstruction, and fractures [33]. Palliative resection results in better long-term outcomes in appropriate candidates. Stenting it is also recommended in patients with GOO secondary to newly diagnosed gastric cancer as a temporizing measure prior to complete oncologic workup and treatment. In patients with GOO secondary to lymphoma, chemotherapy is the first-line indicated therapy. Symptom recurrence with duodenal stents is seen in the majority of patients who survive longer than 6–12 months, and the stent often needs to be replaced.

EUS-guided gastroenterostomy consists on placing a lumen-apposing metal stent under endoscopic ultrasound guidance. According to a recent meta-analysis, EUS-guided gastroenterostomy is an effective and safe minimally invasive treatment for benign and malignant GOO [34]. In contrast with endoluminal stents, EUS-guided gastroenterostomy involves placement of a fully covered stent during a bypass, and the stent is placed away from the tumor, without the risk of tumor ingrowth and occlusion.

Gastrointestinal Bleeding

Acute gastrointestinal bleed (GIB) (Fig. 26.8) may present in the patient with an established cancer diagnosis in a variety of clinical settings. Also, GIB can be the first symptom which allows the diagnoses of cancer such as colorectal cancer.

Bleeding can also be exacerbated or caused by medications such as bevacizumab, nonsteroidal anti-inflammatory drugs (NSAIDs), and anticoagulants, commonly used medications in cancer patients. Anti-inflammatories are often used to treat pain for patients with advanced cancer, but their antiplatelet and anticoagulant properties should be considered. Moreover, patients with advanced cancer are often on anticoagulants such as warfarin or enoxaparin, and the considerations of the risks of further bleeding against the risks of deep venous or pulmonary thromboembolism should be considered. Among patients on anticoagulation, patients with cancer develop bleeding complications at a higher rate than those without cancer.

The effect of chemotherapy agents and radiation therapy on thrombocytopenia should also be considered, as this may increase the risk of bleeding. If considered a critical contributor, these agents may be held to allow bone marrow recovery and resolution of thrombocytopenia.

Bleeding is categorized as upper gastrointestinal bleeding (UGIB) proximal to the ligament of Treitz [35, 36] versus lower gastrointestinal bleeding (LGIB) [37]. UGIB is associated with significant morbidity and differential includes neoplasms including GISTs, esophageal and gastric varices, Mallory-Weiss tears, acute hemorrhagic gastritis and gastric/duodenal ulcers. Diagnostic differential for LGIB includes diverticular disease, neoplasms, radiation proctitis, inflammatory bowel disease (IBD), ischemia, infectious colitis, anorectal disease, coagulopathy, and arteriovenous malformations.

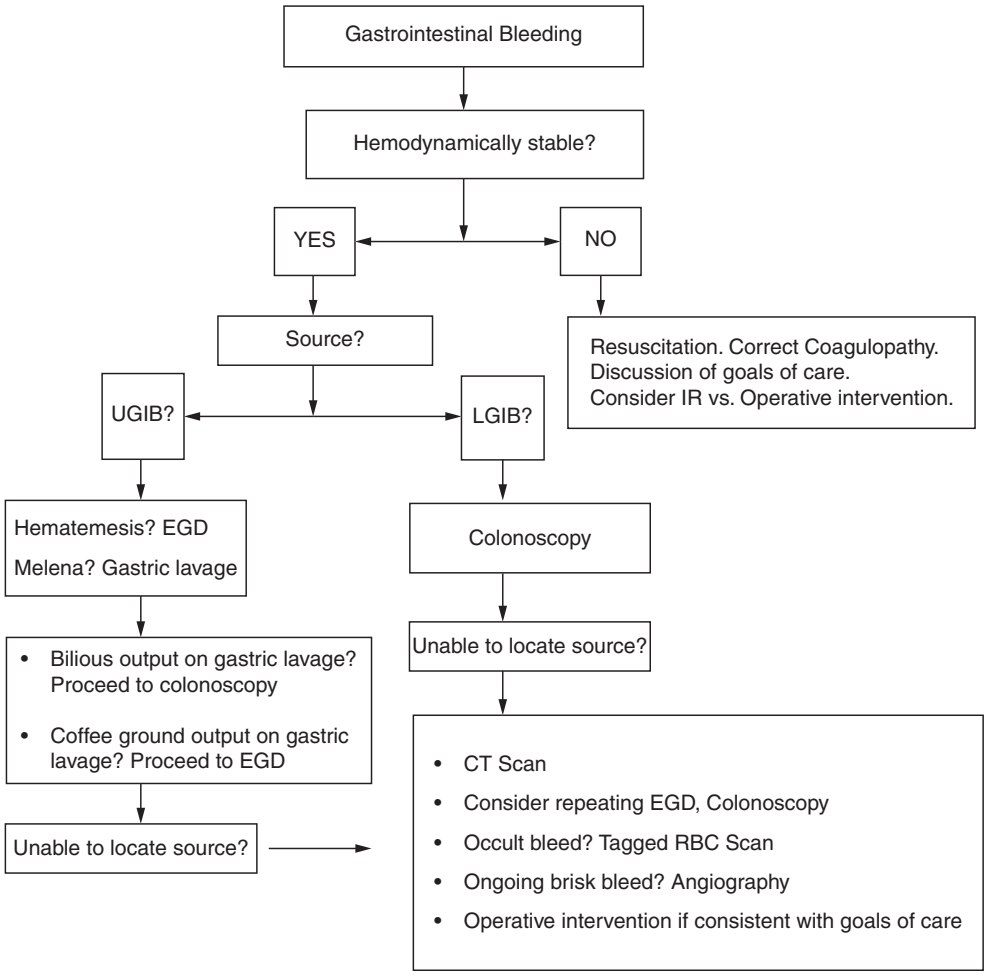

Fig. 26.8 Assessment and management of gastrointestinal bleeding algorithm

Clinical Presentation and Initial Assessment

Patients with acute UGIB may present with melena or hematemesis. Patients may endorse symptoms of hypovolemia including dizziness, dyspnea, or chest pain. Hematochezia might occur as well in patients with coagulation disorders. A history of prior episodes of bleeding is significant as 60% of patients may bleed again from the same source. Special attention should be paid to use of medications that may interfere with coagulation or alter hemodynamic response like beta-blockers. Malignancy should be suspected in a patient with a history of smoking, alcohol abuse, or *H. pylori* infection. Physical exam should begin with vital signs and an evaluation of hypovolemia. Evidence of jaundice, caput medusae, or ascites may point to hepatic disease.

Patient with acute LGIB presents usually with hematochezia, which can be mixed with clots as well. A history of previous episodes of rectal bleeding is common, or recent proctological interventions such as hemorrhoidectomy. LGIB might be present also in patients with previous pelvic malignancies treated with radiotherapy or radiochemotherapy. Radiation might cause radiation proctitis, which can be distinguished in two forms, the acute and chronic. Acute radiation proctitis occurs within 3 months of radiation therapy in 13% of patients, it is usually self-limiting and characterized by diarrhea, urgency, tenesmus, and rectal bleeding. Chronic radiation proctitis occurs in 5–10% of patients after 3 months of therapy completion and the typical complaint is rectal bleeding, while less frequent might cause rectal stenosis. Ulcerative or Crohn's colitis can present with bleeding and are a risk factor for the development of colorectal cancer. In case of rectal bleeding, a complete abdominal exam including rectal exam with proctoscopy should be performed. Even in this case, attention should be paid to current patient's medications.

Diagnostic Evaluation

Initial ED evaluation should include physiological parameters, such as heart rate, blood pressure, respiratory rate, oxygen saturation, and mental status. Initial management should

ensure adequate IV access, either large-bore peripheral IV lines or a central line as indicated. Resuscitation is essential and coagulopathies should be corrected. Urinary output and mental status, markers of end-organ perfusion, should be monitored. Early GI consultation is recommended.

A nasogastric tube is often placed for gastric lavage. A positive aspirate of gross blood or coffee-ground appearance, indicated UGIB should be followed by esophagogastroduodenoscopy (EGD). A bilious aspirate should be followed by colonoscopy. Blood tests should include hemoglobin level, hematocrit, platelet count, prothrombin time, INR, BUN, creatinine, electrolytes, liver function tests, and blood cross-matching.

Treatment and Operative Intervention

PPI therapy should be initiated at the suspicion for UGIB. Crystalloids are recommended for volume replacement.

Coagulopathies should be corrected in these cases. Severe thrombocytopenia may lead to spontaneous GI hemorrhage. The American Society of Clinical Oncologic recommends a prophylactic platelet threshold for transfusion: 10,000/μL for adult patients with leukemia, and multiple studies have found decreased frequency and severity in gastrointestinal hemorrhage in patients with platelet counts above 20,000/μL versus 10,000/μL or 5000/μL [38].

EGD and colonoscopy may be both therapeutic and diagnostic. Erythromycin can be given prior to endoscopy to facilitate gastric emptying, decreasing the need for multiple endoscopic evaluations. Therapeutic endoscopic maneuvers include injection of vasoconstrictors or sclerotherapy, thermal coagulation, and mechanical occlusion of bleeding sites (including clips, bear claw, and over-the-scope clips application). In cancer patients with cirrhotic liver disease, rubber banding, sclerotherapy, or temporizing balloon tamponade may control hemorrhage.

Early endoscopy (<8–12 h from presentation) is ideal in a stable patient and will offer the best chance of localizing and identifying the source of GI bleed and intervening. Therapeutic intervention has been demonstrated to be most successful when performed within 12 h, with declining results as time passed. If bleeding recurs despite medical and endoscopic therapy, endoscopic intervention should be repeated.

Other options for localizing GIB include CT angiography (CTA) which may provide helpful information, including hyperdensity of the mesenteric fat, contrast enhancement of the bowel wall, vascular extravasation of contrast, thickening of the bowel wall, polyps, tumors, and vascular ectasia. CTA has been noted to detect arterial bleeding at rates as low as 0.5 mL/min.

Mesenteric angiography (for bleeding of at least 1 mL/min) may be useful for poor operative candidates where other measures have failed. Should embolization also fail during mesenteric angiography, and operative intervention ultimately required, the area may be still be identified for operative intervention with methylene blue infusion. A recent meta-analysis evaluating embolization therapy versus surgery for non-variceal UGIB found a lower complication rate for embolization (31% vs. 50%) but a higher rate of rebleeding (35% vs. 18%) [39]. Arteriography may be therapeutic but requires active bleeding of more than 1 mL/min and should be reserved for patients with massive, ongoing bleeding in whom endoscopy is not feasible or colonoscopy fails to reveal the source of the hemorrhage.

Colitis may also be a special consideration in the patient undergoing radiation or chemotherapy. Radiation enteritis may lead to LGIB with a minority of patients even requiring hospitalization. Most patients with colonic ischemia respond to bowel rest, IV fluids, and antibiotics.

Rectal bleeding in patients with radiation proctitis might require endoscopic and/or surgical treatment when conservative measures have failed [40]. The aim of endoscopy is to obliterate telangiectasias using different methods, such as laser and argon plasma coagulation, radiofrequency ablation, or cryotherapy. Endoscopy is successful in up to 90% of patients and it is considered the most effective treatment for bleeding associated with radiation proctitis. Surgery is the last resort and can include fecal diversion via colostomy or ileostomy to rescue bleeding and improve other associated symptoms such as tenesmus, incontinence, and pain. More aggressive procedures like proctectomy have a high complications rate (morbidity 15–80% and mortality 3–9%) and they are rarely performed [40].

Indications for emergent operative intervention include hemodynamic instability despite maximal support measures, substantial bleeding (six units or more), or bleeding that is not controlled endoscopically. Rarely, operative intervention is required. Surgical options for LGIB include segmental colectomy when the source of bleeding can be localized. If no source is found, but bleeding is clinically significant and ongoing, a subtotal colectomy should be performed with an end ileostomy and rectal pouch leaving the patient in discontinuity. Such a situation is associated with high morbidity and mortality in the unstable patient.

Neutropenic Enterocolitis

Patients with cancer often develop neutropenia secondary to chemotherapy treatment. Neutropenia is defined as an absolute neutrophilic count (ANC) <1000/mm^3. In patients with hematologic malignancies, neutropenia is commonly due to

failure of bone marrow and therapies damaging the marrow, while in patients with solid tumors, chemotherapy may lead to underproduction of hematopoietic cell lines. Neutropenic patients often have mucositis resulting in reduced enteric mucosal barrier function allowing for bacterial translocation culminating in a characteristic pathology entity known as neutropenic enterocolitis (NEC) or typhlitis.

According to a recent retrospective review [41] conducted over 8 years at MD Anderson Cancer Center among 49,244 patients with neutropenia, 2.7% of them developed NEC, of those 94 (70%) had hematologic malignancies and 48 (36%) underwent hematopoietic stem cell transplantation. Neutropenic enterocolitis can be fatal, resulting in sepsis (11%), focal bowel ischemia and necrosis (2%) and perforation (2%) in patients who are severely immunosuppressed. The cecum is the most commonly affected site likely secondary to its vascularization and distensibility. NEC is associated with severe morbidity and mortality between 74% and 97% [41, 42]. Factors associated with worse prognosis are age, severe neutropenia (<500 cells/μL), prolonged neutropenia, and concomitant systemic infection.

Clinical Presentation and Initial Assessment

The classic presentation of neutropenic enterocolitis is a patient with absolute neutrophil count <1000 cells/μL, new onset abdominal pain and fever. Most commonly, it occurs 2–3 weeks after receiving cytotoxic chemotherapy, when neutropenia is most profound. Patients may have nausea, vomiting, diarrhea, and hematochezia. Patients with prior episodes of neutropenic enterocolitis are at risk for recurrent episodes.

Differential diagnosis should include graft-versus-host disease after allogeneic hematopoietic cell transplantation, infectious colitis including *Cytomegalovirus* and *C. difficile* colitis and *Norovirus* in immunocompromised hosts, ischemic colitis (more commonly left-sided), appendicitis and colonic pseudoobstruction.

Diagnostic Workup

Evaluation should begin with full infectious workup including blood and stool cultures and *C. difficile* toxin assays. Endoscopic findings include ulcerative inflammation, which is present in 50% of cases, nonulcerative inflammation and active bleeding in 40% of cases; colonoscopy is relatively contraindicated and may cause cecal perforation. CT findings may include bowel wall thickening, mesenteric stranding, bowel dilatation, mucosal enhancement, and pneumatosis (Fig. 26.9).

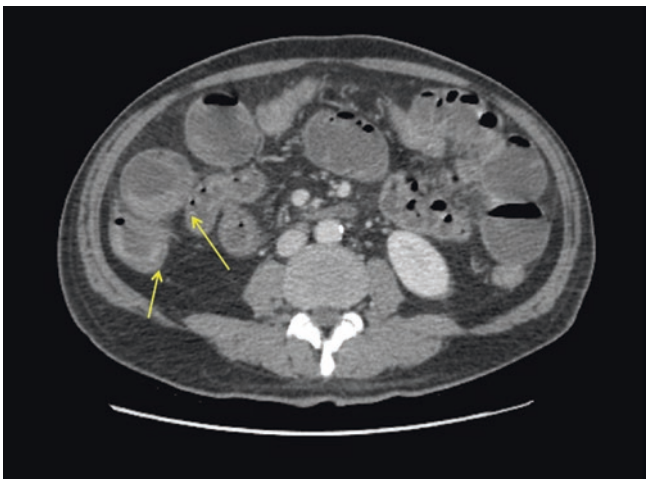

Fig. 26.9 CT—small bowel dilation with diffuse wall thickening and mucosal enhancement in setting of neutropenic enterocolitis

Treatment and Operative Intervention

First-line treatment is conservative, with nasogastric decompression when significant small bowel dilatation is present, intravenous fluids, nutrition support, broad-spectrum antibiotics and blood product support as needed. Broad-spectrum antibiotic regimen should include agents that are active against *Pseudomonas aeruginosa*, *Escherichia coli*, other enteric Gram-negative bacilli and anaerobes. Coverage for *C. difficile* should be included until ruled out. Antifungal coverage should be considered. Antidiarrheal and narcotic pain medications should be avoided. Sepsis is the most common cause for mortality in this group of patients.

Surgical intervention is indicated for patients with bowel ischemia, free perforation, peritonitis, and severe hemorrhage despite correction of coagulopathies. The most common operation performed is right hemicolectomy with formation of stoma, while extended colectomy is rarely indicated and should be avoided.

Radiation Enteritis

Radiation enteritis is an inflammatory process within the intestinal mucosa as a consequence of radiation exposure and might affect both small and large bowel injury due to radiotherapy leading to inflammation, edema, and decreased bowel function. Radiation enteritis and radiation proctitis may be classified as acute versus chronic and localized versus diffuse. Despite attempts to protect the bowel from the radiation field when possible, gastrointestinal epithelium is especially susceptible to injury given its high proliferative rate. Cell damage in the mucosa leads to microvascular damage, inflammation, edema, and decreased absorptive capac-

ity. Initial damage may be seen in hours and continue for weeks. Damage to the intestinal mucosa may lead to fibrosis, perforation, fistulae, or abscess.

There is a lack of consensus about diagnostic criteria and often symptoms are underreported by patients; as a consequence, only a minority of them are reviewed by gastroenterologists. Despite lack of diagnosis, 90% of patients have gastrointestinal symptoms in the first few weeks after receiving abdomino-pelvic radiotherapy and almost 90% of patients report chronic changes in their bowel habit with important consequences in quality of life due to these symptoms. Acute radiation enteritis may occur even transiently in up to 75% of patients undergoing radiation therapy for abdominal and pelvic cancers. Chronic radiation enteritis may occur in closer to 5–20% of patients.

Risk factors might be divided in treatment-related, including radiation dose and fractionation schedule, treatment field size, and intestinal volume irradiated, which is the main determinant of intestinal radiation-induced toxicity. Other patient-related risk factors are: diminished splanchnic perfusion secondary to diabetes mellitus or atherosclerotic disease, hypertension, tobacco smoking, BMI lower than 30, and advanced age. Concomitant administration of chemotherapy is another factor due to increased toxicity for cumulative effect. Previous abdominal surgery is an increased risk of radiation enteritis due to fixed bowel position due to postoperative adhesions.

Clinical Presentation and Initial Assessment

Acute radiation enteritis usually occurs in the second week post-radiotherapy, with a peak on week 4–5. Clinical manifestations include nausea, vomiting, abdominal pain, diarrhea associated with blood and mucus, hematochezia, tenesmus, and incontinence. A possible consequence is systemic sepsis due to bacterial translocation through inflamed intestinal mucosa. Given the diminished absorption compounding an often preexisting cancer-related anorexia, patients often are dealing with malnutrition and weight loss. Patients may bleed from ulceration, have signs of systemic infection from abscess, or present with obstructive symptoms.

Chronic enteritis might occur between 2 months and several years after radiation treatment. Symptoms include chronic abdominal pain, malabsorption, and weight loss, diarrhea, GI bleeding and complications secondary to strictures and fistulae such as obstruction and perforation. Differential diagnosis for the chronic form includes tumor recurrence, inflammatory bowel disease (ulcerative colitis, Crohn's disease), ischemic colitis, infectious colitis, STD proctitis (e.g., lymphogranuloma venereum, and gonorrhea) and inflammatory bowel syndrome.

Diagnostic Evaluation

The diagnosis of acute form of radiation enteritis is mainly clinical, with symptoms previously described, which might be only transient. If more severe a CT scan should be performed to rule out possible serious consequences, such as perforation and or obstruction.

The chronic form might be diagnosed again through patients' symptoms. Obtaining an abdominal CT/MRI is important because both sensitive at delineating subtle strictures and mucosal irregularities as well as cancer recurrence. A further endoscopy evaluation might be considered to evaluate mucosal inflammation, ulceration and possible fistulae/stricture formation, while allowing biopsies.

Treatment and Operative Intervention

Most cases of acute radiation enteritis are self-limited and should be treated with supportive therapy. Initial management includes elemental diet, IV hydration, bowel rest and ± octreotide. Diarrhea can be reduced by the use of bulking agents and antimotility drugs such as loperamide. Antispasmodics and antiemetics might be used for symptoms relief; opioids have the dual function of reducing intestinal motility and providing analgesia. Persistent symptoms despite medical interventions may require a surgical consultation.

In patients with chronic radiation enteritis, conservative management as above is employed, however, up to 30% require surgical intervention to relieve symptoms of obstruction secondary to luminal strictures and to manage fistulae, perforation and/or bleeding. As this is a high-risk intervention with postoperative morbidity and mortality rates of 30% and 5% respectively [43], patient selection is important.

Conclusion

The acute abdomen in the patient dealing with either a new or established cancer diagnosis creates a special challenge for the ED physician to individualize decisions, keeping in mind goals of care and the patient's wishes. One must maintain a broad differential diagnosis and cancer-specific considerations need to be maintained. Evaluation and intervention should proceed with the involvement of a multidisciplinary care team with the patient in the center. Caring for a cancer patient in the setting of an acute change in condition ultimately means knowing not only what is possible surgically and what is indicated medically, but also evaluating what is right for the patient overall.

Diarrhea

27

Sai-Ching Jim Yeung

Case Study

A 36-year-old woman with stage 2 HER2-positive hormone receptor-negative breast cancer presented to the emergency department (ED) with the complaint of severe diarrhea. She had completed neoadjuvant chemotherapy and underwent a left mastectomy with left axillary lymph node dissection 10 days ago. She had mild postoperative wound erythema and had completed a 7-day course of oral clindamycin 3 days ago. She started having watery diarrhea 3 days ago. Two days ago, she was evaluated by the surgical team in the clinic. A stool sample was sent for *Clostridium difficile* toxin analysis, and she was empirically started on metronidazole 500 mg orally every 8 hours. Over the last 2 days, her diarrhea worsened, and she had abdominal cramping and 10 stools in the past 24 hours. She was feeling weak in general and nauseous. She denied having fever, chills, or vomiting.

In the ED, her vital signs demonstrated mild tachycardia and orthostatic hypotension. She had hyperactive bowel sounds, and her abdominal examination was otherwise benign. The report of the analysis of the stool sample collected 2 days ago showed the presence of *C. difficile* toxin. Her laboratory results were remarkable for a serum potassium of 3.0 mEq/L, BUN 40 mg/dL, and creatinine 1.4 mg/dL. Abdominal radiographs showed a normal nonobstructive gas pattern.

She was admitted for intravenous fluid hydration and potassium replacement. Stool samples were collected for stool culture. Metronidazole was discontinued and she was started on oral vancomycin.

Clostridium difficile diarrhea or colitis is a well-known complication of antibiotic therapy. It is also a very common problem among cancer patients. Metronidazole treatment for *C. difficile*, however, has an approximately 20% rate of lack of clinical response and an approximately 30% rate of recurrence within 3 months. Despite the suboptimal response rate, metronidazole is a popular first-line treatment because it is safe and inexpensive.

Introduction

Diarrhea is the frequent (>3/day) passage of loose stools with urgency and it is a frequent comorbidity or adverse event associated with therapy in cancer patients. Diarrhea in cancer patients can be severe; chronic diarrhea can cause electrolyte abnormalities and malnutrition, while uncontrolled diarrhea may lead to severe dehydration and life-threatening electrolyte abnormalities. The need to avoid recurrence of serious diarrheal complications may lead to dose reduction or discontinuation of antineoplastic therapies. Cancer patients frequently present to emergency departments with acute or chronic diarrheal complications that require emergency evaluation and treatment.

Causes

Although cancer and cancer treatments (chemotherapy, radiation therapy, surgery, targeted therapy, and immunotherapy) can cause diarrhea, emergency care providers must not forget causes unrelated to cancer, e.g., lactose intolerance, food poisoning, viral gastroenteritis, side effects of noncancer drugs, inflammatory bowel disease, and irritable bowel syndrome (Table 27.1). In this chapter, we focus on causes relevant to cancer and cancer treatments.

Paraneoplastic Syndromes

Certain cancers can cause diarrhea by secreting hormones, including the following:

- Carcinoid tumors
- Zollinger-Ellison syndrome (gastrinoma)

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_27

Table 27.1 Causes of diarrhea in cancer patients

Paraneoplastic	Carcinoid syndrome, medullary carcinoma of the thyroid, neuroendocrine pancreatic cancer (e.g., gastrinoma, VIPoma), pheochromocytoma
Surgery related	Celiac plexus block, cholecystectomy, esophagogastrectomy, gastrectomy, pancreaticoduodenectomy (Whipple procedure), intestinal resection (malabsorption due to short bowel syndrome), vagotomy
Chemotherapy	Bortezomib, capecitabine, 5-fluorouracil, oxaliplatin, carboplatin, cisplatin, cytosine arabinoside, cyclophosphamide, daunorubicin, paclitaxel, docetaxel, doxorubicin, methotrexate, irinotecan, topotecan
Targeted therapy[a]	Gefitinib (25.9–51.6% [all grades], 1–3% [grades 3–4]) Erlotinib (18%, 3%) Afatinib (95%, 14.4%) Lapatinib (64%, 10%) Trastuzumab (3.7% [grades 3–4]) Pertuzumab (3% [grades 3–4]) Imatinib (20–26%, 1%) Pazopanib (<4%, 52%) Regorafenib (34–40%; 5–8%) Cabozantinib (64%, 12%) Sunitinib (44%, 5%) Sorafenib (55.3%, 7.8%) Ziv-afilbercept (69.2%, 19%) Axitinib (11% [grades 3–4]) Vandetanib (74%, 10%) Everolimus (1% [grades 3–4]) Vemurafenib (5–6% [all grades]) Dabrafenib (1% [all grades]) Trametinib (45–50%, 4%) Selumetinib (45–50%, 4%) Crizotinib (60% [all grades]) Bortezomib (51%, 8%)
Radiation	Radiation therapy to the abdomen, pelvis, para-aortic lymph nodes, lumbar spine
Bone marrow transplantation	Conditioning chemotherapy, total body irradiation, graft-versus-host disease after allogeneic transplants
Immune checkpoint inhibitors	Ipilimumab, cemiplimab, pembrolizumab, nivolumab, atezolizumab, durvalumab, avelumab
Infection	Neutropenic colitis, typhlitis, and ileitis. *Bacillus cereus*, *Campylobacter*, *Clostridium difficile*, *Clostridium perfringens*, *Cryptosporidium*, *Cytomegalovirus* (in immunocompromised hosts), *Giardia lamblia*, *Rotavirus*, *Salmonella*, *Shigella*
Fecal impaction	Liquid stool going around impacted stool
Comorbid diseases	Diabetes mellitus, hyperthyroidism, gastroenteritis, irritable bowel syndrome, celiac disease, inflammatory bowel disease (Crohn's disease, ulcerative colitis), HIV/AIDS
Psychological factors	Stress

[a]Percentage inside parentheses indicate the incidence rate of diarrhea of all grades and severe grades (grades 3–4), respectively

- VIPomas (neuroendocrine tumors that secrete vasoactive intestinal peptide [VIP] autonomously)
- Medullary thyroid carcinoma (sporadic, familial, or as part of Sipple syndrome—multiple endocrine neoplasia type 2 [MEN 2])
- Neuroendocrine tumors as part of the Wermer syndrome—multiple endocrine neoplasia type 1 (MEN 1)

Treatment-Induced Diarrhea

Chemotherapy In addition to cancer cells, cytotoxic chemotherapy kills other fast-growing cells, including those in the intestinal lining. Certain chemotherapeutic agents can disturb the normal absorptive and secretory functions of the small bowel, resulting in treatment-related diarrhea [1]. Chemotherapeutic agents associated with severe diarrhea include fluorouracil, capecitabine, irinotecan, paclitaxel, docetaxel, vinorelbine, etc. The diarrhea caused by irinotecan may be delayed (>24 hours) and severe. Concomitant abdominal or pelvic radiotherapy and recent gastrointestinal surgery are associated with increased severity of treatment-induced diarrhea. Platinum-based therapy can cause diarrhea and colitis. The median time from starting platinum-based therapy to colitis is 66 days and the median duration is 20 days. Colonoscopic examination will show ulceration in one third of cases and nonulcerative inflammation in the colonic mucosa in another one third of cases. About half of patients with platinum drug-induced colitis will require hospitalization [2]. Taxanes also causes colitis. The median time from start of taxanes to colitis symptom is 31 days. Colonoscopy also shows inflammation, but some patients have microscopic colitis [3].

Targeted Therapy Diarrhea induced by anti-EGFR targeted therapy is secretive and due to excess chloride secretion. For small molecule tyrosine kinase inhibitors (TKIs) targeting EGFR (see Table 27.1), diarrhea of all grades occurs in up to 60% of patients [4] and as many as 10% of cases are severe. Anti-EGFR monoclonal antibodies (mAb) (cetuximab and panitumumab) also causes diarrhea of all grades in almost a quarter of patients, and about 1–2% have severe diarrhea. In non–small cell lung cancer, the combination of anti-EGFR TKI and antiangiogenic therapy results in improved antineoplastic activity; however, these combinations also increase diarrhea [5]. The receptor tyrosine kinase (KIT) is highly expressed in the interstitial cells of Cajal, which are pacemakers for intestinal motility. Some TKIs

(e.g., imatinib and sunitinib) may induce diarrhea through inhibition of KIT. Cyclin-dependent kinase (CDK) 4/6 inhibitors (palbociclib, ribociclib, and abemaciclib) cause diarrhea of all grades in about 20% of patients and about 1% are severe [6]. PI3K inhibitors cause a watery nonbloody diarrhea in over 50% of patients [7]. An early onset, less severe diarrhea may occur at a median of 1.9 months after starting PI3K inhibitors, while a more severe diarrhea occurs at a median of 7.1 months after starting treatment. The severe diarrhea is due to immune-mediated colitis [8].

Radiotherapy External beam radiotherapy (XRT) that focuses on the thoracolumbar spine, para-aortic lymph nodes, abdomen and pelvis for cervical cancer, colorectal cancer, prostate cancer, metastatic cancer, etc., as well as pelvic brachytherapy exposes part of the intestine to radiation, causing diarrhea. Diarrhea is the most common side effect of radiotherapy. The overall prevalence of irradiation-induced diarrhea may reach 35% [9]. Factors predicting the severity of XRT-induced diarrhea include total radiation dose, fractionation, the volume of bowel exposed to radiation (related to the method of radiation such as intensity-modulated and image-guided radiotherapy [IMRT] and volumetric modulated arc therapy [VMAT]), and concurrent chemotherapy. Acute diarrhea may occur at about 10 Gy and last up to 3 months after treatment. Chronic radiation enteritis can begin months or even years after treatment. Bile acid malabsorption may be responsible for some portion of radiation-induced diarrhea [10].

Surgery Surgical treatment of cancer may involve removal of sections of the gastrointestinal tract or organs with endocrine and digestive functions. These anatomic changes may limit the ability of the gastrointestinal tract to absorb certain nutrients, e.g., fat, resulting in diarrhea. Bowel resection lessens the surface area for reabsorption of water from food. Pancreatic cancer or its surgical treatment can compromise exocrine pancreatic function, leading to lack of digestion and malabsorption. Surgical changes in biliary anatomy will also compromise emulsification of fat by bile salts and consequently digestion and absorption of fatty food. Diarrhea is also part of the dumping syndrome which occurs when undigested food moves too rapidly into the small intestine. The dumping syndrome is associated with gastrectomy, gastroenterostomy, gastrojejunostomy, vagotomy, pancreaticoduodenectomy, and esophagectomy.

Bone Marrow Stem Cell Transplant In stem cell transplantation, conditioning chemotherapy and total body radiation may cause diarrhea. In autologous peripheral blood stem cell transplantation, in addition to side effects of chemotherapy and radiation, antimicrobials and infectious complications (including *C. difficile*) can also cause diarrhea. *Clostridium difficile* is the most common pathogen with an incidence of 15% during the 7 days before, and the first 30 days after, autologous transplant [11]. After allogeneic hematopoietic cell transplantation, diarrhea can be a frequent and serious complication. The diagnosis of acute graft-versus-host disease as the cause of diarrhea is straightforward if rash, jaundice, nausea, and vomiting are present [12]. However, if only diarrhea is present, the diagnosis may not be so obvious. Nevertheless, infectious (viral, bacterial, and parasitic) causes of diarrhea must be excluded before starting immune-suppressive drugs to treat graft-versus-host disease. Graft-versus-host disease-induced diarrhea usually occurs between 10 and 100 days after transplant and may resolve or become chronic.

Immune Checkpoint Therapy The most frequently seen GI complications secondary to immune checkpoint inhibitor therapy are diarrhea and colitis [13, 14]. Diarrhea can be due to immune-mediated colitis, which mainly involves the descending colon. Although immune checkpoint inhibitor-induced colitis is similar to inflammatory bowel diseases in many aspects, this immune-mediated adverse effect (irAE) can start acutely, progress rapidly, and lead to potential serious complications, including bowel perforation and death [15]. In some cases, enteritis without any colonic involvement may lead to small bowel obstruction [16].

Pancreatic toxicity associated with immune checkpoint inhibitor therapy is uncommon (<2%) and usually presents as a transient asymptomatic increase in lipase or amylase [17, 18]. Acute pancreatitis is rare [17–20] and patients present with a typical pancreatitis picture or with isolated symptoms of nausea, vomiting, fever, epigastric pain, or diarrhea [17]. Pancreatic exocrine insufficiency with or without pancreatitis manifests as irregular stools with diarrhea, discoloration of feces, and weight loss.

Infectious Enteritis Cancer patients are susceptible to infectious diarrhea. Bacteria, viruses, and parasites are all potential culprits. Neutropenia, immune suppressants, antibiotic use, and breakdown of natural defenses against microbes are all factors that increase the risk for cancer patients. *Clostridium difficile* diarrhea or colitis is a common problem.

In neutropenic patients, diarrhea, abdominal pain, and fever are symptoms of neutropenic enterocolitis. The cecum is frequently affected, often extending to the ileum, and occasionally the ascending and transverse colon.

Immunosuppression and frequent use of antibiotics in neutropenic patients alters the normal flora, leading to infection by resistant bacteria or unusual bacterial species. Bacteremia is frequent. Gram-negative rods (*Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella*, *Enterobacteriaceae*), gram-positive cocci (*Streptococci*, *Enterococci*), fungi (*Candida*, *Aspergillus*, or *Zygomycetes*), and viruses (cytomegalovirus) are causative organisms.

Enteral Feeding The composition of tube feeding formula may cause diarrhea. High rate of feeding and high osmolality increase diarrhea incidence. Patients selected for tube feeding are often hypoalbuminemic and data suggest that hypoalbuminemia predisposes to diarrhea by decreasing osmotic pressure and causing edema in the intestinal mucosa. Whether fiber-containing formulas can control diarrhea due to tube feeding is unclear. Contamination of feeding and food poisoning is a common problem if hand washing hygiene, clean mixing of formula, refrigerating mixed formula, and proper handling of the feeding equipment are not observed.

Celiac Plexus Block Celiac plexus block is commonly associated with a self-limiting acute diarrhea; however, occasionally, it may be persistent [21]. This diarrhea may be amenable to treatment with atropine.

Stress and Anxiety The stress and anxiety associated with cancer and treatments can cause diarrhea [22].

Medications Not Intended for Cancer Treatment Excessive doses of laxatives or magnesium-containing antacids commonly result in diarrhea.

Symptoms

Increased frequency and volume of bowel movements per day, incontinence, increase in ostomy output volume compared with baseline, the character of the fecal material (loose, very loose, watery), dizziness, abdominal pain, and fever are pieces of information needed for assessment of diarrhea severity [23]. These questions help classify diarrhea as complicated or uncomplicated and guide therapy [24]. Medication and dietary intake, as well as a history of recent travel, may provide additional etiologic clues. Weight loss and reduced urine output indicate the severity of diarrhea. Bloody stool, stool containing mucous, severe cramping, and abdominal pain are consistent with enterocolitis [25].

The National Cancer Institute Common Toxicity Criteria (version 4.03) is a frequently used standard tool for assessing diarrhea severity (Table 27.2) [26], but it does not include assessment of duration of diarrhea and stool volume. These severity parameters and other coexisting symptoms that are predictive of serious complications were addressed in the clinical practice guidelines [24, 27].

Grade 3 or 4 diarrhea is also classified as complicated. Diarrhea may be considered complicated and potentially serious if a cancer patient with Grade 1 or 2 diarrhea has the following: >6 loose bowel movements a day for >2 days, bloody stool or rectal bleeding, no urine output for >12 h, inability to drink for >1 day, weight loss due to diarrhea, diarrhea after several days of constipation, abdominal distension, or fever. In addition, moderate-to-severe cramping and nausea/vomiting, neutropenia, and the presence of systemic inflammatory response syndrome indicate potentially serious complications. Close monitoring and full investigation is warranted [24].

Diagnosis

Most chronic diarrheal paraneoplastic syndromes would have already been diagnosed in most cancer patients, and the diagnostic evaluation for the specific paraneoplastic syndromes is out of the scope of this chapter. For cancer patients presenting to EDs with diarrhea, the goal of rapid evaluation is to identify life-threatening conditions and complications requiring hospitalization. History should include medications (including antineoplastic agents), travel, and diet.

Table 27.2 National Cancer Institute grading of diarrhea

	Grade					
	0	1	2	3	4	5
Colostomy absent	None	Increase of <4 stools/day compared with baseline	Increase of 4–6 stools/day, or waking up to have bowel movements	Increase of ≥7 stools/day or incontinence; or need for parenteral support for dehydration	Hemodynamic collapse or severe consequences requiring intensive care	Death
Colostomy present	None	Mild increase in loose watery output compared with baseline	Moderate increase in loose watery output compared with baseline, but not interfering with normal activity	Severe increase in loose watery output compared with baseline; or copious output that interferes with normal activity	Hemodynamic collapse or severe consequences requiring intensive care	Death

Adapted from National Institute of Health. National Cancer Institute. Common Toxicity Criteria (version 4.03) for Diarrhea
https://nciterms.nci.nih.gov/ncitbrowser/ConceptReport.jsp?dictionary=CTCAE&ns=ctcae&code=E10575

Physical examination should assess intravascular volume status and ascertain signs of infection and abdominal tenderness.

Although a very crude estimate, information about the frequency of stools in the past 24 hours helps to assess severity of diarrhea. For immune-related diarrhea after immune checkpoint inhibitor therapy, Grade 1 (mild) diarrhea is up to four stools per day over baseline or mildly higher ostomy output from the baseline [13, 14, 16]; Grade 2 (moderate) diarrhea is four to six stools per day over baseline or moderate ostomy output; Grade 3–4 (severe or life-threatening) diarrhea is ≥ seven stools per day over baseline, with fecal incontinence. The patient may present with symptoms such as abdominal pain, rectal bleeding, and mucus in stool [14], and bowel perforation can occur [16].

