Stephen Irwin Goodman (1938–2020)

The Editors take this opportunity to acknowledge Stephen Irwin Goodman, MD—one of the pioneers in the field of diagnosis and treatment of inborn errors of metabolism, who passed away while this book was in press, on October 30, 2020—for his longstanding efforts and contributions to our series Physician's Guide in Inherited Metabolic Disease. A founding member of both the Society for Inherited Metabolic Disorders and the American College of Medical Genetics (and Genomics), Steve spent his entire professional career at the University of Colorado in Denver with his wife, Patricia, their daughters Michelle and Karen, and their families.

Steve is remembered for his role in establishing the diagnostic methods for organic acidemias, for writing a seminal text on use of GC-MS for analysis of organic acids (with Sanford Markey), defining and characterizing glutaric acidurias type I and II, and contributing knowledge to the diagnosis and management of many other inborn errors of metabolism.

In recognition of his constant guidance and valuable contributions (see Chap. 71), we wish to dedicate this edition of the Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases to his memory.

Foreword

A new edition for an old subject

The study of inborn errors of metabolism arguably began with Garrod's seminal 1902 paper on alkaptonuria (Garrod 1902). At the time, the diagnosis of this disorder was achieved using state-of-the-art technology: visual inspection of recently voided urine. Garrod's genius was to use this method to identify and collect a large number of individuals with this rare disorder and to recognize, with input from Bateson, that the familial clustering and distribution of affected individuals (19 affected of 48 individuals in 9 sibships) was consistent with observations made by Gregor Mendel in pea plants some 37 years earlier. An additional feature of alkaptonuria, crucial for Garrod's study, is that, at the phenotypic level, it is a relatively mild disorder with minimal, if any, effect on life span. To quote Garrod, "an alternative course of metabolism, harmless and usually congenital and lifelong." Thus, it was possible for Garrod to collect affected individuals, many of whom were adults at the time of diagnosis.

From this modest beginning, Garrod not only demonstrated that Mendelism held true in humans, but also suggested that alkaptonuria and a handful of similar disorders (cystinuria, pentosuria, and albinism) were "merely extreme examples of variations in chemical behavior which are probably everywhere present in minor degree" so that "just as no two individuals of a species are absolutely identical in bodily structure neither are their chemical processes carried out on exactly the same lines." First stated in 1902, these ideas lead to Garrod's definition in 1931 (Garrod 1931) of "chemical individuality" as genetically determined biochemical characteristics and capabilities which confer "predisposition to and immunities from the various mishaps which are spoken of as diseases." We are only now beginning to put meat on the bones of these prescient predictions.

From Garrod's time to the present, progress in identifying specific inborn errors of metabolism has been dependent on technological advances. Thus, in the early 1950s following the development of the first amino acid analyzer, a host of "new" (really "newly recognized") disorders were described on the basis of abnormal patterns of amino acids in plasma and/or urine. Similarly, the development of GC/MS technology leads to the recognition of many organic acidemias, and the development of tissue culture and somatic cell genetic techniques leads to a burst of newly recognized lysosomal storage diseases.

Currently, we are experiencing at least two technologic revolutions: genomic sequencing methods that began with the seminal 2009 paper of Ng et al. (2009) showing that the cause of rare Mendelian disorders could be identified by applying genomic methods to well-phenotyped patients and, more recently, the development of unstructured metabolomic methods that measure thousands of metabolites not previously examined by classical biochemical methods. Application of genomic methods has already had a profound effect on our identification and diagnosis of patients with inborn errors (Posey et al. 2019; Bamshad et al. 2019). Advances and widespread application of metabolomics seems likely to have a similar effect (Burrage et al. 2019; Miller et al. 2015). Moreover, the two technologies are synergistic in their power to identify newly recognized monogenic disorders and to expose their pathophysiology.

While exciting and gratifying, this rapid expansion of the number of recognizable inborn errors is a daunting challenge to the beleaguered clinicians who take care of these patients; one can never know what the next patient who comes to clinic will have: a defect in purine metabolism; a problem in lysosomal function; a peroxisome biogenesis disorder; or some tRNA charging abnormality impairing translation. The possibilities are as broad as all biology and hence justify newly revised editions of this text and associated online resources.

A salient challenge derived from the rapid expansion of our field and any such effort to describe it, is how to modernize the definition of inborn errors of metabolism, a term, after all, that has been in use since 1908 when Garrod coined it in his Croonian lectures (Garrod 1908). Recent efforts to update the definition have included inclusion of phenotypic features, diagnostic technologies, and limitations to specific biological systems (Morava et al. 2015; Ferreira et al. 2019). While useful, phenotypic features for any disorder are always variable and typically overlap with those of other disorders. Diagnostic technology changes over time and will continue to do so. A focus on biologic systems is useful for understanding pathophysiology, but the margins of any particular system often overlap with those of others and, currently, we do not have a well-defined list of all biological systems.

Based on these considerations, I argue that we consider all monogenic disorders as Garrodian inborn errors of metabolism. This gene-based definition is enriched by a foundation built on genetic principles and emphasizes the discrete monogenic cause of these disorders. It also benefits from the fact that it is easier to enumerate and designate all the genes in the genome than all the phenotypes that bring patients to our clinics. For example, at the time I write this (25 November 2020), OMIM lists 4355 genes with variants that cause monogenic disease (OMIM® n.d.). This number is increasing steadily with no asymptote in sight (Posey et al. 2019; Bamshad et al. 2019). Moreover, all monogenic disorders have an associated biochemical phenotype increasingly recognized by standard or newly developed technologies such as metabolomics or proteomics. Identification of the biochemical abnormalities associated with each monogenic disease is sometimes challenging but feasible and leads to improved understanding of the pathophysiology of each disorder, a necessary step on the path to rational development of treatment.

One possible concern of a gene-based definition of IEM is that for some genes, allelic heterogeneity produces phenotypic variation which in some instances is so extreme that we do not a priori expect variants in the same gene to underlie the apparently discrete phenotypes. For example, variants in *FBN1* can cause either Marfan syndrome (OMIM 154700) with tall stature, arachnodactyly, loose joints, ectopia lentis and aortic root aneurysms or stiff skin syndrome (OMIM 184900) with short stature, no arachnodactyly, limited range of joint mobility, and no ocular nor aortic symptoms. In fact, about a third of disease genes listed in OMIM are responsible for two or more clinically discrete phenotypes (OMIM® n.d.). A gene-based definition of IEM would, however, anticipate this biologic complexity and incorporate it so that each gene would be linked to a specific phenotype or set of phenotypes, with the benefit that we would expect these genotype–phenotype relationships as a part of disease biology and use them to inform our understanding of the disorders and the function of the protein(s) encoded by each gene.

Using this definition, the ultimate number of IEMs depends on how many genes are found to house variants of major effect, sufficient to produce a phenotype. The fact that evolution seems to care about (conserve) the vast majority of protein-coding genes in the genome suggests that certain variants in nearly all protein-coding genes will ultimately be found to be capable of producing a monogenic phenotype (and thus, by this definition, be considered an inborn error of metabolism or, perhaps better, simply an inborn error). This logic suggests that long non-coding RNA genes, which are less well conserved, may play a much smaller role in monogenic disease. How this will end up in the future is an uncertain but exciting prospect.

One thing for sure is that new resources for clinicians and investigators such as this new edition of a *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases* will be much needed and appreciated.

Preface

Our expert faculty of more than 170 recognized authorities has broadened the scope and content of this book, the fourth edition of the Physician's Guide series. We overhauled the structure of the book to accommodate 18 new chapters: 73 chapters now address almost 1200 inherited metabolic disorders. The original edition, published in 1996, focused on diagnosis only and was translated into Chinese in 2001. Today, along with a comprehensive update to this vital aspect of care, the current edition presents the state of the art on the treatment and follow-up, providing insight into the full clinical course of these rare diseases.

Based upon their experience, our expert faculty have created flowcharts and diagnostic algorithms for each disorder. Initially, recommendations on confirmatory tests and initial treatment regimens are provided for practitioners who lack extensive experience in the management of inborn errors of metabolism. The second part of each chapter describes the treatment of groups of disorders in more detail. The book presents the signs and symptoms of most of the recognized inborn errors of metabolism in relation to age, with a chronological sequence of signs and symptoms from infancy through childhood, adolescence, and adulthood. In addition, reference and pathological values are provided for each of the disorders to simplify and facilitate the interpretation of the results of laboratory tests.

The guide will also be available in an eBook format that will allow the user to locate a disorder rapidly, using standard searches with keywords. Additionally, the entire content of this edition is stored in a single database, IEMbase (http://www.iembase.org). This comprehensive online resource provides the foundation for the current and future knowledge base of inborn errors of metabolism.

While the major goals of this edition remain comparable to those of earlier editions, we, the Editors, feel that this new edition takes clinical practice in rare metabolic disorders to the next level. We hope that our readers will find this edition helpful, both now and in the future, for the treatment and care of patients with inborn errors of metabolism.

Finally, we acknowledge the former Editors, Dr. Marinus Duran and Dr. K. Michael Gibson in supporting this book project.

The original version of this book has been updated: fifth Editor Dr. Clara D. M. van Karnebeek's affiliation has been updated. A Correction to this book is available at https://doi.org/10.1007/978-3-030-67727-5_74

How to Use This Book

This book is meant to supply clinicians and clinical biochemists with data that should facilitate the diagnosis of an inherited metabolic disorder. No information about detailed laboratory methods is given; rather, the relationship between laboratory data and clinical signs and symptoms is highlighted. Furthermore the current knowledge on the immediate emergency intervention, standard treatment, and experimental options is given. Entry to the book is achieved by scanning either of the indices, i.e., the signs and symptoms index, the tests index, or the disorders index. Due to the great clinical variability of inherited metabolic diseases, one should not restrict oneself to one disorder when observing a given symptom or sign. Most chapters have a uniform layout as given below. In a few chapters, however, this was not possible, and information is given for the entire related group of disorders in the chapter.

Introduction

The introduction gives a brief overview of the clinical conditions described in the chapter and relates them to the biochemical abnormalities. Key references for further reading are provided.

Nomenclature

Disorders in each chapter are numbered in accordance with the corresponding OMIM number, gene symbols and gene products, and chromosomal localization if known.

Metabolic Pathway

Disorders are identified by corresponding reference numbers at the step where the defect is localized. Pathological metabolites ("markers") are given in most chapters.

Signs and Symptoms

The tables describe most, if not all, of the signs and symptoms for each disorder, including its reference number, and the most important laboratory tests, in relation to age. In all instances, the signs and symptoms are found in the untreated patients. The signs written in **bold** represent characteristic features of the particular disease.

± indicates that a sign or symptom *may* occur but is not inevitably present.

+ indicates that a sign or symptom is always or nearly always present. If there are significant clinical signs and symptoms which exceed the usual, or if changes occur, this is indicated with + to + + +, etc.

n (normal) is used only when it is significant and may be useful in distinguishing one condition from another.

Relative increases or decreases of substances, compounds, metabolites, etc., are indicated with the use of arrows; for example, metabolite X ↑ to ↓↓↓. Where metabolite X *may* change, it would be indicated by n-↑ for a possible increase or ↓-n for a possible decrease, whichever the case.

In all tables, the test substance, material, compound, metabolite, etc., are listed and the source—(U), (B), (CSF), (P), (RBC), etc.—is given in parentheses, with an arrow or arrows indicating increase/decrease or relative increase/decrease.

Body fluids, cells, tissues, etc., are defined as:

P	Plasma	CV	Chorionic villi
S	Serum	AF	Amniotic fluid
B	Blood	AFC	Amniocytes
U	Urine	CCV	Cultured chorionic villi
CSF	Cerebrospinal fluid	PLT	Platelets
RBC	Red blood cells	WBC	White blood cells
LYM	Lymphocytes	Hb	Hemoglobin
FB	Fibroblasts	creat	Creatinine
BM	Bone marrow		

Age groups are defined as:

Neonatal	Birth to 1 month
Infancy	1–18 months
Childhood	1.5–11 years
Adolescence	11–16 years
Adulthood	>16 years

Reference Values/Pathological Values/Differential Diagnosis

Reference and pathological values are listed for all parameters relevant to the diagnosis according to the specimen (e.g., P, U, CSF) and age. For some parameters, reference values depend on methodology and may differ from chapter to chapter. Methods are specified where necessary.

Pathological values are listed either as absolute values or with symbols (e.g., ↑, ↓) according to the disorder. Values are limited to the analyses which can be performed in a laboratory experienced in selective screening. Data on enzyme studies are not given in most cases, but can be found in the pertinent literature.

Loading Tests

There is a brief description of the tests, with a table or figure to illustrate the interpretation.

Diagnostic Flow Chart

The flow charts use simple yes/no algorithms to demonstrate the sequence for differential diagnosis, starting with clinical symptoms or general tests and proceeding to specific tests and a final diagnosis.

Specimen Collection

This table lists preconditions, material, handling, and pitfalls for each parameter used in the diagnosis.

Prenatal Diagnosis

This table lists the tissue or specimen, timing, and pitfalls for each disorder.

DNA Analysis

This table lists the tissue or specimen and methodology for each disorder.

Treatment and Follow-Up

This section outlines urgent treatment to consider before a definitive diagnosis is established for each (or each group of) disorder(s). Long-term treatment and alternative therapeutic options are highlighted in this book.

Indices

Three indices are included: (1) disorders, (2) signs and symptoms, and (3) tests and medications. Each entry is linked to the corresponding disorder or page.

General Subjects and Profiles

Newborn Screening for Inborn Errors of Metabolism

1

Ralph Fingerhut, Janice Fletcher, and Enzo Ranieri

Contents

Abstract

Newborn screening (NBS) is a public health measure for the early detection of inborn errors of metabolism (IEM), endocrinopathies, and a variety of other disorders, where early presymptomatic detection and treatment can prevent mental retardation, disabilities, or death, or at least can improve the quality of life and extend the life span of affected patients. Newborn screening started in the early 1960s, however there are still countries around the world, that do not have a newborn screening program. Newborn screening has evolved over the years and has become a program, that goes far beyond the laboratory test alone. However, long-term follow-up is still very often neglected by stakeholders, health insurance companies, and governmental authorities. Although this chapter focuses on the laboratory tests, which use whole blood, taken by heel prick, dried on special blood collection devices, the so-called dried blood samples (DBS), it also touches additional topics.

Introduction

Newborn screening (NBS) is a public health measure for the early detection inborn errors of metabolism (IEM), endocrinopathies, and a variety of other disorders, where early presymptomtic detection and treatment can prevent mental retardation, disabilities, or death, or at least can improve the quality of life and extend the life span of affected patients. This chapter focuses on the laboratory tests, which use whole blood, taken by heel prick, dried on a special blood collection device, the so-called dried blood samples (DBS). During the last 20 years, other genetic conditions, like hemoglobinopathies, cystic fibrosis, infectious disease like HIV and CMV, immunodeficiencies like SCID, or muscular dystrophies like Duchenne muscular dystrophy (DMD), or spinal muscular atrophy (SMA), were added to the NBS panel. In

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_1

addition, there are also conditions that use point-of-care testing, which are not lab-based tests, like newborn hearing screening, using otoacoustic testing, or screening for critical congenital heart defects (CCHD) using pulse oximetry. This chapter also provides an overview of the history of NBS, principles, goals, and some pitfalls.

History of Newborn Screening

Newborn screening as a laboratory test started with the invention of the bacterial inhibition assay for the detection of phenylketonuria (PKU) in 1963 by Robert Guthrie (Guthrie and Susi 1963; Guthrie 1996). However, sometimes forgotten, at least three mothers of mentally retarded children should be mentioned, who pushed scientists on, because they would not just accept the disability of their children as fate, but wanted a diagnosis or treatment. The first is Pearl S. Buck. Although she was not successful, she wrote down the story of her child in a touching book: *The Child Who Never Grew*. The second are Harry and Borgny Egeland from Oslo who got in touch with Dr. Ivar Asbjørn Følling, who finally could isolate phenylpyruvic acid from the urine of their two disabled children, which also gave the name, phenylketonuria, to the disorder (Fölling 1934). Then in 1951 again there was a mother, Mrs. Jones, who had a diagnosis for her daughter Sheila (PKU), who now insisted that the pediatrician, Dr. Horst Bickel, should look for a possible treatment. Maybe the persistency of Mrs. Jones, lead Horst Bickel to introduce a phenylalanine-free diet (Bickel et al. 1953), which has been proposed a few years before by Woolf et al. (Woolf and Vulliamy 1951; Woolf et al. 1955). The initiation of treatment and the proof of effectiveness have been very well documented also on Super 8 films and can be found at https://www.youtube.com/watch?v=OqZ7QHO5_hs. Sheila Jones' diagnosis was made at the age 2 years with the ferric chloride test, or the Følling-Test as it is called in some countries. But although the treatment with the phenylalanine-free diet could improve the clinical situation of the patient, it could not reverse mental retardation. However, with the introduction of a treatment option for PKU and a simple urine test, all newborn siblings of PKU patients could be tested and treated early, from birth on. The next step was the introduction of the so-called diaper test by Dr. Centerwall et al. (1960). They adopted the ferric chloride test for newborns by just pouring ferric chloride solution onto the wet diapers of newborns to detect excreted phenylpyruvic acid. The test worked in principle, only the sensitivity was poor. With the diaper test only the very severe cases of PKU could be detected, who already had a very high concentration of phenylpyruvate in urine. And again, it was a father of a child with PKU who approached Robert Guthrie at a meeting of families with disabled children, whether he could not try to develop a more sensitive test, so that all children with PKU could be treated early enough to prevent mental retardation. This was the start of NBS for PKU in the USA in 1963, and many countries followed in the following years. And still today, the NBS test, using whole blood taken by heel prick and dried on a special blood collection device, is often called the "Guthrie Test."

Table 1.1 Wilson and Jungner classic screening criteria

1.	The condition sought should be an important health problem
2.	There should be an accepted treatment for patients with recognized disease
3.	Facilities for diagnosis and treatment should be available
4.	There should be a recognizable latent or early symptomatic stage
5.	There should be a suitable test or examination
6.	The test should be acceptable to the population
7.	The natural history of the condition, including development from latent to declared disease, should be adequately understood
8.	There should be an agreed policy on whom to treat as patients
9.	The cost of case finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole
10.	Case finding should be a continuing process and not a "once and for all" project

Then step by step new tests for other disorders were developed and included into NBS in several countries, like galactosemia (Paigen et al. 1982), biotinidase deficiency (Heard et al. 1984), maple syrup urine disease, MSUD (Naylor and Guthrie 1978), homocystinuria (Whiteman et al. 1979), congenital hypothyroidism (Larsen and Broskin 1975; Dussault et al. 1976), and congenital adrenal hyperplasia (Cacciari et al. 1982).

In 1968, the World Health Organization (WHO) had initiated a study to define criteria for the introduction of population screening, which had been accomplished by Wilson and Jungner (Wilson and Jungner 1968; Jungner et al. 2017).

The introduction of tandem mass spectrometry (TMS) has somehow revolutionized NBS. It changed the paradigm from one disorder—one test, to one technology—multiple disorders. This changed the interpretation of criteria no. 9 from the Wilson and Jungner criteria totally. Once TMS was introduced, the cost of adding another disorder, which could be detected in the profile of amino acids or acylcarnitines was more or less zero. Therefore, it was necessary to revise the Wilson and Jungner criteria the new situation (Andermann et al. 2008) (Table 1.1).

Three points of these criteria should be especially discussed. First, criteria no. 7, "The natural history of the condition, including development from latent to declared disease, should be adequately understood." This works easily, while screening an adult population for a certain disease. Medical history of the patients (or probands) are normally available, repeat testing can be easily done, and normally there are well-defined criteria, who should be declared as a patient (criteria no. 8). For conditions that are included in NBS, the knowledge of the natural history is not always well understood, due to several reasons. First of all, it has to be beared in mind that scientific and medical knowledge expands over time. For example, before NBS for PKU was started, variant hyperphenylalaninemias were more or less unknown, and also disorders of the cofactor metabolism of the phenylala-

nine hydroxylase, tetrahydrobiopterine, were unknown or not well understood (see Chap. xx). The introduction of NBS for PKU also developed a new "condition": Maternal PKU, which could not be anticipated beforehand. Another example is NBS for galactosemia. It started with the measurement of total galactose in DBS (Paigen et al. 1982), which was accomplished by the so-called Beutler test (Beutler et al. 1964), which was a qualitative or semiquantitative test to measure the activity of the galactose-1-phosphate uridyltransferase, the enzyme deficient in classical galactosemia. The introduction of the Beutler test led to the detection of a variant form of galactosemia, the so-called Duarte-2 galactosemia. At the beginning, the patients with the Duarte-2 variant were treated the same way as patients with classical galactosemia, and it was only in the 1990s, when increasing knowledge about the natural history of galactosemia showed that these Duarte-2 variant patients normally do not need any treatment at all. And just recently, a fourth disorder in the galactose metabolism has been described, galactose mutarotase (GALM) deficiency (Iwasawa et al. 2019). Other examples are histidinemia, which was introduced in several countries, probably after a single case report (Garvey and Gordon 1969) and a method paper, which afterwards proved that elevated histidine in blood is a condition without clinical significance (Brosco et al. 2010). There are also other conditions, where the clinical relevance or the clinical penetrance of the disorder is unclear or very low, like SCADD, and 3-MCC deficiency. A last example are pilot urine newborn screening programs for neuroblastoma in Quebec, Austria, Germany, the UK, and Japan. But, although early treatment with a combination of surgery and chemotherapy seemed to work well, the death rate from neuroblastoma tumors did not change. Therefore, it was suspected that NBS for neuroblastoma had detected previously unrecognized mild tumors that would have spontaneously regressed, also without any therapy (Riley et al. 2003; Maris and Woods 2008). Secondly, criteria no. 3, "Facilities for diagnosis and treatment should be available" in connection with criteria no. 8 again. A "facility for the diagnosis," together with an "agreed policy on whom to treat," should be interpreted as: ***After a positive NBS test, there should be a definite diagnostic test available to decide directly after the diagnostic test, whether a child has a condition, and needs immediate treatment, or whether the child is not affected, and can be released as healthy.*** There are some disorders that do not fulfill this criteria, for example, VLCADD, where acylcarnitine profiles can be totally normal when the patients are in an anabolic status (Spiekerkoetter et al. 2010), or several of the lysosomal storage disorders, where the residual enzyme activity alone, cannot predict 100% whether the disease will progress, and also genetic analysis is not 100% helpful, and often there is no other metabolic marker available to determine the progression, or normalization. And the third point directly emerges from this problem, it is criteria no. 6, "The test should be acceptable to the population." Different stakeholders of NBS programs can have totally different opinions about it. Pediatricians and patient organizations for a certain disorder can be extremely in favor for NBS, even if there is a long time of uncertainty, whether treatment is necessary or not. At the other end, there may be a big number of parents who rather not want to have this particular disorder included because of this uncertainty. However, informed consent, although it is nowadays included in most countries is not an easy task, and the burden of false-positive NBS results have been described by several groups (Morrison and Clayton 2011; Schmidt et al. 2012; Johnson et al. 2019).

Decision-making for NBS programs is not an easy task. In many countries, it is formalized like in the USA (DHHS 2013), Germany, Switzerland, the UK, for example, but although many countries have celebrated their 50th anniversary of NBS during the last years, there are still a lot of countries around the world that have not started any newborn screening, or just had some pilot programs (Pandey et al. 2019), and sometimes NBS is only available for a small part of the population, who can afford to pay for NBS by themselves.

Newborn Screening: A Public Health Program

Newborn screening is not just a laboratory test; it should be recognized as a whole program. It includes midwives, nurses, gynecologists, neonatologists, the laboratory, special diagnostic centers, and specialized treatment centers. NBS programs should include information material about the extent of the program for parents and midwives, nurses, gynecologists, and neonatologists, for the latter especially also information how a positive NBS result will be communicated. Ideally, there should also be designated specialized centers for the final diagnostic test, and specialized centers for the treatment. And there must be a feedback about the outcome of the diagnostic test, back to the newborn screening laboratory, in order to generate reliable statistical data: Number of newborns screened, and for each disorder, recall rate, positive predictive value (ppv), negative predictive value (npv), and incidence.

The structure of NBS programs is quite diverse worldwide and also the way how new disorders are integrated into existing NBS programs is diverse. A helpful guideline for countries that have no legitimate guideline, the Recommended Uniform Screening Panel (RUSP) of the US Advisory Committee on Heritable Disorders in Newborns and Children could be a helpful guide for decision-making. The latest update can always be found at https://www.hrsa.gov/advisory-committees/heritable-disorders/rusp/index.html.

In addition, the Clinical and Laboratory Standards Institute (CLSI) has published several guidelines (https://clsi.org/standards/products/newborn-screening/) for the implementation of NBS.

One problem that NBS programs are faced with is often the lack of financial support for those parts of the NBS pro-

gram that are not directly related to the laboratory test, and often there is no connection between the DBS-NBS, and newborn hearing screening, and screening for CCHD. One example is the state of Bavaria in Germany, where a public health screening center coordinates tracking of all NBS tests statewide. This includes checking of completeness, follow-up of positive NBS results, and diagnostic tests, and also whether the patients with a definite diagnosis have been admitted to a specialized center (https://www.lgl.bayern.de/gesundheit/praevention/kindergesundheit/neugeborenenscreening/index.htm). Another issue is often the enormous costs of new therapies, for so far untreatable disorders, like enzyme replacement therapy for LSDs, or the treament for SMA.

Principles and Practice in the NBS Laboratory

It should be kept in mind that every NBS test, whether immunoassay, enzymatic assay, metabolite determination by tandem mass spectrometry, determination of profiles by HPLC, IEF, or determination of copy numbers by rtPCR, is ONLY a SCREENING TEST, and not a diagnostic test. A definition of screening (not only NBS) has been published by Wald (1994): "Screening is the systematic application of a test or enquiry **to identify individuals at sufficient risk** of a specific disorder to benefit from further investigations or treatment, among persons who have not sought medical attention on account of symptoms of that disorder." This definition implements three things: (a) Newborn screening is not a diagnostic test, (b) it needs further investigations to confirm a positive screening test, (c) among the screened population there can be individuals that have a low risk of having a certain condition, according to the screening result, but still can have or develop the disease.

Improvements in instrumentation and methodology have continuously improved the detection limits of analytes, and the sensitivity and specificity of laboratory tests. Still every newborn screening laboratory has to define cut-offs for their primary screening test, which will effect sensitivity, specificity, ppv, and npv.

Sensitivity and Specificity

Ideally, the distribution of metabolite concentrations or enzyme activities shows a normal distribution. Ideally, the affected and unaffected individuals are completely seperated from each other (Fig. 1.1a). However, normally there is always on overlap between these two groups (Fig. 1.1b). The cut-off is normally choosen in a way that there are no fn results.

However, this would for some disorders (like CF) result in an enormous number of fp results. In these cases, a second-tier test can improve the situation (Fig. 1.2). But sometimes it has to be accepted that a screening test is not able to pick up all cases. However, sometimes the combination of marker metabolites can result in 100% sensitivity and 100% specificity, like in CPT-I deficiency (Fingerhut et al. 2001) (Fig. 1.3).

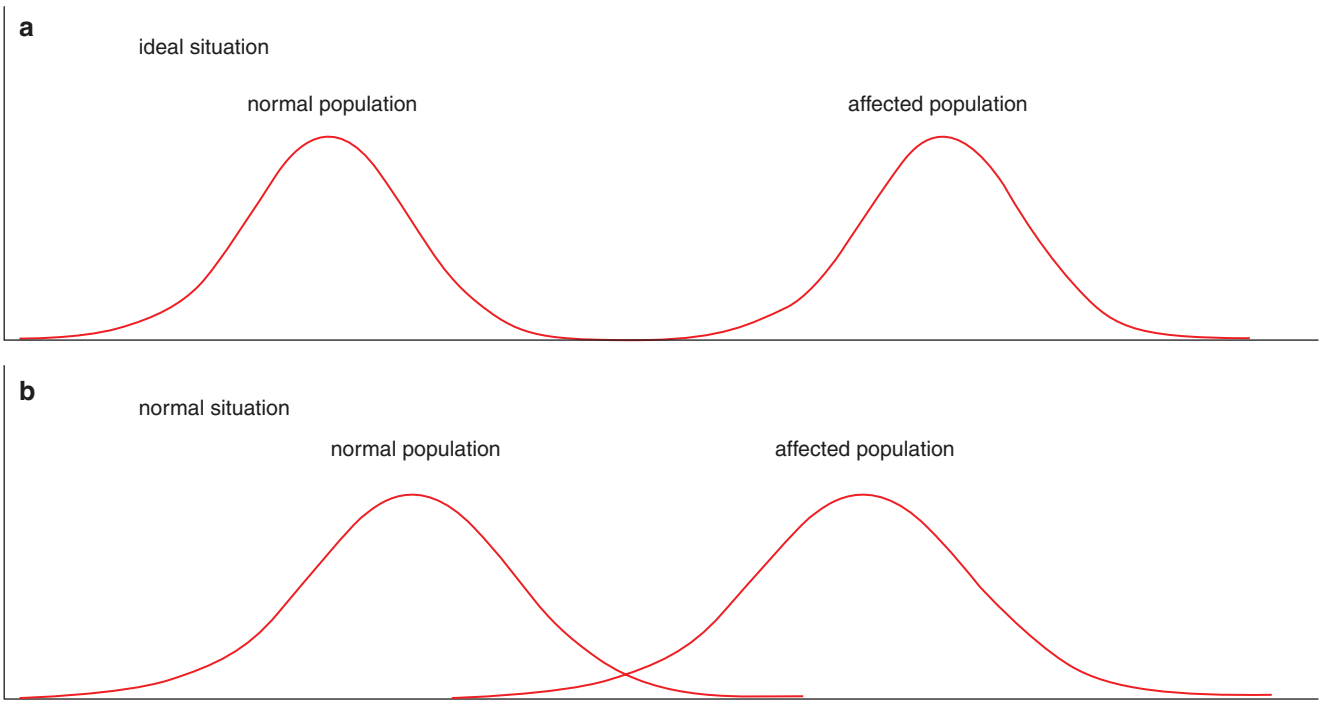

Fig. 1.1 Frequency distributions between normal and affected population

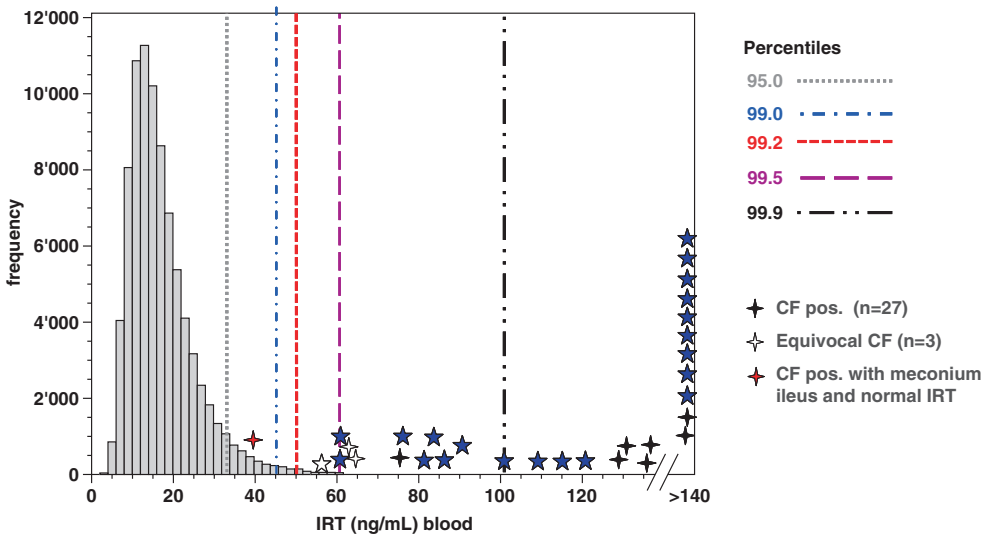

Fig. 1.2 Distribution of IRT values from normal newborns and newborns with CF

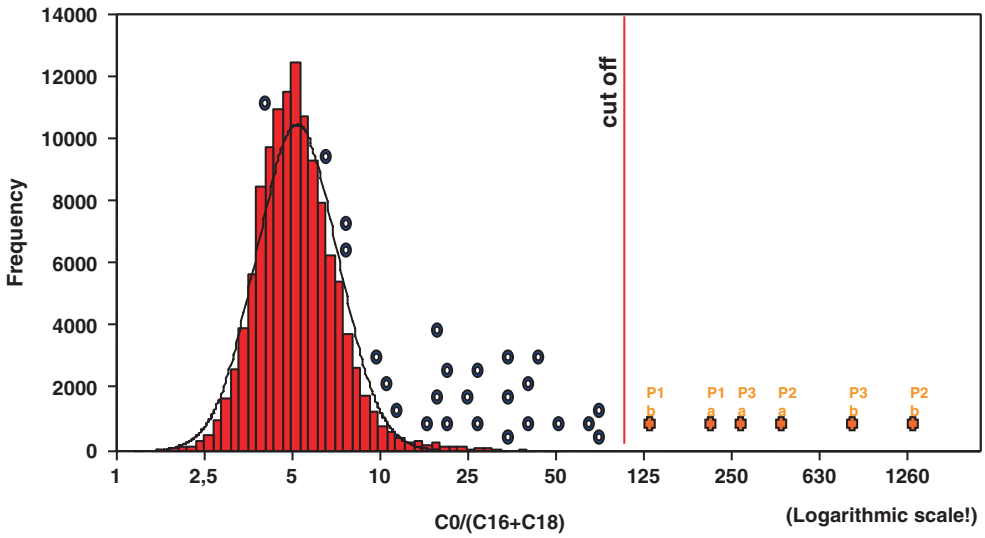

Fig. 1.3 Distribution of the ratio of C0/(C16 + C18) from normal newborns (red bars), newborns on carnitine supplementation (blue circle) and newborns with CPT-I deficiency (orange crosses)

Sensitivity is the percentage of affected individuals that are detected with the respective test.

Specificity is the percentage of unaffected individuals that are correctly detected as unaffected.

$$\text{Sensitivity} = rp / rp + fn, \text{Specificity} = rn / fp + rn$$

(rp = right positive; rn = right negative; fp = false positive; fn = false negative)

What Is a "False-Positive" Result?

Different NBS programs often use different terminology. In this chapter, we will use "abnormal" result and "normal" result, which are ultimately defined by the choosen cut-off for each laboratory test. If the first measurement from a specific NBS card is "abnormal," the test should always be repeated from the same NBS card in duplicate. This will eliminate a laboratory error. If two results are not plausible, the laboratory should search for an explanation. Since every test has also a certain uncertainty of measurement, this needs to be included into the cut-off consideration. If the repeat testing is again "abnormal," this will result in a "Positive Screening Result" for a specific disorder. If then, either a second DBS is taken, or a specific diagnostic test is made, and this second test results in a "normal" test result, or the diagnostic test excludes the condition, for which the initial screening test was "positive," then the initial screening will be called a "False-Positive" result.

False-positive results (fp) are expected in NBS because the major goal is not to miss a patient that has the respective condition. There are several reasons for a false-positive screening result. (a) Screening tests with a high uncertainty of measurement also tend to have a higher fp rate. (b) Higher biological variation of the disease marker will also lead to a higher fp rate. (c) If the marker metabolite is not specific for

a certain disorder. (d) The metabolite level is influenced by nutrition and diet. (e) The metabolite levels are influence by the mother, for example, free carnitine levels in CUD, or Vitamin B12 levels in disorders of cobalamin metabolism.

Fp result can be effectively reduced, when it is possible to use not only one primary disease markers, but several markers or additional ratios. Even more effective are second-tier tests which are more specific than the primary test, but too expensive or labor intensive to apply them directly to all DBS. For example, second-tier genetic testing in CF screening, or the determination of allo-isoleucine by HPLC or UPLC in MSUD screening (Fig. 1.4). Major causes of fp results are summarized in Table 1.2 (Table 46.2 from the previous edition of this book).

When comparing fp rates between different NBS programs and published data, it is important that a clear definition has been given for fp results. For example, a DBS of a newborn with a complete glucose-6-phosphate dehydrogenase deficiency will give an abnormal screening result for classical galactosemia, if only the Beutler test is used. This could be counted as a fp result for galactosemia screening, however from the design of the Beutler test, which uses four different enzymes that are present in the DBS, galactose-1-phosphate uridyltransferase (GALT), phosphoglucomutase (PGM), glucose-6-phosphate dehydrogenase (G6PD), and 6-phosphogluconate dehydrogenase, it is an expected finding, and therefore it could be as well defined as a true positive result.

What Is a "False-Negative" Result?

False-negative results (fn) in screening are unwanted, but it is important to keep in mind that a screening test can never be 100% sensitive. There are several examples, where biological variability will result in fn results. One example is homocystinuria. The primary marker is methionine because the determination of total homocysteine is not feasible as a primary test. However, with methionine as a marker only patients with classical homocystinuria (cystathionine synthase deficiency) can be detected. In addition, earlier sampling due to improved sensitivity, earlier discharge from

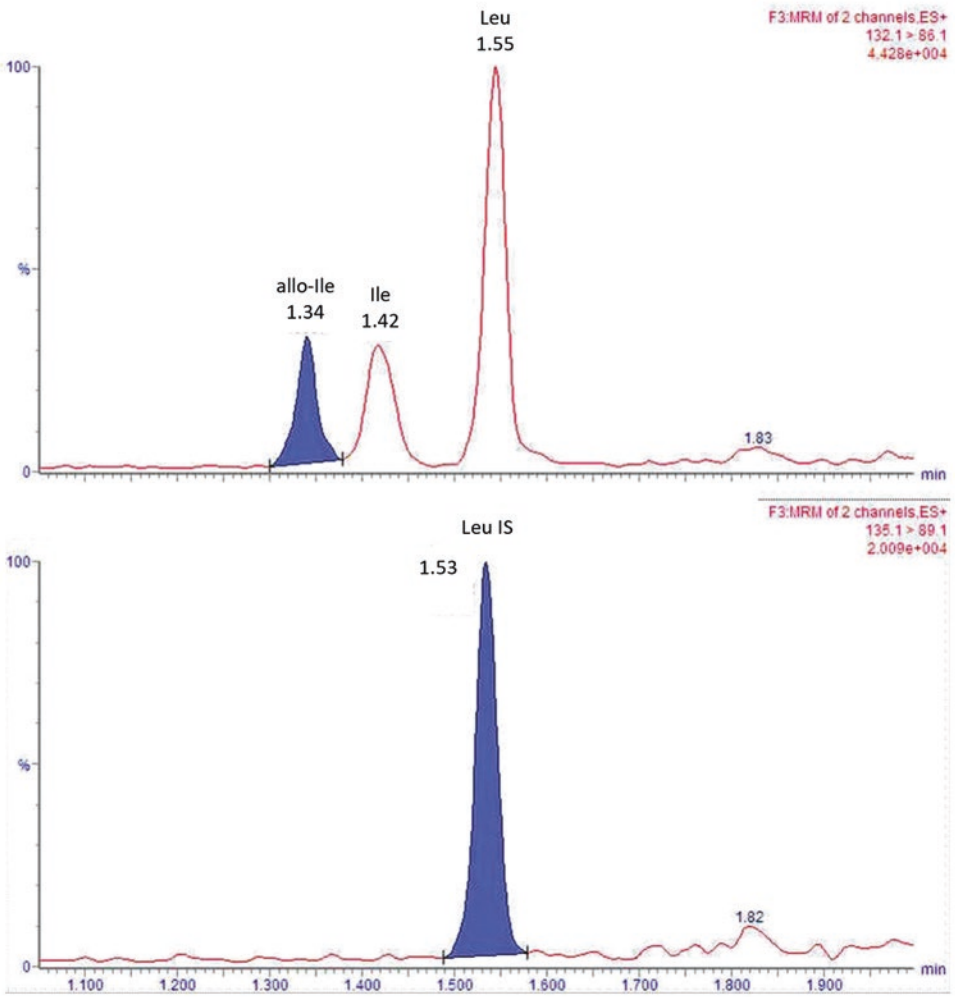

Fig. 1.4 Separation of leucine, isoleucine, and allo-isoleucine by UPLC-MS/MS

Table 1.2 Commonly[a] used methods in bloodspot NBS (historic or currently used)

	Principle	False positives	False negative	Uses and comments
Bacterial inhibition assay	Measures analyte by effect of analyte level on growth of bacteria selected for dependence on analyte	Physiologic variations of analyte levels, effect of other medical conditions, effect of intake (feeding, hyperalimentation)	Physiologic variations of analyte levels, effects of antibiotics	The original method of screening for PKU and other IEM as designed by R. Guthrie and used until replaced by fluorescence and/or MS/MS
Fluorescent or other colorimetric	Measures analyte by the amount of fluorescence or color compared with standard	Physiologic variations and effect of other medical conditions, effect of intake (feeding, hyperalimentation)	Physiologic variations of analyte levels, effects of dietary intake of analytes	PKU, maple syrup urine disease, homocystinuria, galactosemia
Immune assay	Measures the presence of protein based on interaction with an antibody against the protein; various markers for levels, e.g., radioactivity for radioimmunoassay (RIA)	Physiologic variation	Physiologic variation; for CF it is notable that immunoreactive trypsinogen (IRT), the marker for CF, is not elevated in babies with meconium ileus	Thyroid and thyroid-stimulating hormone (for hypothyroidism); immunoreactive trypsinogen (IRT) for cystic fibrosis; steroid hormone analytes for congenital adrenal hyperplasia
Electrophoresis	Measures the presence or absence of protein with specific mass and charge	Transfusion	Transfusion	Hemoglobinopathies; method in use for decades also identifies carrier status
Enzyme assay	Measures the ability of enzyme in sample to transform substrate to product; semiquantitative or quantitative determination	Heat inactivation of enzyme in transport; deficiency of other pathway required for generation of marker for product (Beutler assay for galactosemia depends on integrity of the enzyme G6PD); pseudodeficiency	Transfusion	Galactosemia (by assay called "Beutler"), biotinidase deficiency, some lysosomal enzymes. Can identify carriers, identifies healthy individuals with pseudodeficient states, and (especially for lysosomal disorders) identifies affected individuals who may have adult-onset phenotype
MS/MS	Tandem mass spectrometry, inferring levels of metabolites based on amounts of (and ratios of) molecular fragments compared against isotopically labeled standards	Physiologic variations and effect of other medical conditions, effect of intake (feeding, hyperalimentation), effect of some medications	Physiologic variations of analyte levels, effects of dietary intake of analytes	PKU and other amino acidopathies, methylmalonic acidemia, and other organic acidemias, MCADD, and other disorders of fatty acid oxidation and carnitine metabolism, some urea cycle disorders. The accuracy of levels and the ability to examine ratios dramatically improve sensitivity and specificity compared with bacterial inhibition and fluorescence
DNA mutation analyses	Analyzes the presence or absence of specific sequence changes or specific known deletions or duplications	Unless method identifies all mutations (see false-negative column), it may be necessary to perform diagnostic testing on those identified by screening as having one mutation Two mutations may be present in cis in an individual who is carrier but not affected	For virtually all conditions, there will be false negatives if DNA is the primary screen or required to be positive as a second-tier test in screening. The number of cases missed depends on the number of mutations for which the sample is screened and the frequency with which individuals in the screened population have disease caused by mutation(s) not on the panel	Occasionally used as primary screen but more often used as second-tier test for cystic fibrosis, medium-chain acyl-CoA dehydrogenase deficiency and galactosemia Will identify carriers To screen for spinal muscular atrophy, DNA testing must be used as primary method
DNA repeat size	Analyzes the length of triplet repeat segments	Hypothetically none	Mosaicism for repeat size	Fragile X; should also identify carriers
DNA—TREC	Quantifies fragments of DNA (cell receptor excision circles) generated in T-cell function maturation	Physiologic	Some cases of adenosine deaminase (ADA) deficiency	Severe combined immune deficiency, including several conditions which can present with immune deficiency, such as T-cell deficiency due to deletion of 22q

[a]Includes methods used for IEM and for other (including nongenetic as well as non-metabolic) conditions. Less commonly used methodologies, e.g., HPLC, are not included here

hospital, and inclusion of more severe disorders with earlier onset, like MSUD, will lead to more fn results because methionine rises rather slowly, even in classical homocystinuria. A second example is tyrosinemia type I. Again using tyrosine as the primary marker will lead to fn results because in case of tyrosinemia type I it is not the enzyme block that will lead to the elevation of tyrosine, it is the liver damage that produces the elevation of tyrosine, together with elevated phenylalanine, methionine, and the branched chain amino acids. The third example is glutaric aciduria type I (GA-I). In GA-I, it is well known that the so-called non-excretors, patients with clinically and genetically proven GA-I that do not excrete 3-hydroxyglutaric or glutaric acid in the urine, are missed by NBS (Gallagher et al. 2005). Also for CF it is well known that the sensitivity is only around 95–96%, meaning that 4–5% of cases are missed by NBS (Heidendael et al. 2014).

Positive and Negative Predictive Values

The positive predictive value (ppv) and the negative predictive value (npv) are necessary measures, when communicating a NBS result.

$$npv = rn / rn + fn, ppv = rp / rp + fp$$

The npv and ppv describe, how reliable a test result is, related to the disease state of the respective newborn. If the npv is 100%, it means the risk for a newborn with a normal test result to have this respective disorder is zero. On the other hand, a ppv of 100% means that the chance for newborn with a positive test result, not to have the respective disorder is also zero. In reality, neither npv nor ppv reach 100%. However, the npv is normally >99.9%, but it still means that there is still a chance that a newborn with a normal test result can have the respective disease. The ppv is quite variable, and as already discussed above, dependent on the choosen cut-off. However, very often the ppv can also be dependent on the test value. For example, a TSH value of >100 mU/L has probably a ppv of 100%, while a TSH value of 21 mU/L has probably a ppv of only 1–5%. Or when we look at CF screening with second-tier genetic testing: if second-tier testing finds two disease causing mutations, the ppv is 100%, irrespective of the initial IRT value. However, if no mutation is found, then the ppv is most likely again dependent on the IRT level.

Methodology

Since this book deals with inborn errors of metabolism, the description of methodology focuses on detection of amino acids and acylcarnitines by flow injection tandem mass spectrometry (FI-MS/MS). For the determination of amino acids and acylcarnitines by FI-MS/MS, there are two different methods in use. Extraction into an organic phase either (a) after derivatization to the respective butyl esters, or (b) without derivatization. The method with butylation results in higher signal intensities than the method without derivatization; however, the modern tandem MS instruments tend to be so sensitive that this has no effect on the sensitivity of the test results. It only has to be kept in mind that same isobaric compounds are not isobaric anymore after butylation, e.g., C4DC and C5OH. Dicarboxylic acid will add two butyl ester groups, while the hydroxyacids will only have one butyl group.

Table 1.3 provides an update from Fingerhut (2009) of target diseases for NBS, which can be compared with the RUSP.

Table 1.4 provides a list of the primary marker metabolites that can be detected by FI-MS/MS, and possible secondary markers.

The Newborn Screening Process

The primary responsibility for the whole NBS process is very often in the hands of the newborn screening laboratory, unless it is embedded in a clearly defined NBS program. The integration of non-laboratory screenings, like newborn hearing screening and screening for CCHD, is even more complex and will not be discussed in detail here.

Blood Sampling

The standard specimen for NBS is capillary whole blood dried on a special blood collection device, the so-called dried blood spots (DBS). The test cards should be distributed by the screening laboratory to their customers, midwives, hospitals, pediatricians, and general physicians, and they should include all necessary information that are needed for the correct interpretation of test results. The blood collection device must have a special quality and should (ideally) by approved by FDA, or a comparable national institution (Hall 2017).

Since the number of people involved in blood sampling is normally quite high, it is necessary to provide regular information and education to the customers (Evans et al. 2019).

Laboratory Test

The number of tests, and the methodology used for NBS varies between different countries (Loeber et al. 2021). A summary is given in Table 1.3.

Confirmatory Testing

Confirmatory testing is often not performed in the screening laboratory, but it is a crucial part of the NBS program. It is already mentioned by Wilson and Jungner (criteria no. 8):

Table 1.3 Target diseases for newborn screening

Disease	Methods	Relevance ranking	Screening programs	Test[a] available	Therapy available	Benefit from early detection	Remarks
Aminoacidopathies							
Phenylketonuria	TMS	+ +	a	y	y	y	Alternative therapies for mild phenylketonuria have been introduced, and further new therapies are under investigation
Maple syrup urine disease	TMS	+ +	m	y	y	y	Early blood collection is necessary
Homocystinuria	TMS	+	m	n	y	y	Sensitivity and specificity low with methionine as primary marker; determination of homocysteine would improve NBS
Tyrosinemia type I	TMS	+ +	m	y	y	y	
Citrullinemia	TMS	+	m	y			Positive effect on outcome is not yet certain; patients with a mild biochemical phenotype might never develop symptoms
Argininosuccinic acidemia	TMS	+	m	y			Positive effect on outcome is not yet certain
Arginase deficiency	TMS	+	m	y			Very rare; first results of NBS and early treatment seem promising
Hyperornithinemia (OAT deficiency and HHH syndrome)	TMS		m	n			Normal ornithine levels during the first weeks of life
Nonketotic hyperglycinemia	TMS	- -	m	n	n	n	No therapy available
Histidinemia	TLC	- -	d	- -	- -	n	Benign, does not require treatment
Hydroxyprolinemia	TLC	- -	d	- -	- -	n	Benign, does not require treatment
Serin	TMS				y		No prospective data available
Organic acidemias							
Glutaric aciduria type I	TMS	+ +	m	y	y	y	The so-called non-excretors can be missed by NBS
Isovaleric acidemia	TMS	+ +	m	y	y	y	NBS also detects unaffected patients with mild variants
Propionic acidemia	TMS	+	m	y	y		Acylcarnitine profile in PA and MMA are indistinguishable
Methylmalonic acidemia (mutase)	TMS	+	m	y	y		Acylcarnitine profile in PA and MMA are indistinguishable
Methylmalonic acidemia (disorders of cobalamin metabolism A-D,F)	TMS	+	m	y	y	y	Sensitivity unclear; propionylcarnitine level is soften only slightly elevated
Cobalamin E/G defect	TMS	- -					Low methionine level is the only marker; sensitivity and specificity unknown, but presumably low; determination of homocysteine would improve NBS
Malonyl-CoA decarboxylase deficiency	TMS	+	m	y	y	y	Very rare; no prospective data
3-MCC deficiency	TMS	–	m	y	y		Low clinical expressivity and penetrance
3-Hydroxymethylglutaryl-CoA lyase deficiency	TMS		m	y	y	y	Reliable discrimination from 3-MCC deficiency not possible
Holocarboxylase synthase deficiency	TMS		m	y	y	y	Very rare, but easily treatable with biotin; Reliable discrimination from 3-MCC deficiency not possible
ß-Ketothiolase deficiency	TMS	+	m	y	y	y	Sensitivity and specificity presumably low
Disorders of glutathione metabolism	TMS		m				No prospective data
ß-Oxidation defects/disorders of carnitine metabolism							
SCAD deficiency	TMS	- -	a	y	y	y	Causality between enzyme defect and clinical outcome is not proven

(continued)

Table 1.3 (continued)

Disease	Methods	Relevance ranking	Screening programs	Test[a] available	Therapy available	Benefit from early detection	Remarks
MCAD deficiency	TMS	++	m	y	y	y	Positive effect unquestioned; however patients that might never become symptomatic are also detected
MCHAD deficiency	TMS		m	y	y		Very rare; no prospective data
VLCAD deficiency	TMS	+	m	y	y	y	Mild variants might be missed when the samples are taken under anabolic conditions
LCHAD/TFP deficiency	TMS	+	m	y	y	y	Information on long-term outcome are rare; prognosis for TFP is rather bad
Carnitine transporter deficiency	TMS	+	m		y	y	Sensitivity unclear; free carnitine level can be normal postpartum, depending on maternal supply and renal loss
CPT-I deficiency	TMS	++	m	y	y	y	Ratio of free carnitine to the sum of palmitoylcarnitine and stearylcarnitine is sensitive and highly specific
CPT-II deficiency	TMS	+	m	y	y	y	Neonatal onset form with bad prognosis despite early diagnosis; in the late-onset form mainly skeletal muscle is involved, seems to have normal levels of acylcarnitines in the neonatal period
Translocase deficiency	TMS	+	m	y	y	y	Bad prognosis despite early diagnosis
Endocrinopathies							
Congenital hypothyroidism	ELISA	++	a	y	y	y	
Congenital adrenal hyperplasia	ELISA	++	a	y	y	y	Sensitivity for the salt-wasting form is good, for simple virilizing congenital adrenal hyperplasia approximately 50%
Hemoglobinopathies							
Sickle cell anemia	IEF/HPLC	++	e	y	y	y	
Hemoglobin S/ß-thalassemia	IEF/HPLC	++	e	y	y	y	
Hemoglobin SC disease	IEF/HPLC	++	e	y	y	y	
Hemoglobin H	IEF/HPLC	++	e	y	y	y	
Other inborn errors of metabolism							
Biotinidase deficiency	Enzyme assay	++	a	y	y	y	
Galactosemia	Substrate and/or enzyme assay	++	a	y	y	y	Long-term outcome not as favorable as initially thought in the 1970s
Glucose-6-phosphate dehydrogenase deficiency	Enzyme assay		e	y	y	y	High genetic variability
Phosphoglucomutase deficiency	Enzyme assay			y	y	y	Very rare, no prospective data available
Disorders of creatine metabolism	TMS		p	y	y		Feasibility has been demonstrated, results on long-term outcome not yet available
Lysosomal storage disorders	Enzyme assay (TMS/fluorimetric)		p	y	y		Long delay/uncertainty between the positive NBS result and a clear confirmation of the disease; age of onset extremely variable and not predictable
Cystic fibrosis	IRT/DNA	++	m	y	y	y	
Diabetes mellitus type I	DNA		p		y	y	"Genetic risk" screening
Other diseases							

Hearing screening	Otoacoustic	+ +	m	y	y	y	POCT
Congenital CMV infection	CMV viral load	+	p	y	y	y	
Congenital toxoplasmosis infection	Toxoplasmosis viral load	- -	mat	- -	- -	- -	Not recommended, (prenatal care)
Congenital syphilis infection	Nontreponemal antibodies	- -	mat/epd	- -	- -	- -	Not recommended, (prenatal care)
Neuroblastoma screening[b]	HPLC	- -	d	y	y	n	Not recommended
Duchenne muscular dystrophy	Creatine kinase activity	- -	p	y	n	n	New therapies in development
Spinal muscular atrophy	DNA	+	p	y	y		First outcome studies are promising; however, the observation time is only 4–5 years so far
Severe combined immunodeficiency	TREC/KREC copy numbers	+ +	m	y	y	y	
HIV	ELISA		epd	- -	- -	- -	Not recommended
Hepatitis C	ELISA		epd	- -	- -	- -	Not recommended, (prenatal care)
Hepatitis B	HBsAg		epd	- -	- -	- -	Not recommended, (prenatal care)

CPT-I carnitine palmitoyl transferase I, *CPT-II* carnitine palmitoyl transferase II, *HBsAg* hepatitis B surface antigen, *HHH* hyperornithinemia–hyperammonemia–homocitrullinuria, *HPLC* high performance liquid chromatography, *IEF* isoelectric focusing, *IRT* immunoreactive trypsin, *LCHAD* long-chain hydroxyacyl-CoA dehydrogenase, *MCAD* medium-chain acyl-CoA dehydrogenase, *MCHAD* medium-chain hydroxyacyl-CoA dehydrogenase, *3-MCC* 3-methylcrotonyl-CoA carboxylase, *NBS* newborn screening, *OAT* ornithine aminotransferase, *SCAD* short-chain acyl-CoA dehydrogenase, *SCID* severe combined immunodeficiency, *TFP* trifunctional protein, *TLC* thin-layer chromatography, *TMS* tandem mass spectrometry, *VLCAD* very long-chain acyl-CoA dehydrogenase, *a* all, *d* discontinued, *e* ethnic, *epd* epidemiologic, *m* most, *mat* recommended as a prenatal screening test, *n* no, pilot, *y* yes, + + unquestioned, + favorable, - unfavorable, - - not recommended

[a]With sufficient sensitivity and specificity, economically justifiable

[b]Specimen for screening is urine dried on filter paper

Table 1.4 Primary markers, and secondary markers and/or ratios for FI-MS/MS

Metabolite (primary)		Disorder	Secondary markers/ratios
Free carnitine (C0)	N, ↓	Carnitine transporter deficiency	Total carnitine ↓
Free carnitine (C0)	N, ↓	All OAs, FAO disorders	
Free carnitine (C0)	N, ↑	CPT-I deficiency	C0/(C16 + C18) ↑
Acetyl carnitine (C2)		Unspecific	
Propionylcarnitine (C3)	↑	PA, MMA	C3/C2, C3/C4, C3/C16
	↑	Disorders of cobalamin metabolism	C3/C2, C3/C4, C3/C16 ↑ Met N, ↓
Malonylcarnitine (C3DC)*	↑	Malonyl-CoA decarboxylase deficiency	C3DC/C5DC
Butyrylcarnitine (C4)	↑	MADD	C5DC, C5, C12, C14, C14:1
Methylmalonylcarnitine/Succinylcarnitine (C4DC)*	↑	MMA (mut 0)	
Isovalerylcarnitine (C5)	↑	IVA	C5/C4, C5/C8
Glutarylcarnitine (C5DC)*			C5DC/C4, C5DC/C12, C5DC/C8, C5DC/C3DC
Hydroxyisovalerylcarnitine (C5-OH)*	↑	3-MCC def./3-HMG-CoA lyase def./ß-Ketothiolase	C5-OH/C3, C5:1, C6DC
Pentenoylcarnitine (C5:1)	↑	ß-Ketothiolase	C5-OH; C5-OH/C3
Methylglutarylcarnitine (C6DC)*	↑	HMG-CoA lyase def.	C5-OH; C5-OH/C3
Hexanoylcarnitine (C6)	↑	MCADD	
Octanoylcarnitine (C8)	↑	MCADD	C8/C12, C8/C6, C8/C10, (C6OH)
Decanoylcarnitine (C10)	↑	MCADD	
Decenoylcarnitine (C10:1)	↑	MCADD	
Hydroxyhexanoylcarnitine (C6OH)*	N, ↑	MCADD	
Dodecanoylcarnitine (C12)	↑	VLCADD, LCHADD, MADD	
Tetradecanoylcarnitine (C14)	↑	VLCADD, LCHADD, MADD, CPT-II, Translocase	
Tetradecenoylcarnitine (C14:1)	↑	VLCADD, LCHADD, MADD, CPT-II, Translocase	C14:1/C4
Tetradecadienoylcarnitine (C14:2)	↑	VLCADD, LCHADD, MADD, CPT-II, Translocase	
Hydoxytetradecanoylcarnitine (C14-OH)	↑	LCHADD, CPT-II, Translocase	
Hydroxypalmitoylcarnitine (C16-OH)	↑	LCHADD, CPT-II, Translocase	
Hydroxyhexadecenoylcarnitine (C16:1-OH)	↑	LCHADD, CPT-II, Translocase	
Hydroxyoctadecenoylcarnitine (C18:1-OH)	↑	LCHADD, CPT-II, Translocase	
Palmitoylcarnitine (C16)	↑	CPT-II, Translocase	
Palmitoylcarnitine (C16)	↓	CPT-I deficiency	C0/(C16 + C18) ↑
Stearylcarnitine (C18)	↑	CPT-II, Translocase	
Stearylcarnitine (C18)	↓	CPT-I deficiency	C0/(C16 + C18) ↑
Phenylalanine (Phe)	↑	PKU, liver disease	Phe/Tyr
Tyrosine (Tyr)	↓	PKU	Phe/Tyr
Tyrosine (Tyr)	↑	Tyrosinemia Type I, II, and III	Tyr/Ser
Methionine (Met)	↑	Homocystinuria, MAT	Met/Leu, Met/Phe
Methionine (Met)	↓	Disorders of cobalamin metabolism	C3, C3/C2, C3/C4, C3/C16 ↑
Leucine (Leu)*	↑	MSUD, liver disease, hydroxyprolinemia	Leu/Phe, Leu/Ala, FQ
Valine (Val)	↑	MSUD, liver disease	Val/Phe, Val/Ala, FQ
Citrulline (Cit)	↑	Citrullinemia	Cit/Phe, Cit/Tyr
Citrulline (Cit)	↓	UCDs	
Arginine (Arg)	↓	UCDs	
Arginine (Arg)	↑	Arginase def.	Arg/Phe
Ornithine (Orn)	↑	Hyperornithinemia	Orn/Phe, Orn/Ser
Alanine (Ala)	↑	Lactic acidosis	
Alanine (Ala)	↓	MSUD	
Gly (Gly)	↑	NKH	Gly/Ala
5-Oxoproline/Pyroglutamate (PyrGlu)	↑	5-Oxoprolinemia, Glutathionsynthase def.	PyrGlu/Phe

Metabolites marked with an asterix (*) have isobaric compounds, that cannot be destinguished from each other with the screening method.

"There should be an agreed policy on whom to treat as patients." That means there must be a well-defined testing for the confirmation of the so far "suspicion" that an abnormal NBS result represents. Without a definite positive confirmatory test, no screening program should count an abnormal NBS result as a detected case. Unfortunately, this is often neglected, which can be seen from a lot of publications on screening for CH during the last years that can be summarized under the title: "Increasing incidence for CH by lowering the cut-off for TSH."

Treatment and Follow-up

The last part of the NBS process is the referral of newborns with a positive screening test to a specialized center, initiation of treatment, and follow-up. While the quality of the ***NBS tests*** can be measured by the number of correctly detected cases (e.g., ppv, fp rate, fn), the quality and success of the ***NBS program*** will be measured by the outcome of detected cases. Therefore, long-term outcome studies are extremely important for the evaluation of NBS programs (Badawi et al. 2019). Unfortunately, the costs for this quality assessment are mostly neither covered by the health insurance, within the reimbursement for NBS, nor by the health authorities. This is absolutely incomprehensible in these times of quality control, where nearly everything is certified, or accredited by any "*ISO-XXXX*."

Perspective

Newborn screening will steadily improve and the number of disorders will increase. This will be driven either by improved methods and technology, which makes screening possible, when marker metabolites get measurable, or by new treatment option, when sofar untreatable disorders get treatable by the invention of new therapeutics, like SMA.

And last but not least, the decrease in cost for next-generation sequencing (NGS), whole exome sequencing, or whole genome sequencing, have started the debate, whether this will be the future of NBS (Yang et al. 2019; Phornphutkul and Padbury 2019).

Conclusion

Newborn screening is surely one of the most effective preventive health care programs in the world. It has a history of more than 50 years (in some regions), not to forget those countries, where they just start to think about introducing NBS. During the last 50 years, NBS has evolved from a laboratory test, to a public health care program, still there is work to do to improve. In addition, new technologies will continuously challenge the newborn screening laboratories.

Simple Tests and Routine Chemistry

2

Carlos R. Ferreira and Nenad Blau

Content

Abstract

A variety of routine chemistry tests are useful in both specialist and non-specialist laboratories to assist in the differential diagnosis of inherited metabolic disorders. We provide a list of metabolic diseases associated with abnormalities in urine tests (color, odor, ferric chloride, reducing substances, DNPH, Acetest, nitroprusside test) and routine blood chemistry (hypoglycemia, hyperglycemia, hyperammonemia, hyperlactatemia, low and high creatinine, acidosis, alkalosis, hypocholesterolemia, hypercholesterolemia, hypertriglyceridemia, increased liver transaminases, increased creatine kinase, increased lactate dehydrogenase, hyperphosphatasemia, hypophosphatasemia, decreased and increased urea nitrogen, hyperuricemia and hypouricemia, hyperferritinemia and hypoferritinemia, myoglobinuria, anemia, thrombocytopenia, neutropenia, and reticulocytosis). Although some of these tests are considered obsolete in modern metabolic laboratories, we decided to include them in this chapter from the historic point of view and to maintain the information for laboratories in developing countries.

This chapter draws substantially from previous chapter by Duran M and Gibson KM (Duran and Gibson 2014), which the authors gratefully acknowledge.

A variety of rapid qualitative tests (colorimetric, dipstick, precipitate, color and smell, etc.) are useful in both specialist and non-specialist laboratories to assist in the differential diagnosis of inherited metabolic disorders. Most are limited by some level of interference; yet these tests still have important utility, especially in emergency situations.

The color and odor of a patient's urine may be a valuable analysis for initial testing (Tables 2.1 and 2.2). Odor can only be reliably interpreted when the urine is preserved in an adequate way (pH 5–7, no signs of bacterial contamination as evidenced by a negative nitrite dipstick). Alkaptonuria patients show a rapid blackening of the urine upon standing; this process can be accelerated by adding a few drops of an ammonia solution to the urine test tube.

Although most of the following simple tests are considered to be obsolete in modern metabolic laboratories, we decided to include them in this book from the historic point of view and to maintain the information for laboratories in third world counties.

The ferric chloride test (Table 2.3) is employed to look for the presence of oxo-acids (formed by transamination or oxidation-reduction reactions). This test has been routinely used in the identification of classical phenylketonuria, but several other species (in addition to the intermediates of phenylalanine metabolism) react with ferric chloride to form a number of colored complexes. An alternative for the ferric chloride test is the Phenistix dipstick.

Reducing substances in urine (see Table 2.4; also commonly referred to as Benedict test or Clinitest®, Bayer Corporation) reacts with a broad spectrum of reducing sugars in urine with the formation of colored complexes (green to orange). It is commonly used for the detection of urine galactose on the suspicion of galactosemia in neonates with severe liver disease and renal Fanconi syndrome. One should

Table 2.1 Color (urine)

Color	Compound	Disorder—source
Black	Homogentisic acid	Alkaptonuria
Black	Melanin	Metastatic melanoma; levodopa or alpha-methyldopa in alkaline urine
Black	Ferrous sulfide	Iron sorbitol citrate
Black	Cresol	Intoxication (household disinfectant)
Purple	Indirubin + indigo	Purple urine bag syndrome
Blue	Indican	Hartnup disorder; Drummond syndrome; severe intestinal malabsorption
Green	Pyocyanin	Pseudomonas infection
Green	Biliverdin	Hyperbiliverdinemia
Green	Amitriptyline, indomethacin, metoclopramide, promethazine, cimetidine, methocarbamol, propofol, triamterene, carbolic acid (phenol), methylene blue, mitoxantrone, zaleplon	Drugs
Green	Thymol	Listerine mouthwash
	Chlorophyll	Clorets mints
Green	Imazosulfuron, mefenacet	Herbicide intoxication
Brown	Methemoglobin	Methemoglobinemia
Brown	Myoglobin	Myoglobinuria
Brown	Metronidazole, nitrofurantoin, chloroquine, primaquine	Drugs
Red-brown	Hb/methemoglobin	Hemoglobinuria
Red	Erythrocytes/lysate	Hematuria
Red	Porphyrins	Porphyria
Red	Pyrazolones, phenothiazines (chlorpromazine, thioridazine), deferoxamine, hydroxycobalamin (Cyanokit, ≥5 g IV)	Drugs
Red	Doxorubicin, senna, cascara	Anthraquinone
Red	Phenolphthalein, phenolsulfonphthalein	Chemicals
Light red/pink	Urates	Hyperuricosuria
Red	Beets, rhubarb, blackberries	Nutritional
Orange	Carotene	Nutritional (carrots)
Orange	Rifampin, phenazopyridine, warfarin	Drugs
Orange-yellow	Sulfasalazine	Drugs
Orange-yellow	Fluorescein	Retinal angiography
Yellow	Riboflavin	Vitamins
Yellow	Bilirubin	Hyperbilirubinemia (jaundice)
White[a]	Chyle	Chyluria; filariasis; schistosomiasis
White[a]	Caseous material	Urinary tuberculosis
White[a]	White blood cells	Pyluria
White[a]	Calcium	Hypercalciuria
White[a]	Oxalate	Hyperoxaluria
White[a]	Phosphate	Phosphaturia
White[a]	Fat	Lipiduria

[a]Sediment

be aware that the Fanconi syndrome includes renal glucosuria; hence the presence of galactose cannot be deduced from the positive Clinitest.

Dinitrophenylhydrazine (DNPH, Brady's reagent) reacts with α-ketoacids to produce insoluble hydrazones, forming precipitates in urine samples (Table 2.5); it is seldom used nowadays, partly due to its explosive hazard. Conversely, Acetest analysis in urine (Bayer Corporation) complexes with urinary ketones (Table 2.5). Parallel use of DNPH and Acetest provides slightly more diagnostic capacity. A positive result of either test will always be followed up by an immediate analysis of urine organic acids. Acetest is also frequently used for the home monitoring of patients with MSUD and propionic and methylmalonic acidurias; it will give a good indication for the catabolic state of the patient, necessitating dietary intervention. This test will be of use in establishing hypoketotic hypoglycemia although the degree of ketonuria in several fatty acid oxidation disorders may be marked, especially MCAD.

The cyanide nitroprusside test (or Brand reaction) identifies sulfur-containing amino acids, with the formation of brightly colored complexes (Table 2.6). It will find its primary use in the detection of homocystinuria (both homocysteine and the cysteine-homocysteine disulfide react positively) and cystinuria. Arginine—and at a slower rate argininosuccinic acid—will react by forming a differently colored product (blue/green). A concern with the Brand test is the use of toxic cyanide.

Additional colorimetric tests can be employed for more selective identification. The Ehrlich's test employs 4-dimethylaminobenzaldehyde to assess the presence of uri-

Table 2.2 Odor (urine)

Odor	Compound	Disorder—source
Musty, mousey	Phenylacetic acid	Classical PKU; treatment of urea cycle disorders with phenylacetate
Maple syrup or burnt sugar	Sotolone (4,5-dimethyl-3-hydroxy-2[5*H*]-furanone)	MSUD; fenugreek; lovage
Sweaty feet	Isovaleric acid	Isovaleric acidemia
		3-Hydroxy-3-methylglutaric aciduria
	Idem + butyric + isobutyric acid	MADD (Glutaric aciduria type 2)
Cat urine	3-Hydroxyisovaleric acid/3-methylcrotonic acid	3-Methylcrotonylglycinuria
		Multiple carboxylase deficiency
Cabbage-like	Dimethylsulfide	Methionine adenosyltransferase deficiency (Mudd disease); methanethiol oxidase deficiency; DMSO cryoprotectant (HSCT)
	Methanethiol	Methanethiol oxidase deficiency
	2-Oxo-4-methylthiolbutyric acid	Tyrosinemia type 1
Rancid butter	2-Oxo-4-methylthiolbutyric acid	Tyrosinemia type 1
Rotten eggs	Sulfur	Cystinuria, cysteamine administration
Fish	Trimethylamine	Trimethylaminuria; carnitine supplementation
	Dimethylglycine	Dimethylglycinuria
Dried malt or hops, celery or yeast	Alpha-hydroxybutyric acid	Oasthouse syndrome (methionine malabsorption)
Swimming pool, chlorine	*4*-Hydroxyphenylpyruvic acid (?)	Hawkinsinuria

HSCT hematopoietic stem cell transplantation

Table 2.3 Ferric chloride test (urine)

Color	Compound	Disorder—source
Blue-green	Phenylpyruvic acid	Classical PKU
	Imidazolepyruvic acid	Histidinemia
	Catecholamines	Pheochromocytoma; neuroblastoma
	Xanthurenic acid	Xanthurenic aciduria (B6 def.)
Transient blue-green	Homogentisic acid	Alkaptonuria
Greenish-gray	Branched chain oxoacids	MSUD
Green	4-Hydroxyphenylpyruvic acid	Tyrosinemia types 1 and 2
Yellow	Lactic acid	Lactic acidosis
Gray-black	Melanin	Melanoma
Deep green	Bilirubins	Conjugated hyperbilirubinuria
Cherry red	Acetoacetic acid	Diabetic ketoacidosis; 3-oxothiolase def. + other organic acids
Purple red-brown	2-Oxobutyric acid	Methionine malabsorption
Purple	Ketones	3-Oxothiolase deficiency
	Salicylates	Drug treatment
Purple or green	Phenothiazines	Drug treatment

Table 2.4 Reducing substances (urine)

Compound	Disorder—source
Galactose	Galactosemia
	Galactokinase deficiency
	Fanconi-Bickel syndrome
	Citrin deficiency
Fructose	Hereditary fructose intolerance
	Essential fructosuria
4-Hydroxyphenylpyruvic acid	Tyrosinemia types 1 and 2
Homogentisic acid	Alkaptonuria
Xylose	Pentosuria
Glucose	Diabetes mellitus
	Renal Fanconi syndrome; cystinosis; etc.
Oxalic acid	Hyperoxaluria
Salicylates, levodopa, cephalosporins, tetracyclines, isoniazid, probenecid, nalidixic acid, nicotinic acid	Drug treatment
Uric acid	Hyperuricosuria
Hippuric acid	Treatment with sodium benzoate; severe malabsorption
Ascorbic acid	Excessive vitamin use
Contrast agents	Radiographic evaluation

nary porphobilinogen and urobilinogen, markers for the heritable porphyrias, but it will also react with substances such as hydroxyproline, tryptophan, citrulline, and homocitrulline. The nitrosonaphthol test represents a colorimetric analysis of 4-hydroxylated phenol acids and metabolites of tyrosine metabolism (e.g., 4-hydroxyphenylpyruvate, 4-hydroxyphenyllactate, and 4-hydroxyphenylacetate). Artefactual results with nitrosonaphthol are common in patients with liver disease and severe intestinal malabsorption and those receiving parenteral nutrition. The sulfite dipstick qualitatively assesses urine sulfite, indicative of sulfite oxidase and molybdenum cofactor deficiencies. It is reputedly performed in fresh urine samples, and only few false-positive test results have been reported, a well-known one being the use of 2-mercaptoethanesulfonate (Mesna), which can also cause false-positive results to the nitroprusside reaction. Every faint positive sulfite test result should be verified by *S*-sulfocysteine measurement.

Routine blood chemistry provides a plethora of diagnostic insights (e.g., glucose, ammonia, blood gases, creatinine, urea, uric acid, liver enzymes, etc.) (Table 2.7). Table 2.7

Table 2.5 Dinitrophenylhydrazine (DNPH) and Acetest (urine)

DNPH	Acetest	Positive compound	Disorder—source
+	–	Phenylpyruvic acid	Classical PKU
+	–	2-Oxoisocaproic acid	MSUD
+	–	2-Oxo-3-methylvaleric acid	MSUD
(+)	–	Imidazolepyruvic acid	Histidinemia
+	+	Acetone	3-Oxothiolase def.; ketosis; Succinyl-CoA:3-ketoacid-CoA-transferase deficiency
–	+	2-Methylacetoacetate	3-Oxothiolase deficiency
–	+	2-Butanone	3-Oxothiolase deficiency
+	+	Acetoacetate	Succinyl-CoA:3-ketoacid-CoA-transferase deficiency; ketosis
+	–	4-Hydroxyphenylpyruvic acid	Liver disease; Tyrosinemia types 1 and 2
+	–	2-Oxobutyric acid	Methionine malabsorption
+	+	Pyruvate	Lactic acidosis

Table 2.6 Nitroprusside test (urine)

Positive compound	Disorder—source
Cystine	Cystinuria
Cystine	Generalized aminoaciduria
Cystine	Fanconi syndrome
3-Mercaptolactatecysteine-disulfide	3-Mercaptolactatecysteine-disulfiduria
Homocystine, cysteine-homocysteine mixed disulfide	Homocystinuria
	B 12 def. and cobalamin C, D, E, G
	Methylene tetrahydrofolate reductase def.
	Cystathioninuria (bacterial formation of Hcy)
Glutathione	Glutathionuria
Ketones + high creatinine	Dehydration

Table 2.7 Routine chemistry in blood (plasma or serum)

Glucose ↓ (hypoglycemia)	
Name	Gene
Disorders of nitrogen-containing compounds	
Carbonic anhydrase VA deficiency	*CA5A*
Dopamine beta-hydroxylase deficiency	*DBH*
Adenosine kinase deficiency	*ADK*
Maple syrup urine disease	*BCKDHA, BCKDHB, DBT*
Isovaleryl-CoA dehydrogenase deficiency	*IVD*
2-Methylbutyryl-CoA dehydrogenase deficiency	*ACADSB*
3-Methylcrotonyl-CoA carboxylase 1 and 2 deficiency	*MCCC1*
3-Methylglutaconyl-CoA hydratase deficiency	*AUH*
HSD10 disease	*HSD17B10*
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	*HMGCL*
Propionyl-CoA-carboxylase deficiency	*PCCA, PCCB*
Methylmalonyl-CoA mutase deficiency	*MMUT*
Combined MMA and MA	*ACSF3*
Malonyl-CoA decarboxylase deficiency	*MLYCD*
Alpha-amino adipic semialdehyde (AASA) dehydrogenase deficiency	*ALDH7A1*
2-Ketoadipic aciduria	*DHTKD1*
Disorders of vitamins, cofactors, metals, and minerals	
NFS1 deficiency	*NFS1*
Multiple acyl-CoA dehydrogenase deficiency	*ETFDH, ETFA, ETFB*
Nicotinamide nucleotide transhydrogenase deficiency	*NNT*
Pyridox(am)ine 5′-phosphate oxidase deficiency	*PNPO*
Disorders of carbohydrates	
Fanconi-Bickel syndrome[a]	*SLC2A2*
Fructose-1-phosphate aldolase deficiency	*ALDOB*
Transaldolase deficiency	*TALDO1*
ATP-sensitive potassium channel regulatory subunit deficiency	*ABCC8*
ATP-sensitive potassium channel pore-forming subunit deficiency	*KCNJ11*
Glutamate dehydrogenase superactivity	*GLUD1*
HNF4-alpha deficiency	*HNF4A*
HNF1-alpha deficiency	*HNF1A*
Uncoupling protein 2 deficiency	*UCP2*
Hyperinsulinemic hypoglycemia 5	*INSR*

Table 2.7 (continued)

Name	Gene
AKT2 superactivity	*AKT2*
Glucose-6-phosphate translocase deficiency	*SLC37A4*
Glycogen storage disease type III	*AGL*
Liver glycogen phosphorylase deficiency	*PYGL*
Liver glycogen synthase deficiency[a]	*GYS2*
Hepatic phosphorylase kinase α2 subunit deficiency	*PHKA2*
Phosphorylase kinase β subunit deficiency	*PHKB*
Hepatic phosphorylase kinase γ2 subunit deficiency	*PHKG2*
Constitutional AMP-activated protein kinase activation	*PRKAG2*
Glycogen storage disease type I a	*G6PC*
Fructose-1,6-bisphosphatase deficiency	*FBP1*
Pyruvate carboxylase deficiency	*PC*
Mitochondrial phosphoenolpyruvate carboxykinase deficiency	*PCK2*
Glucokinase superactivity	*GCK*
Mitochondrial disorders of energy metabolism	
2-Oxoglutarate dehydrogenase deficiency	*OGDH*
Acyl-CoA Dehydrogenase 9 deficiency	*ACAD9*
Mitochondrial complex III subunit deficiency (UQCRB)	*UQCRB*
Mitochondrial complex III assembly deficiency (UQCRC2)	*UQCRC2*
Mitochondrial complex III assembly deficiency (TTC19)	*TTC19*
Mitochondrial complex III assembly deficiency (UQCC3)	*UQCC3*
Mitochondrial ATP synthase F1 subunit δ deficiency	*ATP5F1D*
Mitochondrial cytochrome beta deficiency	*MTCYB*
Mitochondrial deoxyguanosine kinase deficiency	*DGUOK*
MPV17 deficiency	*MPV17*
tRNA 5-carboxymethylaminomethyl transferase deficiency	*MTO1*
Mitochondrial transcription factor A deficiency	*TFAM*
Mitochondrial ribosomal small subunit 2, 7,23 and 28 deficiency	*MRPS2*
Mitochondrial tryptophanyl-tRNA synthetase deficiency	*WARS2*
Mitochondrial glutamyl-tRNA(Gln) amidotransferase subunit B deficiency	*GATB*
MEGDEL Syndrome	*SERAC1*
Barth syndrome	*TAZ*
MICOS complex subunit MIC13 deficiency	*MICOS13*
Disorders of lipids	
Organic cation carnitine transporter 2 deficiency	*SLC22A5*
Carnitine palmitoyltransferase 1 deficiency	*CPT1A*
Carnitine palmitoyltransferase 2 deficiency	*CPT2*
Carnitine acylcarnitine translocase deficiency	*SLC25A20*
Short-chain acyl-CoA dehydrogenase deficiency	*ACADS*
Medium-chain acyl-CoA dehydrogenase deficiency	*ACADM*
Very long-chain acyl-CoA dehydrogenase deficiency	*ACADVL*
Short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency	*HADH*
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	*HADHA*
Trifunctional protein deficiency	*HADHB*
TANGO2 deficiency	*TANGO2*
3-Hydroxy-3-methylglutaryl-CoA synthase deficiency	*HMGCS2*
Succinyl-CoA:3-oxoacid CoA transferase deficiency	*OXCT1*
Monocarboxylate transporter gain-of-function	*SLC16A1*
Methylacetoacetyl-CoA thiolase deficiency	*ACAT1*
Glycerol kinase deficiency, isolated	*GK*
Catalytic phosphatidylinositol 3-kinase α subunit superactivity	*PIK3CA*
Congenital disorders of glycosylation	
Phosphomannomutase 2 deficiency PMM2-CDG	*PMM2*
Phosphomannose isomerase deficiency MPI-CDG	*MPI*
Mannosyltransferase 6 deficiency ALG3-CDG	*ALG3*

(continued)

Table 2.7 (continued)

Name	Gene
Mannosyltransferase 8 deficiency ALG12-CDG	*ALG12*
Phosphoglucomutase 1 deficiency PGM1-CDG	*PGM1*
Glucose ↑	
Disorders of nitrogen-containing compounds	
Pterin carbinolamine-4a-dehydratase deficiency	*PCBD1*
Disorders of vitamins, cofactors, metals, and minerals	
Thiamine-responsive megaloblastic anemia syndrome (SLC19A2)	*SLC19A2*
Hereditary hemochromatosis (type 1)	*HFE*
Hereditary hemochromatosis (type 2a)	*HFE2*
Hereditary hemochromatosis (type 2b)	*HAMP*
Hereditary hemochromatosis (type 3)	*TFR2*
Disorders of carbohydrates	
Fanconi-Bickel syndrome[a]	*SLC2A2*
Galactose-1-phosphate uridyltransferase deficiency[b]	*GALT*
Uridine diphosphate galactose-4-epimerase deficiency[b]	*GALE*
ATP-sensitive potassium channel regulatory subunit superactivity	*ABCC8*
ATP-sensitive potassium channel pore-forming subunit superactivity	*KCNJ11*
Glucokinase deficiency	*GCK*
Liver glycogen synthase deficiency[a]	*GYS2*
Mitochondrial disorders of energy metabolism	
Mitochondrial tRNA(Ser) 2 deficiency	*MTTS2*
Disorders of lipids	
3-Oxothiolase deficiency	*ACAT1*
Estrogen resistance	*ESR1*
Storage disorders	
Nephropathic cystinosis	*CTNS*
Ammonia ↑ (Hyperammonemia)	
Disorders of nitrogen-containing compounds	
N-Acetylglutamate synthase deficiency	*NAGS*
Carbamoyl phosphate synthetase I deficiency	*CPS1*
Ornithine transcarbamylase deficiency	*OTC*
Argininosuccinate synthetase deficiency	*ASS1*
Argininosuccinate lyase deficiency	*ASL*
Arginase 1 deficiency	*ARG1*
Mitochondrial ornithine transporter deficiency	*SLC25A15*
Citrin deficiency	*SLC25A13*
Carbonic anhydrase VA deficiency	*CA5A*
Lysinuric protein intolerance	*SLC7A7*
Isovaleryl-CoA dehydrogenase deficiency	*IVD*
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	*HMGCL*
Propionyl-CoA-carboxylase deficiency	*PCCA, PCCB*
Methylmalonyl-CoA mutase deficiency	*MMUT*
Pyrroline-5-carboxylate synthetase deficiency	*ALDH18A1*
Ornithine aminotransferase deficiency	*OAT*
Glutamate dehydrogenase superactivity	*GLUD1*
Glutamine synthetase deficiency	*GLUL*
Disorders of vitamins, cofactors, metals, and minerals	
Adenosylcobalamin synthesis defect—cblD-MMA	*MMADHC*
Adenosylcobalamin synthesis defect—cbl A/B	*MMAA/B*
Mitochondrial coenzyme A transporter deficiency	*SLC25A42*
Disorders of carbohydrates	
Pyruvate carboxylase deficiency	*PC*
Mitochondrial disorders of energy metabolism	
Acyl-CoA Dehydrogenase 9 deficiency	*ACAD9*
Mitochondrial complex III assembly deficiency (UQCRC2)	*UQCRC2*
Mitochondrial ATP synthase F1 subunit δ deficiency	*ATP5F1D*
Transmembrane protein 70 deficiency	*TMEM70*

Table 2.7 (continued)

Name	Gene
Mitochondrial cytochrome c1 deficiency	*CYC1*
FBXL4 deficiency	*FBXL4*
Combined Oxidative Phosphorylation Defect 5	*MRPS22*
Disorders of lipids	
Carnitine-acylcarnitine translocase deficiency	*SLC25A20*
Carnitine palmitoyltransferase 2 deficiency, severe	*CPT2*
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	*HADHA*
Trifunctional protein deficiency	*HADHB*
TANGO2 deficiency	*TANGO2*
Alpha-methylacetoacetic aciduria	*ACAT1*
Lactate ↑	
Disorders of nitrogen-containing compounds	
Glutathione synthetase deficiency, severe	*GSS*
Carbonic anhydrase VA deficiency	*CA5A*
Mitochondrial sulfur dioxygenase deficiency	*ETHE1*
Isovaleric acidemia	*IVD*
Mitochondrial short-chain enoyl-CoA hydratase 1 deficiency	*ECHS1*
HSD10 disease	*HSD17B10*
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	*HMGCL*
Methylmalonate semialdehyde dehydrogenase deficiency	*ALDH6A1*
Propionyl-CoA-carboxylase deficiency	*PCCA, PCCB*
Methylmalonyl-CoA mutase deficiency	*MMUT*
Combined MMA and MA	*ACSF3*
Malonyl-CoA decarboxylase deficiency	*MLYCD*
3-Hydroxyisobutyrate dehydrogenase deficiency	*HIBADH*
Disorders of vitamins, cofactors, metals, and minerals	
Lipoyltransferase 2 deficiency	*LIPT2*
Lipoic acid synthase deficiency	*LIAS*
Lipoyltransferase 1 deficiency	*LIPT1*
NFU1 deficiency	*NFU1*
BOLA3 deficiency	*BOLA3*
Glutaredoxin 5 deficiency	*GLRX5*
IBA57 deficiency	*IBA57*
ISCA1 deficiency	*ISCA1*
ISCA2 deficiency	*ISCA2*
ISCU deficiency	*ISCU*
NFS1 deficiency	*NFS1*
ISD11 deficiency	*LYRM4*
Ferredoxin 2 deficiency	*FDX2*
Biotinidase deficiency	*BTD*
Holocarboxylase synthetase deficiency	*HLCS*
Biotin and thiamine basal ganglia disease	*SLC19A3*
Thiamine metabolism dysfunction syndrome 5	*TPK1*
Mitochondrial NAD kinase 2 deficiency	*NADK2*
Phosphopantothenoylcysteine synthetase deficiency	*PPCS*
Mitochondrial coenzyme A transporter deficiency	*SLC25A42*
PROSC-deficient B6-dependent epilepsy	*PLPBP*
Disorders of carbohydrates	
Glucose-6-phosphatase deficiency	*G6PC*
Glucose-6-phosphate translocase deficiency	*SLC37A4*
Fructose-1,6-bisphosphatase deficiency	*FBP1*
Pyruvate carboxylase deficiency	*PC*
D-lactate dehydrogenase deficiency	*LDHD*
Mitochondrial disorders of energy metabolism	
Pyruvate dehydrogenase complex deficiency E1a	*PDHA1*

MEGDEL Syndrome	*SERAC1*
Tafazzin deficiency	*TAZ*
TIMM50 deficiency	*TIMM50*
GFER deficiency	*GFER*
Mitochondrial processing peptidase β deficiency	*PMPCB*
Mitochondrial intermediate peptidase deficiency	*MIPEP*
CLPB deficiency	*CLPB*
HSP60 deficiency	*HSPD1*
HTRA2 deficiency	*HTRA2*
Pitrilysin metallopeptidase 1 deficiency	*PITRM1*
YME1L1 deficiency	*YMEL1*
Mitochondrial inorganic pyrophosphatase 2 deficiency	*PPA2*
Sideroflexin 4 deficiency	*SFXN4*
Combined Oxidative Phosphorylation Defect 6	*AIFM1*
C1q binding protein deficiency	*C1QBP*
MICOS complex subunit MIC13 deficiency	*MICOS13*
Mitochondrial thioredoxin 2 deficiency	*TXN2*
CoQ2 deficiency	*COQ2*
CABC1/ADCK3 deficiency	*COQ8A*
CoQ9 deficiency	*COQ9*

Table 2.7 (continued)

Name	Gene
Disorders of lipids	
Carnitine acylcarnitine translocase deficiency	*SLC25A20*
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	*HADHA*
Trifunctional protein deficiency	*HADHB*
TANGO2 deficiency	*TANGO2*
Cytosolic acetoacetyl-CoA thiolase deficiency	*ACAT2*
Mitochondrial acetyl-CoA carboxylase 2 deficiency	*ACACB*
Congenital disorders of glycosylation	
Heparan sulfate 6-*O*-sulfotransferase 2 deficiency	*HS6ST2*
COG6-CDG	*COG6*
Creatinine ↓	
Disorders of nitrogen-containing compounds	
Arginine:glycine amidinotransferase deficiency	*GATM*
Guanidinoacetate methyltransferase deficiency	*GAMT*
Ornithine aminotransferase deficiency	*OAT*
Creatinine ↑	
Disorders of nitrogen-containing compounds	
Lysinuric protein intolerance	*SLC7A7*
Prolidase deficiency	*PEPD*
Sarcosine oxidase deficiency[c]	*SDH*
Disorders of vitamins, cofactors, metals, and minerals	
Methylmalonic aciduria due to methylmalonyl-CoA mutase deficiency	*MMUT*
Methylmalonic aciduria, cblB type	*MMAB*
Methylmalonic aciduria and homocystinuria, cblC type	*MMACHC*
Disorders of carbohydrates	
Transaldolase deficiency	*TALDO*
Disorders of lipids	
Lecithin cholesterol acyl transferase deficiency	*LCAT*
Lipoprotein glomerulopathy	*APOE*
Storage disorders	
Fabry disease	*GLA*
Galactosialidosis	*CTSA*
Nephropathic cystinosis	*CTNS*
Disorders of peroxisomes and oxalate	
Alanine-glyoxylate aminotransferase deficiency	*AGXT*
Glyoxylate reductase/hydroxypyruvate reductase deficiency	*GRHPR*
4-hydroxy-2-oxoglutarate aldolase deficiency	*HOGA1*
Acidosis (inc. ketoacidosis and lactic acidosis)	
Disorders of nitrogen-containing compounds	
Glutathione synthetase deficiency, severe	*GSS*
5-Oxoprolinase deficiency	*OPLAH*
Mitochondrial sulfur dioxygenase deficiency	*ETHE1*
Maple syrup urine disease	*BCKDHA, BCKDHB, DBT*
Isovaleryl-CoA dehydrogenase deficiency	*IVD*
3-Methylcrotonyl-CoA carboxylase 1 and 2 deficiency	*MCCC1/2*
3-Methylglutaconyl-CoA hydratase deficiency	*AUH*
3-Hydroxyisobutyryl-CoA deacylase deficiency	*HIBCH*
HSD10 disease	*HSD17B10*
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	*HMGCL*
Propionyl-CoA-carboxylase deficiency	*PCCA, PCCB*
Methylmalonyl-CoA mutase deficiency	*MMUT*
Combined MMA and MA	*ACSF3*
Malonyl-CoA decarboxylase deficiency	*MLYCD*
3-Hydroxyisobutyrate dehydrogenase deficiency	*HIBADH*
2-Aminoadipic 2-oxoadipic aciduria	*DHTKD1*

(continued)

Table 2.7 (continued)

Name	Gene
Disorders of vitamins, cofactors, metals, and minerals	
Adenosylcobalamin synthesis defect—cblD-MMA	*MMADHC*
Adenosylcobalamin synthesis defect—cbl A/B	*MMAA/B*
Multiple acyl-CoA dehydrogenase deficiency DH	*ETFA, ETFB, ETFDH*
2,4-dienoyl-CoA reductase deficiency with hyperlysinemia	*NADK2*
Mitochondrial coenzyme A transporter deficiency	*SLC25A42*
Mitochondrial disorders of energy metabolism	
Pyruvate dehydrogenase complex deficiency E1a	*PDHA1*
Pyruvate dehydrogenase complex deficiency E1b	*PDHB*
Pyruvate dehydrogenase complex deficiency E2	*DLAT*
Pyruvate dehydrogenase complex deficiency E3 X	*PDHX*
Pyruvate dehydrogenase complex deficiency PDHP	*PDP1*
ATP-specific succinyl-CoA ligase β subunit deficiency	*SUCLA2*
GTP-specific succinyl-CoA ligase α subunit deficiency	*SUCLG1*
Fumarase deficiency	*FH*
2-Oxoglutarate dehydrogenase deficiency	*OGDH*
SAM transporter deficiency	*SLC25A26*
Mitochondrial complex I subunit deficiency (NDUFV2)	*NDUFV2*
Mitochondrial complex I subunit deficiency (NDUFS1)	*NDUFS1*
Mitochondrial complex I subunit deficiency (NDUFS4)	*NDUFS4*
Mitochondrial complex I subunit deficiency (NDUFS6)	*NDUFS6*
Mitochondrial complex I subunit deficiency (NDUFA1)	*NDUFA1*
Mitochondrial complex I subunit deficiency (NDUFA9)	*NDUFA9*
Mitochondrial complex I subunit deficiency (NDUFB3)	*NDUFB3*
NADH dehydrogenase β subcomplex subunit 8 deficiency	*NDUFB8*
Mitochondrial complex I subunit deficiency (NDUFB11)	*NDUFB11*
Mitochondrial complex I subunit deficiency (MTND6)	*MTND6*
NADH dehydrogenase α subcomplex subunit 6 deficiency	*NDUFA6*
Mitochondrial complex I subunit deficiency (NDUFB9)	*NDUFB9*
Mitochondrial complex I subunit deficiency (NDUFA11)	*NDUFA11*
Mitochondrial complex I assembly deficiency (NDUFAF1)	*NDUFAF1*
Mitochondrial complex I assembly deficiency (NDUFAF4)	*NDUFAF4*
Mitochondrial complex I assembly deficiency (NDUFAF5)	*NDUFAF5*
Mitochondrial complex I assembly deficiency (NDUFAF6)	*NDUFAF6*
Mitochondrial complex I assembly deficiency (FOXRED1)	*FOXRED1*
Mitochondrial complex III subunit deficiency (UQCRB)	*UQCRB*
Mitochondrial complex III assembly deficiency (UQCRC2)	*UQCRC2*
GRACILE syndrome	*BCS1L*
Mitochondrial complex III assembly deficiency (UQCC3)	*UQCC3*
Mitochondrial ATP synthase F1 subunit δ and e deficiency	*ATP5F1D/E*
Transmembrane protein 70 deficiency	*TMEM70*
Mitochondrial cytochrome c1 deficiency	*CYC1*
FBXL4 deficiency	*FBXL4*
tRNA 5-carboxymethylaminomethyl transferase deficiency	*MTO1*
tRNA methyltransferase 5 deficiency	*TRMT5*
Mitochondrial poly(A) exoribonuclease deficiency	*PDE12*
Mitochondrial ribosomal small subunit 28 deficiency	*MRPS28*
RMND1 deficiency	*RMND1*
Mitochondrial tRNA(Cys) deficiency	*MTTC*
Mitochondrial tRNA(Met) deficiency	*MTTM*
Mitochondrial leucyl-tRNA synthetase deficiency	*LARS2*
Mitochondrial phenylalanyl-tRNA synthetase deficiency	*FARS2*
Mitochondrial tryptophanyl-tRNA synthetase deficiency	*WARS2*
Mitochondrial glutamyl-tRNA(Gln) amidotransferase subunit C deficiency	*GATC*
UGO-1 like protein deficiency	*SLC25A46*
Tafazzin deficiency	*TAZ*
Mitochondrial intermediate peptidase deficiency	*MIPEP*

Table 2.7 (continued)

Name	Gene
Mitochondrial inorganic pyrophosphatase 2 deficiency	*PPA2*
Sideroflexin 4 deficiency	*SFXN4*
CoQ9 deficiency	*COQ9*
Disorders of lipids	
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	*HADHA*
Trifunctional protein deficiency	*HADHB*
Succinyl-CoA:3-oxoacid CoA transferase deficiency	*OXCT1*
Beta-Ketothiolase deficiency	*ACAT1*
Monocarboxylate transporter-1 deficiency	*SLC16A1*
Mitochondrial acetyl-CoA carboxylase 2 deficiency	*ACACB*
Alkalosis	
Disorders of nitrogen-containing compounds	
Urea cycle disorders	Several
Mitochondrial disorders of energy metabolism	
Mitochondrial seryl-tRNA synthetase deficiency	*SARS2*
Disorders of lipids	
Glucocorticoid receptor deficiency	*NR3C1*
Congenital adrenal hyperplasia, 17-alpha-hydroxylase def.	*CYP17A1*
Congenital adrenal hyperplasia, 11-β-hydroxylase deficiency	*CYP11B1*
11-β-hydroxysteroid dehydrogenase type 2 deficiency	*HSD11B2*
Total cholesterol ↓	
Disorders of nitrogen-containing compounds	
Malonyl-CoA decarboxylase deficiency	*MLYCD*
Mitochondrial disorders of energy metabolism	
Tafazzin deficiency	*TAZ*
Disorders of lipids	
Microsomal triglyceride transfer protein deficiency	*MTTP*
Chylomicron retention disease	*SAR1B*
Familial hypobetalipoproteinemia type 1	*APOB*
Familial hypobetalipoproteinemia type 2	*ANGPTL3*
Mevalonate kinase deficiency	*MVK*
Squalene synthase deficiencyl	*FDFT1*
Smith-Lemli-Opitz syndrome	*DHCR7*
3β-Hydroxy-Δ5-C27-steroid dehydrogenase/isomerase deficiency	*HSD3B7*
Peroxisomal branched-chain acyl-CoA oxidase deficiency	*ACOX2*
Storage disorders	
Gaucher disease	*GBA*
Congenital disorders of glycosylation	
PMM2-CDG	*PMM2*
MPI-CDG	*MPI*
ALG9-CDG	*ALG9*
ALG12-CDG	*ALG12*
ALG6-CDG	*ALG6*
B4GALT1-CDG	*B4GALT1*
Total cholesterol ↑	
Disorders of carbohydrates	
Glucose-6-phosphatase deficiency	*G6PC*
Glucose-6-phosphate transporter deficiency	*SLC37A4*
Liver glycogen phosphorylase deficiency	*PYGL*
Hepatic phosphorylase kinase α2 subunit deficiency	*PHKA2*
Disorders of lipids	
LDL receptor deficiency	*LDLR*
LDL receptor adaptor protein 1 deficiency	*LDLRAP1*
Hypercholesterolemia due to ligand-defective apoB	*APOB*
PCSK9 superactivity	*PCSK9*
STAP1 deficiency	*STAP1*

(continued)

Table 2.7 (continued)

Name	Gene
Sitosterolemia due to ABCG5 deficiency	*ABCG5*
Sitosterolemia due to ABCG8 deficiency	*ABCG8*
Apolipoprotein E deficiency	*APOE*
Hepatic lipase deficiency	*LIPC*
Cholesterol 7 alpha-hydroxylase deficiency	*CYP7A1*
Storage disorders	
Acid sphingomyelinase deficiency	*SMPD1*
Lysosomal acid lipase deficiency	*LIPA*
Congenital disorders of glycosylation	
TMEM199-CDG	*TMEM199*
CCDC115-CDG	*CCDC115*
ATP6AP1-CDG	*ATP6AP1*
Triglycerides ↑	
Disorders of carbohydrates	
Fanconi-Bickel syndrome	*SLC2A2*
Fructose-1-phosphate aldolase deficiency	*ALDOB*
Glucose-6-phosphate translocase deficiency	*SLC37A4*
Glycogen storage disease type III	*AGL*
Liver glycogen phosphorylase deficiency	*PYGL*
Hepatic phosphorylase kinase α2 subunit deficiency	*PHKA2*
Phosphorylase kinase β subunit deficiency	*PHKB*
Hepatic phosphorylase kinase γ2 subunit deficiency	*PHKG2*
Glucose-6-phosphatase deficiency	*G6PC*
Fructose-1,6-bisphosphatase deficiency	*FBP1*
Disorders of lipids	
Angiopoietin-like 3 deficiency	*ANGPTL3*
Chylomicron retention disease	*SAR1B*
Apolipoprotein E deficiency	*APOE*
Apolipoprotein E superactivity	*APOE*
Lipoprotein glomerulopathy	*APOE*
Lipoprotein lipase deficiency	*LPL*
Apolipoprotein C2 deficiency	*APOC2*
GPIHBP1 deficiency	*GPIHBP1*
Hepatic lipase deficiency	*LIPC*
Lipase maturation factor 1 deficiency	*LMF1*
Apolipoprotein A5 deficiency	*APOA5*
Familial LCAT deficiency (complete)	*LCAT*
Tangier disease	*ABCA1*
Storage disorders	
Lysosomal acid lipase deficiency	*LIPA*
Congenital disorders of glycosylation	
PIGA-CDG	*PIGA*
ASAT and ALAT (transaminases) ↑	
Disorders of nitrogen-containing compounds	
Carbamoylphosphate synthetase 1 deficiency	*CPS1*
Ornithine transcarbamylase deficiency	*OTC*
Argininosuccinate synthetase deficiency	*ASS1*
Argininosuccinate lyase deficiency	*ASL*
Arginase 1 deficiency	*ARG1*
Mitochondrial ornithine transporter deficiency	*SLC25A15*
Citrin deficiency	*SLC25A13*
Lysinuric protein intolerance	*SLC7A7*
Tyrosinemia type 1	*FAH*
Glycine *N*-methyltransferase deficiency	*GNMT*
S-adenosylhomocysteine hydrolase deficiency	*AHCY*
Adenosine kinase deficiency	*ADK*
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	*HMGCL*

Table 2.7 (continued)

Name	Gene
Disorders of vitamins, cofactors, metals, and minerals	
ISD11 deficiency	*LYRM4*
Multiple acyl-CoA dehydrogenase deficiency	*ETFDH, ETFA, ETFB*
Wilson disease	*ATP7B*
MEDNIK syndrome	*AP1S1*
Hereditary hemochromatosis (type 1)	*HFE*
Hypermanganesemia with dystonia type 1	*SLC30A10*
Disorders of carbohydrates	
Fanconi-Bickel syndrome	*SLC2A2*
Galactose-1-phosphate uridyltransferase deficiency	*GALT*
Uridine diphosphate galactose-4-epimerase deficiency	*GALE*
Fructose-1-phosphate aldolase deficiency	*ALDOB*
Transaldolase deficiency	*TALDO1*
Amylo-1,6-glucosidase (debrancher) deficiency	*AGL*
Glycogen branching enzyme deficiency	*GBE1*
Liver glycogen phosphorylase deficiency	*PYGL*
Hepatic phosphorylase kinase α2 subunit deficiency	*PHKA2*
Phosphorylase kinase β subunit deficiency	*PHKB*
Hepatic phosphorylase kinase γ2 subunit deficiency	*PHKG2*
Glycogen storage disease type II b	*LAMP2*
Glucose-6-phosphatase deficiency	*G6PC*
Mitochondrial disorders of energy metabolism	
GTP-specific succinyl-CoA ligase α subunit deficiency	*SUCLG1*
Mitochondrial complex III assembly deficiency (UQCRC2)	*UQCRC2*
Mitochondrial deoxyguanosine kinase deficiency	*DGUOK*
Mitochondrial transcription factor A deficiency	*TFAM*
Mitochondrial ribosomal small subunit 2 deficiency	*MRPS2*
Mitochondrial ribosomal small subunit 16 deficiency	*MRPS16*
Mitochondrial ribosomal small subunit 28 deficiency	*MRPS28*
Mitochondrial ribosomal large subunit 3 deficiency	*MRPL3*
Mitochondrial valyl-tRNA synthetase deficiency	*VARS*
Disorders of lipids	
Trifunctional protein β subunit deficiency	*HADHB*
3-Hydroxy-3-methylglutaryl-CoA synthase deficiency	*HMGCS2*
Chanarin-Dorfman syndrome	*ABHD5*
3β-Hydroxy-Δ5-C27-steroid dehydrogenase/isomerase deficiency	*HSD3B7*
Δ4-3-Oxosteroid-5β-reductase deficiency	*AKR1D1*
Oxysterol 7α-hydroxylase deficiency	*CYP7B1*
Congenital bile acid synthesis defect	*ABCD3*
Disorders of peroxisomes and oxalate	
Zellweger spectrum disorders	*PEX1* and other PEX genes
Congenital disorders of glycosylation	
PMM2-CDG	*PMM2*
MPI-CDG	*MPI*
ALG3-CDG	*ALG3*
Dolichol-*P*-mannose synthase-2 deficiency DPM2-CDG	*DPM2*
Phosphoglucomutase 1 deficiency PGM1-CDG	*PGM1*
COG4-CDG	*COG4*
ATP6AP1-CDG	*ATP6AP1*
TMEM199-CDG	*TMEM199*
CCDC115-CDG	*CCDC115*
Congenital disorder of glycosylation TMEM165-CDG	*TMEM165*
N-glycanase 1 deficiency	*NGLY1*

(continued)

Table 2.7 (continued)

Name	Gene
Creatine kinase (CK) ↑	
Disorders of nitrogen-containing compounds	
Adenosine monophosphate deaminase deficiency	*AMPD1*
S-adenosylhomocysteine hydrolase deficiency	*AHCY*
Adenosine kinase deficiency	*ADK*
3-Methylglutaconyl-CoA hydratase deficiency	*AUH*
Disorders of vitamins, cofactors, metals, and minerals	
ISCA1 deficiency	*ISCA1*
ISCU deficiency	*ISCU*
NFS1 deficiency	*NFS1*
Ferredoxin 2 deficiency	*FDX2*
Multiple acyl-CoA dehydrogenase deficiency	*ETFDH, ETFA, ETFB*
Mitochondrial coenzyme A transporter deficiency	*SLC25A42*
Disorders of carbohydrates	
Lysosomal alpha-1,4-glucosidase deficiency	*GAA*
Amylo-1,6-glucosidase (debrancher) deficiency	*AGL*
Muscle phosphorylase deficiency	*PYGM*
Muscle phosphorylase kinase deficiency	*PHKA1*
Constitutional AMP-activated protein kinase activation	*PRKAG2*
LAMP2 deficiency	*LAMP2*
Muscle phosphofructokinase deficiency	*PFKM*
Aldolase A deficiency	*ALDOA*
Muscle phosphoglycerate kinase deficiency	*PGK1*
Muscle phosphoglycerate mutase deficiency	*PGAM2*
Beta-enolase deficiency	*ENO3*
Lactate dehydrogenase A deficiency	*LDHA*
Mitochondrial disorders of energy metabolism	
Mitochondrial complex I subunit deficiency (NDUFS6)	*NDUFS6*
Acyl-CoA Dehydrogenase 9 deficiency	*ACAD9*
Transmembrane protein 70 deficiency	*TMEM70*
Mitochondrial cytochrome b deficiency	*MTCYB*
Mitochondrial DNA polymerase gamma accessory subunit deficiency	*POLG2*
Mitochondrial thymidine kinase 2 deficiency	*TK2*
DNA2 helicase deficiency	*DNA2*
Mitochondrial ribonuclease H1 deficiency	*RNASEH1*
Mitochondrial elongation factor Ts deficiency	*TSFM*
Mitochondrial tRNA(Ala) deficiency	*MTTA*
Mitochondrial tRNA(Asp) deficiency	*MTTD*
Mitochondrial tRNA(Glu) deficiency	*MTTE*
Mitochondrial tRNA(Gly) deficiency	*MTTG*
Mitochondrial tRNA(Leu) 1 deficiency	*MTTL1*
Mitochondrial glutamyl-tRNA(Gln) amidotransferase subunit A deficiency	*QRSL1*
Mitochondrial glutamyl-tRNA(Gln) amidotransferase subunit C deficiency	*GATC*
MSTO1 deficiency	*MSTO1*
Tafazzin deficiency	*TAZ*
Valosin-containing protein superactivity	*VCP*
Pitrilysin metallopeptidase 1 deficiency	*PITRM1*
C1q binding protein deficiency	*C1QBP*
Mitochondrial calcium uniporter deficiency	*MICU1*
CHCHD10 deficiency	*CHCHD10*
CoQ2 deficiency	*COQ2*
Disorders of lipids	
Primary carnitine deficiency	*SLC22A5*
Carnitine palmitoyltransferase 2 deficiency	*CPT2*
Carnitine acylcarnitine translocase deficiency	*SLC25A20*
Very long-chain acyl CoA dehydrogenase deficiency	*ACADVL*
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	*HADHA*

Table 2.7 (continued)

Name	Gene
Trifunctional protein deficiency	*HADHB*
TANGO2 deficiency	*TANGO2*
Lipin 1 deficiency	*LPIN1*
Chanarin-Dorfman syndrome	*ABHD5*
Adipose triglyceride lipase deficiency	*PNPLA2*
Chylomicron retention disease	*SAR1B*
Mevalonate kinase deficiency	*MVK*
X-linked spinal and bulbar muscular atrophy, Kennedy disease	*AR*
Congenital disorders of glycosylation	
DPAGT1-CDG	*DPAGT1*
ALG14-CDG	*ALG14*
ALG2-CDG	*ALG2*
RFT1-CDG	*RFT1*
B4GALT1-CDG	*B4GALT1*
POMT1-CDG	*POMT1*
POMT2-CDG	*POMT2*
POMGNT1-CDG	*POMGNT1*
B3GALNT2-CDG	*B3GALNT2*
POMK-CDG	*POMK*
ISPD-CDG	*ISPD*
FKRP-CDG	*FKRP*
FKTN-CDG	*FKTN*
RXYLT1-CDG	*RXYLT1*
B4GAT1-CDG	*B4GAT1*
LARGE1-CDG	*LARGE1*
DPM1-CDG	*DPM1*
DPM2-CDG	*DPM2*
DPM3-CDG	*DPM3*
MPDU1-CDG	*MPDU1*
GNE myopathy	*GNE*
GFPT1-CDG	*GFPT1*
PGM1-CDG	*PGM1*
GMPPB-CDG	*GMPPB*
COG6-CDG	*COG6*
COG7-CDG	*COG7*
COG8-CDG	*COG8*
TRAPPC11-CDG	*TRAPPC11*
TMEM165-CDG	*TMEM165*
Lactate dehydrogenase (LDH) ↑	
Disorders of nitrogen-containing compounds	
Lysinuric protein intolerance	*SLC7A7*
Disorders of vitamins, cofactors, metals, and minerals	
Dihydrofolate reductase deficiency	*DHFR*
Disorders of carbohydrates	
Glucose-6-phosphate dehydrogenase deficiency	*G6PD*
Mitochondrial disorders of energy metabolism	
Pitrilysin metallopeptidase 1 deficiency	*PITRM1*
Alkaline phosphatase (ALP) ↑	
Disorders of nitrogen-containing compounds	
Sodium-dependent multivitamin transporter deficiency	*SLC5A6*
Disorders of carbohydrates	
Transaldolase deficiency	TALDO1
Mitochondrial disorders of energy metabolism	
Valosin-containing protein superactivity	*VCP*

(continued)

Table 2.7 (continued)

Name	Gene
Disorders of lipids	
3β-Hydroxy-Δ5-C27-steroid dehydrogenase/isomerase deficiency	*HSD3B7*
Δ4-3-Oxosteroid-5β-reductase deficiency	*AKR1D1*
Oxysterol 7α-hydroxylase deficiency	*CYP7B1*
Peroxisomal branched-chain acyl-CoA oxidase deficiency	*ACOX2*
Bile acid-CoA:aminoacid *N*-acyl transferase deficiency	*BAAT*
Congenital disorders of glycosylation	
PIGA-CDG	*PIGA*
PIGH-CDG	*PIGH*
PIGW-CDG	*PIGW*
PIGN-CDG	*PIGN*
PIGO-CDG	*PIGO*
PIGT-CDG	*PIGT*
GPAA1-CDG	*GPAA1*
PGAP1-CDG	*PGAP1*
PGAP3-CDG	*PGAP3*
PGAP2-CDG	*PGAP2*
PIGB-CDG	*PIGB*
PIGY-CDG	*PIGY*
Component of COG complex 4 deficiency COG4-CDG	*COG4*
ATP6AP1-CDG	*ATP6AP1*
TMEM199-CDG	*TMEM199*
CCDC115-CDG	*CCDC115*
Alkaline phosphatase (ALP) ↓	
Disorders of vitamins, cofactors, metals, and minerals	
Congenital hypophosphatasia	*ALPL*
Acrodermatitis enteropathica	*SLC39A4*
Urea ↓	
Disorders of nitrogen-containing compounds	
Ornithine transcarbamylase deficiency	*OTC*
Argininosuccinate synthetase deficiency	*ASS1*
Argininosuccinate lyase deficiency	*ASL*
Arginase 1 deficiency	*ARG1*
Mitochondrial ornithine transporter deficiency	*SLC25A15*
Urea ↑	
Disorders of vitamins, cofactors, metals, and minerals	
Methylmalonic aciduria due to methylmalonyl-CoA mutase deficiency	*MMUT*
Methylmalonic aciduria, cblB type	*MMAB*
Methylmalonic aciduria and homocystinuria, cblC type	*MMACHC*
Disorders of carbohydrates	
Transaldolase deficiency	*TALDO*
Disorders of lipids	
Lecithin cholesterol acyl transferase deficiency	*LCAT*
Disorders of peroxisomes and oxalate	
Peroxisomal alanine-glyoxylate aminotransferase deficiency	*AGXT*
Glyoxylate reductase/hydroxypyruvate reductase deficiency	*GRHPR*
Mitochondrial 4-hydroxy-2-oxoglutarate aldolase deficiency	*HOGA1*
Uric acid ↑	
Disorders of nitrogen-containing compounds	
Phosphoribosyl pyrophosphate synthetase 1 superactivity	*PRPS1*
Hypoxanthine guanine phosphoribosyltransferase deficiency	*HPRT1*
Methylmalonyl-CoA mutase deficiency	*MMUT*
Disorders of carbohydrates	
Fanconi-Bickel syndrome	*SLC2A2*
Fructose-1-phosphate aldolase deficiency	*ALDOB*
Glucose-6-phosphate translocase deficiency	*SLC37A4*

Table 2.7 (continued)

Name	Gene
Amylo-1,6-glucosidase (debrancher) deficiency	*AGL*
Muscle phosphorylase deficiency	*PYGM*
Liver glycogen phosphorylase deficiency	*PYGL*
Muscle phosphorylase kinase deficiency	*PHKA1*
Glucose-6-phosphatase deficiency	*G6PC*
Fructose-1,6-bisphosphatase deficiency	*FBP1*
Muscle phosphofructokinase deficiency	*PFKM*
Muscle phosphoglycerate mutase deficiency	*PGAM2*
Lactate dehydrogenase A deficiency	*LDHA*
Mitochondrial disorders of energy metabolism	
Mitochondrial seryl-tRNA synthetase deficiency	*SARS2*
Uric acid ↓	
Disorders of nitrogen-containing compounds	
Pyrimidine 5′-nucleotidase superactivity	*NT5C3A*
Purine nucleoside phosphorylase deficiency	*PNP*
Xanthine oxidase deficiency	*XDH*
Urate transporter 1 deficiency	*SLC22A12*
Urate voltage-driven efflux transporter 1 deficiency	*SLC2A9*
Disorders of vitamins, cofactors, metals, and minerals	
Molybdenum cofactor deficiency A	*MOCS1*
Molybdenum cofactor deficiency B	*MOCS2*
Molybdenum cofactor deficiency C	*GPHN*
Molybdenum cofactor sulfurase deficiency	*MOCOS*
Storage disorders	
Nephropathic cystinosis	*CTNS*
Ferritin ↑	
Disorders of nitrogen-containing compounds	
Lysinuric protein intolerance	*SLC7A7*
Mitochondrial glycine transporter deficiency	*SLC25A38*
Disorders of vitamins, cofactors, metals, and minerals	
Glutaredoxin 5 deficiency	*GLRX5*
Hereditary hemochromatosis	*HFE, HFE2, HAMP, TFR2*
Aceruloplasminemia	*CP*
Hyperferritinemia-cataract syndrome	*FTL*
Mitochondrial disorders of energy metabolism	
GRACILE syndrome	*BCS1L*
Mitochondrial deoxyguanosine kinase deficiency	*DGUOK*
Storage disorders	
Gaucher disease	*GBA*
Disorders of tetrapyrroles	
Erythroid 5-aminolevulinate synthase deficiency	*ALAS2*
Ferritin ↓	
Disorders of vitamins, cofactors, metals, and minerals	
Hypermanganesemia with dystonia type 1	*SLC30A10*
Disorders of tetrapyrroles	
Ferrochelatase deficiency	*FECH*
Erythroid 5-aminolevulinate synthase superactivity	*ALAS2*
Myoglobin (urine) ↑	
Disorders of vitamins, cofactors, metals, and minerals	
ISCU deficiency	*ISCU*
Ferredoxin 2 deficiency	*FDX2*
Disorders of carbohydrates	
Muscle phosphorylase deficiency	*PYGM*
Muscle phosphorylase kinase deficiency	*PHKA1*
Muscle phosphofructokinase deficiency	*PFKM*

(continued)

Table 2.7 (continued)

Name	Gene
Muscle phosphoglycerate kinase deficiency	*PGK1*
Muscle phosphoglycerate mutase deficiency	*PGAM2*
Beta-enolase deficiency	*ENO3*
Lactate dehydrogenase A deficiency	*LDHA*
Mitochondrial disorders of energy metabolism	
Mitochondrial cytochrome B deficiency	*MT-CYB*
Disorders of lipids	
Carnitine palmitoyltransferase 2 deficiency	*CPT2*
Carnitine acylcarnitine translocase deficiency	*SLC25A20*
Very long-chain acyl CoA dehydrogenase deficiency	*ACADVL*
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	*HADHA*
Trifunctional protein deficiency	*HADHB*
TANGO2 deficiency	*TANGO2*
Lipin 1 deficiency	*LPIN1*
Congenital disorders of glycosylation	
PGM1-CDG	*PGM1*
GMPPB-CDG	*GMPPB*
Hemoglobin ↓ (anemia)	
Disorders of nitrogen-containing compounds	
CAD trifunctional protein deficiency 50 CAD-CDG	*CAD*
Orotate phosphoribosyltransferase deficiency	*UMPS*
Pyrimidine-5′-nucleotidase I deficiency	*NT5C3A*
Adenylate kinase 1 deficiency	*AK1*
Gamma-glutamylcysteine synthetase deficiency	*GCLC*
Glutathione synthetase deficiency	*GSS*
Lysinuric protein intolerance	*SLC7A7*
Isobutyryl-CoA dehydrogenase deficiency	*ACAD8*
Propionyl-CoA-carboxylase deficiency PCCA	*PCCA, PPCB*
Methylmalonic aciduria due to methylmalonyl-CoA mutase deficiency	*MMUT*
Prolidase deficiency	*PEPD*
Mitochondrial glycine transporter deficiency	*SLC25A38*
Disorders of vitamins, cofactors, metals, and minerals

[a]Causes fasting hypoglycemia with postprandial hyperglycemia
[b]Causes pseudohyperglycemia, as some point-of-care glucometers will falsely read galactose as glucose (discrepancy between capillary bedside glucose and venous glucose)
[c]False elevation with the enzymatic method but not with Jaffé method

is structured according to the proposed nosology of IEMs (Ferreira et al. 2019), and information on diseases and corresponding laboratory tests was obtained from the knowledgebase of IEMs (Lee et al. 2018). The same information can be found in most chapters of this book. Care should be taken to not only interpret one clinical chemistry test result but also always review the other test results which may guide the diagnostic algorithm in a logical direction. As an example, low blood glucose together with low plasma free fatty acids and the absence of ketones will most likely be the result of endocrine anomalies (hyperinsulinism), whereas sharply increased levels of the free fatty acids generally indicate defects of the mitochondrial fatty acid beta-oxidation.

Summary

The measurement of amino acids in the blood, plasma, urine, and cerebrospinal fluid is essential for the diagnosis and monitoring of patients with different inherited metabolic diseases, including disorders of amino acid metabolism and transport, organic acidemias, and urea cycle defects. Measurement of amino acids in whole blood spotted on filter paper screens for many amino acidopathies and urea cycle defects in newborns. Plasma amino acids can identify patients with a suspected disorder of amino acid metabolism and/or aid in monitoring treatment. Urinary amino acids screen for disorders of amino acid transport (cystinuria, lysinuric protein intolerance, or Hartnup disease) or for generalized renal tubular dysfunction. The analysis of cerebrospinal fluid, usually in addition to plasma amino acids, is necessary in the evaluation of patients with neurometabolic disorders, such as glycine encephalopathy or disorders of serine metabolism. Traditionally, amino acids in biological fluids have been quantified by ion exchange chromatography using post-column derivatization with ninhydrin and spectrophotometric detection. Newer methodologies are based on liquid chromatographic separation with detection by mass spectrometry or spectrophotometry. Liquid chromatography/tandem mass spectrometry (LC-MS/MS) analysis of amino acids is becoming the method of choice by more and more laboratories because of its speed, sensitivity, and increased specificity. The interpretation of the results of plasma amino acid analysis requires the knowledge of metabolic disorders, availability of age-specific reference ranges, and consideration of physiological factors or medications affecting levels of individual or multiple amino acids.

Introduction

Amino acids are the building block of all proteins and are therefore of vital importance for the integrity of the organism. In addition, some amino acids play an additional important role as neurotransmitters (or their precursors), modulators of neurotransmitter action, precursors of hormones, cofactors, purine, and pyrimidines. Amino

acids, with a few exceptions, are water soluble due to the presence of both an amino and a carboxylic group that in water become ionized. Amino acids are filtered by the kidney and could be easily lost in urine in the absence of an efficient renal tubular reabsorption mechanism. There are several amino acid transporters whose deficiency can result in urinary loss of one or a group of amino acids and specific clinical manifestations. Excess amino acids are degraded by specific sets of enzymes, thereby generating energy and urea from the nitrogen group during catabolism. Defects in these enzymes cause inborn errors of amino acid metabolism, almost all of which are transmitted as autosomal recessive traits. This leads to either the buildup of the parent amino acid or its byproducts or of the catabolic products (organic acids) depending on the location of the enzyme block. The nitrogen group of the amino acid upon degradation will result in the formation of ammonia which is then removed by the urea cycle in the liver. The lack of an enzyme or transporter in this cycle will result in hyperammonemia. Accurate measurement of amino acids is essential to diagnose disorders of amino acid metabolism and to follow treatment in patients affected by aminoacidopathies, urea cycle disorders, organic acidemias, or disorders of amino acid transport. This chapter will discuss how amino acids are analyzed in biological fluids and the main alterations encountered in common disorders.

Table 3.1 Amino acid concentrations in plasma (μmol/L). The values represent the central 95% range of normal results by LC-MS/MS. Number of observations for each age group is indicated in parenthesis

Amino acid	<1 month (n = 600)	1–12 months (n = 1300)	>1 year (n = 4000)
Alanine	140–480	150–520	160–530

Valine	80–270	90–310	120–320

Preanalytical Conditions

Specimens

Amino acids can be measured in different sample types (whole blood, plasma, cerebrospinal fluid, urine) depending upon the reason for the amino acids analysis. Whole blood spotted on filter paper is used almost universally for neonatal screening of inherited disorders of metabolism. Analysis of amino acids in plasma represents the first approach to the study of a patient with a suspected disorder of amino acid metabolism (Table 3.1) (Held et al. 2011; Gregory et al. 1986; Applegarth et al. 1979; Armstrong et al. 2007). This will identify elevated phenylalanine in phenylketonuria, elevated branched-chain amino acids, and the presence of alloisoleucine in maple syrup urine disease, abnormalities of citrulline, and glutamine in different urea cycle defects. The study of urinary amino acids is performed to screen for disorders of amino acids transport, such as cystinuria, lysinuric protein intolerance, or Hartnup disease (Table 3.2) (Parvy et al. 1988). In addition, it is a useful test for renal tubular capacity that becomes abnormal in most cases of renal Fanconi syndrome. The analysis of cerebrospinal fluid (CSF), usually in addition to plasma amino acids, is necessary in the evaluation of patients with neurometabolic disorders, such as glycine encephalopathy or disorders of serine metabolism (Table 3.3) (Applegarth et al. 1979).

Amino acids can be measured also in other biological specimens, such as vitreous fluid (Table 3.4) (Honkanen et al. 2003; Bertram et al. 2008), especially in post-mortem samples, when urine is often not available and blood is unsuitable. However, this type of analysis should be limited to laboratories with experience in these studies, since post-mortem changes rapidly occur even in vitreous fluid. Amniotic fluid has limited value in prenatal diagnosis for aminoacidopathies. Unlike the organic acid disorders, in most amino acid disorders the metabolites do not accumulate before birth. Abnormal amino acid patterns in amniotic fluid have only been found in two of the urea cycle disorders, namely, argininosuccinate lyase deficiency (argininosuccinic acidemia) and argininosuccinate synthetase deficiency (citrullinemia type 1). Tables 3.1, 3.2, 3.3, and 3.4 (Held et al. 2011; Gregory et al. 1986; Applegarth et al. 1979; Armstrong et al. 2007; Parvy et al. 1988; Honkanen et al. 2003; Bertram et al. 2008) list amino acid reference ranges in the blood, urine, CSF, and vitreous fluid and are included as examples. However, it should be noted that, even when using the same

Table 3.2 Amino acid concentrations in urine expressed in μmol/g creatinine. The values represent the central 95% range of normal results by LC-MS/MS. Number of observations for each age group is indicated in parenthesis

method and instrumentation, reference values may vary from laboratory to laboratory. Each laboratory should establish its own reference ranges.

Patient Status/Patient Information

Clinical information is a necessary element for the accurate interpretation of amino acid profiles and to correctly diagnose patients with disorders of amino acid metabolism. Several common clinical features should prompt an investigation for a metabolic disorder. These include symptoms related to the CNS (lethargy, seizures, coma); GI tract (vomiting, poor feeding, failure to thrive); liver (hepatomegaly); cardiovascular, respiratory, and renal (kidney stones) systems; eye (lens dislocation, retinitis pigmentosa, optic atrophy); skeletal system; and skin. A positive family history (consanguineous parents, affected sibling or family member) and/or a positive newborn screen result should also initiate a diagnostic metabolic work-up. One should keep in mind that the same disease may present with different symptoms at different ages and that inherited disorders of metabolism are not limited to infants and children, with late-onset diseases presenting in adulthood as well. In other words, a metabolic disorder should not be dismissed because of age. Routine chemistry laboratory tests, such as blood gases, pH, electrolytes, anion gap, glucose, and ammonia, provide clues to the kind of metabolic disorder and guide the testing. These laboratory data, along with a brief clinical history, should be made available to the metabolic laboratory for better interpretation of the results. The physiological status of the patient is also important, since significant variations can be seen in post-prandial specimen, after prolonged fasting, and during catabolism. A list of medications taken at the time of specimen collection should also be provided, since some may interfere with the analysis or may cause alterations in the concentration of some amino acids, such as increased glycine levels secondary to valproate therapy.

Table 3.3 Normal range of amino acid concentrations in CSF, expressed in µmol/L, obtained by LC-MS/MS. The values represent the central 95% range of normal results by LC-MS/MS. Number of observations is indicated in parenthesis

Amino acid	µmol/L (n = 921)
Alanine	16–46
Arginine	8–31
Asparagine	4–13
Aspartate	≤5
Citrulline	≤5
Cystine	≤5
Glutamine	330–630
Glutamic acid	≤5
Glycine	5–20
Histidine	7–24

Methionine	2–7
Ornithine	≤10
Phenylalanine	6–20
Proline	≤5
Serine	18–66
Taurine	≤13
Threonine	14–59
Tryptophan	≤5
Tyrosine	5–23
Valine	8–30

Table 3.4 Concentrations of amino acids in vitreous fluid (average ± SD, µmol/L). Modified from Honkanen et al. (2003); Bertram et al. (2008)

Amino acid	µmol/L (n = 17)
Alanine	159.5 ± 54.9
Arginine	39.4 ± 16.3
Asparagine	35.8 ± 11.6
Aspartate	1.4 ± 1.0
GABA	0.6 ± 0.2
Glutamate	5.2 ± 2.3
Glutamine	1192.9 ± 404.4
Glycine	8.5 ± 2.5
Histidine	38.4 ± 10.0
Isoleucine	37.9 ± 11.6
Leucine	89.7 ± 28.4
Lysine	115.4 ± 33.7
Methionine	22.3 ± 8.1
Phenylalanine	44.4 ± 14.2
Serine	103.9 ± 24.4
Threonine	85.5 ± 28.4
Tyrosine	58.2 ± 18.8
Valine	112.0 ± 4.4

Specimen Collection

The timing of the specimen collection is important in the detection of metabolic disorders. In acutely ill patients, the blood and urine specimens on admission are likely to be most revealing and most appropriate for metabolic screening. It is good practice to save these specimens from all patients in whom the diagnosis is unclear. For the detection of amino-acidopathies, this is not as critical as it is for other metabolic disorders. For amino acid analysis, the volume of specimen required depends on the methodology used, typically 100–500 µL of plasma or CSF are required. The volume of urine required varies depending on creatinine concentration; each laboratory should list the minimum volumes acceptable for each analysis.