Diagnostic testing and imaging studies would follow, including routine complete blood count with differential and complete metabolic panel to assess leukocytosis or neutropenia, electrolyte imbalances, liver function, and renal function. Diarrhea causes dehydration, electrolyte abnormalities, and disturbed acid-base balance. Hypokalemia and nonanion gap acidosis are the main diagnostic features of severe diarrhea. Hypokalemia necessitates aggressive potassium replacement. Prerenal azotemia or renal failure may result from severe dehydration. Other electrolytes, including calcium and magnesium, should be checked and replaced. Hypokalemia, hypomagnesemia, and hypocalcemia can cause EKG changes and cardiac arrhythmias.

Stool samples should be analyzed by culture for the presence of pathogenic bacteria, such as *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *C. difficile*, and yeast; *Clostridium difficile* testing (enzyme immunoassay for *C. difficile* toxins A and B, *C. difficile* DNA PCR); and the presence of cryptosporidium by acid-fast stains and other parasites by standard laboratory methods. In the course of cancer treatment, many patients have infectious complications and exposure to antibiotics. *Clostridium difficile*-related diarrhea should always be excluded in cancer patients who have recently been treated with antibiotics. Viral pathogens can be tested by culture (enteroviruses and adenovirus), enzyme immunoassays (rotavirus and adenovirus), or multiplex PCR. Cytomegalovirus immediate–early antigen tests of blood can detect cytomegalovirus antigenemia.

Stool analysis can classify the diarrhea as watery, fatty, or inflammatory. Watery diarrhea suggests functional, secretory, or osmotic etiology. Functional disorders such as irritable bowel syndrome and functional diarrhea are common in chronic diarrhea. Secretory diarrhea can be caused by bile acid malabsorption, paraneoplastic syndromes, microscopic colitis, endocrine disorders, and some postsurgical changes. Osmotic diarrhea can be due to laxative abuse or malabsorption of nonlipid nutrients. Fatty diarrhea reflects malabsorption of fat, which can be caused by a wide variety of causes

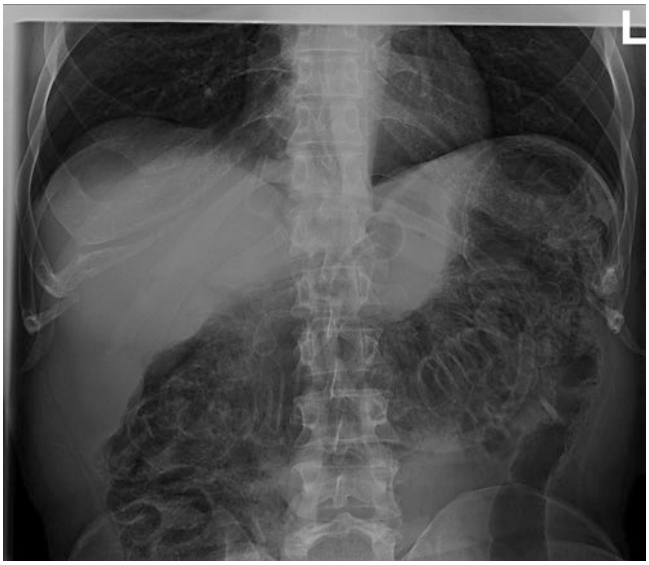

Fig. 27.1 Pneumatosis intestinalis

such as digestive enzyme deficiency, disruption of biliary function, celiac disease, or ileitis. Inflammatory diarrhea warrants further evaluation and can be caused by inflammatory bowel diseases, immune colitis, and infectious enteritis [28]. Fecal lactoferrin and fecal calprotectin can help differentiate between an infectious or inflammatory etiology and can be used to monitor disease activity and treatment response [29].

An abdominal X-ray series is helpful to quickly exclude intraabdominal free air and pneumatosis intestinalis (Fig. 27.1). The suspicion for serious gastrointestinal complication (e.g., perforation and obstruction) should be high and the threshold for CT imaging of abdomen and pelvis should be low. A triad of neutropenia, abdominal tenderness, and diarrhea should raise suspicion for neutropenic enteritis [30]. Perhaps due to neutropenia, abdominal pain or tenderness may not be prominent despite the presence of significant infection. A CT scan of abdomen and pelvis with intravenous and oral contrasts can diagnose neutropenic ileitis, typhlitis, and colitis (Fig. 27.2). MRI may be used if CT is contraindicated (e.g., if the patient is allergic to iodine contrast dyes). Bedside ultrasonic examination of bowel wall thickness can provide a rapid diagnosis [31]. Thickening of bowel wall to >4 mm for >30 mm in length is suggestive of enterocolitis [27].

In cancer patients with significant diarrhea, colonoscopic examination and biopsy are often indicated. A history of allogeneic stem cell transplantation should put graft-versus-host disease high in the differential diagnosis. Infectious colitis (e.g., cytomegalovirus colitis) is also in the differential diagnosis for immunocompromised patients. Immune colitis can also be caused by PI3K inhibitors. A history of ongoing treatment with immune checkpoint inhibition ther-

Fig. 27.2 CT scan imaging of a cancer patient with neutropenic ileitis. A neutropenic leukemic patient presents with profuse diarrhea and minimal abdominal pain but no fever. The CT scan demonstrated significant thickening of the wall of ileum (*arrows*) consistent with ileitis

apy should raise the suspicion for immune-mediated colitis, the confirmation of which would also require endoscopy, with or without biopsy. Viral colitis such as cytomegalovirus infection can also be confirmed by endoscopy with biopsies.

Management

Although many causes of diarrhea in cancer patients require specific therapies, therapies aimed at decreasing or replenishing fluid and electrolyte losses are required [32].

Diet

Regardless of the cause of diarrhea, diet modifications may decrease the symptom burden of diarrhea. Foods that may lessen the burden include the following:

- Six to eight small meals and snacks each day and increased room temperature clear liquids
- Low-fat high-potassium diet with foods containing soluble fiber
- Lactose-free
- BRAT (bananas, rice, applesauce, toast) diet

Foods that may worsen diarrhea should be avoided, such as:

- Fatty, greasy, or fried foods
- Foods high in insoluble fiber content
- Gas-forming foods
- Foods with high sugar contents
- Hot liquids
- Dairy products or foods made with significant amount of dairy products
- Foods sweetened with sugar alcohols (e.g., sorbitol, xylitol, or mannitol)
- Foods that can irritate the digestive tract (e.g., caffeine such as coffee, strong tea, sodas, tomato juice, citrus juices, and alcohol)
- Tobacco

Probiotics before or during chemotherapy may prevent chemotherapy-induced diarrhea [33]. The use of probiotics appears helpful in improving tolerance of, and support for, treatment and radiation-related diarrhea. Sources of probiotics include foods such as yogurt, buttermilk, sauerkraut, and cottage cheese. Most clinical research involves *Lactobacillus* and *Bifidobacterium* to modify gut microflora [34]. However, probiotics are not recommended in immunocompromised neutropenic patients. Food is a potential cause of invasive infectious disease in immunocompromised patients, and *Lactobacillus acidophilus* bacteremia due to yogurt ingestion has been reported in a stem cell transplant patient with mucositis [35].

Medication Adjustment

Medications such as bulk laxatives, stool softener, and promotility agents (e.g., metoclopramide) should be discontinued. Oral magnesium supplements can cause diarrhea and if significant hypomagnesemia is present, parenteral magnesium replacement may be indicated.

Correction of Dehydration and Electrolyte Imbalances

Initial treatment for severe diarrhea is aimed at correcting any volume, electrolyte, and acid-base abnormalities with IV normal saline, potassium chloride, and if acidosis is severe, sodium bicarbonate. These abnormalities are frequently severe enough to necessitate hospital admission.

Pharmacologic Therapy

Treatment goals include slowing intestinal motility, decreasing intestinal secretions, and promoting intestinal absorption. Other pharmacologic therapies for the relief of diarrhea are specific to the underlying mechanism.

- Opioids bind to μ receptors in the gastrointestinal tract and decrease bowel motility to increase transit time:

  - Loperamide; 4 mg followed by 2 mg after each unformed stool up to 12 mg/day [24, 27]
  - Diphenoxylate
  - Codeine
  - Tincture of opium
- Anticholinergics:
  - Atropine
  - Belladonna
  - Scopolamine
- Adsorbents such as kaolin, clays, and activated charcoals have been commonly used and generally considered safe:
  - Kaolin
  - Pectin
- Absorbents give bulk to the fecal material, but one potential drug interaction is that they may bind and inhibit absorption of other oral antidiarrheal medications:
  - Wheat dextrin
  - Psyllium fiber
- Somatostatin analogues:
  - Octreotide; treatment usually start with 100–150 μg every 8 hours
  - Lanreotide
  - Pasireotide
- Mucosal prostaglandin inhibitors has antisecretory effects:
  - Aspirin (may be useful for radiation-induced diarrhea)
  - Bismuth subsalicylate
- Corticosteroids reduce edema associated with obstruction and radiation colitis, reduce hormonal influences of some endocrine tumors (e.g., VIPoma), and treat immune-mediated colitis:
  - Budesonide is an oral steroid medication that is topically active in the gastrointestinal tract. It has a 90% first pass effect; therefore, after liver metabolism, the systemic availability is low
  - Dexamethasone
  - Methylprednisolone, prednisolone, or prednisone
- Antimicrobials: Quinolone antibiotics are effective for salmonellosis. Depending on the degree of immunocompromise, antibiotic treatment may need to continue for several months. Some beta-lactam antibiotics (e.g., cefotaxime, ceftriaxone) and sulfamethoxazole-trimethoprim are alternatives. Campylobacteriosis is treated with azithromycin or quinolone antibiotics, with addition of vancomycin for severe cases. Shigellosis is treated with quinolone antibiotics. Alternatives include sulfamethoxazole-trimethoprim and azithromycin. *Clostridium difficile* may be treated with metronidazole or oral vancomycin. Enterotoxigenic *E. coli* are frequently resistant to ampicillin and sulfamethoxazole-trimethoprim. Quinolone antibiotics are generally effective. Enterotoxigenic *Bacteroides fragilis* is an emerging pathogen causing diarrhea, and metronidazole has excellent activity against this pathogen
  - Bismuth subsalicylate has direct antimicrobial effects on *Escherichia coli*
  - Sulfamethoxazole and trimethoprim
  - Beta-lactam antibiotics, e.g., cefotaxime, ceftriaxone
  - Quinolone antibiotics, e.g., levofloxacin, moxifloxacin, ciprofloxacin
  - Metronidazole
  - Oral vancomycin

Management of Specific Clinical Scenarios

Treatment-Induced Diarrhea

Based on controlled clinical trials and clinical practice guidelines [24, 27], loperamide (4 mg initial dose followed by 2 mg every 4 hours) is the standard first-line therapy for chemotherapy-induced diarrhea. After loperamide for the first day of chemotherapy-induced mild diarrhea, treatment may be escalated by adding octreotide, 100–150 μg every 8 hours [23]. Severe treatment-induced diarrhea with complicated symptoms should be managed with IV fluids, octreotide acetate 100–150 μg SC three times daily or 25–50 μg/hour IV with up to a five-fold escalation as needed, and administration of antibiotics until diarrhea has stopped for >24 hours [24]. Updated guidelines stress the importance of recognizing early warning signs of complicated diarrhea and early intervention such as initiating antibiotic therapy [24].

"Complicated" Chemotherapy-Induced Diarrhea

Patients with mild-to-moderate diarrhea complicated by moderate-to-severe cramping, nausea and vomiting, diminished performance status, fever, sepsis, neutropenia, bleeding, or dehydration, as well as patients with severe diarrhea, are classified as "complicated." These patients should be evaluated further, monitored closely, and treated aggressively. Aggressive management of complicated cases usually necessitates hospital admission and involves IV fluids; octreotide at a starting dose of 100–150 μg three times daily (25–50 μg/h) if the patient is severely dehydrated, with dose escalation up to 500 μg three times daily until diarrhea is controlled, and administration of antibiotics (e.g., fluoroquinolone). These patients should be evaluated with complete blood count, electrolyte profile, and a stool work-up evaluating for blood, fecal leukocytes, *C. difficile*, *Salmonella*, *E. coli*, *Campylobacter*, and infectious colitis.

Targeted Therapy

There are no specific guidelines for the management of targeted therapy-induced diarrhea. As a secretive mechanism is the most frequent cause, the first-line treatment is loperamide and opiates, followed by octreotide.

Neutropenic Enterocolitis

The risk of mortality from neutropenic enterocolitis is high [30, 36]. In the absence of acute complications that require emergency surgery, the initial management is to use broad-spectrum antibiotics. The antibiotics chosen should cover enteric gram-negative organisms, gram-positive organisms, and anaerobes. The choice of antibiotics is basically the same as for neutropenic fever. In cases that do not respond to antibiotics, antifungal agents should be added, just as in the management of neutropenic fever. Depending on the underlying malignancy, neutropenia may not resolve quickly, even when colony-stimulating factors (filgrastim) are used.

Immune-Mediated Colitis

There are quite a few guidelines available for the management of immune-related adverse effects of immune checkpoint inhibitors, including those from the National Comprehensive Cancer Network (NCCN) [37], American Society of Clinical Oncologic (ASCO) [38], Society of Immunotherapy for Cancer (SITC) [39], and European Society of Medical Oncologic (ESMO) [40]. Management is based on grading. Grade 1: Symptomatic treatment with loperamide, oral hydration, the American Dietary Association ulcerative colitis diet, and electrolyte replacement as needed. Grade 2: Diphenoxylate/atropine may replace loperamide and budesonide (or systemically active prednisone/methylprednisolone) may be started. In grade 1 or 2 diarrhea with bleeding or persistent grade 2 diarrhea, endoscopic examination and biopsy are indicated. Grade 3 or 4: Treatment with IV corticosteroid (methylprednisolone 125 mg) and IV replacement of fluid and electrolytes should be started. Infliximab is second-line treatment and is usually started for the lack of improvement in diarrhea after treating with corticosteroids for 72 hours. Corticosteroids are typically the first-line treatment for irAE grade 2 or higher, and the primary therapy that emergency physicians will institute.

GVHD

In addition to antidiarrheal agents, glucocorticoids (e.g., budesonide), and immunosuppressive medications, the diarrhea associated with GVHD may be managed with a specialized five-phase dietary regimen [41]. Octreotide is also effective in diarrhea associated with GVHD [42, 43].

Paraneoplastic Diarrhea

Initial treatment is directed toward correcting volume and electrolyte abnormalities. Somatostatin analogues control diarrhea in up to 90% of patients. Glucocorticoids reduce symptoms in 50% of cases. Tumor resection is the treatment of choice for long-term control of symptoms. In advanced disease, tumor debulking may relieve symptoms, but it is not effective in all cases. Hepatic artery radioembolization or transcatheter chemoembolization with doxorubicin or cisplatin [44], XRT, and percutaneous or intraoperative radiofrequency tumor ablation may be attempted to reduce tumor burden.

Constipation

28

Demis N. Lipe

Case Study

An 82-year-old male with pancreatic cancer presents to the emergency department with complaints of constipation for 5 days. He has tried over-the-counter laxatives without relief. He is nauseated, but not vomiting, and describes a sensation of pressure in his suprapubic region. He can pass gas but is having difficulty urinating. He has not had any recent medication changes. His cancer-associated pain is well controlled by his daily opioid regimen. He has a past history of constipation. On presentation, he is somewhat cachectic and distressed. His vitals are normal, and physical examination reveals a mildly tender lower abdomen, without signs of peritonitis. His complete blood count, chemistries, and urinalysis reveal his baseline anemia of chronic disease, but otherwise, his laboratory findings are normal. A plain radiograph (Fig. 28.1) shows a large stool burden, but no evidence of free air or dilated loops of bowel. Rectal exam reveals hard stool in the vault, but no evidence of stool impaction. The patient is gently hydrated and treated with a soapsuds enema, which successfully leads to a bowel movement in the emergency department and relief of symptoms. He is discharged home uneventfully.

Fig. 28.1 Large amount of stool in upright abdominal radiograph

Introduction

Constipation is a common gastrointestinal symptom that varies widely in severity. Although definitions vary, constipation is generally characterized by the slow movement of feces through the intestines with fewer bowel movements than normal [1, 2]. Constipation may be transient and easily treated or cause major impairment and be resistant to multiple interventions, among both the general population and those with cancer. It is often underappreciated and undertreated in patients with cancer, and it has been reported to affect up to 50% of patients with advanced cancer [3].

Its reported prevalence varies from 1% to 81%. Such wide variation results from nonspecific definitions and differing base populations [2, 4–8]. More specifically, the prevalence of constipation among cancer patients ranges from 30–90%, and increases with age, opioid therapy, hospitalization, and need for palliative care [1, 9]. Age-related increases in constipation occur in the setting of immobility, dehydration, polypharmacy, and with advanced age, a reduced urge to defecate [1]. Among cancer patients receiving palliative care, those under 60 years of age reported a 33% prevalence of constipation, rising to 55% among those 70 years or older [10]. In one cross-sectional study of 520 cancer patients receiving strong opioids, 321 (61.7%) patients were assessed as constipated using a validated constipation questionnaire, while by physicians' subjectively judgment, 438 (85.7%) were constipated [11].

Emergency department (ED) visits related to constipation are common both in the general and cancer population. Highlighting the healthcare burden of constipation, Sommers et al. found that of 131,048,605 total US ED visits in 2011, over 700,000 were related to constipation [12]. In 2019, of 28,424 total patient visits to the MD Anderson Cancer Center ED in Houston, Texas, 15,289 (54%) visits included a diagnosis related to constipation (unpublished data).

ED visits for constipation entail large and increasing healthcare expenditures. US ED visits for constipation increased by 41.5% between 2006 and 2011, from 497,034 to 703,391 visits, while the national cost of constipation visits increased from $733 million to $1.6 billion (in 2014 dollars) [12]. In the United Kingdom, cost to the National Health Service for treatment of constipation in the year 2017–2018 was estimated to be 162 million pounds and on average, 196 people were admitted to the hospital daily during the same time period. In addition, millions of dollars are spent annually on laxatives and primary care visits [8, 13–15].

In addition to healthcare costs, constipation-related symptoms are distressing and debilitating for those with cancer. Stigma and shame may prevent the patient from disclosing constipation symptoms to loved ones or healthcare providers [8, 13].

The Rome Diagnostic Criteria

Due to lack of overarching operational definitions for functional bowel disorders, an international group of gastroenterologists convened in 1988 in Rome, Italy to develop consensus criteria for the diagnosis of irritable bowel syndrome. This led to further attempts to develop systematic nomenclatures for a number of symptom-based functional gastrointestinal (GI) disorders. With an expanding research base, these taxonomical efforts were increasingly supported by physiologic data [16]. To date, Rome diagnostic criteria have become the gold standard for defining a number of functional GI disorders, including constipation. Despite accepted Rome criteria, there is limited agreement between generalist clinicians, expert specialists, and the public in recognizing and differentiating constipation from other functional GI disorders and nonpathologic symptoms. Experts recognize the need to align Rome diagnostic criteria with those symptoms that patients perceive to be important and functionally disabling [17].

The Rome diagnostic criteria categorize functional bowel disorders into five syndromes: irritable bowel syndrome, functional constipation, functional diarrhea, functional abdominal bloating/distention, and unspecified functional bowel disorder. Functional constipation is the most common form of constipation. A diagnosis of functional constipation per the Rome IV criteria requires that symptoms must be present for the last 3 months, with an overall onset of symptoms 6 months prior to diagnosis (Table 28.1). The Rome IV criteria include a new sixth category, opioid-induced constipation (OIC), particularly relevant to cancer patients [18]. OIC is defined as new or worsening constipation when initiating, changing, or increasing opioid therapy. While OIC is considered an adverse effect of opioids rather than a functional bowel disorder, the two often coexist. To meet OIC criteria, patients must experience two or more of the symptoms that define functional constipation with the same frequency cut-off of 25%. The Rome IV criteria also address narcotic bowel syndrome (NBS). NBS was first described over 25 years ago as a chronic or frequently occurring paradoxical development of, or increase in, abdominal pain associated with increasing doses of opioids [18–21].

Table 28.1 Rome IV criteria for functional constipation [18]

Duration of 3 months and symptom onset at least 6 months prior to diagnosis	
1	Presence of ≥2 of the following: Lumpy or hard stools in >25% of defecations Straining during >25% of defecations Sensation of anorectal obstruction/blockage for >25% of defecations Sensation of incomplete evacuation for >25% of defecations Using manual maneuvers such as digital manipulation or pelvic floor support to facilitate >25% of defecations <3 spontaneous bowel movements per week
	and
2	Loose stools rarely present without the use of laxatives
	and
3	Insufficient criteria for irritable bowel syndrome

Pathophysiology

Constipation can be attributed to primary causes such as colonic or anorectal dysfunction or secondary causes such as organic disease or medication use [20]. A number of factors are associated with constipation, including, but not limited to, dietary habits, genetic predisposition, absorption ability, colonic motility, daily behaviors, medication use, spinal cord compression or injury, musculoskeletal disorders such as muscular dystrophy, and external colonic compression (e.g., peritoneal tumors) [7].

Secondary constipation is often adverse effect of chemotherapeutic agents and medications used to treat concomitant diseases and symptoms. Constipation has been cited as the third most common symptom associated with chemotherapy administration [22]. A number of other drug classes cause constipation by reducing smooth muscle contractility (e.g., calcium channel antagonists, antihistamines, antidepressants) [7, 20]. Refer to Table 28.2 for a more comprehensive list of medications causing constipation.

Table 28.2 Common medications causing constipation

Drug class	Example of drug
Alpha-2 agonists	Clonidine, methyldopa
Calcium channel blockers	Verapamil, nifedipine
Tricyclic antidepressants	Doxepin, amitriptyline
Metal ion-containing agents	Iron, aluminum, bismuth, calcium
Opioids	Morphine, fentanyl, hydromorphone
Cannabinoids	Tetrahydrocannabinol (THC)
Antiulcer agents	Sucralfate, antacids
Anti-Parkinson drugs	Methyldopa
Antiepileptics	Phenytoin, carbamazepine
Antipsychotics	Clozapine, olanzapine, quetiapine
Antihistamines	Diphenhydramine, cetirizine
Antispasmodics	Dicyclomine and hyoscyamine
Anticholinergics	Belladonna, rasagiline
5-HT3 receptor antagonist	Ondansetron
Chemotherapeutic agents	Cyclophosphamide, vincristine
Nonsteroidal anti-inflammatories	Toradol, ibuprofen
Bile acid sequestrants	Cholestyramine

Chemotherapy-induced constipation is not well understood, but it is believed that it stems from the effects of the chemotherapeutic agent on nerve endings of the GI enteric nervous system. It is suggested that subtle changes in the enteric nervous system lead to abnormal colonic motor function, prolonged colonic transit time, infrequent bowel movements, and thus, constipation [22].

Opioids reduce bowel motility by binding to specific μ, δ, and κ receptors in the GI tract. Under normal circumstances, these receptors influence fluid and electrolyte transport in the stomach, ileum, and proximal colon, as well as promoting motility. Opioids bind to the μ receptor and lead to a decrease in peristaltic activity as well as reduction in mucosal secretions, ultimately causing decreased intestinal fluid absorption, slowed gastric emptying, and delayed intestinal traffic. Opioids also can weaken the susceptibility of rectal dilation to stimulation, reducing contractility as well as increasing sphincter tone [7, 22–25].

Narcotic bowel syndrome (NBS) is an entity deserving special mention as emergency physicians treating cancer patients may frequently encounter this condition. Pain is one of the most common complaints in the cancer population presenting to the ED and up to 60% of those patients are treated with opioids [26]. With continued opioid use, a paradoxical worsening of abdominal pain can occur despite increased opioid dose. Although the pathophysiology is not fully understood, NBS is thought to be related to heightened pain sensitivity localized to the GI tract. Chronic opioid use can cause neuronal changes that may lead to hyperalgesia. Other mechanisms include interactions with *N*-methyl D-aspartate receptor at the level of the spinal cord, increase in substance P synthesis, interaction with transmembrane G proteins, which have both inhibitory and excitatory effects on sensory neurons, increase in the endogenous opioid peptide dynorphin, which in turn leads to increased pain signaling at the level of the spinal cord, and neuroinflammation resulting in hyperalgesia [21, 27].

Finally, spinal cord compression or injury may cause spasticity in the muscles of the GI tract. Neurogenic bowel dysfunction can be characterized by increased colonic and anal sphincter tone if the compression or injury is above the conus medullaris [28].

Clinical Presentation

Cancer patients with constipation present with an array of symptoms. Given the range of pathophysiology associated with cancer and its treatment, it is imperative that the emergency physician not overlook a more urgent condition that may mimic constipation. The history of present illness should include duration of symptoms, history of similar symptoms, consistency and frequency of stools, sensation of blockage or a feeling of incomplete evacuation, straining, recent dietary changes and recent medication changes, or increase in opioids. A thorough past medical history, to include comorbidities such as diabetes, diverticulitis, past surgeries, and current medication usage, should be elicited [7]. A recent increase in cancer pain, requiring increase in opioids is often an important aspect of the history, thus the pain level should also be recorded.

Patients with NBS may describe a burning or colicky pain that is exacerbated by eating, progressive, and associated with nausea, vomiting, abdominal distention, and bloating [21, 27]. Cancer patients presenting to the ED with NBS are often difficult to diagnose and consultation with their oncologist or continuity physician may be helpful. The diagnostic criteria for NBS are shown in Table 28.3.

Symptoms of abdominal pain, bloating, nausea, inability to pass stool, small stools, straining, rectal pain, urinary retention, and overflow diarrhea are commonly present. More alarming findings such as change in bowel habits, weight loss, anemia, not passing flatus, vomiting, bloody

Table 28.3 Diagnostic criteria for narcotic bowel syndrome [21]

1	*Chronic or frequently recurring abdominal pain that is treated with high dose opioids (acutely or chronically)*
	and
2	Presence of at least three of the following:
	The pain worsens or incompletely resolves with continued or increasing doses of opioids
	There is worsening of pain when the opioid dose wanes and improvement when the opioids are reinstituted
	There is progression of the frequency, duration, and intensity of pain episodes
	The nature and intensity of the pain is not explained by a current or previous GI diagnosis

stools, history of inflammatory bowel disease, or history of colon cancer should prompt an expedited workup. Lower extremity weakness or numbness with urinary retention or in the setting of constipation should be further investigated to ensure there is no cord compression.

The Bowel Function Index three-item tool can be used for screening for opioid-induced constipation. This tool can be administered by the physician at the bedside and it consists of the patient's assessment of easiness of defecation in the last 7 days, the feeling of incomplete bowel evacuation during the last 7 days, and the patient's subjective judgment about the presence of constipation during the last 7 days [29].

Examination

Examination should begin with an evaluation for systemic toxicity. Does the patient appear acutely ill? Does the patient need acute resuscitation? It should then be followed by careful inspection of the abdomen, taking notice of the contour and movements of the abdomen as well as observing for symmetry. Inspection should be followed by auscultation, which can provide information about bowel motility. It is important to listen before palpating the abdomen as palpation can alter the frequency of bowel sounds. Next, palpating the abdomen will help with distinguishing masses, stool, a distended bladder, or signs of peritoneal inflammation. A digital rectal examination may be performed to check for stool impaction and sphincter tone. A history of bloody stools should prompt an examination for hemorrhoids or anal fissures. However, rectal exam in the oncologic population should be postponed until there is evidence that the patient is not neutropenic.

After a focused examination of the abdomen, a more thorough examination may be done in search of other systemic causes of constipation, such a hypothyroidism, hypercalcemia, spinal cord compression, and dehydration.

Differential Diagnosis

The first step in the diagnostic approach is to form a broad differential to ensure more serious causes are not missed. Differential diagnosis possibilities should include the following:

1. *Bowel Obstruction:* Bowel obstruction (small or large) can be caused by scar tissue, hernias, and malignancy. Patients presenting with bowel obstruction can present with severe pain, fever, bilious or nonbilious vomiting, bloating, and obstipation. However, patients can also present with variable, nonclassical symptoms. Having a history of mass in the GI tract, prior surgery, or abdominal hernias may further point to a bowel obstruction. Clinically, patients may appear ill, have a distended abdomen that is often tympanic with decreased or increased bowel sounds, and may be diffusely tender with or without signs of peritoneal irritability. In this case, a supine and upright radiograph may demonstrate distended loops of bowel or air-fluid levels indicating possible obstruction. A CT of the abdomen should be obtained to better evaluate and delineate the cause of obstruction [30]. If the diagnosis is missed, bowel obstructions can progress and cause bowel ischemia.
2. *Bowel Perforation:* Bowel perforation is a surgical emergency. There are multiple etiologies, but commonly neoplasm, diverticulitis, abscesses, inflammatory and infectious colitis, as well as bowel ischemia should be considered as causes of perforation. Stercoral colitis (Figs. 28.2 and 28.3) is a rare complication due to fecal impaction leading to increased intraluminal wall pressure, inflammation, and distention of the colon, which in turn leads to ischemic pressure and necrosis with ulceration and perforation. It can result in peritonitis and rapidly progress to septic shock. Neutropenic colitis may also cause transmural necrosis and perforation if severe. These patients will often present with severe pain, abdominal distention, nausea, and/or vomiting and possibly obstipation or diarrhea, depending on the etiology. On physical examination, the patient appears ill and may exhibit findings consistent with peritonitis. Workup

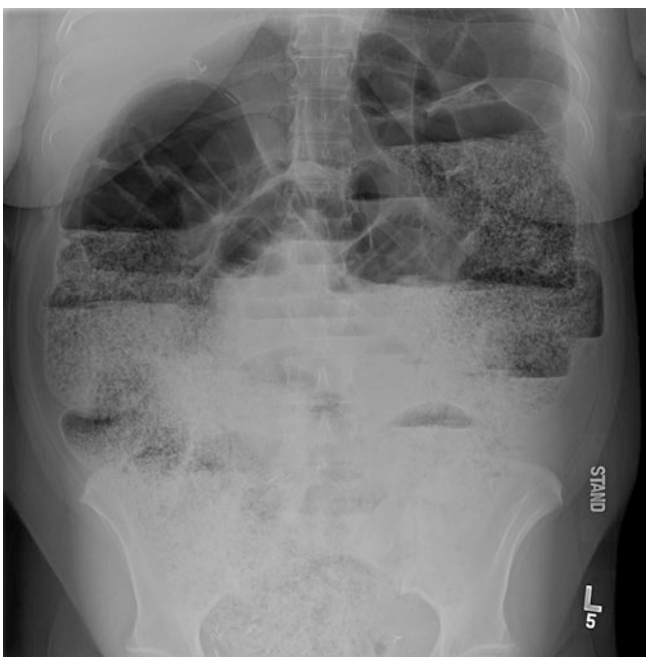

Fig. 28.2 Plain radiograph demonstrating air-fluid levels and a distended bowel in a patient with impacted fecal material

Fig. 28.3 Stercoral colitis in a patient with impacted fecal material

should include an emergent upright chest radiograph to evaluate for free air under the diaphragm. However, if plain radiography is negative, a CT of the abdomen should be immediately obtained, as plain radiographs have only a sensitivity of 50–70% in detecting extraluminal air [31].

3. *Malignant Spinal Cord Compression:* Malignant cord compression is an oncologic emergency and a potentially devastating condition, that if missed can lead to catastrophic neurological deficits. The condition has been reported to occur in approximately 5% of all cancer patients and up to 20% of the time, it is the initial manifestation of cancer [32]. Its incidence in advanced cancer has been reported to be approximately 15% [33]. Constipation may be the initial presenting symptom. A thorough history of present illness and review of systems may allow an early diagnosis. Neurological symptoms may include extremity weakness, numbness, and tingling. Symptoms such as urinary retention or overflow incontinence are also important red flags. Known bony metastatic disease increase the likelihood of cord compression and thorough questioning about back pain and changes in pain intensity may be helpful. The neurological exam may be normal in the early stages of cord compression. Rectal tone should be checked, if the patient is not neutropenic. If malignant spinal cord compression is suspected, an emergent magnetic resonance imaging study of the spine is indicated with concomitant initiation of systemic steroids.
4. *Diverticulitis:* This condition can often present subtly, but if missed can cause complications such as phlegmon formation and perforation. The patients may present with fever and lower abdominal pain. Nausea and/or vomiting may be present or absent and the patient may give a history of diarrhea or constipation. Exam will often show tenderness of the left lower quadrant and the diagnosis can be confirmed with CT scan of the abdomen. The patient may or may not have an associated leukocytosis.
5. *Hypothyroidism:* While most cases of hypothyroidism are due to a primary process in the thyroid, a small percentage are due to other causes, such as neoplasm and medications (e.g., chemotherapeutic agents and immunotherapy). Patients may present with subtle symptoms including constipation, fatigue, muscle cramps, weight gain, voice changes, dry skin, and cold sensitivity. In these patients, again a thorough history is important as is a detailed review of systems. Exam may reveal a goiter, dry skin, pretibial edema, and delayed relaxation of deep tendon reflexes. Checking a serum thyrotropin level (TSH) is the single best screening test for primary thyroid dysfunction, but not adequate for hospitalized or acute ill patients [34]. Additional testing of for free thyroxine levels (T4) as well as triiodothyronine (T3) may assist the diagnosis.
6. *Hypercalcemia of Malignancy:* One of the most common causes of hypercalcemia is malignancy, affecting approximately 30% of patients with cancer at some point. Hypercalcemia may be due to bony metastasis or secretion of parathyroid hormone-related protein. Cancers with higher risk of hypercalcemia are multiple myeloma, renal cell carcinoma, lung, breast, and colorectal cancers. Drugs such as tamoxifen can also cause hypercalcemia. The patient may present with nonspecific complaints such as fatigue, anorexia, constipation, nausea, and abdominal pain. They may also present with pancreatitis and exhibit an elevated lipase, or nephrolithiasis with renal insufficiency. Clinically, the patient may appear dehydrated, lethargic, or even confused, but more often the physical exam is nonspecific. High blood pressure, bony tenderness, lower extremity muscle weakness, and tongue fasciculations may be seen. Workup should include chemistries with ionized calcium as well as liver

enzymes to include albumin, as up to 40% of calcium is protein bound. In this case, the constipation is secondary to the primary disease. An EKG should be obtained to check for QT interval shortening and Osborn or J waves and intravenous fluids initiated in the absence of contraindications [35].

Diagnosis

Assuming an adequate differential has been considered, constipation can be diagnosed simply by history and exam. In fact, the American College of Gastroenterology Chronic Constipation Task Force recommends against routine diagnostic testing in chronic constipation if there are no red flags [36]. However, the presence of cancer will often prompt further diagnostic testing.

In the ED, a complete blood count should be ordered to evaluate for neutropenia prior to performing a rectal exam. Chemistries to include electrolytes should be done to exclude metabolic causes of constipation. Thyroid function tests may be helpful if hypothyroidism is suspected. While imaging is not routinely required in the ED when uncomplicated constipation is suspected, an acute abdominal series radiograph with supine and upright views may reveal free air and air-fluid levels. If there are any red flags in the history suggesting a more serious process, computed tomography of the abdomen should be performed.

Treatment

Once it is determined that the patient has uncomplicated constipation and other emergent causes (e.g., bowel obstruction, spinal cord compression) ruled out, the next step prior to treatment is to determine whether constipation is primary or secondary. Primary constipation is due to intrinsic defects in bowel function and usually is considered only after secondary causes of constipation have been ruled out [20]. The cancer patient is likely to have constipation due to secondary causes, such as medication use, or the malignancy itself.

As constipation is often multifactorial, the treatments will vary. In general, multiple approaches should be employed. These begin with hydration of the patient if the clinical picture warrants it, as well as correction of abnormal electrolytes. Most cancer patients presenting to the ED have already attempted oral medications such as osmotic or stimulant laxatives that have failed to relieve the symptoms. Assuming home treatment has failed, the most common approach in the ED is the administration of enemas and suppositories, followed by oral laxatives. Another less appealing approach (for both physician and patient) is to perform rectal disimpaction.

If a high clinical suspicion exists for NBS as the cause of the constipation, is it imperative to avoid treatment with increasing opioids, although clinicians might be initially inclined to do so to control pain. Emergency physicians should consider that patients and providers alike often exhibit frustration due to negative evaluations and increased healthcare utilization by this cohort of patients. Unrecognized NBS can lead to an increase in opioid therapy worsening pain and repeated cycles of treatment failure. Treatment of NBS begins with detoxification, which will likely require hospital admission. Inpatient detoxification involves placing the patient on a continuous opioid drip while the amount is gradually reduced in a structured fashion. The goal of treatment is to achieve dose reductions of 10–33% per day, while providing anxiolytics during withdrawal. Other options for the emergency clinician are nonopioid pain modulators and anxiolytics. Further outpatient support will be necessary for these patients for behavioral modifications, psychological support, and pain management [21, 27, 37]. For opioid-induced constipation, the emergency physician may consider a peripheral acting μ-opioid receptor antagonist (PAMORA) [1].

Treatment of the elderly patient must be individualized based on other comorbidities such as kidney or heart disease. Saline laxatives should be used with caution in this group due to the risk of hypermagnesemia, while nonabsorbable dietary fiber and bulk agents should be avoided in nonambulatory, elderly patients due to the risk for mechanical obstruction. Osmotic laxatives such as polyethylene glycol are a good option for the elderly, but will not likely cause a bowel movement for 2–3 days [1].

In the next section, we will discuss pharmacologic agents in detail.

Pharmacological Agents in the Treatment of Constipation

Bulk-Forming Laxatives

These are often used as first-line agents in patients with chronic constipation and those who cannot take adequate fiber. Examples of bulk-forming laxatives are psyllium (Metamucil), wheat dextrin (Benefiber), methylcellulose (Citrucel), and polycarbophil (Fibercom). The goal of fiber therapy is to trap water in the GI lumen, which in turn stimulates colonic motility and increases frequency of bowel movements. Abdominal bloating is a common adverse effect. These agents are not adequate to treat constipation in the ED and should be considered preventative therapy [1].

Stool Softeners and Lubricants

Examples include mineral oil and docusate sodium. These agents have detergent-like properties that help lubricate the stool by increasing water content and are often tried by the patients prior to ED presentation. They are most likely to work in those with occasional or short duration constipation, and less likely to work in the acute setting or with fecal impaction [1].