For the diagnosis of most amino acid disorders, blood specimens collected after an overnight fast are preferred or, alternatively, at least 3 h after a meal. Samples from young infants should be collected immediately before the next scheduled feeding (at least 2–3 h after the last feeding). For hyperammonemia screening, postprandial samples are more suited since elevation of blood ammonia may be intermittent and present only in the fed state. It is not uncommon for a laboratory to receive a sample for amino acid analysis collected while the patient is receiving intravenous hyperalimentation. These samples are often uninterpretable as they show elevations in all the amino acids present in the IV solution. If it is possible, intravenous hyperalimentation should be discontinued for at least 2–3 h prior to specimen collection. If intravenous hyperalimentation cannot be discontinued, appropriate care should be taken in drawing the sample away from the site of entry of the solution.

The concentration of the majority of the physiological amino acids is the same in red blood cells and in plasma, with exception of taurine, glutamate, aspartate, and argininosuccinate. Thus, hemolyzed samples may show an increased concentration of these amino acids. The enzyme arginase converts arginine into ornithine and urea and is expressed in red blood cells. Hemolysis will release arginase in the plasma causing hydrolysis of arginine. Therefore, a decrease in arginine with an increase in ornithine is often seen in hemolyzed samples.

Whole blood collected for amino acids analysis should be spun down as soon as possible; the plasma should be kept frozen during transport and until analysis is performed. Refrigerated conditions may be acceptable for a short period of time. Improper handling of specimens can result in artifactual changes in the amino acid contents. Table 3.5 lists possible artifacts due to collection, handling, and storage of samples.

Table 3.5 Collection, handling, and storage artifacts

Factor/condition	Source	Amino acid(s) affected	Value

B blood, *U* urine, *H* increased, *L* decreased

The conversion of arginine into ornithine by arginase can be observed even in unspun samples left at room temperature, even without obvious hemolysis. Free cystine and homocystine bind to protein and will be lost in samples that are not spun immediately and/or are stored for a prolonged period of time. The loss of cystine and homocystine is evident even when samples are stored at −20 °C, while storage at −70 °C prevents this effect. Glutamine is unstable and breaks down with prolonged storage resulting in increased glutamate.

If serum is used for amino acids analysis, depending on how it has been obtained, all the artifacts listed above could be present. Low serine in urine may be due to bacterial contamination, and the presence of hydroxyproline can be due to fecal contamination. Urine is not the fluid of choice in the diagnostic investigation of an aminoacidopathy (phenylketonuria, maple syrup urine disease, homocystinuria, etc.) as plasma is a better sample type. Urine amino acids analysis is, instead, the diagnostic test when disorders of amino acid transport are investigated (cystinuria, lysinuric protein intolerance, Hartnup) or in prolidase deficiency. Although a random specimen is usually sufficient for diagnostic purposes, a timed urine collection may be required for reabsorption studies in conjunction with a plasma sample collected at mid-point. Results of urine amino acids analysis are usually reported in reference to creatinine; however for samples very diluted or very concentrated, this correction may not be very accurate. The interpretation of urine amino acids relies on patterns of amino acids more than on absolute values; therefore, a careful examination of the profile should lead to a correct diagnosis. Tables 3.5, 3.6, 3.7, and 3.8 list artifacts due to specimen collection as well as the effect of nutritional status, illnesses, and medications on amino acids values.

Analysis

Amino acids studies are performed for (1) diagnostic purposes and (2) monitoring of therapy in patients with a known metabolic disorder. Methods for amino acids analysis should be sensitive (to identify even very low concentration of

amino acids), specific (to separate isomeric species), and accurate (to enable monitoring of dietary therapy).

Paper chromatography, thin-layer chromatography, and two-dimensional chromatography by high-voltage electrophoresis for amino acids screening have been used in the past, but are now obsolete and should not be used for amino acids screening.

Quantitative analysis of amino acids in physiological fluids can be performed by ion-exchange chromatography (IEC), reverse-phase high-performance liquid chromatography (HPLC), gas-chromatography (GC), and liquid chromatography/tandem mass spectrometry (LC-MS/MS).

IEC has been the most widely used method in clinical laboratories, and it is still considered the gold standard for amino acid analysis. With this technique, amino acids are separated using a cation-exchange column and a lithium buffer system. The detection is performed by colorimetry after post-column derivatization with ninhydrin. The adduct between ninhydrin and primary amines has a maximum absorbance at wavelength λ_{max} = 570 nm, while the adduct between ninhydrin and secondary amines (hydroxyproline, proline) has a λ_{max} = 440 nm. The samples are monitored at both wavelengths to allow quantification of all physiological amino acids. This method is highly reproducible, with a wide dynamic range and excellent linearity range (5–3000 μmol/L). The disadvantage of the method is the long analysis time (90–150 min) and the lack of specificity. In fact several metabolites other than amino acids, including medications and dietary supplements, react with ninhydrin and coelute with amino acids. This is particularly challenging when evaluating urine samples. Depending on the methodology used, special processing of the sample is required to identify and quantify certain amino acids. A classic example is argininosuccinic acid. With IEC the free acid elutes in the region of neutral amino acids, often coeluting with tyrosine or leucine, depending on the buffer system and column used. Conversion of the free acid into anhydrides by boiling the deproteinized sample increases sensitivity and allows more accurate results.

HPLC-based methods usually require a pre-column derivatization step with chemicals that react with the primary or secondary amino group of amino acids to form derivatives detectable with fluorescent, UV, or electrochemical detectors. The analysis time of these methods is shorter than ion-exchange chromatography, but sample preparation is more laborious and the derivatives may be instable. In addition, the sensitivity for some critical amino acids, such as alloisoleucine (the diagnostic amino acid for maple syrup urine disease), argininosuccinic acid (the diagnostic amino acid

for argininosuccinic acid lyase deficiency), and homocystine may not be sufficient to identify mild elevations of these amino acids and some patients can be missed.

Tandem mass spectrometry analysis of amino acids by flow injection is routinely used for neonatal screening using whole blood spotted on filter paper. Amino acids are extracted from the blood spot using an organic solvent (methanol) containing stable-isotope-labeled amino acids. The limitation of this method is that isomers and isobars cannot be separated; however, the speed of the analysis makes it a superb screening method. For diagnostic and/or monitoring purposes, similar methods can be used, and to increase the specificity, a liquid chromatographic separation is performed prior to MS/MS detection. **Liquid chromatography/tandem mass spectrometry** (LC-MS/MS) analysis of amino acids in physiological fluids is now the method of choice by more and more laboratories, because of its speed, sensitivity, and increased specificity. Accurate quantitation by MS/MS requires the use of stable-isotope-labeled internal standards; ideally each amino acid quantified should have its internal standard. The detection of amino acids by MS/MS is usually done using selective reaction monitoring (SRM); therefore, the analysis is targeted. This method will not detect unusual amino acids, such as cystinylglycine (characteristic of gamma glutamyltranspeptidase deficiency), unless they are included in the method. As a consequence, amino acids analysis methods available for clinical diagnostic application are not suitable for new discovery. With the use of MS/MS for neonatal screening, milder variants of metabolic disorders are now identified, and the biochemical phenotype may be more subtle. Good communication between the testing laboratory and the physicians helps in clarifying these cases.

The method used for quantifying amino acids in physiological fluids should also have a wide dynamic range, high sensitivity, sufficient to measure concentrations as low as a few micromoles/liter, and high upper limit of linearity, to accurately quantify high concentrations of amino acids for diet/therapy monitoring. Citrulline, alloisoleucine, argininosuccinic acid, and free homocystine are examples of amino acids requiring high sensitivity, with citrulline and argininosuccinic acid requiring also high upper limit of linearity. It is important to be able to detect even trace amounts of these amino acids to reach a correct diagnosis. LC-MS/MS-based methods are usually highly sensitive and specific; however, their dynamic range may not be as good as IEC.

Interpretation of Amino Acids Results and Reference Values

Clinical information, age of the patient, diet, and medications are critical to provide an accurate interpretation for metabolic testing in general, including amino acids analysis. The interpretation of amino acid profiles relies on pattern recognition; therefore, laboratories should be familiar with metabolic disorders and the changes observed in presence of a metabolic block. In the past when most laboratories used similar methods, amino acids were reported in the order of chromatographic separation. With the advent of different methodologies, many laboratories report amino acids in alphabetical order to facilitate their reading and personal interpretation by referring physicians. All of our tables now report them in alphabetical order.

Age. The normal concentration range of most amino acids changes with age, and appropriate reference ranges are essential for accurate interpretation. Renal tubular function is not mature in many infants who can have generalized aminoaciduria until several months of age. Homocitrulline in the urine of infants is usually derived from diet and is only rarely due to a metabolic disorder. Taurine is normally excreted in large amounts in the first week of life and decreases thereafter. However, the urine from infants less than 1 year of age often contains taurine from breast milk and/or taurine-supplemented formula, and the amount can fluctuate widely depending on the time of urine collection in relation to the time of feeding. Taurine is not detected in urine from infants fed unsupplemented formulas. Taurine is a constituent of several energy drinks and can increase in adolescents and young adults consuming these products. Administration of parenteral amino acid solutions can also cause altered blood amino acid patterns.

The urinary excretion of glycine is quite variable. It can be of dietary origin (e.g., gelatin) as well as secondary to medication (e.g., valproate). Persistent isolated hyperglycinuria with normal plasma glycine levels suggests familial iminoglycinuria that is usually a benign variant. Urine histidine is increased during pregnancy. The concentration of plasma amino acids is low compared to normal controls during pregnancy, especially in the last trimester, due to hemodilution.

In young infants, particularly in preterm infants, the quantity and quality of protein feeding has a direct effect on the plasma amino acid concentrations. The postprandial rise of total amino acids is more pronounced in infants on higher protein feeding. Transient hypertyrosinemia and hypermethioninemia can result from excessive protein load such as with the use of non-infant milk. The same pattern of elevation can be seen in premature infants or infants with immature hepatocellular function. Table 3.6 lists the most common effects of diet and nutritional status on amino acid values.

Circadian rhythm is a physiological basis for higher amino acid concentrations, up to 10–15%, in the blood in the afternoon. A mild generalized increase in urine amino acids is a relatively common finding in hospitalized children. Branched-chain amino acids are elevated in blood of patients with maple syrup urine disease; however, in these patients the presence of alloisoleucine allows the correct

interpretation of the results. Vomiting and poor oral intake for 1–2 days may cause mild elevations (two- to three-fold) of the plasma branched-chain amino acids, and this should not be mistaken as a disease pattern. In a patient with MSUD and metabolic decompensation, the pattern of branched-chain amino acids will show a disproportionately high leucine compared to isoleucine and valine and a markedly reduced alanine in addition to the presence of alloisoleucine. With ion-exchange chromatography, alloisoleucine coelutes with cystathionine, and laboratories using this method should develop protocols to distinguish the two amino acids, such as the evaluation of the ratio of the absorbance at 570 nm and 440 nm, which is much lower for cystathionine as compared to alloisoleucine.

Secondary amino acid changes can be a clue to other types of metabolic disorders such as galactosemia, organic acidemias, and disorders of pyruvate metabolism.

Gross elevations of many amino acids, particularly glutamine and alanine in blood, have been reported in moribund children; however, elevations of the branched-chain amino acids, citrulline, and arginine can be secondary to hypoxia and liver failure. Post-mortem blood shows similar but more pronounced amino acid changes (Table 3.7).

Citrulline is the amino acid critical in identifying disorders of the urea cycle. It is absent or markedly reduced in proximal blocks of the urea cycle (NAGS, CPS1, OTC deficiencies); it is markedly elevated in citrullinemia type I (argininosuccinate synthase deficiency) and, to a lower extent, in argininosuccinic aciduria (argininosuccinate lyase deficiency); and it is moderately but variably elevated in citrullinemia type II (citrin deficiency). Citrulline can also be used to assess functional enterocyte mass in patients with necrotizing enterocolitis, short bowel syndrome, and intestinal transplant. Very low levels of citrulline can be seen in these patients, usually with a completely normal concentration of all other amino acids, including glutamine.

Several medications can affect the levels or interfere with quantitation of amino acids in blood and urine (Table 3.8). The use of disulfide agents, such as penicillamine, can result in the formation of unusual amino acids whose quantitation can help in determining compliance with therapy.

Table 3.9 lists the amino acids and the disorders in which the amino acid level is abnormal. An abnormal concentration of an amino acid may be suggestive of several different inborn errors. Conversely, some disorders are characterized by abnormalities in several different amino acids, and analysis of the pattern of variation is more important than analysis of a single amino acid level in establishing a diagnosis. This table serves as a quick guide to more detailed information found in other chapters in this book.

Table 3.9 Pathologic conditions associated with abnormal amino acids concentrations

Amino acid	Source	Disorder(s)	Value
All amino acids	U	Classic galactosemia, Renal Fanconi syndrome, Lowe syndrome	↑ H
All amino acids	U	Tyrosinemia type 1, hereditary fructose intolerance	↑ H
All amino acids	U	Vitamin D-dependent rickets, mitochondrial disorders	↑ H
Neutral amino acids	U	Hartnup disorder	↑ H
Alanine	P	Lactic acidosis, disorders of pyruvate metabolism, mitochondrial disorders, hyperammonemic syndromes, glucagon receptor defect	↑ H
Alanine	P	Maple syrup urine disease	↓ L
β-Alanine	P/U	β-Alaninemia	↑ H
β-Alanine	CSF	GABA-transaminase deficiency	↑ H
β-Alanine	U	Pyrimidine disorders, methylmalonate semialdehyde dehydrogenase deficiency	↑ H
Allo-isoleucine	P/U/CSF	Maple syrup urine disease, E_3 deficiency	↑ H
α-Aminoadipic	U	α-Aminoadipic/α-Ketoadipic aciduria	↑ H

Abstract

Organic acid disorders (OAD) are a relevant group of inborn errors of metabolism (IEM), not only in severely ill children but in adults as well, namely, with neurological symptoms. OAD are due to defect in intermediary metabolic pathways of carbohydrate, amino acids, lipids, Krebs cycle, vitamins, and nucleic acids, leading to the accumulation in the body fluids of the so-called organic acids, the metabolic pathways' intermediates. Analysis of organic acids profiles is a powerful tool for the IEM differential diagnosis. Herein, an updated reference guide in OAD is presented, incorporating the affected protein, the altered gene, and the organic acids with diagnostic value. Valuable clues for the correct interpretation of an organic acids profile are discussed with focus on some puzzling organic acids and on the artefacts arising from diet, gut bacterial action, drugs, and sample bacterial contamination.

Introduction

Organic acid disorders (OAD) are a relevant group of inborn errors of metabolism (IEM), not only in severely-ill children but as well in adults, namely, with neurological symptoms.

OAD are due to defects in intermediary metabolism of various cellular components, such as amino acids, lipids, carbohydrates, Krebs cycle, vitamins, nucleic acids, and steroids. It gives rise to the accumulation, in tissues and body fluids, of diverse metabolic pathways' intermediates: the organic acids. More than 65 organic acidurias have been described; the incidence varies, individually, from 1 out of 10,000 to >1 out of 1,000,000 live births. Collectively, their incidence approximates 1 out of 3000 live births (Villani et al. 2017).

Organic acids are low-molecular weight (mass < 300) organic substances, with one or more carboxylic acid groups, and may have keto or hydroxy groups, making them polar compounds. Over all, the physiological organic acids are weak acids, which implies that they are fully ionized at pH > 4, i.e., values observed in plasma or urine. Consequently, accumulation of organic acids in the blood ("acidemia") will lead to a shift in blood pH to lower values with the emerging of the so-called metabolic acidosis, which is accompanied by a negative base excess as well as an increased anion gap. The organic acids are strongly hydrophilic compounds enabling their rapid excretion into the urine ("aciduria"), the preferably biological fluid for the analysis of organic acids. Fatty

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_4

acids with chain length > C_8 such as lauric, palmitic, and oleic acids are non-polar organic acids, which are bound to plasma proteins and are not excreted into the urine.

Physiologically, organic acids are often present as their coenzyme A esters; good examples are propionyl-CoA and isovaleryl-CoA. To facilitate its excretion, the metabolites are conjugated with carnitine or glycine, a process similar to the one leading to the production of acylglucuronides. Formation of acylcarnitines and acylglycines can be regarded as a process aimed at restoring the coenzyme A homeostasis, being at the same time a process of detoxification of the harmful organic acids.

From a biochemical point of view, OAD are characterized by the accumulated organic acids, in body fluids, which may display a panel of organic acids, more or less specific, incorporating primary and unusual secondary metabolites, the by-products of alternative metabolic pathways, as well as specific acylcarnitines and/or acylglycines, often crucial in the unequivocal characterization of the OAD and a single pathognomonic metabolite (cf. *N*-acetylaspartic acid in Canavan disease) or the "normal" physiological metabolites in enhanced concentration (cf. methylmalonic acid in VitB_{12} deficiency).

Organic acid analysis is a key diagnostic hint for the achievement of the differential diagnosis in systemic intoxication, in unexplained metabolic crisis, or in the presence of inexplicable routine biochemical findings such as metabolic acidosis, altered anion gap, and hypoglycemia among others. Amino acids and lipid intermediary metabolic defects, namely, branched chain amino acids and fatty acids catabolic pathways, are the leading causes of organic acidurias. Nevertheless, several hundreds of other organic acids or similar structural compounds with diagnostic value can be identified in a single run; typical examples are orotic acid, thymine, and uracil and their respectively di-hydro derivatives, glycerol, and several others derived from medication or diet. Key metabolites reference guide that may allow the biochemical diagnosis or raise the suspicion of an organic aciduria is shown in Table 4.1, which is organized, whenever possible, according the IEM-adopted classification in this book.

Organic acid analysis by gas chromatography-mass spectrometry (GC/MS) is a powerful methodology providing the identification of normal and abnormal acids, which have allowed for the discovery of new disorders and the biochemical characterization of a great set of diseases. The complementation with acylcarnitine analysis becomes the basis of the expanded newborn screening by tandem mass spectrometry (MS/MS) (McHugh et al. 2011).

Preanalytical Conditions

Organic acids are, in general, highly water-soluble compounds and, thus, efficiently excreted by the kidney leading to their accumulation in urine. Therefore, urine is the biological fluid of choice for the evaluation of organic acid profiles. Other biological fluids such as plasma, CSF, or vitreous humor may be used when urine is not available.

A random urine sample is usually used for the organic acid analysis. The timing of the urine collection is not really important. If the sample collection is planned, the first morning specimen is requested. The chance to detect metabolites with low concentration will be higher as well as the probability to detect key metabolites in patients with fasting intolerance. Whenever an organic acid profile is unclear and does not allow a solid diagnosis, the use of in vivo loading tests is advocated because these tests have proven to substantially enhance the organic acid excretion (Garcia-Villoria et al. 2009). A 24-h urine collection may be requested in special occasions in the follow-up of patients, e.g., in the process of treatment monitoring. For post-mortem screening of organic aciduria, urine should be obtained via bladder puncture. In order avoid as much as possible artefactual alterations, the samples should be kept at −20 °C and shipped frozen. The more unstable organic acids (cf. ketoacids) may be degraded, and several organic acids, namely, the tricarboxylic acids, may be decreased and/or enhanced by bacterial contamination activity.

Diet and drugs are the main disturbing factors of the organic acid profile and may cause serious interpretative difficulties. The best known dietary disturbances are those caused by the use of medium-chain triglyceride containing diets giving rise to the excretion of C_6-C_{10} dicarboxylic acids as well as (ω-1)-hydroxy acids. Also partially hydrolyzed protein sources in infant formula may pose problems due to the interfering components/additives, e.g., dioctyl phthalate, which appears in the organic acid chromatogram. Various dietary carbohydrates do not survive the food processing steps and may give rise to artefacts such as furane-2,5-dicarboxylic acid, 2,4-dihydroxybutyric acid, or glucosan (Table 4.2).

For the correct evaluation of the organic acid profiles, it is mandatory to have precise information concerning the type of diet; the drugs, including vitamers; and the natural supplements under which the patients are submitted or have been, at least 48 h before sample collection.

Analysis/Methods

The gold standard method for the analysis of organic acids in a biological matrix is gas-chromatography coupled with a mass spectrometry detector (GC-MS). Accordingly, the compounds of interest must be isolated from the sample's matrix and further transformed in derivatives suitable for GC-MS analysis.

The extraction of the organic acids is accomplished by solid-phase or liquid-liquid extraction, the latter one being the most widely used. For standardization of the method and internal quality control, one or two internal standards (non-physiological organic acid), such as 2-phenylbutyric acid or pentadecanoic acid, are added to the sample prior the extraction procedure.

Table 4.1 Key metabolite reference guide in organic acids analysis. Symbol (#) shows the corresponding chapter number where the disorder is presented according the classification used throughout this book

Disorder	Affected protein	Altered gene	Key metabolites/profiles	Ch. #
Organic acid disorders in aromatic amino acid metabolism				
Phenylketonuria (PKU)	Phenylalanine hydroxylase	*PAH*	2-Hydroxyphenylacetic acid Phenyllactic acid Phenylacetic acid Phenylpyruvic acid Mandelic acid	20
Tyrosinemia Type I	Fumarylacetoacetase	*FAH*	4,6-Diketoheptanoic acid (=succinylacetone) *N*-Acetyl-tyrosine 4-Hydroxyphenyllactic acid 4-Hydroxyphenylpyruvic acid 4-Hydroxyphenylacetic acid	21
Tyrosinemia Type II Tyrosinemia Type III	Tyrosine aminotransferase 4-Hydroxyphenylpyruvate dioxygenase	*TAT* *HPD*	4-Hydroxyphenyllactic acid 4-Hydroxyphenylpyruvic acid 4-Hydroxyphenylacetic acid *N*-Acetyl-tyrosine	21
Hawkinsinuria	4-hydroxyphenylpyruvate dioxygenase	*HPD*	4-Hydroxycyclohexylacetic acid	21
Alkaptonuria	Homogentisic acid oxidase	*HGD*	Homogentisic acid	21
Organic acid disorders in branched-chain amino acid metabolism				
Maple Syrup Urine Disease (MSUD): MSUD Type 1a MSUD Type 1b MSUD Type 2 BCKDC (PDHC/α-KDHC) deficiency	Branched-chain 2-ketoacid dehydrogenase complex (BCKDC): E1α subunit deficiency/BC ketoacid dehydrogenase E1β subunit deficiency/BC ketoacid dehydrogenase E2 subunit deficiency/Dihydrolipoyl transacylase E3 subunit deficiency/Dihydrolipoyl dehydrogenase	*BCKDHA* *BCKDHB* *DBT* *DLD*	2-Ketoisocaproic acid 2-Ketoisovaleric acid 2-Keto-3-methylvaleric acid 2-Hydroxyisocaproic acid 2-Hydroxyisovaleric acid 2-Hydroxy-3-methylvaleric acid (lactic and ketoglutaric acids)	23
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	*IVD*	Isovalerylglycine 3-Hydroxyisovaleric acid Isovalerylglutamic acid	23
3-Methylcrotonylglycinuria	3-Methylcrotonyl-CoA carboxylase	*MCCC1* *MCCC2*	3-Methylcrotonylglycine 3-Hydroxyisovaleric acid	23
3-Methylglutaconic aciduria Type 1	3-Methylglutaconyl-CoA hydratase	*AUH*	3-Methylglutaconic acid 3-Methylglutaric acid 3-Hydroxyisovaleric acid	23
3-Hydroxy-3-methylglutaric aciduria	3-Hydroxy-3-methyl-glutaryl-CoA lyase	*HMGCL*	3-Hydroxy-3-methylglutaric acid 3-Methylglutaconic acid 3-Methylglutaric acid 3-Hydroxyisovaleric acid Glutaric acid 3-Methylcrotonylglycine C6-C10 Dicarboxylic acids	23

Table 4.1 (continued)

Disorder	Affected protein	Altered gene	Key metabolites/profiles	Ch. #
2-Methylbutyrylglycinuria	2-Methylbutyryl-CoA dehydrogenase	*ACADSB*	2-Methylbutyrylglycine	23
2-Methyl-3-hidroxybutyric acidúria/HSD10 disease	2-Methyl-3-hydroxybutyryl-CoA dehydrogenase	*HSD17B10*	2-Methyl-3-hydroxybutyric acid Tiglylglycine Ethylhydracrylic acid	23
2-Methylacetoacetic aciduria/β-Ketothiolase deficiency	3-Oxothiolase (mitochondrial)	*ACAT1*	2-Methyl-3-ketobutyric acid 2-Methyl-3-hydroxybutyric acid Tiglylglycine 2-Ethylhydracrylic acid	23
Isobutyrylglycinuria	Isobutyryl-CoA dehydrogenase	*ACAD8*	Isobutrylglycine	23
Mitochondrial short-chain enoyl-CoA hydratase 1 deficiency	Mitochondrial short-chain enoyl-CoA hydratase (Crotonase)	*ECHS1*	2-Methyl-2-3-dihydroxy-butyrate 3-Methylglutaconic acid	23
Methacrylic aciduria	3-Hydroxyisobutyryl-CoA deacylase	*HIBADH*	NONE, cf. 3-hydroxyisobutyryl-carnitine	23
3-Hydroxyisobutyric aciduria	3-Hydroxyisobutyrate dehydrogenase	*HIBCH*	3-Hydroxyisobutyric acid 3-Hydroxypropionic acid 2-Ethyl-3-hydroxy-propionic acid Isobutyrylglycine	23
Methylmalonic semialdehyde dehydrogenase deficiency	Methylmalonic semialdehyde dehydrogenase	*ALDH6A1*	Methylmalonic acid 3-Hydroxyisobutyric acid 3-Hydroxypropionic acid	23
Propionic aciduria	Propionyl-CoA carboxylase α-subunit Propionyl-CoA carboxylase β-subunit	*PCCA* *PCCB*	3-Hydroxypropionic acid Methylcitric acid 2-Methyl-3-hydroxybutyric acid 3-Hydroxyvaleric acid Propionylglycine	23
Isolated methylmalonic aciduria	Methylmalonyl-CoA epimerase Methylmalonyl-CoA mutase Mitochondrial Cbl transporter, CblA type Cobalamin adenosyltranferase, CblB type Cobalamin D-MMA type SUCLA2; SUCLG1 (*vd.*Krebs cycle)	*MCEE* *MUT* *MMAA* *MMAB* *MMADHC*	Methylmalonic acid 3-Hydroxypropionic acid Methylcitric acid 2-Methyl-3-hydroxybutyric acid 3-Hydroxy-valeric acid	23
Malonic aciduria	Malonyl-CoA decarboxylase	*MLYCD*	Malonic acid	23
Combined methylmalonic and malonic aciduria	Acetyl-CoA synthase (family member 3)	*ACSF3*	Methylmalonic acid Malonic acid	23
Ethylmalonic aciduria (SCAD deficiency and ETHE1 encephalopathy)	Ethylmalonyl-CoA decarboxylase	*ECHDC1*	Ethylmalonic acid	–
Organic acid disorders in lysine and hydroxylysine metabolism				
2-Amioadipic and 2-ketoadipic aciduria	2-Ketoadipic acid dehydrogenase (?)	*DHTKD1*	2-Ketoadipic acid 2-Hydroxyadipic acid Dicarboxylic acids	–
Glutaric aciduria Type I	Glutaryl-CoA dehydrogenase	*GCDH*	Glutaric acid 3-Hydroxyglutaric acid Glutaconic acid	69
Glutaric aciduria Type III	Succinyl-CoA:glutarate-CoA transferase	*SUGCT (C7orf10)*	Glutaric acid	–

Organic acid disorders in (mitochondrial) fatty acid oxidation metabolism				
Short-chain acyl-CoA dehydrogenase deficiency (Ethylmalonic aciduria)	Short-chain acyl-CoA dehydrogenase (SCAD)	*ACADS*	Ethylmalonic acid Methylsuccinic acid	48
Medium-chain acyl-CoA dehydrogenase deficiency	Medium-chain acyl-CoA dehydrogenase (MCAD)	*ACADM*	Dicarboxylic acids (sat/unsat.) Hexanoylglycine Suberylglycine 5-Hydroxyhexanoic acid 3-Hydroxysebacic acid Phenylpropionylglycine	48
Very long-chain acyl-CoA dehydrogenase deficiency	Very long-chain acyl-CoA dehydrogenase (VLCAD)	*ACADVL*	Dicarboxylic acids (sat/unsat)	48
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency Mitochondrial trifunctional protein deficiency	Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) Mitochondrial trifunctional protein (MTP)	*HADHA* *HADHB*	3-Hydroxyadipic acid + lactone 3-Hydroxydicarboxylic acids Dicarboxylic acids (sat/unsat)	48
Short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	Short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD)	*HADHSC*	L-3-Hydroxybutyric acid 3-Hydroxyglutaric acid	48
Multiple acyl-CoA dehydrogenase deficiency	(*vd.* riboflavin metabolism)	–		32
Organic acid disorders in ketones bodies metabolism				
Succinyl-CoA:3-ketoacid-CoA transferase deficiency Monocarboxylate transporter1 deficiency	Succinyl-CoA:3-ketoacid transferase (SCOT) Monocarboxylate transporter1 (MCT1)	*SCOT* *MCT1*	3-Hidroxybutyric acid 2-Hydroxybutyric acid Acetoacetic acid	50
Organic acid disorders in Krebs cycle				
2-Ketoglutarate dehydrogenase complex (KGDHC): 2-Ketoglutarate dehydrogenase deficiency KGDHC (plus BCKDC/PDHC)	2-Ketoglutarate dehydrogenase (KGDHC-E1 subunit) Dihydrolipoyl succinyltransferase (KGDHC-E2 subunit) Dihydrolipoyl dehydrogenase (KGDHC-E3 subunit)	*OGDH* *DLST* *DLD*	2-Ketoglutaric acid Lactic acid Plus branched chain keto acids/2-hydroxy-keto acids	42
ATP-specific succinyl-CoA ligase β subunit deficiency GTP-specific succinyl-CoA ligase α subunit deficiency	Succinyl-CoA ligase β subunit (SUCLA2) Succinyl-CoA ligase α subunit (SUCLG1)	*SUCLA2* *SUCLG1*	Methylmalonic acid Succinic acid	42
Fumaric aciduria	Fumarase	*FH*	Fumaric acid	42
Malate dehydrogenase deficiency	Malate dehydrogenase	*MDH2*	Citric acid Fumaric acid Malic acid Succinic acid	42
Organic acid disorders in oxalate metabolism				
Primary hyperoxaluria type I	Alanine-glyoxylate amino-transferase	*AGXT*	Oxalic acid Glycolic acid Glyoxylic acid	67
Primary hyperoxaluria type II	Glyoxylate reductase	*GRHPR*	Oxalic acid l-Glyceric acid	67
Primary hyperoxaluria type III	4-Hydroxy-2-oxoglutarato aldolase, mitochondrial	*HOGA1*	Oxalic acid Glycolic acid	67

Disorder	Affected protein	Altered gene	Key metabolites/profiles	Ch. #
Organic acid disorders in pyruvate metabolism				
Pyruvate carboxylase deficiency	Pyruvate carboxylase (PC)	*PC*	Lactic acid; Pyruvic acid 3-Hydroxybutyric acid; acetoacetic acid 2-ketoglutaric acid; Succinic acid Malic acid; Fumaric acid	42
Pyruvate dehydrogenase complex (PDHC): Pyruvate dehydrogenase deficiency PDHC (plus BCKDC / KDHC) deficiency	Pyruvate dehydrogenase (E1α–subunit) Pyruvate dehydrogenase (E1β–subunit) Dihydrolipoyl acetyltransferase (E2-subunit) PDH- componente X Dihydrolipoamide dehydrogenase (PDHC-E3 subunit)	*PDHA* *PDHB* *DLAT* *PDHX* *DLD*	Lactic acid Pyruvic acid Plus branched chain keto acids/2-hydroxy-keto acids	42
D-Lactic aciduria[a]	D-Lactate Dehydrogenase	*LDHD*	D-Lactic acid	–
Diverse organic acid disorders				
Aromatic L-amino acid descarboxylase deficiency	Aromatic L-amino acid descarboxylase (AADC)	*AADC*	3-Methoxy-4-hydroxyphenyl-lactic acid (Vanillactic acid)	19
Canavan disease	Aspartoacylase	*ASPA*	*N*-acetylaspartic acid	69
Ethylmalonic encephalopathy (ETHE)	Mitochondrial sulfur dioxygenase (ETHE1 protein)	*ETHE1*	Ethylmalonic acid Isobutyryl/Isovaleryl-glycine	–
D-Glyceric aciduria	Glycerate kinase	*GLYCTK*	D-Glyceric acid	49
Glycerol kinase deficiency	Glycerol kinase	*GK*	Glycerol	49/46
4-Hydroxybutyric aciduria	Succinic-semialdehyde dehydrogenase	*ALDH5A1*	4-Hydroxybutyric acid + lactone Erythro-/threo- 4,5-dihydroxy-octanoic acids 2,4-dihydroxybutyric acid	24
L-2-Hydroxyglutaric aciduria	L-2-Hydroxyglutaric acid dehydrogenase	*L2HGDH*	L-2-Hydroxyglutaric acid + lactone	69
D-2-Hydroxyglutaric aciduria type I D-2-Hydroxyglutaric aciduria type II	D-2-Hydroxyglutaric acid dehydrogenase Isocitrate dehydrogenase 2	*D2HGD* *IDH2*	D-2-Hydroxyglutaric acid + Lactone	69
Methylglutaconic acidurias (MGA)–secondary: Barth syndrome Costeff syndrome MEGDEL syndrome Others	Mitochondrial dysfunction	*TAZ* *OPA3* *SERAC1* *DNAJ19;CLPB;* *HTRA2;TIMM50;* *TMEM70;ATPAF2;* *QIL1;AGK;ATP5FID*	3-Methylglutaconic acid 3-Methylglutaric acid	70/51
Mevalonic aciduria/Hyper-IgD syndrome	Mevalonate kinase	*MVK*	Mevalonic acid + lactone	54
Disorders of protein lipoilation	Protein lipoilation defects	*NFU1;ISCU;LIPT1;* *LIPT2; BOLA3;LIAS;* *IBA57;ISCA2;* *GLRX5;FSDX2;* *LYRM4;NFS1*	2-Hydroxyadipic acid 2-Ketoadipic acid Glutaric acid 2-Ketoglutaric acid Isobutyryl/Isovaleryl/2-methyl-butyryl-glycine	27

Pyroglutamic aciduria	Glutathione synthase 5-oxoprolinase	*GSS* *OPLAH*	Pyroglutamic acid	16
Reversible leukoencephalopathy	Plasma membrane Na^+/dicarboxylate cotransporter 3	*SLC13A3*	2-Ketoglutaric and succinic acid Fumaric acid *N*-acetylaspartic acid	43
Organic acidurias in vitamin metabolism				
Biotin metabolism				
Multiple carboxylase deficiency	Biotinidase Holocarboxylase synthetase	*BTD* *HLCS*	3-Methylcrotonylglycine 3-Hydroxyisovaleric acid 3-Hydroxypropionic acid 2-Methylcitric acid Lactic and Pyruvic acids	30
Cobalamin metabolism				
GIF, CUBN/AMN, HC, TCbl, TCblR, CblF, CblJ, CblC, CblD, CblD-MMAtype, CblA, CblB and CblX deficiencies	Uptake, intracellular transport, Cbl metabolism deficiencies	*GIF/TCNIII;CUBN; AMN;TCNI;TCNII; CD320;LMBRD1; ABCD4;MMACHC; MMADCH;MMAA; MMAB; HCFC1*	Methylmalonic acid (and homocystinuria)	28
Folate metabolism				
Formiminoglutamic aciduria (FIGLURIA)	Glutamateformimino-transferase	*FTCD*	Hidantoin-5-propionic acid	29
Pyridoxine metabolism				
Pyridox(am)ine-5-phosphate oxidase deficiency Vit 6 dependent epilepsy	Pyridox(am)ine-5-phosphate oxidase (PNPO) Pyridoxal phosphate binding protein	*PNPO* *PROSC*	3-Methoxy-4-hydroxyphenyl-lactic acid (vanillactic acid)	34
Riboflavin metabolism				
Multiple acyl-CoA dehydrogenase (MADD) deficiency/Glutaric aciduria Type II (ETF-Type 2A /2B) Riboflavin-responsive MADD (ETF) MADD (ETF-DH)	Electron transfer flavoprotein (ETF: α or β subunit) Electron transfer flavoprotein (ETF) Electron transfer flavoprotein dehydrogenase (ETF-DH)	*ETFA* *ETFB* *ETFDH* *ETFDH*	Short-chain acylglycines (C4–C8) C5–C10 Dicarboxylic acids 3-Hydroxy-sebacic acid Ethylmalonic acid D-2-Hydroxyglutaric acid Glutaric acid	32
Riboflavin transporter 1 deficiency Brownn-Vialetto-Van Laere Syndrome Type I/Type II; Fazio-Londe Syndrome Flavin adenine dinucleotide synthetase deficiency	Riboflavin transporter 1-RFVT1 Riboflavin transporter 2-RFVT2 Riboflavin transporter 3-RFVT3 Flavin adenine dinucleotide synthetase (FADS)	*SLC52A1* *SLC52A2* *SLC52A3* *FLAD1*	Ethylmalonic acid Glutaric acid C5–C10 Dicarboxylic acids Short- and medium-chain acyl-Glycines (C4–C8) (can be normal)	32

Table 4.2 Dietary, drug, non-IEM disorders and bacterial artefacts in organic acid analysis

Compound	Condition
N-Acetyltyrosine	Parenteral feeding
Aromatic acids (4-hydroxyphenyl)	Gut bacterial action
	Liver diseases
Benzoic acid	Benzoate sodium therapy
	Bacterial contamination
Cyclohexanediol	Medication
$C_{10} > C_8 > C_6$ dicarboxylic acids	MCT-diet
Dicarboxylic acids	Valproate therapy
Ethosuximide metabolites	Antiepileptic therapy
Di-(2-ethylhexyl)phthalate	Nutramigen feeding
	Pregestimil feeding
Ethylmalonic acid	*ACADS* polymorphisms
Furane-2,5-dicarboxylic acid	Heated sugars
Furoylglycine	Heated sugars
Glucosan	Heated sugar
Glutaric acid	Gut bacterial action, 2-ketoadipic decarboxylation
Glycerol	Balm contamination
Glycolic acid	Ethylene glycol poisoning
Hippuric acid	Benzoate sodium therapy
Homovanillic acid	Neuroblastoma
4-Hydroxybutyric acid	Gamma-hydroxyanesthesia
	Illegal use of 4-hydroxybutyrate
2,4-Di-hydroxybutyric acid	Heated sugar
4-Hydroxycyclohexanecarboxylic acid	Food processing
3-Hydroxydicarboxylic acids	Coeliac disease
	Long fasting
	MCT supplementation
2-Hydroxyglutaric acid	2-ketoadipate decomposition (bacterial contamination)
5-Hydroxyhexanoic	MCT-diet
2-Hydroxyhippuric acid	Salicylate ingestion
5-Hydroxyindoleacetic acid	Carcinoid syndrome
D-2-Hydroxyisocaproic acid	Short-bowel syndrome
3-Hydroxyisovaleric acid	Valproate medication
7-Hydroxyoctanoic acid	MCT-diet
3-Hydroxypropionic acid	Gut bacterial action
	Colon rectal cancer
Keppra metabolites	Antiepileptic therapy
D-Lactic acid	Short-bowel syndrome
Mandelic acid	Albumin infusion
Methylmalonic acid	Vitamin B_{12}-deficiency (vegans, vegetarian diet)
D-Phenyllactic acid	Short-bowel syndrome
Phenytoin metabolites	Antiepileptic therapy
Pyroglutamic acid	Glutamine decomposition
	Flucloxacillin toxicity
	Severe denutrition
	Renal disease
Suberylglycine (trace amounts)	MCT-diet
Succinic acid	2-Ketoglutarate decomposition
Valproate metabolites	Depakine therapy
Vanillactic acid	Dopa therapy
Vanilmandelic acid	Neuroblastoma, pheochromocytoma

In native urine (pH 5–7), the acids are present as salts (Na^+, K^+). Therefore, the urine should be acidified (pH 1–2) to promote the protonation of the acids, which turns them suitable to be extracted by an organic solvent of intermediate polarity. Ethyl acetate or di-ethyl ether is the most widely used. Extraction recoveries depend on the polarity of the acid: the more hydroxyl-groups, the less recovery.

For an accurate analysis, some precautions are necessary to be taken prior the extraction procedure. Keto acids deserve special attention due to the fact of being unstable compounds, thus the keto group must be protected by formation of an oxime derivative through reaction with hydroxylamine or methoxyamine; an example is succinylacetone (4,6-diketoheptanoic acid), the key tyrosinemia type 1 metabolite.

The analysis by GC-MS obliges volatile analytes. Organic acids do not fulfil this requirement and must be transformed in volatile derivatives. Derivatization of the acid (COOH), the hydroxy (C-OH), and the keto (C=O) groups increases their volatility. The most widely used derivatization procedure is the formation of a trimethylsilylated (TMS) derivative. This transforms the molecule into a more balloon-like structure which can easily be volatilized upon the injection and move faster along the column. The larger the molecule, the later it elutes having higher retention times that may vary slightly depending on the column and on the instrument.

The derivatives are separated in the GC-capillary column, and the detection is accomplished by MS which allows the unequivocal identification of the detected metabolites. All separated compounds enter the ion source. They are ionized (obtain a positive electric charge) and fragmented and then deflected in an electromagnetic field. Variation of the electromagnetic field will cause the passage of ions with increasing mass to pass the ion exit slit and hit the ion collector (detector). The fragments of any given compound are like a fingerprint and give the unique identification of the compound. Every modern GC-MS instrument has library search facilities. This gives for each peak the most likely structure. Nevertheless, the interpretation of the library data should be done with care and the predicted structure should be cross examined with the determined retention times, i.e., the position in the total ion chromatogram. Unknown compounds with different chromatographic properties may have great similarity with fragmentation spectrum of known compounds. There are even sophisticated methods for the simultaneous deconvolution, identification, and quantitation of organic acids using a dedicated library of mass spectra and a list of retention indices (Halket et al. 1999). Several experienced laboratories have developed search routines in which the mass spectrometer automatically checks for the presence of all diagnostic organic acids listed in Table 4.1.

An organic acid chromatogram may display hundreds of tiny small peaks, and a full quantitative analysis can be really

time-consuming. Therefore, urinary organic acids analysis, in general, is run in a qualitative or semi-quantitative mode. In order achieve a visual comparison of the organic acid total ion chromatograms, the starting volume of urine used in the assay should correspond to a fixed amount of creatinine present in the sample.

Precise quantification of specific metabolites, in particular cases, for differential diagnosis purposes or for the monitoring of treatment may be required. Therefore, accuracy of the organic acid analysis in the lower concentration range can be improved by using a stable isotope dilution assay. This is based on the addition of a stable isotope-labeled (^{13}C or ^{2}H) internal standard which behaves identically in all steps of the analysis, i.e., extraction, derivatization, and chromatographic separation. A range of applications has been developed, for example, succinylacetone for the follow-up of tyrosinemia type 1 patients (Sander et al. 2006), mevalonic acid for hyper IgD patients (Houten et al. 1999), and methylmalonic acid for vitamin B_{12}-related disorders (Blom et al. 2007), among others.

The recent availability of electrospray tandem mass spectrometers (MS/MS) together with a high range of isotope-labeled internal standards has resulted in the introduction of quantitative organic acid analysis in many labs by means of selective mass spectrometric detection and quantification via multiple reaction monitoring (MRM). This targeted analysis is of great value for some applications, particularly for the follow-up of some organic acidurias. However, the untargeted added value of GC-MS for the analysis of organic acids is still difficult to overcome. Recently, quantitative organic acid analysis by LC-QTOF/MS has been revealed as a technique that should be taken into account in the near future, particularly when urine is analyzed as a front-line specimen including also amino acids, acylcarnitines, purine and pyrimidines, and other metabolites in a unique run (Körver-Keularts et al. 2018).

Interpretation/Reference Values

Interpretation of organic acid profiles is a demanding and complex issue. Besides the organic acids with diagnostic value, hundreds of substances are excreted into the urine of healthy and diseased subjects and are also detected in the organic acid chromatogram. It is therefore essential to gain experience in pattern recognition, in order to provide a reliable descriptive interpretation of the organic acid profile. This is one of the major tasks of the Biochemical Genetics Laboratory.

The recognition of a normal excretion profile is the starting point. It is necessary to be aware that the excretion profile depends on the age of the individual, the diet, the use of dietary supplements or vitamers, the intake of drugs, and the physical condition (fasting, exercise, etc.). A set of organic acids will always be detectable essentially in all urine samples of healthy individuals (Table 4.3). Due to differences in

Table 4.3 Organic acids detectable essentially in all urines. Reference values of control individuals on a normal diet, without any medication and without signs of intestinal disease

Compound	Reference values (mmol/mol creat)			
	0–4 months	4 months–2 years	2–10 years	>10 years
Glycolic acid	13–129	32–162	48–164	23–146

Var. variable

The lower and upper reference values represent the 5th and 95th percentiles

methodologies approaches for the sample analytical procedures among laboratories as well as equipment sensitivity, reference values between laboratories are usually not comparable, and available published data (Hoffmann et al. 1989) should be used as guidance only.

Therefore, each laboratory must have its own reference values, since distortions of relative concentrations may be informative. For this reason, ERNDIM (www.erndim.org) has launched a program for quantitative analysis of organic acids in urine, which is expected to be useful for the comparison of interlaboratory results. Moreover, sharing of true patients samples between laboratories will be of great value for the trainee. Organic acid acidurias are a huge group of disorders; some of them are quite rare, and it is easy to miss a diagnosis if one has not seen it before. Participation in the qualitative ERNDIM programs will eventually result in the collection of a series of study rare cases.

The easiest diagnoses rely on the massive excretion of one or a few pathognomonic metabolites. Good examples are mut^0 methylmalonic acidemia and 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) lyase deficiency (*vd.* Table 4.1). On the other hand, there are many defects showing only marginally increased organic acids. Well-known examples are 2-methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency (Ofman et al. 2003; Garcia-Villoria et al. 2009), mevalonate kinase deficiency (Houten et al. 1999), and glutaric acidemia type 1 (Baric et al. 1999; Busquets et al. 2000). In those cases, it is of great importance to have an accurate quantitative organic acid analysis with one's own well-defined normal ranges. Sometimes even a trace amount of a key metabolite may be diagnostic as evidenced by some cases of tyrosinemia type I having only traces of succinylacetone in their urine (Haagen and Duran 1987). Patients with episodic fever and the hyper-IgD syndrome may have urinary mevalonic acid levels which are just twice the upper reference level of 0.8 mmol/mol creatinine (Houten et al. 1999).

As already emphasized, the here described analytical method does not exclusively detect organic acids; other low molecular compounds with diagnostic value may also be picked up. Important findings are the pyrimidines (uracil, thymine, dihydrothymine, dihydrouracil) associated with inborn errors of the pyrimidine breakdown pathway, and orotic acid, a marker of urea cycle defects (Table 4.1).

It is necessary to be aware that not all elevated organic acids may be related to an inherited disorder (Kumps et al. 2002); the primary accumulating organic acid may be the diagnostic hallmark by itself, as exemplified by pyroglutamic acid in oxoprolinase deficiency (Larsson et al. 1981), but it should be noted that pyroglutamic acid can arise from glutamine as an artefact during storage, and it can also be present in the urine of critically ill patients who are being treated with flucloxacillin and paracetamol.

Table 4.4 Impact of acylcarnitines in the diagnosis of organic acidurias

Organic aciduria	Acylcarnitines (P; DBS)
Methylmalonic	C3; C3/C2; C3/C16; C4DC; C16:1OH
Propionic	C3; C3/C2; C3/C16; C16:1OH
Isovaleric	C5; C5/C0; C5/C3; C5/C2
3-Methylcrotonylglycinuria	C5OH; C5OH/C0; C5OH/C8; C5:1
HMG-CoA Lyase deficiency	C5OH; C5OH/C0; C5OH/C8; C6DC
Glutaric type I	C5DC; C5DC/C3DC; C5DC/C5OH; C5DC/C16; C5DC/C8¸ C5DC/C10
Ketothiolase deficiency	C5OH; C5OH/C0; C5OH/C8; C5:1
Biotinidase deficiency/ HCS deficiency	C5OH; C5OH/C0; C5OH/C8; C3; C3/C2; C3/C16
2-Methylbutyrylglycinuria	C5; C5/C0; C5/C3; C5/C2

Abbreviations: *P* plasma, *DBS* dried blood spot, *HMG-CoA* 3-Hydroxy-3-methyl-glutaryl-CoA, *HCS* Holocarboxilase synthetase

The most important non-genetic anomalies currently observed in the organic acid profiling are summarized in Table 4.2. The contribution of the diet, the gut bacterial action, and the anti-epileptic medication is most pronounced and should always be taken in mind.

A number of the organic acid coenzyme A esters will readily form carnitine esters as a mechanism for replenishing free CoA stores and as a tool for detoxifying the potential toxic acyl-CoA's. Table 4.4 shows the acylcarnitine accumulation in the most common organic acidemias in the metabolism of amino acids. Therefore, several organic acidemias may reliably be diagnosed by acylcarnitine analysis, either in plasma or in a dried blood spot (DBS), thereby enabling the large-scale newborn screening of these disorders (McHugh et al. 2011). Due to the diagnostic value of acylcarnitines, namely, for mitochondrial fatty acid oxidation defects (*vd.* acylcarnitines Chap. 5 in this book), it has become good laboratory practice to perform simultaneous GC/MS of urine organic acids and MS/MS of plasma or DBS acylcarnitines in any acutely sick patient in whom an organic acidemia is suspected.

Over the years, experience has been gained about multiple secondary enzyme reactions using the accumulating organic acid as a substrate and giving rise to characteristic diagnostic secondary metabolites (Table 4.5). Knowledge of biochemical pathways as well as enzyme biochemistry will be of great help in putting the identities of the secondary metabolites into place. Sometimes the production of secondary metabolites masks the presence of the primary metabolite such as observed in methylmalonic acidemia (Tavares de Almeida et al. 1991). In this respect, both propionic acidemia (Przyrembel et al. 1979) and isovaleric acidemia (Loots 2009) are notorious for their wealth of secondary metabolites. It is still a matter of debate whether the occurrence of potential toxic secondary metabolites plays a role in the development of specific symptoms in individual patients. Metabolomics studies of groups of patients may be helpful in answering these queries (Reinecke et al. 2012).

Table 4.5 Examples of secondary metabolites derived from key metabolites in the organic acidurias

Key metabolite	Biochemical process	Secondary metabolite
Ethylmalonyl-CoA	Mutase reaction	Methylsuccinicacid
Hexanoyl-CoA	(ω-1)-Hydroxylation	5-Hydroxyhexanoic acid
4-Hydroxybutyric acid	β-Oxidation	3,4-Di-Hydroxybutyric acid
2-Hydroxyglutaric acid	Lactone formation	2-Hydroxyglutaric acid lactone
Isovaleryl-CoA	β-Oxidation	3-Hydroxyisovaleric acid
Isovaleryl-CoA	ω-Oxidation	4-Hydroxyisovaleric acid
Isovaleryl-CoA	Glutamic acid conjugation	*N*-Isovalerylglutamic acid
2-Ketoadipic acid	Decarboxylation	Glutaric acid
3-Methylcrotonyl-CoA	Glycine conjugation	3-Methylcrotonylglycine
3-Methylglutaconyl-CoA	Reduction	3-Methylglutaric acid
Octanoic acid	Glucuronic acid conjugation	Octanoylglucuronide
Propionyl-CoA	Carnitine conjugation	Propionylcarnitine
Propionyl-CoA	Ketone formation	3-Keto-n-valeric acid
Propionyl-CoA	Citrate synthase reaction	Methylcitric acid
Tiglyl-CoA	Carboxylation	2-Methylglutaconic acid

Differential Diagnosis

The interpretation of an organic acid analysis can be a complex task. As already emphasized, for a comprehensive evaluation of the obtained profile, and in order not get lost by the nondiagnostic compounds, it is necessary to have in mind that multiple factors may have influence on the observed pattern, such as the clinical status of the patient, diet plus dietary supplementations, and medication. Moreover, in an emergency situation sample, collection timing may also have impact in the excreted pattern of organic acids. Therefore, detailed clinical and therapeutic information should be provided with the request for organic acid analysis. In these cases, it is mandatory to integrate all the information available. For example, in general, mitochondrial fatty acid beta-oxidation defects are associated with hypoketotic hypoglycemia, a finding that will be useful to differentiate a dicarboxylic acid pattern induced by a physiologic fasting which is accompanied by a gross excretion of ketones. The finding of moderately elevated C6-C12 (hydroxyl) dicarboxylic acids, especially in the absence of excessive amounts of ketones, may indicate mitochondria malfunction, and a mitochondrial beta-oxidation defect should be suspected.

Several key organic acids may be observed in multiple different organic acidurias or, simply, as an artefact from gut bacterial action, drug interactions in metabolic pathways, or sample bacterial contamination.

3-Methylglutaconic acid is a hallmark of 3-methylglutaconic aciduria type I, but it also appears, isolated or in combination with 3-mehylglutaric acid, in multiple conditions without a plausible biochemical support. However, it has been associated with mitochondrial membrane disruption and defective phospholipid remodeling (Wortmann et al. 2015); thus it should be monitored, and a persistent high level must be regarded as a signal for further investigation by molecular genetic analysis (Tort et al. 2019).

Another puzzling organic acid is ethylmalonic acid (EMA) (Duran et al. 1983), which is formed by the catalytic action of acetyl-CoA carboxylase and propionyl-CoA carboxylase upon butyryl-CoA, the substrate for short-chain acyl-CoA dehydrogenase, a member of the ACADs family (van Maldegem et al. 2006). It is a hallmark for SCAD deficiency, but it is also present in ethylmalonic encephalopathy (*ETHE1*) (Tiranti et al. 2004), multiple acyl-CoA dehydrogenase (MAD), respiratory chain, and possibly ethylmalonyl-CoA decarboxylase (ECHDC1) (Linster et al. 2011) disorders. Due to the high incidence of the ACADs-polymorphisms, EMA may be seen in multiple genetic defects.

In the organic acid analysis, low-molecular compounds other than organic acids with diagnostic informative value are detected. These key compounds allow to pursue the investigation through an oriented differential diagnosis flowchart procedure. It is the case of orotic acid, which is associated with urea cycle disorders, lysinuric protein intolerance, and HHH syndrome as well as that of pyrimidine compounds—thymine, uracil, dihydrothymine, and dihydrouracil—allowing the diagnosis of pyrimidine metabolism defects. The extraction recovery of these compounds from the urine matrix is quite low, and an accurate quantitative analysis is recommended or the use of an analytical dedicated method for further evaluation.

Other interesting compounds are the epoxydicarboxylic acids (Korman et al. 2000) suggestive of peroxisomal biogenesis defects, cf. Zellweger syndrome, as well as 3-methyladipic acid and 2,6-dimethylsuberic acid which have been detected in adults with Refsum disease (Greter et al. 1983; Wierzbicki et al. 2003). Therefore, plasma phytanic acid should be evaluated.

In some cases, the pathological excretion levels of the disorders' hallmark may be quite low, and a sensitive quantitative method using isotope dilution analysis will be demanded for an accurate diagnosis in selected cases.

Moreover, one must have in consideration the high informative level of acylglycines, detected in the organic acid run, in the differential diagnosis, as well as in that of acylcarnitines, which will be discussed in Chap. 5 of this book. The organism uses alternative pathways to get rid of the accumulated organic acids, and these metabolites in the form of CoA esters are further conjugated with the amino acid glycine to form the so-called acylglycines. Acylglycines are an important diagnostic tool in branched-chain amino acid breakdown pathways and in fatty acid oxidation defects (Table 4.1).

Finally one should realize that organic acid analysis as a tool for diagnosing inborn errors will always be carried out in conjunction with complementary analyses such as those of acylcarnitines and amino acids. Only an integrated view of the disturbed metabolism will enable the assessment of a presumptive diagnosis, which will then be confirmed by molecular or enzyme studies (Tavares de Almeida and Duran 2014).

Acknowledgments The authors deeply acknowledge the contribution of Dr. Marinus Duran to the Organic Acids chapter in the previous edition (2014, pp 761–773) of this book, on which this chapter is based.

Contents

Abstract

Carnitine and its esters (acylcarnitines) are physiologically present in all biological fluids, but carnitine is most abundant in tissues with high energy requirements, particularly skeletal and cardiac muscle. Acylcarnitine analysis is a useful tool in the evaluation of patients at risk for inborn errors of mitochondrial fatty acid oxidation and for organic acidemias primarily due to defects in branched-chain amino acid metabolism. Given the diverse clinical presentation of these conditions, acylcarnitine analysis has become an integral part of the biochemical genetic laboratory investigation of a large number of patients. With the additional application to newborn screening, acylcarnitine analysis is the most widely used biochemical genetic laboratory test. Aside from clinical and newborn screening indications, a relevant family and/or prenatal history, and sudden unexpected death also represent valid reasons to pursue an acylcarnitine analysis. However, several preanalytical and analytical pitfalls must be considered when interpreting acylcarnitine profiles.

Introduction

Carnitine and its esters are physiologically present in all biological fluids, but carnitine is most abundant in tissues with high energy requirements, particularly skeletal and cardiac muscle. In 1973, the first two clinically relevant disorders affecting this pathway were described: primary carnitine deficiency and carnitine palmitoyl transferase type II deficiency (DiMauro and DiMauro 1973; Engel and Angelini 1973). To date, more than 20 different enzyme deficiency states affecting fatty acid transport and mitochondrial β-oxidation (FAO) are known, and additional enzymes involved in this pathway are still being discovered (Bosch et al. 2011; Knottnerus et al. 2018; Rinaldo et al. 2002).

Carnitine is involved as a detoxifying agent in branched-chain amino acid metabolism. Most of the classic organic acidurias are associated with secondary carnitine deficiency.

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_5

In fact, the clinical utility of acylcarnitine analysis was first identified for several organoacidopathies, and urine was the preferred specimen. However, plasma became the specimen of choice because acylcarnitine profiles are less complex in plasma than in urine and because the sensitivity of acylcarnitine analysis is higher when plasma is analyzed, especially for the diagnosis of long-chain FAO disorders (Millington et al. 1992). Today, urine acylcarnitine analysis is limited to specific analytes where diagnostic value is added to the metabolic work up of patients with organic acidemias but inconclusive or borderline abnormal urine organic acid and plasma acylcarnitine profiles (Ensenauer et al. 2004; Oglesbee et al. 2007; Tortorelli et al. 2005). Blood dried on filter paper is analyzed for newborn screening and, together with bile, in the postmortem evaluation of cases of sudden and unexpected death (Rinaldo et al. 2004). Cell-free supernatant of amniotic fluid can be used for the prenatal diagnosis of selected inborn errors of metabolism (Rinaldo et al. 2001).

Cultured fibroblasts or amniocytes can be probed with FAO substrates and carnitine. Cell cultures deficient of an FAO enzyme will accumulate specific acylcarnitine species when incubated with substrates such as palmitate, allowing for the diagnosis of FAO disorders (Roe et al. 2001; Shen et al. 2000; Young et al. 2003). Modifications of this assay system have also been developed for the diagnosis of defects affecting the metabolism of branched chain amino acids and for the study of peripheral blood mononuclear cells (Schulze-Bergkamen et al. 2005).

Acylcarnitine analysis is almost exclusively performed by tandem mass spectrometry (MS/MS) using stable isotope-labeled internal standards that allow quantitation of acylcarnitine species. However, to provide meaningful results to referring healthcare providers, it is critical to complement analytical proficiency with in-depth interpretation of results as is true for many other examples of complex metabolic profiles.

Carnitine and Acylcarnitines

Carnitine, L-3-hydroxy-4-(trimethylammonium)butyrate, is a water-soluble, trimethylammonium derivative of γ-amino-β-hydroxybutyric acid which is formed from trimethyllysine via γ-butyrobetaine (Vaz and Wanders 2002) (Fig. 5.1). Carnitine originates to about 75% from dietary intake of meat, fish, and dairy products containing proteins with trimethyllysine residues. Under normal conditions, endogenous synthesis from lysine and methionine plays a minor role. Carnitine is excreted in urine and bile as free carnitine or as conjugated carnitine esters. Adequate intracellular levels of carnitine depend on diet, endogenous synthesis, reabsorption, and cellular uptake.

Under physiologic conditions, carnitine is primarily required to shuttle long-chain fatty acids across the inner mitochondrial membrane for fatty acid β-oxidation and products of peroxisomal β-oxidation to the mitochondria for further metabolism in the citric acid cycle (Vaz and Wanders 2002). Acylcarnitines (the carnitine esters) are formed by conjugating acyl-CoA moieties to carnitine which for activated long-chain fatty acids is accomplished by carnitine palmitoyl transferase type I (CPT-I) (Fig. 5.1). The acyl-group of the activated fatty acid (fatty acyl-CoA) is transferred by CPT-I from the sulfur atom of CoA to the hydroxyl group of carnitine (Knottnerus et al. 2018). Carnitine acylcarnitine translocase (CACT) then transfers the long-chain acylcarnitines across the inner mitochondrial membrane, where CPT-II reverses the action of CPT-I by formation of acyl-CoA and release of free carnitine.

In pathologic conditions, such as FAO disorders or organic acidemias due to acyl-CoA dehydrogenase deficiencies, the functions of carnitine as regulator of substrate flux and energy balance across cell membranes and as modulator of intracellular concentrations of free CoA become crucial. In such conditions, acyl-CoAs accumulate inside the mitochondrial matrix, and carnitine is utilized to shuttle

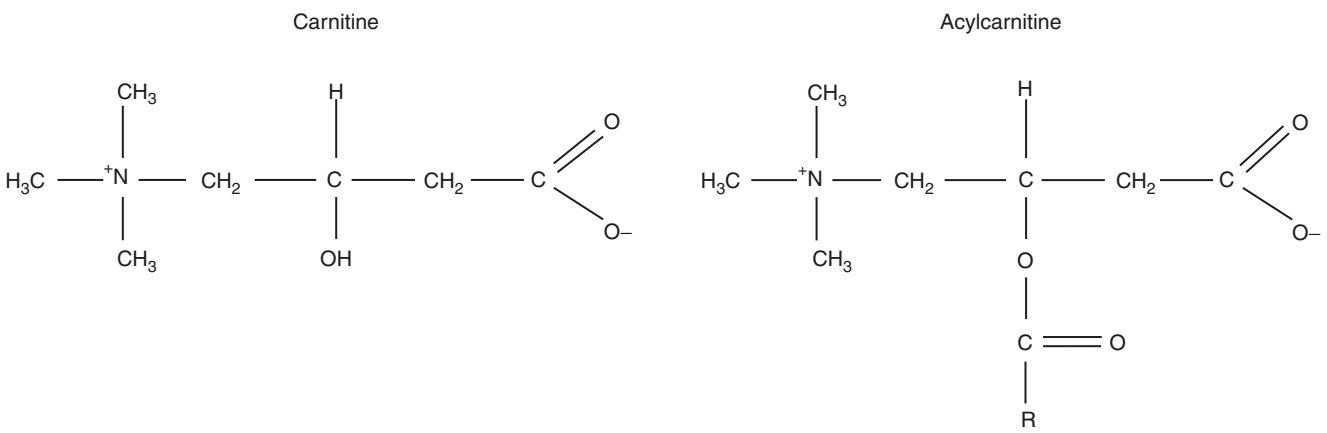

Fig. 5.1 Structures of carnitine and acylcarnitine. The R represents the acylcarnitine species with up to 18 carbons which are typically the aim of an acylcarnitine analysis

these compounds out of the mitochondria as acylcarnitines, thereby restoring free CoA.

Carnitine and its esters are present in all biological fluids albeit very low in the CSF, and depending on the enzyme defect, a particular acylcarnitine pattern becomes apparent where those acylcarnitine species serving as direct substrates for the defective enzyme accumulate disproportionately to the down- and upstream metabolites (Table 5.1).

Table 5.1 Clinically relevant acylcarnitine species (as butylesters) included in a typical acylcarnitine analysis and their relevance when abnormally elevated (unless otherwise noted)

Acylcarnitine species		Disorder
C0	Free carnitine	Carnitine supplementation (deficiency if low)
C2	Acetyl-	Carnitine supplementation or ketosis (deficiency if low)
C3	Propionyl-	PA, MCD, MMA, SUCLA2 (Carrozzo et al. 2007), treatment with heptanoic acid
m/z 287	FIGLU (Malvagia et al. 2006)	Glutamate formimino-transferase deficiency
C4	Butyrl-/isobutyryl-	SCAD, IBDH, MADD, EE
C5:1	Tiglyl-	MAT, MCC, MHBD, MCD
C5	Isovaleryl-/2-methylbutyryl-/Pivaloyl-	IVA, SBCAD, MADD, EE, antibiotics derived artifact (Abdenur et al. 1998), treatment with heptanoic acid
C4-OH	3-hydroxybutyryl-	SCHAD, ketosis
C6:1	3-methylglutaconyl-	MGA
C6	Hexanoyl-	MCAD, MKAT, MADD
C5-OH	3-hydroxyisovaleryl-	BIOT[a], HMG, MCC, MCD, MGA
	2-methyl-3-hydroxybutyryl-	MAT, MHBD
m/z 322	Benzoyl-	Treatment with Na-benzoate
m/z 325	Dextrose (fragment)	Sample contamination with dextrose
C7	Heptanoyl-	Treatment with heptanoic acid
m/z 336	Phenylacetyl-	Treatment with phenylacetic acid
m/z 338	Salicylyl-	Treatment with salicylic acid
C8	Octanoyl-	MCAD, M/SCHAD, MKAT, MADD
C3-DC	Malonyl-	Malonic aciduria
C8-OH	3-hydroxyoctanoyl-	MKAT
C10:2	Decadienoyl-	DCR (Houten et al. 2014)
C10:1	Decenoyl-	MCAD
C10	Decanoyl-	MCAD, MADD
C4-DC	Methylmalonyl-/succinyl-	MMA[a], SUCLA2 (Carrozzo et al. 2007)
C5-DC	Glutaryl-	GA-1
C10-OH	3-hydroxydecanoyl-	M/SCHAD, MKAT
m/z 399	Dextrose (fragment)	Sample contamination with dextrose
C12	Dodecanoyl-	MADD
C6-DC	3-methylglutaryl-	HMG
C12-OH	3-hydroxydodecanoyl-	LCHAD/TFP
C14:1	Tetradecenoyl-	MADD, VLCAD, LCHAD/TFP
C14	Tetradecanoyl- (myristoyl-)	CACT, CPT-II, MADD, VLCAD, LCHAD/TFP
C14-OH	3-hydroxytetradecanoyl-	LCHAD/TFP
C16	Hexadecanoyl- (palmitoyl-)	CACT, CPT-II, MADD, VLCAD, LCHAD/TFP; CPT-I[b]
C16:1-OH	3-hydroxyhexadecenoyl-	Antibiotics derived artifact (Vianey-Saban et al. 2004)
C16-OH	3-hydroxyhexadecanoyl-	LCHAD/TFP
m/z 473	Dextrose (fragment)	Sample contamination with dextrose
C18:2	Octadecadienoyl- (linolyl-)	CACT, CPT-II, MADD, VLCAD, LCHAD/TFP
C18:1	Octadecenoyl- (oleyl-)	CACT, CPT-II, MADD, VLCAD, LCHAD/TFP; CPT-I[b]
C18	Octadecanoyl- (stearyl-)	CACT, CPT-II, MADD, VLCAD, LCHAD/TFP
C18:1-OH	3-hydroxyoctadecenoyl-	LCHAD/TFP
C18-OH	3-hydroxy octadecanoyl-	LCHAD/TFP deficiency

[a]Respective analyte is not consistently elevated in this disorder

[b]CPT type I is suggested by low concentrations of long-chain acylcarnitine species and relatively high free carnitine; *BIOT* biotinidase deficiency, *CACT* carnitine-acylcarnitine translocase deficiency, *CPT* carnitine palmitoyl transferase deficiency, *DCR* 2,4-dienoyl-CoA reductase deficiency, *EE* ethylmalonic encephalopathy, *FIGLU* formininoglutamate, *GA-1* glutaric acidemia type I (glutaryl-CoA dehydrogenase deficiency), *HMG* 3-hydroxy 3-methylglutaryl-CoA lyase deficiency, *IBDH* isobutyryl-CoA dehydrogenase deficiency, *IVA* isovaleric acidemia (isovaleryl-CoA dehydrogenase deficiency), *LCHAD* long-chain 3-hydroxy acyl-CoA dehydrogenase deficiency, *MADD* multiple acyl-CoA dehydrogenase deficiency, *MAT* mitochondrial acetoacetyl-CoA thiolase (β-ketothiolase) deficiency, *MCAD* medium-chain acyl-CoA dehydrogenase deficiency, *MCC* 3-methylcrotonyl-CoA carboxylase deficiency, *MCD* multiple carboxylase (holocarboxylase synthetase and biotinidase) deficiency, *MGA* 3-methylglutaconic aciduria type I (3-methylglutaconyl-CoA hydratase deficiency), *MHBD* 2-methyl 3-hydroxy butyryl-CoA dehydrogenase deficiency, *MMA* methylmalonic acidemias, *PA* propionic acidemia (propionyl-CoA carboxylase deficiency), *SCAD* short-chain acyl-CoA dehydrogenase deficiency, *SCHAD* short-chain 3-hydroxy acyl-CoA dehydrogenase deficiency, *SUCLA2* succinate-CoA ligase ADP-forming beta subunit, *TFP* mitochondrial trifunctional protein deficiency, *VLCAD* very long-chain acyl-CoA dehydrogenase deficiency

Indications for an Acylcarnitine Analysis

Acylcarnitine analysis has proven a useful tool in the evaluation of patients at risk for inborn errors of mitochondrial fatty acid oxidation and for organic acidemias that are primarily due to defects in branched-chain amino acid metabolism. Given the diverse clinical presentation of these conditions, acylcarnitine analysis has become an integral part of the biochemical genetic laboratory investigation of a large number of patients. Other laboratory studies that should be considered in such patient evaluations include urine organic acid and acylglycine, as well as plasma free fatty acid analyses. With the additional application to newborn screening, among esoteric tests acylcarnitine analysis has the highest sample throughput. Aside from clinical and newborn screening indications, a relevant family and/or prenatal history and sudden unexpected death also represent valid reasons to pursue an acylcarnitine analysis (Table 5.2). An unequivocal indication as a test to monitor treated patients has not yet been established, although it is frequently being performed for this purpose.

Especially since newborn screening for X-Adrenoleukodystrophy was proposed, attempts have been made to expand the typical acylcarnitine profile (see Table 5.1) to include acylcarnitine species with chain lengths greater than 18 carbons (up to C26) in order to identify patients with this and other peroxisomal disorders. However, this approach was found to have less sensitivity and specificity than the traditional analyses of very long chain fatty acids and corresponding lysophosphatidylcholines described in "Chap. 66" (Herzog et al. 2017; Huffnagel et al. 2017).

Table 5.2 Indications for acylcarnitine analysis

Clinical signs and symptoms	Routine laboratory findings
Respiratory distress	Acidosis
Lethargy	Ketosis
Coma	Hypoglycemia
Recurrent vomiting	Hyperammonemia
Failure to thrive	Elevated liver enzymes
Feeding difficulty	Elevated creatine kinase
Apnea	
Hypotonia	
Bradycardia	**Other abnormal laboratory findings**
Ventricular arrhythmias	Dicarboxylic aciduria (excluding dietary MCT)
Cardiomyopathy	Hydroxydicarboxylic aciduria
Hepatic steatosis	Abnormal acylcarnitines by newborn screening
Hepatomegaly	Fatty acid profile suggestive of a FAO disorder
Encephalopathy	
Seizures	
Dystonia	**Family history of**
Myopathy	Affected sibling(s)
Rhabdomyolysis	Sudden unexplained death or SIDS in sibling(s)
Renal tubular acidosis	Maternal pregnancy complications (AFLP, HELLP)
Polycystic kidneys	
Reye or Reye-like syndrome	
Apparent life-threatening event/"near-miss" SIDS	

Methods

Several techniques have been described to differentiate and eventually quantify specific carnitine esters. These include gas chromatography-mass spectrometry (GC-MS), thin layer chromatography (TLC) and radioisotopic exchange/HPLC, liquid-chromatography (LC) MS, and LC-MS/MS. However, the predominant method applied is flow injection analysis (FIA) MS/MS using triple quadrupole analyzers combined with electrospray ionization (ESI). The advantage of this approach is its sensitivity that allows for simple, but efficient preparation procedures of small sample volumes and fast analytical times, therefore providing for a rapid throughput of large numbers of samples. The disadvantage is that a few isomeric acylcarnitine species are not distinguishable by FIA-MS/MS (see Sect. 5.11 Pitfalls) which is why some laboratories opt for methods based on chromatographic separation by LC-MS/MS analysis with longer analytical times and at higher cost (Minkler et al. 2015). In a typical set up, acylcarnitines are extracted from the sample by mixing with methanol or an acidified acetonitrile solution containing isotopically labeled acylcarnitines of various chain lengths at defined concentrations as internal standards. Following centrifugation the supernatant is evaporated, and the residue is usually derivatized with either *n*-butanol HCl or *n*-methanol HCl yielding the acylcarnitines for analysis by flow injection ESI-MS/MS. Of note, some laboratories, in particular, newborn screening laboratories, omit the derivatization step, although problems may arise with the identification particularly of dicarboxylic species at the decision level due to lower ionization efficiency (De Jesús et al. 2010). Following analysis, a graphical acylcarnitine profile is generated which can be interpreted qualitatively. (Semi-)quantitative calculation of the concentration of each individual acylcarnitine species is based on the abundance of the assigned internal standard (Smith and Matern 2010).

Specimen

A variety of body fluids can be used for acylcarnitine analysis, but testing of plasma or whole blood spotted on filter paper is most common. All sample types, except for dried blood and bile spots and fibroblast cultures which can be sent

at room temperature, should be kept frozen until analysis. Reliable results, particularly for short-chain acylcarnitine species, for any sample, liquid or dried on filter paper, cannot be achieved following long-term storage at ambient temperatures (Matern et al. 1999).

Plasma and Serum

Heparinized plasma is the preferred specimen for acylcarnitine analysis, but EDTA plasma and serum are also acceptable. Hemolyzed or lipemic specimens can also be analyzed without negative impact on sensitivity or specificity as long as the laboratory considers the effect of hemolysis on the abundance of long-chain acylcarnitine species when interpreting results. An amount of 100 μL is typically sufficient material to conduct the analysis and repeat it at least once if necessary. Most informative results are generally achieved when samples are obtained during acute illness. Because inborn errors of metabolism are traditionally not entered early into differential diagnostic considerations, sample collection should alternatively be timed before a meal, preferably after an overnight fast. A prolonged fasting challenge, however, should not routinely be undertaken as these require close surveillance typically not possible in an outpatient setting.

Dried Blood and Dried Bile Spots

Acylcarnitine analysis has been introduced into newborn screening laboratories in the late 1990s and is now part of almost all newborn screening programs. Because newborn screening tests make use of dried blood spots (DBS) collected after a heel prick on the second to fifth day of life, the DBS is the most common specimen used for acylcarnitine analysis. In addition, many biochemical genetics laboratories offer clinical testing of acylcarnitines in DBS for patients at any age. As is true for plasma samples, the most informative results are obtained when blood samples are collected during acute illness or at least prior to a meal. Blood should be obtained by capillary stick of well perfused skin (heels in young infants or fingers) and free dripping of a few drops of blood directly on the filter paper card. For postmortem analysis, blood and bile are collected at the latest at the time of autopsy.

Following complete drying at room temperature for at least 3 h, the sample can be sent ambient. While diagnostic results can be obtained in most cases of medium- and long-chain FAO defects even after prolonged storage time at room temperature, samples should be stored frozen (with desiccant) because particularly short-chain acylcarnitine species are not reliably measurable several months after collection (Matern et al. 1999). At least one blood or bile spot with a diameter of 1 cm should be collected to allow for any necessary repeat testing which usually requires only a DBS punch of 3 mm in diameter.

Urine

While initially the favored specimen, urine acylcarnitine analysis is the least appropriate when a FAO disorder is under diagnostic consideration. Long-chain acylcarnitines are typically bound to plasma albumin and are not excreted by the kidney. Urine is collected from patients suspected to have an organic acidemia preferably during an acute metabolic decompensation. As this is often not possible, an early morning specimen should be collected. The minimum volume of urine is 1 mL which allows for acylcarnitine and creatinine analysis; the latter is essential to normalize quantitative acylcarnitine results. The sample should be sent frozen and without preservatives.

Fibroblast Culture Medium

Most FAO disorders present similarly, and their biochemical diagnosis can be difficult because common metabolite screens, such as urine organic acids, plasma acylcarnitines, and fatty acids, are influenced by dietary factors and the clinical status of the patient (Van Hove et al. 2000) leading to incomplete diagnostic information or even false-negative results (Browning et al. 2005). Enzyme assays are limited to one enzyme per assay, and molecular genetic analysis of a relevant gene or gene panels can be complicated by the discovery of genotypes of uncertain significance. The in vitro probe assay offers screening for several defects of FAO and organic acid metabolism under controlled laboratory conditions using fibroblast cultures (Table 5.3). The principle of this assay relies on the assumption that skin fibroblasts of patients affected with relevant conditions will accumulate certain acylcarnitine species reflecting the metabolic defect when the cell medium is supplemented with a long-chain fatty acid, branched-chain amino acids, and L-carnitine. An acylcarnitine analysis can be performed in the post-incubation cell medium by tandem mass spectrometry as for the other sample types (Smith and Matern 2010).

Fibroblasts are typically grown from a small skin biopsy collected during an outpatient visit or as part of a planned surgical procedure following routine culturing techniques. Cell cultures may also derive from umbilical cord or, for prenatal diagnostic purposes, from amniocytes obtained by amniocentesis. Samples should be sent at ambient temperatures.

Table 5.3 Disorders detectable by the in vitro probe assay

Fatty acid β-oxidation disorders	Short-chain acyl-CoA dehydrogenase (SCAD) deficiency
	Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency
	Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency
	Mitochondrial trifunctional protein (TFP) deficiency
	Very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency
	Carnitine palmitoyl transferase type II (CPT-II) deficiency
	Carnitine-acylcarnitine translocase (CACT) deficiency
Organic acid disorders	Electron transfer flavoprotein (ETF) deficiency, ETF-dehydrogenase deficiency (multiple acyl-CoA dehydrogenase deficiency, MADD; glutaric acidemia type II)
	Isovaleric Acidemia
	Short-branched-chain acyl-CoA dehydrogenase deficiency (SBCAD deficiency; 2-methylbutyrylglycinuria)
	Isobutyryl-CoA dehydrogenase (IBD) deficiency

Interpretation and Reference Ranges

The laboratory director, typically a board certified Clinical Biochemical Geneticist or equivalent, reviews all profiles and provides an interpretation based on pattern recognition and not on single abnormal values (Tables 5.1, 5.4, 5.5, 5.6, and 5.7). Simple reporting of numeric results is not appropriate because most physicians are not familiar with pattern recognition. A comprehensive interpretation takes into consideration any available clinical and dietary information and other laboratory results and provides possible differential diagnoses, recommendations for additional biochemical testing, and confirmatory studies if indicated, as well as contact information for the laboratory director in case the referring physician has additional questions.

Pitfalls

The ordering physician must be aware of the limitations of a laboratory test and should consider involving the biochemical genetics laboratory in discussions regarding the most appropriate diagnostic work up of patients.

Pitfalls in Acylcarnitine Analysis of Plasma, Serum, Blood Spots, and Bile Spots

Acylcarnitine profiles are dependent on the clinical status of the patient at the time of sample collection (Van Hove et al. 2000). Accordingly, all samples should be submitted to the biochemical genetics laboratory with information regarding the clinical context during which the sample was collected. The laboratory must be aware of the fact that carnitine deficiency states can cause seemingly normal acylcarnitine profiles due to the lack of carnitine as substrate for carnitine palmitoyl transferases. Accordingly, it is crucial to review the complete profile and to initiate follow-up when even bor-

derline elevated acylcarnitines are noted in the presence of abnormally low free and acetylcarnitine. If clinically indicated, a repeat sample should be collected as early as 24 h after L-carnitine supplementation.

The laboratory must also note when specimens are hemolyzed because it will lead to an increase in long-chain acylcarnitines which needs to be considered when interpreting the acylcarnitine profile to avoid unnecessary follow-up investigations to rule out a long-chain FAO disorder (Mancinelli et al. 2007).

While FIA-MS/MS allows for unequivocal identification of most metabolites, there are a few exceptions (Table 5.1). In particular, the short-chain acylcarnitines of 4 and 5 carbons represent more than one analyte. C_4-Acylcarnitine is known to be a mixture of butyrylcarnitine derived from fatty acid metabolism and isobutyrylcarnitine derived from the metabolism of valine (Oglesbee et al. 2007). C_4-OH acylcarnitine can be a mixture of the D-3-OH-butyrylcarnitine, associated with ketosis; L-3-OH-butyrylcarnitine, associated with SCHAD-deficiency; or 3-OH-isobutyrylcarnitine, characteristic of the valine degradation defect 3-OH-isobutyryl-CoA hydrolase deficiency. C_5-Acylcarnitine is a mixture of isovalerylcarnitine and 2-methylbutyrylcarnitine derived from leucine and isoleucine degradation, respectively (Ensenauer et al. 2004; Matern et al. 2003). Samples of patients treated with antibiotics containing pivalic acid (trimethylacetic acid) such as pivampicillin, may contain pivaloylcarnitine, another C5 species. Several other metabolites are also nonspecific markers for several disorders. For example, C_5-OH acylcarnitine, which represents 3-hydroxyisovalerylcarnitine and 2-methyl-3-hydroxybutyrylcarnitine, can be elevated in seven different organic acidemias. The interpretation of elevated C_5-OH acylcarnitine in newborns or breast-fed infants is further complicated by the fact that it can indicate maternal 3-methylcrotonylglycinuria while the infant is only an unaffected carrier (Gibson et al. 1998). Differentiation is of clinical importance and most efficiently achieved by urine acylglycine and organic acid analyses, or by plasma acylcarnitine analysis by LC-MS/MS.

CPT-I deficiency, characterized by high free carnitine and relatively low long-chain acylcarnitine species, is more challenging to detect in plasma than in DBS because of already lower abundance of long-chain acylcarnitines in plasma. The long-chain FAO disorders of CACT deficiency and CPT-II deficiency cannot be differentiated because both cause accumulation of the same long-chain acylcarnitine species which is explained by the fact that neither enzyme is involved in the chain-shortening action of FAO. Isolated LCHAD deficiency and complete mitochondrial TFP deficiency also cannot be differentiated by routine acylcarnitine analysis (Van Hove et al. 2000). When such profiles are encountered, delineation of the correct defect is only possible by either specific enzyme assay in cell cultures or molecular genetic analysis of the relevant genes. MCAD and multiple acyl-CoA dehydrogenase (MAD) defects require the identification of medium-chain acylcarnitines. In this respect, it is important to realize that patients on a medium-chain triglyceride containing diet may accumulate C8 and C10 carnitine, potentially obscuring the diagnosis.

Isolated elevations of propionylcarnitine (C_3) are not specific for propionic acidemia but also observed in methylmalonic acidemias of various etiologies. Because methylmalonylcarnitine (C_4-DC) is not consistently elevated in methylmalonic acidemias, elucidation of the correct diagnosis requires at a minimum urine organic acid analysis.

Another antibiotic that may cause problems in the interpretation of butylated acylcarnitines is cefotaxime

(Vianey-Saban et al. 2004). This antibiotic or metabolites thereof reveals itself by acylcarnitine analysis (following derivatization to butylesters) at m/z 470 which otherwise represents monounsaturated 3-hydoxyhexadecenoylcarnitine ($C_{16:1}$-OH). In poorly resolved scans, this may be difficult to differentiate from m/z 472 which is a marker for LCHAD and TFP deficiencies. However, whereas m/z 472 (C_{16}-OH) is more abundant than $C_{16:1}$-OH in these FAO disorders, the profile of a patient treated with cefotaxime usually reveals an m/z 470 to m/z 472 ratio that is greater than 1. Furthermore and in contrast to cefotaxime treatment, both LCHAD and TFP deficiencies are usually accompanied by elevations of other long-chain species (Table 5.1) (Van Hove et al. 2000).

Formiminoglutamate (FIGLU), a marker for glutamate formimino-transferase deficiency, is revealed in acylcarnitine profiles by a peak with m/z 287 (Malvagia et al. 2006). In poorly resolved acylcarnitine profiles, this peak may be confused with iso-/butyrylcarnitine (m/z 288). To avoid the incorrect interpretation of acylcarnitine profiles, the analysis is best performed in product scan mode as opposed to multiple reaction monitoring (MRM) mode.

Pitfalls in Acylcarnitine Analysis of Urine

Aside from the abovementioned potential problems (see D.7.1) such as the inability to discriminate isomers and interfering metabolites of antibiotics, urine also often contains a variety of non-identified substances. This makes the interpretation of urine acylcarnitine profiles inherently more complex, and overinterpretation must be avoided. Therefore, urine acylcarnitine analysis should not be included in the first line of screening investigations but be targeted to specific diagnostic considerations, in particular, organic acidemias. A role of urine acylcarnitine analysis for the diagnosis of FAO disorders has not been established.

Pitfalls in Acylcarnitine Analysis of Post-incubation Fibroblast Culture Medium

The in vitro probe assay is performed under standardized conditions and is independent of the patient's status at the time the skin biopsy is obtained. The accumulation of acylcarnitines in this assay system appears to be dependent on potentially present residual enzyme activity and therefore provides information regarding the severity of an enzyme deficiency state for some disorders such as VLCAD and SCAD deficiencies. Furthermore, as is true for acylcarnitine analysis of other sample types, TFP and isolated LCHAD deficiencies as well as CPT-II and CACT deficiencies cannot be differentiated. The analysis of fibroblasts also does not allow for the diagnosis of enzyme deficiency states that are not expressed in this tissue (e.g., the liver-specific SCHAD deficiency). Finally, conditions not associated with an abnormal accumulation of acylcarnitines, such as CPT-I or primary carnitine deficiencies, are not identified by this assay.

Abstract

Lysosomal storage diseases (LSDs) are a group of inherited metabolic disorders that result from lysosomal dysfunction. Most LSDs are autosomal recessively inherited disorders, with only three exceptions that are X-linked. The overall incidence is about 1 in 5000 live births. Mutations in genes encoding lysosomal proteins cause lysosomal malfunction with the gradual accumulation of substrates leading to cell dysfunction and cell death. LSDs are generally classified based on the biochemical type of accumulated substrate that leads to a heterogeneous spectrum of clinical manifestations. The diagnostic suspicion of LSDs is based on clinical symptoms, and the measurement of the abnormal accumulation of substrates in biological fluids. The diagnosis is confirmed by enzymatic and/or genetic analysis, including next-generation sequencing and whole exome sequencing. In the last years, many efficient therapies have been developed. New treatments and the evidence that the early treatment shortly after birth can permit a better outcome have led to the development of several pilot newborn screening programs for some LSDs. Early detection in a presymptomatic state and prompt treatment can modify the natural history of LSD disease preventing irreversible damage of the involved key organs.

Introduction

Lysosomal storage diseases (LSDs) are a group of more than 70 inherited metabolic disorders that result from lysosomal dysfunction. Most LSDs are autosomal recessively inherited disorders, with only three exceptions that are X-linked. These disorders are individually rare, but collectively the incidence is about 1 in 5000 live births (Platt et al. 2018). Mutations in genes encoding lysosomal proteins, such as proteases, transporters, or integral membrane proteins,

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_6

cause lysosomal malfunction with the gradual accumulation of substrates that lead to cell dysfunction and cell death. LSDs are classified based on the biochemical type of accumulated substrate, or on whether disorders involve integral membrane proteins or lipofuscin production (Table 6.1). The storage process leads to a heterogeneous spectrum of clinical manifestations depending on the specific substrate and site of accumulation. Age at onset can range from newborns to adults, and these disorders are progressive. The diagnostic suspicion of LSDs is based on clinical symptoms, and the valuation of the abnormal accumulation of substrates in biological fluids (mostly urine) is the first step in the diagnos-

tic flow chart. Although in very recent years many papers have been published with very high potentiality, there is no single instrument platform/analytical technique that currently can analyze all metabolites involved in LSDs, and the metabolomics approach is still not widely available. LSD analysis is generally performed on a single category of molecules with classical biochemical tests ranging from thin layer chromatography, liquid chromatography, or electrophoresis. The diagnosis must be confirmed by enzymatic and/or genetic analysis, including next-generation sequencing and whole exome sequencing. In the last years, many therapeutic options, such as enzyme replacement therapy (ERT), hematopoietic stem cell transplantation, substrate reduction therapy, pharmacological chaperone therapy, and gene therapy, have been developed. New treatments and the evidence that the early treatment shortly after birth often leads to a better outcome have led to the development of several pilot newborn screening programs for some LSDs (Gelb 2018). Early detection in a presymptomatic state and prompt treatment can modify the natural history of LSD disease preventing irreversible damage of the involved key organs.

Preanalytical Conditions

Glycosaminoglycans in Urine

Urine samples should be collected for 24 h, when possible. But considering that prolonged urine collections are quite difficult especially in newborns or very young babies, a random sample, preferably the first morning voiding, is acceptable (not less than 15–20 mL). Storage temperature must be −20 °C until analysis. No preservatives are required.

Oligosaccharides in Urine

Urine samples collected for 24 h are mandatory. The minimum volume of urine is 5 mL, and the storage temperature must be −20 °C until analysis. No preservatives are required.

Free and Total Sialic Acid

Urine samples collected for 24 h are mandatory. The minimum volume of urine is 5 mL, and the storage temperature must be −20 °C until analysis. No preservatives are required.

Enzymatic Assays on Dried Blood Spot

1. Newborn screening: dried blood spot is collected by neonatal heel prick. It is important to apply single drops of blood only on one side of the filter paper (not apply multiple drops of blood in the same circle or in front and behind the filter). Avoid touching the area within the circles on the filter paper section before, during, and after collection of the specimen. Cards with blood spots must be dried at room temperature, far from heat sources, for not less than 90 min. Most enzymes are stable at room temperature for the first 20 days, but storage temperature between +4 °C and −20 °C is advised for greater stability.
2. Venous blood collection: dried venous blood spot is collected by finger prick. For the collection and storage, follow the previous indications.
3. Venous blood collection from tubes: apply 20 μL of blood from heparin/EDTA tubes and follow the previous indications.

Chitotriosidase in Plasma

For this analysis, 1–2 mL of blood in heparinized tube is needed. Plasma must be separated from blood within 1 h, and it can be stored at −20 °C until the assay.

Enzymatic Assays on Leukocytes

For most assays, 6–10 mL of blood in heparinized/EDTA tube at room temperature is needed. It is important to use a needle with less chance of hemolysis. The separation of leukocytes from whole blood must be performed within 24 h from the collection. Leukocyte pellets can be stored at −20 °C until the assay.

Enzymatic Assays on Fibroblasts

Fibroblast cultures are generally derived from forearm skin biopsies. For most testing, two 75 cm^2 flasks are sufficient. Fibroblast pellets can be stored at −20 °C until the assay.

Other Specimens

Amniotic fluid, tear fluid, chorionic villi, and amniocytes can be used in some isolated cases.

Analysis

Glycosaminoglycans Assay

The mucopolysaccharidoses are a group of LSDs characterized by an accumulation of mucopolysaccharides, also known as glycosaminoglycans (GAGs), causing dysfunction of cells, tissues, and organs. Each disorder results from a specific lysosomal enzyme defect that affects the normal degradation pathway of glycosaminoglycans. Undegraded or partially degraded GAGs are accumulated in lysosomes and then excreted in the urine. The correlation between biochemical findings and enzymatic defect is reported in Table 6.2, and the correlation between structure and catabolism is reported and shown in Fig. 6.1.

Total Glycosaminoglycans Analysis in Urine

An initial screening test to check for an elevation in total GAGs concentration can be a useful tool when a MPS disorder is suspected. Several methods have been developed for GAGs quantification in urine. One first approach is an Alcian blue (tetravalent cationic dye) spot test, which semi-quantitatively estimates the amount of total GAGs present. Even if the complex formation with Alcian blue depends on the sulfation patterns and keratan sulfate fragments with low degree of sulfation may not be detected, patients with Morquio syndrome can be equally detected due to excretion of chondroitin 6-sulfate. Cetylpyridinium chloride (CPC) is generally used to extract urinary GAGs prior to analysis. Quantitation can be performed by carbazole method determining uronic acid formation. Another simple test is based on the modification of dimethylmethylene blue (DMB) assay (de Jong et al. 1992). It allows the measurement of all GAGs without response difference among urinary metabolites. By using all methods, false-negative results may occur especially in MPS-I, MPS-III, MPS-IV, MPS-VI, and MPS-VII. Many cases of false-positive results have been reported in literature. Some of these concerned other LSD non-mucopolysaccharidoses with normal total concentrations of urinary GAGs but isolated increment such as in multiple sulphatase deficiency (HS), GM_1 (KS), Morquio IV A and B (KS), and fucosidosis (KS). A new DMB-based method named GAG-Test® has been recently reported with a referred sensitivity of 100% (Lage et al. 2011). In addition, total GAGs can be quantified and analyzed by HPLC (Studelska et al. 2006) and capillary electrophoresis (Ucakturk et al. 2014).

Total urinary GAGs show significant age-related difference: infants tend to have higher average GAG levels than adults. Reference values of urine GAGs are reported in Table 6.3.

Qualitative and Quantitative Glycosaminoglycan Analysis in Urine

Eleven enzymes are involved in the catabolic pathways of GAGs. Deficiencies in each of these enzymes result in specific GAG accumulation: chondroitin sulfate (CS), dermatan sulfate (DS), heparan sulfate (HS), keratan sulfate (KS), or hyaluronan.

Table 6.2 Classification of the mucopolysaccharidoses

Mucopolysaccharidoses	Glycosaminoglycans excreted in urine	Defective enzyme	Inheritance
MPS-I H/S	DS; HS	Alpha-L-iduronidase	AR
MPS-II	DS; HS	Iduronate sulfatase	XR
MPS-IIIA	HS	Heparan *N*-sulfatase	AR
MPS-IIIB	HS	Alpha-*N*-acetylglucosaminidase	AR
MPS-IIIC	HS	Acetyl CoA:alpha-glucosaminide acetyltransferase	AR
MPS-IIID	HS	*N*-acetylglucosamine-6-sulfatase	AR
MPS-IVA	KS; C 6-S	*N*-acetylgalactosamine-6-sulfate sulfatase	AR
MPS-IVB	KS	Beta-galactosidase	AR
MPS-VI	DS	*N*-acetylgalactosamine-4-sulfatase	AR
MPS-VII	DS; HS; C 4,6-S	Beta-glucuronidase	AR
MPS-IX	Hyaluronan	Hyaluronidase	AR

DS Dermatan sulfate, *HS* heparan sulfate, *KS* keratan sulfate, *C 6-S* chondroitin 6-sulfate, *C 4,6-S* chondroitin 4,6-sulfate, *AR* autosomal recessive, *XR* X-linked recessive

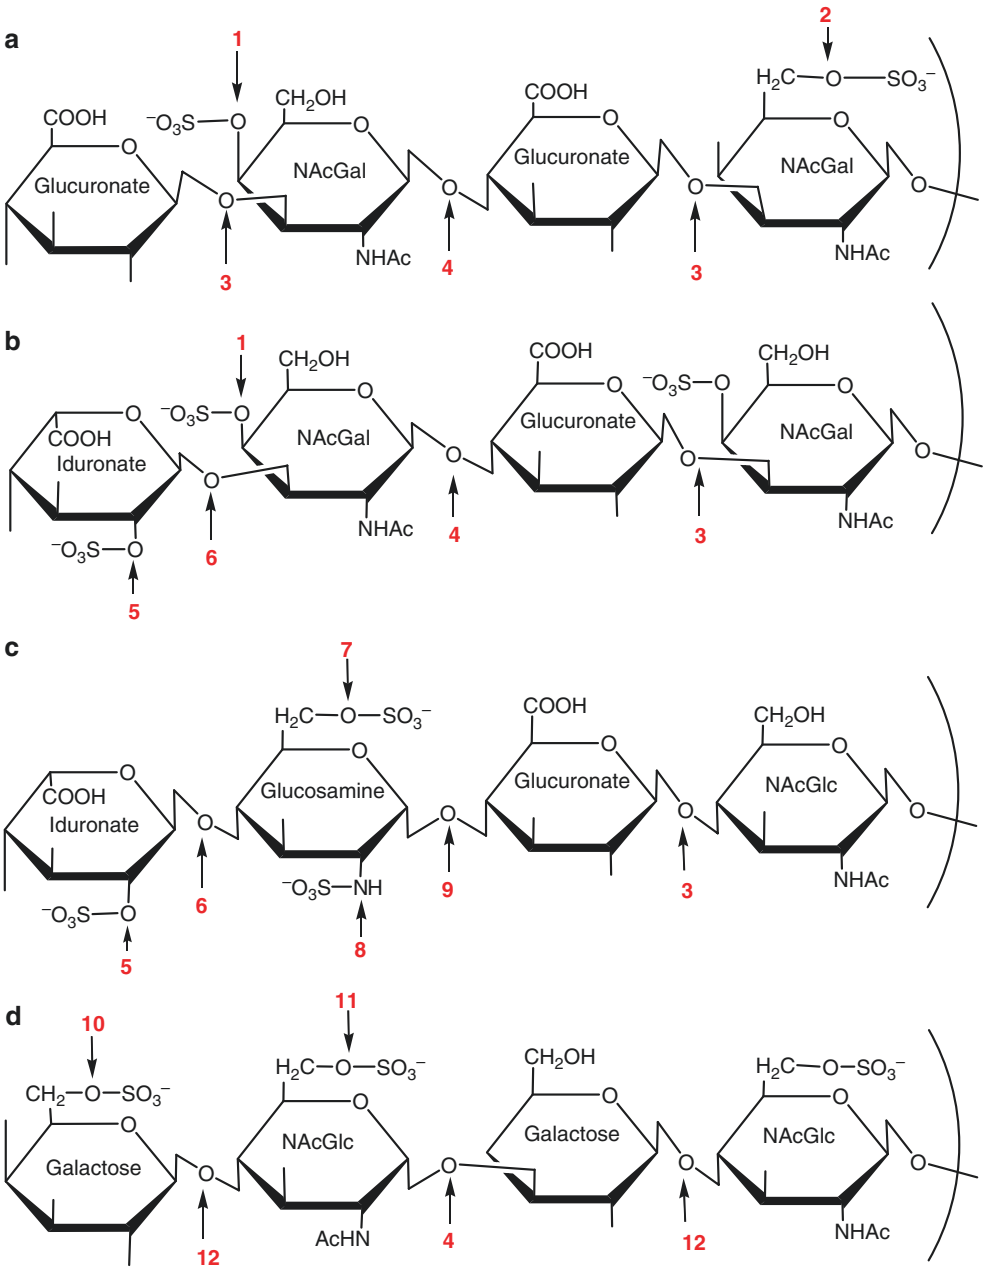

Fig. 6.1 NAcGlc: *N*-acetylglucosamine; NAcGal: *N*-acetylgalactosamine. Several methods have been proposed for quantitative analysis of specific GAGs (Kubaski et al. 2017). Paper or thin layer chromatography, gas-liquid chromatography, capillary electrophoresis, and high performance liquid chromatography were reported to be able to identify and separate different GAGs.

Mass spectrometry has been used in recent years for its high sensitivity and accuracy. A limitation of MS-based technologies is that large molecules such as GAGs need to be broken down into sulfated disaccharide fragments before analysis. An alternative method to enzymatic digestion for GAG identification by mass spectrometry is based on chemical cleavage. A fast test able to quantify glycosaminoglycans in urine by a LC-MS/MS method has been recently developed for selective MPS-I, MPS-II, and MPS-VI mucopolysaccharidoses (Auray-Blais et al. 2011). The test is performed on random urine samples and the concentration expressed as a ratio to creatinine for normalization purposes. Dermatan sulfate (DS) and heparan sulfate (HS) are measured as derivatives by using calibration curve in urine, after a chemical degradation step (methanolysis). The authors reported glycosaminoglycan quantification on 28 patients and 55 controls. Besides DS and HS, chondroitin sulfate was measured in all samples and confirmed it was not a useful marker for the diagnosis of MPS due to the fact that it is normally excreted in urine. No DS and HS were found in control urines, while DS and in most cases HS were quantified in MPS-I, MPS-II, or MPS-VI patients. Based on the

Table 6.3 GAGs reference ranges in urine

Age (year)	Alcian blue[a] (mg/mmol creatinine)	DMB-Tris (mg/mmol creatinine)	CPC/Carbazole (μmol uronic acid/mmol creatinine)	GAG-Test® (mg/mmol creatinine)

consideration that residual glycosaminoglycans are present in patient urine even after treatment, this test is also useful for monitoring therapeutic enzyme replacement treatment.

An MS-based method using butanolysis to quantify HS showed higher signal responses compared to those generated by using methanolysis (Trim et al. 2015). Recently, Forni and colleagues have developed a new fast LC–MS/MS assay for the simultaneous quantification of HS and DS using small amounts of urine. This method requires an easy sample preparation by using butanolysis, and it is less time consuming if compared with enzyme-digestion process (Forni et al. 2019).

For the definitive diagnosis, enzyme activity test is needed. Appropriate enzyme sources are summarized in Table 6.4. Considering that no homogeneous data of the different enzyme activity are present in literature, normal values are not referred.

Oligosaccharide Assay

Oligosaccharidoses/glycoproteinoses are lysosomal storage disorders due to lost activity of one of the lysosomal hydrolases involved in the degradation of oligosaccharide components of glycoproteins.

Oligosaccharides are molecules containing a small number (3 to approximately 10) of monosaccharide residues connected by glycosidic linkages. Small amounts of carbohydrates and oligosaccharides are present in normal urine depending on different factors (diet, medication, blood group type, etc.). Oligosaccharides can be studied by thin-layer chromatography of urine samples (Palo and Savolainen 1972; Humbel and Collart 1975; Friedman et al. 1978; Sewell 1981; Tsai and Marshall 1979).

One-dimensional thin layer chromatography is performed on 20 × 20 silica gel plate. Urine samples containing about 15 μg of creatinine are applied directly on silica gel plate. Lactose, maltotetraose, and sialic acid at concentration of 1 mg/mL are used as reference standards.

The plate is developed overnight in a freshly prepared mobile phase containing *n*-butanol–glacial acetic acid–distilled water (10:5:5 v/v/v). The plate is then removed, dried at room temperature (about 1 h), and sprayed with freshly prepared solution containing 3,5-dihydroxytoluene (orcinol) 400 mg/dL in sulfuric acid 10%. Spots corresponding to oligosaccharides develop by heating the plate at 130 °C for about 10 min and are looked by transparency. The excretion of oligosaccharides is identified by the presence of colored bands. This method is suitable for screening purposes. Interpretation can be difficult and requires experience. Specific oligosaccharide patterns are indicative of diagnostic suspicion of a specific disease (Sewell 1991). Neonatal urine samples could present many bands, mimicking an α-mannosidosis pattern, due to parenteral nutrition. This fact is not indicative of disease. In this case, it is recommended to repeat the assay after the age of 6 months. Alternatively, the combination of two one-dimensional TLC systems proposed

Table 6.5 Source material for oligosaccharidurias enzymatic assays

Disorder	Enzyme defect	Material	
		Postnatal	Prenatal
Aspartylglucosaminuria	Glycosylasparaginase	WBC, FB	CV, CAFC
Fucosidosis	Alpha-L-fucosidase	P, WBC, FB	CV, CAFC
Galactosialidosis	Cathepsin A/beta-galactosidase/neuraminidase	WBC, FB	CV, CAFC
α-Mannosidosis	Alpha-mannosidase	P, WBC, FB	CV, CAFC
β-Mannosidosis	Beta-mannosidase	P, WBC, FB	CV, CAFC
Mucolipidosis I	Alpha-neuraminidase	FB, WBC[a]	CV, CCV, CAFC
Mucolipidosis II	*N*-acetylglucosamine-1-phosphotransferase	FB	CV, CCV, CAFC
Mucolipidosis III	*N*-acetylglucosamine-1-phosphotransferase	FB	CCV, CAFC
Schindler disease	Alpha-*N*-acetylgalactosaminidase	WBC, FB	CV, CAFC
GM1 Gangliosidosis	Beta-galactosidase-1	WBC, FB	CV, CAFC
Krabbe disease	Galactosylceramidase	WBC, FB	CV, CAFC
GM2 Gangliosidosis type I	Beta-hexosaminidase A	P, WBC, FB	CV, CAFC
GM2 Gangliosidosis type II	Beta-hexosaminidase A + B	P, WBC, FB	CV, CAFC

by Abeling and collaborators (Abeling et al. 1996) can be performed to distinguish urine of breastfed newborns from that of α-mannosidosis patients.

Some authors reported a new useful semiquantitative method based on tandem mass spectrometry for the diagnosis of the oligosaccharidurias (Ramsay et al. 2005). It is a 1-phenyl-3-methyl-5-pyrazolone (PNP) in ammonia derivatization-based method, followed by a liquid/liquid extraction with $CHCl_3$ and solid-phase extraction on a C18 column. The mass spectra were acquired on a triple quadrupole mass spectrometer operating in both precursor ion scan and multiple reaction monitoring (MRM) modes, in positive ionization. Patients with I-cell disease, mucolipidoses type II and III, alpha–mannosidosis, Pompe disease, GM_1 gangliosidosis, GM_2 type II, sialidosis, alpha-fucosidosis, Gaucher disease, and SADS (sialic acid storage disorders) have been analyzed and differentiated from controls. This new procedure seems to be sensitive, robust, automatable, and faster than classical TLC ones. When stable isotope labeled internal standards will become commercially available, this method will be considered a powerful tool for quantitative determination of oligosaccharides in urine.

To date, in any case, a confirmatory enzyme assay must be performed in serum, fibroblasts, or leucocytes for the definitive diagnosis. Appropriate enzyme sources are summarized in Table 6.5.

Analysis of Free and Total Sialic Acid in Urine

Sialic acid (SA) represents the *N*- or *O*-substituted derivatives of monosaccharide neuraminic acid. It is a major component of complex glycoproteins and glycolipids, in which it commonly forms the terminal constituent of sugar side chains. Many forms of sialic acid exist in every tissue, but *N*-acetylneuraminic acid (NANA) is the predominant one in humans. Sialic acids often represent part of antigenic determinants of glycolipids or glycoproteins. Urine total SA is increased in some lysosomal disorders such as sialidosis, galactosialidosis, Kanzaki disease, and mucolipidosis II and III. Heterozygotes do not excrete increased amounts of bound sialic acid. It has been reported that an increase in urine total SA is also found in individuals with chronic glomerulonephritis and rheumatoid arthritis, in lupus erythematosus, in pseudohypoparathyroidism, and in diabetic patients. In all these diseases, the excretion of bound SA is lower than in conditions involving the neuraminidase enzyme. About 40% of SA is in a free form although the majority of urine SA is bound to glycoproteins and oligosaccharides. Urine SA also can be increased (predominantly as free SA) in other inborn errors of metabolism such as infantile sialic acid storage disease (ISSD), sialuria, and Salla disease. The excretion of free SA is tenfold higher in patients with Salla disease and with ISSD than normal subjects, while patients with sialuria display free SA levels about 100-fold higher than those in the healthy population. However, only few patients have been reported in the literature; therefore, a distinction among these forms of sialuria cannot be made on the basis of the sialic acid excretion. Many methods have been described for the determination of both free and bound SA. In many laboratories, the measurement of urinary SA is performed by using a modified colorimetric assay (thiobarbituric acid test) developed to eliminate the ubiquitary interferent 2-deoxyribose. As an alternative method, Okamura-Oho et al. (1984) proposed an enzymatic procedure based on cleavage of NANA by aldolase to *N*-acetylmannosamine and pyruvic acid with following spectrophotometric determination (340 nm) with NADH and lactic dehydrogenase. For the measurement of free sialic acid, an incubation step with neuraminidase is

Table 6.6 Free and total sialic acid reference ranges in urine

Free sialic acid (mmol/mol creatine)		Total sialic acid (mmol/mol creatine)	
Age (year)	Mean ± 2SD	Age (year)	Mean ± 2SD
<0.5	45 ± 38	<0.5	156 ± 120
<1	32 ± 28	<1	100 ± 70
1–3	29 ± 21	1–3	90 ± 70
3–5	21 ± 13	3–5	63 ± 40
5–10	15 ± 12	5–10	51 ± 37
10–20	9 ± 8	10–20	34 ± 30
>20	7 ± 6	>20	31 ± 25

Modified from van der Ham et al. (2007)

performed. Many kits are now commercially available based on this modified method. Free sialic acid is oxidized by an enzyme reaction and in the presence of a chromogenic probe develops a red complex. The content of sialic acid can be calculated by measuring the OD value at 560 nm. Some authors (van der Ham et al. 2007) have proposed an LC-MS/MS-based method for the assay of total and free sialic acid. For free SA assay, the procedure required a filtration step followed by a dilution. Quantitative results were obtained by using isotope dilution technique and an eight-point calibration curve. Total SA analysis was performed after a hydrolytic step in sulfuric acid 63 mmol at 80 °C per 1 h. MS data were obtained in a triple quadrupole system operating in MRM mode in negative ionization. The method is rapid (6 min), semi-automatic, specific, robust, and sensitive and therefore could be considered suitable for high-throughput analysis. Reference ranges of urinary free and total sialic acid are reported in Table 6.6.

Enzymatic Tests in Dried Blood Spots

For the majority of LSD, the measurement of the specific enzyme activity in white cells (leukocytes, lymphocytes) or fibroblast is still considered the gold standard for the diagnosis. Chamoles et al. (2001) introduced for the first time the use of the whole blood dried spot (DBS), the traditional NBS sample, to determine enzymatic activity for several LSDs using a commercially available fluorogenic substrate (4-methlyumbelliferone).

Successively, the use of a DBS for the enzymatic determination has been proposed as alternative for a rapid detection of LSDs, mainly in newborn screening and in high-risk population screening. Experimental approaches on DBS were adopted for pilot studies on Fabry disease and/or Pompe disease in Italy, Taiwan, and Japan (Spada et al. 2006; Chien et al. 2008; Oda et al. 2011).

However, conventional methods for quantifying enzymatic activity have the limitations of specificity and limited capacity for multiplexing. Moreover, not all lysosomal enzymes can be assayed by traditional methods because the incorporation of a chromophore or fluorophore into the substrate can cause false-negative results.

The use of mass spectrometric techniques has shown advantages over fluorometric or spectrophotometric assays in the simultaneous quantification of several enzyme activity (Gelb et al. 2006). In fact, based on the studies of Chamoles, the group of Gelb and coworkers used tandem mass spectrometry (MS/MS) and internal standards to detect multiple enzymatic products in a multiplex analysis for Fabry, Gaucher, Krabbe, mucopolysaccharidosis-I (MPS-I), Niemann-Pick-A/B, and Pompe diseases.

Since the first description of the flow injection analysis (FIA) MS/MS assay, modifications including the number of enzymes, sample preparation steps, and the addition of liquid chromatography (LC) have been reported in order to simplify the analysis (Zhang et al. 2008; la Marca et al. 2009; Metz et al. 2011).

More recently, Gelb and coworkers developed a UHPLC-MS/MS multiplex assay with up to 9 LSD (the above-described 6-plex plus MPS-II, MPS-IVA, and MPS-VI) using a single 3 mm DBS punch incubated with 9 substrates and internal standards in a single buffer (Spacil et al. 2013). The MS/MS has been adopted in LSD newborn screening programs worldwide including in Taiwan (Chiang et al. 2018), Italy (Burlina et al. 2018), and the USA (Burton et al. 2017).

The entire assay comprises a 2-day process. On day 1, incubation cocktail containing buffers, substrates, and internal standards for the six enzymes was added to a 3.2 mm DBS and incubated overnight. On day 2, the reaction was stopped and a liquid-liquid extraction was performed. For the quantitation measurements, the tandem mass spectrometer was operated in MRM mode.

The activities of GAA, ABG, GLA, ASM, GALC, and IDUA enzymes in newborns (<7 days of life) and non-newborns tested by multiplex MS/MS are reported in Table 6.7.

The median enzyme activity in non-newborns was lower than in newborns due to lower leukocyte counts on older patient's dried blood spots. Since correction for white blood cell count was not possible on DBS, it is necessary to establish age-matched reference values. All samples collected from affected patients (newborn and non-newborns) had low enzyme activities that could be clearly distinguished from those of age-matched healthy controls, with the exception of female patients tested for Fabry disease, for whom the enzyme activity assay does not reliably discern heterozygosity. The screening panel for LSDs was expanded and includes MS/MS assays for MPS-II, MPS-IVA, and MPS-VI. The activities of IDS, ASB, and GALNS are reported in Table 6.8.

Recently, the group of Gelb described a new 7-plex assay by MS/MS for the mucopolysaccharidoses (MPS-I, MPS-II, MPS-IIIB, MPS-IVA, MPS-VI, and MPS-VII) and type 2 neuronal ceroid lipofuscinosis (LINCL) (Liu et al. 2017). Another analytical multiplex approach to NBS for

LSDs, also based on Chamoles' fluorometric enzyme activity assays, was developed by Advanced Liquid Logic, Inc. (ALL; now called Baebies Inc.) (Sista et al. 2011). Their procedure has the ability to simultaneously perform up to five different enzyme assays on a single DBS. The method utilized minimal sample (DBS extract, 3.4 μL) and reagent volumes that are applied on disposable cartridges for 48 samples and analyzed on a small table-top instrument. Submicroliter droplets of sample are moved by electrowetting on an electrode-plate chip under a layer of oil to prevent evaporation. Since 2013, the Missouri state was using the method for the newborn screening of MPS-I, Fabry, Gaucher, and Pompe diseases (Hopkins et al. 2015). The latest version of this "digital microfluidics" (DMF) that include these four diseases obtained the approval from the US FDA for its use as a medical device in 2017.

The literature highlights the fact that either method, MS/MS or DMF, can be used for efficient LSD newborn screening. Both platforms are liable to false-positive results due to the presence of pseudo-deficiency alleles that exhibit low enzyme activity in an individual with no disease phenotype and normal endogenous enzyme function. These false-positives have complicated the implementation of LSD NBS, especially for Pompe and Hurler diseases (Donati et al. 2018; Chuang et al. 2018). Second-tier testing for some LSDs has recently become available and may also be effective, especially in Pompe and MPS-I diseases (Tortorelli et al. 2018; de Ruijter et al. 2012).

Contents

Summary

This chapter paints a picture of a new dawn for clinicians and laboratory specialists in the metabolic field that arises from the clinical application of untargeted metabolomics. This technology offers unprecedented opportunities to diagnose patients with inborn errors of metabolism and to gain insight in disease mechanisms at the molecular level. The most recent generation of untargeted metabolomics analyses relies on the use of high-resolution mass spectrometry technology, which can be successfully applied to body fluids to reveal known as well as yet unknown IEMs in an individual patient. As such, the technique holds the capacity to replace a large number of current targeted diagnostic techniques. Additionally, it can be applied for the discovery of novel biomarkers for long-known metabolic diseases, which may provide further insight into the pathophysiology of such IEMs. Typically, the analysis of a single sample results in over 10,000 metabolite-related signals (referred to as "features"). It requires a sophisticated bioinformatic pipeline to extract the clinically relevant features from the "big data" that is generated and ignore features from diet- or medication-derived molecules. The application of untargeted metabolomics for IEM diagnostics has been coined next-generation metabolic screening (NGMS). This chapter describes four different ways of applying NGMS in the clinical diagnostic setting and briefly touches on clinical indications for requesting NGMS.

Introduction

Traditionally, the laboratory diagnosis of inborn errors of metabolism has largely relied on targeted hypothesis-driven measurements of metabolites in body fluids. The hypothesis is usually based on the phenotypic characteristics of the patient, defined through deep clinical phenotyping. The biochemical phenotype, or rather the "metabolite profile," reflects both endogenous factors such as genotype(s), gene expression, the different chemical reactions taking place in the body, as well

as exogenous factors such as dietary habits, drug metabolism, and products from the microbiome. The last decade has seen the emergence of untargeted, hypothesis-free measurements of the human metabolome in body fluids. Nuclear magnetic resonance (NMR) spectroscopy is well-known as an untargeted metabolomics technique to analyze body fluids. In the last couple of years, mass spectrometry (MS) techniques have entered the stage of untargeted metabolomics with the advantage of being a factor of roughly thousand times more sensitive than NMR. Mass spectrometry with or without prior separation techniques paves the way to an important next step in our understanding of inborn errors of metabolism.

In this era of increasing use of whole exome sequencing (WES) techniques, an unmet need for functional proof supporting pathogenicity of unknown variants in the genomic DNA comes forward. The metabolic laboratory may help interpreting variants of unknown significance (VUS) found in WES analysis when these occur in genes encoding enzymes or transporters. The diagnostic future may be that WES/WGS and untargeted omics techniques are applied in parallel for patient diagnostics, which further integrates the functional genomics and metabolic laboratories.

The aim of untargeted metabolomics is to capture the complete metabolic profile or fingerprint in a patient's body fluid, including yet unknown metabolites, in order to unravel genetically determined metabolic defects. Typically, untargeted MS-based metabolomics techniques show more than 10,000 "features" in a single body fluid sample. Bioinformatic and chemometric techniques are required to reveal the relevant diagnostic features and filter out dietary- and medication-derived signals. This is essential to find the specific biomarkers for the metabolic derangement in the individual patient. This approach is rather different from classical metabolomics studies that usually describe the comparison between a patient group and a control group. NGMS techniques now enable the use of untargeted metabolomics for diagnostics in a clinical setting. Examples from NMR spectroscopy and untargeted MS analyses have already been described that unravel the identity of hitherto unknown inborn errors of metabolism or uncover novel biomarkers for long-known metabolic diseases.

NMR-Based Metabolomics

Proton NMR spectroscopy is considered the cornerstone of classical untargeted metabolomics. It provides an overview of proton-containing metabolites in the micromolar and higher concentration range. All metabolites in the NMR spectrum can be quantitatively evaluated without the use of individual internal standards. The signal from a particular proton or group of equivalent protons may consist of one or more peaks under the influence of its chemical environment. These can be singlet, doublet, triplet, quartet, and multiplet resonances. Figure 7.1a gives the NMR spectra of lactate and alanine to illustrate that molecules with a high degree of similarity can be observed as separate resonances in the spectrum. The methyl groups of lactate and alanine show as doublet resonances. The proton from their methylene group gives a quartet in the spectrum.

Body fluid NMR spectroscopy can detect a vast array of IEMs, including most organic acidurias, aminoacidurias, and diseases in purine and pyrimidine metabolism. Figure 7.1b shows the accumulation of dimethylglycine in dimethylglycine dehydrogenase deficiency. This example also shows that metabolites that usually are not detected in conventional targeted metabolic screening techniques can also be seen in the NMR spectrum. This has contributed to the discovery of seven novel diseases with the use of NMR. The discovery of squalene synthase deficiency may serve as the most recent example (Coman et al. 2018). A comprehensive overview of the diagnostic potential including the spectral characteristics of over 100 IEMs is available in book form and online (Engelke et al. 2014).

MS-Based Metabolomics

In the field of inborn errors of metabolism, targeted MS-based metabolomics methods, mostly on triple quadrupole (QqQ) instruments, have been well established in clinical diagnostics. These targeted methods are focused at quantitative determination of a predefined set of known metabolites, such as acylcarnitines or purines and pyrimidines. However, to uncover yet unknown metabolic diseases, an unbiased, holistic screening of the metabolite profile, or metabolome, is required. Technological innovations in high-resolution mass spectrometry (HRMS) now allow for the simultaneous detection (and semi-quantification) of as many individual metabolites as possible in a very small volume of biological sample (Fig. 7.2). This ability relies on the unprecedented mass accuracy that can be achieved by HRMS instruments, which reaches the parts per million (ppm) range. Based on this very accurate mass, which is up to four digits precise, the elemental composition of a metabolite can be deduced, which enables metabolite identification without the need for previous knowledge on which metabolites are expected to be present in the sample. Additionally, HRMS methods offer high sensitivity, reaching the low nanomolar range. These characteristics of HRMS make it a powerful tool to identify yet unknown metabolic derangements in patients suspected of an inborn error of metabolism.

HRMS-based metabolomics can be either performed by direct injection into a mass spectrometer such as direct infusion mass spectrometry (DI-HRMS; (Haijes et al. 2019a); Fig. 7.2) or preceded by chromatographic separation of metabolites on a column in liquid (LC; Fig. 7.2) or gas phase (GC), capillary electrophoresis (CE), or using ion mobility (Coene et al. 2018; Tebani et al. 2018). DI-HRMS and LC-HRMS are currently applied in clinical diagnostics for IEM and will be discussed in more detail below.

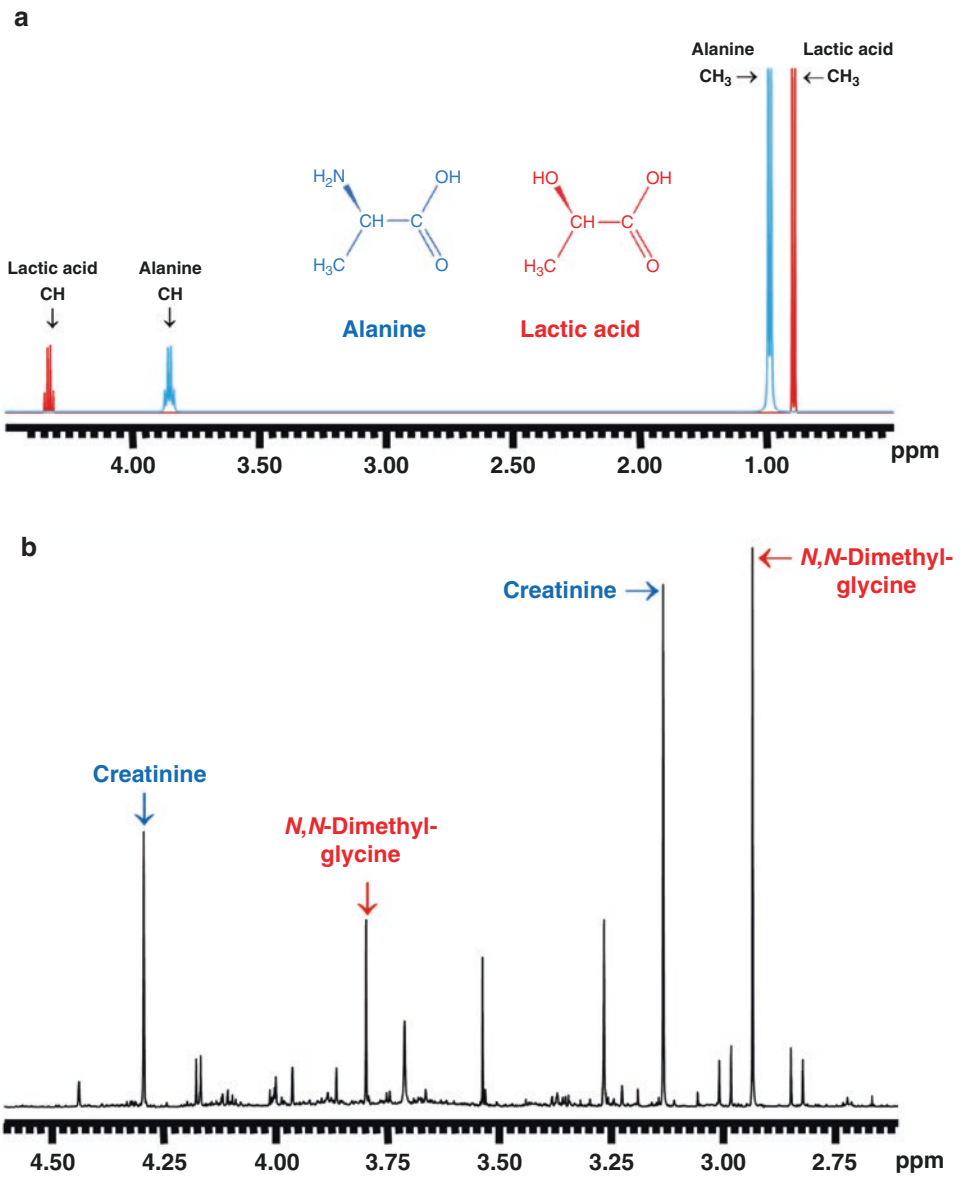

Fig. 7.1 Typical examples of proton NMR spectra. (**a**) NMR spectrum of chemically similar molecules: lactate and alanine. The doublet resonance derives from the methyl group protons ($–CH_3$) and the quartet from the methylene protons (–CH). (**b**) The two singlet resonances in the NMR spectrum of this urine sample both derive from dimethylglycine. The increased concentration of this metabolite is the biomarker for the diagnosis dimethylglycinuria (# 605850) in this patient

– Direct infusion mass spectrometry (DI-HRMS)

In DI-HRMS, no chromatographic separation is performed (Fig. 7.2). Sample preparation is technically uncomplicated, and only a very small sample volume is needed (20 µL plasma, one 3 mm punch from a dried blood spot (DBS), 10 µL cerebrospinal fluid). Features measured through DI-HRMS contain two dimensions of metabolite information: accurate mass to charge ratios (m/z) and signal intensity. Subsequent annotation and putative identification of detected metabolites are solely based on accurate mass. As a consequence, metabolites with an identical mass (e.g., leucine and isoleucine) cannot be distinguished by DI-HRMS. DI-HRMS circumvents the need to create an experimental library containing metabolite masses and retention times, and no alignment of chromatographic peaks is necessary (Haijes et al. 2019a, b; de Sain-van der Velden et al. 2017).