Osmotic Laxatives

This class includes saline laxatives such as magnesium citrate and milk of magnesia, as well as poorly absorbed sugars such as lactulose, sorbitol, and polyethylene glycol. Their mechanism of action is to induce water movement into the GI lumen and therefore increase bowel movement frequency by means of softening the stool and increasing volume. Osmotic laxatives are frequently used in the ED as initial treatment for uncomplicated constipation; however, there are instances in which they should be avoided. Due to the potential for electrolyte absorption, saline laxatives are not recommended for patients with renal or cardiac insufficiency. Poorly absorbed sugars, such as lactulose, can lead to abdominal bloating and flatulence, limiting its use due to poor tolerability. Finally, polyethylene glycol is an option, when other therapies have failed if the patient can tolerate oral intake [1].

Stimulant Laxatives

Included in this class are drugs such as bisacodyl, senna, sodium picosulfate, and aloe. These work by increasing intestinal secretions and promoting neurotransmitter release, increasing colonic motility. This class is less helpful in the acute setting but are generally well tolerated with minimal side effects [38].

Enemas

Commonly used enemas include Fleet, soapsuds, and milk and molasses enemas. While these can be very effective in the acute setting, they can also cause severe adverse events (e.g., perforation, metabolic derangements) and as such should be applied carefully [39]. Enemas are contraindicated in those with neutropenia or thrombocytopenia, paralytic ileus, intestinal obstruction, recent colorectal or gynecological surgery, rectal trauma, toxic megacolon, colitis, or recent radiotherapy in the abdominopelvic area [1].

Newer Agents

These include the secretagogues and peripheral acting μ-opioid receptor antagonists (PAMORAs). OIC can be treated with both lubiprostone (a secretagogue) and PAMORAs, such as naloxegol and methylnaltrexone. PAMORAs selectively and competitively bind to the peripheral acting μ-opioid receptors in the enteric nervous system. All PAMORAs have shown effectiveness in treating OIC.

Naloxegol was the first orally dosed PAMORA for the treatment of OIC. It is a PEGylated derivative of naloxone. The recommended dose is 25 mg daily, which may be reduced if patient becomes symptomatic. It is generally well tolerated and will produce a bowel movement in most patients with OIC in approximately 1 week. There are no significant and severe associated adverse events and no reduction in analgesia [1, 25]. It is recommended that other laxatives are discontinued when taking naloxegol and other PAMORAs to decrease adverse side effects such as bloating [40].

Methylnaltrexone is a fast-acting PAMORA, derivative of naltrexone, that is administered subcutaneously and may be useful in the ED [38]. Most patients achieve defecation within 90 minutes of administration. Treatment has not been reported to impact pain control or precipitate opioid withdrawal [1, 41]. Although there is a theoretical risk of perforation among patients with structural abnormalities of the bowel wall, a recent review of 333 adults and children with peritoneal carcinomatosis receiving methylnaltrexone for the treatment of OIC found only one perforation [42].

Naldemedine is an oral PAMORA that has been reported to produce a spontaneous bowel movement in about 16 hours. Naldemedine has no effect on analgesia and there is no increase in opioid withdrawal symptoms [41]. The most effective dose to manage OIC is 0.2 mg [1, 41, 43].

Lubiprostone is a secretagogue that activates type-2 chloride channels in the intestine allowing for an increase in liquid contents and promoting spontaneous bowel movements [25].

Disposition

If the patient is nontoxic appearing and appears to be responding well to the interventions in the ED, they may be discharged with close follow up. However, patients with advanced cancer or unmet palliative care needs may require admission for symptom control or monitoring for complications. Similarly, patients who appear dehydrated, cannot take adequate oral intake, have uncontrolled pain, or constipation that is not resolving must be admitted.

Prevention and Patient Education

Dietary and lifestyle modifications should be encouraged at every visit with the oncologist, as well as discussed during discharge from the ED. Increasing water and fiber content is a simple preventive measure, however, it is a difficult task for some cancer patients due to appetite loss. Probiotics can help as gut microbiota plays a significant role in the GI motility. However, while these recommendations are generally given, the data to support their efficacy are limited [38]. At a minimum, when prescribing opioids for the cancer patient, the clinician should discuss the issue of complication and initiate a bowel regimen.

Conclusion

Constipation in cancer patients offers a specific set of challenges that emergency physicians will need to be familiar with. To improve quality of life in the cancer patients suffering from constipation, more research and data will be needed to further align patient's perception of constipation, clinician's practice, and clinical guidelines. Agreement on a unifying definition can help with earlier recognition and treatment of the disturbing GI symptoms and help reduce morbidity and distress. Questionnaires in existence can be further improved for usability in the ED and to make effective decisions with regard to the best treatment for the chronic constipation patient in the acute setting. Continued education of ED clinicians on the management and opioid-induced constipation and narcotic bowel syndrome is important in the care of cancer patients who often use narcotics. This can help reduce patient distress and increase understanding, which can help the doctor-patient relationship that is often fractured by these patients with difficult clinical presentations and increased healthcare utilization. Increased awareness of NBS by all clinicians can be helpful to these patients as they often need a multidisciplinary team approach including inpatient and outpatient care. In closing, continuing education efforts can greatly help improve the cancer patient's quality of life and help clinicians address the specific set of challenges associated with this cohort.

Endocrinology and Metabolism

29

Sai-Ching Jim Yeung

Introduction

Routine clinical chemistry analyses including electrolyte and metabolic panels are frequently ordered as part of an emergency department (ED) evaluation to identify abnormalities in electrolyte or acid-base imbalance and to monitor treatments of known abnormalities. In cancer survivors and patients with active malignancies presenting for emergency care, abnormalities in the electrolyte and metabolic panel are very common. Moreover, while serum magnesium is very often not part of the electrolyte and metabolic panel in many EDs, it should be routinely checked in cancer patients because hypomagnesemia is highly prevalent in this population.

In addition to "reflex" treatments in the ED to normalize electrolytes and glucose, early diagnosis or initiation of the diagnostic work-up to identify the underlying cause of the abnormalities will minimize morbidity and mortality as well reduce costs of care. In general, the past medical, medication, and dietary histories will help to determine the cause of abnormalities. A synthesis of physical examination findings with the histories will give clues to specific clinical syndromes.

Case Study

A 65-year-old male previous heavy smoker with chronic obstructive pulmonary disease was recently diagnosed with stage 4 squamous cell lung carcinoma. He had received his third cycle of pembrolizumab and carboplatin plus paclitaxel 11 days ago. He presents with the complaint of palpitations that woke him up this morning. He felt that his heart was racing and would not slow down with rest. He was brought to the ED by ambulance. On arrival, his heart rate was 160/min. His systolic blood pressure was 100 mmHg. He was otherwise at his baseline condition. Stat cardiac monitoring and electrocardiogram showed atrial fibrillation with fast ventricular response. Metoprolol 10 mg was given stat intravenously and was repeated after 15 minutes. The heart rate was controlled at about 100/min. The heart rhythm remained atrial fibrillation. Serum chemistry showed that potassium was 3.3 mEq/L and serum magnesium was 1.4 mg/dL. Potassium chloride and magnesium sulfate infusions were initiated to correct electrolyte abnormalities. Thyroid function tests were sent to the lab, and later TSH was reported to be <0.001 mU/L, with a free thyroxine of 3.0 ng/dL. Cardiology was consulted and evaluation did not reveal underlying atherosclerotic heart disease. Elective cardioversion was performed, and he was successfully converted back to sinus rhythm.

His thyrotoxicosis was due to anti-PD1 antibody-induced thyroiditis and managed with beta-adrenergic blockade. The patient required close follow-up as the thyrotoxic state could resolve, and metoprolol might need to be discontinued. The clinical course of immune thyroiditis may result in hypothyroidism after the thyrotoxic phase, and the patient would then need thyroid hormone replacement.

Metabolic Emergencies

Hypernatremia

Hypernatremia results from loss of balance between sodium and water: excess sodium intake, low water intake, high water loss, and changes in renal reabsorption of water and/or sodium.

The original version of this chapter was revised. A correction to this chapter can be found at https://doi.org/10.1007/978-3-030-67123-5_72

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_29

Causes:

- Inadequate water intake: obstruction of the gastrointestinal tract, treatment-induced nausea and vomiting, and treatment-induced mucositis. A debilitated bed-bound cancer patient may not have free access to water. Primary hypodipsia is loss of thirst due to abnormality in the supraoptic nucleus of the hypothalamus caused by a primary or metastatic malignancy or treatment (surgery or radiation) of a central nervous system tumor.
- Increased water loss: diuretic use, high fever, burns, or diarrhea.
- Iatrogenic causes: inappropriate intravenous (IV) fluid administration, total parenteral nutrition, and dialysis.
- Diabetes insipidus:
  1. Central: Caused by changes affecting the anterior pituitary or related hypothalamic nuclei (e.g., neurosurgery, destruction by tumors, hemorrhage, head injury, infarction, and infection).
  2. Nephrogenic: Most familial nephrogenic diabetes insipidus cases are caused by mutations of the V2 receptor mutations or aquaporin-2 water channel. However, these are rare among cancer patients. Acquired nephrogenic diabetes insipidus can result from some common drugs (e.g., demeclocycline, lithium, foscarnet, clozapine, amphotericin, glyburide, colchicine, acetohexamide, tolazamide, and methoxyflurane) and chemotherapy agents (e.g., ifosfamide, vinblastine, and streptozocin).

Symptoms The clinical manifestations of hypernatremia are primarily related to cellular dehydration leading to central nervous system dysfunction and are more pronounced with a high level or a fast rate of increase. Thirst is frequently the first symptom. Muscle weakness and central nervous system changes (restlessness, weakness, and lethargy) are usually not manifested until the sodium level is >160 mEq/L, and at this point, the patient may become comatose. Diabetes insipidus is characterized by polyuria, urine hypo-osmolality, and polydipsia. Symptoms of intravascular volume depletion may appear if water loss exceeds water intake.

Diagnosis The cause of hypernatremia is usually evident by history alone. Accurate measurement of fluid intake and output is helpful. A water deprivation test may differentiate between central and nephrogenic diabetes insipidus. Urine osmolality and urinary sodium concentrations should be measured. A serum uric acid >5 mg/dL with polyuria and polydipsia is suggestive of central diabetes insipidus.

Management:

- Total body water deficit can be estimated as 0.6 × (body weight in kg) × ((serum sodium level/140) − 1). In patients with acute hypernatremia, free water can be replaced rapidly. In patients with chronic hypernatremia, the serum sodium level should be decreased by <2 mEq/L/hour until the symptoms resolve. The remaining water deficit can be corrected in 48 hours.
- Give water enterally, or infuse IV solutions low in sodium (e.g., 0.2% NaCl or dextrose 5% in water).
- Central diabetes insipidus usually is treated with various dosage forms of desmopressin (DDAVP) (5–20 μg intranasally every 12 hours, 1–2 μg subcutaneously once a day, or 0.1–0.2 mg orally twice a day).
- Nephrogenic diabetes insipidus may be managed with a low-salt diet and thiazide diuretics to induce natriuresis and/or indomethacin. Drugs that contribute to nephrogenic diabetes insipidus should be discontinued if possible.

Hyponatremia

Multiple (integumentary, gastrointestinal, cardiovascular, renal, and nervous) organ systems are integrated into regulatory networks for homeostatic control of intravascular volume and serum osmolality, and perturbations of these regulatory networks in patients by cancer or cancer treatments frequently cause hyponatremia.

Causes:

- Risk factors for hyponatremia include chemotherapy, nausea and vomiting, hydration with hypotonic fluid, pain, opioids, and stress
- Hypothyroidism (see section about thyroid dysfunction below)
- Adrenal insufficiency (see section about adrenal dysfunction below)
- Congestive heart failure
- Cirrhosis
- Syndrome of inappropriate secretion of antidiuretic hormone (SIADH), characterized by normal or increased intravascular volume, low serum osmolality, and inappropriately high urine osmolality in the absence of diuretics, cirrhosis, heart failure, hypothyroidism, and adrenal insufficiency:
  1. Cancers secreting vasopressin (e.g., about 15% of SCLC, 1% of other lung cancers, and 3% of squamous cell head and neck cancers) [1]
  2. Abnormal secretory stimuli for ADH (e.g., intrathoracic infection, positive pressure ventilation)
  3. Cytotoxic chemotherapeutic agents affecting paraventricular and supraoptic neurons (vinca alkaloid [vincristine and vinblastine], high-dose cyclophosphamide)
- Renal salt wasting:
  1. Tumor-induced: Mediated by atrial natriuretic peptide [2]
  2. Drug-induced: Damage to the renal tubules and resulting defects in salt and water transport may be the major cause of hyponatremia associated with low-dose cyclophosphamide therapy [3] and platinum compounds [4]

Symptoms The signs and symptoms of hyponatremia include general weakness, fatigue, nausea, and vomiting, all of which are nonspecific. The severity of symptoms depends on the rate of decline and degree of hypo-osmolality. Significant symptoms usually appear as the serum sodium concentration falls below 120 mEq/L. Neurologic symptoms of headache, behavioral changes, lethargy, confusion, seizure, stupor, and coma may manifest, while progressive cerebral edema causes brain damage, brain stem herniation, respiratory failure, and death.

Identifying the causes of hyponatremia requires additional laboratory evaluations, including urinary sodium measurement, thyroid and adrenal function tests, and correlation with clinical history.

Diagnosis Figure 29.1 outlines the evaluation and treatment of hyponatremia. Evaluation of intravascular volume status is very important in diagnosing the underlying cause of hyponatremia. Hypotonicity must be confirmed by measuring osmolality. Pseudohyponatremia caused by hyperlipidemia, hyperproteinemia, severe hyperglycemia, and administration of hypertonic mannitol should be excluded.

Management:

- If the patient is not hypovolemic, free water intake may be restricted to 500–800 mL/day.
- There are several ways to increase free water excretion:
  1. Drug-induced nephrogenic diabetes insipidus (e.g., demeclocycline 600–1200 mg/day)
  2. Loop diuretics (e.g., furosemide 20–40 mg/day)
  3. Blockade of V2 receptors to promote free water excretion (aquaresis) (e.g., conivaptan, lixivaptan, tolvaptan, and satavaptan) [5]
- Fludrocortisone (0.1–0.6 mg/day) is a mineralocorticoid that may be used to decrease renal sodium excretion.
- For patients with hypovolemia, oral intake of sodium may be increased by sodium chloride tablets along with intravascular volume expansion by infusing normal saline (0.9% NaCl).
- For emergent cases of hyponatremia in which central nervous system symptoms are evident and significant, infusion of hypertonic saline (3% NaCl) at a rate of 1 mL/kg/hour may be indicated with close monitoring (in an intensive care unit).

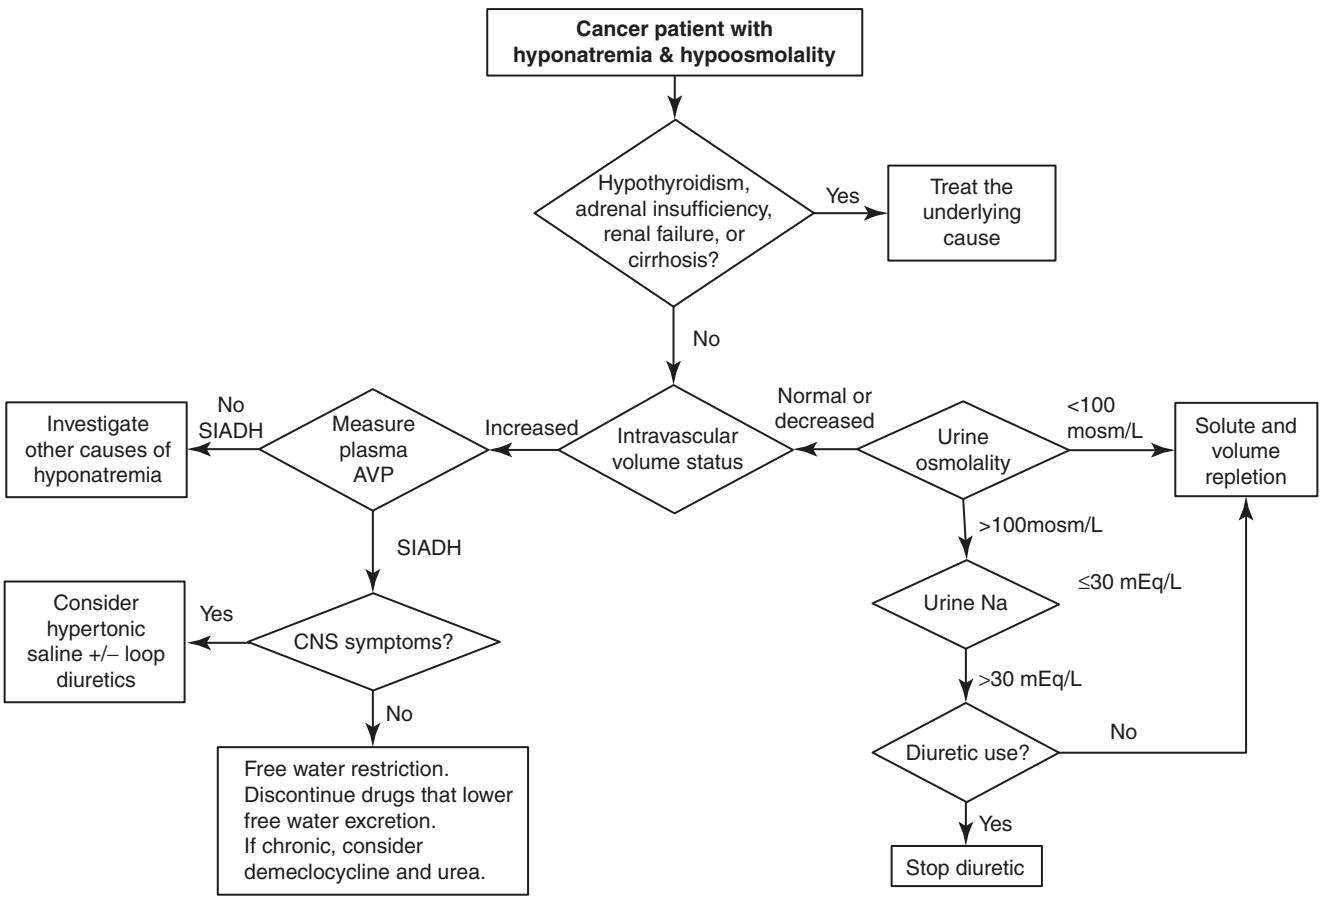

Fig. 29.1 Algorithm for the evaluation and management of hyponatremia

Hyperkalemia

In the absence of excessive intake of potassium, hyperkalemia is an electrolyte abnormality often associated with renal abnormalities in cancer patients.

Causes:

- Diminished renal excretion of potassium occurs in patients with acute or chronic renal failure, renal hypoperfusion, or type 4 renal tubular acidosis.
- Drugs that can lead to decreased potassium excretion include potassium-sparing diuretics and angiotensin-converting enzyme inhibitors.
- Excessive oral potassium supplementation and inappropriate potassium content in IV fluid or total parenteral nutrition.
- A significant release of intracellular potassium will cause hyperkalemia, as in the case of tumor lysis syndrome.
- Transcellular shifts of potassium may be seen in insulin deficiency, β-blocker therapy, and acidemia, elevating serum potassium levels.
- Drug-induced hyperkalemia often occurs with preexisting impaired renal excretion of potassium. The drugs commonly used by cancer patients that cause hyperkalemia include cyclosporin A, tacrolimus, heparin, mitomycin-C, and pentamidine.

Symptoms Severe clinical manifestations of hyperkalemia are usually absent until the serum level is >7.5 mEq/L. Some patients (e.g., those with chronic renal failure) can tolerate high serum potassium levels without having any clinical signs or symptoms. Hyperkalemia causes depolarization of excitable membranes. This membrane depolarization leads to the excitability of nerves and muscles, causing cramps, muscle weakness, and paralysis. At >7.5 mEq/L, nonspecific symptoms, such as muscle weakness, cramping and paralysis of different muscle groups, may occur.

Diagnosis The most vital organ with excitable membranes is the heart. Electrocardiogram (EKG) changes and potentially fatal arrhythmias may be present. An early EKG abnormality associated with hyperkalemia is peak T waves (Fig. 29.2) followed by progressive QRS widening to a "sinusoidal" wave (Fig. 29.3) [6]. Ventricular tachycardia, fibrillation, and asystole may occur.

Hypotension and hypoglycemia with hyperkalemia suggest possible adrenal insufficiency. Serum electrolytes, blood urea nitrogen, serum creatinine, urinalysis, urine electrolytes, and arterial blood gases will often elucidate the cause of hyperkalemia.

Management:

- If possible, discontinue medications that may contribute to hyperkalemia (e.g., potassium supplements, spironolactone, amiloride, β-adrenergic blockers, nonsteroidal anti-inflammatory drugs, angiotensin receptor blockers, and angiotensin-converting enzyme inhibitors).

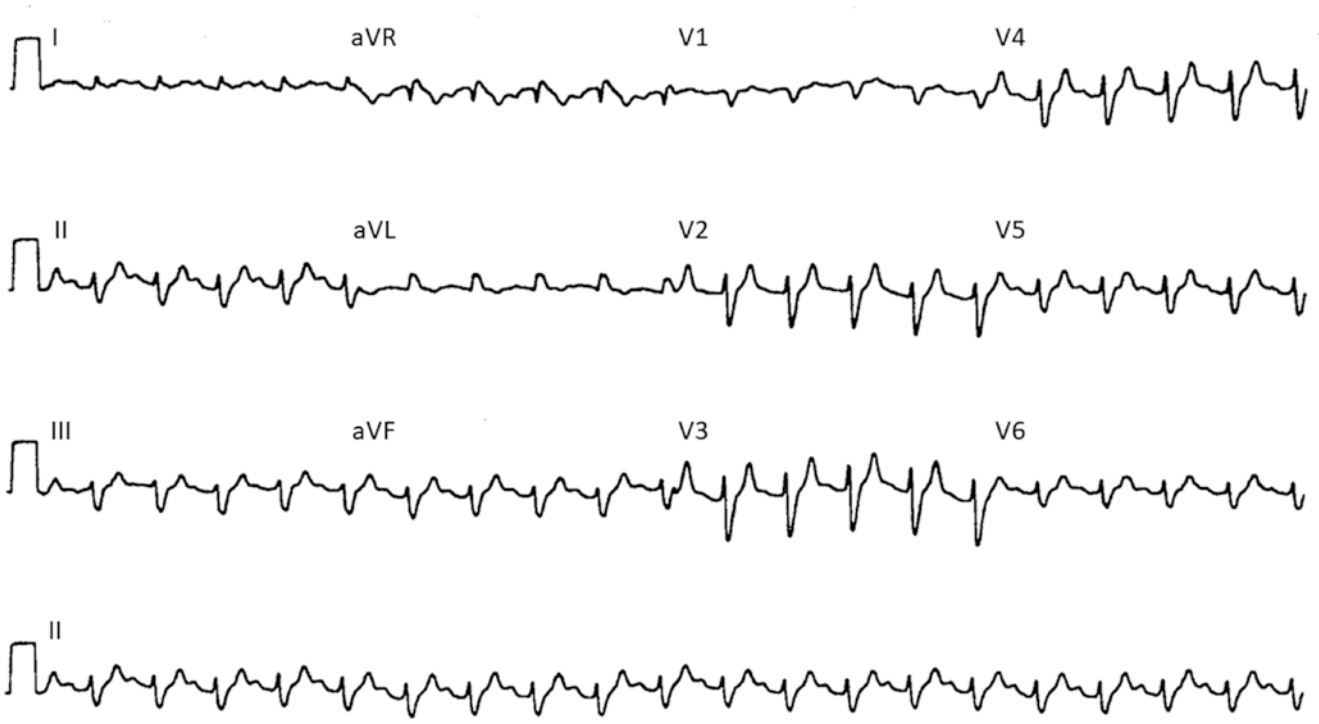

Fig. 29.2 Peaked T wave in an electrocardiogram of a hyperkalemic patient. The serum potassium was 7.3 mEq/L

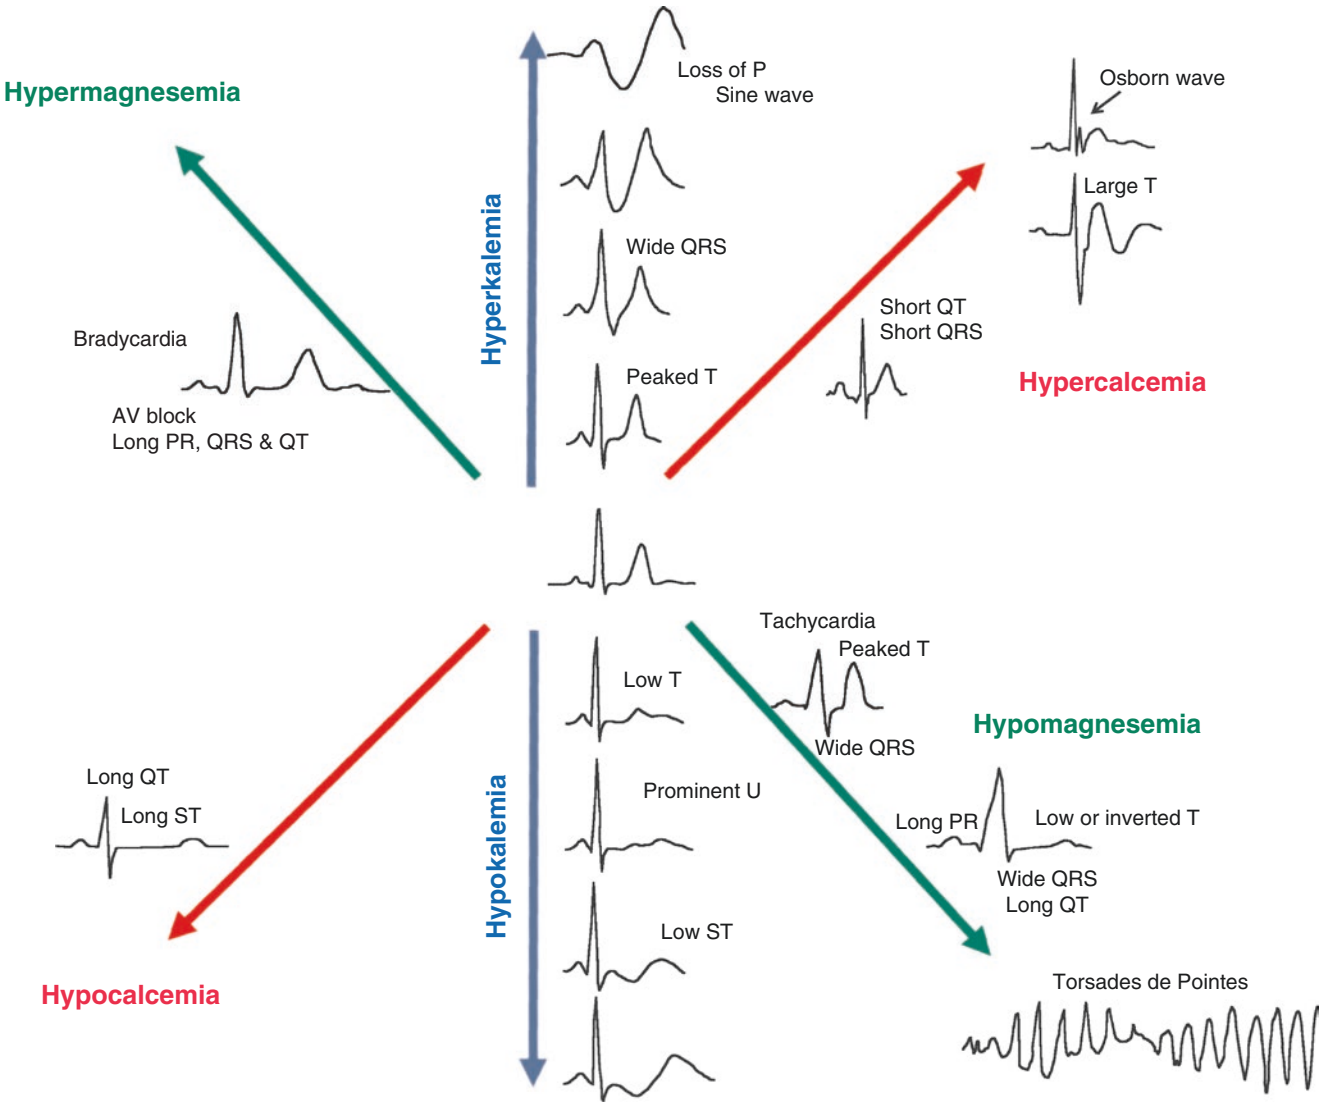

Fig. 29.3 EKG changes in the presence of electrolyte abnormalities [6]

- Hyperkalemia due to calcineurin inhibitors cyclosporine and tacrolimus may respond to treatment with fludrocortisone.
- For severe hyperkalemia (>6.5 mEq/L) and/or EKG changes, monitor EKG continuously and treat with the following:
  1. IV calcium (1–2 g of calcium gluconate or 0.5–1.0 g of chloride).
  2. IV sodium bicarbonate (1 mEq/kg).
  3. IV glucose (usually 25 g) plus 6–8 U of regular insulin.
  4. β-adrenergic agonists (e.g., albuterol 2.5 mg nebulized inhalation). Loop diuretics may be used to promote natriuresis and kaliuresis.
- Ion exchange resins, such as sodium polystyrene sulfonate (Kayexalate), which can be administered orally (15–30 g/dose) or rectally (30–60 g/dose) as a retention enema, may remove potassium from the body via the gastrointestinal tract.
- Emergent hemodialysis may be used in refractory cases.

Hypokalemia

Hypokalemia is a very common electrolyte abnormality in cancer patients.

Causes:

- Potassium intake in cancer patients may decrease for various reasons, such as nausea, vomiting, anorexia and gastrointestinal obstruction.
- Potassium may be lost from the gastrointestinal tract via vomiting or diarrhea, and from the kidneys as a result of intrinsic tubular defects and type 1 renal tubular acidosis.

- Drug-related effects (e.g., loop diuretics, aminoglycosides, cyclophosphamide, ifosfamide, carboplatin, cisplatin, and amphotericin B).
- Hypokalemia owing to excess mineralocorticoid activity may result from deregulated aldosterone production by adrenal tumors or other renin-secretion cancers [renal (Wilms tumor, renal cell carcinoma, or hemangiopericytoma), lung (SCLC, adenocarcinoma), hepatic, pancreatic, or ovarian carcinomas] [7].
- Exogenous corticosteroids, fludrocortisone, and Cushing syndrome, which includes ectopic secretion of ACTH by some cancers (e.g., small cell lung cancer [SCLC], carcinoid tumors).
- Alkalosis, either respiratory or, on a larger scale, metabolic, may precipitate hypokalemia via a transcellular potassium shift. Drugs that cause potassium redistribution include insulin, β-adrenergic agonists, theophylline, and chloroquine.

Symptoms Patients with mild hypokalemia (3.0–3.5 mEq/L) are usually asymptomatic. In those with severe hypokalemia (<3.0 mEq/L), symptoms may range from mild to severe (and potentially fatal). Cardiac manifestations range from flat T waves, T-wave depression, and prominent U waves to serious arrhythmias (ventricular tachycardia or fibrillation) (see Fig. 29.3). Neurologic manifestations include muscle weakness, paresthesia, and paralysis.

Diagnosis Medications and dietary histories will help determine the cause of hypokalemia. Physical examination will give clues regarding Cushing syndrome. Measurement of serum electrolytes, including magnesium, blood urea nitrogen, and creatinine; urinalysis; and urine electrolyte measurement will help to diagnose renal potassium loss.

Management The oral route for potassium replacement is preferred over other routes if feasible. The IV route may be used in patients with severe hypokalemia or those unable to tolerate enteral replacement. The rate of IV administration should not exceed 20 mEq/hour diluted in IV fluid through a peripheral vein. The infusion rate may be as high as 40 mEq/hour through a central venous catheter. In general, the relationship between the degree of hypokalemia and total body deficit is linear. For each 1 mEq/L decrease in serum potassium level, the total body deficit would be about 300 mEq. This total body deficit may be corrected over days. Almost half of the cancer patients with hypokalemia have concurrent hypomagnesemia. Potassium-sparing diuretics, such as amiloride and spironolactone, inhibit potassium excretion and may have a role in decreasing renal potassium wasting.

Hypermagnesemia

Hypermagnesemia is uncommon.

Causes:
- Renal failure.
- Increased intake of magnesium in the presence of renal insufficiency.
- Excessive magnesium in IV fluid or parenteral nutrition.
- In the absence of renal insufficiency, hypermagnesemia owing to excessive intake of magnesium is very rare, as excess magnesium in the gastrointestinal tract leads to diarrhea.

Symptoms The clinical manifestations of hypermagnesemia correlate well with the serum level of magnesium. Early signs include nausea, vomiting, weakness, and cutaneous flushing, which can occur when the serum magnesium level is greater than 3 mg/dL. With levels greater than 4 mg/dL, hyporeflexia and loss of deep tendon reflexes may occur. At levels greater than 5 mg/dL, hypotension and EKG changes (QRS widening, QT and PR prolongation, and conduction abnormalities) may occur (see Fig. 29.3). Respiratory depression, coma, and complete heart block may occur at levels greater than 9 mg/dL. Asystole and cardiac arrest occurs at levels greater than 10 mg/dL.

Diagnosis Excessive magnesium intake usually is evident in the patient's dietary and medication histories. Renal function should be assessed by measuring blood urea nitrogen and serum creatinine.

Management:
- Medications and IV fluids containing magnesium should be discontinued.
- Patients with mild symptoms and normal renal function can be observed without intervention.
- Magnesium excretion can be accelerated by hydration with crystalloid fluid and loop diuretics.
- In severe cases with hypotension and/or cardiac arrhythmia, IV calcium should be administered to reverse respiratory depression, hypotension, and cardiac arrhythmia. Emergent dialysis should be considered to correct life-threatening hypermagnesemia in the presence of impaired renal function.

Hypomagnesemia

Magnesium is a major inorganic cation in the body, of which only 1–2% is present in the extracellular space.

Hypomagnesemia is defined as a plasma serum concentration of magnesium less than 1.5 mg/dL. However, magnesium levels that are persistently less than 1.8 mg/dL indicate depletion of total body magnesium. The prevalence of hypomagnesemia in hospitalized cancer patients is about 20%.

Causes:

- Low oral intake, impairment of renal reabsorption, prolonged IV feeding, chronic alcoholism, intestinal malabsorption, and diarrhea.
- The renal toxicity of chemotherapy (e.g., platinum-based drugs, cyclophosphamide, ifosfamide) or anti-infective medications (e.g., amphotericin, aminoglycosides) will also cause hypomagnesemia. Platinum agents cause morphologically evident nephrotoxicity that may result in long-term or even permanent damage to renal functions. Hypomagnesemia occurs in approximately 90% of patients treated with cisplatin [8], and 10% of the hypomagnesemic patients have symptoms of muscle weakness, tremors, and dizziness. Hypomagnesemia may persist long after cessation of cisplatin therapy.
- Anti-EGFR targeted therapy (cetuximab, panitumumab, and anti-EGFR small molecular inhibitors such as gefitinib) reduces renal magnesium reabsorption through a reversible effect of epidermal growth factor receptor (EGFR) inhibition in the renal distal convoluted tubule without inflicting extensive cell or organ injury [9].

Symptoms Magnesium is needed for a wide variety of enzymatic reactions, including those involving ATP and nucleic acid metabolism. Magnesium is also directly involved in the regulation of calcium and potassium metabolism. The clinical manifestations of hypomagnesemia may be nonspecific and include anorexia, nausea, vomiting, lethargy, dizziness, muscle weakness, tremor, muscle fasciculation, tetany, and tonic-clonic seizures.

Diagnosis Hypomagnesemia is often associated with other electrolyte abnormalities, such as hypokalemia and hypocalcemia [10]. Concurrent measurement of other electrolytes, such as calcium, phosphate, and potassium, should be considered. Significant hypomagnesemia is associated with EKG changes (see Fig. 29.3). According to CTCAE version 4, hypomagnesemia is Grade 1 when magnesium is below normal to ≥0.5 mM; Grade 2, <0.5–0.4 mM; Grade 3, <0.4–0.3 mM; and Grade 4, <0.3 mM with life-threatening consequences.

Management Magnesium replacement is indicated in cancer patients when serum magnesium is repeatedly below normal. Oral replacement is preferred over parenteral when feasible. However, diarrhea may be a dose-limiting side effect. When IV replacement is required, the usual practice is to replace half of the estimated dose over 1 day and the remaining half over the next 3–4 days. Hypomagnesemia induced by anti-EGFR-therapy is reversible.

Hypercalcemia

The incidence of hypercalcemia in cancer patients is about 1% [11].

Causes:

- Hypercalcemia of malignancy accounts for more than 90% of hypercalcemia cases:
  1. Parathyroid hormone-related protein (PTHrP)-mediated hypercalcemia [12, 13] is a paraneoplastic syndrome associated with a short survival. PTHrP causes hypercalcemia by binding to the parathyroid hormone (PTH) receptor and activating the expression of an osteoblast-specific cell surface protein, RANK ligand (RANKL). Interaction between RANKL and the RANK receptor on the osteoclast precursor causes increased osteoclast differentiation, bone resorption, and hypercalcemia. PTHrP production is found commonly in squamous cell carcinoma, breast, neuroendocrine, renal, and prostate cancers, as well as melanoma.
  2. Other tumor-secreted humoral factors, such as interleukin-1 and -6, prostaglandins and tumor necrosis factor, may contribute to hypercalcemia.
  3. In multiple myeloma, increased expression of RANKL causing localized osteoclast proliferation appears to be the most important cause [13].
  4. Lymphomas commonly express 1α-hydroxylase, the enzyme that converts 25-hydroxy vitamin D3 to 1,25-dihydroxy vitamin D3 (calcitriol), leading to increased gastrointestinal absorption of calcium [14].
- Primary hyperparathyroidism should be considered in the differential diagnosis of hypercalcemia. No cancer treatment has been identified as a cause of hypercalcemia, except that low-dose (2–7.5 Gy) external-beam irradiation of the head and neck area increases the incidence of primary hyperparathyroidism by 2.5- to 3-fold many years after irradiation of the neck (29–47 years) [15]. Primary hyperparathyroidism may also develop in multiple endocrine neoplasia (MEN), especially type 1.