– *Ultra high performance liquid chromatography–high-resolution mass spectrometry* based metabolomics (UHPLC-HRMS)

By performing chromatographic separation before MS analysis, the complex composition of a biological sample can be reduced, as it enables sequential MS analysis of the different metabolites (Fig. 7.2). In this way, matrix effects on ionization efficiency are minimized. Importantly, the retention time of a metabolite adds an additional layer of information for metabolite identification: potential isomers with similar masses can be resolved based on their retention time, and also retention time provides insight in general chemical properties of a metabolite. Ions or "features" measured through UHPLC MS therefore contain

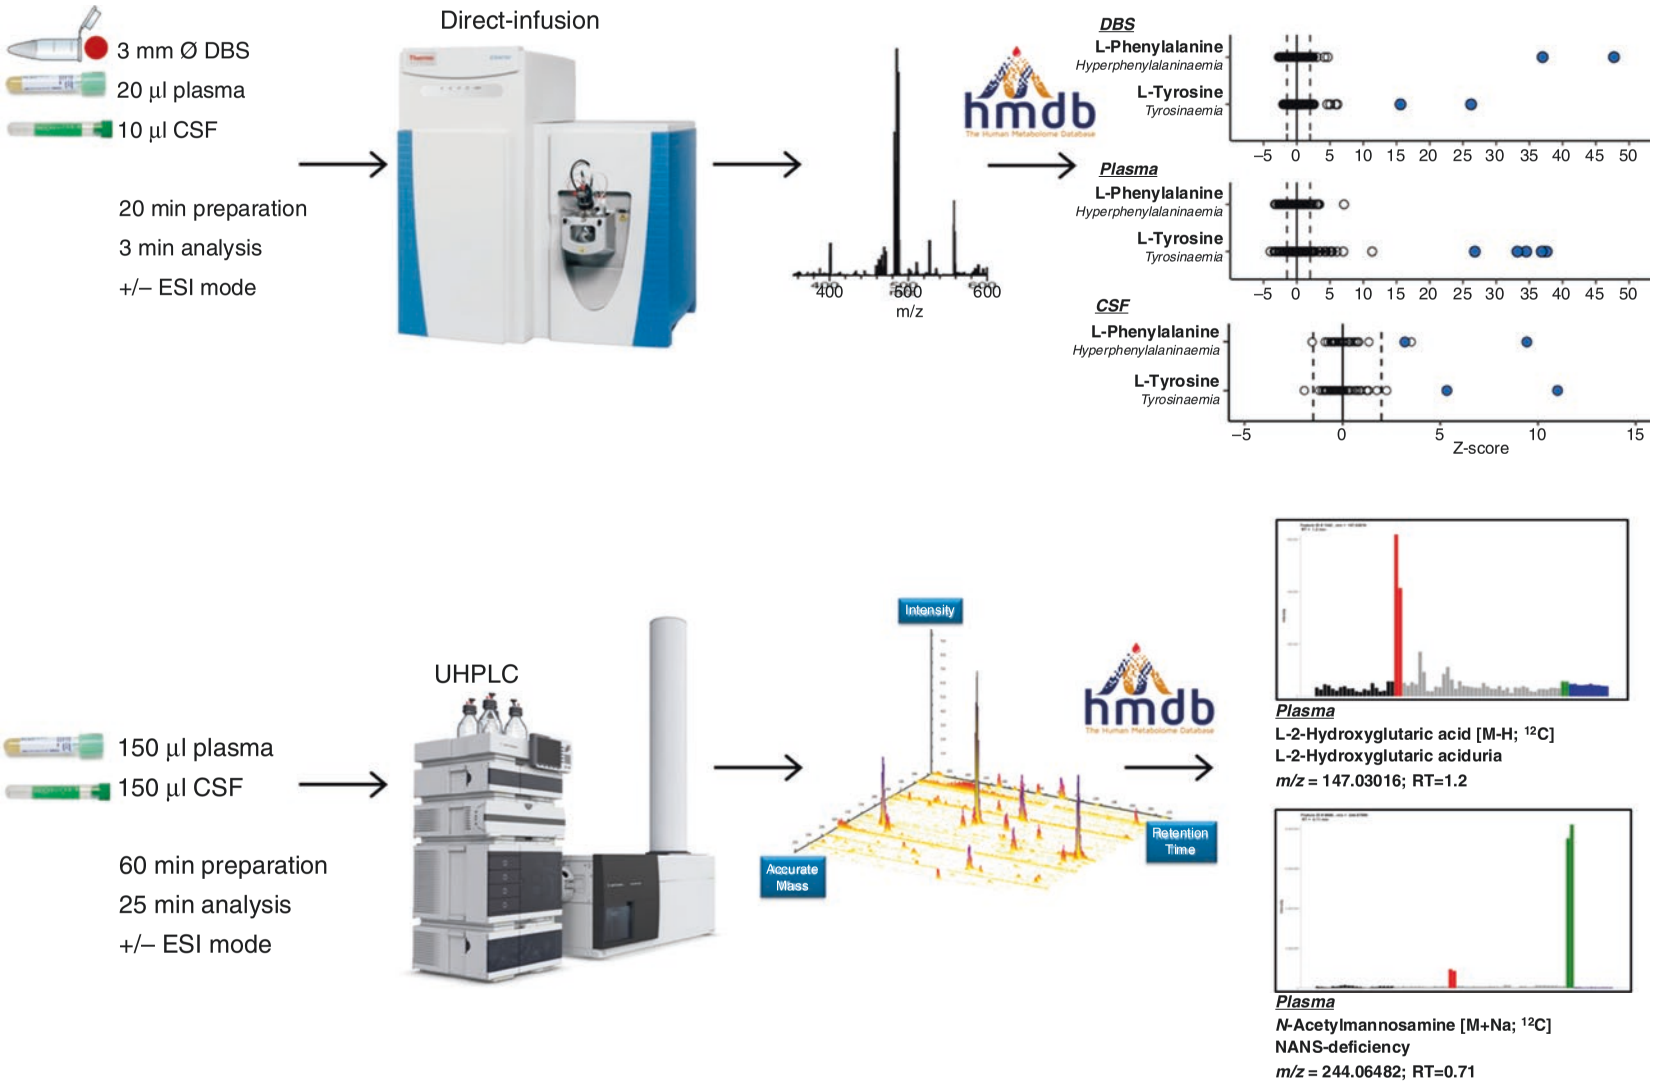

Fig. 7.2 Next-generation metabolic screening: Schematic representation of untargeted metabolomics workflows. The upper workflow shows a direct infusion HRMS strategy, which provides two-dimensional (m/z and intensity) information on detected features. The human metabolome database (HMDB) is used to annotate features for putative identification. Significantly disrupted metabolites can be evaluated and visualized using *Z*-scores. Examples of increased phenylalanine and tyrosine in plasma, DBS, and CSF for hyperphenylalaninaemia and tyrosinaemia are shown, with patients depicted as blue circles and controls as white circles. The lower workflow depicts an ultrahigh pressure liquid chromatography (UHPLC) HRMS approach, which provides three-dimensional (m/z, retention time and intensity) information on detected features. Features can be aligned through XCMS and subsequently annotated using HMDB. Significantly disrupted metabolites can be evaluated based on Bonferroni-corrected *p*-values and visualized in bar plots. To illustrate this, bar plots of L-2-hydroxyglutaric acid in L-2-hydroxyglutaric aciduria and *N*-acetylmannosamine in NANS-deficiency are shown. In red, the patient signal is shown (two bars represent duplicate measurement), black signals represent control individuals; gray signals other patients in the analytical run; blue signals the control plasma, used for analytical quality control purposes; and in green the validation plasma, used for data analysis quality control purposes. The validation plasma is a plasma pool to which different diagnostic metabolites were spiked, including *N*-acetylmannosamine

three dimensions of metabolite information: accurate m/z, retention time, and signal intensity. When using UHPLC-HRMS metabolomics, a minimal volume of 150 μL of a body fluid sample (plasma, urine or cerebrospinal fluid) is required for a single measurement; however, the analyzing laboratory prefers to receive an amount of 500 μL to be able to perform additional measurements or further feature identification.

Different column types exist, which vary in their separation performance for polar metabolites. For untargeted metabolomics, reversed-phase (RP) chromatography can be used, which provides optimal separation for nonpolar and weakly polar metabolites with highly reproducible retention times. Hydrophilic interaction liquid chromatography (HILIC) may provide more optimal separation of polar compounds.

For analysis of UHPLC-HRMS data, typical processing of the raw data involves nonlinear alignment of feature peaks between the different samples in an analytical batch. Several commercial, open-access tools are available for feature alignment, including XCMS (Forsberg et al. 2018). This processing step results in a feature matrix output that contains the m/z ratios, retention time, and intensities of all features identified for each sample analyzed in an analytical batch. This matrix can be used as input for subsequent annotation of metabolites and statistical comparison of metabolites between patients and controls.

Interpretation and Data Statistics

The interpretation of the features detected, whether they come from a DI-HRMS or UHPLC-HRMS experiment, begins with annotation of the exact feature masses to metabolites. The exact masses of features can be queried in open-access databases such as HMDB or Metlin, which contain information on metabolites matching these exact masses for putative identification.

The initial application of untargeted metabolomics has covered comparative analysis of predefined patient groups to controls, both outside and inside the field of inborn errors. The aim of this kind of experiment is to identify a metabolic fingerprint that can make a clear distinction between the disease and control group. For comparing metabolomics data of a disease group versus an unrelated control group, two popular multivariate analysis methods are principal component analysis (PCA) and partial least squares projection–discriminant analysis (PLS-DA). It is beyond the scope of this chapter to further discuss these methods.

To unlock the full clinical potential of untargeted metabolomics for diagnostics in inborn errors of metabolism, however, the focus should be on the analysis of the individual patient suspected of a metabolic disease. Features that are significantly perturbed in a patient sample compared to controls or other patient samples should be identified from the data. Since untargeted metabolomics methods render semi-quantitative results on feature intensity, no reference concentration ranges for individual features can be defined. Absolute intensities can vary between analytical runs; therefore, in general, evaluation of altered metabolite concentrations is based on comparison to a within-run average intensity. The magnitude of the feature alteration can be expressed as fold change or *Z*-score. Statistical testing to assess the significance of individual features can be performed, by a student T-test (if data is normally distributed) or a Mann-Whitney test (no normal distribution). Since the number of univariate comparisons made in such statistical analysis will be equal to the number of features detected (>10,000), there will be a large number of false positives, which is undesirable. Therefore, the *p*-value assigning significance to a finding should be corrected for multiple testing. Two commonly used approaches include the Bonferroni and the False Discovery Rate corrections. Subsequently, metabolites identified as aberrant should be further assessed for clinical relevance.

Examples of Diagnostic and Research Applications of Untargeted Metabolomics/Next-Generation Metabolic Screening

Three consecutive steps in the diagnostic application of untargeted metabolomics data can be recognized. As a first step, the laboratory specialists can focus the interpretation of the untargeted metabolomics data of an individual patient on known biomarkers for known IEMs. In a second interpretation step, candidate genes that derive from exome or genome sequencing can be taken into account to specifically evaluate biochemical signatures of possibly pathogenic gene variants. In a third step, the full untargeted metabolomics data is available to "open the metabolome." This means that the more than 10,000 features that typically result from a single sample are taken into account. The laboratory will use a strategy to prioritize relevant aberrant metabolites for further study. The remaining list of aberrant metabolites may contain features that seldom or never occur in controls and features that are always present but have an abnormally high or low concentration in the specific patient sample. These features may represent the metabolic signature of a genetic disease, but they also may be the result of exogenous factors such as medication, diet, or the microbiome. A fourth application of untargeted metabolomics in IEM is the discovery of novel biomarkers for known diseases, which can provide further insight in the molecular mechanism of a disease or can predict the clinical status of the patient. The four different applications of untargeted metabolomics in IEMs are

further discussed below, and specific examples of the four applications are given.

1. **Analysis of a selection of metabolites known to be associated with IEMs (IEM panel)**

   Analogous to disease gene panel analysis for whole exome sequencing data (WES), a predefined selection of metabolites can be extracted from untargeted metabolomics data as a first step in diagnostic evaluation. This strategy minimizes the risk of missing a diagnosis because a specific targeted assay was not performed based on clinical information. This metabolite panel approach has been shown to be successful in the diagnosis of a broad range of known IEMs in plasma (Coene et al. 2018). For patients with a complex, nonspecific IEM-suspected phenotype, showing clinical signs of neurological dysfunction, energy deficiency, intoxication and/or aberrant storage, a holistic metabolic screening starting with an IEM panel analysis is highly relevant. Figure 7.3a gives an example of the diagnosis in a patient with renal stones due to xanthinuria.

   It should be noted that at present, there is no single metabolomics method which can cover all diagnostically relevant metabolites in one analytical run, due to the diverse chemical nature of different classes of metabolites. The laboratory performing IEM panel analysis from untargeted metabolomics data should be able to provide information on which metabolites and diseases are covered (also comparable to sharing the composition of exome panels) and should perform complementary targeted assays to provide optimal metabolite coverage if indicated based on the clinical phenotype.

2. **Targeted evaluation of metabolites putatively linked to a variant of uncertain significance (VUS) in a metabolically active gene**

   The clinical application of whole exome sequencing techniques generates an unmet need for functional evidence on the pathogenicity of genomic DNA variants (variants of uncertain diagnostic significance, VUS). When these variants occur in metabolically active genes, the untargeted metabolomics data can be mined for the presence of a specific biochemical signature of the variant, which can provide insight in its pathogenicity (e.g., see (Haijes et al. 2019a; Coene et al. 2018; Van Karnebeek et al. 2016; Tarailo-Graovac et al. 2016)). This approach also prevents the need to develop separate targeted assays to evaluate functional consequences of VUS identified in open exome data in metabolically active genes that have not yet been associated with human disease. Based on combining information from the KEGG database with the IEMbase (Lee et al. 2018), it is estimated that over 1200 genes have a function in human metabolism, but have not yet been linked to a known IEM.

   Additionally, upon identification of a heterozygous variant that is known to be pathogenic for an autosomal recessive IEM, functional information can provide the answer whether a second variant may have been missed in the exome data, or whether there could be allelic expression imbalance of the pathogenic variant (Falkenberg et al. 2017). Figure 7.3b shows an example of a patient with a homozygous VUS in the *ASPA* gene in WES analysis. The untargeted metabolomics data show that this VUS is nonpathogenic.

   To assure that a diagnostic link can be made between metabolomics and exome data, the metabolic and genetic laboratory should be tightly connected to discuss patient results and integrate genetic and functional data when reporting to the clinician.

3. **Unbiased analysis of untargeted metabolomics data ("open the metabolome")**

   When no diagnostic leads have been found in IEM panel analysis and clinical suspicion of an IEM remains high, a patient's untargeted metabolomics data can be investigated beyond known IEM-associated metabolites, thereby venturing into the unknown areas of the human metabolome. This is still a challenging endeavor, as the majority of metabolites detected in an untargeted setting are of unknown or uncertain identity. Especially when exome data did not render clear metabolic leads or is not available, the diagnostic interpretation of the untargeted metabolome can be difficult and time-consuming. A combined approach of exome sequencing and MS-based untargeted metabolomics in an individual patient is the discovery of NANS-deficiency (Fig. 7.3c). This was the first example of the ability of this combined approach to find as yet unknown IEMs (Van Karnebeek et al. 2016). To select clinically relevant metabolites and prioritize unknown features for further identification, it is advisable to collect at least two samples of an individual patient at different timepoints to eliminate dietary effects on the metabolome. Also, an accurate overview of the patient's medication should be provided to the laboratory performing untargeted metabolomics, as features arising from medication can obscure the metabolomic profile. Valproic acid, for example, is notorious for this.

4. **Identification of novel biomarkers for known IEMs**

   For the diagnosis and follow-up of therapy of an IEM, current methods often rely on single biomarkers, usually the substrate of the defective enzyme. This may work very well to delineate the diagnosis; however, metabolites further down- or upstream of the metabolic block may prove to be more relevant when it comes to reflecting the clinical signs and symptoms, as is known for neurotransmit-

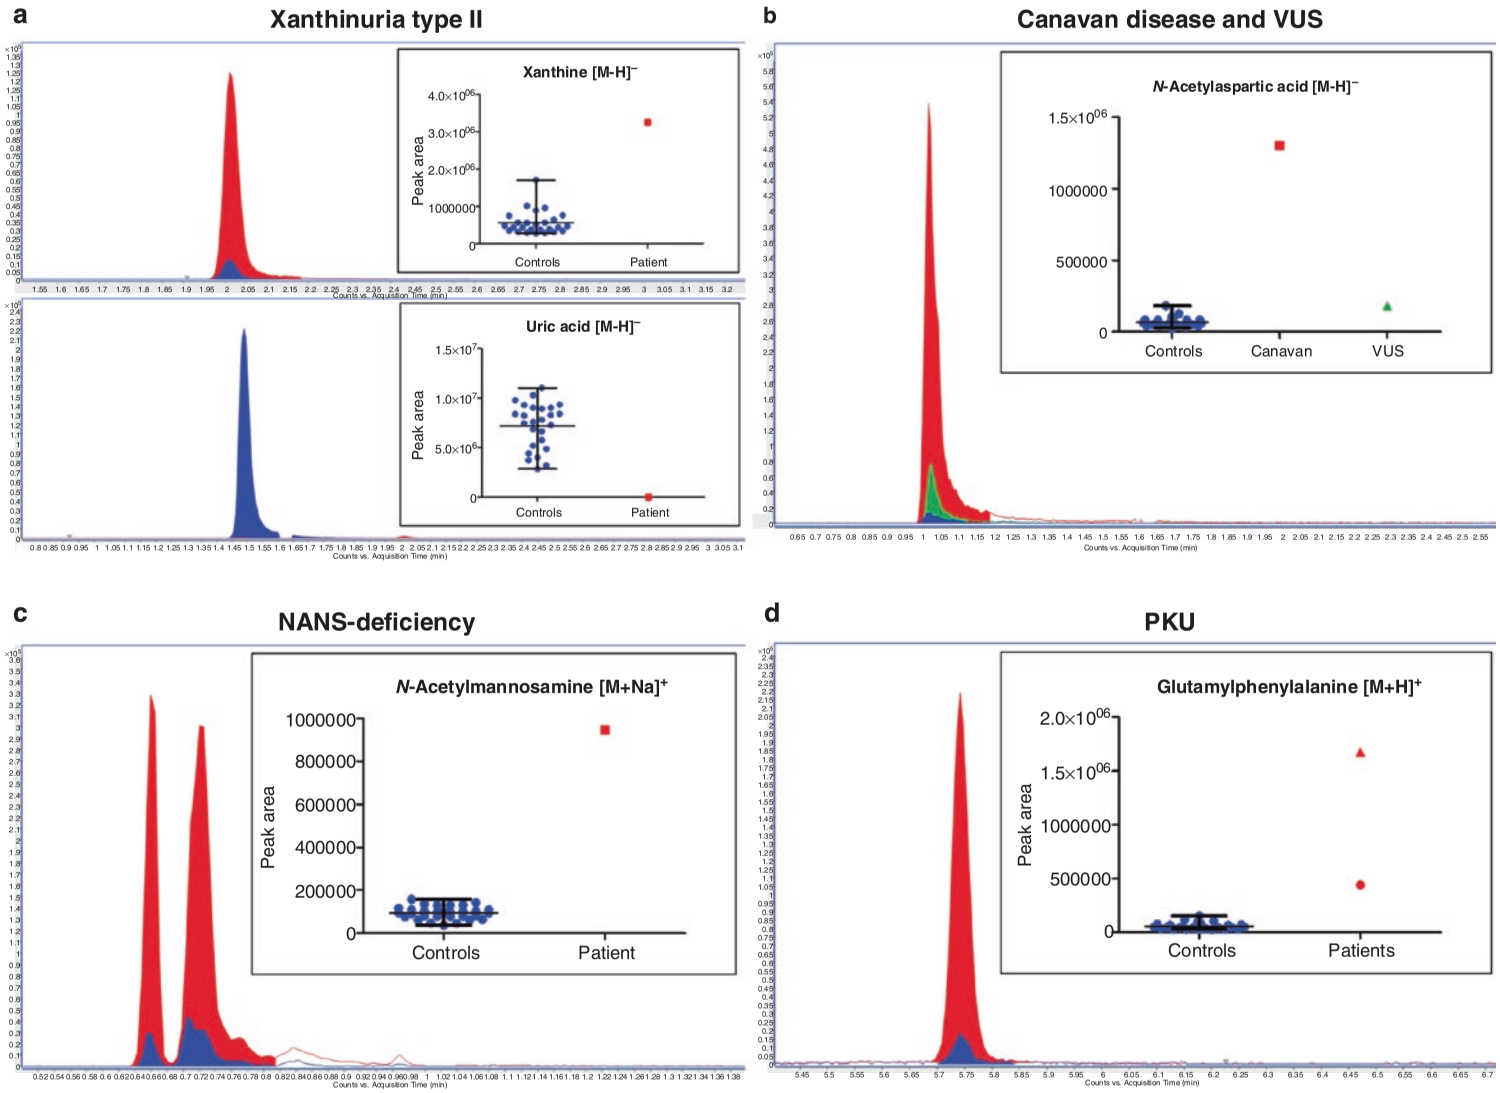

Fig. 7.3 Four different applications of untargeted plasma metabolomics in IEM. (**a**) Extracted ion chromatogram (EIC) of masses 151.0261 and 167.0211 from xanthine $[M-H]^-$ and uric acid $[M-H]^-$, respectively, in plasma of a patient with xanthinuria type II and one representative control (blue). The insets show the feature intensity distribution in a scatter plot of xanthine and uric acid (blue, controls $n = 26$; red, patient $n = 1$). (**b**) EIC of mass 174.0408 from *N*-acetylaspartic acid $[M-H]^-$ in plasma of patient with Canavan disease (red), a patient with a VUS in the Canavan-associated *ASPA* gene (green) and one representative control (blue). The inset shows the feature intensity distribution in a scatter plot of *N*-acetylaspartic acid (blue, controls $n = 26$; red, Canavan patient $n = 1$; green VUS patient $n = 1$). The profile allows the conclusion that the VUS is nonpathogenic and the patient does not suffer from classical Canavan disease. (**c**) EIC of mass 244.0792 from *N*-acetylmannosamine $[M + Na]^+$ in plasma of patient with NANS-deficiency (red) and one representative control (blue). The inset shows the feature intensity distribution in a scatter plot *N*-acetylmannosamine (blue, controls $n = 31$; red, NANS patient $n = 1$). (**d**) EIC of mass 295.1289 from glutamylphenylalanine $[M + H]^+$ in plasma of patient with PKU (red) and one representative control (blue). The inset shows the feature intensity distribution in a scatter plot of glutamylphenylalanine (blue, controls $n = 28$; red, PKU patients $n = 2$) (*red triangle* untreated, *red circle* treated)

ter defects. Additionally, alternative metabolism of the accumulating substrate may be pivotal for our understanding of the pathophysiology of a disease. The untargeted metabolomics technology may provide us with a window of opportunity for this. Because of the holistic and highly sensitive character of this approach, it will enable us to simultaneously evaluate an array of relevant metabolites from the affected pathway and from other pathways that maybe are influenced by the defect. The paper of Václavík et al. nicely illustrates this for PKU (Václavík et al. 2018). In a group of seven clinically stable PKU patients under adequate treatment, six novel biomarkers for PKU were discovered (in Fig. 7.3d the novel biomarker glutamylphenylalanine, a dipeptide with m/z 295.1289, is shown as an example) (Václavík et al. 2018). Such additional metabolic disturbances that now come to light will inspire investigators to do future studies on the pathophysiology of PKU. Another example concerns Snyder-Robinson syndrome (SRS). At the metabolite level, this disease was hitherto diagnosed by analysis of the spermine/spermidine ratio in lymphoblasts. Untargeted plasma metabolome analysis revealed significantly elevated levels of N8-acetylspermidine, a precursor of spermine biosynthesis, as an easy plasma biomarker for SRS (Abela et al. 2016). These studies illustrate the potential of metabolomics in clinical practice and research.

Features of Unknown Significance

A significant percentage of features in MS-based untargeted metabolomics data cannot be easily identified using the existing knowledge stored in public databases like HMDB. They are features of unknown identity. These may be "known unknowns" that are commonly occurring in the population, which are not clinically relevant when their concentration is not unusual. In that case the bioinformatic pipeline may be able to filter these out. Potentially more interesting are the "unknown unknowns" that are specifically abundant in the patient under investigation and not in controls. Biomarkers of an IEM of that patient may be among them. Collectively, the features in this latter group are coined as **Features of Unknown Significance (FUS).** Further they reflect known intermediates of primary human metabolism, metabolites from secondary metabolism, but also metabolites from uncharted metabolic pathways. Additionally, they may derive from the diet, the microbiome, or the medication that the patient uses. For the metabolic laboratories, it is therefore of utmost importance to have the information about medication used when interpreting an untargeted metabolomics profile. These unknowns may warrant additional strategies to identify the metabolite behind that feature. To identify a feature of unknown significance, the University of Alberta offers a web-based program, "My Compound ID" (http://mcid.chem.ualberta.ca/) that allows a user to search a query mass to generate a list of possible matches with metabolites in an evidence-based metabolome library. This library is composed of 8021 known human endogenous metabolites and their predicted metabolic products (375,809 compounds from one metabolic reaction and 10,583,901 from two reactions). If the MS/MS spectrum of the query mass ion is available, this program also allows the user to interpret the MS/MS spectral pattern against the list of metabolite candidates generated from the mass search to narrow down the list into one or a few unique structures.

Currently, there are four other options that may help to identify the so-called FUS: (1) First there are the in-source fragments that are formed in the MS-detector from the feature at stake. (2) Multistep fragmentation techniques (so-called MS^n) as used in the paper by Václavík (Václavík et al. 2018). (3) NMR spectroscopy as illustrated in the paper of van Karnebeek et al. (Van Karnebeek et al. 2016). (4) LC-infrared ion spectroscopy as explained and shown in the paper of Martens et al. (2018).

When more groups around the world will be using untargeted metabolomics techniques and start sharing their data, the issue of the substantial amount of features that cannot be identified will gradually diminish.

Future Perspectives and Challenges

HRMS-based untargeted metabolomics methods now offer an unprecedented opportunity to fully dissect the human metabolome, down to metabolites in the low nanomolar concentration range. Whereas the use of untargeted metabolomics in diagnostic practice for IEM is currently limited to a few clinical laboratories, we anticipate that its application will increase exponentially in the near future. More laboratories will gain access to HRMS set-ups, and bioinformatics solutions will allow for the integration of NGMS data with WES or WGS data in a combined diagnostic report.

However, several challenges in the application of untargeted metabolomics in clinical practice still exist. A major challenge is formed by the detection of features of unknown clinical significance or even of unknown identity in the vast amount of untargeted metabolomics data.

For building knowledge on clinical significance, many factors need to be taken into account including genomic variation as well as exogenous factors such as medication, food intake, age, microbiotic composition, etc. This daunting amount of information that we cannot judge appropriately yet can only be addressed by recording as much information as possible and sharing the information on these big data internationally. The multifactorial nature of the metabolome is also partially represented in "The Virtual Metabolic Human"

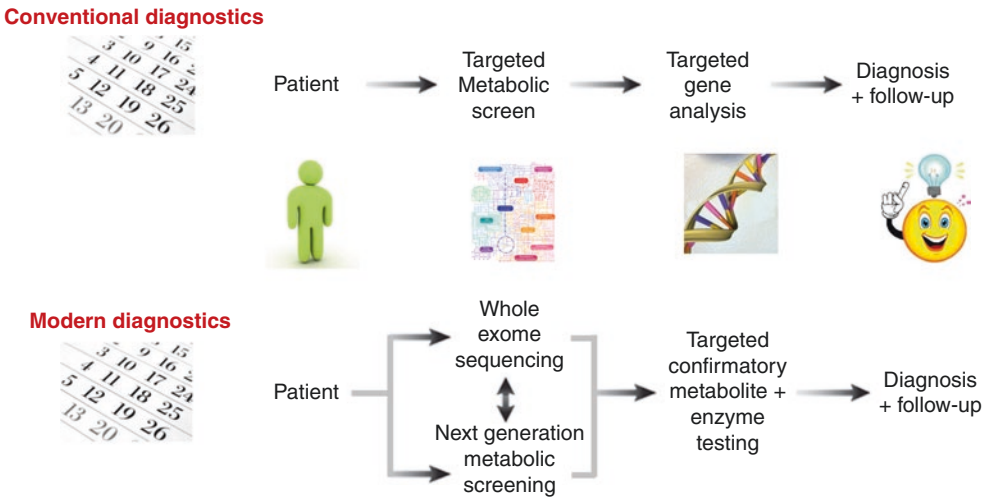

Fig. 7.4 NGMS and WES/WGS in concert. The conventional method of finding the diagnosis of an IEM compared to the proposed contemporary approach where WES/WGS is used in parallel with NGMS to obtain an optimal diagnostic efficacy

(VMH, www.vmh.life), a database capturing information on human and gut microbial metabolism and linking this information to diseases and nutritional data. The VMH at the time of writing this chapter captures 5180 unique metabolites, 17,730 unique reactions, 3695 human genes, 255 Mendelian diseases, 818 microbes, 632,685 microbial genes, and 8790 food items (Noronha et al. 2019).

Public databases like the Human Metabolome Database (HMDB) and Metlin are essential in the interpretation of the large amount of features in the untargeted metabolomics data. It will be a major effort, requiring the input of many colleagues and laboratories, to identify all small molecule features occurring in human body fluids. Analogous to deciphering the significance of genetic variants of unknown significance, national and international collaboration in the metabolic community will be pivotal to bring our understanding of human metabolism to the next level. Databases such as the HMDB are a perfect vehicle to store new metabolic knowledge and share it with the IEM and broader scientific community. Although there is progress, it is at the same time clear that we are far from understanding the full complexity of the many metabolites in our body fluids.

In addition to expanding our knowledge on interpreting the metabolome of an individual, efforts will be directed toward making untargeted metabolomics accessible and integrating it smoothly in diagnostic practice. An integrated diagnostic report of WES/WGS and metabolomics results report should be feasible within the near future by combining the various existing databases with genetic and metabolic information using bioinformatics (Fig. 7.4). Despite the multifaceted functions, untargeted metabolomics can serve in diagnostics of IEMs, an important role of targeted metabolomics in patient care will remain in the foreseeable future. MS-based untargeted metabolomics provides semi-quantitative data. For patients with a known disease, requiring quantitative assessment of specific metabolites for therapy follow-up, a dedicated quantitative analysis may be desired.

Unfortunately, no single analytical technique will be able to reveal the complete spectrum of metabolites in body fluids or cell extracts. The untargeted metabolomics techniques in this chapter are not suited for holistic analysis of lipids, which requires dedicated lipidomics techniques. Metabolic workup of a patient traditionally relies on metabolite analysis in body fluids. This also means that metabolites that cannot escape the cellular surroundings will generally not be detected when assessing plasma. Examples are phosphorylated metabolites and again the lipids. This stresses the relevance of analyzing the intracellular metabolome for future diagnostic purposes.

Summary

Most inborn errors of metabolism (IEMs) have a potential for central nervous system (CNS) injury resulting in chronic encephalopathy. IEMs may affect CNS structures in a manner dependent upon disorder type, stage of brain development, severity, and/or duration. Several of the disorders share a final common pathway to brain dysfunction such as disruption of astrocyte function, excitotoxicity, and/or energy failure.

Neuroimaging has emerged as a powerful clinical tool to study the brain in a noninvasive manner in order to assist in distinguishing disorders from one another, despite very similar clinical manifestations. As there are limited ways in which the CNS can respond to insults, imaging manifestations are often nonspecific. Nonetheless, there is a striking anatomical pattern of vulnerability in many IEMs. Some IEMs cause reasonably predictable disease patterns that can be suggestive or diagnostic. Specific neuroimaging patterns of inborn metabolic errors are the focus of this chapter.

Introduction

It is important to alert the radiologist or neuroradiologist whenever there is clinical concern for a metabolic abnormality affecting the CNS. The MRI armamentarium contains numerous sequences that can be chosen to identify alterations in brain structure, texture, water movement, metabolism, and mineralization and to detect hemorrhage. Time constraints limit sequence selection to only those most necessary and relevant. Therefore, the provided history should be as specific as possible to ensure that the imaging exam will be tailored using an appropriate pulse-sequence prescription most likely to determine the IEM type and/or answer the clinical question. "New onset generalized seizures and developmental regression" is an example of an adequate history, while "encephalopathy" is more nonspecific and "rule out pathology" is simply unacceptable. "Rule out x" is never appropriate in isolation, but welcomed after explaining *why* x needs to be excluded. Pertinent lab values and head circumference are useful to include in the neuroimaging order request in some cases. A history of prematurely and estimated gestational age should always be disclosed as the expected normal appearance of the brain changes over time, especially with regard to myelination. This concept is best captured by the idiom "garbage in, garbage out." Inadequate exam indications have a higher chance of yielding the unsavory phrase, "correlate clinically."

Dominant factors influencing modality selection and examination protocols include patient age, past medical history (especially contraindications to contrast material and/or MRI), signs, symptoms, and the history of present illness. Head ultrasound is often the initial imaging exam in the neonatal setting given its near universal access, portability, ease of acquisition, and lack of ionizing radiation. Drawbacks of ultrasound include a relative insensitivity and poor specificity for brain pathology. CT excels in the detection of calcifications and hemorrhage. It can also be useful in the acute setting to quickly identify actionable intracranial abnormalities and when sonographic findings require clarification. However, MRI is the reigning gold standard in the neuroimaging assessment of the CNS. In addition to its ability to demonstrate multiplanar fine structural details, it exploits inherent and acquired differences in tissue properties to reveal changes in disease states. Therefore, the sensitivity and specificity of MRI generally exceed those of ultrasound and CT.

A typical brain MR protocol for suspected metabolic abnormalities should include both conventional sequences (i.e., T1WI, T2WI) and advanced imaging techniques such as diffusion tensor imaging, perfusion, and proton magnetic resonance spectroscopy (1H MRS). A magnetization transfer sequence is also useful in the evaluation of leukodystrophies to determine the type of white matter disturbance. Intravenous gadolinium-based contrast agents (GBCAs) may be useful when the specific diagnosis is uncertain as these add specificity to some IEMs and help exclude mimics such as infection and subacute infarction. Spine MR imaging can also be useful in some disorders to improve diagnostic specificity.

1H MRS has great utility in the initial work-up and subsequent follow-up of metabolic disturbances/disorders. Although a nonspecific pattern (elevated choline, depressed NAA) is common in many types of brain disease, short echo 1H MRS (TE < 40 ms) can reveal more specific metabolic signatures. Furthermore, temporal changes on subsequent exams can support or refute the benefit of ongoing

therapeutic measures. A simple single voxel technique boasts better signal-to-noise ratios and allows shorter TE options when compared with multivoxel technique (Bluml and Panigrahy 2013). Voxel size is a balance between signal-to-noise (SNR) and tissue specificity; ideally, it should be as large as possible to achieve satisfactory SNR but small enough to target the area of interest. Generally, a 2 × 2 × 2 cm voxel is used; voxels smaller than 1 cm^3 are unlikely to be worthy of the acquisition time it would require to achieve reasonable SNR. Voxel location and echo times should be selected based on the suspected and/or discovered disease patterns. Hemorrhage, iron, and calcification hamper 1H MRS quality and impact SNR; these should be avoided, and if unavoidable, 1H MRS should not be performed as misleading information could be returned. In our experience, two acquisitions using two different echo (short and longer) are more useful and preferable to one whenever feasible. The reasons are multifactorial, but some notable issues relate to the fact that metabolites in small concentrations tend to be more visible using short echo times, metabolic peak overlap may be more or less apparent at different echo times, J coupling and J modulation are altered at different echo times, longer echo times have less inherent noise, and metabolites have different T2 properties. We typically perform ultrashort (TE 14, TR 1500; STEAM technique), short (TE 35, TR 1500–2000; PRESS technique), and intermediate (TE 144, TR 1500–2000; PRESS) or long (TE 288, TR 1500–2000; PRESS) echo time sequences. Magnetic field strength dictates the choice of the longest echo time; because lactate detection is unreliable at 144 ms TE at 3 T field strength, we use a 288 ms TE at 3 T instead (Lange et al. 2006).

The vast majority of inborn errors of metabolism (IEM) have a nonspecific neuroimaging phenotype. Imaging manifestations often overlap among IEMs and more broadly with other CNS diseases. This is especially true at the extremes of the disease time course where normal exams may be found early on and in presymptomatic individuals, and diffuse chronic brain changes are often present in the end-stage patient. However, some IEMs tend to be more specific, and others can be diagnostic using MRI and/or MRS. After a deviation from the age-expected normal appearance is recognized, the next step in interpretation is to determine the disease pattern, if present, using images from all available modalities and time points. Several imaging features raise concern for the possibility of an IEM: symmetric abnormalities in brain signal/density/echogenicity, disease patterns atypical for ischemic and infectious insults, mixed aged lesions, temporal variability inconsistent with the expected evolution of a static encephalopathy, and unexpected spectroscopic abnormalities. Of course, the imaging results should always be interpreted in the context of the clinical picture. Metabolic disorders with suggestive or diagnostic neuroimaging appearances in the therapeutic naive state are discussed in the following paragraphs with associated figures.

Intoxication Type Disorders/Acute Metabolic Encephalopathy

The disorders typically defined as intoxication type share a similar clinical presentation. Several groups of IEM including the organic acidemias, urea cycle disorders, and certain disorders of amino acid metabolism typically present with acute life-threatening symptoms and a rapidly evolving encephalopathy. These symptoms are the result of a toxic accumulation of metabolites in the CNS. Symptoms may include seizures, apnea, respiratory distress, and lethargy progressing to coma due in part to ensuing brain edema. While nonspecific in nature and clinically difficult to differentiate the underlying diagnosis, several of these diseases have characteristic imaging patterns, some of which are illustrated below.

Maple Syrup Urine Disease (MSUD)

Neonatal encephalopathy is the most common presentation of this aminoacidopathy. Marked, extensive brain edema is typical, comprised of mixed subtypes: vasogenic edema in unmyelinated white matter and intramyelinic edema in myelinating white matter (Whitehead and Gropman 2018; Jan et al. 2003; Sakai et al. 2005; Terek et al. 2013; Ha et al. 2004). White matter reduced diffusion is usually quite profound, especially in the projectional fibers, thalami, globus pallidus, pontocerebellar fibers, and deep cerebellar nuclei (Whitehead and Gropman 2018; Jan et al. 2003; Ha et al. 2004; Barkovich and Patay 2019) (Fig. 8.1). Diffusion abnormalities may in part reflect spongiotic dysmyelination with intramyelinic edema rather than demyelination given the lack of magnetization transfer signal, prolonged persistence in patients under dietary control, and the presence in presymptomatic patients (Terek et al. 2013; Ha et al. 2004; Sener 2002; Myers et al. 2012). Diffusion abnormalities in more maturely myelinated brains may be more widespread (Sakai et al. 2005). Milder phenotypes may show only hypomyelination and mild atrophy, T2 prolongation in the globus pallidus, and/or deep cerebral white matter hyperintensity (Ishikawa et al. 1991; Li et al. 1997; Muller et al. 1993). In adolescent and adults, extensive cerebral cortical restricted can occur during metabolic decompensation (Jan et al. 2003). Central spinal cord T2 prolongation has been shown in a sibling pair with MSUD (Bhat et al. 2013).

MRS shows multiple enlarged macromolecular peaks corresponding to branched chain amino acids (BCAAs), branched chain ketoacids (BCKAs), lipid, and lactate along with elevated choline and myoinositol and depressed *N*-acetylaspartate (NAA) (Bluml and Panigrahy 2013; Jan et al. 2003; Terek et al. 2013) (Fig. 8.1). Notably, longer echo times improve diagnostic specificity in MSUD by eliminating the normal background macromolecular signal that can hide BCAA/BCKA peaks (Jan et al. 2003).

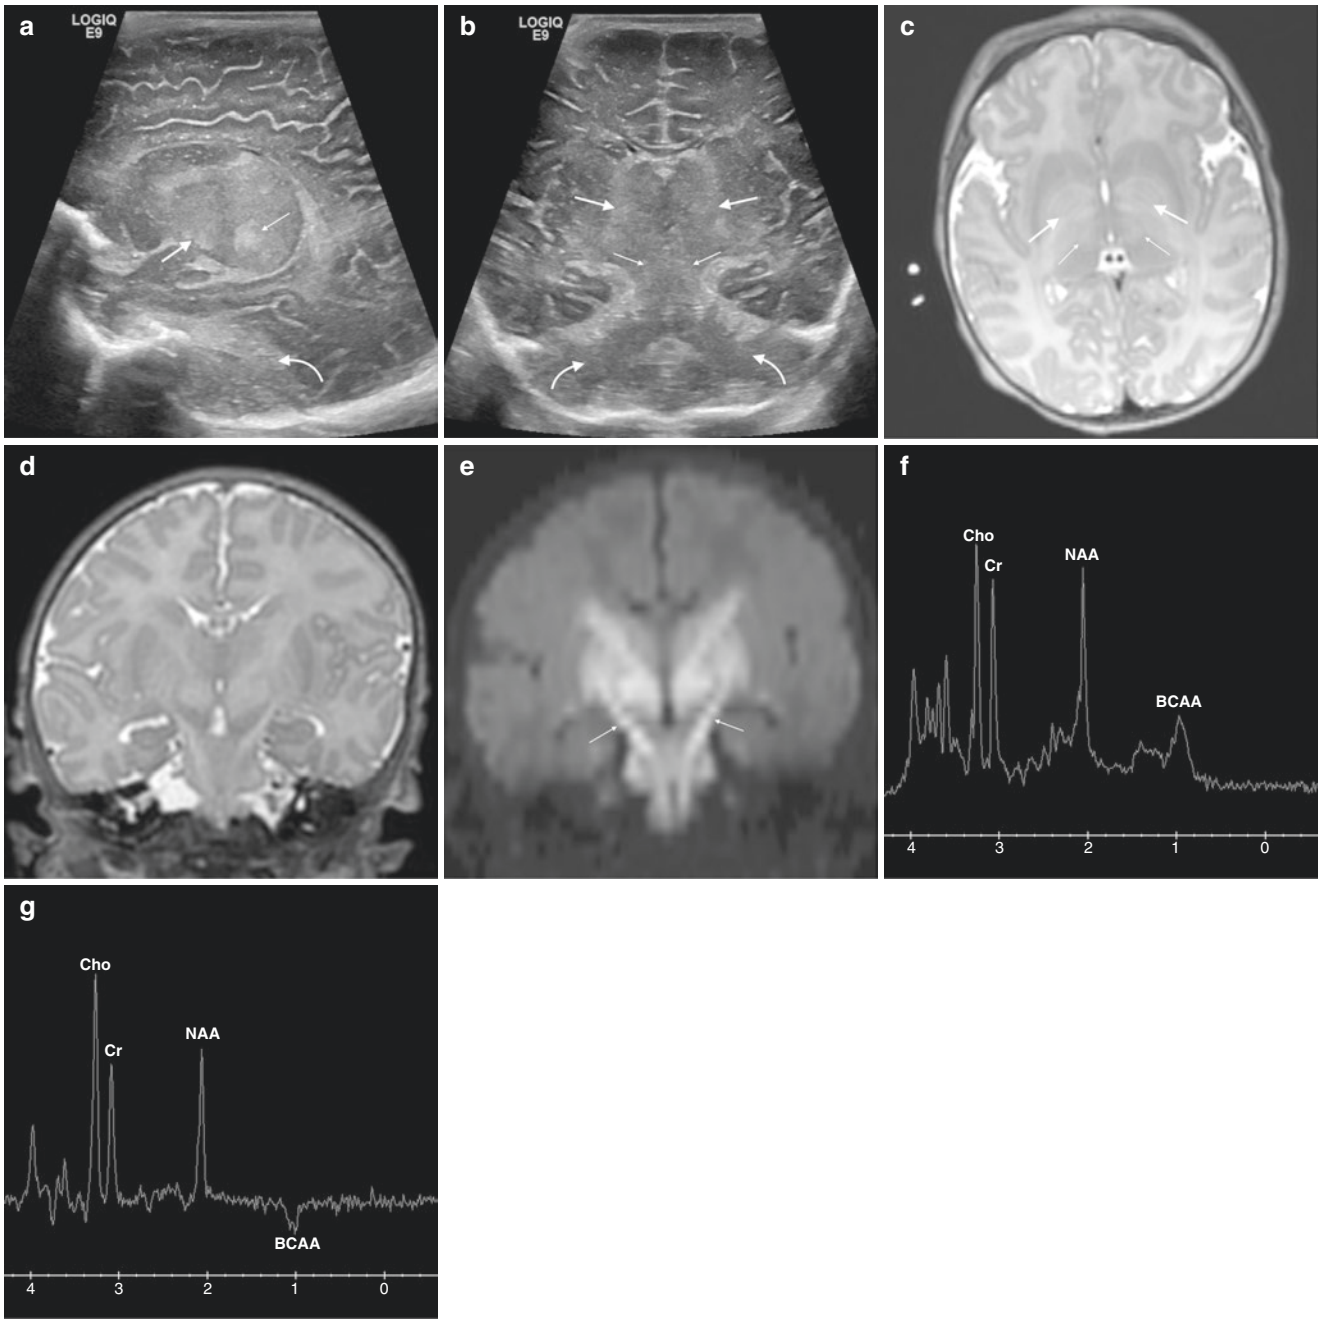

Fig. 8.1 Neonatal female with maple syrup urine disease (MSUD). (**a**) Parasagittal gray-scale ultrasound image of the brain shows abnormal hyperechogenicity in the cerebral white matter, lentiform nuclei (thick arrow), thalamus (thin arrow), and imaged cerebellum representing edema (curved arrow). (**b**) Coronal gray-scale ultrasound image of the brain shows thalamic (thick arrows), brainstem (thin arrow), and cerebellar (curved arrow) hyperechogenicity representing edema. (**c**) Axial T2-weighted MR image (TR/TE msec, 2500/65) through the basal ganglia depicts abnormal hyperintense signal in parts of the globi pallidi (thick arrows), thalami (thin arrows), and white matter. Coronal T2WI (TR/TE msec, 2500/65) (**d**) and corresponding diffusion weighted image (TR/TE msec, 8000/84) (**e**) in a similar plane to (**b**) show signal abnormality and reduced diffusion representing intramyelinic edema in the basal ganglia, thalamus, and brainstem with notable involvement of projectional fibers representing intramyelinic edema (arrows, **e**). Single voxel MRS over the left basal ganglia (TR/TE msec, 1500/35) (**f**) and (TR/TE msec, 1500/144) (**g**) reveal a broadened metabolic peak at 0.9–1.1 ppm that inverts on the longer echo time MRS (arrows), representing branch chain amino acids/branch chain keto acids (BCAA)

Nonketotic Hyperglycinemia (NKH)

NKH is an amino acidopathy that typically presents in the neonatal period with encephalopathy, seizures, and hypotonia. Neuroimaging features can be quite specific when MRI and 1H MRS are obtained and interpreted in parallel. Namely, intramyelinic edema manifested by reduced diffusion can be seen in the myelinating fibers of the cerebrum, cerebellum, and brainstem, with excessive hyperintense signal on T2WI in the unmyelinated white matter either representing undermyelination and/or vasogenic edema (Whitehead and Gropman 2018; Whitehead et al. 2015; Stence et al. 2019) (Fig. 8.2). These changes occur in similar locations as those found in maple syrup urine disease (MSUD), but are typically much less severe and extensive. The corpus callosum is often hypogenetic and the total brain volume small (Whitehead and Gropman 2018; Whitehead et al. 2015; Stence et al. 2019) (Fig. 8.2). Wei and colleagues reported a case of long tract hyperintensity on T2WI spanning from the dorsal medulla into the cervical and thoracic dorsomedial spinal cord (Wei et al. 2011).

1H MRS reveals elevated glycine at 3.55 ppm that correlates more reliably with the clinical status than plasma and CSF glycine concentrations (Bluml and Panigrahy 2013; Whitehead and Gropman 2018; Whitehead et al. 2015; Heindel et al. 1993) (Fig. 8.2). It is necessary to obtain at least one 1H MRS data point using an intermediate (i.e., 144 ms) or long (i.e., 288 ms) echo time to remove the spectral contamination of MI around 3.5 ppm.

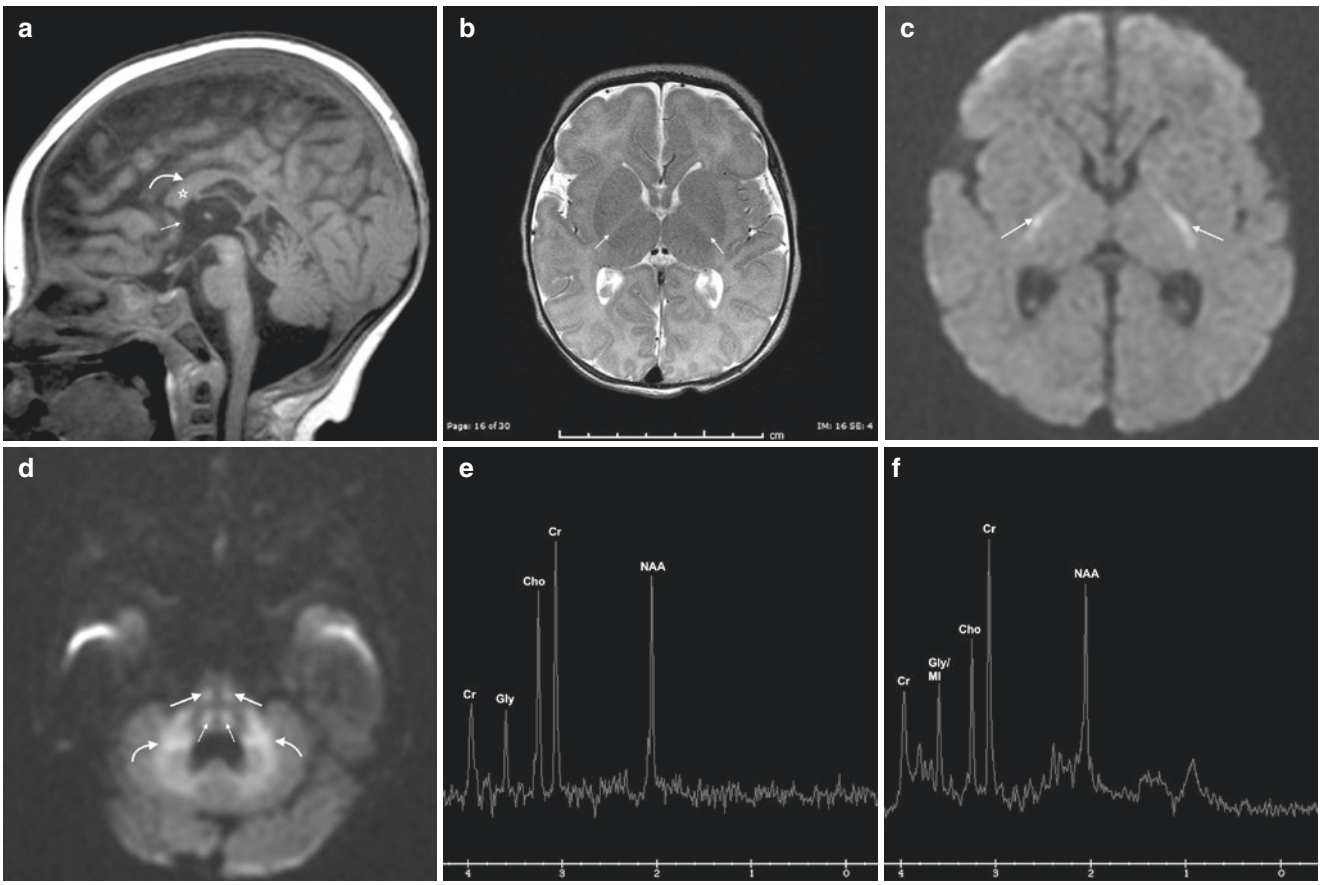

Fig. 8.2 Neonatal female with nonketotic hyperglycinemia. (**a**) Sagittal midline T1WI (TR/TE msec, 7/2) demonstrates multiple structural midline abnormalities including a thin, shortened hypogenetic corpus callosum (curved arrow), marked hypoplasia of the anterior commissure (thin arrow), hypoplasia of the septum pellucidum (star), and mild pontine hypoplasia. (**b**) Axial T2WI (TR/TE msec, 3183/96) at the level of the basal ganglia shows lack of normal myelination-related hypointensity of the posterior limb of the internal capsule (PLIC) (arrows). Axial DWI (TR/TE msec, 80,000/85) through the basal ganglia (**c**) and posterior fossa (**d**) shows increased signal/reduced diffusion in the PLIC (arrows, **c**), corticospinal tracts (thick arrows, **d**), central tegmental tracts (thin arrows, **d**), and middle cerebellar peduncles/deep cerebellar white matter (curved arrows, **d**). Single voxel MRS over the left basal ganglia (TR/TE msec, 1500/144) (**e**) and (TR/TE msec, 1500/35) (**f**) reveals an abnormal metabolic peak at 3.6 ppm that overlaps with myoinositol on the short echo MRS consistent with glycine (gly). Creatine (Cr) is elevated, while choline (Cho) is mildly depressed, altering the normal ratios of NAA, Cr, and Cho

Methylmalonic Aciduria (MMA)

Typical presentation of metabolic acidosis and coma is not enough to differentiate this clinically from other intoxication disorders. In MMA, the basal ganglia are commonly affected with or without concurrent involvement of the substantia nigra and dentate nuclei. In particular, the globus pallidi are involved dominantly or in isolation (Whitehead and Gropman 2018). In decompensation, reduced diffusion is present in the basal ganglia, and chronic injury leads to regional volume loss and hyperintense signal on T2WI with facilitated diffusion (Fig. 8.3). Lactic acidosis is often shown on 1H MRS (Bluml and Panigrahy 2013).

Glutaric Aciduria Type I

This IEM may be differentiated clinically due to movement disorders that may present acutely and may have associated macrocrania. On MRI, hyperintense basal ganglia signal on T2WI with restricted diffusion sparing the thalami may be found in acute symptomatic patients (Whitehead and Gropman 2018; Barkovich and Patay 2019; Whitehead et al. 2015) (Fig. 8.4). Cerebral white matter hyperintensity and cerebellar deep gray nuclear involvement may also be present. Important structural features that help distinguish glutaric aciduria from other IEMs include underopercularization and enlarged extra-axial spaces in the middle cranial fossae (Whitehead and Gropman 2018; Barkovich and Patay 2019; Whitehead et al. 2015) (Fig. 8.4). Progressive atrophy often leads to development of nontraumatic subdural hemorrhage. Glutaric acid has been found using 1H MRS, along with reduced NAA and creatine, elevated choline, and lactate (Bluml and Panigrahy 2013; Harting et al. 2015).

L-2-Hydroxyglutaric Aciduria

In this rare IEM, clinical symptoms overlap with those of other intoxicating disorders. Conversely, neuroimaging features are quite suggestive when present, as this is one of the few disorders that manifests a centropedal cerebral lesion severity gradient from superficial to central (Barkovich and Patay 2019; Fourati et al. 2016) (Fig. 8.5). Thus, subcortical precedes deep white matter involvement, and external and extreme capsules are affected prior to the deep gray structures. Cerebellar deep gray nuclei are also quite commonly affected (Barkovich and Patay 2019; Fourati et al. 2016). In addition to decreased NAA and choline concentrations, L-2-hydroxyglutaric acid elevation has been suggested on MRS at 2.5 ppm (Fourati et al. 2016; Anghileri et al. 2016).

Urea Cycle Disorders (UCD)

Acute metabolic decompensation associated with hyperammonemia (HA) and intermediate metabolite toxicity causes brain swelling, edema, and variable injury, especially in the neonatal period and more commonly in complete proximal urea cycle defects (Helman et al. 2014; Pacheco-Colon et al. 2013). Patients may have mild (partial deficiencies, later onset) to severe HA (infant onset). There is a metabolic alkalosis that can, for example, help distinguish UCD from MMA that can have lower levels of HA. Disease patterns may vary based on the specific enzymatic or transporter defect, though phenotypic similarities are common among UCD subtypes (Barkovich and Patay 2019). The most familiar imaging patterns are "diffuse" and "central" with the latter isolated to the insular/peri-insular, perisylvian, perirolandic, internal capsular, and/or basal ganglia regions

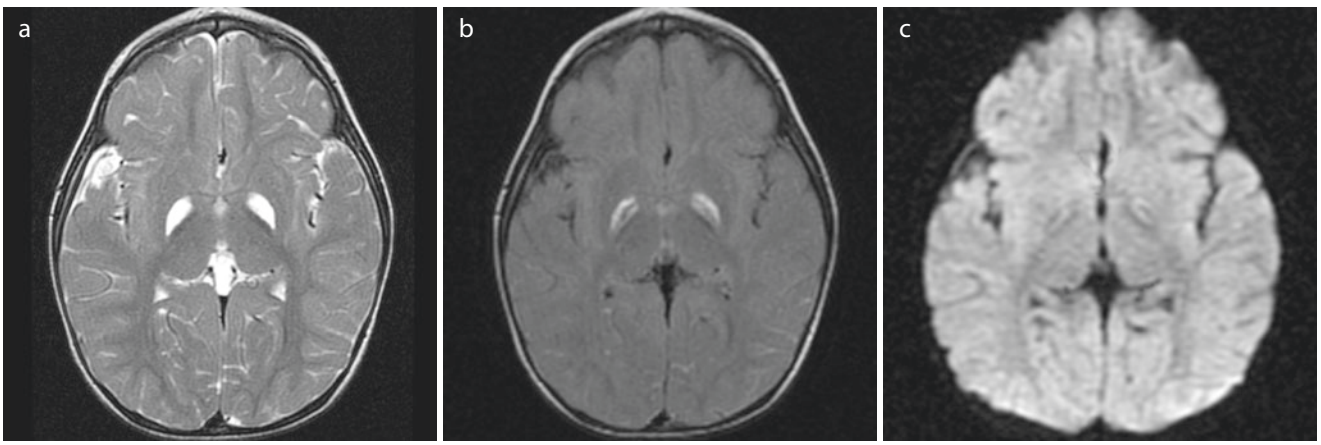

Fig. 8.3 A 15-year-old female with methylmalonic aciduria. (**a**) Axial T2WI (TR/TE msec, 4217/101) through the basal ganglia shows hyperintense globi pallidi. The corresponding T2/FLAIR sequence (TR/TE/TI msec, 10,000/136/2200) (**b**) and diffusion-weighted sequence (TR/TE msec, 9300/93) (**c**) demonstrate mixed globi pallidi signal changes with central suppression/necrosis and peripherally reduced diffusion, representing acute on chronic metabolic injury

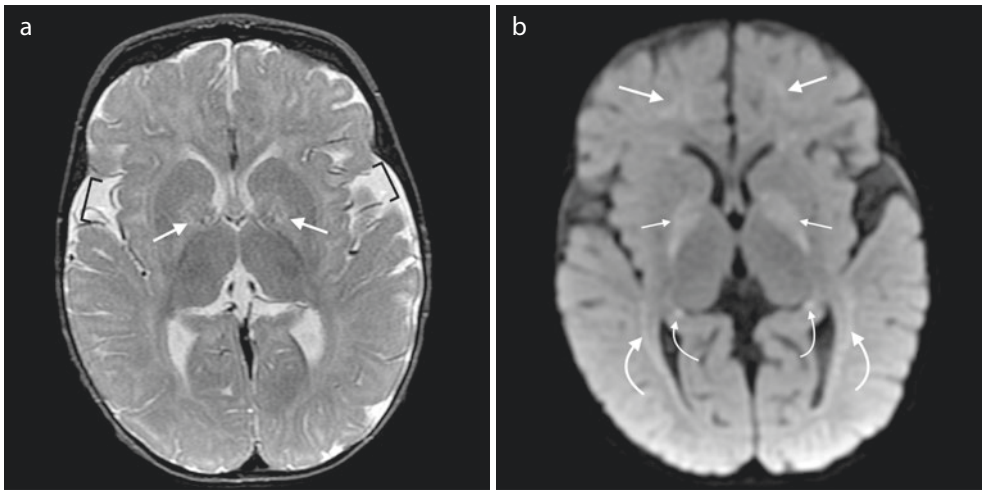

Fig. 8.4 A 9-month-old female with glutaric aciduria type I. (**a**) Axial T2WI (TR/TE msec, 3200/90) through the basal ganglia reveals hyperintense signal in the globi pallidi (arrows) and underopercularization (brackets). (**b**) The corresponding axial diffusion-weighted image (TR/TE msec, 10,000/91) shows hyperintense signal in the globi pallidi (small straight arrows), frontal subcortical white matter (large straight arrows), sagittal stratum (large curved arrows), and hippocampal tails (small curved arrows) representing reduced diffusion/white matter intramyelinic edema and seizure-related changes in the hippocampi

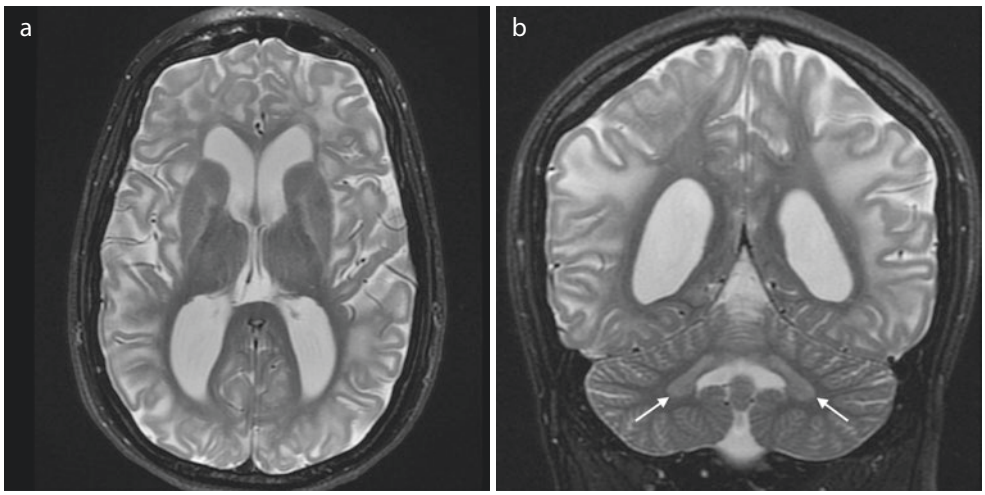

Fig. 8.5 A 2-year-old female with L-2-hydroxyglutaric aciduria. (**a**) Axial T2WI (TR/TE msec, 5347/101) at level of the basal ganglia shows a centropedal pattern of white matter hyperintensity affecting the superficial more than deep white matter with relative sparing of the corpus callosum. (**b**) Coronal T2WI (TR/TE msec, 5347/101) redemonstrates the centropedal pattern of white matter hyperintensity and shows abnormal hyperintensity of the cerebral deep gray nuclei (arrows). Ventriculomegaly reflects white matter volume loss

(Barkovich and Patay 2019; Gunz et al. 2013; Takanashi et al. 2003; Bireley et al. 2012) (Fig. 8.6). An unsolicited imaging diagnosis can be tricky as UCD disease patterns overlap considerably with that of the far more common hypoxic ischemic encephalopathy (HIE) (Whitehead and Gropman 2018; Pacheco-Colon et al. 2013).

UCD brain edema is often mixed; vasogenic (facilitated diffusion), cytotoxic (gray matter, restricted diffusion), and/or intramyelinic (white matter, restricted diffusion) edema may be present depending on the imaging timing and disease activity. Diffusion abnormalities evolve quickly toward hyperintense signal on T1WI, representing laminar, deep gray, and white matter necrosis with associated volume loss. In all but the most severe cases, the thalami and brainstem are spared, which may help distinguish it from HIE (Whitehead and Gropman 2018; Barkovich and Patay 2019; Pacheco-Colon et al. 2013; Bireley et al. 2012). Also, a perinsular and cingulate predilection can be a clue, but these structures may also be involved in HIE as well (Whitehead and Gropman 2018; Barkovich and Patay 2019). In distal UCD subtypes, later onset cases, and/or milder phenotypes, brain lesions and volume deficits tend to be less severe and

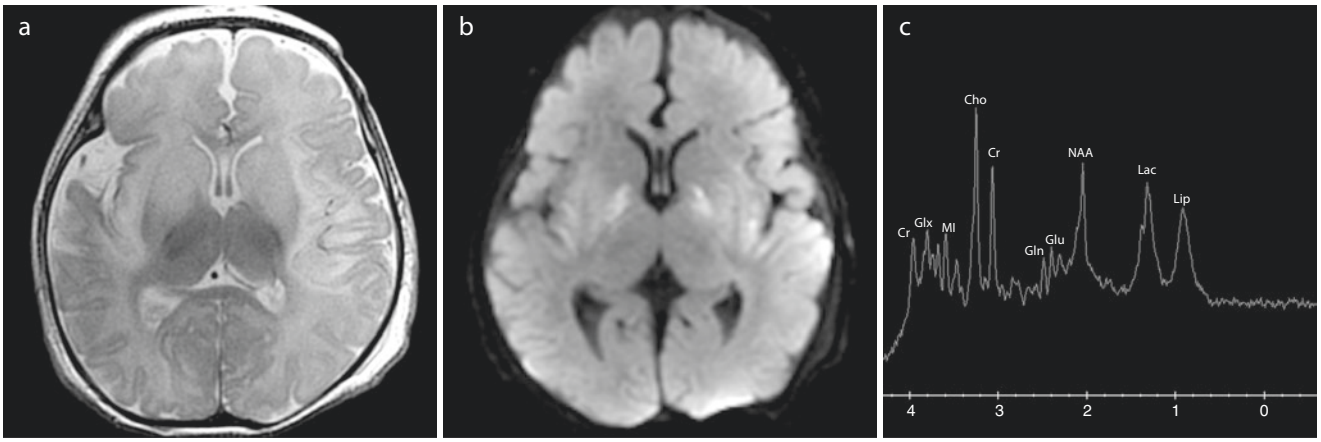

Fig. 8.6 A 10-day-old male with citrullinemia (argininosuccinate synthetase deficiency). (**a**) Axial T2WI (TR/TE msec, 5725/78) at the level of the basal ganglia shows cortical/subcortical temporo-insular/perisylvian predominant and striatal hyperintensity consistent with edema; note thalamic sparing. The corresponding DWI (TR/TE msec, 10,000/95) (**b**) shows reduced diffusion in the same regions representing cytotoxic and intramyelinic edema. Short echo single voxel MRS over the left basal ganglia (TR/TE msec, 1500/35) (**c**) shows elevated glutamine (Gln), glutamate (Glu), lipids (Lip), and lactate (Lac) with reduced myoinositol (MI). Elevated alpha proton-associated metabolic peak at 1.8 ppm confirms glutamine and glutamate elevation (Glx)

less extensive. In these cases, DTI can reveal decreased microstructural integrity in otherwise normal appearing white matter (Pacheco-Colon et al. 2013; Gropman et al. 2008a, b).

1H MRS can reveal elevated brain glutamine and glutamate in presymptomatic, symptomatic, convalescent, and asymptomatic phases (Pacheco-Colon et al. 2013; Gropman et al. 2008a, b) (Fig. 8.6). Myoinositol, an osmotic buffer, is typically depressed prior to and is inversely correlated with glutamine concentration (Pacheco-Colon et al. 2013; Gropman et al. 2008a, b). Accumulated guanidinoacetate has been shown in arginosuccinate lyase deficiency (Sijens et al. 2006). Arginine elevation has been described in arginase deficiency (Gungor et al. 2008).

Molybdenum Cofactor Deficiency

A devastating neonatal IEM, molybdenum cofactor deficiency results in massive destructive changes throughout the cerebral white matter and deep gray structures with progression to cystic necrosis and marked volume loss (Whitehead and Gropman 2018; Barkovich and Patay 2019; Schuierer et al. 1995; Stence et al. 2013) (Fig. 8.7). Lesional hemorrhages and deep gray nuclear and/or cerebral white matter calcifications may also be present. Widespread cortical restricted diffusion has also been described, especially affecting sulcal depths and leading to ulegyria (Stence et al. 2013). Changes can mimic HIE, but the pattern is less typical, often sparing the thalami, and destruction more severe in the majority of cases. Mixed aged lesions, pontocerebellar hypoplasia, and enlarged cisterna magna are additional features that favor molybdenum cofactor deficiency over HIE. Disease onset can be either pre- or postnatal; cystic necrosis encountered in the first week of life is most indicative of a prenatal onset. MRS may show elevated lipid and lactate in the active phase of disease (Salvan et al. 1999).

Chronic Metabolic Encephalopathies

Several of the IEMs do not typically present initially with an acute decompensation, but rather with ongoing brain injury in recognizable patterns. These are discussed below.

Phenylketonuria (PKU)

Phenylketonuria, an autosomal recessive condition, is characterized by deficiency in phenylalanine hydroxylase, an essential precursor to an array of neurotransmitters, notably dopamine which is critically involved in higher order cognition. The majority of patients have extensive white matter damage, in both untreated and early treated PKU cases. Classic MR imaging features include posterior predominant cerebral periventricular hyperintensity on T2WI with or without reduced diffusion, usually sparing the juxtacortical white matter, cortex, brainstem, and cerebellum (Whitehead and Gropman 2018; Anderson and Leuzzi 2010; Kono et al. 2005) (Fig. 8.8). White matter diffusion restriction reflecting intramyelinic edema tends to occur when plasma phenylalanine levels exceed 8.5 mg/dL (Kono et al. 2005).

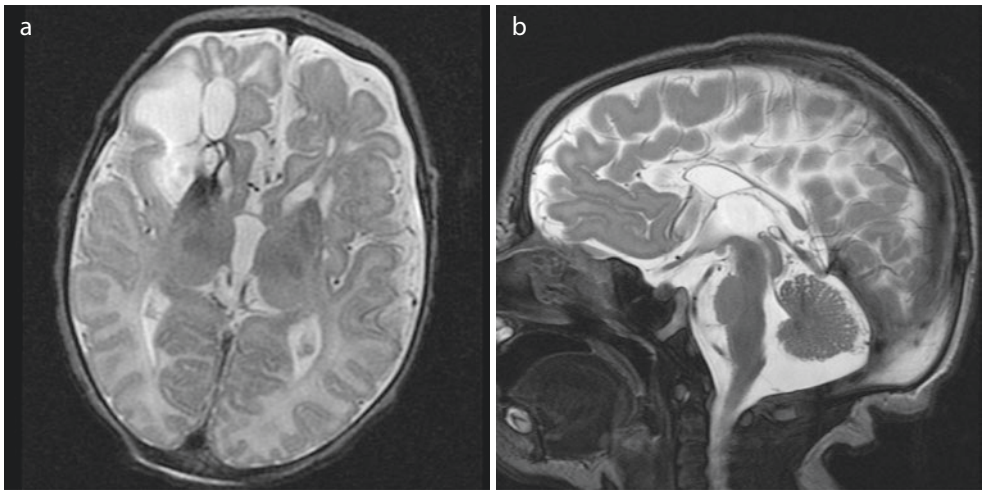

Fig. 8.7 A 3-day-old female with molybdenum cofactor deficiency. (**a**) Axial T2WI (TR/TE msec, 3500/126) at the level of the basal ganglia demonstrates frontal volume loss and heterogenous, mixed hyperintense and hypointense signal in the basal ganglia and frontal white matter, right more than left, consistent with chronic sequela of prior hemorrhages and infarctions with resultant cystic/necrotic encephalomalacia. (**b**) Sagittal midline T2WI (TR/TE msec, 3500/126) shows marked thinning of the corpus callosum most pronounced anteriorly reflecting the cerebral white matter volume loss

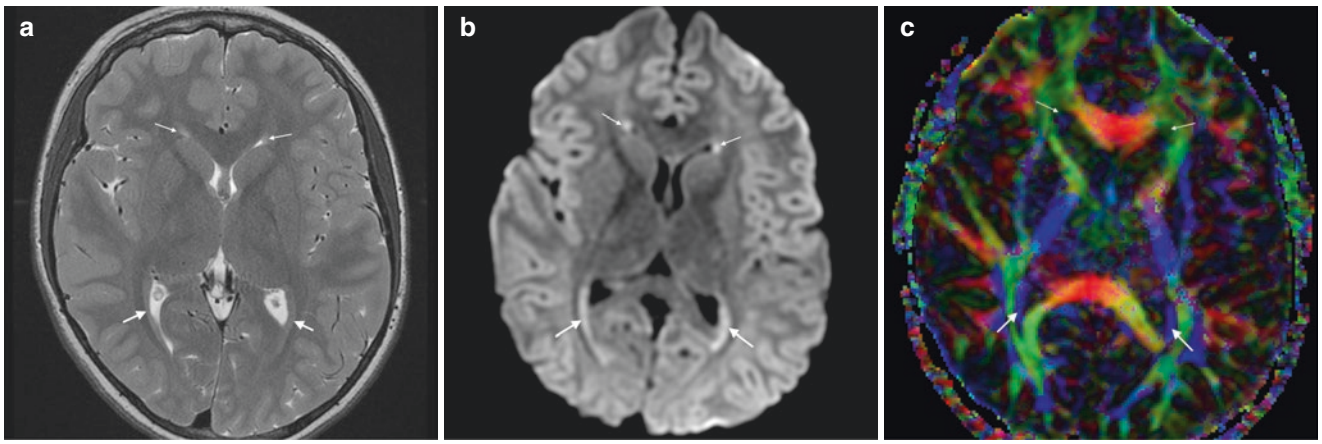

Fig. 8.8 A 9-year-old male with phenylketonuria (PKU). Axial T2WI (TR/TE msec, 3350/102) (**a**) and corresponding DWI (TR/TE msec, 10,000/82) (**b**) at the level of the basal ganglia show hyperintense signal in the paraventricular frontal and temporo-occipital tissues; in correlation with the directionally encoded DTI color map (**c**), the signal changes correspond to myelin edema in the frontal subependymal white matter fibers (small arrows) and temporo-occipital tapetum (large arrows), typical sites of PKU-associated intramyelinic edema

1H MRS in isolation or in combination with MRI is specific to the diagnosis when correctly performed using a specialized short-echo sequence and postprocessing to identify the generally small phenylalanine peak at 7.3–7.4 ppm downstream beyond the suppressed water peak (Bluml and Panigrahy 2013). The alpha proton associated with elevated phenylalanine can be seen at 3.8 ppm; however, there is considerable overlap with other metabolites at this same location (Sener 2003). NAA, creatine, choline, and other conventional metabolites tend to be normal.

Pantothenate Kinase-Associated Neurodegeneration (PKAN)

A form of neurodegeneration with brain iron accumulation (NBAI), PKAN is classically known for its "eye of the tiger sign" on MRI (Fig. 8.9). Dark iron deposition in the globus pallidus and bright central necrosis contribute to this appearance. Accelerated iron deposition is also common in the substantia nigra, while the dentate nucleus is rarely affected (Hayflick et al. 2018). These features help distinguish PKAN

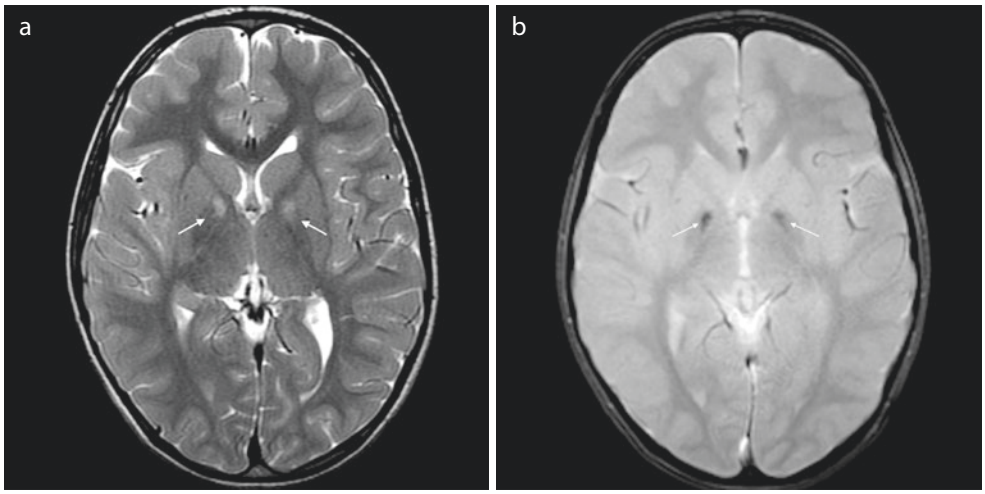

Fig. 8.9 A 5-year-old male with pantothenate kinase-associated neurodegeneration (PKAN). Axial T2WI (TR/TE msec, 6350/97) (**a**) through the basal ganglia shows globi pallidi signal abnormality with peripheral hypointensity and central hyperintensity representing accelerated iron deposition and central necrosis, the "eye of the tiger" sign of PKAN (arrows). The corresponding axial gradient echo sequence (**b**) confirms increased iron deposits with dark susceptibility effect (arrows)

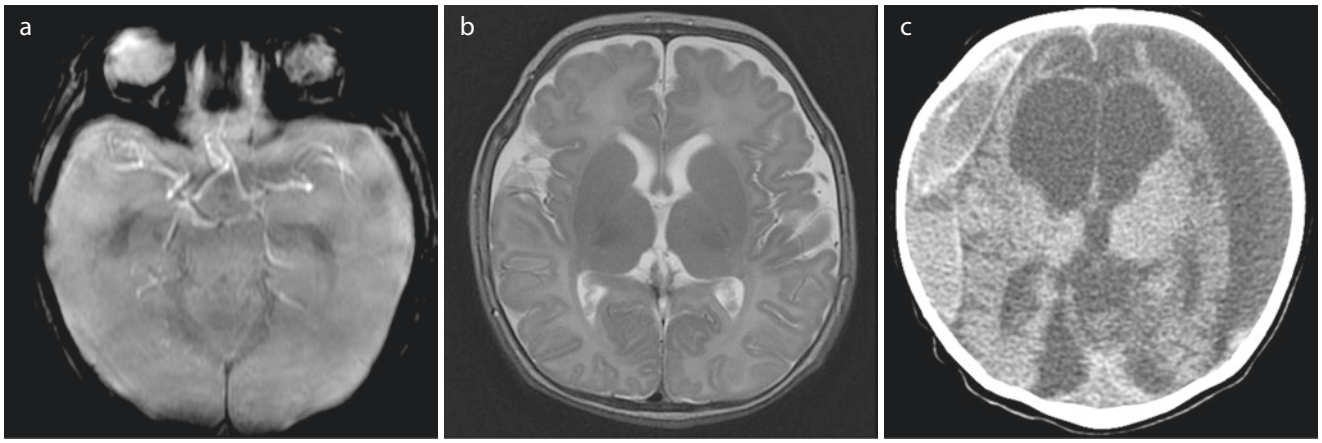

Fig. 8.10 Menkes disease in a male child performed at 3 months (**a**, **b**) and 12 years (**c**) of age. (**a**) Axial susceptibility weighted angiography (SWAN; TR/TE msec, 68/24) at the level of the circle of Willis shows multiple tortuous, elongated intracranial arteries. (**b**) Axial T2WI (TR/TE msec, 5900/91) of the cerebrum at the level of the basal ganglia is normal for age. (**c**) Follow-up head CT at age 12 years reveals interval development of bilateral subdural hemorrhages of varying age, marked parenchymal atrophy, and bilateral cerebral encephalomalacia

from other forms of NBAI, such as infantile neuroaxonal dystrophy that lacks "eye of the tiger sign," beta-propellar protein-associated neurodegeneration (BPAN) with dominant subtantia nigra involvement showing a hyperintense "halo", and neuroferritonopathy and aceruloplasminemia where iron deposition is more widespread to name a few (Hayflick et al. 2018).

Menkes Disease

Deficient tissue copper results in various vascular and brain abnormalities. Elongated, tortuous intracranial arteries have a disorganized, spaghetti-like appearance (Whitehead et al. 2015; Manara et al. 2017a, b) (Fig. 8.10). Cerebral white matter disease with delayed myelination and basal ganglia lesions are characteristic (Manara et al. 2017a, b). Transient tumefactive temporal lobe vasogenic edema is reasonably common in the infantile period (Whitehead et al. 2015). Progressive volume loss and subdural hemorrhages are frequent features in the chronic disease stage (Manara et al. 2017a, b) (Fig. 8.10). MRS reveals lactate, reduced NAA, and/or increased choline in some cases (Ito et al. 2011; Munakata et al. 2005).

Congenital Disorders of Glycosylation (CDG)

Reduced brain volume and variable signal changes are common in CDG. There are now over 30 subtypes of CDG. The prototypical subtype, CDG Type Ia, commonly shows pontocerebellar hypoplasia and superimposed cerebellar volume loss with cortical hyperintensity, referred to as the "shrunken, bright cerebellar sign" (Whitehead et al.

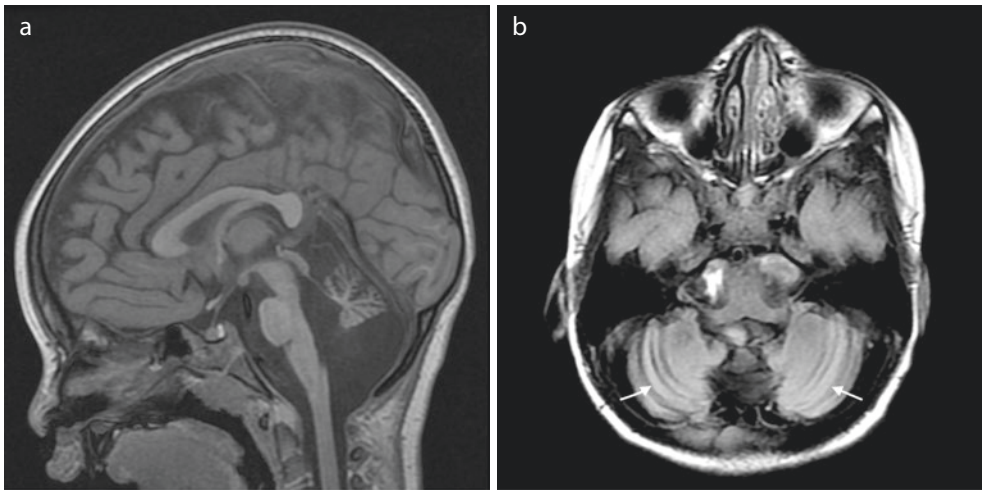

Fig. 8.11 A 3-year-old male with congenital disorder of glycosylation type Ia. (**a**) Sagittal midline T1WI (TR/TE msec, 11/5) shows a markedly small cerebellum that is shortened with widened fissures representing combined volume loss and hypoplasia. Mild pontine hypoplasia is also present. The fourth ventricle and posterior fossa cisterna spaces are enlarged secondary to the rhombencephalic volume deficit. (**b**) Axial T2 FLAIR image (TR/TE/TI msec, 10,000/126/2250) through the cerebellum shows volume loss and cortical hyperintensity, the "shrunken, bright cerebellar sign" consistent with CDGIa (arrows)

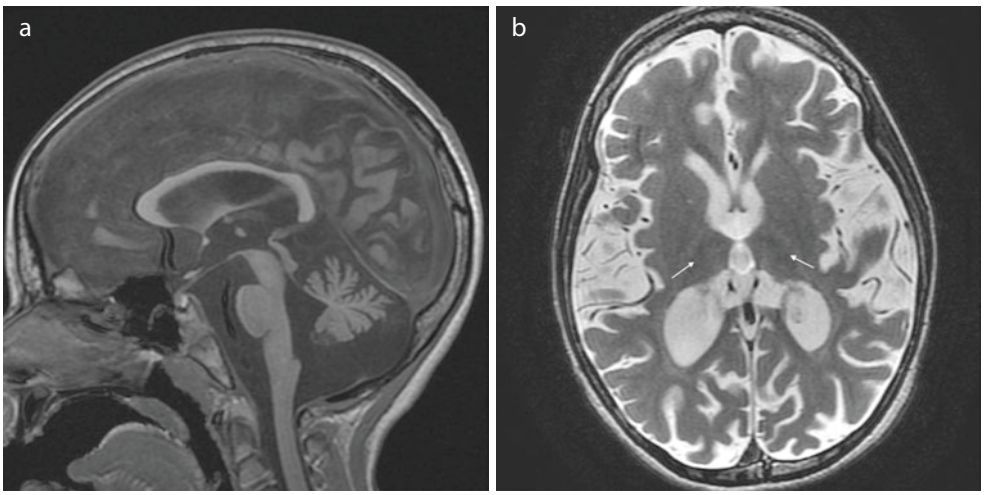

Fig. 8.12 A 5-year-old female with neuronal ceroid lipofuscinosis. (**a**) Sagittal midline T1WI (TR/TE msec, 11/5) demonstrates diffuse moderate cerebral and cerebellar cortical volume loss with enlarged sulci, cerebellar fissures, and cisternal spaces. (**b**) Axial T2WI (TR/TE msec, 4250/97) also shows the moderate diffuse gray matter predominate cerebral volume loss and relative hypointensity of the thalami (arrows)

2015; Feraco et al. 2012) (Fig. 8.11). Vasculopathy and/or hemorrhages may occur at some point in the disease course, occasionally as the presenting symptom (Stefanits et al. 2014; Cohn et al. 2006). MRS shows decreased NAA, decreased choline, increased myoinositol, and/or increased glutamine and glutamate (Takeuchi et al. 2003; Holzbach et al. 1995).

Neuronal Ceroid Lipofuscinosis (NCL)

This group of neurodegenerative disorders causes progressive cerebral and cerebellar cortical gray matter brain volume loss and white matter signal alteration (Whitehead and Gropman 2018) (Fig. 8.12). As with other lysosomal storage disorders, thalamic hypointensity is also common, but an often overlooked feature (Autti et al. 2007). NAA may be decreased in keeping with neuronal loss (Bluml and Panigrahy 2013; Whitehead and Gropman 2018).

Mucopolysacharidoses (MPS)

Concurrent brain and bone abnormalities are key diagnostic features in MPS. Leukoencephalopathy with enlarged perivascular spaces is the most common brain manifestations (Barkovich and Patay 2019; Whitehead et al. 2015; Zafeiriou and Batzios 2013) (Fig. 8.13). Hydrocephalus is another frequent disease attribute. Dysostosis multiplex is found in the spine, commonly with craniocervical junction abnormalities

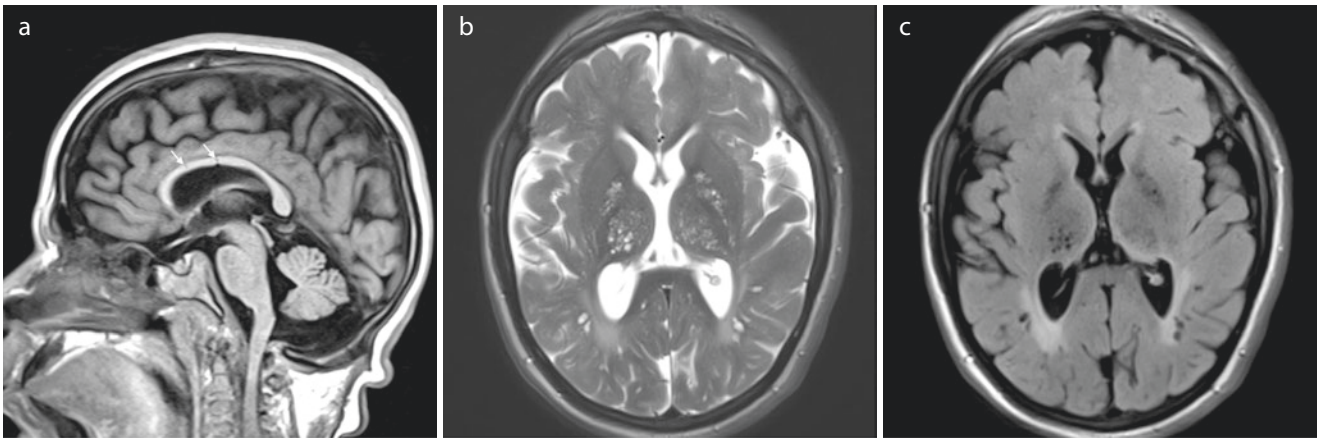

Fig. 8.13 A 19-year-old male with mucopolysacharidosis (Hunter syndrome). (**a**) Sagittal midline T1WI (TR/TE msec, 15/7) demonstrates skullbase and spinal hypopoplasia/dysplasia with underdevelopment of the clivus, dysmorphic cervical vertebrae, and spinal/foramen magnum stenosis. The callosal genu and body are thin with small foci of hypointensity representing perivascular space enlargement (arrows). Hazy hypointense signal in the brainstem represents enlarged perivascular spaces. Axial T2WI (TR/TE msec, 3500/120) (**b**) and T2/FLAIR sequence (TR/TE/TI msec, 8000/82/2200) (**c**) reveal multiple prominent perivascular spaces in the white and deep gray matter (T2 hyperintense, FLAIR hypointense) on the background of FLAIR hyperintense white matter signal

and skull base dysplasia (Whitehead et al. 2015; Zafeiriou and Batzios 2013) (Fig. 8.13). MRS may demonstrate elevated myoinositol, increased glutamate, increased or decreased choline, decreased NAA, and/or abnormal lactate (Zafeiriou and Batzios 2013).

Mitochondrial Disorders

The mitochondrial respiratory chain disorders have a multisystem presentation and genetic origin. The combination of any symptom, organ or tissues, compounded with any age of presentation accounts for the challenge in diagnosing these conditions. From a neuroimaging standpoint, there are several hallmark features that when taken together with the clinical history should alert one to the possibility of these conditions. The more common disorders with characteristic imaging features are discussed below.

Leigh Disease

Leigh disease may be caused by a mitochondrial defect in a nuclear or mitochondrial gene and may have multiple organ system involvement. The most common presentation is the early infancy onset associated with severe neurodegeneration with encephalopathy, seizures, blindness, and progressive psychomotor regression typically resulting in death within 2–3 years, usually due to respiratory failure (Thorburn et al. 2003). MRI results in a distinctive brain disease characterized by variable signal changes in the basal ganglia, thalami, brainstem, and/or cerebellum with restricted diffusion ultimately evolving to combination of gliosis and necrosis (Whitehead and Gropman 2018; Whitehead et al. 2016) (Fig. 8.14). Arterial spin-labeling (ASL) perfusion sequence can show hyperperfusion in regions of active brain disease that may correspond to small vessel proliferation described on pathology (Whitehead et al. 2016) (Fig. 8.14). 1H MRS demonstrates elevated lactate in many cases; however, its absence does not exclude the disease.

MELAS Syndrome

Mitochondrial encephalopathy with lactate acidosis and stroke-like episodes (MELAS) syndrome is typically of childhood onset characterized by stroke-like episodes, migraine, hearing loss, diabetes, and seizures. In those patients that survive into the late teens and early twenties, a severe gastroparesis is seen (Gagliardi et al. 2019). Characteristic brain lesions involve overlapping large vascular territories that help distinguish it from a non-metabolic thromboembolic infarction (Whitehead and Gropman 2018) (Fig. 8.15). Posterior predominant cortical and subcortical disease is typical, with progressive atrophy. The "black toenail sign" corresponding to gyral necrosis is a common neuroimaging finding associated with cerebral lesions of sufficient severity and chronicity (Whitehead et al. 2017a) (Fig. 8.15). Abnormal T2 FLAIR hyperintensity in and along cortical veins may predict disease severity and future development of brain lesions (Whitehead et al. 2017b) (Fig. 8.15). Deep gray nuclear mineralization is often present, though these structures may be spared of significant volume loss and focal lesions unlike in other mitochondrial diseases. MR spectroscopy shows elevated lactate most commonly at times of metabolic decompensation and may show reduced NAA in the setting of neuronal loss.

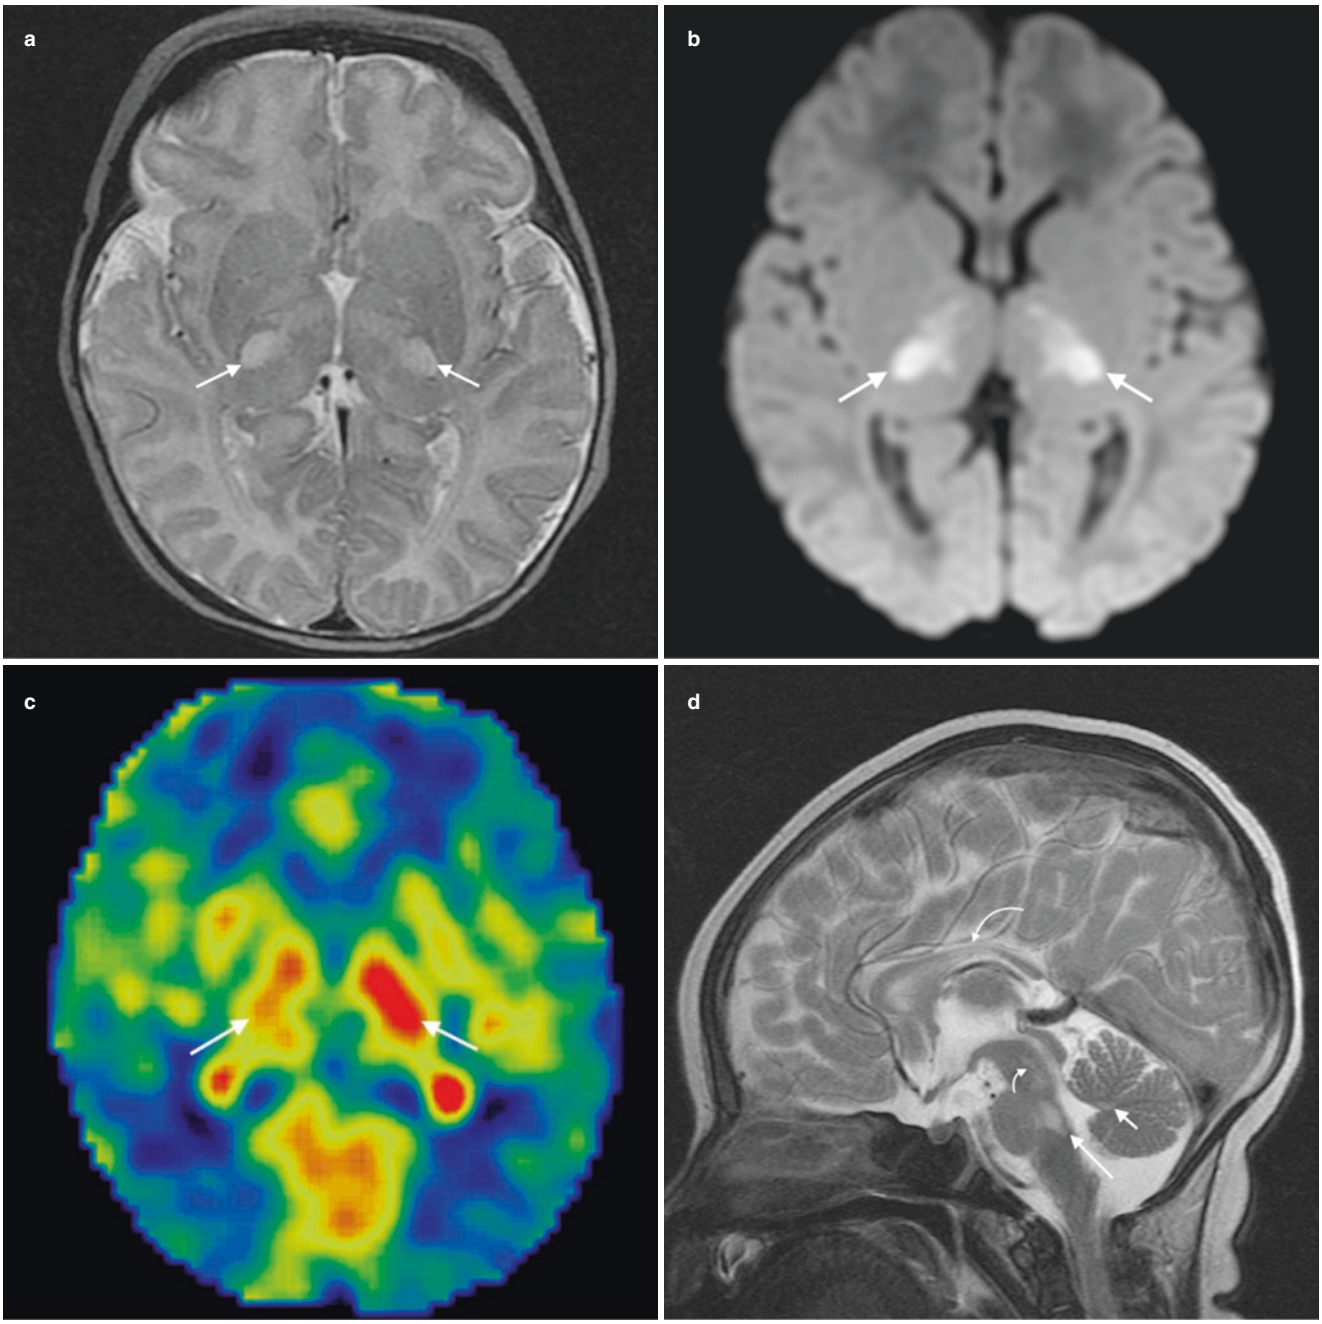

Fig. 8.14 A 2-month-old female with Leigh disease due to a TRMU gene defect. (**a**) Axial T2WI (TR/TE msec, 3500/120) and (**b**) diffusion weighted image (TR/TE msec, 8000/85) at the level of the basal ganglia demonstrate T2 prolongation and reduced diffusion in the thalami (arrows). (**c**) The corresponding arterial spin labeling (ASL) perfusion sequence shows thalamic hyperperfusion (arrows). (**d**) Sagittal midline T2WI (TR/TE msec, 3500/156) shows hyperintense lesions in the callosal body (long curved arrow), midbrain tegmentum (short curved arrow) pontine tegmentum (long straight arrow), and central vermis (short straight arrow). There is mild pontine hypoplasia and thinning of the corpus callosum

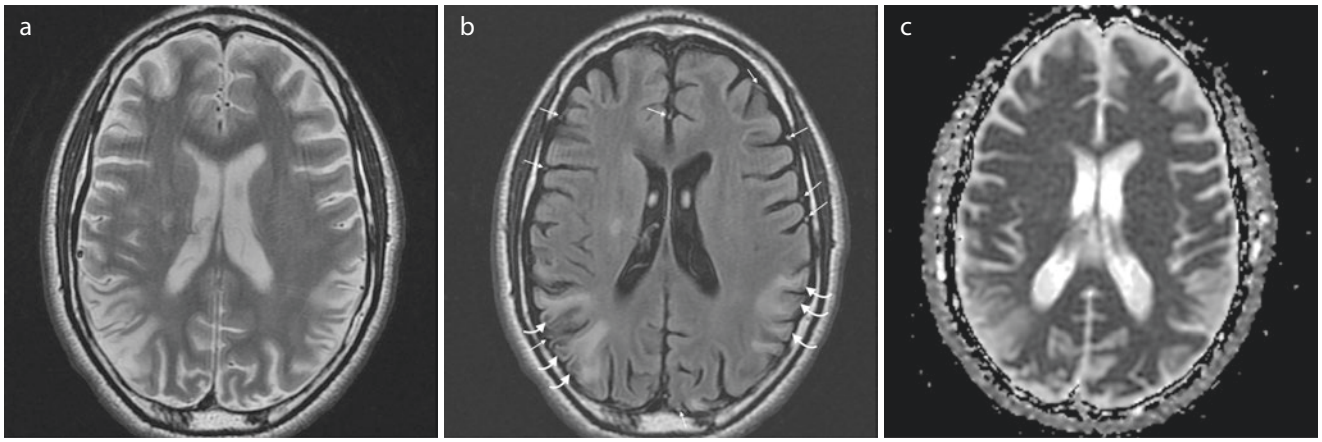

Fig. 8.15 A 19-year-old male with MELAS. Axial T2WI (TR/TE msec, 3543/98) (**a**), T2 FLAIR (TR/TE/TI msec, 10,000/124/2200) (**b**), and apparent diffusion coefficient map (TR/TE msec, 10,000/95) (**c**) at the level of the lateral ventricles show bilateral parieto-occipital cortical/subcortical hyperintensity not confined to large arterial territories with partial signal suppression superficially consistent with necrosis and the "black toenail" sign compatible with chronic MELAS-related brain injury (curved arrows, **b**). Note several cortical veins show FLAIR hyperintensity that may represent venopathy (straight arrows, **b**)

White Matter Disorders/Leukodystrophies

Leukodystrophy is one of a group of disorders characterized by degeneration of the white matter in the brain. Many are of genetic etiology due to IEMs (van der Knaap and Bugiani 2017). Leukodystrophies are often degenerative in nature, but some only impair white matter function. The clinical course may be static or progressive, but may also improve with time. Progressive leukodystrophies are often fatal. There has been a large increase in the number of genetically defined leukodystrophies in recent years due to recognition of magnetic resonance imaging patterns coupled with next-generation and whole exome sequencing (van der Knaap and Bugiani 2017).

X-linked Adrenoleukodystrophy (X-ALD)

The prototypical leukodystrophy for which there is significant MRI literature is X-ALD. The three recognizable clinical phenotypes are childhood cerebral disease, adrenomyeloneuropathy (AMN), and Addison disease. AMN manifests most commonly in an individual in his twenties or middle age with progressive lower extremity spastic weakness, sphincter disturbances, sexual dysfunction, and, often, impaired adrenocortical function. Addison disease only presents with primary adrenocortical insufficiency between age 2 years and adulthood and most commonly by age 7.5 years, usually without neurologic abnormality (Raymond et al. 1999). All are associated with elevation of very long chain fatty acids due to a mutation in the ABCD1 gene, which encodes for a peroxisomal very long chain fatty acid transporter.

The callosal splenium is usually the earliest and most commonly affected part of the brain in X-ALD (Barkovich and Patay 2019) (Fig. 8.16). Lesions quickly spread to the forceps major and, in worse cases, involve the projectional white matter fibers extending into the brainstem along with other brain white matter (Whitehead and Gropman 2018; Barkovich and Patay 2019; Loes et al. 1994). Laminated signal changes in the corpus callosum and adjacent commissural fibers are common in the subacute and chronic phases, reflecting multiple bouts of active brain disease and representing combined edema, inflammatory changes, and destructive changes (demyelination and necrosis). Therefore, the signal intensity is heterogenous and variable, often with mixed restricted diffusion and facilitated diffusion and variable contrast enhancement in the areas of active inflammation. Corticospinal tracts, visual, and auditory pathways are often involved. Loes score associated with lesion location and extent has been validated to determine brain disease severity and transplant candidacy (Loes et al. 1994). MRS is nonspecific, often depicting lactate, increased lipids, decreased NAA, and elevated choline (Bluml and Panigrahy 2013). However, an NAA:Cho less than 5 has been shown to predict clinical decline (Barkovich and Patay 2019).

Zellweger Syndrome

Another peroxisomal-based disorder, Zellweger syndrome is a severe IEM with multisystemic manifestations. From a neurological standpoint, there is both gray and white matter

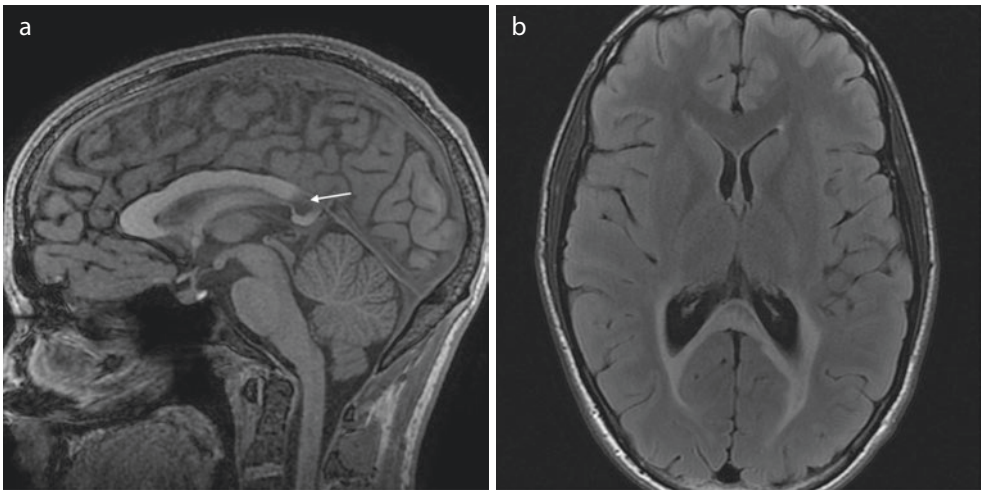

Fig. 8.16 A 16-year-old male with X-linked adrenoleukodystrophy. (**a**) Sagittal midline T1WI (TR/TE msec, 8/3) demonstrates marked hypointensity within a mildly thinned callosal splenium (arrow). (**b**) Axial T2/FLAIR (TR/TE/TI msec, 10,000/144/2250) shows signal abnormality in the callosal splenium and forceps major with partial signal suppression in the splenium representing chronic demyelination/gliosis and necrosis

involvement. Neuroimaging findings are typified by cerebral polymicrogyria, often perisylvian predominant, caudothalamic groove germinolytic cysts, and white matter hyperintensity on T2WI (Whitehead et al. 2015) (Fig. 8.17). Germinolytic cysts carry a differential diagnosis of prior germinal matrix hemorrhage, TORCH infection, genetic, and toxic/metabolic disturbances (Herini et al. 2003). Significant hydrocephalus is unusual, unlike in the dystroglycanopathies. MRS can show elevated lipids associated with hepatic disease and decreased NAA (Bluml and Panigrahy 2013).

Aicardi-Goutieres Syndrome (AGS)

Imaging manifestations in AGS are typified by leukoencephalopathy (diffuse or displaying an anteroposterior severity gradient), frontotemporal white matter rarefaction, reduced brain volume, and, importantly, parenchymal calcifications collectively overlapping with the appearance of some TORCH infections (La Piana et al. 2016; Vanderver et al. 2015) (Fig. 8.18). Brain malformations may include dysgenesis of the corpus callosum and/or cerebellar hypoplasia; however, malformations of cortical development are typically absent unlike in many cases of congenital CMV. Calcifications, a cornerstone feature, are generally detectable using certain gradient echo sequences; however, CT is more sensitive and may be required if the diagnosis is suspected, but no calcifications are found using MRI (La Piana et al. 2016). Central spinal cord signal hyperintensity has been described (Samanta and Ramakrishnaiah 2019). 1H MRS demonstrates reduced NAA and elevated MI (Robertson et al. 2004).

Krabbe Disease

There are two main age-specific neuroimaging manifestations of Krabbe disease. In the infantile period, dentate hilar and basal ganglia signal abnormalities are present, whereas in later onset forms, a cerebral leukodystrophy with a posteroanterior (PA) and centrifugal gradient predominates often manifesting a "tigroid" pattern of signal alteration (Whitehead and Gropman 2018; Whitehead et al. 2015) (Fig. 8.19). The cerebral corticospinal tracts are often affected from the corona radiata to the cerebral peduncles. Cauda equina and cranial nerves (especially the optic pathway) may be thickened and show abnormal contrast enhancement. Deep cerebral white and gray matter mineralization is common; CT is useful for confirmation (Whitehead and Gropman 2018; Whitehead et al. 2015). MRS shows variable metabolic changes that may include elevated myo-inositol and/or glutamate, increased or decreased choline, decreased NAA, and/or abnormal lactate (Bluml and Panigrahy 2013; Whitehead and Gropman 2018; Whitehead et al. 2015).

Metachromatic Leukodystrophy (MLD)

Metachromatic leukodystrophy is an inherited disorder characterized by the accumulation of sulfatides. Sulfatide accumulation in myelin-producing cells causes progressive destruction of white matter throughout the nervous system, including the brain, spinal cord, and peripheral nerves. Imaging features of MLD are similar to Krabbe in

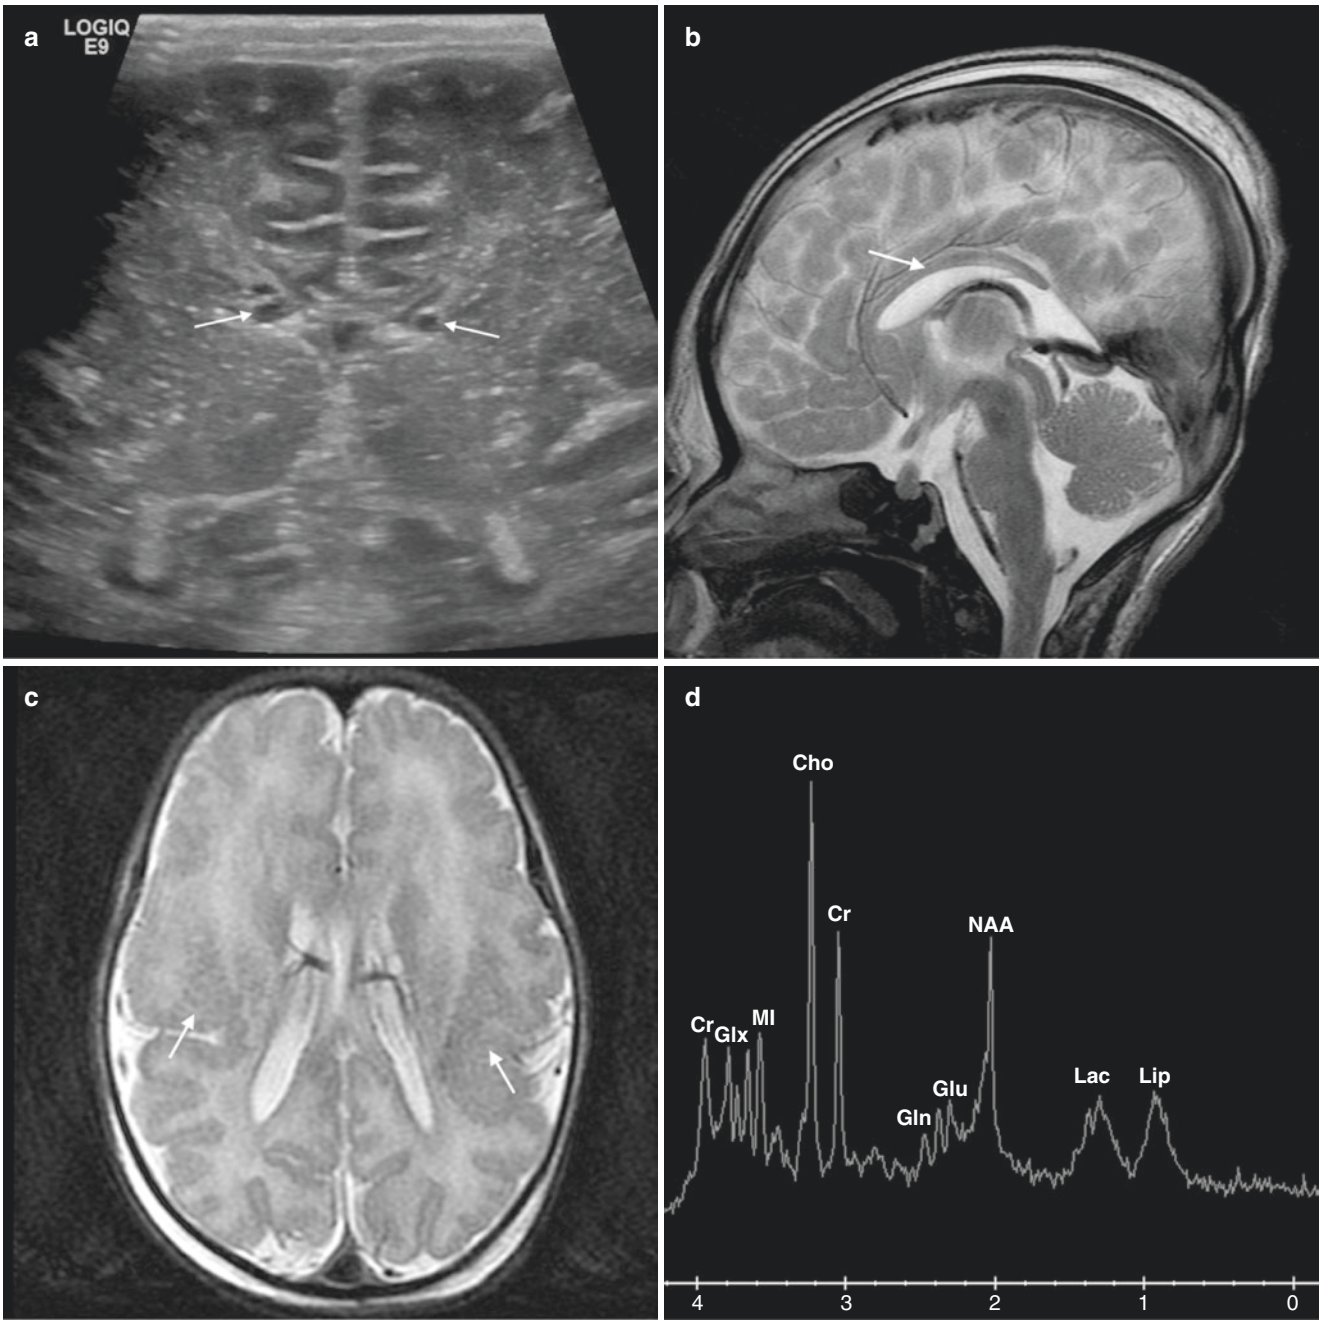

Fig. 8.17 Neonatal female with Zellweger syndrome. (**a**) Coronal gray-scale head ultrasound shows bilateral caudothalamic groove germinolytic cysts (arrows). (**b**) Sagittal midline T2WI (TR/TE msec, 3500/158) shows mild thinning/dysmorphia of the corpus callosum consistent with hypogenesis/dysgenesis (arrow) and pontine hypoplasia. (**c**) Axial T2WI (TR/TE msec, 3500/120) through the lateral ventricles depicts perisylvian predominant polymicrogyria (arrows). Short echo single voxel MRS over the left basal ganglia (TR/TE msce, 1500/35) (**d**) shows elevated lipids (Lip) and lactate (Lac), increased glutamine (Gln; Glx), and glutamate (Glu; Glx). NAA, Cr, and Cho ratios are borderline but within normal range

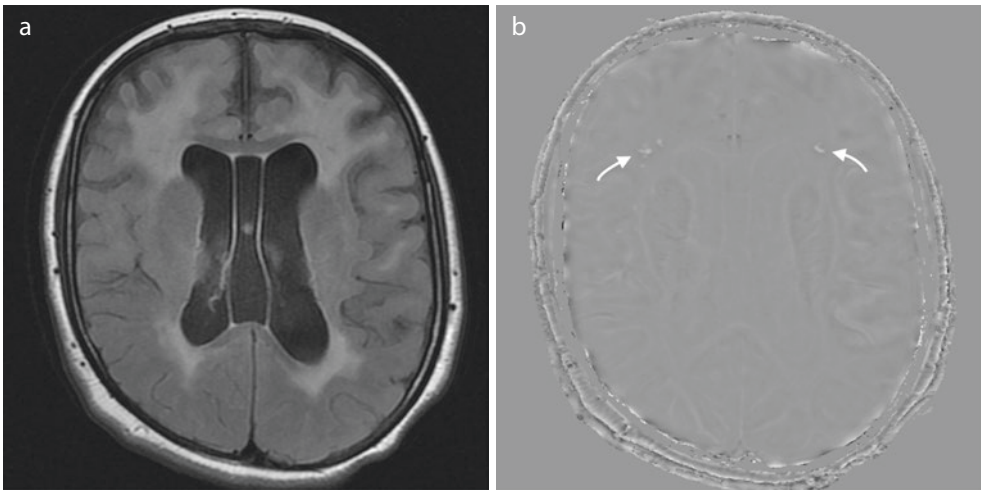

Fig. 8.18 A 12-year-old female with Aicardi-Goutieres syndrome. (**a**) Axial T2 FLAIR (TR/TE/TI msec, 10,000/149/2200) MR image through the lateral ventricles shows anterior predominant white matter signal hyperintensity and ventriculomegaly reflecting cerebral volume loss. (**b**) The corresponding phase map from a susceptibility weighted sequence (SWAN; TR/TE msec, 38/23) shows bright dystrophic calcifications in the frontal subcortical white matter (arrows)

many ways including the tigroid cerebral white matter pattern, a PA and centrifugal gradient (in children), cranial nerve and cauda equina involvement, and elevated myo-inositol (Whitehead and Gropman 2018) (Fig. 8.20). Dentate nuclei tend to be spared and calcifications are absent, however.

Canavan Disease

Aspartoacylase deficiency induced dysmyelination in Canavan disease causes diffuse spongiform thickening of the cerebral, cerebellar, and brainstem white matter with resultant macrocephaly in the infant brain (McAdams et al. 1990; Brismar et al. 1990). Neuroimaging shows swelling and widespread hyperintense white matter signal on T2WI often involving the thalami, globus pallidus, and cerebellar deep gray nuclei with relative sparing of the striatum (McAdams et al. 1990; Brismar et al. 1990) (Fig. 8.21). Sometimes the capsules, corpus callosum, and deep cerebellar white matter are also spared with more pronounced subcortical white matter involvement unlike in Krabbe and MLD. The absence of contrast enhancement and presence of restricted diffusion thought to represent water trapping associated with vacuolization helps distinguish Canavan from Alexander disease (Brismar et al. 1990; Sener 2004). Parenchymal volume loss may be present at diagnosis or develop over time; therefore macrocephaly is not universal (Brismar et al. 1990). MRS shows abnormally accumulated/elevated NAA, characteristic to the disease (Bluml and Panigrahy 2013) (Fig. 8.21). Milder juvenile forms of the disease have differing imaging changes including mild or absent leukodystrophy, striatum signal changes, and lack of NAA elevation (Toft et al. 1993; Nguyen and Ishak 2015).

tRNA Synthetase Disorders

Brain disease in tRNA synthetase disorders includes leukodystrophy, hypomyelination, Leigh-like, and/or MELAS-like patterns with metabolic strokes; lactate may be present on MRS. AARS2, DARS2, and EARS2 are three of the most well-described gene defects with fairly specific imaging manifestations. In AARS2, a deep anterior frontal and posterior parietal leukodystrophy develops, relatively sparing frontoparietal junctional tissue but involving the corticospinal tracts, frontopontine, and parietooccipital pontine fibers (Dallabona et al. 2014). DARS2 genetic abnormalities cause leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL); the deep cerebral white matter is involved with or without a PA severity gradient, multiple brainstem white matter tracts are affected (corticospinal, spinocerebellar, medial lemniscus, cerebellar peduncles, and intraparenchymal trigeminal nerve fibers), and spinal cord signal changes are present (Kassem et al. 2014). In EARS2, neuroimaging patterns may include hypomyelination, deep cerebral leukodystrophy with relative periventricular sparing, and Leigh-like involvement of the thalamus, dentate nucleus, and dorsal brainstem (Steenweg et al. 2012).

Substrate Depletion Disorders

The more common disorders with substrate depletion are discussed below.

Creatine Deficiency Syndromes

The cerebral creatine deficiency syndromes are inborn errors of creatine metabolism that include the creatine biosynthesis disorders, guanidinoacetate methyltransferase (GAMT) defi-

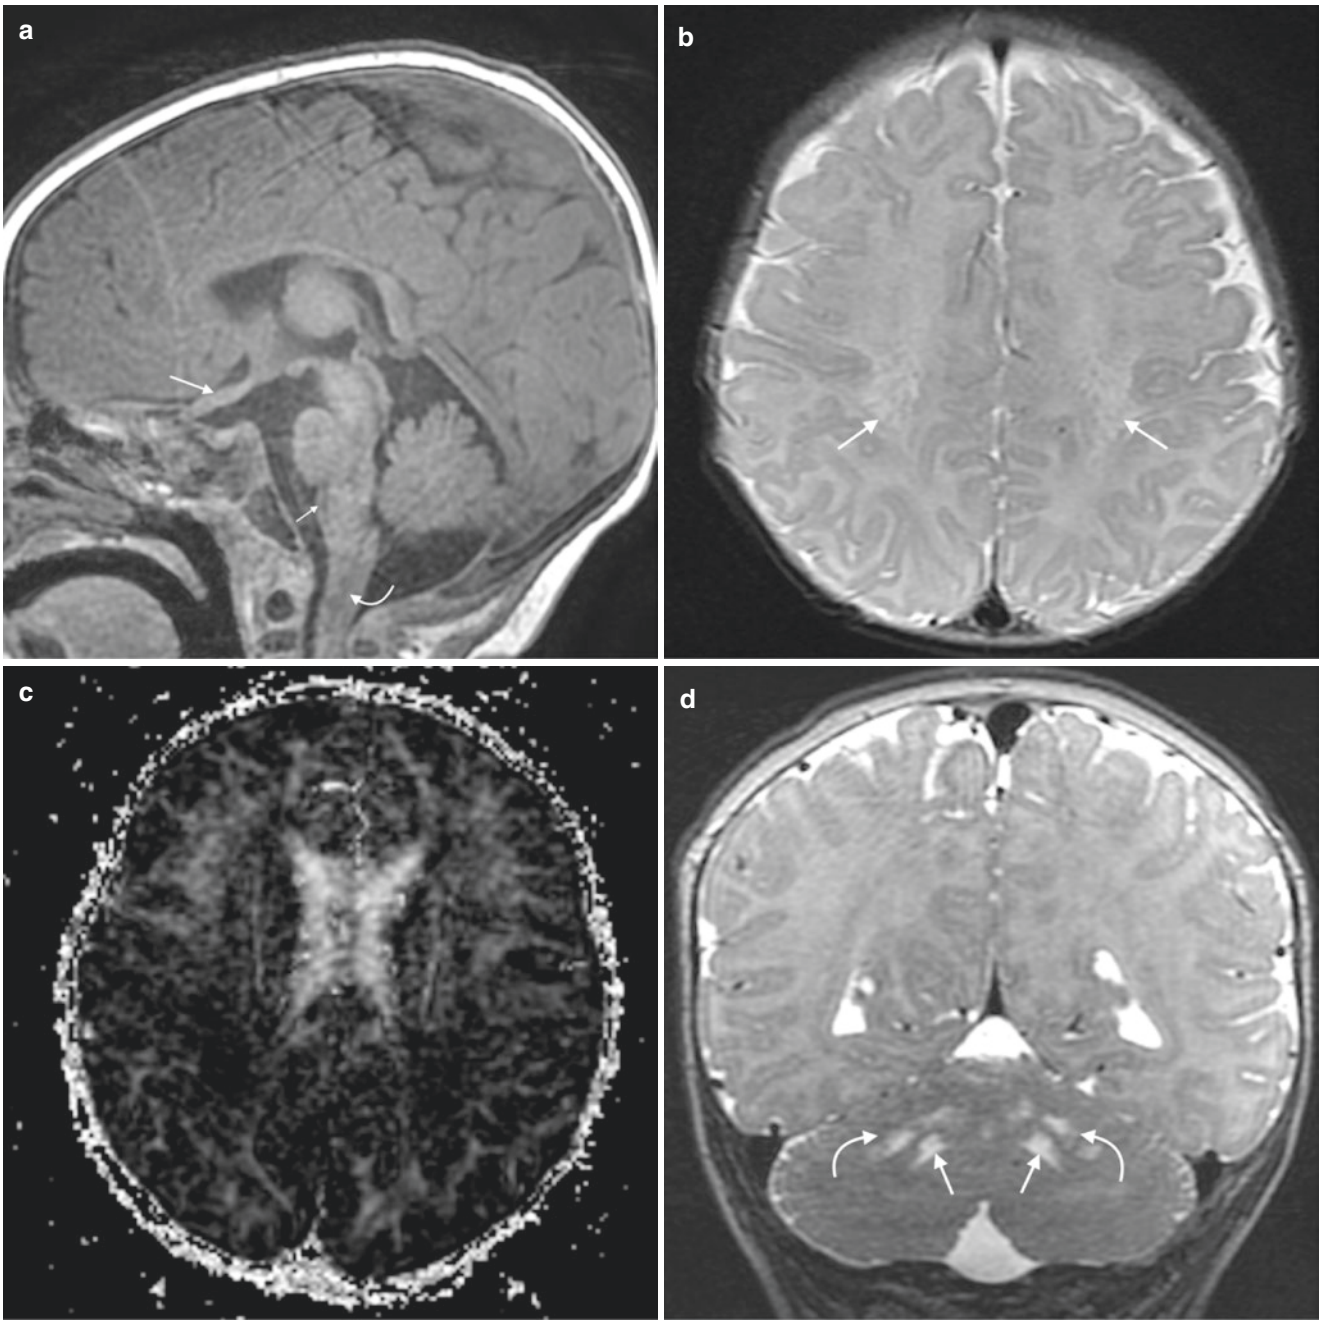

Fig. 8.19 A 4-month-old male with Krabbe disease. (**a**) Sagittal midline T1WI (TR/TE msec, 8/3) shows thickening of the optic chiasm (large arrow), thickening of the medulla oblongata and hypointensity of the pyramidal tracts (small arrow), and thickening of the upper cervical spinal cord with abnormal hypointense signal (curved arrow). (**b**) Axial T2WI (TR/TE msec, 3500/90) at the level of the corona radiata depicts striated/tigroid deep frontoparietal white matter signal (arrows). (**c**) DTI image (TR/TE msec, 10,000/92) at a slightly lower section of the cerebrum demonstrates a posterior to anterior gradient of diffused anisotropy with hypointense white matter. (**d**) Coronal T2WI (TR/TE msec, 3500/90) through the cerebellum shows abnormally increased signal in the dentate hila (straight arrows) and cerebellar white matter (curved arrows)

ciency, and L-arginine:glycine amidinotransferase (AGAT or GATM) deficiency, as well as the creatine transporter (SLC6A8) deficiency. All three are characterized by clinical presentation including seizures and intellectual disability, although behavioral difficulties such as autism spectrum and an extrapyramidal movement disorder may be seen. Onset is between ages 3 months and 3 years. The phenotype of SLC6A8 deficiency in affected males ranges from mild intellectual disability and speech delay to significant intellectual disability, seizures, and behavioral disorder. GAMT and

AGAT deficiency are autosomal recessive conditions, whereas the transport defect is an X-linked disorder (Gropman 2012). Apart from occasional periventricular white matter signal hyperintensity, structural imaging fails to disclose significant abnormalities. MR spectroscopy is critical for the diagnosis and useful in follow-up by demonstrating reduced concentration of creatine compounds at 3 and 3.9 ppm (Whitehead and Gropman 2018) (Fig. 8.22) (Table 8.1).