Symptoms Patients with mild hypercalcemia (calcium level <12 mg/dL) usually have no symptoms, whereas those with moderate or severe hypercalcemia are frequently symp-

tomatic. Central nervous system symptoms are lethargy, ataxia, stupor, coma, mental status changes, and psychosis. Gastrointestinal tract symptoms are anorexia, nausea, constipation, ileus, dyspepsia, and pancreatitis. Renal signs are polyuria, nephrolithiasis, and nephrocalcinosis. Cardiovascular manifestations can be a short QT interval, ST segment depression, sinus arrest, and atrioventricular block (see Fig. 29.3). Musculoskeletal symptoms are myalgia, arthralgia, and weakness. Severe hypercalcemia (>13 mg/dL) frequently causes depression of cerebral function or coma.

Diagnosis Serum calcium levels should be interpreted in the context of protein binding (corrected calcium level = [0.8 × (normal albumin level - patient's albumin level)] + serum calcium level). Measurement of the ionized calcium can confirm hypercalcemia. Laboratory studies of the following help diagnose the etiology of hypercalcemia: intact PTH, PTH-related protein, 25-hydroxy vitamin D_3, and 1,25-dihydroxy vitamin D_3. The combination of hypercalcemia and an elevated PTH level combined with increased urinary calcium excretion provides reasonable evidence for primary hyperparathyroidism. Suppression of the PTH below the normal range is found in PTHrP or calcitriol-mediated hypercalcemia, which can be diagnosed by measuring 25-hydroxy vitamin D3 and 1,25-dihydroxy vitamin D3.

PTHrP-mediated hypercalcemia is characterized by a suppressed PTH level and a low or normal calcitriol level. This contrasts with the finding of elevated PTH and calcitriol levels in primary hyperparathyroidism. The characteristic clinical features of hypercalcemia in lymphoma include a suppressed serum PTH, a normal or slightly increased phosphate level due to suppression of PTH, hypercalciuria, absence of bone metastasis, and an elevated serum calcitriol level [14].

Management:

- The initial and first-line treatment of hypercalcemia is hydration by infusion of normal saline at rates between 100 and 300 mL/h. Hydration alone can lower the serum calcium by 10% or more over 6–12 hours. In patients with overall fluid overload, use of a loop diuretic would be helpful.
- Calcium-containing medications and thiazide diuretics (which inhibit renal tubular excretion of calcium) should be discontinued.
- Bisphosphonates inhibit bone resorption by osteoclasts, and their peak impact on hypercalcemia is usually seen after a couple of days. Zoledronate (4–6 mg IV over 30 minutes) [16] is more widely used than pamidronate (60–90 mg IV over 4–24 hours) because of its higher potency and efficacy [17].
- Second-line agents include calcitonin (salmon calcitonin 4 IU/kg subcutaneously every 12 hours). Calcitonin has a rapid onset of action, but its effectiveness may decrease within 2–3 days.
- Glucocorticoids (40–60 mg/d prednisone equivalent) may be used in hypercalcemia associated with myeloma and lymphoma.
- Denosumab (anti-RANKL antibody) is a new drug for hypercalcemia of malignancy [18].
- Primary hyperparathyroidism can be cured via parathyroidectomy. Removal of adenoma is usually curative, but in the context of MEN1, the surgical procedure of choice is three-and-a-half-gland parathyroidectomy [19].

Hypocalcemia

Hypocalcemia is a common complication of chemotherapy [20].

Causes:

- Nephrotoxicity of platinum compounds: Hypocalcemia has been reported in 6–20% of cisplatin-treated and 16–31% of carboplatin-treated patients. Hypomagnesemia may decrease secretion of PTH and reduce its calcium-mobilizing effects. Hypomagnesemia also inhibits the formation of 1,25-dihydroxy vitamin D_3. Platinum compounds may inhibit the mitochondrial function in the kidneys and thereby inhibit conversion of 25-hydroxy vitamin D_3 to 1,25-dihydroxy vitamin D_3.
- Plicamycin (mithramycin) and dactinomycin are two infrequently used antineoplastic agents that are known to cause hypocalcemia.
- Surgical procedures in the neck that sacrificed or damaged the parathyroid glands (e.g., total laryngectomy, total thyroidectomy) can cause primary hypoparathyroidism, leading to hypocalcemia.
- Vitamin D deficiency causes rickets and osteomalacia along with hypocalcemia.
- Tumor lysis syndrome.

Symptoms Hypocalcemia can be asymptomatic if it is mild. Life-threatening problems such as seizures, cardiac dysrhythmias, and laryngospasm can occur if hypocalcemia is severe. Acute hypocalcemia is characterized by neuromuscular irritability. Acute symptoms are muscle weakness, paresthesia, spasm, tetany, hyperreflexia, Chvostek sign, Trousseau sign, seizure, bronchospasm, laryngeal spasm, and respiratory failure. Cardiovascular presentations are bradycardia, hypotension, QT-interval prolongation (see Fig. 29.3), congestive heart failure, and cardiac arrest. Chronic hypocalcemia with hypoparathyroidism causes extrapyramidal disorders and cataracts, as well as skin and hair changes.

Diagnosis Measuring ionized calcium can exclude pseudohypocalcemia owing to low albumin and serum protein levels. In most cancer patients, the etiology of hypocalcemia is obvious. The major causes of hypocalcemia are hypoparathyroidism, hypomagnesemia, and chemotherapy toxicity. If the cause of hypocalcemia is not clear, laboratory analysis of intact PTH, magnesium, phosphate, 25-hydroxy vitamin D3, 1,25-dihydroxy vitamin D3, creatinine and 24-hour urinary calcium levels is helpful.

Management:
- Severe hypocalcemia is treated parenterally with IV calcium chloride (0.5–1.0 g) or gluconate (1–2 g) over 5–10 minutes.
- Hypomagnesemia is a common cause of hypocalcemia. Concurrent hypomagnesemia should be treated with IV magnesium sulfate followed by oral replacement.
- Chronic hypocalcemia is treated with oral calcium preparations (e.g., gluconate, carbonate) containing 1–2 g of elemental calcium per day.
- Patients with hypoparathyroidism often require life-long supplementation of calcium and vitamin D. Vitamin D supplements can be given in 1-hydroxylated form or as calcitriol.
- Recombinant $PTH_{1–34}$ (teriparatide) is now approved for the treatment of osteoporosis. Its use in hypoparathyroidism remains to be studied.
- For hypocalcemia secondary to hyperphosphatemia, hyperphosphatemia often requires correction first. See below for management of hyperphosphatemia.

Hyperphosphatemia

In the absence of renal failure, the fasting serum phosphate level is determined primarily according to the renal tubular reabsorption rate.

Causes:
- A massive amount of phosphate can be released into the extracellular fluid via extensive cellular breakdown (e.g., tumor lysis syndrome, rhabdomyolysis, and hemolysis).
- Translocation of phosphate from cells in response to metabolic or respiratory alkalosis can lead to acute hyperphosphatemia.
- Chronic hyperphosphatemia is present in patients with hypoparathyroidism on long-term treatment with oral calcium and vitamin D.
- Excess phosphate intake (e.g., phosphate-containing laxatives), especially in the presence of renal insufficiency.

Symptoms The clinical manifestations of acute hyperphosphatemia are similar to those of associated hypocalcemia. Paresthesia, muscle cramps, tetany, and QT-interval prolongation may be induced directly by severe hyperphosphatemia. Chronic hyperphosphatemia, especially associated with hypercalcemia, may lead to diffuse visceral deposition of calcium phosphate. Deposition of calcium phosphate in the kidneys may lead to renal failure.

Diagnosis In patients with hyperglobulinemia, pseudohyperphosphatemia must be excluded with a specimen that is free of protein (removed via precipitation with sulfosalicylic acid). In those with hyperphosphatemia, renal function must be assessed. In addition, measurement of lactic dehydrogenase, uric acid, potassium, and calcium levels is necessary to diagnose and manage hyperphosphatemia due to extensive cellular lysis.

Management:
- In patients with normal renal function, infusion of isotonic saline increases phosphate excretion.
- Administration of dextrose and insulin drives phosphate into cells, temporarily lowering the serum phosphate level.
- When hyperphosphatemia is life-threatening, hemodialysis or peritoneal analysis should be considered.
- Blocking phosphorus absorption in the gastrointestinal tract:
  1. Aluminum hydroxide
  2. Calcium-based phosphate binders (e.g., calcium acetate)
  3. Nonabsorbable phosphate binders that are aluminum- and calcium-free (sevelamer 800–1600 mg with each meal)

Hypophosphatemia

Hypophosphatemia is found in about 2–3% of all hospitalized patients and about 30% of cancer patients.

Causes:
- Relative nutritional deficiency:
  1. Hypophosphatemia in malnourished patients (especially alcoholics) is due to a combination of magnesium deficiency, vitamin D deficiency, and malabsorption. Acute hypophosphatemia may occur in hospitalized patients with serious illnesses and preexisting phosphate depletion.
  2. Refeeding with high-calorie contents in severely malnourished patients.

3. Rapid cancer proliferation may cause hypophosphatemia (e.g., Burkitt's lymphoma).
4. Rapid normal cell proliferation, as with the use of granulocyte colony-stimulating factors, hematopoietic reconstitution after stem cell transplantation, or stem cell harvesting in preparation for transplantation.

- Renal wasting of phosphorus and calcium:
  1. Tumor-induced osteomalacia is a rare paraneoplastic syndrome characterized by hypophosphatemia, excessive urinary phosphate loss, reduced 1,25-dihydroxy vitamin D concentrations, and osteomalacia. Fibroblast growth factor-23 may be the humoral mediator of this paraneoplastic syndrome [21]. Tumors that produce this clinical syndrome include mesenchymal tumors (osteoblastomas, giant cell osteosarcomas, hemangiopericytomas, hemangiomas, nonossifying fibromas) [22] and, rarely, malignant tumors such as prostate or lung cancer.
  2. Intrinsic renal tubular defect in phosphate reabsorption, or acquired renal tubular defect (e.g., after ifosfamide [23], cisplatin [24], and estramustine [25]).
- Transcellular shift of phosphate (e.g., respiratory alkalosis, IV glucose administration, hyperalimentation, gram-negative sepsis, or insulin therapy).
- Elevated PTH (primary hyperparathyroidism) or PTHrP (hypercalcemia of malignancy).
- Accelerated bone formation (e.g., extensive blastic bone metastasis in prostate cancer, hungry bone syndrome after resection of parathyroid adenomas).
- Loss of liver function: The liver also plays a significant role in phosphate homeostasis. Serum phosphate decreases after right or extended right hepatic lobectomy and in hepatocellular carcinoma complicating liver cirrhosis.
- Consumption of aluminum-containing medications/antacids.

Symptoms Acute severe hypophosphatemia may lead to general neurologic findings such as lethargy, confusion, disorientation, hallucinations, and focal neurologic findings such as dysarthria, dysphagia, oculomotor palsy, anisocoria, nystagmus, ataxia, cerebellar tremor, ballismus, hyporeflexia, distal sensory deficits, paresthesia, and hyperesthesia. Severe neurologic symptoms, such as muscle paralysis, seizure, and coma, are observed only when the serum phosphate level is <0.8 mg/dL. In severe hypophosphatemia, reversible left ventricular dysfunction can occur.

Muscle weakness is the most common complaint. Bone pain is another prominent complaint of phosphate-depleted patients. Prolonged hypophosphatemia leads to rickets. Osteomalacia, a condition characterized by unmineralized bone matrix, should be considered in osteopenic patients with bone pain and proximal myopathy. Waddling gait, bone tenderness, pseudo-fractures, and fractures can occur in patients with chronic hypophosphatemia. Osteomalacia and moderate to severe proximal myopathy are also characteristics of tumor-induced osteomalacia [26].

Diagnosis Measurement of renal function and potassium, magnesium, ionized calcium, vitamin D metabolites, and PTH level is helpful in the initial evaluation of the cause of hypophosphatemia. If urinary loss of phosphate is suspected, urine should be collected to measure the renal phosphate threshold/glomerular filtration rate to confirm phosphaturia.

Management:

- Significant hypophosphatemia (phosphate level less than 2 mg/dL), especially in the context of underlying phosphate depletion, should be corrected promptly.
- Phosphate can be safely administered IV at an initial dose of 0.2–0.8 mmol/kg over 6 hours (i.e., 10–50 mmol over 6 hours). Higher doses (1.5–3.0 mmol/kg over 12 hours) should be reserved for patients with phosphate levels less than 1.5 mg/dL and normal renal function.
- Mild hypophosphatemia can be treated with oral phosphate in divided doses of 750–2000 mg/day.
- For tumor-induced osteomalacia, oral or IV supplementation of phosphate combined with vitamin D therapy is generally effective for eradicating or improving clinical symptoms. Complete surgical removal of the tumor is generally curative.

Hyperglycemia

Diabetes mellitus type 2 (DM2) is a common disease, and a large number of cancer patients have co-existing DM2. Extensive epidemiologic data suggest an important role of DM2 in carcinogenesis [27–32] and cancer survival [33], and DM2 is associated with an elevated risk of pancreatic, liver, colon, gastric, breast, and endometrial cancer [27–32].

Causes:

- The administration of glucocorticoids (e.g., for antineoplastic therapy in combination regimens, for edema of brain metastasis, for prevention of transplant rejection, for graft-versus-host disease in BMT, and for nausea/vomiting) is probably the most common cause of drug-induced diabetes in cancer patients.
- Treatment with streptozocin [34] or L-asparaginase [35] may result in insulin-deficient diabetes mellitus.
- Diabetes mellitus may also develop as a consequence of serious pancreatitis secondary to treatment with L-asparaginase.
- Interleukin-2 and interferons may cause toxicity to pancreatic β cells and lead to insulin-dependent diabetes [36].

Immune checkpoint inhibitors may cause acute development of type I diabetes and precipitate the serious complication of diabetic ketoacidosis.

- Some targeted therapy antineoplastic agents interfere with the insulin signaling pathway and can cause hyperglycemia. PI3K inhibitors (alpelisib, copanlisib, duvelisib, and idelalisib) and mTOR inhibitors (e.g., rapamycin (sirolimus), everolimus, and temsirolimus) are associated with a high incidence of hyperglycemia [37, 38]. Some tyrosine kinase inhibitors (TKIs) (e.g., niltinib and sunitinib) are associated with hyperglycemia, but some TKIs (e.g., imatinib and pazopanib) may be associated either with hyperglycemia or with hypoglycemia [38].
- Tacrolimus, an immunosuppressive agent used to prevent graft-versus-host disease in bone marrow stem cell transplantation, also increases the incidence of diabetes, perhaps by damaging pancreatic β cells [39]. Patients who received allogenic stem cell transplantation are likely to be receiving both glucocorticoids, cyclosporine A and tacrolimus, and are particularly at risk for developing diabetes mellitus [40].

Symptoms Most patients with significant hyperglycemia have symptoms of polydipsia, polyuria, and polyphagia. Dehydration of the lenses owing to hyperglycemia leads to blurry vision. Patients with hyperosmolar nonketotic coma experience mental status changes, hypotension, and severe dehydration. Nausea, vomiting, and abdominal pain are present in almost half of patients with diabetic ketoacidosis. Tachypnea with Kussmaul respiration, tachycardia, hypotension, orthostatic blood pressure changes, acetone breaths, and severe signs of dehydration can be present in patients with diabetic ketoacidosis.

Diagnosis A random plasma glucose >200 mg/dL or a fasting plasma glucose >126 mg/dL on more than one occasion can indicate diabetes mellitus. Abnormal glucose may require further diagnostic evaluation with a glucose tolerance test or mixed meal tolerance test or glycosylated hemoglobin (hemoglobin A1C).

Diabetic ketoacidosis is diagnosed according to the triad of metabolic acidosis, hyperglycemia, and the presence of ketone bodies in the urine or blood. Arterial blood gas testing will demonstrate acidemia and respiratory compensation for metabolic acidosis by hyperventilation. Also, the anion gap will be elevated, and serum ketone testing will be positive. A urine dipstick test for ketones can provide timely information for a quick bedside diagnosis. Absence of ketones from the urine practically excludes diabetic ketoacidosis. Leukocytosis may be associated with ketosis, but an infection must be considered as a precipitating factor for diabetic ketoacidosis. The serum creatinine level can be falsely elevated because of ketosis. Potassium, phosphate, and magnesium abnormalities result from transcellular shifts caused by acidosis.

In hyperosmolar hyperglycemic nonketotic coma, the plasma glucose level may be >800 mg/dL and the serum osmolality may be >100 mOsm above normal. Mild ketosis may be present because of starvation, but ketoacidosis is absent. In severe cases, when volume depletion compromises tissue perfusion, lactic acidosis will develop.

In immunocompromised cancer patients in particular, sepsis must be ruled out as the precipitating event for diabetic ketoacidosis or hyperosmolar hyperglycemic coma.

Management:

- In general, insulin will be needed in patients who are insulin deficient.
- Diabetic ketoacidosis is decompensated catabolism triggered by a relative or absolute deficiency in insulin secretion.
- Treatment of diabetic ketoacidosis or hyperosmolar hyperglycemic coma:
  1. Hydration with IV crystalloid fluid.
  2. Regular insulin, which usually is given as an IV bolus of 0.1 U/kg, followed by a maintenance IV infusion of 0.1 U/kg/hour. The amount of insulin required for treatment of hyperosmolar hyperglycemic coma may be less than that required for diabetic ketoacidosis.
  3. Correction of electrolyte abnormalities, but beware of transcellular shift of electrolytes related to blood pH and the effect of insulin.
  4. Identification of the precipitating factors (particularly important to rule out sepsis).

Hypoglycemia

Glucagon and epinephrine immediately stimulate hepatic glycogenolysis followed by gluconeogenesis and are the two major counterregulatory hormones in response to hypoglycemia. Other counterregulatory hormones are norepinephrine, cortisol, and growth hormone, but their effects are delayed.

Causes:

- Cancer-related malnutrition, fat and muscle wasting, cirrhosis, and extensive liver metastases may impair glycogenolysis and gluconeogenesis.
- Adrenal insufficiency is associated with hypoglycemia; refer to the section on adrenal crisis below for detailed discussion.
- For diabetic cancer patients receiving sulfonylurea or insulin, the most common cause of hypoglycemia may be delayed or decreased food intake. The kidneys contribute to overall gluconeogenesis during hypoglycemia stress in

about one third of cases and are important to extrahepatic degradation of insulin. Moreover, a number of oral hypoglycemic drugs are excreted by the kidneys. Therefore, decline in renal function often leads to hypoglycemic episodes in diabetic patients.

- Tumor-induced hypoglycemia is an uncommon but challenging cause of morbidity for cancer patients. Three different clinical syndromes have been identified: (1) secretion of insulin by islet cell malignancy; (2) insufficient gluconeogenesis due to near complete replacement of hepatic parenchyma by tumor; and (3) secretion of insulin-like growth factor II (IGF2), which activates the insulin receptor and causes hypoglycemia [41–43] by tumors (e.g., fibrosarcomas, hemangiopericytomas, and hepatomas).
- Excessive glucose consumption by large tumors also may cause hypoglycemia. Hypoglycemia may also occur in patients with lactic acidosis in the context of end-stage leukemia or lymphoma [44].

Symptoms A pattern of hypoglycemia symptoms progresses as the availability of glucose to the brain decreases. At a plasma glucose level of about 70 mg/dL, brain glucose uptake can be reduced and counterregulatory hormone responses are triggered. At <60 mg/dL, autonomic symptoms, such as hunger, anxiety, palpitations, sweating, and nausea, become evident. When glucose <50 mg/dL, neuroglycopenic symptoms of blurry vision, slurred speech, inability to concentrate, and confusion appear. When glucose <40 mg/dL, the patient may become drowsy, confused, or combative. A prolonged decrease below 30 mg/dL can cause seizures, permanent neurologic damage, and death.

Diagnosis Hypoglycemia is diagnosed by blood chemistry, but rapid bedside measurement of blood glucose should be expeditiously performed in the evaluation of all ED patients with altered mental status. The timing of symptoms relative to a fasting or postprandial state or to anti-diabetic medications can distinguish among various causes of hypoglycemia.

The most common presentation for paraneoplastic syndromes of hypoglycemia is fasting hypoglycemia, and patients are most likely to develop symptoms during normal periods of fasting, particularly during nocturnal hours. Simultaneous measurement of fasting plasma glucose, insulin, proinsulin, C-peptide, IGF1, and IGF2 during a period of hypoglycemia is the most important diagnostic tool for separating the first clinical type (insulin production) from the second (replacement of liver by tumor) and third (IGF2) types. Proper diagnostic evaluation of cancer patients with fasting hypoglycemia usually will need a 72-hour fast in the hospital with endocrinology consultation.

Management:

- For mild hypoglycemia (glucose level of 50–60 mg/dL), 15 g of simple carbohydrates, such as 4 oz of unsweetened fruit juice or a non-diet soft drink, is sufficient.
- For more severe hypoglycemia without loss of consciousness, 15–20 g of simple carbohydrates should be ingested quickly followed by 15–20 g of a complex carbohydrate, such as crackers or bread.
- For severe hypoglycemia with change in mental status, glucagon (1–2 mg subcutaneously or IV) or glucose (50 mL of 50% dextrose in water IV) should be given promptly.
- The most effective therapeutic approach for non-islet cell tumor-induced hypoglycemia is to resect or debulk the tumor. If unresectable, reducing the tumor bulk via external beam irradiation, intra-arterial chemoembolization, or percutaneous alcohol injection may be attempted.
- Counterregulatory hormones such as glucocorticoids (20–40 mg prednisone equivalents per day) and glucagon (1–2 mg IV or IM) may be administered to raise the blood glucose level. Glucagon infusion (0.5–2 mg/h) to stimulate hepatic gluconeogenesis is an effective therapy for patients with insulin-producing tumors or those with IGF2-mediated hypoglycemia [45].
- A continuous IV infusion of 5–20% dextrose may be required to maintain normal blood glucose in some patients.
- Diazoxide (3–8 mg/kg/d in 2–3 divided doses) has been used successfully to inhibit insulin secretion, but it causes fluid retention, thereby limiting its usefulness at effective doses.
- Treatment of postprandial hypoglycemia is primarily dietary. The diet should have a low carbohydrate content. α-Glucosidase inhibitors (acarbose or miglitol) may be helpful.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) consists of severe hyperphosphatemia, hyperkalemia, hyperuricemia, azotemia, hypocalcemia, and metabolic acidosis (out of proportion to renal insufficiency) due to the massive release of cell contents and degradation products of dead tumor cells into the bloodstream [46].

Causes:
Factors associated with increased risk of TLS include the following:

- Type of malignancy (e.g., acute lymphocytic leukemia, acute myeloid leukemia with WBC >75,000/μL, Burkitt's

lymphoma). TLS can also occur in patients with nonhematologic malignancies, including small cell carcinomas, non-small cell lung cancer, breast cancer, and ovarian cancer.
- Responsiveness to therapy.
- Rapid malignant cell turnover.
- Large tumor burden [47]; pretreatment serum lactate dehydrogenase levels, which tend to correlate with tumor bulk in lymphoma or lymphocytic leukemia may predict the risk of tumor lysis syndrome.
- Preexisting renal insufficiency.
- Acute renal failure shortly after antineoplastic treatment.

Symptoms The symptoms of TLS are nonspecific. Common symptoms include nausea, vomiting, cloudy urine, weakness, fatigue, and arthralgia. Other signs and symptoms related to metabolic and electrolyte abnormalities include neuromuscular irritability, seizures, muscle weakness, and arrhythmia. Arrhythmia may cause sudden death in patients with TLS [48]. Precipitation of uric acid in the renal tubules may lead to nephropathy and acute renal failure [49]. The acute cause of death in TLS is arrhythmia secondary to severe electrolyte abnormalities (especially hyperkalemia) and renal failure. Early recognition of metabolic abnormalities and prompt treatment can avoid fatal outcomes.

Diagnosis TLS can occur spontaneously, but it usually occurs within 72 hours after chemotherapy in patients with leukemia and lymphoma, but new therapeutic regimens may alter the timing of onset. The diagnosis of TLS requires a high level of suspicion because there are few signs or symptoms in the early stage. Routine uric acid and electrolyte screening (including measurement of calcium and phosphorus levels) is indicated in patients with high tumor bulk or hematologic malignancies. The diagnosis of TLS may be based on the Cairo-Bishop definition [47, 50].

Management:
- Once diagnosed, patients with severe TLS should have continuous monitoring of hemodynamic and electrocardiographic parameters in intensive care.
- Management of hyperuricemia:
  1. Allopurinol (up to 900 mg/day)
  2. Rasburicase (150–200 μg/kg IV daily or one-time dosing with a rescue dose as needed) is a recombinant urate oxidase that converts uric acid to allantoin [51]
  3. IV fluid hydration may be coupled with diuresis using loop diuretics (e.g., furosemide, 20–200 mg IV every 4–6 hours) and acetazolamide (250–500 mg IV daily).
  4. Urinary alkalinization by sodium bicarbonate or acetate IV infusion to increase the solubility of urate in urine should only be considered in cases of severe hyperuricemia when rasburicase is not available.
- Frequent electrolyte measurements (every 4–6 hours) may be required. See the sections above about management of hyperkalemia, hypocalcemia, and hyperphosphatemia.
- Prompt dialysis should be instituted with continued monitoring until biochemical abnormalities resolve. Indications for dialysis in patients with TLS include the following:
  1. Symptomatic hypocalcemia and a serum phosphorus level greater than 3.3 mmol/L (>10.2 mg/dL)
  2. Severe azotemia and renal failure (creatinine >10 mg/dL)
  3. Persistent hyperkalemia (>6 mEq/L)
  4. Severe hyperuricemia (> 10 mg/dL)
  5. Oliguria or anuria despite diuretic use
  6. Refractory academia
  7. Volume overload

Endocrine Emergencies

Cushing Syndrome

Inappropriate secretion of ACTH, although uncommon, is an important cause of morbidity and mortality in certain types of malignancies. There are at least two different mechanisms: ectopic ACTH production or ectopic production of CRH, the hypothalamic peptide that normally stimulates ACTH synthesis and release.

Causes:
- The most common cause of ectopic ACTH production is the expression of proopiomelanocortin (POMC) by a tumor, producing melanocyte-stimulating hormone and ACTH. The most common tumor associated with ACTH production is small cell lung cancer (SCLC), although pulmonary carcinoid, medullary thyroid carcinoma, islet cell malignancy, pheochromocytoma, and occasional ganglioneuromas can also produce this hormone.
- The second cause of excessive ACTH production is tumor production of CRH [52]. Ectopic production of this peptide causes a clinical syndrome characterized by pituitary corticotroph hyperplasia leading to adrenal cortical hyperplasia and Cushing syndrome. Identification of excessive CRH production requires that the clinician consider this possibility and measure CRH in blood. Neoplasms that can produce CRH include medullary thyroid carcinoma, paragangliomas, prostate cancer, and islet cell neoplasms.

Symptoms Patients with ectopic ACTH syndrome may present with clinical features of Cushing syndrome—easy bruising, centripetal obesity, muscle wasting, hypertension, diabetes, and metabolic alkalosis predominate. Alternatively,

patients with rapidly growing SCLC may present with a clinical syndrome characterized by wasting, muscle atrophy, profound hypokalemic metabolic alkalosis, and hypertension without the other clinical signs of Cushing syndrome.

Diagnosis The hallmark of ectopic ACTH syndrome is the finding of an elevated plasma ACTH concentration. However, in the differential diagnosis of hypercortisolism with an elevated plasma ACTH concentration, the clinician should consider the possibility of an ACTH-producing pituitary tumor [53]. Differentiation between pituitary ACTH production and ectopic tumor production of ACTH or ectopic CRH production should be performed by a consultant endocrinologist, and therefore will not be discussed in detail here. In brief, the diagnostic evaluation starts with confirmation of hypercortisolism and measuring plasma ACTH, followed by dynamic testing, and may involve MRI of pituitary or petrosal venous sinus sampling.

Management:

- Medical management to inhibit cortisol production:
  1. Metyrapone (1–4 g/d orally).
  2. Aminoglutethimide (250 mg orally four times per day with upward titration).
  3. Ketoconazole (200–400 mg twice a day orally) [54].
  4. Etomidate rapidly inhibits cortisol synthesis at subhypnotic doses [55]. It may be titrated from 0.3 to 4 mg/kg/h IV to normalize serum cortisol in some selected patients.
- Surgical removal or treatment of the tumor with chemotherapeutic agents is the primary therapy for an ACTH- or CRH-producing tumor.
- Patients with rapidly progressive small cell lung cancer and ectopic ACTH syndrome have a unique challenge due to the need to initiate chemotherapy quickly. High susceptibility to opportunistic infections after initiation of chemotherapy will often lead to death or serious morbidity [56]. Laparoscopic adrenalectomy, following normalization of electrolyte abnormalities and hypertension, may rapidly treat hypercortisolism to decrease the risk of infectious complication after chemotherapy.
- Replacement glucocorticoid therapy will be needed after adrenalectomy or during pharmacologic inhibition of cortisol production.
- Prophylactic therapy for opportunistic infections caused by *Pneumocystis carinii* or fungi should be considered if chemotherapy is initiated shortly after normalization of the serum cortisol.

Adrenal Crisis

Cancer patients are at increased risk for adrenal insufficiency.

Causes:

Central Adrenal Insufficiency:

- Radiotherapy is a common cause of insidious development of hypothalamic dysfunction; hormonal deficiency can manifest years after radiation. In general, the rapidity of onset and severity of dysfunction depend on the total dose of radiation and the rate of delivery. The somatotropic axis is the most susceptible while the thyrotropic is the least susceptible [57–60].
- High-dose glucocorticoids may suppress the hypothalamic-pituitary-corticotropic axis. In cancer patients who have recently discontinued glucocorticoid therapy, acute stress (usually from infection/sepsis) may precipitate an adrenal crisis.
- Acute central adrenal insufficiency may occur in cancer patients in the following settings:
  1. Pituitary apoplexy
  2. Autoimmune hypophysitis after starting cancer immunotherapy (especially with immune checkpoint inhibitors, i.e., anti-CTLA4, anti-PD1, or anti-PD-L1 antibodies)
- Metastasis to the hypothalamic region or the pituitary gland is uncommon [61].
- Benign tumors such as pituitary tumors and craniopharyngiomas frequently affect this anatomic region and cause endocrine dysfunction.

Primary Adrenal Insufficiency:

- About 20–30% of patients with bilateral adrenal metastasis will have adrenal insufficiency [62], which occurs when more than 80% of adrenal tissue is destroyed or replaced by metastatic cancer [63].
- Bilateral infectious adrenalitis: Many cancer patients may be immunocompromised. In immunocompromised patients with hematological malignancies or stem cell transplantation, infection of the adrenal glands by cytomegalovirus, mycobacteria, or fungi may lead to adrenal insufficiency.
- Bilateral adrenal hemorrhage (e.g., in coagulopathy and thrombocytopenia).
- Bilateral adrenalectomy (e.g., radical nephrectomy and contralateral adrenalectomy for renal cell carcinoma and bilateral adrenal metastasis).
- Autoimmune adrenalitis (e.g., immune checkpoint inhibitors).
- Drugs that are known to inhibit glucocorticoid synthesis: etomidate [62], ketoconazole, aminoglutethimide, metyrapone, megestrol, and mitotane. At high doses, fluconazole and itraconazole may also inhibit the cytochrome P450-dependent enzymes in glucocorticoid synthesis.

Symptoms The symptoms of adrenal insufficiency include weakness, fatigue, nausea, vomiting, and weight loss. In

patients with chronic primary adrenal failure, hyperpigmentation may occur. Acute adrenal crisis involves hypoglycemia and hypotension. The cachexia and weakness seen in adrenal insufficiency can mimic cancer cachexia observed among end-stage cancer patients. Electrolyte abnormalities due to adrenal insufficiency are difficult to distinguish from poor intake, malnutrition, side effects of chemotherapeutic agents, or paraneoplastic syndromes. Both pituitary apoplexy and hypophysitis may be associated with headache.

Diagnosis The medication history should be reviewed for recent glucocorticoid exposure and medications that may inhibit steroid synthesis. Screening tests include basal 8:00 a.m. plasma cortisol measurement, dynamic testing with 1 μg of cosyntropin (synthetic $ACTH_{1–24}$) or metyrapone (30 mg/kg given orally overnight), and insulin tolerance testing (insulin-induced hypoglycemia).

Without other evidence of metastatic disease elsewhere, whether an adrenal mass is actually a metastatic tumor is critical information in determining the appropriate antineoplastic therapy. In addition to hormonal evaluation, functional scintigraphy using ^{131}I-6-iodomethyl-19-*nor*-cholesterol (NP-59), CT, and MRI may aid in the diagnosis of a unilateral adrenal mass greater than 2 cm [64, 65]. In immunocompromised patients, the possibility of infection of both adrenal glands with cytomegalovirus, mycobacteria, or fungi should be investigated. A high degree of suspicion for hypopituitarism is recommended for patients given ipilimumab, or perhaps other drugs with similar mechanisms of action.

Management If a cancer patient presents to an E with hemodynamic instability, physicians may have insufficient time to wait for the results of serum cortisol measurement or other tests to evaluate adrenal insufficiency. Under such circumstances, empiric treatment with a stress dose of hydrocortisone should be considered based on risk assessment.

- In the event of circulatory instability, sepsis, emergency surgery, or other major complications, stress dosages of parenteral glucocorticoid should be given (e.g., hydrocortisone succinate 100 mg IV every 8 hours).
- Fludrocortisone (0.05–0.20 mg/day) for mineralocorticoid replacement.
- Treat hypotension with IV normal saline or other crystalloid fluid.
- Treat hypoglycemia immediately if symptomatic. Dextrose 50% in water 50–100 mL IV, followed by D5W IV. If IV access is not quickly available, glucagon (2 mg) may be given subcutaneously or intramuscularly, but the effect may be delayed by about 10–20 minutes.
- If and when the patient is clinically stable, arrangement should be made for endocrinology consultation and the ACTH stimulation test.

Hyperthyroidism

Thyrotoxicosis is a common disease with a prevalence of 20–25 per 100,000 in the general population and a female:male ratio of 5:1.

Causes:

- Graves disease, toxic multinodular goiters, and solitary toxic nodules are the three forms of primary hyperthyroidism that account for most cases of hyperthyroidism in the general population. The risk of Graves disease after radiotherapy for Hodgkin disease is estimated to be at least 7.2 times that in the general population [66]. Immune checkpoint inhibitors may induce Graves disease in rare occasions.
- Large quantities of iodide are present in many drugs (e.g., approximately 9 mg of iodine following a daily amiodarone dose of 300 mg), antiseptics (e.g., povidone-iodine), and contrast media used in radiology. Iodine-induced hyperthyroidism usually occurs in patients with underlying thyroid diseases.
- Autoimmune thyroiditis may be precipitated by bioimmunotherapy for cancer with cytokines or immune checkpoint inhibitors. In addition to being a source of excess iodide described above, amiodarone may induce thyroiditis. Transient hyperthyroidism is usually followed by hypothyroidism.
- Radiation-induced painless thyroiditis with hyperthyroxinemia is an uncommon side effect of external beam radiotherapy to the head and neck area. Transient hyperthyroidism is also followed by hypothyroidism.
- Thyroid metastasis occurs in 1.25–24.00% of patients with metastatic carcinoma; however, thyrotoxicosis owing to follicular destruction by metastasis is rare.
- Structural homology in the human chorionic gonadotropin and TSH molecules as well as receptors provides the biochemical basis for the ability of human chorionic gonadotropin to stimulate the TSH receptor. Trophoblastic tumors, hydatidiform moles, and choriocarcinomas secrete human chorionic gonadotropin in large amounts, often causing hyperthyroidism. Hyperthyroidism is likely for human chorionic gonadotropin level >200 IU/mL.

Removal or effective therapy for the underlying tumor is the most effective therapy for clinical syndromes caused by excessive β-HCG production. Hyperthyroidism can be treated short term with thionamide therapy if there is belief that chemotherapy or other strategies to treat the underlying malignancy are likely to be effective. In patients with less responsive tumors, thyroidectomy or radioactive iodine may be required.

Symptoms Thyrotoxicosis is characterized by a hyperadrenergic state. Sinus tachycardia, systolic flow murmur, and water-hammer pulse are common. Atrial dysrhythmias (atrial

fibrillation, atrial flutter, and premature atrial contractions) and congestive heart failure are often observed. Eye signs include exophthalmos, lid lag, and upper lid retraction. Neuropsychiatric symptoms include agitation, anxiety, restlessness, fear, paranoia, and mood swings. Neuromuscular symptoms include fine tremor in the hands and proximal myopathy (common in the elderly). Gastrointestinal symptoms include hyperphagia, diarrhea, nausea, vomiting, and abdominal pain. Skin signs include flushed skin, hair loss, and pretibial myxedema. Apathetic hyperthyroidism is seen in the elderly with prominent features of congestive heart failure, atrial fibrillation, and weight loss.

Diagnosis Thyrotoxicosis is diagnosed by measuring thyroid hormone (thyroxin and triiodothyronine) and TSH levels. Measurement of free thyroid hormones instead of total serum hormone prevents changes introduced by variations in thyroxine-binding globulin. Pituitary and hypothalamic causes of thyrotoxicosis are very rare. Measurements of thyroid-stimulating immunoglobulin and anti-thyroperoxidase antibodies are helpful in evaluating autoimmune etiologies. A radionuclide scan is helpful in distinguishing hyperfunction of the thyroid gland from thyroiditis.

Thyroid storm should be considered in the differential diagnosis of hyperpyrexia in the emergency care setting, particularly in cancer patients with risk factors for Graves disease (e.g., bioimmunotherapy and history of irradiation of the neck or chest area) or tumors that may secrete human chorionic gonadotropin. A scoring system for thyroid storm and a set of diagnostic criteria, including fever, tachycardia, tachyarrhythmias, and mental status changes, have been proposed [67, 68].