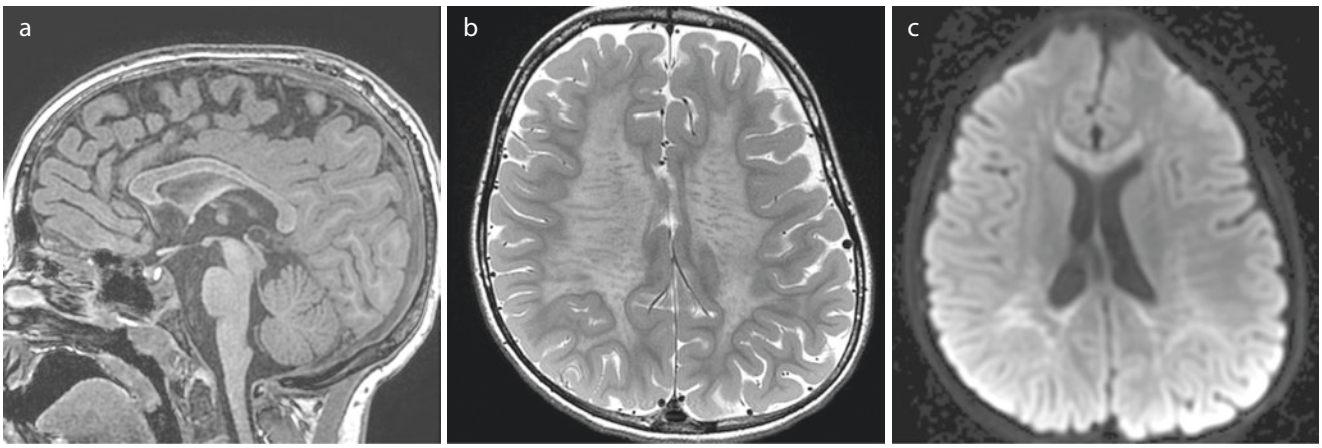

Fig. 8.20 A 6-year-old female with metachromatic leukodystrophy. (**a**) Sagittal midline T1WI (TR/TE msec, 8/3) demonstrates extensive hypointense signal throughout most of the corpus callosum, sparing peripheral most fibers and some central fibers with a stippled appearance; the posterior fossa structures are normal. (**b**) Axial T2WI (TR/TE msec, 3205/102) at the level of the corona radiata depicts striated/tigroid deep frontoparietal white matter signal. (**c**) Axial diffusion weighted image (TR/TE msec, 10,000/70) at a slightly lower section of the cerebrum demonstrates striated and confluent deep and periventricular white matter reduced diffusion consistent with intramyelinic edema

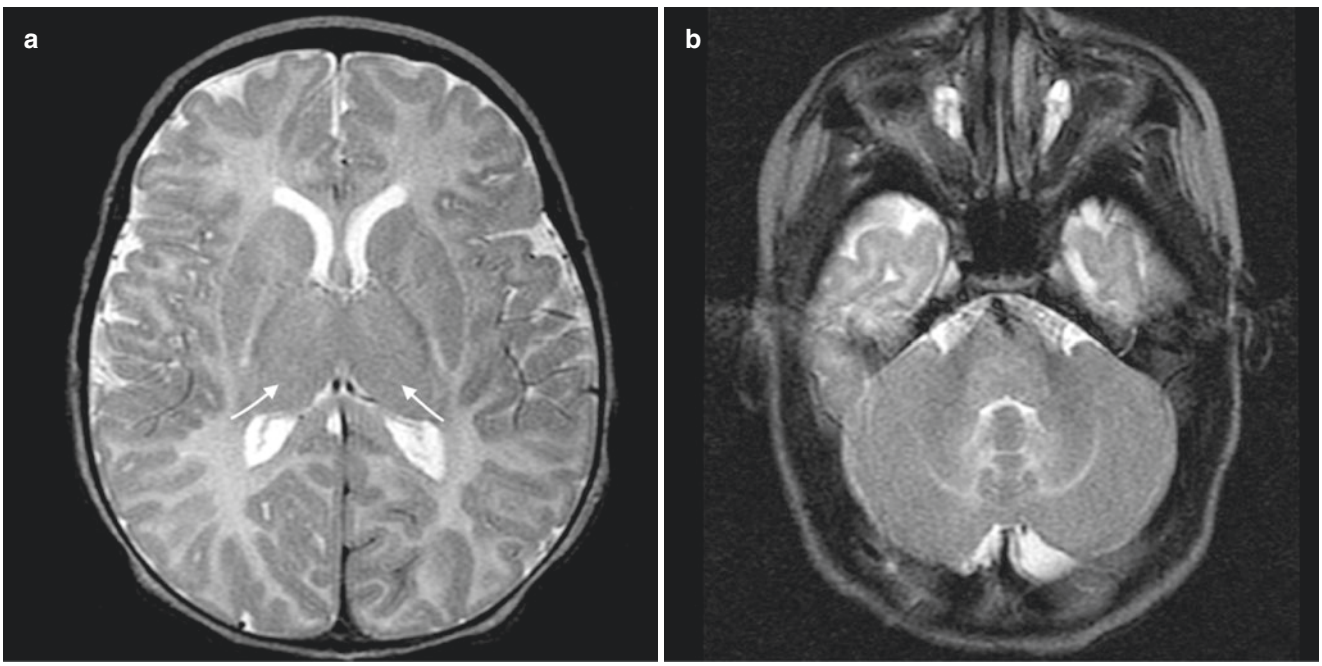

Fig. 8.21 A 2-month-old female with Canavan disease. Axial T2WI (TR/TE msec, 3500/10) through the basal ganglia (**a**) and cerebellum (**b**) reveals generalized mild cerebral, cerebellar, and brainstem white matter hyperintensity for age and subtle increased signal in the thalami (arrows, **a**). (**c**) Axial diffusion weighted image (TR/TE msec, 7500/61) through the basal ganglia hyperintense signal of the cerebral white matter and thalami representing reduced diffusion/intramyelinic edema; note sparing of the striatum. (**d**) Single voxel MRS over the left basal ganglia (TR/TE msec, 1500/35) shows abnormal NAA elevation (NAA), diagnostic of Canavan disease

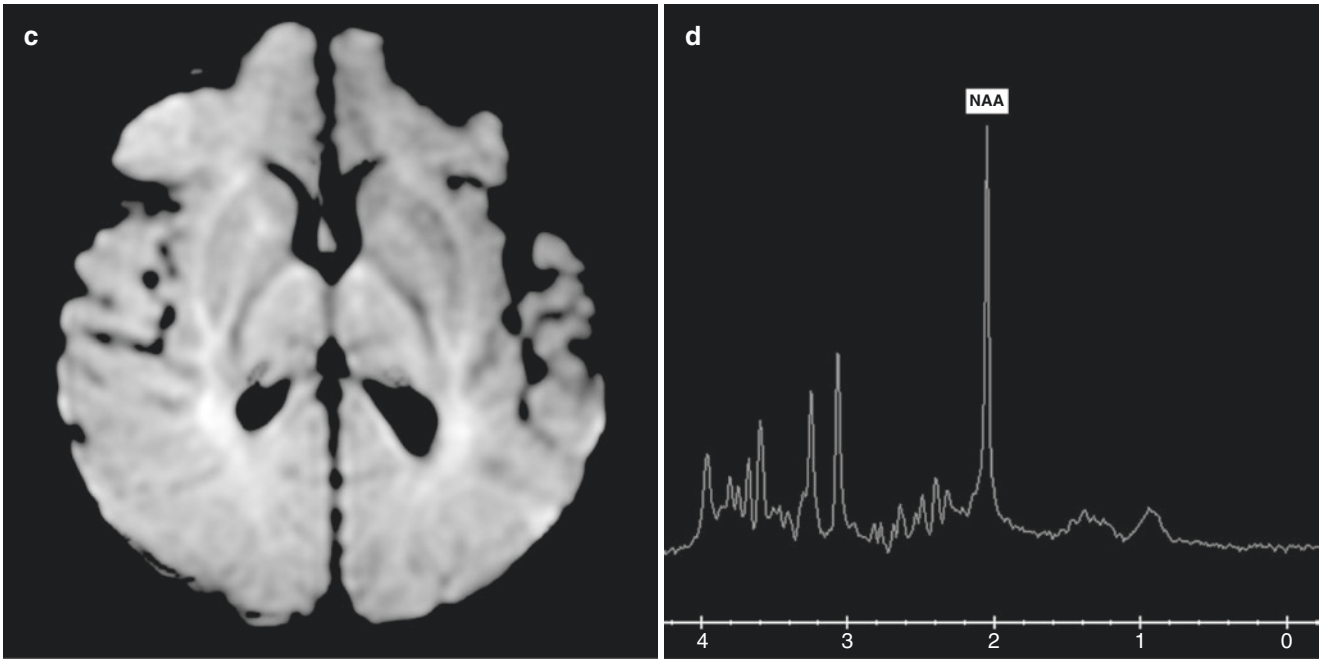

Fig. 8.21 (continued)

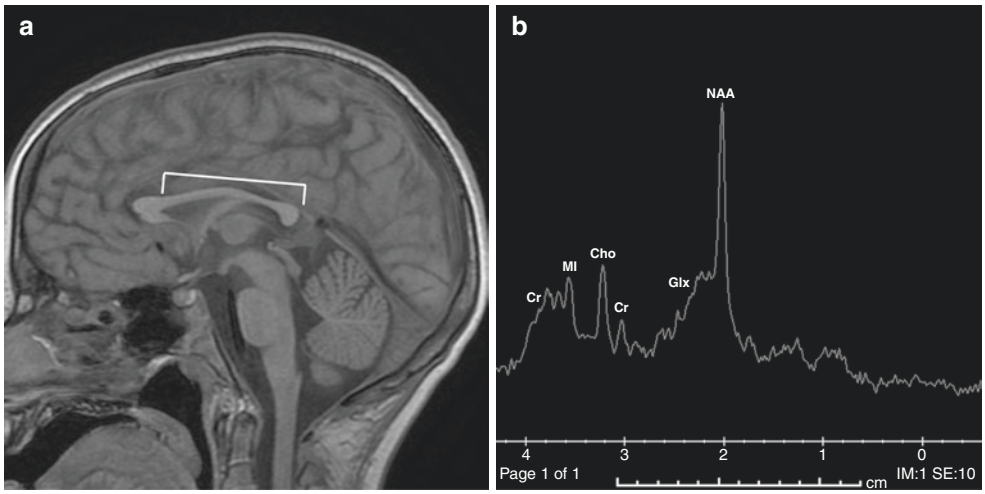

Fig. 8.22 An 11-year-old male with X-linked creatine transporter deficiency secondary to a SLC6A8 gene defect. (**a**) Sagittal midline T1WI (TR/TE msec, 11/5) shows thinning of the body, isthmus, and genu of the corpus callosum representing mild posterior predominant cerebral white matter volume loss without signal alterations (bracket). (**b**) Single voxel MRS over the left basal ganglia (TR/TE msec, 1500/35) shows marked reduction of creatine compounds (Cr) at 3 and 3.9 ppm; other metabolites including *N*-acetylaspartate (NAA), glutamine and glutamate (Glx), choline (Cho), and myoinositol (MI) are normal

Table 8.1 This table was constructed after a thorough review of existing medical literature and is arranged consecutively by chapter. Brain/spine MR imaging patterns were compiled based on lesion location within the cerebrum, cerebellum, brainstem, and/or spinal cord, texture (signal changes on different sequences), volume, concurrent malformations, and other manifestations for each disease process. The range of reported brain MRS alterations was also documented. Diseases with normal or nonspecific imaging patterns were excluded. We emphasize that the current medical literature does not accurately reflect the entire imaging spectrum of all metabolic disease phenotypes. Therefore, the information in this table should be considered dynamic and no more than a loose guideline. We hope that this information will be elaborated upon and altered when it becomes necessary to enhance specificity as new data comes to light in the future

Summary

The implementation of whole-exome sequencing (WES) in molecular diagnostics has resulted in increased understanding of the genetic basis of inborn errors of metabolism (IEM) and genotype-phenotype relationships. As a consequence, there has been acceleration in the implementation of genomics in clinical medicine. Though whole-genome sequencing (WGS) is not yet well established in routine clinical practice, increasing evidence of clinical validity and utility is moving WGS towards integration in the near future.

Introduction

Inborn errors of metabolism (IEM) are a heterogeneous group of more than 1000 genetic disorders, where genetic variation leads to deficient activity of an enzyme or structural protein involved in a cellular biochemical pathway, resulting in one or a combination of energy deficiency, intolerably low essential products, and toxic substance accumulation (Ferreira et al. 2019). Mutations in a growing number of more than 900 nuclear encoded genes and 37 mitochondrial DNA (mtDNA) encoded genes are known to cause IEM, with further novel disease causative genes recognised year on year (Ferreira et al. 2019; Schlieben and Prokisch 2020; Gusic and Prokisch 2021). The increase in our knowledge of the genetic landscape of IEM is predominantly due to the advent of the unbiased genomic approaches: whole-exome sequencing (WES) and whole-genome sequencing (WGS).

Querying genome-wide, for rare variants predicted to be damaging, allows a swift and precise diagnosis to be pursued. This is of great importance: firstly, in establishing the genetic aetiology and inheritance pattern of the disease, which in turn informs genetic counselling, provides insight into the prognosis, allows estimation of the recurrence risk, and informs future family planning; secondly, in circumventing the need for invasive diagnostic procedures, such as a muscle biopsy; and thirdly, in allowing initiation of personalised disease surveillance for genotype-specific complications and exploration of defect-specific treatment options (Ouwehand 2019; Distelmaier et al. 2016).

"Functional and Metabolite Tests First"

The routine diagnostic workup in IEM includes biochemical and metabolic investigations of the blood, urine, and cerebrospinal fluid (CSF), enzyme analyses, radiological investigations such as magnetic resonance imaging (MRI) of the brain, electroencephalography (EEG), and where appropriate invasive muscle biopsy or biopsy of the affected organ for biochemical and histochemical study. Having formed a clearer picture of the patient's disease manifestation, these investigations have conventionally informed the decision on which individual candidate gene(s) to test via Sanger sequencing. This diagnostic workup can encompass consultations with multiple medical specialists and is referred to as a "diagnostic odyssey" (Vissers et al. 2017). Moreover, despite all efforts, it can result in an inconclusive outcome. The diagnostic yield of each individual test is low, leaving ample room for improvement.

Challenges in the Diagnosis of IEM

The IEM disease subsets can be encoded by a single gene to vast collections of genes (Fig. 9.1) (Ferreira et al. 2019). The largest subsets of disease are the congenital disorders of glycosylation (CDG), accounting for over 10% of IEM, where more than 75 genes are involved, and mitochondrial diseases, accounting for over 30% of IEM, where variants in more than 300 genes, represented within 24 disease subsets in Fig. 9.1, result in defects in energy production at the mitochondrial level, rarely with defect-specific biomarkers (Stenton and Prokisch 2018; Ferreira et al. 2019). Given that no single gene accounts for more than a few per cent of IEM as a whole, the conventional gene-by-gene approach to diagnosis in the "functional and metabolite tests first" approach is often laborious, expensive, and time-consuming.

Furthermore, the genetic heterogeneity in IEM is mirrored by phenotypic heterogeneity. IEM manifest with a broad range of phenotypes from non-specific global developmental delay to acute decompensation and premature death with multi-organ failure and severe metabolic acidosis. The clinical phenotype and metabolic profile can vary within individual genetic defects, and conversely, with the exception of a small number of IEM, such as in phenylketonuria (PKU), one clinical phenotype can result from a vast number of different genetic defects, such as in Leigh syndrome, a clinical presentation due to defects in over 75 different disease genes (Lake et al. 2016). Though clinical criteria are established to assist in their diagnosis, misdiagnosis and delayed diagnosis in IEM are commonplace, predisposing to irreversible organ damage and early demise.

Due to their heterogeneity, the vast number of different diseases involved, and the capability to prove a genetic diagnosis, IEM are most effectively characterised by the underlying genetic defect (Wanders et al. 2019). This paves the way for the successful application of genomic sequencing (WES and WGS) as the first-tier diagnostic test, to provide a conclusive genetic diagnosis without incurring higher costs (Farnaes et al. 2018; Vissers et al. 2017 Tan et al. 2017).

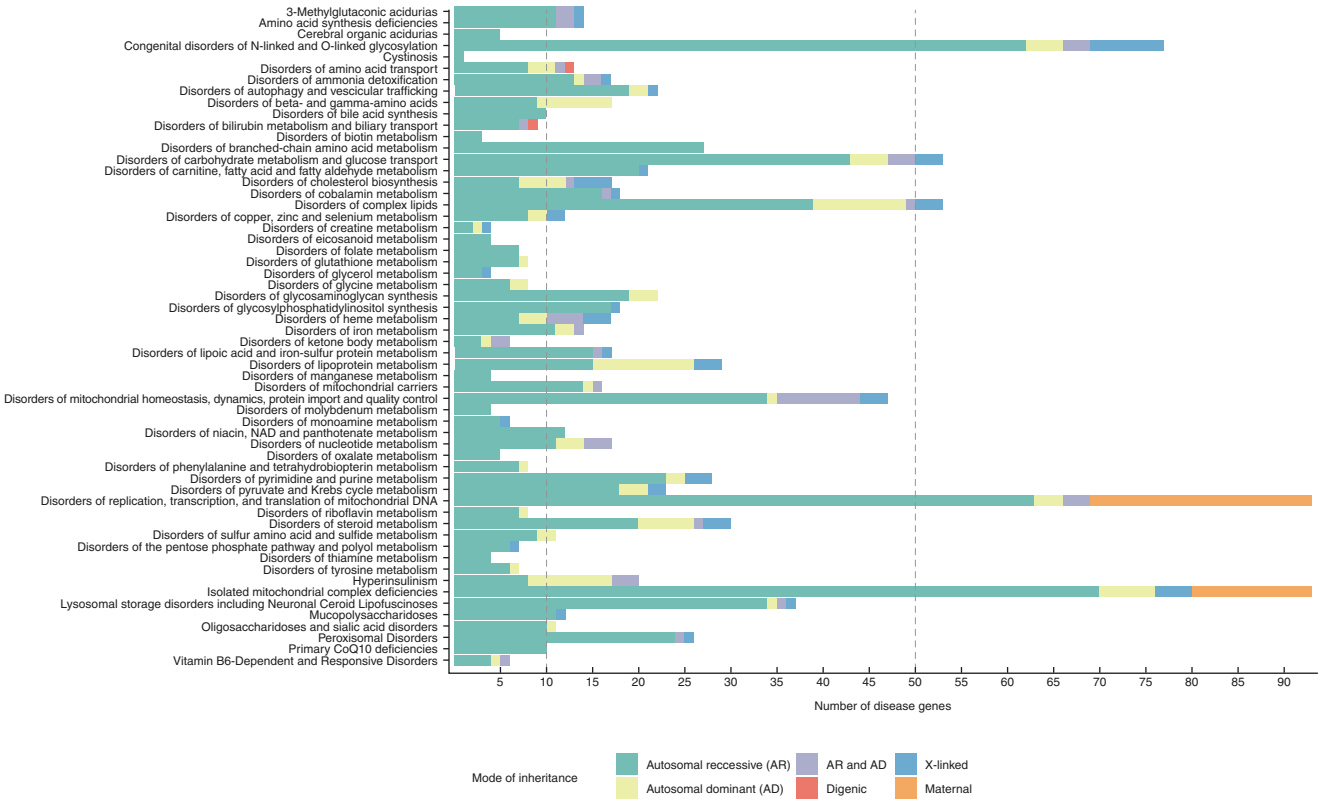

Fig. 9.1 IEM is an umbrella term for subsets of disease encoded by a single gene to vast collections of genes. The number of genes, and mode of inheritance by gene, per disease subset is depicted

"Genetics First"

Next-generation sequencing (NGS) is a term encompassing technologies for the rapid sequencing of a large number of DNA segments, up to and including the entire exome (WES) and genome (WGS). At the beginning of the NGS era, a full low-pass genome with low coverage and a base error rate of around 1% would cost 20,000 Euro. However, in recent years, this price has decreased tenfold, allowing a high-coverage genome to be sequenced for around 1–2000 Euro with a base error rate lower than 0.1%. Given the rapidly decreasing costs, we foresee WES and WGS reaching the affordable level of just a few 100 Euro in the near future.

WES and WGS have an immense advantage over other genetic investigations, by providing one assay for all genetic diseases, with the potential to be automated from collection of the blood sample to genotype. Digital phenotyping allows further automated support in variant interpretation by the integration of available genotype-phenotype associations. By sequencing genome-wide, these approaches maintain the power to detect the underlying variants in genes not known to be associated with IEM, however presenting clinically as such, in known disease genes where the patient is presenting atypically, and in novel disease genes. This is helpful in bridging the diagnostic gap left by candidate gene sequencing by eliminating the need for a priori assumptions (Stenton and Prokisch 2020). Therefore, with the exception of a strong genotype-phenotype correlation, which can suitably direct selection of a candidate gene(s) for sequencing or where the gene panel of interest is small and the diagnostic rate high (Fig. 9.1), genome-wide sequencing is in many ways the diagnosis tool of choice.

The ever-increasing availability and decreasing cost have led to the adoption of NGS in clinical laboratories. These tests can be divided into two fundamentally different approaches: the unbiased techniques of WES and WGS and the targeted technique of gene panels. In the setting of IEM, the advantage of these approaches has been illustrated by achieving diagnostic yields of around 45% and subsequently enabling change in management in over 30% of cases (Tarailo-Graovac et al. 2016).

Whole-Exome Sequencing (WES) and Whole-Genome Sequencing (WGS)

Whole-Exome Sequencing

WES describes sequencing of the protein-coding regions of the genome, the exons. Exons account for ~2% of the genome. These protein-coding regions are the most likely

components of the genome to contain mutations resulting in a clinical phenotype and are reported to harbour ~85% of known monogenic disease-causing mutations. In a standard WES protocol, over 95% of bases are covered reliably on average at least 20 times, with some regions of far higher coverage (Van Hout et al. 2019). This is in the range of sensitivity achieved by Sanger sequencing.

Whole-Genome Sequencing

WGS describes sequencing of the entire genome, providing a comprehensive overview of all variants in the coding and non-coding regions. The principal advantages and limitations of WGS are displayed in Table 9.1. Technically, WGS has higher sensitivity than WES for certain coding variants, indels, chromosomal rearrangements, copy number variants, and short-tandem repeats (STR), and is able to detect complex rearrangements, such as inversions and transposons. It is however unable to reliably detect repeat expansions, some insertions, and some deletions. This is a limitation of WGS which may be overcome by long-read sequencing in the near future (Ouwehand 2019; Valente and Bhatia 2018). Moreover, WGS enables the detection of variants in the non-coding regions such as regulatory and intronic variants. Our understanding of the non-coding regions is incomplete in comparison to the protein-coding regions, which results in difficulty in interpretation of the detected variants. To further investigate and functionally validate variants of uncertain significance (VUS) in the non-coding regions, transcriptomics (RNA sequencing) has been employed (please see Sect. 9.6). Theoretically, all laboratories with NGS established can also provide RNA sequencing. Therefore, it is recommended to always consider taking biological samples for RNA extraction and functional validation, such as a skin biopsy to establish a fibroblast cell line, when taking blood samples from patients.

Table 9.1 The principal advantages and limitations of whole-genome sequencing (WGS)

	Advantages	Limitations and requirements
Comprehensive	WGS (and WES) analysis provide knowledge of all variants in all genes; therefore we learn about allele frequency of all (non) pathogenic variation If the patient does not have an IEM the diagnosis can still be found All medically actionable genes can be investigated There is complete capture of the mtDNA. Aggregated genome-wide data will allow the search for modifiers in regulatory regions in the affected gene in addition to other genes	WES is limited to the detection of pathogenic intronic variants close to the exon-intron boundaries The coverage of mtDNA is lower than for targeted mtDNA sequencing The more comprehensive the assay, the more variants of uncertain significance (VUS) are detected. With functional follow-up studies, the diagnostic yield but also the workload is increasing
Time	Provides one assay for all genetic diseases and allows automation from blood to genotype While WES requires enrichment of the target region, WGS can be undertaken in <50 h and even <21 h which is faster than Sanger sequencing (Clark et al. 2019; Saunders et al. 2012) WGS can meet the need for an urgent diagnosis, for treatment initiation, and for optimisation	High computational power and storage is required in the analysis of the vast amount of data generated While finding the clear diagnosis may save considerable time and effort, the time for clinical interpretation will increase with the number of candidate genes
Technical	PCR-free genome amplifies GC-rich regions which are problematic in Sanger, WES, and gene panel approaches WGS has higher sensitivity than WES and gene panels for certain coding variants, indels, copy number variants, and chromosomal rearrangements, and can define breakpoints	Currently repeat expansions and certain indels are not detected reliably
Cost	The cost of WES/WGS is rapidly decreasing and may reach a few 100 Euro in the near future WES/WGS is cost-effective as it reduces the number of other investigations needed in the diagnostic workup	There are barriers to funding WES, WGS, and RNA sequencing which are currently rarely covered by health insurance
Availability	WGS is gradually becoming more accessible, including through national programmes such as Genomics England (Turnbull 2018) and Genomic Medicine France (Lethimonnier and Levy 2018)	WGS is established in very few centres to date
Automation and reanalysis	Potential to automate workflow, such as in prioritisation of genes for manual curation Reanalysis of negative cases periodically, with increasing bioinformatic capabilities and genetic discoveries implicating novel genes in IEM, can reach a conclusive diagnosis in an additional 15% of cases (Nambot et al. 2018)	Assays for functional validation of variants of uncertain significance (VUS) are rarely established or are only established for a specific subset of diseases in diagnostic genetic departments A global registry and funding for functional validation of specific genetic defects is missing

Targeted Gene Panel Sequencing

Gene panels allow the targeted sequencing of a selection of genes specific to suspected disease. The panels vary in size and selection of genes, based on the choices of the individual lab. Panels can be custom designed or a commercially available panel can be chosen. If variants in a small number of genes explain nearly all cases in a disease subset (Fig. 9.1), panel sequencing is a cost-effective strategy. When optimised, gene panels cover 100% of the targeted regions and provide the highest sensitivity for variant detection within those regions.

The diagnostic success of a gene panel is subject to the selection of genes and to the stringency of patient selection, such as paediatric, biochemically confirmed cases in suspected mitochondrial disease. In IEM, published gene panels achieve diagnostic rates of 10–50% (Ponzi et al. 2018; Legati et al. 2016; DaRe et al. 2013). Phenotypic mimicry is of particular importance in large heterogenous IEM subsets such as congenital disorder of glycosylation (CDG) and mitochondrial disease, where the diagnosis might fall outside of the genes captured, allowing the diagnosis to evade detection. Furthermore, the shelf-life of the gene panel is limited, and as the molecular genetic underpinning of the disease group is further elucidated, it becomes nearly impossible to keep up-to-date.

An intermediate option between targeted gene panel sequencing and WES or WGS, or an initial step in exome investigation, is the virtual gene panel. Here, WES or WGS data is filtered to focus the analysis to a virtual panel of genes. This approach, however, combines the disadvantages of both the panel and WES or WGS approaches concerning comprehensibility and sensitivity (coverage), respectively, and is restricted to known disease genes selected according to the clinical presentation. However, it has the advantage of reduced time needed for the clinical interpreation.

Variant Calling

The development of WES and WGS has been reflected by a synergistic improvement of bioinformatic pipelines in terms of sequence alignment and variant calling capabilities. Sequencing reads are aligned to the reference genome in order to call variants encompassing single-nucleotide variants (SNV), deletions, insertions, and copy number variants (CNV), in addition to structural variants such as translocations and inversions (Fig. 9.2) (Pfundt et al. 2017). Around 80% of known pathogenic variants are missense, stop gain, stop loss, and small insertions or deletions, all well covered with current sequencing approaches. Larger deletions and variants affecting splicing (accounting for ~15% of pathogenic variants) are more difficult to detect and can be missed by exon-based methods. Complex rearrangements and repeat variations are more likely to be discovered by WGS than any other sequencing method. Disease variation database are therefore biased by exon targetted methods.

WES reveals an estimated 50,000 variants per individual, of which 20,000 are coding variants (Van Hout et al. 2019; Kremer et al. 2017). Of these variants, 9000 are predicted to alter the protein, 400–500 of which are rare with a minor allele frequency (MAF) <1% (Van Hout et al. 2019; Kremer et al. 2017). As an expected consequence of expanding the genomic space sampled, WGS reveals an estimated 3–5 million variants per individual, 30,000 of which are rare and predominantly non-exomic (Ouwehand 2019). With such vast numbers of intronic variants called in WGS, variant prioritisation to distinguish pathogenic and clinically relevant variants from benign variants present in the healthy individual becomes the primary challenge without the availability of complementary functional data (Fig. 9.3).

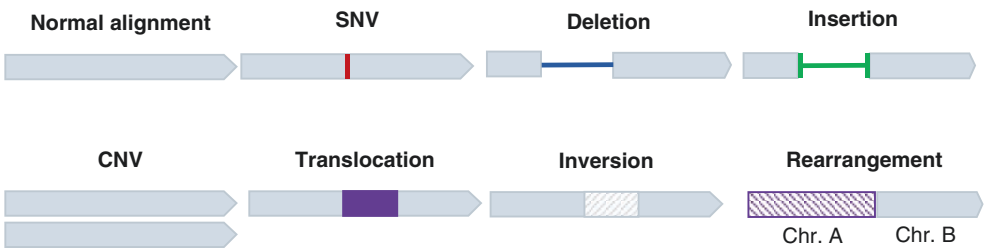

Fig. 9.2 Once aligned to the reference genome, sequencing reads are used to analyse genomic sequence and copy number to call variants. These variants encompass single-nucleotide variants (SNV), deletions, insertions, copy number variants (CNV), and structural variants such as translocations, inversions, and chromosome rearrangements

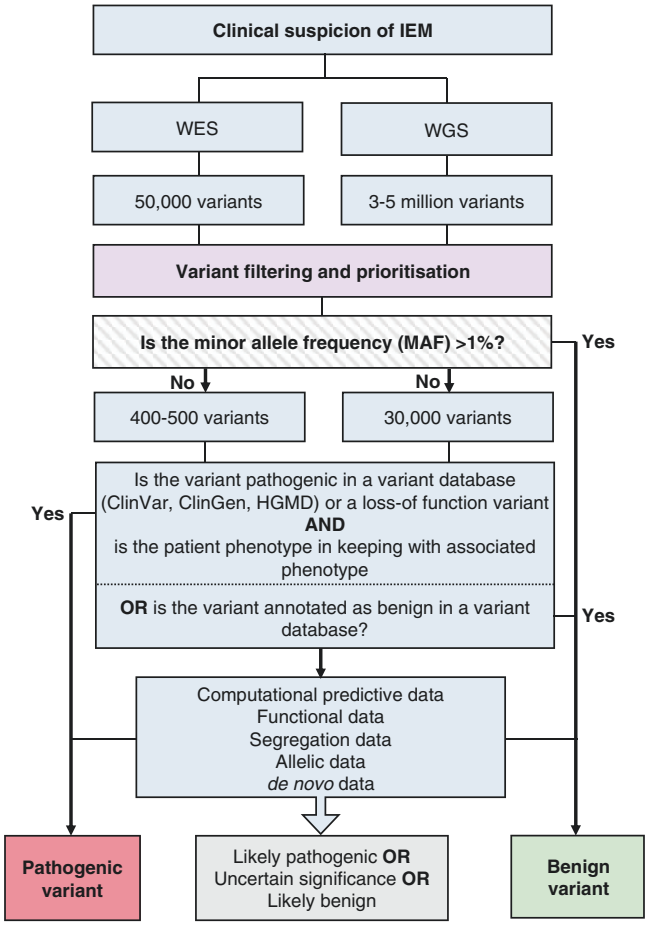

Fig. 9.3 Variants called from whole-exome sequencing (WES) and whole-genome sequencing (WGS) are filtered and prioritised. A minor allele frequency (MAF) filter of >1% removes the vast majority of variants from the analysis as presumably benign. Variants with known pathogenic status and in keeping with the patient's phenotype or variants with known benign status in variant databases such as ClinVar, ClinGen, and HGMD can be identified and prioritised accordingly. The remaining variants require further exploration to determine pathogenicity. These steps allow allocation of variant pathogenicity to the classification benign (class 1), likely benign (class 2), uncertain significance (class 3), likely pathogenic (class 4), and pathogenic (class 5)

mtDNA Sequencing

mtDNA is a circular genome of 16.5 kb encoding two rRNAs, 22 tRNAs, and 13 polypeptides. Disease-causing variation in the mtDNA encompasses copy number alterations (mtDNA depletion, single or multiple mtDNA deletion(s)) and mtDNA point mutations. Sanger sequencing or targeted massive parallel sequencing of mtDNA (mtDNA-NGS) can be applied in detection of such variants, and long-range PCR can be applied for deletions with Southern blot for quantification, as a first-line approach in clinically suspected mitochondrial disease cases.

The extraction and annotation of the mitochondrial genome from WES is now recognised as a highly precise method for the discovery of variants in mtDNA-encoded disease genes, reducing the cost and duration of investigating both the nuclear and mtDNA by separate methods (Wagner et al. 2019; Griffin et al. 2014; Diroma et al. 2014). The validity of this approach has been investigated by direct comparison of WES with both complete mtDNA Sanger sequencing and the gold standard targeted mtDNA-NGS, showing high sensitivity and precision (96.2% and 99.5%, respectively). This implies that WES can be reliably used in the diagnostic setting as a single test to identify pathogenic variants in both nuclear DNA-encoded and mtDNA-encoded genes. The naturally high abundance of the mtDNA molecules (100–10,000) in each cell allows the off-target capture of mtDNA variants as contaminants together with the reliable quantification of mitochondrial heteroplasmy, crucial for the clinical interpretation of mtDNA variants.

Tissue specificity plays an important role in the discovery of mtDNA variants. The absence of pathogenic mtDNA mutations in WES from DNA derived from peripheral blood does not exclude the possibility of a pathogenic mtDNA point mutation in the primary affected tissue such as skeletal muscle, together with somatic mutations. This argues in favour of conducting WES analysis on DNA extracted from the clinically affected tissue. Furthermore, single and multiple deletions and depletion of the mtDNA are problematic to detect by WES. It therefore remains inferior to targeted mtDNA-NGS of affected (and other) tissues.

Variant Prioritisation

Variant annotation and prioritisation play a central role in clinical sequencing (Fig. 9.3). Prioritisation is defined as the process of determining which of the called variants have the potential to damage function and manifest with the patient's disease phenotype. Comprehensive, clearly structured guidelines have been developed by the American College of Medical Genetics (ACMG), a workgroup formed with the goal of ensuring unambiguous designation of variant pathogenicity status, for the interpretation of genetic variants (Richards et al. 2015). The objective framework allows classification of variants into a five-tier system: "pathogenic", "likely pathogenic", "uncertain significance", "likely benign", and "benign". This designation takes into consideration population, computational and predictive, functional,

segregation, de novo, and allelic data, amongst others. Of note, WES and WGS, as holistic approaches, also include copy number variant (CNV) analysis.

To optimise analysis, WES and WGS should ideally be carried out by familial "trio" sequencing, by sequencing the parents of the affected individual, for the following reasons: (1) trio sequencing provides quality control, for example, in sample swapping, (2) it provides validation of variants seen in the affected individual, (3) it allows phasing of variants and ensures the variants segregate with the phenotype in the family, (4) mtDNA variants can be contextualised by comparison to the mutational load in the mother, and (5) autosomal dominant (AD) and de novo variants can be detected. As a consequence, it significantly improves the diagnostic rate (Clark et al. 2018). Together, these advantages argue for "trio" sequencing as a cost-effective approach. Of note, though "trio" sequencing allows optimal analysis, AD and de novo variants can be prioritised also in "index-only" WES by consideration of the pLI score, a score indicating the probability that a gene is intolerant to loss-of-function, and common prediction algorithms.

Most benign variants are easily identified by allele frequency. A minor allele frequency (MAF) >1% accounts for the vast majority of called variants which are presumably common benign polymorphisms (Van Hout et al. 2019). Filtering by MAF keeps only rare variants, statistically more likely to be pathogenic in nature. The frequency of the disease determines the selection of the MAF threshold. Assuming complete penetrance, everything above this threshold is designated as benign. MAF data is readily available in population variation databases such as the Exome Aggregation Consortium (ExAC) database (exac.broadinstitute.org), containing the sequence data of over 60,000 individuals, and the Genome Aggregation Database (gnomAD) (gnomad.broadinstitute.org), containing over 125,000 exomes and 15,000 genomes. ExAC and gnomAD provide information on allele frequency from the general "healthy" population. However, these individuals may be presymptomatic of a disease at the time of inclusion, and indeed almost 3% of the ExAC population has been found to carry "likely pathogenic" or "pathogenic" variants reported in ClinVar (Tarailo-Graovac et al. 2017). Presence of a variant in this database does not therefore automatically exclude it as pathogenic.

Pathogenic variants can be identified as those confirmed to be disease-causing in curated databases, such as ClinVar (ncbi.nlm.nih.gov/clinvar), ClinGen (clinicalgenome.org), and HGMD (hgmd.cf.ac.uk), and those which are loss-of-function in nature, identified within a known disease gene, and in keeping with the patient's clinical phenotype. Loss-of-function variants encompass (1) nonsense variants, where a single-nucleotide variant introduces a premature stop codon; (2) splice-site variants, disrupting the canonical splicing of the gene; and (3) frameshift variants, insertions or deletions involving a number of base pairs that are not a multiple of three, consequently disrupting the reading frame of the coding sequencing and often resulting in a truncated protein due to introduction of a premature stop codon. However, not all annotations are correct, and not all protein truncation variants cause loss-of-function. These variants therefore still need clinical interpretation and in certain cases functional validation.

For all other variants, interpretation of pathogenicity is more challenging and is managed by enforcing a number of criteria. The challenge is referred to as identifying the "needle in the haystack" and requires the expertise of, and discussion amongst, medical physicians, geneticists, and bioinformaticians. The resultant evidence must be considered in aggregate in the context of the patient's phenotype to make a clinical assertion. The analysis can be guided by metabolic profiles, clinical signs and symptoms, the identification of one established pathogenic variant in a recessive disorder, or a candidate gene list.

Computational and predictive data arises from in silico tools developed to predict the potential impact of a variant on the protein. These tools can predict the following:

1. Whether a missense variant, a single-nucleotide variant changing the encoded amino acid, is damaging to the resultant protein function or structure (this depends on criteria such as evolutionary conservation, location within the protein sequence, and consequence of the amino acid substitution); such in silico prediction tools include VEP, CADD, MutationTaster2, PolyPhen-2, and SIFT.
2. Whether the variant has an effect on splicing (given that these predictions are highly sensitive and poorly specific, they result in a high number of false-positive and should be interpreted with caution and in combination).

There is currently no single point of contact for comprehensive functional data on all genetic variants. Functional validation provides evidence for pathogenicity of variants and helps to delineate novel pathways underlying disease, providing a basis for the development of novel defect-specific therapy (Distelmaier et al. 2016). In the field of inborn errors of metabolism (IEM), the underlying pathophysiology is often measurable in the metabolome and on the cellular level giving rise to many possibilities for functional validation, such as to be modelled in vitro in personalised and patient-derived cellular model and in vivo in a wide range of animal models. Furthermore, when validating variants in a novel disease gene, identification of multiple cases with a similar phenotype is enabled by collaborative platforms such as GeneMatcher and Matchmaker Exchange for all genes and networks for specific diseases such as GENOMIT for mitochondrial diseases, amongst others (Bruel et al. 2019; Philippakis et al. 2015).

The variant(s) should segregate with the disease phenotype in the pedigree. Assuming autosomal recessive inheritance, variant must be homozygous or compound heterozygous. Where "trio" sequencing is not available, biallelic inheritance of compound heterozygous variants can be determined by manual inspection of the sequencing data in Integrative Genomics Viewer (IGV) (when the variants are of close proximity), by long-range PCR of DNA or reverse transcribed mRNA and allele-specific sequencing, or by Sanger sequencing of the parents. The latter is most convenient, if parental DNA is available. Where a variant is observed to have arisen de novo, parental samples should be confirmed to be negative, and consideration must be made for germ-line mosaicism with regard to recurrence risks.

Movement has been made towards standardisation of phenotypic data collection to increase interpretive capacity. HPO ("Human Phenotype Ontology") terms describe over 13,000 clinical abnormalities with 156,000 annotations to hereditary diseases mapped into an ontological multitiered structure (HPO.jax.org). Such standardisation of data promotes the inclusion of clinical information into computational development to assist clinical interpretation and increase sensitivity of variant discoveries which have a known genotype-phenotype correlation.

In unsolved cases, with or without candidate variants, complementary "multi-omics" such as transcriptomics (RNA sequencing) may be incorporated into the analysis.

Challenges in Interpretation

Penetrance, variability of clinical phenotype, and genetic modifiers present future challenges to be overcome in variant interpretation. This will require the accumulation of large databases, as opposed to case-by-case analyses.

Incomplete Penetrance and Phenotype Variability

Incomplete penetrance is well documented in IEM and creates difficulty in accurately determining the risk of having a symptomatic child and predictions of disease progression in order to determine the necessity for intervention. Penetrance describes whether individuals with a given genotype express a phenotype. Incomplete penetrance means that not all individuals with a given genotype express the phenotype. It is associated primarily with autosomal dominant and maternal inheritance, however was recently also demonstrated for an autosomal recessive mitochondrial disease gene *DNAJC30* (Stenton et al. 2021). The phenomenon of variable penetrance describes the degree to which individuals express the corresponding phenotype, and substantial difference in clinical phenotype can be observed. This explains why genetic diseases are occasionally transmitted through seemingly "unaffected" parents and, conversely, why healthy individuals can harbour numerous variants of pathogenic effect without manifestation of a disease. Many variables are proposed to be involved in penetrance such as differential allelic expression; copy number variation; the modulating influence of additional genetic variants in cis or in trans, termed "genetic modifiers"; epigenetic changes; and environmental factors, amongst others.

Genetic Modifiers

The aforementioned WES and WGS analysis pipelines consider Mendelian inheritance of autosomal recessive (AR), autosomal dominant (AD), de novo, genetic mosaic, X-linked, and mitochondrial nature in a "one-gene one-disease" manner. However, the ultimate aim should be to understand how an individual's phenotype arises given their primary disease-causing mutation on the background of the sum of variation within their entire genome. The concept of such "genetic modifiers" is particularly poignant in IEM as patients often present with a spectrum of disease phenotypes showing poor correlation with the underlying pathogenic mutation.

This phenomenon was recognised early in IEM in phenylketonuria (PKU), a typical monogenic autosomal recessive disease. In PKU, genetic variation in *PAH* leads to the enzymatic phenotype of impaired function of phenylalanine hydroxylase. However, PKU is further characterised by cognitive and metabolic phenotypes, beyond the control of the *PAH* gene itself. This gives rise to the idea of a major locus in determining certain parameters of phenotype, but additionally a role for further modifier genes accounting for the complexities of, variation in, and additions to, the phenotype, not entirely unlike complex genetic traits. The identification of genetic modifiers may not only aid in prediction of variant pathogenicity and penetrance but also aid in the discovery of novel therapeutic targets in a movement towards personalised precision medicine.

Multiple Diagnoses

Almost 5% of solved cases have a diagnosis involving two or more disease genes (Posey et al. 2017). These diseases can be distinct or overlap in phenotype, resulting in phenotype blending. This is a challenge for genotype-phenotype driven searches and also indicates that the analysis should not be prematurely stopped when a pathogenic variant is found as this may not provide the complete picture.

Transcriptomics

The end of the twentieth century marked the dawn of the "multi-omics" era, most importantly to IEM, in transcriptomics, proteomics, and metabolomics (Stenton et al. 2020; Wanders et al. 2019; Graham et al. 2018; Alston et al. 2021). In "multi-omics", thousands of variables can be measured simultaneously, be it transcript, protein, or metabolite, and can complement genomic sequencing data by the parallel detection and functional annotation of variants. These approaches have the power to track the impact of a variant from RNA abundance and form to protein level and the influence on metabolite level given the function of the respective gene products, and vice versa, tracing the abnormal metabolite level, aberrant expression, and splicing pattern back to the responsible variants. The comprehensive capture of the functional consequence of variants can bridge the evidence gap in support of a definitive IEM diagnosis, thereby reducing our reliance on individually tailored, sophisticated, and often time-consuming functional validation experiments.

Here, we focus on transcriptomics as it is also based on NGS and therefore likely available in the same laboratory. Transcriptomics can be applied in two settings: (1) in validation of variants of uncertain significance (VUS) prioritised in the analysis of WES and WGS and (2) in reprioritisation and validation of variants eluding the WES/WGS analysis pipelines, where it can step into a discovery role. Transcriptomics (RNA sequencing) describes the comprehensive, systematic identification and quantification of messenger RNA transcripts (and also other facultative RNA species) in a given sample. Around 10,000 transcribed protein-coding genes are reliably detected in most tissues, providing insight into the pathogenicity of genetic variants, both exonic and intronic, that result in changes in mRNA expression level and form (Fig. 9.4) (Kremer et al. 2017; Cummings et al. 2017; Frésard et al. 2019; Gonorazky et al. 2019).

Pathogenic variants are detected by (1) loss or reduced expression of a given gene; (2) mono-allelic expression (MAE) of a heterozygous pathogenic variant, eluding prioritisation in WES and WGS due to absence of a second pathogenic allele for biallelic inheritance; and (3) aberrant splice patterns, frequently resulting in a frameshift, a premature stop codon, and provoking nonsense-mediated decay (NMD) of the transcript (Fig. 9.4). The complementation of WES with transcriptomics allows a further 10–35% of inconclusive cases to be solved (Kremer et al. 2017; Cummings et al. 2017).

Aberrant expression results in expression outliers (Yépez 2021). These statistically significant deviations from normal physiological range result from coding variants, from non-coding variants in regulatory regions, such as promoters, enhancers, and suppressors, and from RNA degradation by NMD. Mono-allelic expression (MAE) describes the silencing of one allele (Gonorazky et al. 2019; Kremer et al. 2017; Cummings et al. 2017). It allows reprioritisation of rare heterozygous SNVs, mimicking homozygosity and thereby fitting the recessive mode of inheritance (most commonly seen in IEM). Aberrant splicing is an important phenomenon in Mendelian disease genetics, accounting for at least 10% of pathogenic variants (Soemedi et al. 2017; Lee et al. 2017) and readily detectable by RNA sequencing (Mertes et al. 2021). It results from variation in splice sites, near splice sites,

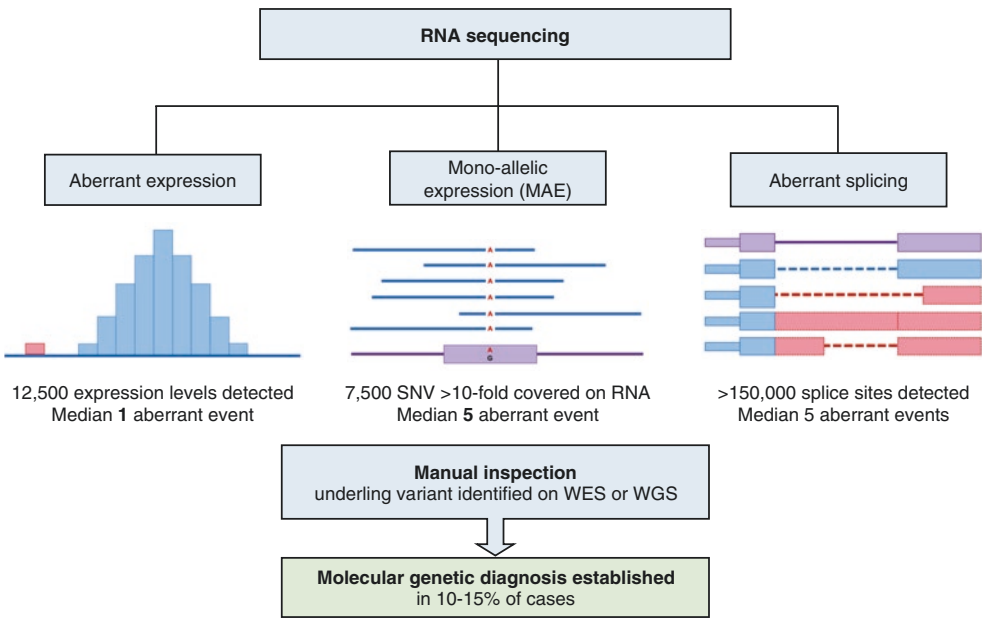

Fig. 9.4 The transcriptomic (RNA-sequencing) analysis pipeline. Pathogenic variants are detected by aberrant expression, mono-allelic expression, and aberrant splice pattern. This results in a manageable number of candidates for manual inspection and typically achieves diagnostic rates of 10–15% when applied as a complementary analysis tool to unsolved WES cases

splicing regulatory elements, and activation of cryptic splice sites deep within the intronic regions. The variants can result in a plethora of aberrant splice isoforms, ranging from exon creation, skipping, extension, and truncation, to intron inclusion. The subsequent splice isoforms can be quantified (Fig. 9.5) to determine the percentage of functional transcript and thereby gene product in the patient. For the discovery of aberrantly expressed genes, in all three analyses, stringent filtering must be applied for rare events with strong effect size. This typically results in a median of one aberrant expression, six MAE, and five aberrant splicing events per sample when searching genome-wide for aberration (Kremer et al. 2017). This is a feasible number of candidates for manual inspection to identify the responsible pathogenic coding and non-coding variants within the WES and WGS data, in order to provide a definitive diagnosis to the patient.

Notably, RNA sequencing can both prove the pathogenicity of seemingly benign variants, such as synonymous variants creating novel splice sites, and disprove the pathogenicity of a seemingly loss-of-function variants resulting in a normal transcript (Fig. 9.6). With regard to synonymous variants, defined as single-nucleotide variants (SNVs) which do not cause a change in the encoded amino acid, the variants are typically filtered out as "benign" in the WES and WGS analysis pipeline; however, evidence for pathogenicity can be brought to light by transcriptomics and may lead to synonymous variants being reprioritised in inconclusive cases. With regard to nonsense variants, those arising early in the transcript mark the termination of translation, however, it is feasible for post-termination ribosomes to reinitiate translation at a downstream AUG codon, the RNA equivalent to the DNA-encoded ATG start codon. This can lead to the expression of a truncated, yet functional, protein. And equally, nonsense variants late in the transcript, also resulting in expression of a truncated protein, may result in normal function, especially when the C-terminus is poorly conserved. Moreover, most genes have several transcripts and clinical interpretation needs to consider the affected subset of transcripts. This highlights the need to take care when assuming the pathogenicity of seemingly loss-of-function variants. Moreover, by the quantification of aberrant expression and splice isoforms, the impact of a given patient's phenotypic severity may be queried. Again, highlighting that though splice variants are typically deemed to be loss-of-function in nature, they do not strictly lead to complete loss of the native transcript, and thus the phenotype may be dependent on the

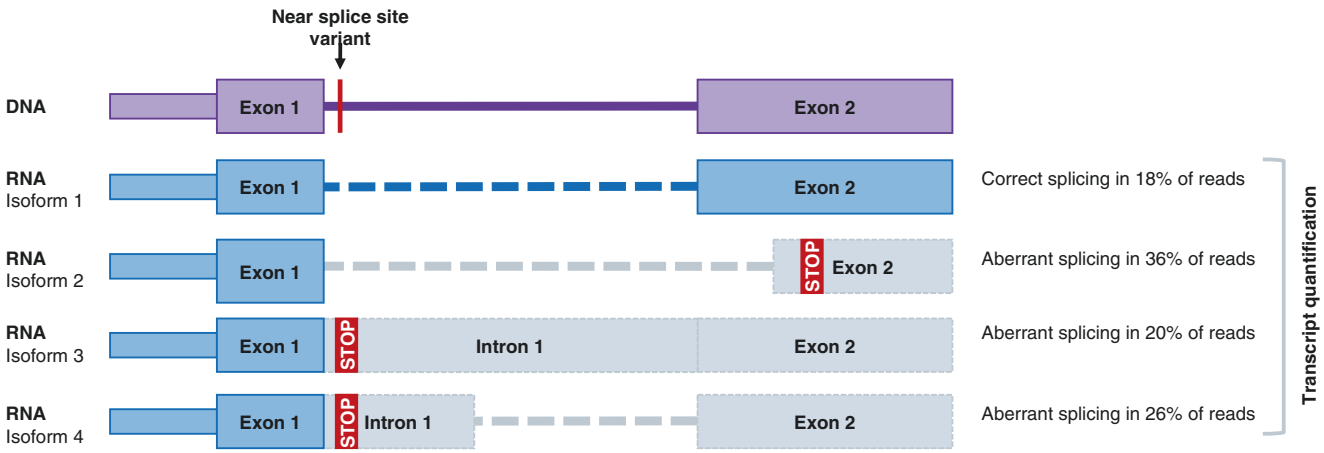

Fig. 9.5 A example of a complex pattern of aberrant splicing due to a near splice site variant in *MRPL44*. Each isoform detected in the transcriptomic analysis can be quantified, and the percentage of functional transcript and thereby gene product, can be determined

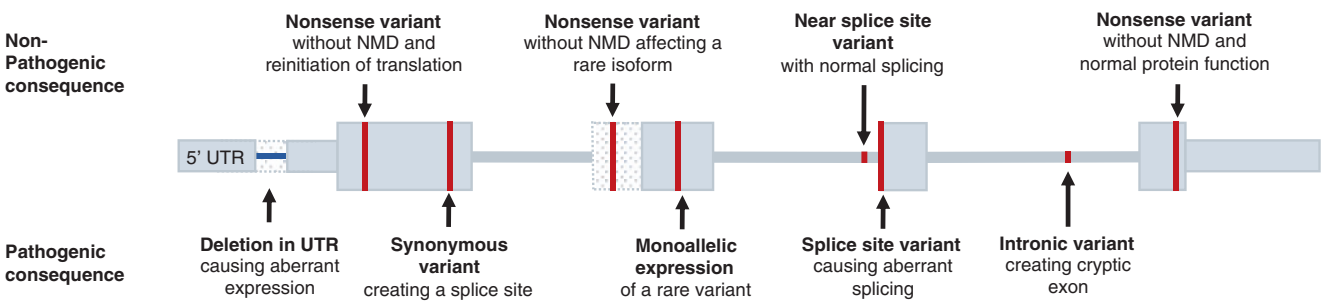

Fig. 9.6 Select examples where transcriptomic analyses provide complementary information to genomic sequencing to prove or disprove the pathogenicity of a given variant

balance between aberrantly and normally spliced transcripts.

The principal limitation of RNA sequencing is the choice of tissue for interrogation. Easily accessible tissues such as blood and fibroblasts, from a minimally invasive punch biopsy of the skin, reliably detect over 65% and 70% of known IEM disease genes, respectively (Stenton et al. 2020; Ferreira et al. 2019). The primary affected tissue provides a further option. However, it is often inaccessible to minimally invasive sampling, such as heart, brain, and liver. Moreover, tissue-specific physiological consequences of the underlying variant are likely to cause further aberrations in expression of a number of genes and cloud the detection of the underlying causative aberrant event. Selection of the optimal surrogate tissue for RNA sequencing, in which the disease genes of interest are optimally expressed, can be guided by gene expression databases, such as GTEx comprising approximately 11,500 RNA-sequencing samples across more than 50 tissues (gtexportal.org/home/).

The Value of a Molecular Genetic Diagnosis

Knowledge of the molecular genetic defect and inheritance pattern is essential for provision of counselling for the patient and their family. This includes the implication for family members of presymptomatic testing, only permitted in children where there is a therapeutic consequence, and for future family planning such as in recurrence risks and the possibility for preimplantation and prenatal diagnostics. Furthermore, prognostic counselling can be provided when the natural history of the disease is well established and may allow for the prevision of a targeted precision therapy (Zhou et al. 2020; Zhou et al. 2020), such as for one of the increasing number of recognised cofactor metabolism defects, amongst others (Distelmaier et al. 2016). However, for many IEM, effective defect-targeted treatment options are still sough-after.

Given the vast spectrum of IEM, the mode of inheritance of a given defect can be autosomal recessive, autosomal dominant, de novo, genetic mosaic, digenic, X-linked, or maternal, by mitochondrial DNA (mtDNA) (as seen in Fig. 9.1). The majority (80%) are inherited in an autosomal recessive (AR) manner with onset in childhood, whereby one disease allele is typically inherited from each parent of carrier status (Ferreira et al. 2019). The recurrence risk is 25% in future offspring. Siblings of the affected child may be presymptomatic, asymptomatic carrier of the variant, or unaffected. Following genetic counselling, their status can be confirmed by targeted sequencing of the disease gene. Where carrier status is known, unrelated partners of carriers can choose to undergo testing to determine whether they are also a carrier of a pathogenic variant in the same gene.

Autosomal dominant (AD) inheritance occurs in over 15% of IEM (Ferreira et al. 2019). The disease allele is inherited from one affected parent and a healthy "wild-type" allele from the second parent. The recurrence risk is 50% in future offspring of the affected parent. Siblings of the affected child may be presymptomatic (depending on the age of onset of the disease), affected, or unaffected. Following genetic counselling, their status can be confirmed by targeted sequencing of the disease gene. Complexities in genetic counselling arise in AD disease due to incomplete or variable penetrance, such as in PEO due to *POLG* or *TWNK* defects, whereby inheritance of the disease allele does not mean with absolute certainty that the individual will be symptomatic.

De novo inheritance describes the occurrence of a variant in the child which is present in neither of the parents and therefore arose "de novo". The recurrence risk for de novo defects in future offspring is on average low, at ~1%, due to gonadal mosaicism but may vary from case to case. If the de novo mutation arose on the paternal allele, the actual risk may be determined by genotyping of sperm cells. Recurrence risk in the offspring of the affected individual increases to 50% as per AD inheritance. In IEM, de novo mutations are a rare, yet present, disease-causing mechanism. Moreover, in a number of genes, de novo mutations occur with higher frequency termed "recurrent de novo". Such examples include early-onset mitochondrial depletion syndrome due to recurrent de novo variants in *SLC25A4* and X-linked adrenoleukodystrophy due to recurrent de novo variants in *ABCD1* (Thompson et al. 2016; Wang et al. 2011).

In X-linked inheritance, the causal variant harbours on the X chromosome. This accounts for ~5% of IEM (Ferreira et al. 2019). Typically, males are more severely affected than females as they have only one X chromosome (46XY). As females have two X chromosomes (46XX), they can either be affected, usually to a lesser severity, or unaffected. This is dependent on the phenomenon of X-inactivation, a random process in each female cell where the expression of one X chromosome is inactivated. Skewed X-inactivation towards inactivation of the healthy "wild-type" allele may result in manifestation (or increase in severity) of the disease phenotype. The male offspring of a female X-linked disease carrier has a 50% chance of being affected and the female offspring a 50% chance of being a carrier. Where a male is affected, the X-linked condition cannot be transmitted to his male offspring as he will pass on only the Y chromosome; however, he will transmit the defect to all of his female offspring. Examples of X-linked inheritance in IEM include Barth syndrome due to *TAZ* defects and pyruvate dehydrogenase deficiency due to *PDHA1* defects.

Digenic inheritance requires defects in two genes for the syndrome to manifest. Two digenic IEM are described, Rotor syndrome, a disorder of bilirubin metabolism and biliary transport resulting in hyperbilirubinemia due to AR defects in both the *SLCO1B1* and *SLCO1B3* genes, and iminoglycinuria, inherited in either an AR or digenic pattern in *SLC36A2* (±*SLC6A20*).

Maternal Inheritance of IEM

Maternal inheritance of mtDNA defects is common in adult-onset mitochondrial disease. mtDNA is exclusively inherited from the mother as mtDNA from sperm is actively excluded upon fertilisation of the oocyte. The disease phenotype is expressed when the level of heteroplasmy, the "mutational load", crosses a specific threshold. This threshold is typically dependent on the minimum percentage of healthy mtDNA required to support the energy demand, and therefore healthy functioning, of a given tissue. For this reason, the most frequently affected organs in mitochondrial disease are the high-energy demanding organs such as the brain, heart, muscle, and liver. In both homoplasmic and heteroplasmic mtDNA defects, it is difficult to predict with certainty whether the offspring will express the phenotype. Variable penetrance occurs in homoplasmic mtDNA defects such as in LHON, where only 50% of males of 10% of females express the phenotype. With regard to heteroplasmic mtDNA defects, a higher heteroplasmy level may result in an affected individual as compared to a lower heteroplasmy level resulting in an asymptomatic individual. Accurate annotation of the level of heteroplasmy, tissue-specific threshold, and influence of mitochondrial haplogroup are currently not reported in publicly available databases; this would be of great value to aid genetic counselling in the future. Furthermore, as with nuclear DNA defects, variants can arise de novo in the mtDNA. The recurrence risk of de novo mtDNA mutations is ~1% based on the possibility of gonadal (oocyte) mosaicism.

Possibility for Prevention

Predictive testing can be used to determine whether an embryo or foetus carries a given genetic defect. This can be undertaken in the preimplantation setting by testing of the embryo or in the prenatal setting by testing of the foetus and helps to guide clinician and parental decisions for further evaluation and management of the pregnancy.

Preimplantation genetic diagnosis (PIGD) requires harvesting of the gametes and in vitro fertilisation (IVF) to generate multiple zygotes. The embryo is allowed to divide until reaching a multicellular stage at ~3–5 days. At this stage, one to two cells are removed for genetic testing of the specific pathogenic mutation(s) identified in the family. The unaffected embryo(s), where available, can subsequently be implanted and additional unaffected embryos frozen for future cycles. It is recommended that further prenatal testing is undertaken during the pregnancy to form an accurate picture of the genotype—options available include chorionic villus sampling (CVS) and amniocentesis. PIGD can be problematic, as a chromosomally normal, mutation-free embryo for transfer may not be generated in the cycle, or damage may occur to the embryo while removing the cells for testing. Furthermore, in mtDNA defects, from the mutational load in the embryo at 3–5 days, it is difficult to extrapolate the mutational load for different tissues in the future child, and it is unlikely to generate an embryo with an absent mutational load, creating limitations in predictive accuracy.

Prenatal Diagnosis

Chorionic villus sampling (CVS) can be offered at 10–12 weeks of gestation. Chorionic villi cells, surrounding the foetus and later developing into the placenta, are sampled transabdominally or transcervically. The cells are cultured and subsequently tested to determine the genetic status. The chorionic villi cells are genetically identical to the foetus, with the rare exception of confined placental mosaicism, where the genetic abnormality occurs in the placenta and not the foetus. Results from CVS are typically available within 2 weeks and can therefore guide the decision on continuation of the pregnancy.

Amniocentesis can be offered at 14–16 weeks of gestation. Amniotic fluid surrounding the foetus is removed by a needle biopsy transabdominally. The amniotic fluid contains cells from the foetus which are subsequently tested to determine the genetic status. Results from amniocentesis are typically available within 2–6 weeks and can guide the decision on continuation of the pregnancy.

While CVS and amniocentesis in combination with advances in cytogenetics and molecular technologies have expanding and improved prenatal diagnostic, the small risk of miscarriage is a deterrent to their acceptance by the patient.

Noninvasive Testing of Foetal DNA in Maternal Circulation

Noninvasive prenatal testing relies on distinguishing the foetal and maternal genomes by identification of the minor proportion of cell-free foetal DNA (cfDNA) in the maternal circulation. This can be detected earlier in the pregnancy and with significantly less risk than conventional approaches. The cfDNA molecules are tagged, followed by enrichment and next-generation sequencing (NGS). The approach is currently targeted towards the detection of foetal aneuploidies and chromosomal abnormalities, such as trisomy 13, 18, or 21, sex chromosome aneuploidies, and microdeletions, with high sensitivity and specificity. Promise is now emerging in the detection of de novo and paternally inherited disease-causing

variants in monogenic diseases (Zhang et al. 2019). However, at this time, the approach cannot reliably identify recessive conditions and maternally inherited monogenic diseases.

Specific Considerations in Mitochondrial Disease

Recent advancements in the mitochondrial disease field have led to the opportunity for mitochondrial donation including pronuclear transfer, metaphase II spindle transfer, and polar body transfer with the hope to prevent transmission of the mtDNA defect from mother to child. Mitochondrial donation is currently permitted in the UK in licenced centres under the regulation of the Human Fertilisation and Embryology Authority (HFEA). Although some studies suggest good safety and efficacy profiles of these techniques, an international consensus is needed on the regulation of these approaches.

The Concern with the Genomic Approach

Secondary Findings

As capabilities in the era of genomic medicine increase, so do the incidence of secondary findings. This has arisen as a key issue in recent years, catalysed by the American College of Medical Genetics and Genomics (ACMG), who in 2013 first released recommendations for reporting of secondary findings in exome and genome sequencing (Green et al. 2013). In the years following, at national-, European-, and global-level, debates on the development of recommendations for handling such findings, encompassing ethical commentaries, guidelines, and diverse policies, have ensued. The principal areas of debate regard the suitability of terminology, application of opportunistic screening, informed consent and genetic counselling procedures, opt-out possibilities, reporting in minors, and values surrounding professional duty, patient autonomy, and actionability (Fig. 9.7) (Saelaert et al. 2018; Mackley and Capps 2017).

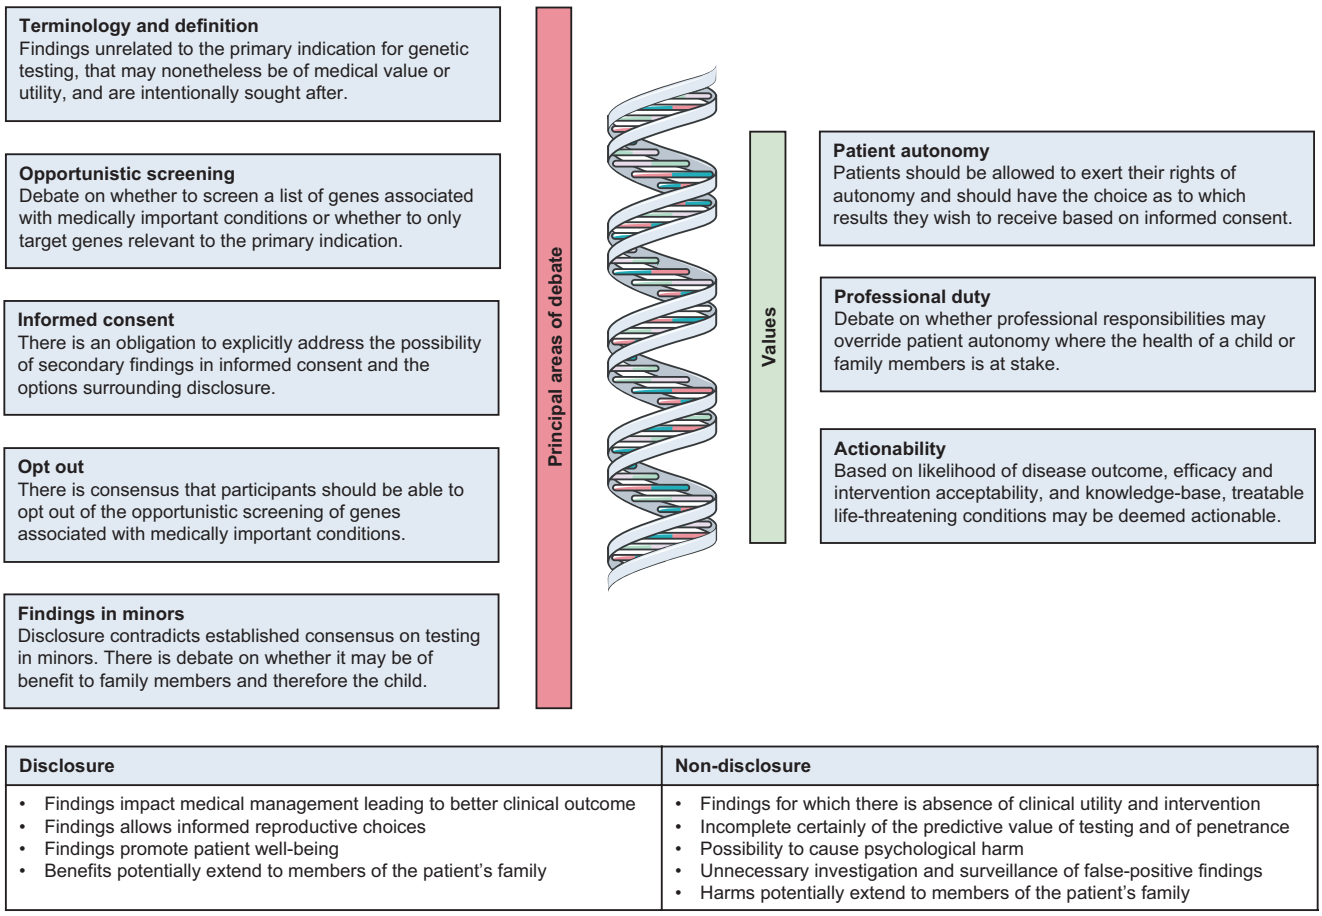

Fig. 9.7 Exploration of the principal areas of debate and values surrounding the key issue of secondary findings in exome and genome sequencings

Secondary findings are defined as pathogenic alterations in genes unrelated to the primary diagnostic indication for sequencing, which may nevertheless be of significant medical value to the patient and the clinician. The findings are termed "secondary findings" as opposed to "incidental findings", the first term applied to such findings, as they result from the deliberate search for pathogenic alterations. The term "secondary" is, however, not without objection as it may minimise the significance of the result, relative to the "primary" finding.