Management:

- Treatment of Graves disease includes anti-thyroid medications, radioactive iodine, and surgery.
- Treatment of thyroiditis primarily involves removing the causative factors and controlling the hyperadrenergic symptoms with β-blockers.
- If thyroid storm is highly likely on the basis of clinical criteria, diagnostic studies should be performed, and therapy should be initiated immediately. In addition to support for systemic decompensation and correction of precipitating factors, acute management may involve the following:
  - Propylthiouracil 100–600 mg/day or methimazole 10–60 mg/day.
  - β-blockers, both cardioselective and noncardioselective, are important adjuncts in treating hyperthyroidism. β-blockade provides rapid relief of hyperadrenergic symptoms and signs of thyrotoxicosis. High doses of propranolol (greater than 160 mg/day) can inhibit peripheral conversion of T4 to T3.
  - Saturated solution potassium iodide (3–5 drops) is administered orally every 8 hours to block release of thyroid hormones in patients with thyrotoxicosis. At pharmacologic concentrations (100 times the normal plasma level), iodides decrease thyroid gland activity through the Wolff-Chaikoff effect.
  - The oral contrast agents also are potent inhibitors of T4-to-T3 conversion, making them ideal for treatment of severe or decompensated thyrotoxicosis. They are generally given after starting treatment with thioamide. Although physicians have used IV iodinated radiographic contrast medium to treat a case of thyroid storm, this approach is highly nephrotoxic, and its efficacy has yet to be firmly established.
  - Other treatment options include corticosteroids (e.g., dexamethasone, which inhibits peripheral thyroxine conversion), colestipol, lithium, amiodarone, ipodate, iopanoic acid, and potassium perchlorate.
  - Plasmapheresis and hemoperfusion are effective ways to remove excess thyroid hormone.

Myxedema Coma

The prevalence of hypothyroidism is 2–3% in the general population with a female-to-male ratio of 10:1. Therefore, female cancer patients with preexisting or co-existing hypothyroidism are common. Hypothyroidism may also be a complication of cancer or its treatment.

Causes:

- Total or near-total thyroidectomy may be performed for a variety of oncologic reasons in the management of thyroid cancer, head and neck cancer, or thyroid metastasis. Thyroid replacement is needed in this group of patients.
- Irradiation can cause primary, secondary, or tertiary hypothyroidism.
- Primary hypothyroidism is caused by thyroid cell destruction, inhibition of cell division, vascular damage, and possibly an immune-mediated phenomenon. Factors that increase the risk of developing primary hypothyroidism include a high radiation dose to the vicinity of the thyroid gland, duration since therapy, lack of shielding of the thyroid during therapy, and combined irradiation and surgical treatments [69].
- Hypothyroidism after radiation therapy is related to the radiation dose. The threshold for causing clinical hypothyroidism is about 10 Gy [66, 70].
- Chemotherapy
  - The incidence of primary hypothyroidism is increased in patients treated with multiple combination drug regimens [71, 72], with or without radiation [71].

  - L-Asparaginase, in addition to inhibition of TBG synthesis discussed above, may also inhibit TSH synthesis reversibly and lead to temporary hypothyroidism with decreased free T_4 levels [73].
- Immunotherapy
  - Thyroid dysfunction is a recognized side effect of cytokine treatments. Treatment with interleukin-2 produces thyroid dysfunction in approximately 20–35% of patients [74]. These patients have hypothyroidism, hyperthyroidism, or hyperthyroidism followed by hypothyroidism [75]. Approximately 10% of interferon-treated patients develop primary hypothyroidism [76]. Patients with anti-thyroid antibodies before therapy are at higher risk of cytokine-induced thyroid dysfunction.
  - Immune checkpoint inhibitors induce immune thyroiditis. In the late phase of thyroiditis, long-term or permanent hypothyroidism results.
- Targeted therapy
  - Bexarotene (a retinoid X receptor [RXR]-selective ligand to treat cutaneous T-cell lymphoma) caused secondary hypothyroidism dose-dependently [77]. In addition to suppressing transcription of TSH by an RXR-mediated thyroid hormone-independent mechanism [78], bexarotene also increases clearance of thyroid hormones by a metabolic pathway not involving deiodinase [79].
  - Many TKIs (e.g., pazopanib, nilotinib, axitinib, cabozantinib, sorafenib, dasatinib, sunitinib, and imatinib) may cause primary hypothyroidism. Tyrosine kinase receptors (e.g., VEGFR, EGFR, RET, KIT, MET) and downstream signaling pathways (e.g., BRAF, PI3K, and mTOR pathways), especially RET and BRAF, play important roles in thyroid physiology. Imatinib and sunitinib may have additional mechanisms for inhibition of thyroid function. These inhibitors inhibit different targets with varying potencies/selectivity, and relative contribution of inhibition of specific pathways or specific etiologic mechanisms may vary.
  - Using high-dose (100–1000 mCi) [^{131}I]-metaiodobenzylguanidine to treat unresectable pheochromocytoma may result in primary hypothyroidism.

Symptoms Hypothyroid symptoms are nonspecific and include fatigue, general weakness, cold intolerance, depression, weight gain, joint aches, constipation, dry skin, and menstrual irregularities. Signs of moderate to severe hypothyroidism include hypertension, bradycardia, coarse hair, periorbital edema, carpal tunnel syndrome, and delayed relaxation of the tendon reflexes. Unusual signs of severe hypothyroidism include megacolon, cardiomegaly, and congestive heart failure.

Myxedema coma may occur in patients with hypothyroidism and be life-threatening as the severity of hypothermia, bradycardia, and hypoventilation increases. Pericardial, pleural, and peritoneal effusions are often present. An ileus is present in about two thirds of cases. Central nervous system changes in these patients include seizures, stupor, and coma.

Diagnosis The diagnosis of hypothyroidism is confirmed by thyroid function tests. Myxedema coma is rare since screening for thyroid dysfunction in cancer patients on targeted therapy or immunotherapy is routine. In most cases, TSH and free T4 testing is adequate for initial evaluation. In patients with myxedema coma, serum thyroid hormone levels are usually very low, whereas the TSH level is quite high (except in cases of secondary hypothyroidism).

Anemia, hyponatremia, hypoglycemia, hypothermia, and hypotension can occur. Arterial blood gas measurement usually reveals retention of carbon dioxide and hypoxemia. An EKG often shows sinus bradycardia, various types and degrees of heart block, low voltage, and T-wave flattening.

Management Recognition of hypothyroidism may be difficult in the emergency care setting. Thyroid function test results typically are not available expeditiously. The emergency physician's responsibility is to consider the diagnosis of hypothyroidism, provide acute care, and order the appropriate thyroid function tests to expedite diagnosis. Myxedema coma occurs most often in elderly hypothyroidism patients with a superimposed precipitating event, which must also be treated.

Rapid clinical diagnosis with early therapy may be lifesaving. In critically ill patients, if free thyroxine is very low and myxedema coma is highly suspected, 0.3–0.5 mg of levothyroxine should be given IV once, followed by 0.025–0.100 mg/day. Other supportive measures, such as correction of hypothermia using slow rewarming and ventilatory and circulatory support, are critical.

Case Study

A 70-year-old woman with a history of ovarian cancer s/p debulking surgery was started on chemotherapy with carboplatin and paclitaxel. Bevacizumab was added to the last 6 chemotherapy cycles. The patient developed relative thrombocytopenia with a drop in the platelet count from 276 to 71 K/μL. Nifedipine XL 60 mg PO daily was added to bisoprolol 10 mg PO daily due to worsening blood pressure. The patient was subsequently evaluated in the emergency department due to elevated blood pressure (BP 216/93) and worsening renal function. Serum creatinine increased from a baseline of 1.2–1.9 mg/dL. She was treated with clonidine and hydralazine and admitted to the hospital with a presumptive diagnosis of drug-induced thrombotic microangiopathy due to bevacizumab (anti-VEGF therapy) and further treatment was withheld. However, the serum creatinine continued to increase over the next 5 months to 4.5 mg/dL. A renal biopsy was performed at that time which confirmed acute thrombotic microangiopathy (TMA). Since she had persistent disease despite stopping bevacizumab therapy, she was started on eculizumab, a terminal complement inhibitor. After 6 months of therapy, the serum creatinine stabilized at 2.6 mg/dL. Platelet count recovered to 273 K/μL. She has remained off of eculizumab for over 1 year with no evidence of recurrence of TMA.

Chapter Overview

Renal emergencies are common during the care of patients with cancer and require a multidisciplinary approach between the emergency physician, nephrologist, oncologist, and interventional radiologist. Acute kidney injury (AKI) is a frequent complication of cancer treatment associated with a higher mortality rate and hospital length of stay. General causes of AKI such as acute tubular necrosis and hypovolemia are still common in patients with cancer. However, there are other etiologies of AKI that are more specific to cancer, such as AKI in the setting of multiple myeloma, stem cell transplant, tumor lysis syndrome, targeted therapy, and immunotherapy. Patients with cancer may also present with severe electrolyte derangements requiring immediate treatment by the emergency physician.

Introduction

The kidneys are important in regulating electrolyte and acid-base levels, eliminating waste products and fluid, and producing enzymes and hormones. Compared to other organs, the kidneys receive the highest amount of blood supply from the heart on a per-gram basis. Therefore, the kidneys are vulnerable to AKI from toxins, drugs, or metabolites circulating in the bloodstream. Advances in conventional chemotherapy, targeted therapy, and immunotherapy have improved the overall survival of patients with cancer. However, many of these therapies entail a higher risk of AKI. Prevention is essential since there is no effective therapy available for AKI. This chapter emphasizes some of the more common renal problems that emergency physicians encounter during cancer treatment.

Acute Kidney Injury in Cancer Patients

The incidence of AKI in the setting of cancer varies with the underlying population, tumor type, and treatment. A 7-year study in Denmark examining the incidence of AKI among 37,267 patients with cancer reported a rate of 17.5% within 1 year of cancer diagnosis [1]. Long-term dialysis was required in 5.1% of patients developing AKI. However, other studies involving higher risk, critically ill patients report the

need for dialysis in up to 60% of patients with AKI. Patients with renal cell carcinoma, hepatocellular carcinoma, multiple myeloma, lymphoma, and leukemia were at highest risk of AKI. A Canadian study between 2007 and 2014 found the overall cumulative incidence of AKI among 163,071 patients undergoing cancer treatment to be 9.3% [2]. Patients with myeloma, bladder cancer, and leukemia were at highest risk. The annual incidence of AKI also increased from 18 to 52 per 1000 person-years during that time period. Development of AKI correlates with increased hospital length of stay, health-care costs, and mortality rates [3]. AKI increases the toxic effects of chemotherapy, excludes patients from clinical trials, and limits further cancer treatment. The causes of AKI are generally classified into three main categories: renal hypoperfusion, intrinsic renal disease, and postrenal obstruction (Table 30.1).

Varying definitions of AKI have been historically used in patient care and clinical research. In 2004, a standard classification termed the Risk, Injury, Failure, Loss, End-Stage (RIFLE) criteria was proposed based on relative rise in serum creatinine (SCr) or progressive oliguria [4]. A 50% rise in SCr from baseline defined the earliest stage of AKI. The criteria were recently modified by the Kidney Disease Improving Global Outcomes (KDIGO) AKI Workgroup to include even smaller increases in SCr (>= 0.3 mg/dL) as well as a time constraint for the rise in creatinine elevation (Table 30.2). While decreased urine output is also part of the definition, it is often cumbersome to measure and not used as routinely. The KDIGO criteria for AKI are now universally accepted both in clinical practice and research. AKI as defined by RIFLE or KDIGO has been validated as a negative prognostic marker [5, 6]. In a study of patients with newly diagnosed AML undergoing induction chemotherapy, there was a stepwise increase in mortality associated with the no-AKI, Risk, Injury, and Failure categories (3.8%, 13.6%, 19.6%, and 61.7%, respectively) [7]. Another study of critically ill patients with cancer found a 1.3-, 3.0-, and 14-fold increase in 60-day mortality for the Risk, Injury, and Failure categories, respectively [3]. More recent studies using the KDIGO definition have found a similar stepwise increase in mortality with progressive AKI [8].

A brief clinical exam, routine labs, and optimization of hemodynamics are necessary for patients presenting with AKI upon arrival to the emergency department (ED). Volume depletion can manifest by orthostatic hypotension, tachycardia, poor skin turgor, dry mucous membranes, and low central venous pressure. Intravenous (IV) hydration, preferably with crystalloid solutions, should be given to target a mean arterial pressure greater than 65 mmHg. Patients with prerenal azotemia may have a blood urea nitrogen-SCr ratio greater than 20, a fractional excretion of sodium less than 1%, a urine sodium level less than 20 mEq/L, and the presence of hyaline casts. A fractional excretion of sodium greater than 2%, a urine sodium level greater than 40 mEq/L, and the presence of coarse granular casts are suggestive of acute tubular necrosis. Acute interstitial nephritis is a common cause of AKI in patients with cancer given the high

Table 30.1 Common causes of acute kidney injury in patients with cancer

Renal hypoperfusion
Volume depletion
Nausea, vomiting, diarrhea
Decreased oral intake due to mucositis (5-fluorouracil, methotrexate, taxanes)
Polyuria caused by hyperglycemia (steroids) or diabetes insipidus (pituitary tumor)
"Third spacing" (hypoalbuminemia, liver or peritoneal metastases, interleukin 2)
Insensible loss of fluid from skin lesions (mycosis fungoides)
Hemodynamic mediated
Sepsis
Renal arteriolar vasoconstriction (NSAIDs, calcineurin inhibitors, hypercalcemia)
Congestive heart failure
Hepatorenal syndrome/hepatic sinusoidal obstruction syndrome
Budd-Chiari syndrome
Intrahepatic inferior vena cava compression or thrombosis caused by hepatomegaly or a tumor
IV iodinated contrast agent
Abdominal compartment syndrome
Intrinsic renal disease
Acute tubular necrosis
Chemotherapy (cisplatin, ifosfamide)
Anti-infectives (amphotericin B, foscarnet, cidofovir, aminoglycosides, vancomycin)
Bisphosphonates
Sepsis
Prolonged prerenal azotemia
Acute interstitial nephritis (penicillins, cephalosporins, fluoroquinolones, NSAIDs, checkpoint inhibitors)
Crystal nephropathy (methotrexate, acyclovir, ciprofloxacin, sulfonamides, rifampin)
Osmotic nephrosis (IV immunoglobulin, mannitol, starch)
Thrombotic microangiopathy (post-HSCT, gemcitabine, anti-VEGF therapy, prior radiation therapy)
Myeloma-related kidney disease
Tumor lysis syndrome
Tumor infiltration of the kidney
Glomerulonephritis
Lysozymuria (CMML or AML) with direct tubular injury
Cytokine release syndrome (engraftment syndrome, CAR T-cell therapy)
Postrenal obstruction
Bladder outlet obstruction (malignancy of the cervix, prostate, bladder, or uterus)
Retroperitoneal disease (metastasis, lymphadenopathy, fibrosis)
Hemorrhagic cystitis (cyclophosphamide, BK* virus, adenovirus)
Ureteral strictures (prior radiation therapy, BK virus)

HSCT hematopoietic stem cell transplantation, *VEGF* vascular endothelial growth factor, *CMML* chronic myelomonocytic leukemia, *AML* acute myeloid leukemia, *CAR* chimeric antigen receptor
[a]Initials of the patient in whom it was first detected in 1971

Table 30.2 Kidney Disease Improving Global Outcomes (KDIGO) criteria for AKI (https://kdigo.org/guidelines/acute-kidney-injury/)

KDIGO stage (corresponding RIFLE stage)	Increase in creatinine level	Decrease in urine output
1 (Risk)	≥50% from baseline within 7 days or ≥0.3 mg/dL within 48 h	<0.5 mL/kg/h × 6 h
2 (Injury)	≥100% from baseline	<0.5 mL/kg/h × 12 h
3 (Failure)	≥200% from baseline, absolute SCr level ≥4 mg/dL with acute rise ≥0.5 mg/dL, or need for dialysis	<0.3 mL/kg/h × 24 h or anuria × 12 h

usage of antibiotics, NSAIDs, proton pump inhibitors, and immune checkpoint inhibitors. Acute interstitial nephritis is likely under-diagnosed, as patients may not present with classic hypersensitivity reactions such as fever, rash, or eosinophilia. Patients with severe bladder outlet obstruction can present with suprapubic pain and a palpable bladder. The use of a portable bladder scanner quickly confirms obstruction by measuring a post-void residual urine volume greater than 100 mL. Renal ultrasonography is sensitive in detecting hydronephrosis, although this characteristic finding of urinary tract obstruction may not be apparent in patients with significant retroperitoneal disease or in the setting of early obstruction.

There has been much controversy as to the optimal solution for fluid resuscitation of the patient with AKI, especially in the setting of sepsis. Mechanisms to maintain renal blood flow through autoregulation are impaired in the setting of AKI. While initial use of fluids to optimize cardiac output is beneficial, prolonged use can lead to harm from fluid overload. A fine balance is often necessary between fluids and vasopressors, as several retrospective studies associate fluid overload with increased mortality [9]. Colloid solutions such as IV albumin and starch have not proven to be more effective than crystalloid solutions and are considerably more expensive [10]. Intravenous starch may cause AKI by inducing osmotic nephrosis of the renal tubules; thus, in general, its use should be avoided in patients with AKI. Albumin and starch leak out of the intravascular compartment within hours after administration, thereby potentially worsening peripheral edema. However, patients with cirrhosis can benefit from IV albumin in the setting of sepsis or large volume paracentesis. We generally prefer using crystalloid solutions such as isotonic saline (0.9% saline) for volume resuscitation. Interestingly, animal studies have demonstrated vasoconstriction of the renal arteries from chloride-containing solutions, which could theoretically worsen renal function. However, balanced (low-chloride) crystalloid fluids such as Plasma-Lyte or lactated Ringer's solution have not consistently demonstrated better outcomes when compared to normal saline [11–13]. Early goal-directed therapy (EGDT) for sepsis (protocol-driven fluid resuscitation, transfusions, inotropes, and vasopressor support) showed promise in a single-center RCT [14], but did not decrease mortality or need for renal replacement therapy (RRT) in three subsequent larger RCTs [15–17]. Furthermore, a meta-analysis of individual patient data demonstrated that EGDT had equivalent outcomes but higher hospitalization costs when compared to standard of care [18]. Continuous infusion of norepinephrine (2–12 μg/min) or vasopressin (0.01–0.04 U/min) is generally used if fluid resuscitation alone is unable to maintain a target mean arterial pressure of 65 mmHg. Placement of a Foley catheter should be considered if the patient has signs of bladder outlet obstruction or urinary retention. Emergent placement of a percutaneous nephrostomy (PCN) tube may be necessary if the site of obstruction is above the level of the bladder outlet. The use of nephrotoxic medications and iodinated contrast agents should be avoided, if possible.

RRT is indicated in patients who present with persistent hyperkalemia, fluid overload refractory to diuretics, severe metabolic acidosis, uremia, or marked tumor lysis syndrome (TLS). Early nephrology consultation from the ED expedites dialysis in these patients. Intermittent hemodialysis (IHD) is generally sufficient for volume and metabolic clearance in patients who are hemodynamically stable; however, patients with septic shock or hemodynamic instability may require continuous renal replacement therapy (CRRT) in the intensive care unit. In patients with sepsis and AKI, the use of CRRT has not demonstrated a survival advantage over IHD but can be more effective in minimizing fluid overload [19, 20].

AKI and Conventional Chemotherapy

The most common cause of AKI due to conventional chemotherapy is acute tubular necrosis (ATN). Offending drugs include platinum agents (cisplatin and carboplatin), ifosfamide, and pemetrexed. Cisplatin can cause ATN, thrombotic microangiopathy, and hypomagnesemia. Carboplatin is much less injurious to the kidneys but may still cause ATN and hypomagnesemia. Injury from platinum drugs is generally dose dependent and can lead to chronic kidney disease despite drug discontinuation. ATN from ifosfamide can lead to progressive decline in renal function over several years. Severe injury from ifosfamide manifests as Fanconi's syndrome (hypokalemia, hypophosphatemia, acidosis, and glucosuria), which may persist long after discontinuation of therapy. Pemetrexed, a derivative of methotrexate, can be associated with ATN and diabetes insipidus. Hydration with isotonic fluid is the mainstay to prevent ATN.

High-dose methotrexate (MTX) ranging from 1 to 15 g/m^2 can precipitate in the renal tubules leading to obstruction,

inflammation, and AKI. Bicarbonate-based intravenous fluids help to clear MTX crystals in the urine by increasing its solubility. Although dialysis lowers serum MTX levels, the effect is temporary due to the high level of protein binding and rebound of serum levels. In patients with impaired renal function, glucarpidase can be administered to metabolize MTX into two inactive compounds that are subsequently cleared by the liver.

Endothelial injury due to gemcitabine, mitomycin C, and cisplatin leads to activation of complement and generation of thrombi within the renal microvasculature leading to thrombotic microangiopathy (TMA). This diagnosis should be suspected in patients with Coombs (−) hemolytic anemia, thrombocytopenia, and AKI. Treatment includes holding the offending drug and possibly the use of complement inhibitors.

AKI and Immunotherapy

Immunotherapy, which is based on regulating the immune system to recognize and eradicate tumor cells, is currently used in the treatment of malignant melanoma, Hodgkin's lymphoma, renal cell and urothelial carcinoma, non-small cell lung cancer, and head/neck cancer. Immune checkpoint inhibitors (ICIs) release inhibition of T-lymphocytes to generate a long-lasting anti-tumor response. Current ICIs target cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), programmed cell death protein 1 (PD-1), and programmed cell death ligand 1(PD-L1). Renal toxicity occurs in approximately 2% of patients and increases to 5% for patients on dual therapy [21]. This renal injury is usually granulomatous interstitial nephritis, but less commonly presents as lupus-like nephritis, pauci-immune glomerulonephritis, IgA nephropathy, and focal segmental glomerulosclerosis. Onset of kidney disease varies anywhere from 1 to 8 months after initiation of therapy and up to 2 months after the last dose. Nephritis should be considered in any patient treated with ICIs and presenting with AKI, proteinuria, or hematuria. Early administration of steroids should be considered.

AKI and Anti-VEGF Therapy

Angiogenesis inhibition by blocking vascular endothelial growth factor (VEGF) or its receptor inhibits endothelial cell proliferation and vessel formation. Side effects include proteinuria, hypertension, and renal-limited thrombotic microangiopathy in severe cases. Proteinuria due to compromise of the filtration barrier of the nephron ranges from mild to fulminant nephrotic syndrome. Hypertension is mediated by decreased nitrous oxide levels leading to endothelial dysfunction. First-line agents for treatment of hypertension include angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs), while calcium channel blockers are suitable alternatives. Centrally acting drugs or diuretics may be added for a goal blood pressure less than 140/90 mm Hg. Patients who develop hypertensive crisis or encephalopathy should discontinue anti-VEGF therapy immediately and admitted to the ICU. Patients who develop TMA in the setting of anti-VEGF therapy will present with de novo hypertension and unexplained renal failure. TMA can resolve with time after withholding further therapy, although some patients will benefit from anti-complement therapy such as eculizumab.

Chronic Kidney Disease in Cancer Patients

The prevalence of CKD ranges from 12% to 53% at the time of cancer diagnosis [22, 23]. Older patients with cancer have a relatively higher incidence of hypertension and diabetes, which are the two most common risk factors for CKD. Cancer therapy is also associated with progressive CKD. A retrospective study of patients with solid tumors demonstrated a reduction in eGFR of 13 mL/min/1.73 m^2 after 2 years, and 17.7% of patients with CKD stage II advanced to stage III or IV [23]. The incidence of CKD is even higher in patients with kidney cancer and bladder cancer (28.7% and 46%, respectively) [24, 25].

Glomerular filtration rate (GFR) as measured by inulin or iohexol clearance is the gold standard for measurement of kidney function but is difficult to perform in the clinical setting. Therefore, the estimated GFR (eGFR) as calculated by formulas using SCr, age, gender, and race is commonly reported by most hospital laboratories. Estimates of GFR as measured by the Modification of Diet in Renal Disease (MDRD) [26] and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) [27] equations are felt to be most accurate, and have largely supplanted the older Cockcroft Gault (CG) equation [28]. However, most pharmacokinetic studies of drugs were based on the CG equation. It is important to remember several caveats concerning estimating equations for GFR. Ninety percent of patients will have a true GFR within 30% of their eGFR. The equations are less valid in patients with extremes in body mass. Additionally, they tend to underestimate GFR in patients with normal or near-normal SCr levels. Most importantly, these equations are not reliable estimates when the SCr is not in steady state as seen in AKI. It should be assumed that any patient that has oliguric AKI unresponsive to hydration has a GFR <10 ml/min *regardless* of the SCr level.

Most estimates of glomerular filtration rate (eGFR) are based on SCr levels that are affected by many different factors. Elevation in SCr is a relatively late marker of CKD, and only manifests after a 50% decline in glomerular filtration

rate. Reduced creatinine production due to acute illness and sarcopenia, as well as creatinine dilution during volume overload, can further complicate the estimation of renal function in patients with cancer.

Multiple Myeloma and AKI

Multiple myeloma is a clonal malignancy of plasma cells that results in the overproduction of immunoglobulins, their fragments, or free light chains that circulate in the blood (paraproteins). These paraproteins cause injury by depositing in peripheral organs such as the heart, kidney, and liver. AKI from paraprotein deposition in the kidneys is often the initial presentation of patients with multiple myeloma. Cast formation in the distal tubule occurs when paraproteins filter through the glomeruli and bind to Tamm-Horsfall mucoprotein causing obstruction, tubular injury, and inflammation. Amyloid light chain amyloidosis (AL amyloidosis) develops when paraproteins undergo conformational changes and deposit as microscopic fibrils in the glomeruli and vessels. Light chains or heavy chains are deposited within the glomerular and tubular basement membranes, leading to monoclonal immunoglobulin deposition disease (MIDD).

The clinical presentation of AKI in patients with multiple myeloma varies from asymptomatic proteinuria to nephrotic syndrome and rapidly progressive renal failure. AKI is diagnosed in more than half of all patients with multiple myeloma at initial presentation, of which 10% require dialysis. Multiple myeloma should always be part of the differential diagnosis in elderly patients with unexplained acute or chronic kidney disease. Initial workup for multiple myeloma consists of serum and urine protein electrophoresis, immunofixation electrophoresis, and serum-free light chain assays to detect a monoclonal protein. Monoclonal proteins in the urine (Bence-Jones proteins) are not detected by routine qualitative dipstick urinalysis, which detects mainly albuminuria. However, paraprotein deposits from MIDD and AL amyloidosis can damage the filtration barrier of the glomerulus, leading to significant albuminuria detectable on dipstick urinalysis. In contrast, myeloma cast nephropathy has minimal glomerular involvement and typically presents with only mild albuminuria. Other clinical manifestations from light chain amyloid deposits include restrictive cardiomyopathy, hepatomegaly, carpal tunnel syndrome, and orthostatic hypotension. Definitive diagnosis is confirmed by a renal biopsy revealing characteristic casts, light chains, or amyloid deposits.

Early aggressive treatment of patients presenting with multiple myeloma and renal disease helps stabilize or improve kidney function. Initial hydration consists of normal saline infusion, with a urine output goal of 2.5–3.0 L a day, which helps prevent precipitation of casts within the distal tubule. Steroids are often used initially to decrease the production of paraproteins and alleviate end-organ damage. Aminoglycosides, IV contrast agents, diuretics, and nonsteroidal anti-inflammatory drugs (NSAIDs) exacerbate renal injury and should be avoided. Hypercalcemia commonly occurs in patients with multiple myeloma and aggravates acute kidney injury. If hypercalcemia does not resolve with the use of hydration and calcitonin, therapy with a bisphosphonate should be considered (e.g., 3–4 mg of zoledronic acid diluted in 100 mL of normal saline administered in an IV infusion for at least 15 min). Plasmapheresis to remove circulating paraproteins has not been shown to improve clinical outcomes. Similarly, the use of high-cutoff filters in hemodialysis, which is much more effective in removing paraproteins than plasmapheresis, does not definitely improve outcomes when used concurrently with effective chemotherapy [29, 30].

Hematopoietic Stem Cell Transplantation (HSCT) and AKI

AKI is a frequent complication of HSCT and has an incidence between 10% and 73% depending on the type of transplant and conditioning regimen [31]. Risk factors include older age, female gender, allogeneic transplant, myeloablative regimen, graft versus host disease (GVHD), hypertension, diabetes, and preexisting CKD. Common causes of AKI include nephrotoxic drugs (e.g., calcineurin inhibitors, foscarnet, amphotericin), sepsis, volume depletion, hepatic sinusoidal obstruction syndrome (HSOS), thrombotic microangiopathy (TMA), and viral nephritis (e.g., BK virus, adenovirus).

Workup in the ED should include a thorough search for nephrotoxic medications and assessment of volume status. A urinalysis, urine protein/creatinine (UPC) ratio, urine sodium, and urine creatinine help determine the etiology of AKI. A low urine sodium level <20 meq/L or fractional excretion of sodium (FENa) <1% suggests volume depletion. Patients with GVHD of the GI tract can present with prerenal azotemia due to vomiting and diarrhea.

HSOS occurs due to endothelial damage of the liver sinusoids from the conditioning regimen given prior to transplant. Patients with HSOS generally present early after HSCT with jaundice, right upper quadrant pain, ascites, edema, and hepatorenal syndrome. Other causes of cholestasis such as GVHD, sepsis, fungal infection, and TPN should be excluded. Doppler imaging of the portal vein in the setting of HSOS reveals reversal of flow. Initial management includes sodium restriction and diuretics, while RRT will be necessary for severe cases.

Viral infections of the genitourinary tract (e.g., adenovirus, BK virus) cause gross hematuria and bladder outlet

obstruction from clots. A three-way urethral catheter should be inserted for continuous bladder irrigation, and urologic consultation should be obtained. Measurement of serum and urine BK and adenovirus levels by PCR should be sent.

Paraneoplastic glomerular disease such as membranous nephropathy or minimal change disease can occur months to years after HSCT while tapering immunosuppression. This diagnosis should be suspected in patients with a history of HSCT that present to the hospital with de novo nephrotic range proteinuria and edema. Symptoms are initially managed with diuretics, but renal biopsy is required for definitive diagnosis.

Electrolyte Abnormalities

Tumor Lysis Syndrome (TLS)

TLS is a common life-threatening emergency in patients with cancer presenting to the ED. Tumor cells rapidly release potassium, phosphorus, and uric acid into the extracellular space and overwhelm the excretory capacity of the kidneys. Hyperkalemia predisposes patients to cardiac dysrhythmias and sudden death. Hyperphosphatemia and secondary hypocalcemia may lead to AKI, muscular irritability, cardiac dysrhythmias, and metastatic calcification. Uric acid precipitating as crystals in the renal tubules causes obstruction, vasoconstriction, and inflammation. Patients with rapidly proliferating chemosensitive hematologic malignancies are at the greatest risk for TLS. Risk factors for TLS include a white blood cell count greater than 50,000/μL, elevated lactate dehydrogenase level, bulky disease, marrow or organ infiltration, advanced age, and chronic kidney disease. Cases of TLS in patients with a solid tumor undergoing chemotherapy and/or radiation therapy have been reported; however, patients with non-Hodgkin's lymphoma or acute leukemia are at greatest risk.

The identification of TLS is generally straightforward in patients who present with marked derangements in electrolyte levels. However, patients with impaired renal function secondary to an effective prerenal state, such as volume depletion or hypotension, can also develop hyperkalemia, hyperphosphatemia, and hyperuricemia. Unlike patients with TLS, patients with prerenal azotemia will rapid normalize electrolyte levels and renal function with hydration and optimization of blood pressure.

Intravenous hydration to maintain adequate urine output and xanthine oxide inhibitors (allopurinol or febuxostat) to prevent the formation of uric acid are the mainstays of preventing TLS. Infusion of isotonic saline should be instituted 24 h prior to chemotherapy at 100 mL/m^2/h and titrated accordingly to maintain a urine output of at least 2.5 L a day. Conservative fluid management strategies are necessary in patients with underlying congestive heart failure. High-risk patients or those who have elevated uric acid levels prior to chemotherapy should receive rasburicase (0.2 mg/kg [IV] daily for up to 5 days). Rasburicase converts uric acid to allantoin, which is 5–10 times more soluble in the urine. Fixed dosing of rasburicase (3 or 6 mg) up to 2 doses has been shown to be just as effective as weight-based dosing and leads to significant cost savings [32]. Rasburicase causes production of hydrogen peroxide that can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Patients at risk should have G6PD levels checked prior to receiving rasburicase.

Management of established TLS also consists of judicious hydration as well as rasburicase for hyperuricemia. Alkalization of the urine retards the formation of uric acid crystals but increases the risk of calcium phosphate crystal deposition. Therefore, routine urine alkalization in patients with TLS is no longer recommended. Nephrology consultation should be sought for patients presenting to the EC with TLS who have peaked T waves on electrocardiogram (EKG), dysrhythmias, or oliguria. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and NSAIDs should be avoided in patients with TLS because they worsen hyperkalemia and AKI. Although some patients deemed high risk of developing severe TLS have been preemptively started on CRRT prior to chemotherapy, this is not standard practice. Pseudohyperkalemia occurs in the setting of extreme leukocytosis, due to spurious elevations in serum potassium levels resulting from ex vivo lysis of white blood cells. The diagnosis should be considered in patients without other signs of TLS and the absence of EKG changes suggestive of hyperkalemia. If a patient is suspected of having pseudohyperkalemia, potassium level should be measured on a heparinized plasma sample placed on ice or on the whole blood by a point-of-care analyzer.

Hyponatremia

Hyponatremia (serum sodium levels less than 135 mEq/L) has been reported in 14–23% of patients with cancer on admission to the hospital. Increased hyponatremia severity is a negative prognostic factor for survival in patients with non-small cell lung cancer, renal cell carcinoma, gastric cancer, and non-Hodgkin's lymphoma. The two most frequent causes of hyponatremia in patients with cancer are hypovolemia and syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common etiologies of SIADH include malignancy (e.g., the lung, gastrointestinal, central nervous system), pneumonia, drugs (e.g., antidepressants, haloperidol, carbamazepine, cyclophosphamide, platinum compounds, vinca alkaloids), nausea, and pain. Other considerations when assessing patients with hyponatremia in

the setting of cancer include renal salt wasting secondary to chemotherapy, "tea and toast syndrome" resulting from malnutrition, water intoxication, and adrenal insufficiency secondary to adrenal metastases or steroid withdrawal.

Symptoms in patients with hyponatremia may be absent, mild (confusion, dizziness, nausea, and lethargy), or severe (seizures, coma, and death). The occurrence of symptoms depends primarily on the rate of decline in the serum sodium level as opposed to the absolute level. Adaptation of the brain to hyponatremia occurs gradually by the excretion of osmolytes from cells to prevent cerebral edema. Cerebral edema with eventual brain stem herniation is a risk if the rate of decline in serum sodium level outpaces the excretion of osmolytes. Immediate treatment is required to raise the serum sodium level until the patient is asymptomatic. If the decline in serum sodium level is more gradual, the patient may be asymptomatic or have only mild symptoms. Rapid correction of hyponatremia is not indicated in this situation.

Initial workup for hyponatremia should include a physical examination to assess the patient's volume status, chemistry profile, plasma osmolality, urine electrolyte levels, and urine osmolality. Patients with volume depletion generally have urine sodium levels less than 20 mEq/L and concentrated urine (urine osmolality greater than plasma osmolality). Patients with hypervolemia (those with heart failure, cirrhosis, third spacing caused by peritoneal or liver metastases, hypoalbuminemia, or inferior vena cava compression or obstruction) have signs of fluid overload upon physical examination (e.g., edema, ascites, effusions) but are in an effectively prerenal state. Therefore, they also will have urine sodium levels less than 20 mEq/L and concentrated urine. Patients with SIADH have urine sodium levels greater than 40 mEq/L and inappropriately dilute urine (urine osmolality less than plasma osmolality). Patients with "tea and toast syndrome" have serum sodium levels less than 20 mEq/L and appropriately dilute urine (urine osmolality less than plasma osmolality). Urine sodium levels are variable in patients with water intoxication, but urine osmolality is appropriately dilute, typically less than 150 mOsm/kg.

Urgent treatment is not indicated for hyponatremic patients who are asymptomatic or have only mild symptoms. Rapid correction of hyponatremia in these patients will increase the risk of osmotic demyelination syndrome. Patients with volume depletion should receive isotonic fluids such as normal saline. Otherwise, total fluid intake should be restricted to less than 1 L daily. Loop diuretics should be considered in patients with hypervolemia. The treatment of patients with SIADH consists of fluid restriction, salt tablets (initially, 1 g three times daily) and possibly, loop diuretics. The introduction of vasopressin receptor antagonists has revolutionized treatment of hyponatremia in patients with hypervolemia or SIADH. These drugs block the effect of antidiuretic hormone on the collecting ducts of the kidney, thereby preventing water reabsorption and stimulating water diuresis. Currently, two drugs within this class are available, oral tolvaptan (initially 7.5–15.0 mg daily) and IV conivaptan (20-mg loading dose with 20 mg administered over the ensuing 24 h). Serial sodium levels should be monitored every 4–6 h with a goal correction rate of less than 8 mEq/L in 24 h.

Patients with severe symptoms require more urgent intervention with hypertonic saline and close neurologic monitoring. Treatment consists of infusion of 3% saline at a rate of 0.8 mL/kg/h and initial monitoring of serum sodium levels at least every 2–4 h. Alternatively, 3% saline can be administered as 100 ml bolus over 10 min with repeat dosing as needed. The infusion is continued until the sodium level is greater than 120 mEq/L, symptoms have resolved, or the rate of sodium level correction has exceeded 8 mEq within 24 h. Rates of correction in excess of 10–12 mEq per 24 h causes osmotic demyelination syndrome, which results in altered mental status, quadriparesis, quadriplegia, pseudobulbar palsy, coma, or death. Therefore, frequent neurologic assessments and titration of the 3% saline infusion to prevent overcorrection of hyponatremia are necessary.

Hyperkalemia

Hyperkalemia is a particular concern in patients presenting to the ED, as it can be life threatening. Common causes of hyperkalemia in patients with cancer include AKI, TLS, the use of certain drugs (e.g., calcineurin inhibitors, NSAIDs, angiotensin-converting enzyme inhibitors, trimethoprim-sulfamethoxazole, potassium-sparing diuretics) and metabolic acidosis. In most patients, the etiology is multifactorial.

Most patients with hyperkalemia are clinically asymptomatic unless their potassium levels are very high. Cardiac dysrhythmia is the most concerning manifestation. Electrocardiographic changes progress from peaked T waves, flattened P waves, and widened QRS complexes to eventual sine waves. It should be noted that up to 50% of patients with significant hyperkalemia may not manifest EKG abnormalities. Skeletal muscle weakness should also be present in the setting of severe hyperkalemia. Stabilization of the myocardial membrane with IV administration of calcium gluconate (10 mL of 10% IV) or calcium chloride (2 g over 5 min) to counter the effects of hyperkalemia is imperative. A repeat infusion of calcium may be necessary if EKG changes persist. Temporizing measures that shift potassium to the intracellular space involve administration of regular insulin (10 U intravenous), glucose (50 mL of 50% dextrose intravenous), and nebulized albuterol (20 mg in 4 mL). Sodium bicarbonate administration is helpful in patients with concurrent metabolic acidosis by shifting potassium to

the intracellular space as the acidosis is corrected. If severe hyperkalemia persists despite correction of its underlying cause, an urgent nephrology consultation should be sought as dialysis might be necessary. For patients with milder hyperkalemia, monitoring serial potassium levels after discontinuation of the causative drug is sufficient. Loop diuretics can be administered to patients with adequate renal function to enhance potassium excretion in the urine. Sodium polystyrene sulfonate (15–30 g oral) is commonly given to facilitate potassium elimination from the gut; however, its clinical effectiveness is unproven in clinical studies, and its use is rarely associated with intestinal necrosis [33]. Newer potassium-binding agents, patiromer (K^+/Ca^{2+} exchange) and sodium zirconium cyclosilicate (K^+/Na^+ and H^+ exchange), are now clinically available. These newer agents have a more predictable onset of action with less incidence of diarrhea.

Hypercalcemia

Hypercalcemia occurs in 20–30% of all malignancies and is the most common paraneoplastic syndrome. The majority (~80%) of cases are mediated by production of parathyroid hormone-related peptide (PTHr-P) as seen in squamous cell carcinoma, breast cancer, kidney cancer, prostate cancer, and bladder cancer. Local osteolysis due to cytokine release comprises the remaining cases. Lymphoma may cause upregulation of 1,25-hydroxy vitamin D causing hypercalcemia. Rarely, ectopic PTH production occurs in certain tumors. Hypercalcemia causes AKI by vasoconstriction of the afferent arteriole and hypovolemia from polyuria. Intravenous saline should be started to maintain urine output greater than 100 mL/h. Calcitonin begins to decrease serum calcium levels within 15 min of IM or SC administration and has a peak effect within 4 h. Many patients will require a more durable response with osteoclast inhibitors such as pamidronate or zoledronic acid. Denosumab, an inhibitor of receptor activator of nuclear factor-kappaB (RANK) ligand, also provides a long-lasting response to normalize calcium levels. However, patients can develop profound hypocalcemia several weeks later if they have concurrent vitamin D deficiency.

Key Practice Points

- Patients with renal cell carcinoma, multiple myeloma, leukemia, and lymphoma are at highest risk of developing AKI.
- The KDIGO criteria provide a standardized definition of AKI based on increases in serum creatinine level relative to baseline and have prognostic value in the care of patients with cancer.
- Immune checkpoint inhibitors cause AKI by interstitial nephritis, glomerulonephritis, or vasculitis.
- Renal toxicity from anti-VEGF therapy presents with a spectrum of disease from mild proteinuria to malignant hypertension.
- More than half of all patients with multiple myeloma will initially present with some degree of renal injury, and AKI improves with immediate treatment of the underlying myeloma.
- Treatment of TLS includes aggressive IV hydration, rasburicase for hyperuricemia, and, possibly, dialysis for AKI.
- Vasopressin receptor antagonist drugs have revolutionized the treatment of hyponatremia associated with hypervolemia or SIADH, but administration of 3% saline is still required for patients with hyponatremia and severe symptoms (seizures or coma).
- Hyperkalemia may not manifest clinically until potassium levels are severely elevated, and emergent treatment of it includes IV calcium to stabilize the myocardial membrane, IV insulin with glucose, inhaled beta-agonists, and dialysis in refractory cases.

Urology

31

Shawn Dason, Cheryl T. Lee, and Ahmad Shabsigh

Case Study

A 72-year-old male smoker presented with lower abdominal pain and an inability to urinate. He endorsed several months of gross hematuria, fatigue, and worsening urinary symptoms. On presentation, he was tachycardic, hypertensive, and had acute renal insufficiency with a creatinine of 4 mg/dL. There were no indications for dialysis. The on-call urologist was contacted early (Fig. 31.1) *and recommended catheterization with a 24-Fr 3-way Foley catheter as they made their way to assess the patient. Catheterization and manual irrigation resulted in evacuation of a significant amount of blood clot along with resolution of pain, tachycardia, and hypertension. Despite 45 min of manual irrigation, significant hematuria and clot continued. A noncontrast CT scan revealed bilateral hydroureteronephrosis with a transition point at the level of the bladder. The bladder was distended with hyperdense material concerning for a large bladder mass or blood clot. The patient was admitted by the urology service for continuous bladder irrigation. The next morning, the patient's hematuria continued and creatinine remained elevated. He was taken to the operating room for an endoscopic assessment and ureteral stent placement. Cystoscopy revealed a large hemorrhagic bladder mass that was completely resected for diagnosis and management of the bleeding. The ureteral orifices were not found and ureteral stents could not be placed. The patient was taken to the interventional radiology suite for bilateral nephrostomy tube placement. Creatinine subsequently normalized although there was a period of post-obstructive diuresis. Pathology from the transurethral resection of his bladder tumor revealed urothelial carcinoma with involvement of the muscularis propria. After his hematuria, elevated creatinine and diuresis normalized, the patient was discharged. He had multidisciplinary consultation for his bladder cancer as an outpatient. Following negative staging scans, he received neoadjuvant chemotherapy with four cycles of gemcitabine and cisplatin with his nephrostomy tubes* in situ. *He then had a radical cystectomy and ileal conduit.*

Hematuria

Hematuria is a common urologic issue assessed in the emergency department (ED). Hematuria can be divided into gross (or visible) hematuria and microhematuria. While the rate of a cancer diagnosis is 1–3% with microhematuria [1, 2], this rises to 25% with gross hematuria [3]. Discolored urine [4], vaginal bleeding, or rectal bleeding may sometimes mimic hematuria and should be considered. True hematuria can usually be determined by history or examination of the urine. If the diagnosis of hematuria is in question, microscopy can be performed to confirm the presence of visualized red blood cells in the urine.

Microhematuria

Microhematuria refers to red blood cells in the urine visualized on microscopy but not with the naked eye. A threshold of three or more red blood cells per high-powered field is traditionally used to define microhematuria [1]. Although some definitions accept chemical urinalysis (dipstick) findings of blood as being consistent with microhematuria, it is generally thought that microscopy is required due to the potential for dipstick false positives (e.g., myoglobinuria) [5]. Microhematuria in the ED setting can often be an incidental finding as it is present in 6.5% of the general population [1]. Numerous nonpathologic causes exist for microhematuria including instrumentation, dehydration, exercise, menses, and other intraabdominal pathology. Nonetheless, the differential diagnosis for microhematuria includes numerous pathologies and its presence should warrant consideration of a urologic etiology to the presenting

K. H. Todd et al. (eds.), *Oncologic Emergency Medicine*, https://doi.org/10.1007/978-3-030-67123-5_31

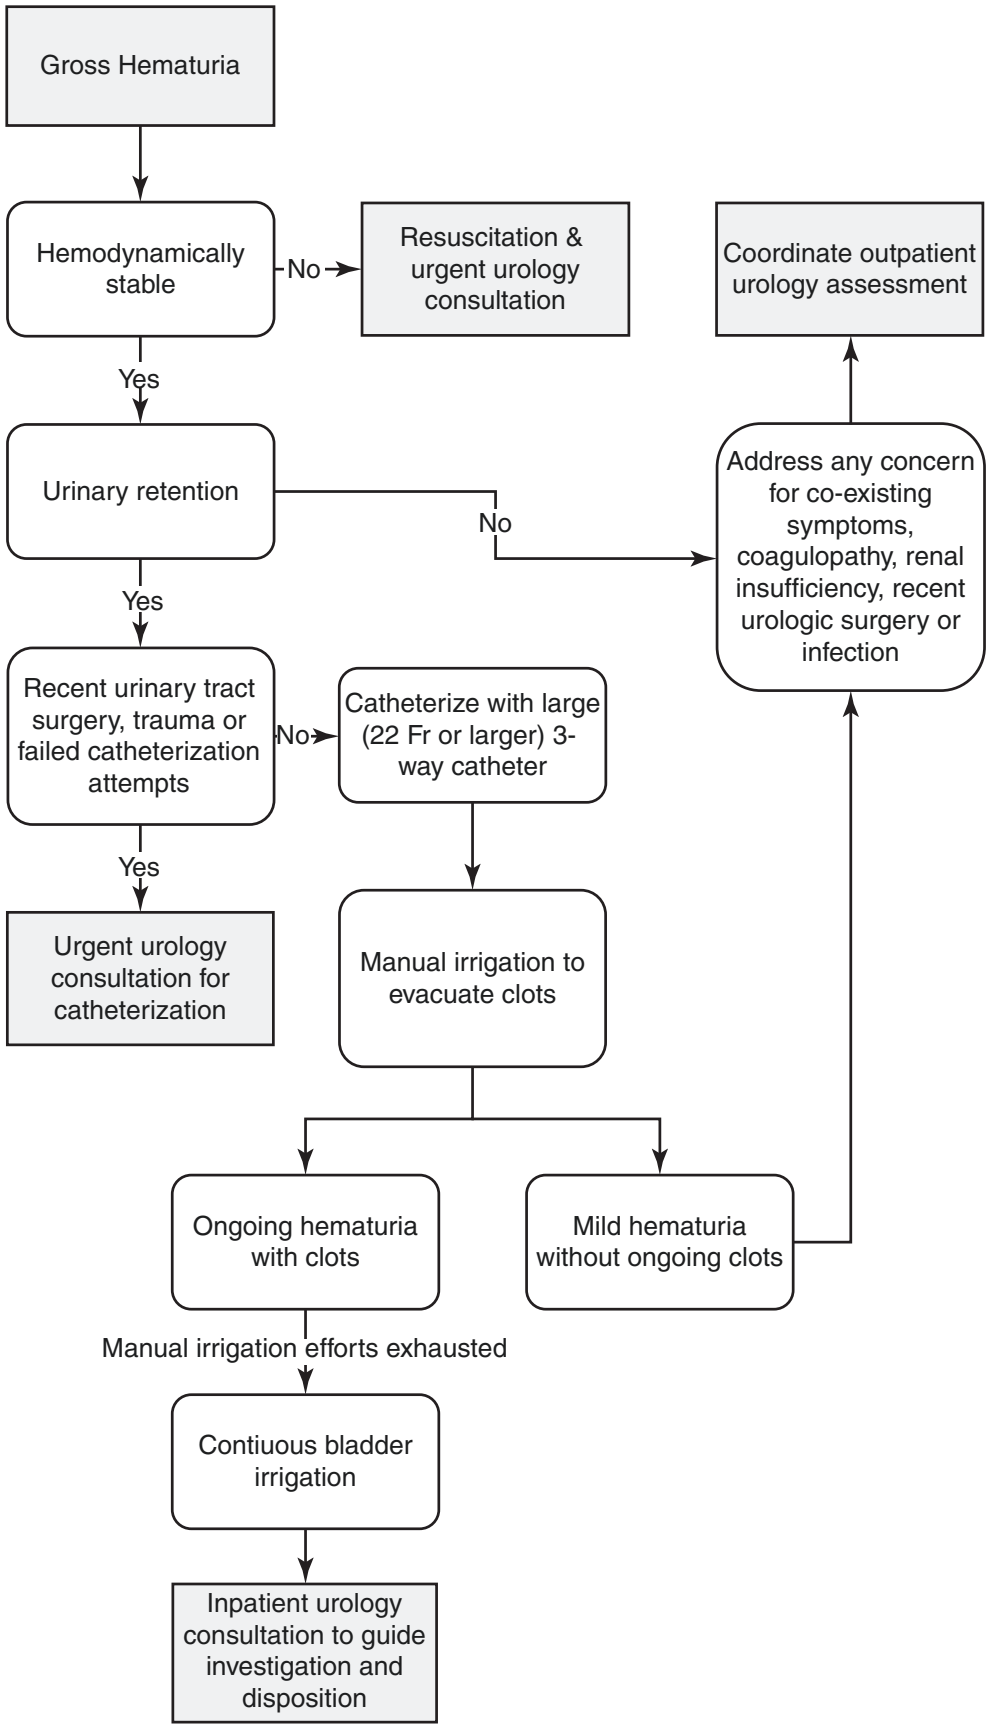

Fig. 31.1 A management algorithm for gross hematuria presenting to the ED. Please refer to the text for additional details

complaint. Microhematuria associated with proteinuria, casts, hypertension, or renal dysfunction should also prompt a nephrologic workup [1]. While microhematuria alone does not generally require any acute management, microhematuria outside of the context of a clearly documented infection warrants outpatient follow-up with the patient's primary care physician and/or urologist. This can be especially important as the rate of cancer diagnosis with microhematuria is 1–3% [2, 6]. Risk factors for malignancy are numerous but include symptomatic microhematuria, smoking status, degree of microhematuria, exposure to pelvic radiation or chemicals, and age [1, 2].

Gross Hematuria

Gross hematuria is visibly apparent to the patient and on examination of the urine. Nonetheless, gross hematuria may be intermittent, and a normal urinalysis, after symptoms have resolved, does not obviate a subsequent outpatient workup. Gross hematuria is likely urologic in origin with a cause identified in 50% of patients and a malignant etiology identified in 25% [3]. Although rare, a nephrologic cause should be considered in patients with red blood cell casts on microscopy, proteinuria, hypertension, and renal dysfunction [1].

The first step in assessing gross hematuria is to identify and manage any associated hemodynamic compromise because hemorrhagic shock can occasionally occur (see Fig. 31.1). Consideration should be given to an alternate etiology of hypotension as this is infrequent. Aggressive resuscitation should be undertaken in parallel with urgent urology consultation in the unstable patient as certain scenarios may necessitate immediate transfer straight to the operating room or interventional radiology suite.

The stable patient with gross hematuria should be assessed for urinary retention (see Fig. 31.1). Blood in the urinary tract will have a tendency to clot and obstruct the lower urinary tract or an indwelling urinary catheter. In this scenario, patients may endorse an inability to urinate, urinary urgency, a reduction in urine output, overflow incontinence, suprapubic pain, abdominal distension, or edema. Signs include generalized discomfort, a palpable painful bladder, visible voided blood clots or a clotted urinary catheter, edema, hypertension, and tachycardia.

The patient with suspected clot urinary retention should be catheterized emergently as long as there are no indications for urology consultation prior to catheter placement (see Fig. 31.1). Generally those with recent urinary tract surgery, trauma, or failed catheterization attempts should be catheterized only by a urologist due to the potential for further trauma to the urinary tract [7]. Patients should be catheterized in a private setting where vital signs can be measured, as a vagal response can sometimes result following bladder decompression [8]. In the setting of suspected clot retention, the initial catheter placed should be a 3-way catheter that has a large-caliber (22 Fr or 24 Fr). A 3-way catheter should be placed to facilitate continuous bladder irrigation with saline should this be required following bladder drainage and manual irrigation. A larger catheter (22 or 24 Fr) will allow for significantly improved evacuation of blood clots (initially with hand irrigation of the Foley) than the conventional first-line urinary catheter used in other situations (16 Fr) [9]. Special "hematuria catheters" are commercially available and may be stocked in the urology supply area of the operating room. If available, these catheters are ideal for this clinical situation, as they are large-bore 22- or 24-Fr 3-way catheters with a large opening at the tip for clot evacuation and are stiffer to prevent catheter collapse from aspiration. Initial placement of an appropriate catheter will permit efficient clearance of obstructive clots and minimize subsequent catheter changes. Lubricating the catheter well and use of 2% lidocaine gel intraurethrally can minimize discomfort in the placement of a larger catheter. If the patient is not in painful acute urinary retention, waiting for 10–20 min after injection of the gel prior to catheter placement is advised to allow for the lidocaine to take effect. A urologist should be involved following any concerns about catheterization failure such as ongoing symptoms, inability to advance the catheter to its hub, lack of drainage on catheter insertion, inability to irrigate a catheter, discomfort or excess resistance with irrigation, or Foley balloon inflation.

In the event that the patient presents with urinary retention and an obstructed catheter, the catheter should first be flushed with a cone-tipped (Toomey) syringe and sterile saline to relieve the obstruction. Ensure that a cone-tipped syringe is being used since a Luer-lock syringe does not have a tip diameter large enough to aspirate clots. The largest port on the catheter (center port in a 3-way catheter) should be used for irrigation and aspiration. After the bladder has started draining and discomfort is resolving, clot irrigation should be performed. If the catheter blocks and cannot be unobstructed by flushing, it may require replacement. Before removing the obstructed catheter, any anticipated challenges with replacing it should be carefully considered. Especially in the setting of recent urinary tract surgery, a urologist should generally be contacted before removal and/or replacement of the obstructed catheter.

After catheter placement and initial bladder decompression, further manual irrigation should be performed to evacuate the bladder of clots. If the catheter is draining, manual irrigation may be delayed to ensure that the bladder drains as much as possible, vagal response has not occurred, basic labs are sent, and any necessary imaging requests or consultations are in process. The catheter should be well lubricated prior to manual irrigation, as subtle motions during catheter manipulation can be uncomfortable. Manual irrigation is performed

through the middle (largest caliber) port of a 3-way catheter or the larger caliber port of a 2-way catheter. For both a 2-way and 3-way catheters, the Luer-lock port is used to inflate the balloon only. A 60 ml sterile syringe is filled with sterile saline and instilled slowly. In the case of a low-capacity bladder or a bladder filled with clot, the patient may not tolerate a full 60 cc and overfilling is suggested by increased resistance to fluid instillation or excessive patient discomfort. Overfilling the bladder can cause bladder trauma. After instillation, the syringe should be gently aspirated to draw back clot. Thick dense clot can sometimes require some force to aspirate, although care should be taken to ensure that one is not aspirating the bladder mucosa, which may be in contact with the catheter tip. If a regular (i.e., 16 Fr) catheter is in place and aspiration is not proceeding smoothly, a larger catheter should generally be placed if no contraindications to catheter exchange exist. If 60 ml of instillation is tolerated but limited clot returns on aspiration, a number of maneuvers can be attempted to completely irrigate the bladder. First, an additional 60 cc can be instilled into the bladder such that irrigation can now take place with 120 cc of fluid in the bladder. This additionally distends the bladder, reducing contact of bladder mucosa and the catheter eyelet. Rotating the catheter during irrigation, withdrawing or advancing the catheter, rapidly alternating a low-volume instillation aspiration, and deflating the balloon can also be helpful maneuvers to maximize clot irrigation. Clot irrigation can sometimes require 30–60 min and a reasonable attempt should be made to clear the bladder of clot prior to moving onwards.

Once the bladder has been completely evacuated of clots, consideration is given to continuous bladder irrigation (CBI) (see Fig. 31.1). CBI should not be used unless manual evacuation has ensured that large clots have been evacuated from the bladder. This is because these clots are unlikely to clear with CBI alone and may obstruct the catheter during passage. An obstructed catheter outflow with unattended continuous inflow in the setting of CBI can result in bladder trauma and recurrent symptoms of retention. CBI does not replace manual irrigation but can be useful to ensure that ongoing bleeding is efficiently evacuated from the bladder such that large clots will not form. Large bags of saline are connected to a cone-tipped tubing that will be attached to the small cone-tipped port of a 3-way catheter. Generally Y-tubing should be used to facilitate hanging two bags at once such that the need to exchange bags can be minimized. Only one bag should be unclamped and actively flowing at a time. The rate of continuous bladder irrigation can be varied by adjusting the tightness of a valve that will be present on CBI Y-tubing, which can constrict this tubing to reduce inflow. CBI rate is also dependent on the height of the irrigation bags above the bladder because irrigant flow is gravity dependent. Generally, CBI rate should ensure the urine is a dilute pink and can be slowed or stopped if the urine is clear. Red urine with clots should prompt the CBI rate to be increased.

The stable patient with an appropriately draining bladder is now assessed for the etiology of hematuria and appropriate disposition.

Generally, the stable gross hematuria patient without any clots should be fairly safe for discharge and timely outpatient workup. At least a urine culture should be obtained and a mechanism should be in place to follow-up culture results to ensure prompt antibiotic treatment in the event of a positive result. Those with urinary symptoms or features on urinalysis concerning for infection may be given empiric antibiotics for urinary organisms, which include gram-negative bacteria +/− enterococcus, and staphylococcus. Even with an empiric diagnosis of a urinary tract infection (UTI), it is still imperative that the patient be referred to a urologist for workup as this diagnosis is often revised when culture results return and an underlying malignancy may also be present. The risks and benefits of interrupting anticoagulation for co-existent conditions should be discussed and the prescribing physician notified. Patients on anticoagulation still require a full hematuria workup [1]. Patients can be counseled that their outpatient workup will generally include a detailed history and physical examination, repeat urinary testing, and additional workup such as a flexible cystoscopy under local anesthetic and upper tract imaging [1, 10]. Specific reasons to return to the ED include symptoms of worsening anemia, difficulties urinating due to urinary clots, and symptoms of worsening infection.

Even if a patient has presented in urinary retention from clots, they can sometimes still be discharged for an outpatient workup. Generally, this is in the setting of a limited resolved amount of bleeding that has resulted in clot-related obstruction but is now clear after catheter placement and limited manual and/or continuous bladder irrigation. Patients are generally discharged with an indwelling urethral catheter and short-term urological follow-up.

Patients with clot retention and significant acute renal insufficiency should be observed for possible post-obstructive diuresis (POD). POD can be life threatening and is discussed further in the section on urinary retention. It is very hard to estimate urine output in the patient on CBI, and POD monitoring will generally require additional clinical monitoring and serum electrolytes. Urologic consultation in this setting is advised.

The unstable patient or patient with persistent bleeding will require further inpatient assessment and management. After stability and urinary tract drainage are ensured, the initial steps of management include correcting any underlying coagulopathy and treating coexisting infection empirically. The source of bleeding in these patients should be determined. Sometimes the source of bleeding is readily apparent given the history or physical examination. Urology

consultation should then be obtained, as most sources of bleeding cannot be controlled in the ED. A discussion of selected oncologic etiologies is detailed below. If the source of bleeding is not readily apparent, differential diagnosis can broadly be categorized as upper or lower urinary tract. The best initial imaging test is a triphasic CT scan with noncontrast, early-contrast, and delayed-contrast images [10]. This test is sometimes called a CT urogram or CT intravenous pyeloureterogram. This will allow for an assessment of a variety of sources of bleeding in the upper and lower urinary tracts. Generally, most upper urinary tract causes can be excluded by imaging, while lower urinary tract etiologies are sometimes not readily apparent and findings within the bladder can be obscured by bladder clot. When a timely CT urogram is contraindicated (e.g., severe contrast allergy, renal failure, lack of availability, or an unstable patient), urology consultation is most appropriate to decide on the best initial imaging modality. Depending on the situation, this may include a renal ultrasound, MR urogram, noncontrast CT, or deferring upper tract imaging if a source is known [10].

Management of the specific source of bleeding will depend on its etiology. A discussion of selected oncologic etiologies of hematuria is detailed below.

Renal Mass

Although most renal masses are detected incidentally, a proportion will still present with hematuria, flank pain, nonspecific abdominal or back symptoms, or a palpable mass [11]. Generally, larger and more centrally located masses are more likely to cause hematuria. An antecedent history of trauma may have precipitated the hematuria but it usually occurs spontaneously. Hematuria associated with renal masses can be associated with ipsilateral flank pain, particularly if there is an ipsilateral perirenal hematoma or clot-related urinary obstruction. Paraneoplastic symptoms may also be present [12]. Most large renal cortical masses will be renal cell carcinoma [13], and masses involving the collecting system are likely to be urothelial carcinoma [14]. One should be wary of assuming that a small peripherally located renal mass or cyst is the cause for hematuria as these are common incidental findings. In some settings, an associated retroperitoneal hematoma may be of higher concern than the hematuria itself. A spontaneous retroperitoneal hematoma requires follow-up imaging, as sometimes the renal mass where the bleed originated is not initially visible amidst hematoma. In rare cases, spontaneous intra-tumor hemorrhage may cause significant pain or gross hematuria. Renal artery embolization can be considered after urologic consultation. Large renal masses should also prompt careful consideration of the presence of intraluminal renal vein or inferior vena cava tumor involvement, which can be present in up to 30% of patients undergoing radical nephrectomy [15] (Fig. 31.2). Vascular involvement may not be readily apparent if a noncontrast CT was obtained or if imaging identifying the mass is old. A further discussion of tumor thrombus is found later in this chapter.

Renal mass–related hematuria often requires intervention. In surgical candidates, this generally involves partial or radical nephrectomy or nephroureterectomy. A stable patient with limited hematuria may be discharged and have nephrectomy following a comprehensive outpatient workup. Significant ongoing hematuria may require a more timely nephrectomy. Nonsurgical candidates are often managed by angioembolization. In metastatic renal cell carcinoma or upper tract urothelial carcinoma, systemic therapy [16] and/or radiation [17] can also be of assistance in managing hematuria in nonsurgical candidates.

Ureteral Mass

Ureteral masses are often due to urothelial carcinoma [14]. A benign etiology such as a clot from hematuria originating in the ipsilateral kidney, papillary necrosis, or a radiolucent stone may mimic a ureteral mass. Hematuria associated with a ureteral mass is generally managed surgically. The degree of hematuria from a ureteral mass is usually limited and unlikely to require emergent intervention. Concomitant ipsilateral ureteral obstruction will often result in hydronephrosis. Obstructive uropathy and pain, renal dysfunction, or infection should be ruled out prior to outpatient assessment. Management of ureteral obstruction is discussed in more detail below.

Bladder Mass

Bladder masses diagnosed on imaging or prior cystoscopy are most commonly urothelial carcinoma [18]. Clot, mucosal folds, or debris in the bladder however can often mimic a bladder mass and accurate determination can be challenging radiologically. The patient with limited hematuria and a bladder mass is safe for outpatient urologic assessment. A urine culture should be sent to facilitate outpatient workup. A brief period of time until their assessment to await resolution of hematuria may actually be beneficial, as this will improve visualization during office flexible cystoscopy. For those with clot urinary retention, initial management is similar to undifferentiated hematuria as described above with manual followed by continuous bladder irrigation. The stable patient with timely resolution of their hematuria and a limited clot burden can be discharged for an outpatient assessment with an indwelling urethral catheter or following a trial of void. Ongoing hematuria or those with a significant clot burden

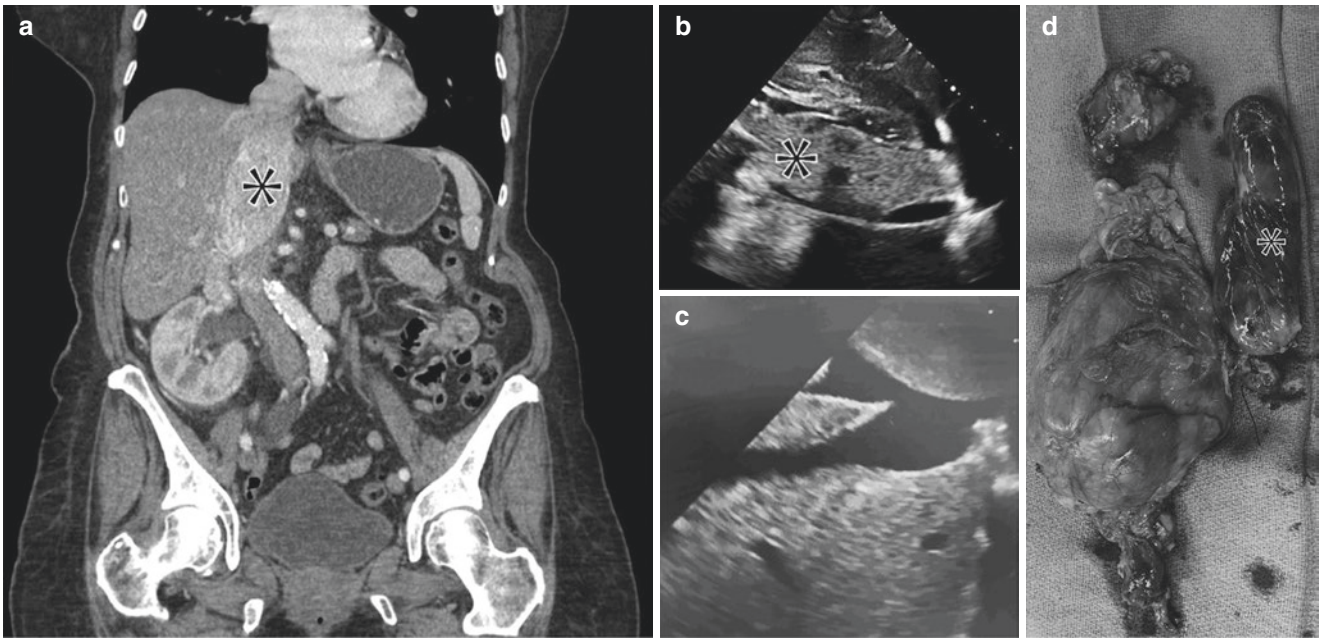

Fig. 31.2 Renal cell carcinoma with inferior vena cava tumor thrombus. A 71-year-old female presented to the ED with worsening back and abdominal pain, hematuria, and shortness of breath. She had a mild acute kidney injury along with normal liver function testing. She had an urgent CT pulmonary angiogram, which revealed no evidence of pulmonary embolus. (**a**) Abdominal CT scan revealed a large right renal mass (not pictured) along with a tumor thrombus in the inferior vena cava veins (*). (**b**) Echocardiography revealed that the tumor thrombus (*) extended to the level of the right atrium. (**c**) Echocardiography also revealed that the hepatic veins were free of tumor. Staging investigations were otherwise negative, and her severe symptoms prevented discharge. Because it was evident on CT that the inferior vena cava thrombus was comprised of tumor rather than bland thrombus, therapeutic anticoagulation was not initiated. She had a right radical nephrectomy and tumor thrombectomy with cardiopulmonary bypass shortly after admission. (**d**) The pathologic specimen from radical nephrectomy and tumor thrombectomy is pictured with a large right renal mass, adrenal gland, and tumor thrombus (*). Pathology revealed pT3c clear cell renal cell carcinoma with 0 of 33 lymph nodes involved. Expected long-term cancer-specific survival is above 50%

likely warrant inpatient urologic assessment. The management of a patient with suspected bladder mass on continuous bladder irrigation is usually to await resolution for a period of time followed by inpatient cystoscopy if resolution does not occur. Some patients with a bladder mass and very significant hematuria may be taken urgently to the operating room for cystoscopy under general anesthetic to evacuate the clots, control bleeding, and resect the bladder mass for diagnosis and staging. Patients with an advanced bladder mass and recalcitrant hematuria may require numerous interventions, including focused bladder radiotherapy.

Urethral Pathology

A variety of urethral pathology may present to the ED including tumors, strictures, trauma, and infections. Urethral pathology will present with bleeding, urinary symptoms, and a mass. Limited urethral bleeding will present as hematuria at the beginning of urinary stream, which resolves as the stream continues. Significant urethral bleeding will manifest as ongoing hemorrhage that continues outside of micturition if the source is distal to the urinary sphincter. Lower urinary tract obstruction may result in urinary retention or symptoms such as hesitancy, intermittency, slow stream, frequency, urgency, incomplete emptying, dysuria, post-void dribbling, and overflow incontinence.

For patients in urinary retention, the appropriate catheter placement technique will depend on the pathology. Urology should be involved prior to catheter attempts in patients with suspected external or iatrogenic urethral trauma to avoid worsening the degree of urethral trauma [7]. Often, these patients present with blood at the meatus or gross hematuria that clears during the void. In the patient with a suspected urethral stricture or bladder neck contracture after radical prostatectomy, a smaller (12–14 Fr) catheter should generally be used. Upfront cystoscopy for catheter placement may be required if initial gentle attempts fail and an inability to catheterize the urethra may require suprapubic tube placement.

Women in urinary retention may be especially difficult to catheterize when a urethral or vulvar lesion obscures the native urethral meatus or when prior perineal resection or radiation results in meatal retraction and/or stenosis. Lithotomy position, a speculum blade to retract the posterior vaginal wall posteriorly, additional lighting, and an assistant

to part the labia will help with difficult female catheterization. Some women may require a catheter be passed by palpation alone without visualization along the anterior vaginal wall when the urethral meatus is not visible. Additionally, ongoing bleeding and/or severe symptoms may require semi-urgent removal of a urethral lesion in women (e.g., strangulated urethral prolapse or caruncle).

Successful catheter placement in a patient with urethral pathology will often lead to clear urinary drainage because the eyelet of an appropriately placed catheter sits in the bladder, proximal to the site of a potentially bleeding urethral lesion. Ongoing urethral bleeding following catheter placement in a patient with urethral pathology may manifest as bleeding around the catheter. This bleeding may be controlled by gentle traction on the catheter along with compression of the distal urethra around the catheter for a period of time to allow for tamponade. This tamponade occurs when a closed system is created by the balloon of the Foley catheter on gentle traction at the bladder neck and the compressed urethra distally. In men requiring ongoing compression, gentle wrapping of the penis with a strip of gauze or Coban dressing can be helpful. A tourniquet effect resulting in penile ischemia and necrosis can result if the penile compression is overly restrictive, and so any dressing placed must be slightly loose and should be removed once the bleeding is controlled. Vigilant penile status monitoring is required if a penile tourniquet is used to avoid ischemic complications.

Once the acute presentation of a urethral lesion is managed, further evaluation will generally be handled as an outpatient. This workup includes a cystoscopy with a biopsy. Imaging for urethral pathology is best approached with MRI due to its enhanced soft-tissue resolution [19].

Urinary Retention

Urinary retention refers to an inability to empty the bladder appropriately. This is common in patients with cancer and may be an acute or chronic finding. The etiology of urinary retention may be an obstruction of the bladder outlet (i.e., the prostate or urethra) or from insufficient contraction of the bladder itself. The specific etiology for urinary retention is often multifactorial and both the bladder and outlet may play a role. Elucidating the factors contributing to urinary retention generally fall into the realm of outpatient urology.

Chronic urinary retention refers to a longstanding inability to empty the bladder. While this may manifest as recently worsening urinary symptoms, patients do not endorse an inability to void or acute pain. Chronic urinary retention is diagnosed by an elevated post-void residual. Post-void residual may be measured by portable bedside ultrasonography [20], but a variety of false positives exist for these machines including obesity, ascites, peritoneal dialysis, malignancy, and anatomic abnormalities such as bladder diverticuli and pregnancy. Post-void catheterization with measurement of the catheterized output is an alternative way to accurately measure post-void residual [20]. There is also no clear agreement on what is an abnormal post-void residual, but chronic urinary retention is often considered for PVRs above 300–400 ml [21]. Chronic urinary retention is generally assessed on a nonurgent outpatient basis unless an acute complication exists. Decompensation of chronic urinary retention may result in acute urinary retention, UTI, and renal failure. Generally, these issues are managed initially with urethral catheterization. Subsequent management is coordinated by urology and involves discharge and close follow-up in many cases.

Acute urinary retention refers to an acute inability to empty the bladder. Typically, patients have significant difficulty or total inability to void, pelvic pain, and overflow incontinence, which does not relieve their symptoms. They may have baseline urinary symptoms that have worsened recently including a weak stream, straining to void, incomplete emptying, hesitancy, intermittency, urgency, and frequent small volume voids. Those with a preceding or complicating infection may also have dysuria, fevers, flank pain, or testicular symptoms. Hematuria is a frequent presenting symptom for those with clot urinary retention. Signs include abnormal vital signs, a visually uncomfortable and restless patient, abdominal distension, and a palpable bladder. Other abnormalities on the genitourinary exam may be associated with the cause of the urinary retention. The emergency physician should have a low threshold to suspect acute urinary retention in any patient presenting with pelvic discomfort or urinary complaints.

A clinical diagnosis of acute urinary retention is usually confirmed by an elevated post-void residual measured by bedside ultrasonography [20]. If this is not immediately available, the patient should be catheterized empirically if acute urinary retention is suspected. A high volume of output upon catheter placement along with resolution of symptoms will confirm this diagnosis. Following catheter placement, the patient should be assessed for conditions associated with urinary retention including infection, hematuria, and renal failure. If isolated urinary retention is present and symptoms have resolved following catheter placement, the patient may be discharged with an indwelling urethral catheter for an outpatient workup and trial of voiding.

The amount of urine output following relief of urinary tract drainage is important. It is normal to have significant output upon initial relief of urinary tract obstruction (i.e., several hundred milliliters up to several liters in a short time period may be normal). If the urine output is less than expected, consideration should be given to an alternate diagnosis or to a mispositioned or obstructed catheter. Alternatively, a post-obstructive diuresis (POD) can result

following urinary tract drainage [22]. A patient is considered to have POD when they have a persistently high urine output (usually >200 mL/h) following relief of obstruction. This generally occurs following relief of obstruction in a patient with urinary retention that has resulted in renal failure. A similar phenomenon occurs following relief of bilateral ureteral obstruction or unilateral ureteral obstruction in a patient with a solitary kidney. A certain degree of POD is physiologic as longstanding obstruction and/or renal failure may have resulted in fluid retention requiring excretion following relief of obstruction. Pathologic POD may continue beyond this physiologic period resulting in fluid status and electrolyte abnormalities that may be life threatening.

Post-obstructive diuresis should be suspected in any patient presenting with retention and significant renal insufficiency. These patients should have urine output, volume status, vital signs, and electrolytes monitored following relief of their urinary tract obstruction. Patients without mental status changes should be provided free access to water, as thirst will allow them to self-regulate their fluid status. Aggressive fluid replacement should be avoided as this can prolong diuresis. The patient with limited polyuria, no electrolyte abnormalities, normal vital signs, normal volume status, and adequate mentation to drink when they are thirsty should be safe for discharge after a period of observation (e.g., 6 h). Patients not meeting these criteria will generally require admission for monitoring. In patients with a severe diuresis or who lack the ability to self-regulate their fluid status, fluid replacement is generally administered at a rate of half the urine output with 0.45% normal saline. Patients with severe renal failure, electrolyte abnormalities, or fluid status imbalance will benefit from nephrology consultation and modification of their fluid replacement based on urinary and/or serum electrolytes.

Hydronephrosis

Hydronephrosis refers to dilation of the collecting system of the kidney including the renal pelvis and calyces. This may be associated with ureteral dilation or hydroureter. The combination of renal and ureteral dilation is termed hydroureteronephrosis. The etiology of hydronephrosis may be obstructive or nonobstructive.

The first consideration in any patient with hydronephrosis is whether it may relate to urinary retention due to a lower urinary tract pathology. This will present with a distended bladder and bilateral hydroureteronephrosis. A urethral catheter will relieve lower urinary tract obstruction and should be placed expediently for patients with acute urinary retention, concern for infection, or renal failure. Concomitant bilateral ureteral obstruction may be present, and this should be considered in the patient with urinary retention and ongoing hydronephrosis, oliguria, signs of infection, or renal failure.

Although nonobstructive hydronephrosis may be relevant in certain populations, most hydronephrosis in the cancer population is obstructive. This is because ureteral obstruction by abdominopelvic malignancy is a fairly common complication of advanced malignancy [23]. The specific etiology of upper urinary tract obstruction may be intraluminal or extraluminal. Common intraluminal etiologies include ureteral tumors, stones, strictures, or an encrusted indwelling ureteral stent. External compression may result from any number of different intraabdominal pathologies. Malignant etiologies such as retroperitoneal or pelvic lymphadenopathy or a pelvic mass are fairly common [23]. Otherwise, ureteral obstruction may be iatrogenic, post-traumatic, inflammatory, infectious, congenital, or idiopathic. Although the differential diagnosis of ureteral obstruction is lengthy, the main consideration for the emergency physician can be simplified into whether urgent decompression is required or not.

It is also important to understand that urinary tract obstruction may also be present without significant hydronephrosis [24]. This is particularly true in the setting of acute obstruction when hydronephrosis may not have had a chance to develop. Accordingly, the patient with a clinical history suggestive of obstruction, even with limited or absent hydronephrosis, should be evaluated by a urologist (e.g., the patient with anuria despite urethral catheterization and radiographically evident pathology that may cause ureteral obstruction on CT). Moreover, changes in the extent of hydronephrosis between interval studies is difficult to quantify and interpret and can vary based on numerous factors other than the degree of obstruction [25].

The indications for urgent upper urinary tract decompression are a concern for obstructed UTI, renal failure, and uncontrolled flank pain. The emergency physician should have a low threshold to suspect infection in a patient with hydronephrosis and signs of sepsis or a positive urinalysis. The urinalysis may be falsely negative as a complete obstruction may disconnect the obstructed urinary tract from voided urine. Given the gravity of missing an obstructed UTI, the threshold should be low to consult urology in the setting of hydronephrosis with a concern for infection. Significant recent worsening of renal insufficiency, particularly with associated oliguria, should also be considered an indication for urgent decompression. It is sometimes challenging to elucidate whether a minor degree of acute kidney injury relates to limited hydronephrosis in the acute setting. When in doubt, a urology consultation is reasonable, but consultants may elect to observe this hydronephrosis in the stable patient and trend their renal function. Ongoing symptoms despite analgesia are also an indication for upper urinary tract decompression.

Upper urinary tract drainage is accomplished by ureteral stenting or nephrostomy tube placement. In the infected patient, randomized data have not supported any difference in meaningful outcome such as time to fever resolution [26]. Ultimately, the decision on which to perform is very nuanced and dependent on patient factors. In the patient requiring urgent intervention, the best measure will depend on what is available first. It is known that there is significant regional variation in stent versus nephrostomy tube placement likely for this reason [27]. Contraindications to each decompression method are first assessed. Nephrostomy tubes will generally be contraindicated in those with coagulopathy and may be more difficult in the patient who cannot be placed prone, has morbid obesity, or lacks hydronephrosis. Ureteral stents will not be feasible in the patient who does not have easy endoscopic access to the ureter—in the oncologic setting this is due to trigonal invasion of a large pelvic mass or due to prior lower urinary tract surgery. Additionally, suspicion of longstanding complete obstruction will be very difficult to bypass with a ureteral stent and consideration should initially be made for nephrostomy tube placement. While a ureteral stent can be placed under local anesthetic, it is often painful and usually performed with sedation or a general anesthetic. Anesthetic requirements are likely less for nephrostomy tube placement and this procedure can be conducted at the bedside in an emergency if necessary.

If no specific factors indicate one procedure over the other, the choice for nephrostomy tube versus ureteral stent is generally undertaken by shared decision-making. Ultimately, patient and practitioner factors heavily influence the choice of urinary diversion modality [28].

Following decompression of the upper urinary tract by either stent or nephrostomy tube, it is important to consider the possibility of post-obstructive diuresis. This will generally occur in the setting of significant renal insufficiency associated with the relieved obstruction. This is discussed further in the setting on urinary retention.

One particular etiology of obstruction that warrants discussion in the oncologic patient is stent failure. Abdominal malignancies often cause ureteral compression requiring ureteral stent placement. Due to progressive growth of these malignancies or encrustration of an indwelling stent over time, recurrent obstruction can develop despite an indwelling stent. The diagnosis of stent failure can be hard to assess in the ED as degree of hydronephrosis is not necessarily indicative of impaired drainage. Generally, stent obstruction should be suspected if the patient has recurrent clinical sequelae of obstruction. One should look for signs of obstructed infection, renal dysfunction, worsening hydronephrosis, and acute or subacute worsening of flank pain. This diagnosis of stent obstruction can sometimes be difficult to make as indwelling stents or the underlying obstructive pathology may cause urinary symptoms or flank discomfort. Theoretically, renography could assist in the diagnosis, but it is often not necessary. Management is generally either with a stent exchange or conversion to nephrostomy tube with subsequent stent removal. The latter approach is warranted particularly if re-obstruction occurs quickly, a stent is poorly tolerated, or stent exchange is complicated.

Although nonobstructive hydronephrosis is possible, this is a difficult initial diagnosis to make in the ED. The diagnosis generally requires diuretic nuclear renography to rule out obstruction. Nonetheless, nonobstructive hydronephrosis may be evident from the history, particularly if diuretic renography has previously demonstrated a lack of obstruction. Possible nonobstructive etiologies include vesicoureteral reflux, pregnancy, excessive hydration, congenital anomalies, and prior corrected obstruction. A parapelvic renal cyst may also often masquerade as hydronephrosis [24]. Patients with history of radical cystectomy with urinary diversion can have physiologic hydronephrosis without obstruction and a loopogram or pouchogram will be diagnostic. Because of the relative infrequency of nonobstructive hydronephrosis and the difficulty in making this diagnosis, it would be reasonable to consider most new hydronephrosis in the ED as obstructive.

Testicular Cancer

Testicular cancer is the most common solid organ malignancy in men aged 15–44 years [29]. As men in this age group infrequently see a healthcare practitioner in the outpatient setting, they often have delayed diagnosis [30–32] and may present symptomatically to the ED. Presenting symptoms include a testicular mass, enlargement, and discomfort (Fig. 31.3). They may also have symptoms of systemic disease including abdominal or back pain, respiratory symptoms or hemoptysis, breast enlargement or tenderness, or neurologic symptoms [33]. The physical exam will usually reveal a palpable testicular mass with ipsilateral hemiscrotal enlargement. A reactive hydrocele, discomfort, contralateral or multifocal masses are also sometimes present. The genitourinary examination is often otherwise unremarkable. An abdominal mass may be present in the setting of bulky retroperitoneal adenopathy. Gynecomastia may also be present in the setting of elevated tumor markers or a testicular stromal tumor. The respiratory exam may be abnormal due to thoracic metastases. A Virchow's node (supraclavicular) may be palpable along with additional neck adenopathy. Patients will rarely also have symptoms from brain metastases, bone metastases, venous obstruction, or thromboembolism [34]. The differential diagnosis for testicular masses includes epididymoorchitis with possible abscess formation, testicular torsion, hernias, paratesticular lesions, hydroceles, varicocele, inflammatory conditions, and trauma. Various other

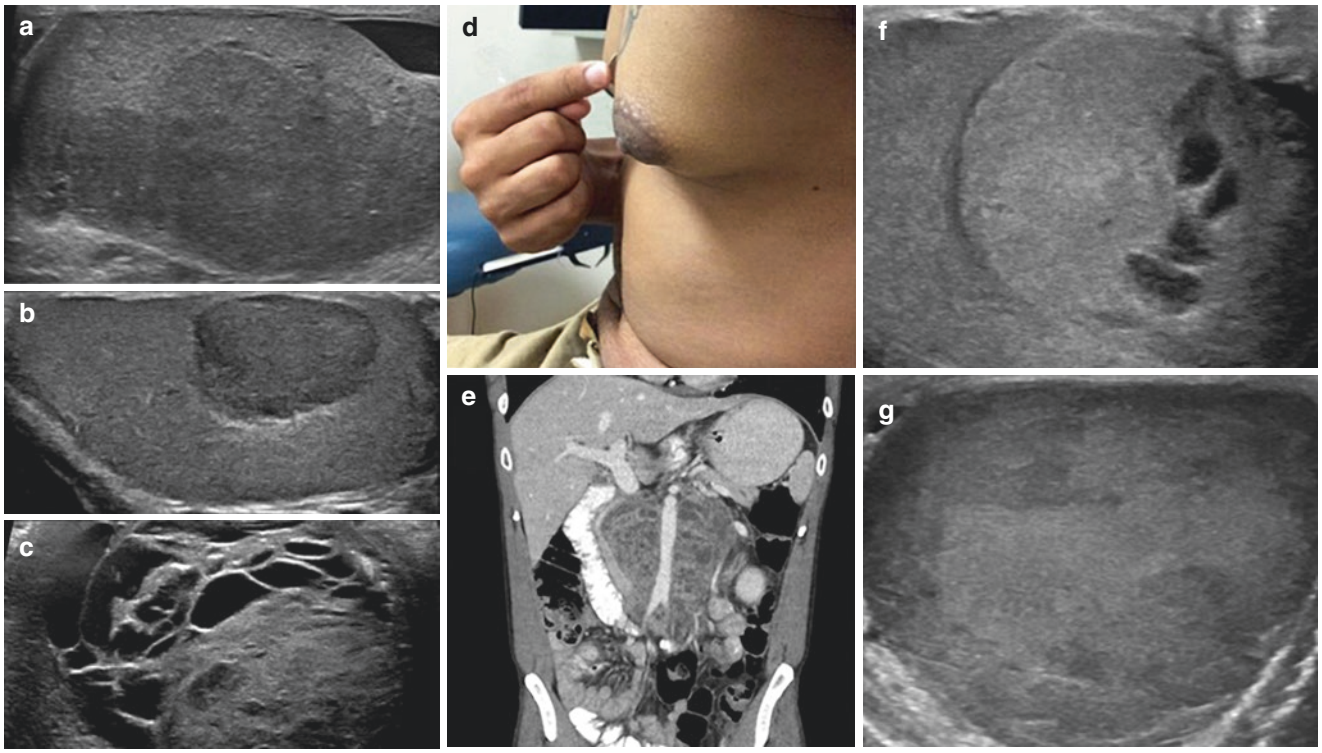

Fig. 31.3 Testicular tumors. These patients presented initially with scrotal complaints, were imaged with a scrotal ultrasound, and ultimately underwent radical orchiectomy. (**a**) This poorly circumscribed hypoechoic mass was found to be lymphoma. (**b**) This well-circumscribed, small, and difficult-to-palpate lesion was found to be a Leydig cell tumor. (**c**) Some testicular tumors have significant hypoechoic areas consistent with cystic components—this finding is suggestive of teratoma, which comprised the majority of this patient's nonsemonimatous germ cell tumor. (**d**) Gynecomastia is sometimes associated with testicular tumors. This can occur due to hormonal secretion from testicular stromal tumors (in this patient estradiol was being secreted by the Leydig cell tumor depicted in **b**). Gynecomastia can also occur due to elevated beta-HCG secreted by germ cell tumors. (**e**) This patient had increasing abdominal pain and leg swelling during chemotherapy for nonseminomatous germ cell tumor. He had multiple presentations to the ED for pain control. He was eventually diagnosed with growing teratoma syndrome as his large retroperitoneal mass was expanding during chemotherapy. This mass also compressed and laterally displaced the inferior vena cava. The diagnosis of growing teratoma syndrome should be suspected in the patient presenting with worsening symptoms during chemotherapy for nonseminomatous germ cell tumor. Imaging will reveal progressive growth of metastatic disease from pre-chemotherapy scans. In this patient, chemotherapy was interrupted and the patient was taken for surgical resection. Pathologic findings from surgery revealed pure teratoma. (**f**, **g**) Germ cell tumors can be hypo-, iso-, or hyperechoic, and can sometimes be difficult to distinguish from surrounding normal parenchyma

malignancies or conditions can cause the systemic findings detailed above. Although the differential diagnosis is broad, testicular cancer should always be considered for any scrotal complaint in the young man.

Initial workup for a testicular complaint should include scrotal ultrasonography to confirm the presence of a testicular mass with a urinalysis to rule out infection [35] (see Fig. 31.3). The mass will generally appear as a circumscribed hypoechoic hypervascular lesion on sonography that is within the testicle itself. The presence of blood flow on Doppler sonography will assist in ruling out testicular torsion, although cases of torsion may be present with vascularity. Although these findings are characteristic, testicular cancer can sometimes be present without visible flow on Doppler or a visible mass [35]. A negative urinalysis will generally rule out an infectious etiology, but additional sexually transmitted infection testing may be indicated in certain scenarios. Complete blood counts, a complete metabolic panel, and testicular tumor markers (alpha-fetoprotein [AFP], beta-human choriogonadotropin [beta-HCG], and lactate dehydrogenase [LDH]) should also be sent. Generally a high AFP (>20 ng/mL) or beta-HCG along with a characteristic testicular mass will strongly suggest the diagnosis of testicular cancer. Those with extra-testicular signs or symptoms warrant emergent imaging with a CT scan of the chest, abdomen, and pelvis. Extremity complaints or concern for pulmonary embolism should also prompt extremity duplex and/or CT pulmonary angiography. Neurologic complaints or a very elevated beta-HCG (>5000 IU/mL [36]) warrant brain imaging or spine imaging with MRI. Patients with an equivocal diagnosis or without any extra-testicular complaints can have staging imaging deferred to the outpatient

setting where it may be omitted if they are diagnosed with a benign lesion. Alternatively, a chest X-ray rather than CT may be sufficient in staging patients with suspected stage I seminoma [35].

If the patient has systemic symptoms or significant metastatic disease burden, a conversation with a urologic oncologist or genitourinary medical oncologist prior to discharge is warranted. In this uncommon scenario, urgent inpatient treatment is sometimes required and may be undertaken based on a presumptive diagnosis from the clinical scenario and serum tumor markers even without a formal tissue diagnosis [36]. It is more common that a new testicular cancer patient will be assessed as an outpatient with close interval follow-up with a urologist. In general, biopsy of retroperitoneal lymph nodes is not pursued and a prompt radical orchiectomy is sufficient for diagnosis.

Retroperitoneal Mass with Venous Involvement

Renal cell carcinoma is associated with venous involvement in 30% of patients undergoing radical nephrectomy [15]. Other retroperitoneal tumors, including adrenal, upper tract urothelial, sarcoma, and testicular cancers can also involve the venous system. The level of venous involvement can range from thrombus within the small intrarenal vessels alone to complete involvement of the renal veins, inferior vena cava, and right atrium. Patients are often symptomatic, and the degree and pattern of morbidity will depend on their level of venous involvement (see Fig. 31.2). One should have a high degree of suspicion for venous involvement in the patient with a known or suspected renal mass presenting with worsening symptoms. Symptoms can include hematuria, lower extremity edema, ascites, abdominal flank or back pain [11], and a variety of other symptoms associated with generalized malignancy, renal failure, hepatic failure, or cardiac failure. Physical exam and lab findings are variable and will also associate with degree of impact on various organs. The diagnosis of venous involvement is generally made by CT scan with IV contrast. Pulmonary embolism should be ruled out with a CT pulmonary angiogram in any patient presenting with respiratory symptoms. Budd-Chiari syndrome must be considered in the patient presenting with a thrombus close to the hepatic veins [37]. An echocardiogram will be helpful in assessing the patient with intra-atrial thrombus and evidence of heart failure. Ultimately, urologic oncologic consultation should be obtained to develop a plan for the patient prior to considering discharge. Anticoagulation is not necessarily indicated if venous involvement relates to tumor thrombus rather than bland thrombus and should be started as a shared decision with urologic oncologic [38]. Particularly in the case of intracardiac thrombus, use of heparin should be discussed with urologic oncologic prior to initiation because the development of heparin-induced thrombocytopenia may prevent safe cardiopulmonary bypass [39].

The first consideration for a patient with a venous tumor thrombus is whether they are a surgical candidate for tumor thrombectomy and the timeline in which this operation needs to occur (see Fig. 31.2). Depending on the primary malignancy and degree of symptoms, these patients may be admitted for symptom control, workup, and timely inpatient intervention. This is a complex problem, and some patients may not be candidates for surgery due to patient or malignancy-related factors. In these situations, systemic therapy can sometimes be effective [40].

Penile Cancer

Penile cancer is rare with 2200 cases a year in the United States [41]. Nonetheless, the delayed presentation of this cancer is well documented [42, 43]. It is essential that this diagnosis be considered in any patient presenting with a penile lesion (Fig. 31.4). Clinical presentations can range from a subtle asymptomatic erythematous plaque that may be associated with carcinoma in situ to a large fungating penile mass causing urethral obstruction. Patients with a "rash" of the genitals are frequently treated with antifungals and steroids for a prolonged period prior to delayed diagnosis of penile cancer [42]. Additionally, one should also have a low suspicion for the patient with a condyloma to have penile cancer as the enlarging verrucous lesion is also a fairly common presentation and penile cancer is associated with HPV in 40% [44]. When in doubt, urology or dermatology consultation should be obtained. A patient with a penile mass involving the urethra may sometimes present with urinary retention or significant urinary symptoms. Urethral catheterization can be attempted, but the meatus may not be visible amidst a large mass on the glans penis. In some situations, this will require suprapubic catheterization by urology or interventional radiology. Patients with penile cancer may also present with superinfection of a necrotic penile mass, including Fournier's gangrene, albeit an infrequent situation.

Another acute presentation associated with penile cancer is inguinal adenopathy. The first site of metastasis from penile cancer is to the inguinal lymph nodes [45]. These are generally palpable when they are involved in the nonobese patient (see Fig. 31.4). There are also some situations of bulky inguinal adenopathy without a diagnosed primary, which may ultimately lead to a diagnosis of anal, urethral, vulvar, or lower extremity cancers that drain into these nodal basins. The patient with asymptomatic inguinal adenopathy is likely safe for an outpatient assessment. However, in some situa-

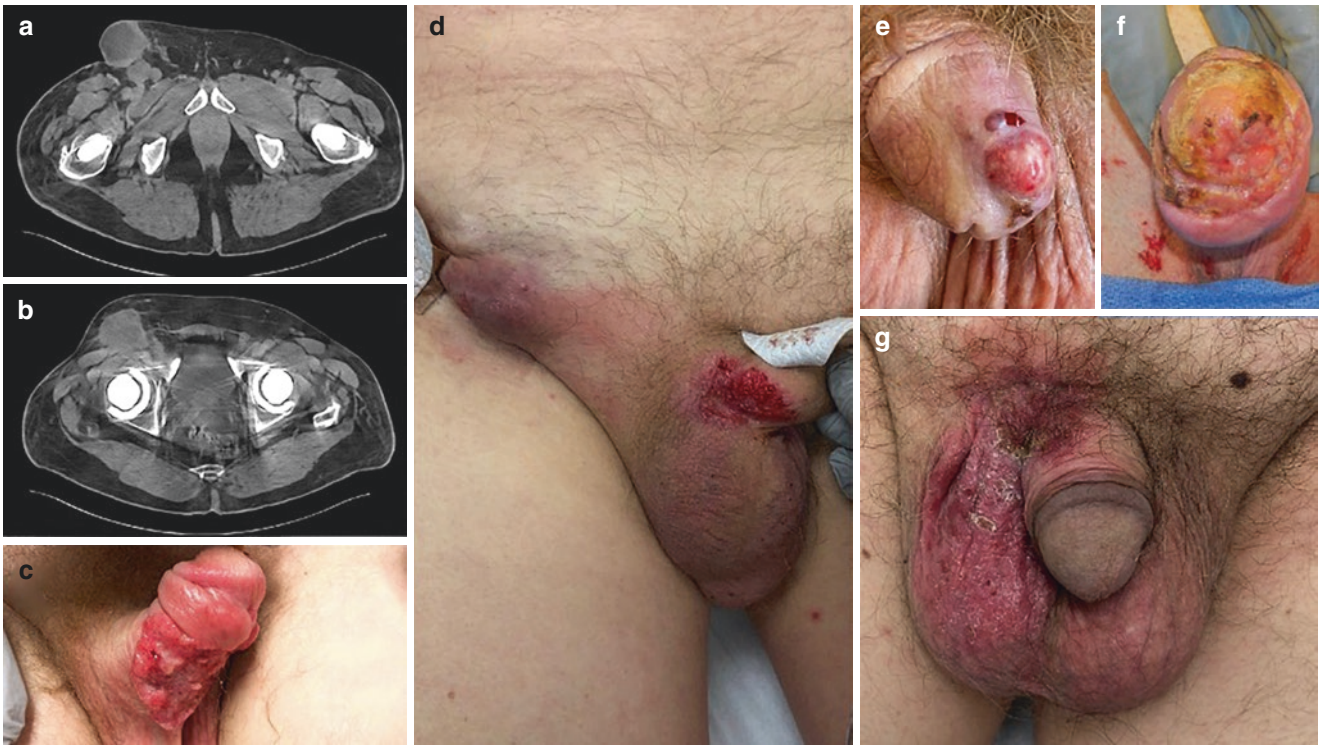

Fig. 31.4 Penile cancer. (**a**, **b**) Inguinal adenopathy associated with penile cancer can lead to various complications. In (**a**) a necrotic lymph node has eroded through the skin and resulted in a nonhealing wound and ongoing purulent discharge. Bulky inguinal adenopathy can also erode into the femoral vessels. In (**b**) there is no separation between the bulky right inguinal lymph node and either the femoral artery or vein. This can eventually result in life-threatening hemorrhage. (**c**) Sometimes a penile mass is not immediately evident as in this patient with penile squamous cell carcinoma who did not look at the ventral aspect of his penis in several years. (**d**) Penile cancers can also be limited in size relative to associated adenopathy. Here a small squamous cell carcinoma is seen on the penile shaft. Bulky inguinal adenopathy is evident on exam. This patient's pelvic CT scan is depicted in panels (**a**), (**b**), and (**e**). Cancers can rarely metastasize to the penis as in this patient with renal cell carcinoma involving the glans penis. (**f**, **g**) Penile cancers may initially be confused for a benign process. The patient in (**f**) had a circumcision for what was thought to be chronic balanitis. The pathology from this circumcision revealed squamous cell carcinoma. He then needed a partial penectomy and inguinal lymph node dissection. This patient in (**g**) was treated with steroids for months due to a penoscrotal rash. Progression of the lesion prompted a biopsy revealing extramammary Paget's disease. He required excision of all the superficial tissues of his penis and scrotum

tions inguinal adenopathy may erode into the femoral vessels, which can cause massive hemorrhage [46, 47]. Urgent urologic oncologic and vascular surgery consultation should be obtained in this case. Additionally, patients with inguinal adenopathy present with severe leg, perineal, or penoscrotal lymphedema, with pain and skin changes. Superimposed infection and deep vein thrombosis are important to rule out. Primary cancer treatment along with symptom control, palliative care consultation, and lymphedema clinic referral can all be useful.

Prostate Cancer

Prostate cancer is the most common cancer in American men with 174,650 cases in 2019 [48]. Although many prostate cancers are localized, metastatic disease is still a large cause of morbidity, and it is the second most common cause of cancer death in America with 31,620 deaths in 2019 [48]. Generally, prostate cancer can present to the ED in three ways.

(i) Urinary retention and/or hematuria. The ED management of these conditions is addressed above. Patients should be referred to a urologist for further management.
(ii) Upper urinary tract obstruction is also common in advanced prostate cancer. This is also discussed above. Patients should be referred to a urologist for further management.
(iii) Spinal cord compression. Prostate cancer is the second most common etiology of malignant spinal cord compression [49]. Those with bony metastatic disease can experience bony pain, pathologic fracture, and spinal cord compression. Patients with cord compression require timely management to minimize permanent

neurologic sequelae [50]. The crucial difference in managing prostate cancer cord compression compared to other cancer sites is the need to institute androgen deprivation therapy. It has been known since the 1940s that prostate cancer is sensitive to the lowering of serum testosterone, which induces atrophy in prostate cancer cells [51]. In the setting of cord compression, a tissue diagnosis of prostate cancer is not required to institute androgen deprivation therapy. Nonetheless some clear evidence of prostate cancer should be present such as a significantly elevated PSA, osteoblastic metastases, and an abnormal rectal examination. Rapid reduction of testosterone is essential in the setting of cord compression. The conventional method of doing this in the outpatient setting is to start the patient on an androgen receptor blocker (e.g., bicalutamide) along with delayed administration of GnRH agonist. This is not appropriate in suspected cord compression because these methods take a long time to work and may induce a testosterone flare [52]. Instead patients must be started on either a GnRH antagonist [52], ketoconazole, or have an urgent bilateral orchiectomy. Other than androgen deprivation therapy, management of prostate cancer cord compression has the same basic principles as other cancer types, including complete spine imaging, high-dose steroids, and early involvement of spine surgery and radiation oncologic consultants. The prostate cancer patient can sometimes present with spinal cord compression after having received multiple prior lines of systemic therapy with progression of disease. Testosterone is generally already castrate in this situation and androgen manipulation will have little effect.

Postoperative Issues

Prostatectomy

Catheter or Urinary Issues Following prostatectomy, patients will be discharged with a urethral catheter as the vesicourethral anastomosis heals. Patients may present with decreased urine output, catheter discomfort, catheter bypassing, hematuria, or debris in the catheter. Usually the only intervention that should be undertaken in the ED is to consider gently irrigating or flushing the catheter. The catheter should generally not be removed, repositioned, or replaced by anyone other than a urologist because of the recent anastomosis and the potential that this has already disrupted or may potentially be disrupted by catheter manipulation. At times, patients will present with urinary retention or new urinary symptoms following prostatectomy catheter removal. Urinary retention and a UTI should be ruled out. Generally, patients should not have a urethral catheter inserted unless the issue is discussed with a urologist due to a concern for traumatizing a recent vesicourethral anastomosis. Catheter bypassing and urinary incontinence after prostatectomy catheter removal are normal, and patients should be reassured, provided it is clear that their bladder is empty and they are not retaining urine.

Pelvic Collections Pelvic collections are commonly found in the patient presenting post-prostatectomy who might receive a CT scan for a variety of indications. The differential diagnosis includes lymphocele, abscess, urinoma, seroma, hematoma, or bowel injury. Radiologic characterization is often not possible, and these collections may frequently be described as abscesses because they contain gas, although this appearance can relate to hemostatic products used at the time of surgery (e.g., oxidized cellulose) [53]. Patients with signs or symptoms of an infection require prompt antibiotic treatment, resuscitation, and percutaneous drainage. Those with bleeding, urinoma, or findings concerning for bowel injury require additional procedures. Generally urologic consultation should be obtained following the initial management of a patient with a pelvic collection post-prostatectomy.

Radical Cystectomy

The readmission rate after radical cystectomy (RC) for bladder cancer is 20–30%; thus, these patients are frequently seen in the ED after undergoing surgery [54].

Fever

Fever is one of the most common reasons for readmission after RC as infectious concerns comprise 25% of postoperative complications [54]. The patient with a fever after RC should be worked up broadly. Specific etiologies include pyelonephritis, intraabdominal infections, wound infections, urinary leak, bowel leak or bowel injury, pulmonary embolism or pneumonia, *Clostridioides difficile* colitis, and line sepsis. Broad workup including chest imaging and abdominal imaging are warranted. Due to bowel being routinely used as part of the urinary diversion, urinalysis and culture may be falsely positive and not indicative of the true source of infection. Patients will often have received multiple antibiotics recently around the time of surgery and prior readmissions; thus, consideration should be given to coverage of MRSA and ESBL in the choice of empiric antibiotic. CT scan of the abdomen and pelvis is essential in the early postoperative period. Timely urologic consultation is advised.

Hydronephrosis

Hydronephrosis is a common finding on a CT scan performed in the patient after RC. The approach to these patients is similar to the general approach detailed above. Strong consideration should be given to prompt nephrostomy placement in the patient presenting with sepsis or renal failure. Retrograde attempts at stent placement are not usually possible.

Urinary Tract Infection

UTIs after RC are relatively common. Symptoms include fever, chills, and flank pain. Presentation can be insidious in the patient presenting with lethargy and mental status changes. Early antibiotic treatment and resuscitation is essential. Urinalysis and culture can both be misleading as this will usually be positive in a patient with a urinary diversion even in the absence of UTI. The urinary findings will have to be correlated with the clinical picture to make a diagnosis, and urology consultation can be helpful in making this determination. Concern for UTI should prompt abdominal imaging, and hydronephrosis generally requires nephrostomy placement. Although hydronephrosis may sometimes be physiologic in the patient with a urinary diversion, the consequences of missing this source of infection in an obstructed UTI is usually an indication for nephrostomy.

Dehydration

Gastrointestinal issues are the most common complication after RC and associated dehydration is common [54]. Patients will present with malaise, fatigue, reduced appetite and oral intake, diarrhea, nausea, vomiting, and reduced urine output. Labs will often reveal an increased creatinine and electrolyte abnormalities. Intraabdominal pathology should be ruled out; the diagnosis of dehydration is one of exclusion. Patients presenting with dehydration will often require admission for rehydration and closer monitoring on discharge to avoid another readmission. Associated gastrointestinal issues should be managed by the surgical team.

Leg Swelling

In addition to the usual differential, the emergency practitioner should be especially suspicious of deep vein thromboses due to a high rate of venous thromboembolism after RC [55]. Additional etiologies include postoperative fluid overload, pelvic fluid collection, and lymphedema related to a pelvic lymph node dissection.

Diarrhea

Diarrhea can be a challenge after RC due to bile acid malabsorption from use of the terminal ileum as part of most forms of urinary diversion. The ileocecal valve may also not be present in the patient with an Indiana pouch. Diarrhea should be differentiated from tenesmus or pelvic discomfort, which can often be secondary to intraabdominal pathology. Nonetheless, patients are at risk of infectious etiologies including *Clostridioides difficile* colitis. Patients presenting with diarrhea should be resuscitated, and infection with dehydration and electrolyte abnormalities ruled out. Antidiarrheals such as loperamide or cholestyramine can be used once infection is ruled out.

Acute Abdomen

Patients presenting with an acute abdomen are managed similarly to other surgical patients. Early surgical consultation is obviously warranted. Etiologies could relate to the gastrointestinal or urinary system and the differential diagnosis is complex [54]. Patients should be resuscitated and if imaging is performed before urologic consultation, a CT urogram is often more useful than a standard CT scan because this will aid in differentiating many complications associated with the urinary diversion. Oral contrast and/or rectal contrast may also be useful depending on the situation.

Stomal Complications

Most patients will have an ileal conduit after RC. Patients may develop various issues with these conduits, including pouch leakage, parastomal hernias, parastomal dermatitis or infections, or issues with the stoma itself (e.g., bleeding, varices, stenosis, prolapse, and necrosis). Stomal bag-related issues and parastomal dermatitis are often best handled by involving a wound ostomy continence nurse to help with troubleshooting and finding the best ostomy supplies. Stomal stenosis will present with a distended conduit on imaging along with oliguria and renal dysfunction; management is generally by stomal catheterization and surgical consultation is advised. Patients with portal hypertension may present with stomal varices, and management is similar to varices elsewhere in the gastrointestinal tract. Blood loss anemia is common in this clinical context. Parastomal hernias are very common on imaging, present in 50% of patients [56]. Although parastomal hernias may be dramatic on the physical examination, these are generally not an acute issue in the ED unless hernia-related complications develop. If there is concern for obstruction or strangulation associated with a parastomal hernia, early surgical consultation is advised.

Continent Diversion Problems

Continent urinary diversion includes both continent cutaneous diversions and orthotopic neobladders. Many types exist and the exact configuration of the urinary diversion is often unclear to the emergency physician. Patients with continent cutaneous diversions will have some form of catheterizable abdominal stoma, while those with an orthotopic neobladder will void per urethra. Various issues with these complicated urinary diversions will cause patients to present to the ED. The emergency provider should seek urologic consultation in devising the management plan and always keep urinary retention or diversion rupture within the differential diagnosis. Generally, procedural interventions should be avoided by the nonspecialist as the anatomy of the urinary diversion is often unfamiliar.

Nephrectomy

Hematuria

Patients presenting after partial nephrectomy with hematuria may develop a pseudoaneurysm or arteriovenous fistula [57]. These patients can present with hemorrhagic shock. In the stable patient, initial resuscitation should be commenced and a pseudoaneurysm/AVM ruled out with CT angiography. In the unstable patient, urologic consultation should be obtained immediately. Management should be coordinated with urology and will often involve selective angioembolization by interventional radiology [58]. Patients should not have hematuria after radical nephrectomy and thus should be assessed as any other patient presenting with hematuria.

Abdominal Collections

Patients after partial or radical nephrectomy may frequently receive a CT scan for abdominal complaints revealing an abdominal fluid collection. The differential diagnosis includes abscess, urinoma, seroma, hematoma, pancreatic leak, bowel injury, or biloma. Generally, initial management includes stabilization with empiric antibiotics if signs of infection are present. The patient should receive nothing by mouth and urologic consultation should be obtained to assess for management of the collection. Many postoperative collections are incidental and asymptomatic but occasionally percutaneous drainage by interventional radiology is required. The rare situation of an acute abdomen suggestive of peritonitis or bleed may warrant an exploratory laparotomy.

Pulmonary Symptoms

The common nonsurgical causes should be ruled out including pulmonary embolism, heart failure, myocardial infarction, and pneumonia. Nephrectomy-specific etiologies can include a pneumothorax, pneumomediastinum, or pneupericardium, which can result from diaphragmatic entry [59], diaphragmatic neuromuscular pathology [60], or difficulty with inspiration due to a nephrectomy bed collection or incisional pain.

Conclusion

Urologic oncologic emergencies present frequently to the ED. Knowledge of urologic anatomy and common presenting issues aids greatly in the triage and initial management of these patients. Most acute presentations will relate to bleeding, obstruction, or infection of the urinary tract. A thorough history and physical exam with pertinent laboratory studies will clarify the presenting complaint, but imaging is frequently essential in diagnosis. Initial management focuses on stabilizing the patient, controlling pain, and ensuring appropriate urinary tract drainage. Early coordination with urologic consultants can be helpful to ensure that appropriate steps are taken in a timely fashion. Once the acute situation has been managed, a full assessment is nuanced and usually best performed in the outpatient setting by a specialist. When an outpatient assessment is appropriate, timely coordination of an appointment is essential to ensure optimal patient care and avoiding repeated ED presentation.

Gynecology

32

Loise W. Wairiri, Tatjana Bozanovic, Tanja Pejovic, and Jenna M. Kahn

Case Study 1

A 63-year-old woman with stage IIIC high-grade undifferentiated ovarian cancer underwent extensive surgery followed by chemotherapy. However, the disease rapidly progressed and the course was complicated by ureteral obstruction that was relieved by bilateral percutaneous nephrostomy tubes, and deep venous thrombosis.

After the fifth cycle of carboplatin and Taxol, she presented to the emergency department with several days of worsening abdominal pain, distension, and nausea, and was found to be neutropenic with lactate level of 8. CT scan showed high-grade small bowel obstruction, closed loop in nature. The distal point was associated with a segment of edematous bowel, normal in caliber. A differential diagnosis of bowel obstruction due to malignancy or adhesions, and possible bowel ischemia seen on CT as edema, was made. Overall, the tumor disease burden seemed to have improved with no new disease sites.

The dilemma of emergent surgery for bowel obstruction and possible bowel ischemia and high mortality rate versus *conservative management in the setting of progressive disease with a poor prognosis was discussed with the patient. A decision was made to proceed with surgery. During exploratory surgery, two distinct adhesive lesions that were tethering the bowel to the base of mesentery were found. They were lysed and the area of closed loop was released. There was no extensive disease in the abdomen, and only few 5 mm areas of tumor implants, ablated by chemotherapy, were at the small bowel mesentery. This case illustrates the management dilemma frequently faced in the cases of bowel obstruction in patients with pelvic malignancies.*

Case Study 2

An 80-year-old woman presents to the emergency department with abdominal pain, vomiting, and confusion. She has a history of ovarian cancer diagnosed 1 year ago s/p chemoradiation treatment. On examination; temp: 39.20c, HR: 110 bpm, BP: 85/60 mmHg, and RR: 26 breaths/min. Physical examination reveals a diffusely tender abdomen but no rebound tenderness, rigidity, or palpable masses. Discuss her plan of management and differential diagnosis.

Management This patient presents with septic shock, a complication arising from a possible differential diagnosis of bowel obstruction (malignant/ non-malignant bowel obstruction) or pelvic infection. According to the Third International Consensus Definitions Task Force, sepsis is defined as "life threatening organ dysfunction due to a dysregulated host response to infection" [1].

Aggressive fluid resuscitation and empiric parenteral broad-spectrum antibiotics are required as initial management. Monitor vital signs and input/output as well as central venous pressure.

Sepsis is associated with organ failure. Comprehensive metabolic panel, liver function tests, and complete blood count are recommended laboratory studies. Leukocytosis can be seen in cases of pelvic infection, bowel obstruction, or sepsis.

Imaging may be done once the patient's condition is stable. Abdominopelvic CT with IV contrast is useful to rule out pelvic abscess, bowel perforation, or bowel ischemia. Pelvic abscess and bowel perforation are surgical emergencies, and early surgical management improves the outcome of the patient. It is crucial to evaluate the stage of the disease, patient's prognosis, and quality of life before considering surgical management as it is associated with high morbidity and mortality in terminal disease.

The patient's nutritional needs should also be considered. Evaluate the need for parenteral nutrition and consider the benefits vs *the associated risks such as catheter infection, sepsis, and renal/hepatic failure.*

It is important to have an appropriate and adequate pain management plan for the patient. The goal of care especially in palliative cases must include patient comfort.

Introduction

Gynecologic cancer patients can suffer unexpected emergencies at any stage of disease and treatment. Emergencies may be due to complications of the disease, toxic effects of treatments used in managing the malignancies including chemotherapy, surgical procedures, and radiotherapy, as well as multifactorial underlying causes. Different approaches in handling each emergency depend on the etiology. In this chapter, we discuss emergencies and complications frequently encountered in gynecologic oncology. We will also review the management of these emergencies taking into consideration that goals of care should be dependent on the patient's disease status and prognosis.

Acute Blood Loss

Hemorrhage is a frequent and potentially life-threatening complication in gynecologic oncology. The causes of bleeding are related to tumor invasion, tumor angiogenesis, clotting factor deficiencies arising from hepatic impairment, and systemic effects of cancer, such as chemotherapy and radiation therapy [2].

Primary or recurrent neoplasms of the uterus, cervix, vagina, or vulva may present with small bleeds or with massive life-threatening hemorrhage. Hemorrhage due to metastasis can also be of varying degrees with massive hemorrhage signifying the terminal event in late-stage disease. The most common cause of bleeding in gynecologic malignancies is advanced cervical cancer. Due to the varied incidence and stage of diagnosis of cervical cancer in the world, studies report incidence of vaginal bleeding ranging from 0.7% to 100%, with an attributable mortality of up to 6% in these patients [3]. Palliative treatment options for bleeding are used in different health-care settings depending on available resources.

Many gynecologic surgical procedures are also associated with significant bleeding due to the vascular tumor surgical sites. While most of the causes and areas of bleeding can be controlled by conventional management, it is important to mention presacral bleeding, which is not easily controlled by standard management and often fatal. However, presacral bleeding is uncommon and is seen in gynecologic oncology procedures such as pelvic exenteration and radical hysterectomy [4].

Other significant causes of acute blood loss in gynecologic malignancies include hemorrhagic cystitis and radiation proctitis, both of which are late toxic effects of pelvic radiation.

Radiation proctitis is radiation-induced inflammation of the rectal mucosa occurring as a result of pelvic radiation therapy. The rectum is particularly susceptible to radiation injury due to its proximity to the pelvic organs and fixed position in the pelvis [5]. Acute radiation proctitis, which is usually self-limiting, occurs in the first 3 months of radiation treatment and may present with mild rectal bleeding and tenesmus. Chronic radiation proctitis occurs 3 months after completion of radiation therapy and presents with more overt bleeding due to predominance of fragile telangiectatic vessels and a friable mucosa.

Hemorrhagic cystitis (HC) is a common adverse effect of chemotherapeutic agents, such as cyclophosphamide and isofosphamide used in bone and soft tissue sarcomas and also as immunosuppressive agents for hematopoietic cell transplantation. In gynecologic cancers, HC has been described as a late toxicity of pelvic radiation treatment. Depending on the severity and the cause of hemorrhagic cystitis, different grading systems are used (Table 32.1).

Radiation-induced hemorrhagic cystitis may present in the acute or chronic phase. Acute radiation-induced HC occurs in 10% of gynecologic cancers treated with pelvic radiation [6] and presents with bladder pain that resolves ~ 4–6 weeks after the last fraction of radiotherapy. It is prudent to rule out a urinary tract infection, which presents with similar symptoms. The chronic phase of HC occurs 2–10 years post radiotherapy, and presents with bladder irritation and hematuria. This stage is irreversible. It is important to rule out bladder cancer, which can occur either as a primary disease or secondary late complication of pelvic radiation. Therefore, urinary examination, CT urogram, and cystoscopy with biopsy of lesions should be done to differentiate malignancy from chronic inflammation. Confirmation of chronic radiation inflammation is achieved by demonstrating that the inflammatory lesion occurred in the same site of radiation as per the dosimetry plan (Table 32.1) [7].

Severe hemorrhagic cystitis, though not common, has significantly high mortality despite vigorous treatment. A large study conducted to study the incidence, severity, timing, clin-

Table 32.1 Grading of hemorrhagic cystitis [8]

Grade	Features
0	No symptoms
1	Microscopic hematuria
2	Macroscopic hematuria
3	Macroscopic hematuria with small clots
4	Massive hematuria requiring clot evacuation

ical management, and outcome for patients who developed hemorrhagic cystitis following pelvic therapy for Federation of Gynecology and Obstetrics (FIGO) stage IB cancer of the cervix showed the incidence of HC to be 6.5%, with grade 3 occurring in 18% of the HC cases. After actuarial analysis, they demonstrated an increase in incidence with increasing duration from the last pelvic radiotherapy treatment [9]. Clinicians should be aware and recognize hemorrhagic cystitis emergencies that occur as late effects of radiation toxicity.

Management

Immediate assessment of hemodynamic stability is important for timely resuscitation to be initiated. Adequate volume replacement with crystalloids, followed by blood products, should be administered with frequent reassessment and monitoring of the patient's clinical status and vital signs. In patients with cardiorespiratory impairment, titration against central venous pressure may be necessary. Insert a Foley catheter to monitor output and also to avoid urinary retention by inserting prior to vaginal packing. Management depends on individual needs including platelets and clotting factors replacement. Depending on the cause, options to control bleeding include non-invasive and invasive methods.

When the cause of bleeding is due to advanced cervical cancer, palliative interventions have been used with no single intervention demonstrated to be more superior. Resources play a major role regarding the choice of intervention used in the management of bleeding [3]. Non-invasive techniques are utilized first to control hemorrhage, and when these fail, more invasive methods are applied.

Non-invasive Bleeding Management Vaginal packing is a simple initial measure to control vaginal bleeding, a common presentation in advanced cervical cancer. Sedation or short-acting general anesthesia may be utilized to ensure patient comfort. The source of bleeding is visualized and by use of speculum, the vaginal fornices are packed tightly to maintain an even pressure on the bleeding vessels. Measures to enhance the effectiveness of the packing include decreasing patient mobility, elevating the foot of the bed, and using hemostatic agents (oral, local, or parenteral). Tranexamic acid is an example of a parenteral agent that increases clotting by inhibiting plasmin in the clotting cascade. Topical/locally acting hemostatic agents can be used, including Monsel solution, formalin, and Moh's paste [3, 10].

Monsel solution(ferric subsulfate) can be applied directly on the bleeding site on the cervix or soaked in the vaginal pack and causes agglutination of protein resulting in sealing of the blood vessels [3]. Although Monsel solution has been reported in numerous studies as an excellent hemostatic agent, great care should be observed that minimal amounts of the solution are used. Due to its action, it can induce full-thickness necrosis, perforation, and life-threatening peritonitis when exposed to the peritoneal cavity [11]. Moh's paste has been used as a safe and effective method in cases of vaginal bleeding due to advanced cervical cancer though clinical trials are warranted for adoption of widespread use. It works by releasing zinc ions when in contact with cervical tumors and precipitates wound proteins to enhance hemostasis [12]. Formalin has been used in limited resource settings to enhance the effectiveness of the vaginal pack by acting as a chemical cauterization agent inducing contact coagulative tissue necrosis of the neovasculature to stop bleeders [10]. Formalin is also used to control bleeding in radiation proctitis with documented success rates of up to 75%. Caution must be taken to prevent damage to normal rectal mucosa, which can cause anal pain, strictures, fistulas, and stool incontinence [5, 13]. (Detailed management of radiation proctitis is covered in another chapter of the book.)

When using a vaginal pack to control bleeding, oral broad-spectrum antibiotics and metronidazole are required to treat underlying infections that are common in necrotic, bleeding tumors [10].

Another non-invasive method to control bleeding in gynecologic tumors is hemostatic radiotherapy.

Hemostatic radiotherapy (RT) is effective for emergent palliation of bleeding tumors with lower recurrence of re-bleed and minimal treatment burden for patients with advanced disease. Short-course hypo-fractionated RT is effective and well-tolerated for vaginal bleeding control in 93.8% of patients with advanced cervical cancer, with an additional benefit of pelvic pain control in 66.7% of the patients [14]. Comparable results have been reported of symptomatic relief of vaginal bleeding in 85–100% of patients when treated with two or three 10 Gy fractions of pelvic radiation therapy [15]. More evidence also supports palliative-dose radiotherapy at standard curative treatment fraction of 1.8–2.0 Gy in a single-dose fraction effective for vaginal bleeding in cervical cancer [3, 10].

Invasive Bleeding Management Invasive methods such as interventional radiology and surgery are reserved for use in cases of uncontrolled bleeding in carefully selected patients due to associated morbidity. Uterine artery embolization using metal coils, foam, or glue-like agents is done by the interventional radiology (IR) team, and when IR is not available, laparotomy with ligation of vessels (uterine artery and divisions of the hypogastric arteries) serve as an alternative [4].

Hemorrhagic Cystitis Treatment Radiation-induced hemorrhagic cystitis poses challenges in management due to the ischemic nature of the disease. There are no existing guide-

lines and clinical trials for treatment. Resuscitation with fluids or blood products should be used for hemodynamically unstable patients while carefully monitoring the vital signs and central venous pressure.

Management depends on the severity and grading of HC. Various options are used to alleviate symptoms, including steroids, vitamin E, trypsin, intravesical therapy with formalin and hyaluronic acid for clot evacuation and chemical cauterization, and hyperbaric oxygen with varying degrees of success. Visualization of the fragile telangiectatic vessels by cystoscopy and selective embolization of the bleeders can be used after non-invasive steps are ineffective. Surgery may be considered for refractory cases as a last treatment option. Strict dose constraints to the bladder and tailoring the field are employed to reduce the incidence of hematuria [7, 8, 16].

Summary: Management of Hemorrhagic Cystitis (Fig. 32.1) [7]

Pelvic Infections

Radical gynecologic oncology surgery is associated with a high rate of postoperative complications. Gynecologic procedures increase the risk of pelvic infections due to migration of potential microorganisms from the skin, vagina, and endocervix [17].

Additionally, inefficient defense mechanisms as seen in gynecologic cancer patients, impaired venous or lymphatic circulation after radical hysterectomy or radical vulvectomy [18], and a history of radiation therapy further increase the risks of infection [17].

Pelvic infections in gynecologic cancer patients included in this chapter are vaginal cuff cellulitis, pelvic cellulitis, and pelvic abscesses. Vaginal cuff cellulitis is an infection of the superficial tissues at the vaginal surgical margin, while pelvic cellulitis involves deep soft tissue at the incision.

Prior to routine antibiotic prophylaxis, pelvic infection rates post-hysterectomy were up to 33% [16]; however, widespread implementation of routine antibiotic prophylaxis has led to a significant decrease of pelvic infection rates to 2.7% [18, 19]. Other studies report that pelvic abscesses occur in 3.9% of patients within 30 days after surgery and 6.6% of patients as a late complication in post-trachelectomy for cervical cancer [20, 21].

Infections are often polymicrobial in nature, composed of both endogenous non-pathogenic and pathogenic bacteria. Frequently isolated pathogen includes Gram-negative bacteria, enterococci, group B streptococci, and anaerobes.

Typically, patients with pelvic abscess present with pelvic pain, fever, tachycardia, and tachypnea. On physical exam, the abdomen/pelvis is diffusely tender and a fluctuant mass may be palpable. Vaginal cuff cellulitis presents as acute onset of fever, chills, and macular erythema, with swelling over the lower abdominal wall and inguinal region, that may extend to the proximal thigh. The adnexa and parametrium are non-tender to physical exam. Pelvic cellulitis presents with fever, vague abdominal pain, and anorexia. Physical

Table 32.2 Choice of antibiotic therapy for pelvic infections

Diagnosis	Treatment regimen	Notes
Vaginal cuff cellulitis	Amoxicillin/clavulanate 875/125 mg every 12 h *or* Ciprofloxacin 500 mg every 12 h with metronidazole 500 mg every 12 h *or* TMP-SMX DS every 12 h with metronidazole 500 mg every 12 h	Empiric broad-spectrum antibiotics outpatient management with close follow-up
Pelvic cellulitis	Clindamycin 900 mg every 8 h *or* metronidazole 500 mg every 12 h *plus* Penicillin five million units every 6 h *or* ampicillin 2 g every 6 h *plus* Gentamicin 5 mg/kg every 24 h In case of *renal impairment substitute gentamicin for aztreonam 2 g every 8 h*	Empirical inpatient parenteral broad-spectrum antibiotics, administered intravenously until patient is afebrile for 24–48 h and can then be discharged with oral antibiotic regimen for 14 days with close follow-up
Pelvic abscess	1. Metronidazole 500 mg every 12 h plus Ceftriaxone 2 g every 24 h[a] or 2. Piperacillin-tazobactam 3.375 g every 6 h or 3. Aztreonam *plus* clindamycin or carbapenem[b]	Empiric parenteral broad-spectrum antibiotics continued until patient is afebrile for 48–72 h and clinical improvement is seen. Choice of oral antibiotics should depend on culture and sensitivity results

[a]Recommended first line
[b]In case of penicillin or cephalosporin allergy

examination of pelvic cellulitis will reveal tenderness with absence of masses unlike pelvic abscess [18, 22].

Laboratory findings include leukocytosis, elevated erythrocyte sedimentation rate, and elevated C-reactive protein. Fluid collections in pelvic abscess can be visualized by ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI).

Management

Management depends on the clinical status of the patient and the characteristics of the infection. Initial assessment includes evaluation of the hemodynamic stability of the patient. Hemodynamically unstable patients are likely to have a ruptured abscess, which is life-threatening and requires prompt emergent surgical intervention. In addition, these patients require aggressive fluid resuscitation and empiric parenteral broad-spectrum antibiotics [22].

Vaginal cuff cellulitis is managed in the outpatient setting with broad-spectrum antibiotics and close follow-up to monitor treatment efficacy. Pelvic cellulitis and pelvic abscess require in-hospital management. Surgical abscesses require drainage if; the pelvic abscess is >8 cm, there is no adequate response/clinical deterioration to antibiotic treatment for 24–48 h, and progressively increasing abscess size [23]. There is sufficient evidence that suggests early drainage of all abscesses combined with broad-spectrum antibiotics is safe and improves clinical outcomes with reduced mean hospital stays [24, 25]. However, due to associated morbidity in these patients, the clinician should evaluate the increased risks versus potential benefits.

The suggested regimens (Table 32.2) are based on broad consensus rather than clinical trials. If the patient does not respond 48–72 h on treatment, consultation with an infectious disease specialist is warranted.

Gastrointestinal Emergencies in Gynecologic Cancer Patients

Malignant Bowel Obstruction

Acute intestinal obstruction is a surgical emergency that is often associated with pelvic tumors. It is a relatively common complication of advanced gynecologic malignancies with reported rates of 6% to 50% in patients with advanced or recurrent ovarian cancer and ~5% in cervical cancer [26, 27]. Bowel obstruction can be classified according to etiology as malignant bowel obstruction (MBO) or non-malignant bowel obstruction [26].

The causes of MBO in gynecologic cancer include peritoneal carcinomatosis, extrinsic bowel compression by tumor, adhesions, enlarged pelvic lymph nodes, tumor infiltration of the mesentery, bowel muscle or nerves, edema of the bowel wall, and post-radiation changes [28, 29].

In gynecologic cancer patients, MBO has a relatively poor prognosis with some studies reporting 3-month median survival rates. MBO has often been cited as a pre-terminal event for majority of the patients regardless of treatment. Therefore, the goal is palliative management for comfort and improving their quality of life [30].

Diagnosis of intestinal obstruction is made by presenting clinical symptoms and diagnostic imaging. Proximal bowel obstruction presents more abruptly with abdominal pain, nausea, and vomiting. Repeated vomiting may lead to metabolic alkalosis and hypokalemia. Distal bowel obstruction is more insidious and progressive in onset, presenting with prominent abdominal distension, abdominal pain, and constipation.

Plain abdominal radiography is the initial imaging of choice and demonstrates features of obstruction that include dilated loops of bowel with multiple air fluid levels [31]. Abdominopelvic computed tomography (CT) gives more clinical information, which is relevant in planning management. It determines presence and level of obstruction and complications of bowel obstruction such as ischemia or perforation of involved bowel, both of which are surgical emergencies [32].

Laboratory studies are also useful as they evaluate presence of complications such as metabolic derangements (acidosis, hyperkalemia) and leukocytosis which can be suggestive of infection.

Management The aim of management in gynecologic cancer patients with MBO is symptom control and maintain the patient's quality of life due to the associated high comorbidities and low median survival rates.

Therapy starts with conservative management, which includes restoration of fluid and electrolyte balance, alternatives for feeding, restriction of medication that have paralytic effect on the intestines, and nasogastric tube placement for decompression with stimulation of intestinal passage for distal obstructions [33]. This conservative regimen will keep the patient in optimal condition and allow time for to identify the origin of the obstruction, stage of the malignant disease, and obtain multidisciplinary evaluation. Conservative treatment provides time for diagnostic procedures as well as to see if the obstruction will resolve spontaneously, but no longer than 3–7 days [34, 35]. After this period of time, decisions have to be made either for surgery or refraining from intervention and providing symptomatic and supportive care.

There are contradicting clinical and ethical accounts supporting and against parenteral nutrition for patients with advanced malignancies receiving parenteral care. Patients with MBO have limited/no oral intake, and parenteral nutrition (PN) is a way of providing macro- and micronutrients, fluids, and electrolytes. There is still very low evidence whether parenteral nutrition plays a role in improving survival and quality of life in people with malignant bowel obstruction [36]. TPN has been shown to be of benefit only to improve immediate survival in patients who may otherwise die of starvation than the malignancy [37]. In retrospective studies, PN has been associated with improved survival in patients with a Karnofsky Performance Score (KPS) of greater than 50 [38]. However, the benefits of home PN in patients with inoperable malignant MBO are uncertain and must be balanced against risk of central line infections, thrombosis, electrolyte abnormalities, and increased cost with no associated increase in mean survival for the patient. Consider PN when the risk of starvation or malnutrition is higher than that of disease progression. The European Society for Clinical Nutrition and Metabolism (ESPEN) recommends PN should be offered if the expected survival with tumor progression is longer than 2–3 months [38].

When the cause of obstruction is benign, laparotomy should be performed for adhesiolysis or bowel resection [39]. In the case of radiation enteritis, it is important to resect the entire diseased bowel segment to reduce recurrence, postoperative complications, and mortality [40]. In malignant obstruction, surgical interventions such as bowel resection, bypass, or ileostomy may seem to provide good palliation by reduction of symptoms and obstruction recurrence in progressive disease, but these interventions depend on the extent of the disease in the individual patient [41]. Palliative surgery offers limited benefits in improving quality of life and survival. Family members should be involved in critical discussions prior to undertaking such drastic measures [36]. Surgery in patients with peritoneal carcinomatosis is related with a 30-day mortality of 21–40% and high recurrence rates [42].

Gastrointestinal Perforation and Fistula

Gastrointestinal (GI) perforation and fistulas are potentially life-threatening events that can develop in gynecologic cancer patients. Patients are prone to bowel injury of various forms, including complications arising from tumor invasion, pelvic radiation, and chemotherapy. Tumor invasion of the bowel is common in advanced ovarian, fallopian tube, and primary peritoneal cancers. Pelvic radiation, frequently used in advanced cervical cancer treatments, is a known cause of radiation-related bowel toxicities.

Bevacizumab, an antiangiogenic drug that was approved in 2014 for patients with advanced cancer, has significantly improved overall survival when used in combination with other chemotherapy agents. However, it is associated with clinically significant rates of GI fistula: grade 2 and grade 3 (requiring intervention), at rates of 5% and 3%, respectively. The risk of developing fistulas is increased by additional clinical factors such as concurrent tobacco use, pre-existing hypertension, pelvic tumor (as an independent risk factor), and pelvic radiation [43]. Gastrointestinal perforation in bevacizumab is a serious but uncommon adverse effect that has been well documented in phase III clinical trials, as well as subsequent surveillance trials, with reported incidence rates of 0–11% [44].

Paclitaxel has also been associated with GI perforations, and it is believed it is caused by cellular necrosis induced

by mitotic arrest of GI epithelium. The exact incidence is unknown. However, while it is infrequent, it has a high mortality rate of 57%. Therefore quick diagnosis and a high index of suspicion in a patient presenting with abdominal pain and neutropenic fever following paclitaxel chemotherapy are warranted [45, 46, 68].

Presentation of bowel perforation and fistulas may be asymptomatic. Non-specific signs also include diffuse abdominal pain and tenderness, fever, and tachycardia.

Sepsis is a life-threatening complication of GI perforation and presents with hemodynamic instability, altered mental status, hypothermia/hyperthermia, and organ dysfunction, including acute respiratory distress syndrome, acute renal injury, and disseminated intravascular coagulopathy. Elevation of inflammatory markers (C-reactive protein, serum amylase) may be present, but is non-specific.

Patients with a suspected bowel perforation should be evaluated by abdominopelvic CT, which has higher sensitivity than plain films and can demonstrate small amounts of extraluminal gas.

Management Initial management should include an assessment of hemodynamic stability and monitoring of electrolytes. Resuscitation with intravenous fluid therapy is the next step in management for hemodynamically unstable patients.

Bowel injury in patients with advanced gynecologic malignancies tends to have a poor prognosis independent of the bowel injury.

Depending on the clinical status of the patient, appropriate conservative or definitive surgical management should be instituted. Non-invasive interventions include broad-spectrum antibiotics and, depending on the level of perforation, appropriate drainage tubes. Patients with suspected perforation whose clinical condition is unstable require immediate surgical repair or diversion. Factors that should be considered before surgical management are the patient's comorbidities, general clinical health condition, and overall prognosis. Extent/stage of the malignancy at the time of bowel perforation is the main prognostic indicator regardless of the type of management approach. Patients with advanced disease may be appropriate candidates for less invasive management [47].

Genitourinary Emergencies in Gynecologic Cancer Patients

Vaginal Cuff Dehiscence

Vaginal cuff dehiscence is a rare, but devastating, complication of hysterectomies (common procedures done in gynecologic oncology) and is associated with high morbidity requiring urgent management. A large study review of hysterectomies reported an annual cumulative incidence rate of vaginal dehiscence of ~ 0.14% of total abdominal and vaginal hysterectomies. Various studies report a similar low incidence. There is a slightly higher incidence reported in laparoscopic- and robotic-assisted total hysterectomies [48, 49].

Patients with vaginal cuff dehiscence may present with abdominal pain, serous vaginal discharge, vaginal bleeding, and vaginal bulge, as well as with more severe complications, such as peritonitis and bowel evisceration.

Vaginal cuff dehiscence is a clinical diagnosis. A comprehensive physical and vaginal examination is adequate to make a definitive diagnosis. Recommended laboratory studies include a metabolic panel and complete blood count. Leukocytosis can signify complications such as infection, peritonitis, and bowel ischemia/injury. Imaging such as abdominopelvic CT may be used to rule out complications and comorbidities such as pelvic abscess, bowel injury, and hematoma [50].

Management The clinical status of the patient is an important aspect to consider in management of vaginal cuff dehiscence.

Initial management includes resuscitation of the patient with fluids and/or blood depending on the hemodynamic status of the patient. Broad-spectrum antibiotics that adequately cover for Gram-negative and anaerobic organisms (ampicillin, gentamicin, and clindamycin) should also be administered [50].

Expectant or definitive management is dependent on the patient's clinical status, size of the defect, and presence of bowel evisceration. Peritonitis and bowel evisceration are surgical emergencies. If bowel evisceration is present, while waiting to take the patient to the operating room, insert a Foley catheter, position the patient in Trendelenburg, and cover the bowel with a warm moist towel, frequently irrigating the structures with warm normal saline. The surgical approach relies on the surgeon's experience and status of bowel viability. Intraoperatively, in the absence of infections and with signs of viable bowel, the prolapsed bowel can be gently reduced to the peritoneal cavity transvaginally. Other surgical approaches include abdominal, laparoscopy, or a combination of both. Debridement of necrosed tissue, dissection, and bowel resection are common intraoperative procedures for surgical management of vaginal cuff dehiscence [51, 52].

Urinary Tract Obstruction

Urinary tract obstruction is an important cause of renal failure in gynecologic cancer patients, especially in advanced cervical cancer. Obstruction can be caused either by extraluminal compression on ureters or direct infiltration of tumor into ureters. Benign causes for acute obstruction of urinary

tract in cancer patients can be fibrosis or pelvic inflammatory disease after surgery, catheter-induced edema, or strictures after radiation therapy [53].

Tumors causing obstruction include cervical cancer (most common), ovarian cancer, and other pelvic tumors. Large pelvic masses such as ovarian cancer can cause bilateral ureteric obstruction [54]. When bilateral obstruction develops, it leads to anuria and renal failure, with progressive rise in serum creatinine [55].

Commonly, obstruction of the urinary tract leads to hydronephrosis. Ultrasound of the abdomen, cystoscopy, retrograde ureteric investigations, and CT scan are helpful diagnostic options in assessment of the etiology and extent of the obstruction.

Management The basic principle of management is decompression of ureters because it preserves renal function [56]. This can be accomplished by percutaneous nephrostomy or cystoscopy and retrograde placement of an internal ureteric stent [56, 57, 69]. Percutaneous nephrostomy is a temporary measure used for patients with undiagnosed malignancy or in patients with cervical cancer who have available treatment modalities and a good chance of treatment response. Ureteric stent insertion is reserved for patients with advanced malignancy for palliative relief of the obstruction and associated symptoms.

Pain

Acute pain is the most common symptom in gynecologic malignancies and is the leading cause of emergency department visits [58, 59]. Several retrospective studies have shown that gynecologic cancer patients have higher rates of moderate to severe pain and higher rates of opioid use as compared to patients with other solid tumors [60].

In advanced cancers, pain can be caused by involvement of the regional nerves, pelvic muscles, and bones. Pelvic tumors can also encroach the presacral area causing visceral pain. The mechanisms of pain are not completely understood and are thought to include tissue destruction or stimulation of cytokine secretion [61].

Pain management depends on the mechanism and location of pain. The American Pain Society recommends the prompt treatment of patients with acute pain with numerous trials advocating multimodal therapy [61]. For patients with acute uncontrolled pain not responding to oral or IV analgesics, techniques such as epidural opioids and neurolysis can be used [10]. The National Comprehensive Cancer Network (NCCN) also confirms the use of opioids for severe to moderate pain and non-opioids as adjuncts. Neuropathic pain is frequently resistant to opioids and adjuncts such as tricyclic antidepressants (TCAs), selective serotonin receptor inhibitors (SSRIs), and gabapentin can be considered although there are limited clinical trials attesting to their efficacy [62].

The revised World Health Organization (WHO) analgesic ladder (Fig. 32.2) describes a simple four-step bidirectional approach for pain management, with opioids being the cornerstone of treatment for active cancer pain [63]. This approach should be used with caution due to the risk of opioid dependency and misuse. The American Society of Clinical Oncology (ASCO) policy statement on the use of opioids in the cancer population states that access to opioids must be assured, and law and regulations intended to address abuse and overdose should be crafted to avoid creating impediments to this treatment [64]. The European

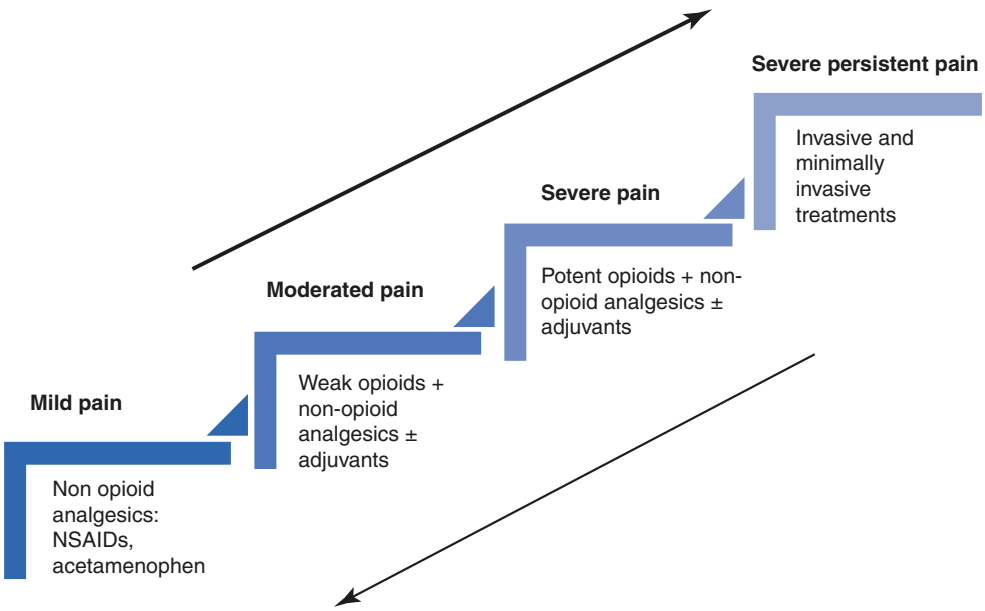

Fig. 32.2 The revised WHO analgesic ladder [63]

Association for Palliative Care advises that the skilled use of opioids is crucial to the relief of cancer pain [65].

Palliative radiation therapy is the standard for management of pain in bone metastasis. Radiation therapy (RT) has been proven to provide effective palliation of painful bone metastases with few adverse effects. The American Society for Radiation Oncology (ASTRO) has strong recommendations based on high quality evidence for the use of palliative RT for pain management. Updated reviews show equivalent pain relief for single fractions for patients with previously unirradiated bone metastases, with no increased risk for pathologic fractions, as with fractionated therapy. This is desirable and convenient for patients with advanced disease and limited life expectancy [66].

Conclusion

Emergencies in patients with a history of gynecologic malignancy can occur at any time during the course of cancer disease. Specific features of emergency presentations in these patients require knowledge of the patient's cancer history and medical knowledge of principles that should be applied in emergency situations. Therapy is individually tailored and depends on the underlying cause for the emergency, stage of the malignant disease if still present, previous cancer treatments, and immunological and general condition of the patient. Prompt therapy is crucial and diagnostic imaging should not delay initial management. Computerized tomography imaging guidelines and early gynecologic oncology consultations have significantly decreased CT utilization rates in the ED, therefore avoiding unnecessary imaging [67].

Case Study

A 57-year-old female with no known primary cancer presents to the emergency department (ED) with a 3-week history of progressive right groin pain. She denies any associated trauma. She previously ambulated independently without assistive devices, but now requires a cane. Her pain is most significant when ambulating, but she admits to pain at night and at rest. Over-the-counter pain medication has been ineffective. She denies any numbness, tingling, or weakness.

On physical exam, she has no gross neurovascular deficits, but is unable to perform straight leg raise and has marked pain with passive internal rotation of the right hip. Radiographs show a large lytic lesion in the femoral neck, which combined with her pain, results in a Mirels' score of 12 (Fig. 33.1). Laboratory workup is remarkable for an elevated TSH. CT of the chest, abdomen, and pelvis shows an enlarged thyroid, and bone scan shows no additional sites of bony disease.

The patient underwent core needle biopsy of her femoral neck lesion and was diagnosed with metastatic follicular thyroid carcinoma. She underwent total hip arthroplasty followed by postoperative radiation. She additionally underwent a complete thyroidectomy.

Introduction

Orthopedic emergencies are common in oncologic patients because of the prevalence of cancer and secondary effects of oncologic treatment. While the anatomic considerations are the same as those in the general population, the altered biology and physiology consequent to cancer can increase the complexity of treatment. Providers must consider tumor histology, natural history of underlying disease, disease stage, and overall prognosis to achieve optimal, individualized care [1]. With that said, some of the more prevalent emergencies seen in the musculoskeletal oncologic have common features, such that an organized and systematic approach will set the physician up for success.

Trauma

Although the term "trauma" is usually associated with high-impact injuries, it also includes harm that occurs with minor force, which may pertain more to oncologic patients. In general, the core principles of trauma apply to oncologic patients, but there are several important distinctions for this population.

Pathologic Fractures

Pathologic fractures comprise a large portion of orthopedic oncologic emergencies, as they occur in 9–25% of patients with bone metastases [1]. The most common site is the proximal femur. In addition to pain and tenderness, patients may present with ecchymosis, deformity, edema, and joint effusion. The occurrence of a pathologic fracture can be the result of a long, complex process. Once disease is present in bone, it manipulates local biology, induces osteoclastic bone resorption, and ultimately causes loss of structural integrity.

Recognizing fractures as pathologic may not always be straightforward. This is particularly true for patients who present to the emergency department (ED) without a cancer diagnosis. Many patients are elderly with presumed osteoporosis. X-rays may be misleading because comminution around a fracture can hide a pre-existing bone lesion (Fig. 33.2). Failure to diagnose a fracture as pathologic can lead to grave consequences, including inappropriate surgery, delays in cancer treatment, and even loss of the limb.

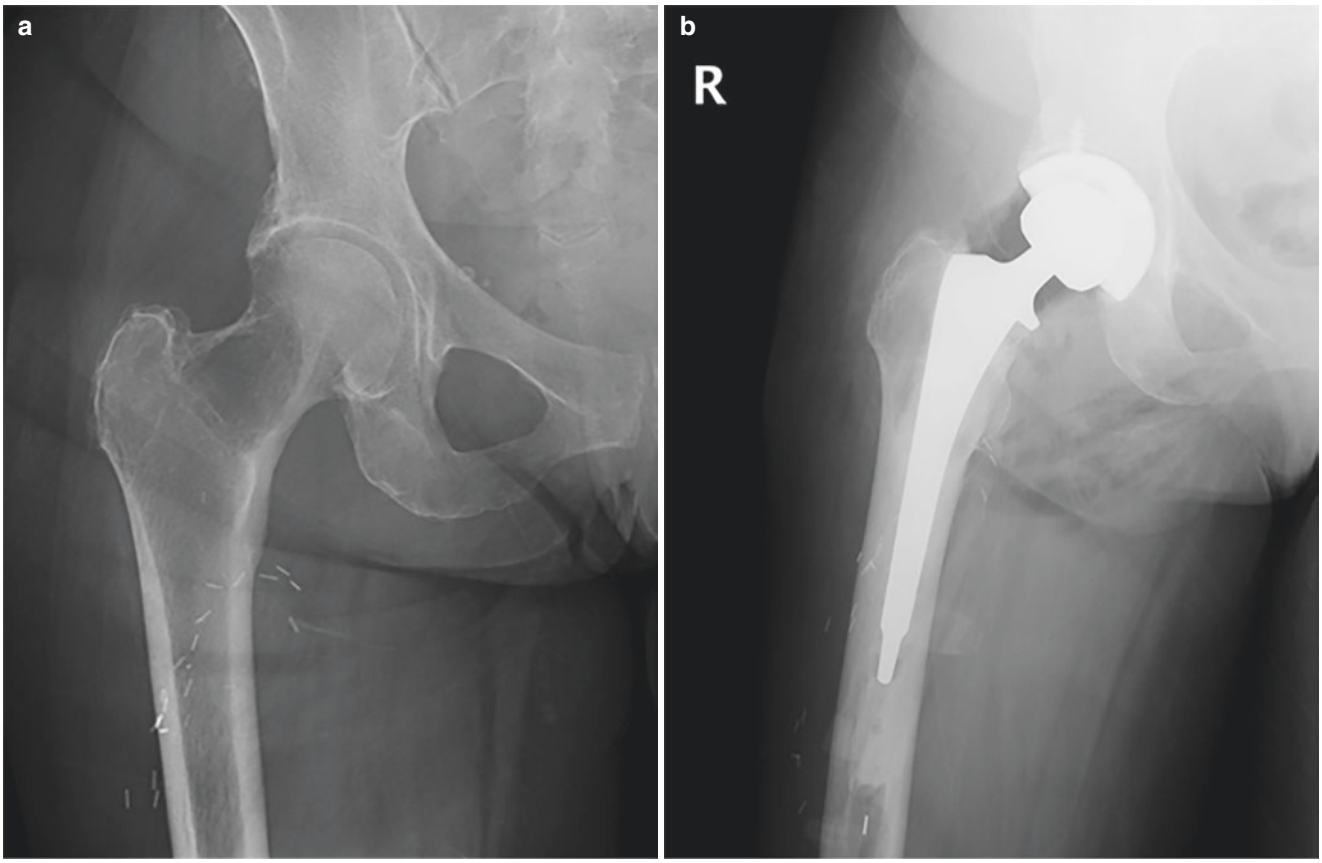

Fig. 33.1 (**a, b**) Preoperative and postoperative radiographs, respectively, of a 57-year-old female with metastatic thyroid carcinoma to the right femoral neck. Based on peritrochanteric location, lytic nature, large size, and significant pain clinically, Mirels' score of this patient is 12, and thus, prophylactic surgery was recommended

The history is critical. Certain diseases, such as breast and renal cancer, can present years after the initial diagnosis with metastatic bone disease as the first manifestation of relapse. The practitioner should inquire about pre-existing pain. A deep-seated, constant ache prior to fracture should raise suspicion of an insidious process in the bone. Systemic signs such as weight loss, night sweats, and fatigue are relevant clues. The mechanism of injury can be revealing as minimal trauma, such as rolling over in bed, can result in pathologic fractures. In general, a break that occurs with a force equivalent to (or less than) a fall from a standing height suggests a pathologic fracture.

Most pathologic fractures are best treated surgically. The pain relief from surgical stabilization is far superior to the analgesia of opioids. If a patient has extensive metastatic disease, palliative surgery is still justified if the patient is expected to live for >1 month. Not offering an orthopedic consultation simply because a patient has advanced disease can be a mistake.

On the other extreme, it is also errant to perform surgery prematurely. Because metastases are common and pathologic fractures cause severe pain, it is easy to fall into the trap of rushing to surgery. Without clear cancer staging indicating metastatic disease, it can be grossly negligent to operate on a presumption of metastasis. Primary sarcomas can also be a cause of pathologic fractures. A common mistake is nailing a lesion, which later turns out to be primary osteosarcoma. This frequently results in amputation due to marrow and soft tissue contamination.

When the etiology of a pathologic fracture is uncertain, additional preoperative workup is necessary. Imaging includes whole body bone scan, chest radiographs, and CT scan of the chest, abdomen, and pelvis [2]. Not only will this help identify other sites of disease, but it will also help identify the most accessible lesion to biopsy [1]. The most common primary carcinomas to metastasize to bone are breast, prostate, thyroid, lung, and kidney [3]. To help make a specific diagnosis, laboratory workup may include serum and urine protein electrophoresis (SPEP/UPEP) to assess for myeloma, thyroid-stimulating hormone (TSH), and prostate-specific antigen (PSA). A complete blood count (CBC) and inflammatory markers (erythrocyte sedimentation rate (ESR) and C reactive protein (CRP)) may be helpful if osteomyelitis is in the differential diagnosis.