The distinction between clearly focussed diagnostic testing and opportunistic screening loses much of its sharpness in the context of genome sequencing, and there is much debate on the genes in which opportunistic screening for pathogenic variants should be conducted, if at all. The term "actionability" is frequently used here to describe genes in which there is a high likelihood of disease outcome (high penetrance) and there is efficient and acceptable intervention and a robust knowledge-base, thereby impacting on the clinical management and reproductive choices. The ACMG defines a list of medically actionable genes which are regularly refined and updated (ncbi.nlm.nih.gov/clinvar/docs/acmg/), selected due to strong evidence of high probability of severe adverse medical outcome, the possibility for verifiability by other diagnostic methods, and early intervention likely to prevent or ameliorate serious morbidity or early mortality. Of note, only one metabolic disease is included in this list, X-linked OTC deficiency (ornithine carbamoyltransferase deficiency). Secondary findings within these genes fall into two descriptive categories: "sequence variation previously reported and recognised as a cause of the disorder" or "sequence variation previously unreported and of the type which is expected to cause the disorder" which are labelled as known pathogenic (KP) and expected pathogenic (EP), respectively. The rate of discovery of secondary findings within this defined list of genes is currently reported as between 1 and 3.5% for patients undergoing clinical sequencing (Van Hout et al. 2019; Dewey et al. 2016; Green et al. 2013). The European Society of Human Genetics (ESHG) and Canadian College of Medical Genetics (CCMG) take a more cautious approach to "actionability" and its implication in disclosure, acknowledging the current lack of empiric knowledge on their utility, and do not endorse the intentional analysis of all "actionable" genes, preferring to use a targeted approach to the primary clinical question in order to minimise secondary findings.

Though challenging, the informed consent procedure, inclusive of a level of information and counselling required to realise a truly informed consent and an acceptable understanding of secondary findings and their implications, is essential. This includes decisions on whether to "opt out" of intentional opportunistic screening and decisions on disclosure. There is also discussion of the potential role for dynamic or staged consent procedures, in which the validity of patient preferences is not limited to a single moment prior to testing. Regarding the screening and reporting of results in minors, guidelines are widely disputed, and the ACMG argues that disclosure of findings for adult-onset conditions may be clinically useful to the parents and, in turn, benefit the child themselves. However, this argument departs from well-established paediatric genetic testing practice recommendations and is therefore not unanimously supported.

Many challenges surrounding secondary findings are grounded in difference in prioritisation of values. It is widely agreed that patients should be allowed to exert their rights of autonomy and have the choice as to which results they wish to receive, defined in the informed consent, with the decision to "opt out" of opportunistic screening. Debate arises in the duty of the doctor in beneficence and non-maleficence, such as in disclosing information on potentially treatable life-threatening conditions, and whether professional responsibilities may override patient autonomy where the health of the patient or their family members is at stake. Non-disclosure of a clinically actionable variant conveying with near certainty an adverse, yet potentially preventable, medical outcome, in order to uphold patient autonomy, requires convincing ethical justification and remains of intense debate. While absence of a strong evidence for benefit may justify the disinclination to disclose, "actionability" is not an objective medical criterion; therefore, the possibility for dynamic or staged consent would further allow weighing of these values differently and situation-specifically, to reach contextualised decisions on the disclose.

To harness the benefits of genomic medicine, policies need to be evidence-based. Important considerations arise in the predictive value of testing and penetrance of disclosed variants. Current knowledge of variant penetrance is largely derived from symptomatic patients and those with a positive family history. Plentiful evidence regarding the penetrance of variants amongst asymptomatic carriers with absence of a family history is missing. For understanding of variant penetrance to evolve and to generate informative penetrance estimates, it is encouraged for cohorts of cases in which secondary findings are disclosed, to be followed longitudinally (Green et al. 2013).

To summarise, the two extreme positions of full disclosure and complete non-disclosure are seldom supported in clinical practice. Balance in disclosure decisions should consider the potential benefits to the patient and their family of optimised medical management, reproductive choices, and well-being, versus the risk of the psychological burden, the potential exposure to iatrogenic harm due to unnecessary diagnostic investigation, and the clinical surveillance of a false-positive findings, amongst others. Given the complexity of the issue, regarding the integration and alignment of terminology, policy, and values, international disagreement remains, and the pursuit of consensus on future well-grounded practice is yet to be established.

A Perspective for WGS in Newborn Screening

The need for early recognition and initiation of rational therapeutics, also in presymptomatic stages of disease, has led to the inclusion of many IEM in newborn screening programmes. This has been pivotal in initiating therapy before the onset of progressive irreversible organ damage. The era of newborn screening has been greatly influenced by Wilson and Junger, whom in 1969 formulated a report commissioned by the World Health Organization, defining a number of screening criteria to guide the selection of medical conditions suitable for screening. These standards, considered the gold standard in making screening test decisions, covered the concept of disease importance, natural history, detectability at an early stage, treatability, the associated risk benefit, and cost-effectiveness.

Newborn screening aims to achieve presymptomatic diagnosis of treatable diseases for which timely intervention proves vital in preventing disability or death. With recent advancement of genomic sequencing technology, the rate at which novel disease genes are identified is out-pacing the ability of professionals and policy-makers to assess the potential benefits and pitfalls of introducing or expanding genetic screening programmes, propelling WGS into discussion as a first-tier test in newborn screening programmes. This would also allow screening for disorders for which no other biomarker is known or is difficult to be implemented in current screening procedures, including, for example, a number of cofactor deficiencies.

Genomic screening has a number of positives over conventional newborn screening: Firstly, WGS is time-independent and can be performed from birth, a limitation of biochemical profiling, allowing earlier intervention. Secondly, as a global approach, WGS hold to potential to reveal all actionable disease variants, inclusive of far rarer conditions often not included in routine screening in a "one-test-fits-all" manner, providing a comprehensive picture of future disease status, unachievable by a targeted screen as discussed earlier in diagnostics in general.

Interpretation of genetic variants prior to symptomatic onset requires confidence in prior knowledge of function and genotype-phenotype correlation. A further consideration is treatment requirement. This becomes particularly problematic when the proposed treatment is not curative, has significant complications, or is inherently not without risk itself. In diseases where the natural history is well documented, to reach a balance in variant disclosure, information could be provided to the individual at the age when treatment should be started or specific tests should be performed.

Genetic screening is therefore an area of growing importance and controversy, arising as a potential player in translating genomic advances into improvement in population health. However, prior to implementation, we must have the knowledge to clearly distinguish affected from unaffected newborns.

Conclusion

In conclusion, advances in molecular genetics in the last decade have revolutionised the field of IEM and are challenging our long-standing, stepwise approach, to the diagnosis of IEM in clinical practice. The unbiased and reliable manner in which genomic sequencing can pinpoint the underlying cause of a patient disease is propelling WES and WGS into the first tier of diagnostics in suspected IEM, which is now well established in routine clinical practice. Further consideration is required of the role of WES and WGS in prenatal testing and newborn screening. Furthermore, as the interpretation of "multi-omics" data evolves, we are likely to see increased integration of these comprehensive functional data into analysis of the ever-growing number of variants of uncertain significance (VUS) detected by genomic sequencing and of inconclusive cases in the near future. High-throughput functional validation studies will therefore play a pivotal role in the years to come.

10 Other -omics Approaches and Their Integration for the Diagnosis and Treatment of Inborn Errors of Metabolism

Clara D. M. van Karnebeek and Nanda Verhoeven-Duif

Contents

Summary

Here we provide an overview of the different -omics approaches and their application and integration for the purpose of improving diagnosis and treatment of patients with inborn errors of metabolism. Given the molecular diversity of biomarkers, the high-throughput -omics technologies offer an amazing opportunity for holistic investigation and contextual pathophysiologic understanding of disease, as well as their identification and management. Phenomics, genomics, metabolomics, lipidomics, glycomics, proteomics, and transcriptomics are each important to systems medicine, but some are clear more mature than others, reflected in the varying applications as a clinically reimbursed test versus a research tool only. Generation of big data is relatively easy; the challenge lies in the integration and interpretation of these systems biology data and functional characterization and translation of the results into something clinically meaningful for our patients. Partnerships with patients and families and multidisciplinary collaboration between clinicians and researchers are essential for success in the -omics era.

Introduction

The era of big data promises to accelerate the diagnostic and treatment process dramatically. Given the molecular diversity of biomarkers, the high-throughput -omics technologies offer

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_10

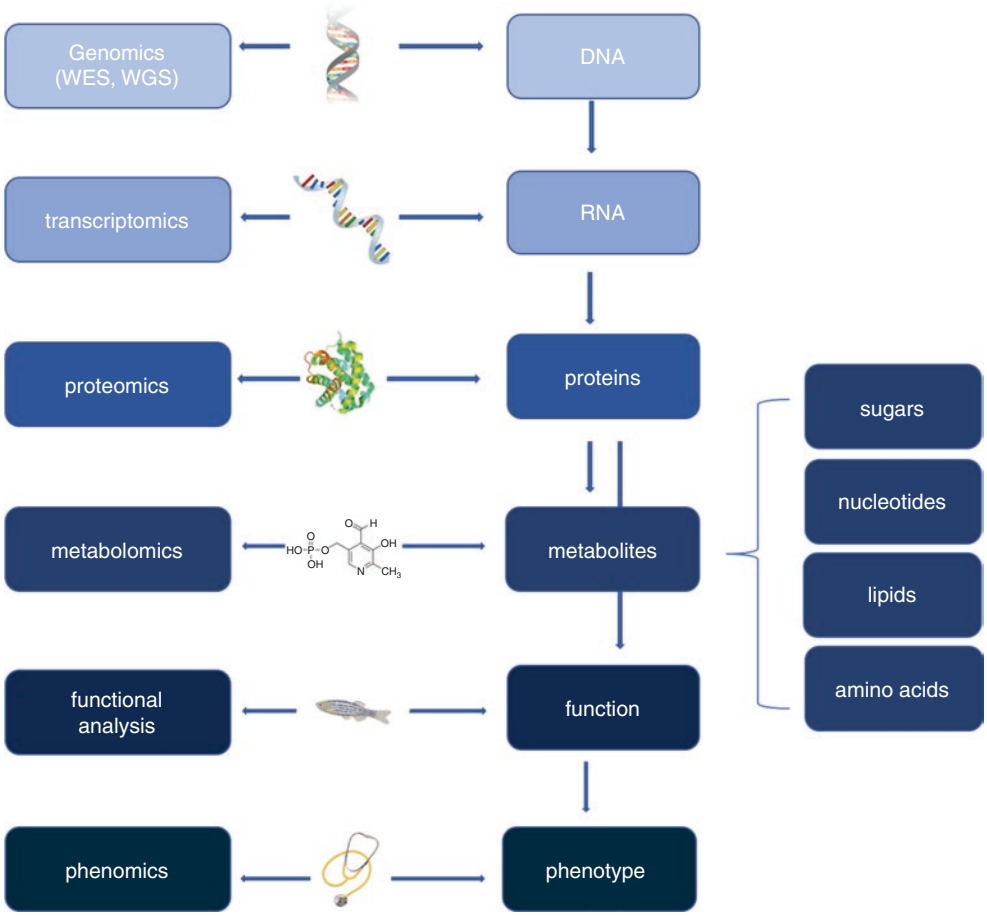

Fig. 10.1 -Omics refers to the study of biological processes by analysing pools of biological molecules: DNA molecules by genomics (WES and WGS), RNA expression by transcriptomics, proteins by proteomics, and metabolites by metabolomics, including the subgroups of glycoproteins (glycomics) and lipids (lipidomics). Altogether, these molecules define function (as can be tested by functional analyses, e.g. in model systems) and phenotype (phenomics)

an amazing opportunity for holistic investigation (Benson 2016) and contextual pathophysiologic understanding of disease for better diagnosis and treatment (Alyass et al. 2015; Ahn et al. 2006; Tebani et al. 2016). While each of the -omics technologies depicted in Fig. 10.1 is important to systems medicine, some are clearly more mature than others (Julkowska et al. 2017). WES is slowly emerging as a reimbursed test in clinics around the world, while epigenomics and exposomics (the environmental effects ranging from exposures to toxic substances or drugs to diet) are applied mainly in research settings. Of the mass spectrometry (MS)-based technologies, metabolomics is much closer to being introduced into clinical practice than proteomics, because targeted MS-based metabolite analyses to improve pathophysiologic understanding and enhance accurate diagnostics and tailored care have already been adopted in clinical chemistry laboratories. Whether in the research or clinical setting, the challenge lies in the integration and interpretation of these systems biology data and translation of the results into something clinically meaningful for our patients. A daunting task, this challenge can only be overcome through partnership with the patients and families and close collaboration between clinicians and researchers in the basic, computer, and clinical sciences (van Karnebeek et al. 2018).

Phenomics

Phenomics is the acquisition of detailed phenotypic data on an organism-wide scale. In practice, this includes the dysmorphologic, neurologic, and systemic characterization of the patient, as well as in vivo technologies such as neuroimaging/spectroscopy, and electrophysiologic, biochemical, and other functional studies. The dimensionality of phenomes is high, and so analyses of phenomic data call for new concepts and techniques. To integrate phenomic information, non-linear models that integrate information across the phenotypic hierarchy are necessary (Rahman and Rahman 2019).

Phenomic data allow a better understanding of the pathways that connect genotypes to phenotypes. Caveat of WGS or WES outputs are the variants of unknown significance (VUS), which can number in the thousands. It is often difficult to disentangle pathogenic variants from variants caused by genetic variation in the population and naturally occurring individual mutations (an average of ~100 naturally occurring loss-of-function variants per genome). The annotation of phenotypic abnormalities and their integration into the diagnostic pipeline can identify functional groups of

Table 10.1 Online databases and knowledge bases

Name	Abbreviation	Description	URL
ClinVar	–	An archival database that aggregates information about genomic variation and its relationship to human health	www.ncbi.nlm.nih.gov/clinvar/
Clinical genome resource	ClinGen	An authoritative central resource that defines the clinical relevance of genes and variants, for use in precision medicine and research	www.clinicalgenome.org
The Leigh map	–	A novel gene-to-phenotype interaction network which can be used as a diagnostic resource for Leigh syndrome	vmh.uni.lu/#leighmap
Phenomizer	–	A web-based application for clinical diagnostics in human genetics, using semantic similarity searches in ontology	compbio.charite.de/phenomizer_orphanet
Human phenotype ontology	HPO	A standardized vocabulary of phenotypic abnormalities encountered in human disease	www.human-phenotype-ontology.org
Inborn errors of metabolism knowledge base	IEMbase	An online knowledge base and smart system (artificial intelligence) for curation and diagnosis support of inborn errors of metabolism	www.iembase.org

genes, which can help to pinpoint truly pathogenic variants and obtain definitive genetic diagnoses.

In recent years, several gene-to-phenotype databases and knowledge bases have emerged (Table 10.1), including large-scale international expert-curated knowledge bases such as ClinVar and ClinGen. In addition, there are several niche phenomic resources (e.g. Leigh Map) which were developed by experts within a specific disease field to enhance diagnosis and clinical management (Rahman et al. 2017). Other tools can be integrated within the bioinformatic pipeline of WES/WGS and use machine learning and data mining of several clinical and biological knowledge bases to enhance prediction. One example resource is Phenomizer, which automatically consults several rare disease knowledge bases and, based on text inputs from the user, provides a candidate gene list based on both known gene-phenotype associations and alternative genes within the same gene family.

The increasing availability of phenomic repositories is an exciting addition to the field of -omics, yet has its challenges. Phenomic resources are supplements to, and not replacements for, clinical and genetic expertises. If a particular genetic defect is associated with a pathognomonic clinical presentation well-known to clinicians, it is unlikely that there will be a need to consult a phenomic resource. Conversely, some resources generate hundreds of outputs that may be too large to be manageable or interpreted meaningfully. Critical to the success are computer-readable patient descriptions; the Human Phenotype Ontology project (HPO) has been developed to meet this need (Table 10.1). Its main components are phenotype vocabulary, disease-phenotype annotations, and algorithms that operate on these. However, there are still several phenotypes, for example, some biochemical phenotypes, which do not yet have an HPO number and cannot be integrated in resources linked with HPO. Efforts to standardize the collection, annotation, and storage of phenotypic data are crucial for the interoperability between different resources and geographical regions. An internationally recognized nosology for the increasing numbers of IMDs is equally important and currently in the last phase of development (Ferreira et al. 2019).

IEMbase meets many of these needs (Table 10.1, (Lee et al. 2018)). It is an expert-generated and continuously updated database on IMDs, which accepts an array of biochemical and clinical symptoms from a user, maps these to HPO terms, and returns a ranked list of possible IMDs that match the input profile. In addition, the system can explain the rationale of its results, suggest possible tests that would assist in narrowing down the differential diagnosis, and provide access to its database of biochemical, molecular, and clinical information if more evidence is desired.

We emphasize that contributions by the IMD clinical and research community to the curation and updating of biochemical data are urgently needed to fully enable the application of text-based phenomics to facilitate data-sharing for IMD patients (Maiella et al. 2018). Expert curation, crowdsourcing, and automated machine learning methods can facilitate the process and should be a priority for funding.

Exome and Genome Sequencing

The exome is the collection of all protein-encoding parts, exons, of the genome. It is estimated that 85% of mutations that have a large impact on disease are within the exome. Diagnostic whole exome sequencing (WES) aims to identify genetic variants that alter proteins and thus will identify mutations in genes encoding enzymes and transporters. WES consists of two steps: selection of all 180,000 exons and sequencing of this exonic DNA by high-throughput sequencing technology followed by bioinformatic data analysis. In whole genome sequencing (WGS), the entire genomic DNA of an organism is sequenced. WGS has technical advantages over WES, as no selection step is needed and sensitivity (coverage) is higher. Furthermore, disease-related variants in intronic DNA and regulatory domains can be detected, as well as copy number variants. The percentage of WES-

solved cases is with 30% still quite low, which is likely caused by either the lack of sequence coverage of the variant, by disease causes outside the coding sequences, or the misinterpretation of "variants of unknown significance". WGS is therefore postulated as a superior tool to identify unsolved IMD (Gilissen et al. 2014; Belkadi et al. 2015; Stavropoulos et al. 2016; Lionel et al. 2018). Convincing examples of the added value of WGS in IMD disease discovery is the description of glutaminase deficiency in ataxia patients caused by short tandem repeat expansions in *GLS* (van Kuilenburg et al. 2019) and the discovery of a coenzyme Q10 biosynthesis defect (Malicdan et al. 2018). WGS may reveal multiple genetic conditions in a single patient, as recently demonstrated by the discovery of a new defect in pyrimidine metabolism in a patient with an additional known genetic disease, probably leading to a blended phenotype (Perez-Torras et al. 2019) as well as a novel sialic catabolism disorder in a patient with skeletal and cardiomyopathy due to recessive *NPL* mutations, as well as deafness caused by *GJB2* mutations (Wen et al. 2018).

Both in WES and WGS, interpretation of variants often has to be based on *in silico* prediction with an accurate prediction score of only 60–70%. Five different classes of sequence variants are distinguished, of which only the extremes, "clearly not pathogenic" and "clearly pathogenic", are consequential in clinical practice. Thus, additional -omics techniques and functional studies are valuable in making a definite diagnosis. The *in vivo* treatment response should also be taken into consideration when classifying variants (Shen et al. 2021).

Proteomics

Proteomics gives insight into the composition, structure, and function of the proteome, the entire set of proteins that is produced in a specific state of an organism or a cell population. Interrogation of proteomic data is a powerful approach to reveal impaired protein synthesis, folding, stability, and degradation, by detecting reduced protein levels and by detection of specific proteomic signatures (Stenton et al. 2020). There are many approaches to characterizing the human proteome, which is estimated to contain between 20,000 and 25,000 nonredundant proteins. Most currently used methods are mass spectrometry-based and involve separation by capillary electrophoresis or liquid chromatography.

Quantification is a real challenge in proteomics, and several approaches, including incorporation of stable isotopes, chemical derivatization, and label-free strategies have been reported (McAlister et al. 2014). Proteins frequently function in dynamic and labile multiprotein complexes, the function and stability of which depend on the availability of all constituents. Thus, one can look not only for aberrant expression of an isolated protein but also for all constituents of a protein complex. This may add evidence for the characterization of VUS (Kremer et al. 2017; Lake et al. 2017; Stroud et al. 2016). Complexome analysis, specifically developed to yield insight into the size, composition, and stability of protein complexes, is a powerful method to study the impact of VUS on protein complex assembly. Complexome analysis separates native intact proteins and protein complexes, indicating the composition of functional complexes by the identification of co-migrating proteins (Heide and Wittig 2013). Prokisch and colleagues illustrated that over 4500 proteins can be detected in total, around 50% of which appear within protein complexes (Prokisch 2018). Indeed, complexome analysis has proven fruitful in novel disease gene validation (Heide et al. 2012).

Similar to RNA-seq, outliers can be detected in the proteomic data. Strongly reduced protein level in one sample compared to other samples or to controls provides robust evidence for pathogenicity of underlying variants in autosomal recessive traits. Indeed, although proteomics has not singlehandedly uncovered an IMD, it certainly contributes to the diagnostic and validation process. A proteome-wide screen for expression outliers provides valuable information—by inferring the protein-encoding gene(s) in which pathogenic variants may harbour—and paves the way for proteomics, above and beyond functional validation, as a routine test in the diagnostic pipeline (Ferreira et al. 2019; Kremer et al. 2017).

Transcriptomics

The transcriptome is a quantitative snapshot of all (m)RNAs present in a specific cell population, in time, and under specific circumstances, thus reflecting gene expression. The study of the transcriptome by high-throughput methods is known as transcriptomics. RNA sequencing (RNA-seq), the state-of-the-art technique for transcriptomics, starts with the isolation of RNA from the target tissue or cells, after which it is enzymatically copied to complementary DNA (cDNA). The cDNA is sequenced, after which a transcriptome is assembled using bioinformatic tools.

RNA-seq requires the availability of disease-relevant tissue as the source of RNA. Genetic disorders usually show specificity to some tissues, most of which require invasive methods to obtain or cannot be obtained at all. For disorders in which biopsy of the target tissue is unfeasible, analyses are possible through identification of proxy tissues. In a recent study, the use of whole-blood RNA-seq transcriptomics was investigated in 94 individuals with undiagnosed rare disease, comparing data from these individuals with large sets of RNA-seq data from controls. Across this cohort, transcriptomics yielded a 7.5% diagnostic rate and an additional 16.7% with improved candidate gene resolution (Fresard et al. 2019). Another study demonstrated a 10% diagnostic yield, using dermal fibroblasts, taken during mus-

cle biopsy in patients suspected of a mitochondriopathy (Kremer et al. 2017). A study in muscle biopsies in 50 patients with rare muscle disorders showed splice-altering variants in 35% (Cummings et al. 2017). Alternative to the use of blood or tissue biopsies, patient cells can be reprogrammed into induced pluripotent stem cells and differentiated into disease-relevant cells of interest.

RNA-seq reveals gene expression patterns, indicating which cellular processes are active and which are dormant. In genetic disease, the disease gene may show normal expression when mutations in the coding region affect the function of the gene without affecting its expression level. RNA-seq, however, can also expose coding and noncoding variants, aberrant splicing, allelic expression imbalance, post-transcriptional modifications, and gene fusion, all relevant for diagnosing genetic diseases (Gonorazky et al. 2019). Allelic expression imbalance is especially important to detect, as heterozygous pathogenic variants not prioritized after WES or WGS may have a dominant effect in case the unaffected gene is not expressed. Kremer et al. (2018) reviewed how transcriptomics led to a molecular diagnosis in 10–35% of patients in whom whole exome sequencing failed to do so (Kremer et al. 2018). Recent advances in RNA-seq include direct RNA sequencing, single-cell sequencing, and in situ sequencing of fixed tissue.

Metabolomics

Metabolomics is described in Chap. 7.

Lipidomics

Lipids are highly diverse molecules which are traditionally best known for their role in the formation of biological membranes in cellular systems and as a way to store energy. They were traditionally analysed by thin-layer chromatography, gas chromatography, and mass spectrometry. Technical advances in mass spectrometry have paved the way for the realization of a new type of metabolomics: lipidomics. Lipidomics aims to study the pathways and networks of cellular lipids by characterization and quantitation of all lipids present in a biological system. Especially the development of "soft" ionization techniques as electrospray ionization (ESI) and exact mass resolution, high-resolution mass spectrometers have greatly propelled the field of lipidomics. In addition, new bioinformatic tools have been developed to cope with the increasing amounts of raw data and extract relevant information to yield biological insight. The association of lipidomic data with gene expression and sequencing of lipid-specific proteins/enzymes should be furthermore clarified (Zhang et al. 2018).

State-of-the-art lipidomic platforms can annotate about 2000 lipid species in cellular systems, and in plasma about 900 species can be identified (Vaz et al. 2015). The cellular lipidome includes organelle-specific lipids that are not present in extracellular media such as plasma, which is important for the identification and elucidation of organelle-related and other metabolic disorders (Herzog et al. 2018).

Lipidomics is being applied to find biomarkers suitable for diagnosis, follow-up, and ideally prognosis in order to characterize the course of the patient's disorder. Also it can play a central role in the discovery of novel IMDs as underlying cause of phenotypes such as complex hereditary spastic paraplegias ((Vaz et al. 2019), currently under review).

In addition to validating new monogenetic inborn errors of lipid metabolism, there are a growing number of links being uncovered between lipid metabolism and complex genetic traits as obesity, diabetes, atherosclerosis, and cancer (Hyotylainen and Oresic 2014). The corresponding research communities increasingly use lipidomics underscoring the broad application of this technique for research in general.

Glycomics

Glycosylation is considered the most common post-translational modification of proteins. In the biological process of protein glycosylation, many genes are involved. These genes encode not only the enzymes of N- and O-glycosylation steps but also nucleotide sugar transporters, vesicular transport, and dolichol biosynthesis, which influence protein glycosylation. Clinical glycomics is an approach to gain insight into protein glycosylation and includes diverse analytical methodologies for the analysis of protein-bound, protein-derived, or free glycans.

In general, the methods include the enzymatic or chemical cleavage of N- or O-linked glycans from a single purified protein like transferrin or from multiple proteins present in a biological sample. Then, glycans are separated by electrophoresis or chromatography, after which they are detected by mass spectrometry (Van Scherpenzeel et al. 2016). This approach can be quantitative, which is of high relevance as some type II congenital disorders of glycosylation subtypes are associated with specific N-glycan structures, but others only produce changes in relative levels (Barbosa et al. 2019). In addition to the analysis of protein-released glycans, advances in technology allow the analysis of intact glycoproteins, which obviates the need for enzymatic cleavage of N-glycans, is fast and robust, and enables high-throughput analysis (Van Scherpenzeel et al. 2016; Abu Bakar et al. 2018).

As a source of protein, plasma, serum, urine, and cerebrospinal fluid are all suitable. A recent study used mass spectrometry to identify abnormalities of N-linked and O-linked glycans in plasma and free oligosaccharides in the urine of

207 undiagnosed patients. Sixty percent of these patients had a glycome profile that differed from control values in at least one of the body fluids. Whole exome sequencing revealed some patients with CDGs, along with several others having disorders indirectly altering glycosylation. Thus, glycomics not only is of diagnostic relevance to CDGs but also adds to the pathogenic knowledge in a much larger group of IEMs (Davids et al. 2019). Furthermore, glycomics reflects environmental influences on glycosylation, which makes it of interest for application in monitoring therapeutic interventions.

Function First

Even with the application of big data technologies, additional functional work is often required, setting the stage for a functional genomics laboratory (Thompson et al. 2019). Model organisms including flies, yeast, worms, zebrafish, rodents, and other mammals are indispensable for the functional investigation of novel genes and variants as well as for delineation of pathophysiology and treatment strategies (Wangler et al. 2017). To accelerate rare disease discovery, the Rare Disease Model Organisms and Mechanisms was established in 2013 and demonstrates success in the connection between clinicians and model organism researchers for a large number of diseases including IMDs (Wangler et al. 2017; Foley 2015).

Integration: "-omics in Concert"

Diagnosing IMDs should, with some exceptions, not be based on a single approach. Especially when a new inborn error is encountered, the diverse platforms should be combined to generate a solid diagnosis that can form the base for intervention and family counselling.

Phenomics, the thorough description of the patient's phenotype, should always be part of integrated approaches. Furthermore, WES or WGS will give a definite answer to a diagnostic question in case a gene with known function is mutated with a proven pathogenic mutation. In all other cases, additional, functional studies are warranted.

An example of genomics and metabolomics in concert is the discovery of NANS deficiency in patients with intellectual disability, dysmorphisms, and skeletal dysplasia (van Karnebeek et al. 2016). WES in one of the patients, a 3-year-old boy, yielded variants in 19 different genes, whereas untargeted metabolomics performed at the same time led to the discovery of elevated levels of the metabolite *N*-acetylmannosamine, which could only be caused by two enzymatic deficiencies in the de novo sialic acid synthesis pathway. Putting the data sets together facilitated the disease gene (NANS) identification, validation of the deleterious impact of the recessive variants through accumulation of the substrate of the enzyme (*N*-acetylmannosamine), which also serves as a new biomarker with which multiple patients around the world have been subsequently diagnosed. Importantly, knockdown zebrafish recapitulated the human phenotype which was rescued with early sialic acid supplementation, opening up avenues for treatments similar to what is in trial for GNE myopathy, a rare muscle disease resulting from the upstream enzymatic defect (Argov et al. 2016).

The combination of using WES/WGS and transcriptomics and, potentially, proteomics has recently be reviewed (Stenton et al. 2020). Depending on the part of metabolism that is presumably affected, metabolomics, glycomics, and lipidomics may have added value. However, no established strategy is available yet, as these techniques are still evaluated for general diagnostic purposes. Their values, however, have been illustrated by small studies.

Bioinformatic-based integration of technologies is easier said than done. Currently, a combined pipeline for WES and metabolomic data is under construction in some laboratories. This approach prioritizes the genes with potential disease-causing mutations based on alterations in the metabolome of the patient. In cases of inborn errors, this will improve the interpretation of WES and will elucidate defects that may be missed by prediction software.

Clinical caution in the -omics era: Ultimately, the optimal approach to an undiagnosed patient with a suspected IMD remains embedded in clinical expertise and laboratory tests available in a given jurisdiction; however, we expect these broad assessment technologies will merge in the future as a single test for a patient with a suspected IMD. At the same time, proper interpretation of these big data will require functional assays, and the clinician must be cautious in assigning etiologic diagnoses based on -omics findings alone. Also, blended phenotypes caused by two distinct genetic conditions are more frequent than previously assumed (Posey et al. 2017) and should motivate us to perform a complete analysis yielding an explanation for the full phenotype observed.

The combined "omics" technologies will, by elucidating new disease-causing genes, allow the identification of novel points of therapeutic intervention, like splice variants amenable to antisense oligonucleotide treatment. Antisense oligonucleotides are single strands of nucleic acid, 20–25 bases in length, that can bind to a specific RNA sequence, altering splicing. This approach is currently used in spinal muscular atrophy (SMA) and Duchenne muscular dystrophy (DMD) (Bergsma et al. 2018).

Acknowledgements We are grateful to the patients and families for inspiring us, to our clinical and research colleagues for teaching us and collaborating with us, and finally to Ms E Ferreira (Amsterdam UMC) for her writing support.

Emergency Diagnostic Procedures and Emergency Treatment

Contents

Summary

Metabolic emergencies need to be recognized promptly, and effective treatment needs to be initiated immediately to optimize clinical outcomes. A significant proportion of patients with inborn errors of metabolism are at risk of developing a metabolic emergency at some time of their life, particularly those children affected by an inborn error of metabolism that manifests as an acute intoxication or energy deficiency. These patients usually present as a neonate—typically after an initial symptom-free interval of some days—in an emergency situation. Treatment needs to be initiated immediately even without having arrived at the exact diagnosis.

Introduction

Inborn errors of metabolism, especially those causing acute biochemical intoxication, can present with metabolic emergencies that require prompt recognition and early initiation of appropriate treatment. Many such patients present in the neonatal period, typically after an initial symptom-free interval, although later-onset forms of the conditions can present for the first time at any age including in adulthood. Furthermore, in patients with an established diagnosis and who are on appropriate treatment, acute "decompensation episodes" can occur.

Metabolic crises potentially leading to catabolism can be triggered by infections, vomiting, fasting, or strenuous exercise. Other exogenous triggers include exposure to inappropriate dietary protein in a patient with an aminoacidopathy (AA), organic aciduria (OA), or urea cycle disorder (UCD), exposure to dairy products in patients with galactosemia, or long-chain fat in those with fatty acid oxidation (FAO) disorders. Drugs including valproic acid can result in deterioration in those with mitochondrial disorders.

Although there are numerous metabolic conditions, the acute manifestations share common biochemical and clinical features, and there are a limited number of immediate thera-

peutic measures that are needed. They should be available in any clinical setting (Saudubray 2012; Dionisi-Vici and Ogier de Baulny 2012; Häberle et al. 2019; Baumgartner et al. 2014). Frequent biochemical presentations include hypoglycemia, hyperammonemia, and metabolic acidosis (including lactic acidosis and ketosis). Emergency treatment should proceed in parallel with specific diagnostic tests to correct the abnormal biochemistry even before the underlying diagnosis is known.

The Acutely Unwell Neonate

The differential diagnosis for an acutely unwell neonate will include sepsis, peripartum hypoxic-ischemic encephalopathy (HIE), intraventricular hemorrhage, congenital viral infection, congenital cardiac disease, and inborn errors of metabolism. Thus as part of the initial assessment of a neonate in an emergency situation, information needs to be gathered about the preceding pregnancy, delivery and neonatal resuscitation, family history (including consanguinity and unexplained sibling deaths), feeding history, presence of symptom-free period, and progression of symptoms. Typically, neonates with an inborn error of metabolism will present after an initial "well period" with progressive refusal of feeds, weight loss, hypotonia, and lethargy progressing to coma.

Initial examination and baseline clinical chemistry will identify the key clinical and biochemical features: encephalopathy manifesting as hypotonia, decreased feeding, irritability, seizures, lethargy, or coma, hepatopathy with coagulopathy and increased transaminases/hepatomegaly, cardiac failure, respiratory distress or failure as compensation for metabolic acidosis, and tachypnea due to the respiratory stimulant effect of hyperammonemia.

Neurological deterioration: Toxic encephalopathy is the commonest presentation and most often associated with urea cycle disorders (UCDs); "classical" branched-chain organic acidemias (BCOAs) such as propionic, methylmalonic, or isovaleric acidemia; and maple syrup urine disease (MSUD). Toxicity in UCDs is caused by hyperammonemia and hyperglutaminemia, in BCOAs by metabolic acidosis with/without hyperammonemia, and in MSUD by accumulating leucine and isocaproic acid. Intractable convulsions are associated with amino acid disorders (particularly nonketotic hyperglycinemia (NKH), vitamin B6 deficiency) or purine disorders (adenylosuccinate lyase (ADSL) deficiency or molybdenum cofactor or sulfite oxidase deficiency).

Liver failure: Hepatic manifestation of galactosemia, hereditary fructose intolerance, and tyrosinemia type I usually manifest with some delay in the first weeks of life and are amenable to emergency treatment. Some mitochondrial cytopathies can present with early liver failure, as can neonatal hemochromatosis.

Cardiac failure: In neonates, fatty acid oxidation defects and mitochondrial trifunctional protein deficiency can present with cardiac failure. Pompe disease presents with hypertrophic cardiomyopathy and hypotonia.

Later-Onset Patients

Older children, adolescents, or even adults may encounter any of the abovementioned clinical threats. Any type of coma or acute psychiatric symptom can be the presenting sign of a metabolic disorder. In addition, patients may suffer from recurrent attacks of unexplained dehydration, abdominal pain, muscle pain and rhabdomyolysis, or peripheral neuropathy.

A summary of the most characteristic acute signs and differential diagnoses is listed in Table 11.1.

Emergency Diagnostic Procedures

Basic biochemical tests should be obtained in any acutely unwell neonate or child and will help guide immediate therapeutic decision-making. Basic tests should include full blood count, liver and kidney function tests, electrolytes, blood gas, and calculation of anion gap [$(Na^+ + K^+) - (Cl^- +$ bicarbonate)], lactate, glucose, ammonia, and urine or blood ketones. Creatine kinase (CK) and uric acid should also be tested. These basic laboratory investigations should be available in any hospital offering emergency treatment at any time.

If the basic biochemical tests raise the possibility of a metabolic disorder, second-line metabolic investigations should be obtained, including:

- Acylcarnitine profile (blood spot or plasma)
- Plasma amino acids
- Urine organic acids and orotic acid
- Hypoglycemia screen if low blood glucose (see below)

These results should be available within 24–48 h.

Depending on the differential diagnosis, additional specific tests will be required as directed by discussion with a metabolic expert clinical team.

Emergency Scenarios

The most frequently observed metabolic emergencies present biochemically as hyperammonemia, metabolic acidosis, or hypoglycemia.

Table 11.1 Characteristic acute signs, symptoms, and metabolic differential diagnoses

Sign	Disease
Acute cardiorespiratory signs	
Cardiomyopathy	FAO, carnitine transporter def., OXPHOS, Fabry, GSD III, GSD II, BCOAs, MPS-LYSO, Barth syndrome, TMEM70
Arrhythmia	FAO, Kearns-Sayre, Danon, cardiac glycogenosis, triose phosphate isomerase, D-2-hydroxyglutaric aciduria, thiamine deficiency/dependency
Pulmonary hypertension	MTHFR, OXPHOS, NFU1, LYSO, Cbl-C, TMEM70
Stridor	Biotinidase, PDH, OXPHOS, Gaucher II, Krabbe
Acute neurological signs	
Coma	UCDs, BCOAs, MSUD, multiple carboxylase, GA-1, MADD, OXPHOS, FAO, ketolysis, hyperinsulinism, gluconeogenesis
Seizures	UCDs, BCOAs, hyperinsulinism, NKH, SO-XO def., PEROX, pyridoxine-dependent epilepsy, pyridoxal phosphate-dependent epilepsy, biotinidase def., cerebral folate receptor-alpha, creatine transporter, GAMT, AGAT, holocarboxylase synthetase, Menkes disease/occipital horn syndrome, PGDH, phosphoserine phosphatase, phosphoserine aminotransferase, OXPHOS, LYSO (Gaucher III, NP disease type C, MLD, GM1, GM2), NCL, GABA transaminase, PDH, ADSL, GS, GLUT1, homocystinuria and remethylation disorders, CDGs
Oculogyric crisis	Neurotransmitter disorders, DGUOK def., PUS1, COQ2, KARS
Dystonia	BCOAs and vitamin B12 metabolism disorders, GA-1, MEGDEL, OXHPHOS, Wilson disease, aceruloplasminemia, biotin-responsive basal ganglia disease, neurotransmitter disorders, GAMT, homocystinuria, MHBD, HMG-CoA lyase, HMG-CoA synthetase, LSD, NKH, beta-ketothiolase, Lesch-Nyhan, P5CS deficiency
Stroke-like episode	OXPHOS (MELAS), OTC, CDGs, homocystinuria, BCOAs, MSUD, Fabry, beta-ketothiolase
Ataxia	MSUD, PDH, multiple carboxylase, UCDs, BCOAs and inborn errors of cobalamin metabolism, GLUT1, Hartnup, CoQ10, CTX, LYSO (NP disease type C), NKH, SSADH, thiamine-responsive encephalopathy
Dementia	Aceruloplasminemia, Wilson disease, alpha-mannosidosis, X-ALD, CTX, Gaucher disease type III, MPS I, MPS II, MPS III, NP disease type C, MLD, MHBD, MELAS
Psychiatric signs	UCDs, citrin def., porphyria, MPS VII, MTHFR, Hartnup, creatine transporter, GAMT, homocystinuria, cobalamin and remethylation disorders, metabolism, MSUD (variant), MELAS, MLD, BCOAs, NP disease type C, SSADH, Wilson disease
Sudden visual loss	MELAS, LEBER, MMA, PA, homocystinurias, X-ALD, porphyria, biotinidase def.
Sudden hearing loss	MELAS, biotinidase def.
Pain	Fabry, Gaucher, Krabbe, prolidase deficiency
Acute peripheral neuropathy	PDH, biotinidase, porphyria, MSUD (variant), MLD, tyrosinemia type I, LCHAD/MTP
Basal ganglia lesions	OXPHOS, BCOAs, MSUD, beta-ketothiolase, GA I, MADD, HMG-CoA lyase, HMG-CoA synthetase, MHBD SCOT, biotin-responsive T1 transporter, Wilson disease, aceruloplasminemia, GAMT, sulfite oxidase def., MOCO def.
Hydrocephalus	MPS I, MPS II, MPS VI, Cbl-C, Cbl-D, MTHFR, Gaucher, NKH, mannosidosis
Myoglobinuria	FAO, muscle GSD, OXPHOS, LIPIN1, LIPIN2, porphyria, Wilson disease
Cramps	FAO, muscle GSD
Acute hematological and vascular signs	
Hemolytic anemia	GSH synthetase, gamma-glutamylcysteine synthetase, Wilson disease, Cbl-C
Nonhemolytic anemia	Orotic aciduria, inborn errors of cobalamin metabolism, methionine synthetase, inborn errors of folate metabolism, MK, Pearson syndrome, OXPHOS, BCOAs, thiamine-responsive megaloblastic anemia
Non-macrocytic and hemolytic anemia or anemia due to combined mechanisms	Abetalipoproteinemia, adenylate kinase, adenosine triphosphatase carnitine uptake, porphyria, di-metal transporter 1, porphyria, galactosemia, glycolytic and pentose-phosphate enzyme, hemochromatosis, IRIDA, LCAT, MK, mitochondrial tyrosyl-tRNA synthetase, MLASA syndrome, pyroglutamic aciduria, pyrimidine 5-nucleotidase, red blood cell glycolysis defects, TALDO, Wilson disease, Wolman disease, X-linked sideroblastic anemia, pyridoxine-responsive epilepsy
Neutropenia	GSD1b, Barth syndrome, CLPB, BCOAs
Thrombocytopenia	BCOAs, CDGs
Pancytopenia	Pearson syndrome, BCOAs, Gaucher types I and III, NP types A and B, OXPHOS, adenylate kinase 2, TALDO
Macrophage activation syndrome, HLH	LPI, Cbl-C, Wolman disease, Gaucher disease, NP disease
Coagulopathy	CDGs, HHH
Subdural hematoma	HHH, GA-I, Menkes disease
Thromboembolism	CDGs, homocystinurias
Acute liver and digestive signs	
Fetal hydrops	LYSO (GM1 gangliosidosis; sialidosis type II; I-cell disease; Niemann-Pick type A/C; MPS I, IV, VI, VII; galactosialidosis; mannosidosis; Farber; Austin; Wolman), TALDO, CDGs, mevalonic aciduria, Smith-Lemli-Opitz, PEROX

(continued)

Table 11.1 (continued)

Sign	Disease
Acute liver failure	Tyrosinemia type I, UCDs, citrin def., OXPHOS, CDGs, HFI, FAOD, galactosemia, TALDO, HHH, Wilson disease, neonatal hemochromatosis, Wolman disease, NBAS, SCYL1, RINT2
Cholestatic jaundice	Arginase, bile acid synthesis, CDGs, CTX, cholesterol synthesis defects, citrin, galactosemia, LCHAD/MTP, MK, Niemann-Pick type A/C, Gaucher, PEROX, TALDO, tyrosinemia type I, ADK, ARC syndrome
Pancreatitis	FAOD, BCOAs, GSD1, CBS, OXPHOS (MELAS), Pearson syndrome, LPL
Intestinal pseudo-obstruction	MNGIE, MK def., MELAS, NARS2 def.
Recurrent vomiting	UCDs, OAs, HFI, LPI
Acute endocrinological signs	
Adrenal insufficiency	SLO, ALD, OXPHOS
Hyperinsulinemic hypoglycemia	HI, HI/HA, SCHAD, CDGs, ADK
Diabetes	Abnormal proinsulin cleavage, diabetes, deafness and TRMA Kir 6.2, glucokinase, MMA, PA, IVA, ketolytic, OXPHOS, Wolfram syndrome, Pearson and Kearns-Sayre syndrome
Acute nephrological signs	
Hemolytic uremic syndrome	Cbl-C, MTHFR
Fanconi syndrome and renal tubular acidosis	Tyrosinemia type I, galactosemia, OXPHOS, cystinosis, HFI, Fanconi-Bickel, Wilson disease, LPI, CPT1, EHHADH, ARC syndrome, HNF4A
Acute renal failure	Oxalosis, FAOD
Nephrotic syndrome	CoQ10, CDGs
Acute dermatological signs	
Skin rash	Biotinidase, MK, holocarboxylase synthetase, Hartnup, porphyria, steroid sulfatase, MEDNIK
Orthostatic cyanosis, petechiae	ETHE1 def.
Abnormal urine and sweat odor	
Sweaty feet odor	IVA, 3-methylcrotonylglycinuria, MADD
Maple syrup odor	MSUD
Musty odor	PKU
Fish odor	Trimethylaminuria, dimethylglycine dehydrogenase
Other	
Febrile episodes	MK
Maternal disease of pregnancy/HELLP	LCHAD/MTP

Supportive Care

There is an extensive group of metabolic disorders with acute life-threatening presentation. Long-term outcome is often poorer in patients with early onset of symptoms and/or where initiation of treatment is delayed.

Many acutely sick patients, especially newborn infants, will require circulatory and ventilatory support. Most of them will need rehydration and correction of mineral and/or electrolyte imbalances (Ca^{2+}, PO_4, Mg^{2+}). Given their importance, such treatment should be started immediately and should not delay the initiation of more specific therapeutic measures. Patients with a metabolic crisis might suffer from infections and septicemia, which can result in catabolism and lead to therapeutic failure. Consequently, infections must be prevented, thoroughly investigated for, and, if present, treated aggressively.

In disorders of the intoxication type, such as OAs, AAs, UCDs, FAOs, galactosemia, or fructose intolerance, the oral intake of toxic precursors must be stopped immediately.

Hyperammonemia

Hyperammonemia should be considered in any unexplained encephalopathy. Hyperammonemia is a major contributor to the pathophysiology of protein catabolism disorders (urea cycle disorders and organic acidurias). Early initiation of treatment is of utmost importance to provide the best possible outcome, since the neurological sequelae depend on the extent and duration of hyperammonemia.

Table 11.2 lists inborn errors of metabolism leading to hyperammonemia, guiding the differential diagnosis.

Table 11.2 Bedside differential diagnosis of hyperammonemia

	Urea cycle enzyme defect	Urea cycle intermediate transporter defects	Organic aciduria	Fatty acid oxidation defect	HIHA	PC	HMG-CoA lyase def.	Carbonic anhydrase Va def.	TMEM70/SERAC	PEPCK

↑ elevated, ↓ decreased, n-↑ normal to elevated, n-↓ normal to decreased, ↑↑ very elevated, (↓) inappropriately low, – no
[a]Only in neonates

Secondary (acquired) disorders can also be associated with hyperammonemia, and these should be considered in the history, examination, and investigations of a child with unexplained hyperammonemia. These include the so-called transient hyperammonemia of the newborn, liver failure from any cause, valproate therapy, and systemic herpes simplex in neonates (Häberle et al. 2019).

Diagnostic Tests

Hyperammonemia in a newborn patient should trigger investigations to exclude or confirm differential diagnosis such as urea cycle disorders, organic acidemias, and fatty acid oxidation disorders, as well as the more common neonatal septicemias, liver failure, and congenital infections. In late-onset cases, hyperammonemia and metabolic decompensation can be triggered by infection, catabolism, excessive protein intake, medication, and other stressing events, both physiological and psychological (Broomfield and Grunewald 2012; Häberle et al. 2019). Therapy must not be delayed and should proceed simultaneously with the diagnostic workup. Specific metabolic investigations required are:

- Ammonia level (urgent confirmatory sample)
- Liver function tests and clotting profile
- Plasma amino acids
- Urinary organic acids (and orotic acid)
- Blood/plasma acylcarnitine profile
- Urinary amino acids (for transporter defects)
- DNA (for confirmation of diagnosis)

Hyperammonemia is an acute toxic event. It is particularly harmful to the brain as hyperammonemia and the associated hyperglutaminemia lead to astrocyte swelling and brain edema, resulting in irreversible brain damage (Albrecht and Norenberg 2006; Rama Rao and Norenberg 2014). The prognosis of any hyperammonemic patient is strongly influenced by the extent and duration of hyperammonemia, and therefore treatment should not be delayed.

Acute Management

Stop Protein Intake and Promote Anabolism

All protein intake (oral feeds and any parenteral nutrition) need to be stopped immediately, and intravenous glucose commenced to stop catabolism (see table). At least 110% of daily energy demand should be provided.

To promote anabolism give:

Age (years)	Weight	Glucose to provide (mg/kg/min)	Glucose 10% (mL/kg/day)
0–2		10	150
2–6		8	120
>6	<30 kg	6	90
>6	30–50	4.5	67
>6	>50	3	45

Hyperglycemia may occur, but glucose infusion should not be reduced. Insulin infusion following local protocols should be given if necessary.

Nitrogen Alternative Pathway Therapy

Nitrogen scavenger therapies provide an alternative pathway to the urea cycle for the removal of nitrogen and hence lower ammonia. It is useful to start with a combination of different drugs. The use of these ammonia scavengers represents the

mainstay of therapy for detoxification of ammonia in UCDs (Feillet and Leonard 1998; Batshaw et al. 2001; Summar 2001; Häberle et al. 2019). Their use is still debated in BCOAs because of the potential risk of increasing intramitochondrial accumulation of CoA esters and of further depleting free CoA pools (Griffith et al. 1989; Baumgartner et al. 2014). However, sodium benzoate has been reported to be safe (Walter et al. 1995), and most metabolic centers regularly use this drug in organic acidurias. The use of sodium phenylbutyrate in organic acidurias raises further concern because in these diseases hyperammonemia is usually associated with decreased levels of glutamine, with a risk of further depletion of the glutamine/glutamate pool (Filipowicz et al. 2006; Baumgartner et al. 2014).

Recently published UCD guidelines (Häberle et al. 2019) suggest an IV equimolar solution of sodium benzoate and sodium phenylacetate can be used: 250 mg/kg as intravenous bolus over 90–120 min and then 250 mg/kg as continuous IV infusion over 24 h. The combination of sodium benzoate and sodium phenylacetate is available as a drug, registered by the FDA (available in the EU on named patient basis), and can be used as an adjunctive therapy for the treatment of acute hyperammonemia and associated encephalopathy in patients with UCDs.

Benzoate is conjugated with glycine to form hippurate, which is then rapidly excreted into the urine. Approximately 1 mole of nitrogen (=ammonia) is then lost for each mole of benzoate administered.

An intravenous loading dose (if the child is not on the drug already) of 250 mg/kg can be administered over 90–120 min followed by 250 mg/kg/day as a continuous infusion. The infusion may be increased to 500 mg/kg/day if required. Subsequent oral dosing is given in 4–6 divided doses.

If patient's weight is >20 kg, the suggested dose for benzoate is 5.5 g/m^2/day (up to 12 g/day).

Phenylbutyrate is first oxidized to phenylacetate and then conjugated with glutamine to form phenylacetylglutamine. This is excreted into the urine, and theoretically 2 moles of nitrogen are removed for each mole of phenylbutyrate given. An intravenous loading dose (if the child is not on the drug already) of 250 mg/kg can be administered over 90 min followed by 250 mg/kg/day as a continuous infusion. The infusion may be increased to 500 mg/kg/day if required. Subsequent oral dosing is given in 4–6 divided doses. If patient's weight is >20 kg, the suggested dose for phenylbutyrate is 5.5 g/m^2/day (up to 12 g/day).

If the patient is undergoing extracorporeal detoxification, maintenance dose for sodium benzoate and phenylbutyrate/phenylacetate should be adjusted.

Other Drugs

L-*arginine* is normally synthesized in the urea cycle, but in urea cycle, disorders may become a semi-essential amino acid, especially in ornithine transcarbamylase (OTC) and carbamoyl phosphate synthetase (CPS) deficiency. In citrullinemia and argininosuccinic aciduria, the arginine additionally replaces ornithine that is not reformed in the cycle and thereby facilitates the removal of ammonia in the form of citrulline or ASA.

An intravenous loading dose (if the child is not on the drug already) of 250–400 mg/kg can be administered over 90–120 min followed by 250 mg/kg/day as a continuous infusion. Suggested maximal dose for arginine is 12 g/day. Subsequent oral dosing is given in 4–6 divided doses. Arginine is to be avoided in patients known to have arginase deficiency.

N-carbamylglutamate is an alternative activator of carbamoyl phosphate synthetase, the first enzyme in the urea cycle. *N*-carbamylglutamate can be used to treat *N*-acetylglutamate synthetase deficiency or CPS deficiency. It has been shown to be helpful as an adjunctive medication in the treatment of hyperammonemic crises secondary to organic acidemias (Daniotti et al. 2001). A loading dose (100 mg/kg, enteral route), followed by 25–62.5 mg/kg every 6 h can be considered in a neonate with unexplained hyperammonemia or in known patient with NAGS deficiency (Häberle et al. 2019).

l-*carnitine*: (See below for details.) In a child with unexplained hyperammonemia, L-carnitine may be given as an organic aciduria may be the cause. An intravenous loading dose (if the child is not on the drug already) of 100 mg/kg can be administered over 90 min followed by 100 mg/kg/day as a continuous infusion. The infusion may be increased to 300 mg/kg/day if required. Subsequent oral dosing is given in 3–4 divided doses. Carnitine should *not* be given if there is evidence of a cardiomyopathy and any cardiac arrhythmia or if a long-chain fatty acid oxidation disorder is suspected.

L-Arginine, sodium benzoate, and sodium phenylbutyrate should be made up separately in 10% glucose in 50 mL syringes or 500 mL bags (maximum concentration 2.5 g in 50 mL or 25 g in 500 mL bag) and given by a syringe pump or by an infusion pump. They can be infused via Y-connectors into a single venous line running with the 10% glucose infusion as close to the entry site as possible.

Extracorporeal Detoxification

In neonates and children, the response to emergency pharmacological treatment should be evaluated after 4 h; if considered inadequate, extracorporeal detoxification should be started (Häberle et al. 2019). Even patients receiving efficient extracorporeal detoxification may still have a poor cog-

nitive prognosis (Kido et al. 2012; Hediger et al. 2018). As a prompt start of acute management is crucial to improve outcome in UCDs, recent publications suggest that dialysis should be initiated as early as possible (Hediger et al. 2018) and that patients with a peak ammonia level >180 μmol/L at the onset should be immediately considered hemodialysis to improve prognosis (Kido et al. 2012).

Of the available techniques, continuous venovenous hemodiafiltration (CVVHDF) and hemodialysis (HD) are far more efficient than peritoneal dialysis (PD) (Picca et al. 2001). PD should therefore only be used if no other form of dialysis is feasible and the patient cannot be rapidly transferred (Picca et al. 2001, 2015). Since the modality of dialysis is dependent on the local facilities, a rapid referral of patients to centers with expert metabolic clinicians and full dialysis facilities is the main determinant for the success of treatment.

Monitoring

Ammonia levels should be monitored every 3–4 h. Electrolyte should be added to IV fluids as needed, and electrolyte supplementation needs monitoring, taking into account sodium is already given (sodium benzoate (7 mmol sodium per 1 g) or sodium phenylbutyrate (5.4 mmol sodium per 1 g)).

Subsequently the aim is to restart protein by no later than 24–48 h, and monitoring of ammonia should be performed every 12 h. Reintroducing feeds might necessitate a nasogastric or other enteral feeding tube.

Metabolic Acidosis

Metabolic acidosis (low blood pH, low bicarbonate, base deficit) may be due to either loss of bicarbonate (renal or gastrointestinal losses) causing a normal anion gap acidosis or accumulation of acids such as keto acids (3-hydroxybutyrate and acetoacetate), lactic acid, or other organic acids resulting in an increased anion gap metabolic acidosis. Lactic acidemia (lactate >4 mmol/L) is seen in organic aciduria, gluconeogenesis disorders, or disorders of the oxidative phosphorylation (OXPHOS) system.

Table 11.3 provides a list of inborn errors of metabolism leading to metabolic acidosis. Lactic acidosis is also seen in any acutely unwell infant or child especially where there is circulatory insufficiency, ischemia, bleeding or shock, sepsis, or cardiac disease.

Diagnostic Tests

The tests described above (Sect. 11.2) will identify the patient with metabolic acidosis and determine the anion gap. Further specific metabolic tests will aid in the differential diagnosis.

Acute Management

Attention should be paid to identifying and treating secondary causes of acidosis, including circulatory insufficiency and sepsis. These factors should be assessed also in patients with a known diagnosis of an inborn error of metabolism as they may precipitate or worsen the metabolic acidosis.

Table 11.3 Metabolic acidosis

Disease	Organic acidurias	MSUD	GSDs (Ia–Ib) GSD III	Ketolysis defects	OXPHOS defects	PC def.	PDH def.	FAO defects	Ketotic hypoglycemia	Fructose 1,6 bisphosphatase deficiency	Multiple carboxylase deficiencies

↑ elevated, ↓ decreased, n-↑ normal to elevated, n-↓ normal to decreased, ↑↑ very elevated, (↓) inappropriately low, + yes, – no

Fluid Resuscitation

If the child is clinically shocked with poor perfusion, *give normal saline (0.9% sodium chloride) 20 mL/kg* immediately, and repeat the saline bolus if poor circulation persists as for a shocked non-metabolic patient.

Give glucose 200 mg/kg at once (2 mL/kg of 10% glucose or 1 mL/kg of 20% glucose) over a few minutes. This promotes anabolism and stops catabolism.

Continue with i.v. infusion of glucose 10%/sodium chloride 0.45% at full maintenance rates (if this is not immediately available, continue with normal saline or 5% dextrose/saline fluids until it is ready).

If there is a strong suspicion of an underlying mitochondriopathy resulting in disturbed energy supply, correcting the metabolic acidosis is the major goal; glucose supply may need to be reduced to maintenance 5% dextrose to restrict the lactic acidosis.

Acid-Base Correction Therapy

If acidosis is not improved after correction of circulatory status, treatment with sodium bicarbonate will be required. Prolonged acidosis will impair cellular function and adversely affect cardiac contractility.

Give sodium bicarbonate 8.4% as half correction (calculated as [0.15 × weight × base deficit (mmol/L)]) over 20–30 min diluted with i.v. fluids. One milliliter of sodium bicarbonate 8.4% contains 1 mmol of sodium bicarbonate and must be diluted with *at least* 5 mL of 5% glucose for peripheral infusion. Repeat blood gases 30 min after the first dose. Consider continuous bicarbonate infusion if the bicarbonate requirement remains high.

If significant hypernatremia occurs, trometamol (THAM, tris(hydroxymethyl)aminomethane) may be considered as an alternative base therapy.

Other electrolyte imbalances, in particular hypokalemia and hypocalcaemia, must also be concurrently corrected as there is a risk of cardiac arrhythmia as the acidosis is corrected.

Promote Anabolism

See above.

Other Drugs

Carnitine: In organic acidurias, such as PA and MMA, the intramitochondrial accumulation of CoA esters results in the inhibition of various pathways of intermediary metabolism, as well as in depletion of free CoA and in increased levels of acylcarnitines (particularly propionylcarnitine) resulting in a depletion of the carnitine pool. Carnitine is therefore given to compensate for secondary carnitine deficiency caused by urinary excretion of carnitine-bound organic acids. As a rule, L-carnitine supplementation is never contraindicated in these disorders (Baumgartner et al. 2014). Only if a long-chain fatty acid oxidation defect is suspected, the administration of carnitine should be avoided, at least as a bolus, because of the acute accumulation of toxic long-chain acylcarnitines and the potential risk of a fatal cardiac arrhythmia (Bonnet et al. 1999).

Vitamin therapy: Patients with isolated methylmalonic acidemia might respond to vitamin B12 treatment. Pharmacological doses of specific vitamins should be systematically tested in each case. Vitamin responsiveness is more likely in late-onset forms than in patients presenting in the newborn period:

- Hydroxocobalamin, the cofactor of methylmalonyl-CoA mutase (and of methionine synthetase), should be tried in all suspected cases; the recommended dose is 1 mg/day given parenterally (Deodato et al. 2006; Baumgartner et al. 2014). Cyanocobalamin is less efficient but may be used temporarily until hydroxocobalamin is available.
- Biotin is the treatment of choice in both holocarboxylase synthetase and biotinidase deficiency, while there are doubts whether biotin-responsive forms of PA really exist; the recommended dose is 10 mg/day given either orally or i.v. (Grünewald et al. 2004).
- Some patients with lactic acidosis due to primary or secondary thiamine deficiency may benefit from thiamine administration (Mayatepek and Schulze 1999; Pérez-Dueñas et al. 2013).
- Riboflavin is the vitamin of choice for treating new patients with MADD, as well as patients with the riboflavin transporter defect, who may have acute paralysis of the diaphragm necessitating ventilation (Bosch et al. 2012).

Hypoglycemia

Hypoglycemia is a common biochemical disturbance seen in children who are unwell and is also frequently seen in neonates. Specific disorders that shorten fasting tolerance include disorders of glucose homeostasis (glycogen storage disorders, disorders of gluconeogenesis, galactosemia, and congenital hyperinsulinism), disorders of inappropriate ketone synthesis (fatty acid oxidation disorders (FAO)), or inappropriate ketone utilization (ketolysis defects). In disorders of FAOD and hyperinsulinism, hypoglycemia will be combined with decreased ketone body production ("hypoketotic hypoglycemia"). Affected patients become symptomatic with hypoglycemia, particularly after prolonged fasting. Hypoglycemia can also be observed in disorders of amino acid metabolism (MSUD, tyrosinemia type 1). Glucose administration needs to meet at least the rate of hepatic glucose production.

Table 11.4 Hypoglycemia

Disease	GSD 1	GSD 3	HFI	F 1,6 DP	GALT	HI-HA	HI	Adrenal insuff.	FAO defects	HMG lyase	KH	OHPHOS	HTy1	MSUD
Lactate	↑	n-↑		↑					n-↑	n-↑		↑↑		n-↑

Post-meal hypoglycemia			+ fructose		+ galactose	+ protein								

↑ elevated, ↓ decreased, n-↑ normal to elevated, n-↓ normal to decreased, (↓) inappropriately low, + yes, – no

Table 11.4 provides a list of inborn errors of metabolism leading to hypoglycemia.

The definition of hypoglycemia is debated, but in general a blood glucose <2.6 mmol/L (46.8 mg/dL) is considered abnormal. Neonates may tolerate lower blood glucose asymptomatically, and a neonate who is otherwise well and in whom hypoglycemia resolves promptly with feeding may not need detailed investigation. Conversely the neonate with resistant hypoglycemia requiring high glucose infusion rates may have congenital hyperinsulinism.

Diagnostic Samples

Diagnostic samples should be collected (when clinically safe) before correction of the hypoglycemia. Critical samples include:

- Glucose and lactate
- Blood gas
- Free fatty acids (nonesterified fatty acids)
- 3-hydroxybutyrate
- Bloodspot acylcarnitine profile
- Insulin and C-peptide
- Cortisol

Urine for ketones (bedside test) and urine organic acids (the first urine passed after the hypoglycemic episode should be collected for this, but correction of hypoglycemia should not be delayed waiting for the urine sample).

Additional samples for urate, creatine kinase, liver function tests, and plasma amino acids should also be collected but do not have necessarily to be during the hypoglycemia.

Hypoglycemia: Emergency Treatment

Hypoglycemia should be corrected. Oral/buccal glucose gel can be administered. Intravenous glucose can be given as 2 mL/kg 10% dextrose bolus. This should be followed with an infusion of 10% dextrose-containing fluids (there may be rebound hyperinsulinism and secondary hypoglycemia after the bolus).

In a child with a suspected IEM, promote anabolism (see above). Supplement sodium, potassium, and phosphate as required.

Blood glucose should be monitored and glucose infusion rate escalated to maintain normoglycemia. This may necessitate the use of higher concentrations of dextrose infusion which may require central venous access. Glucose infusion requirements of >10 mg/kg/min are suggestive of hyperinsulinism.

Seizures

If intractable seizures dominate the clinical picture, pyridoxine (B6)-responsive, pyridoxal phosphate-responsive, and folinic acid-responsive seizures and congenital hypophos-

phatasia should be considered (Mills et al. 2005; Stockler et al. 2011; Rahman et al. 2013). In the case of a positive response, the therapeutic trials might be diagnostic. Many intracellular enzymes require pyridoxal phosphate as a cofactor.

Low uric acid in a neonate with intractable seizures should raise the suspicion of molybdenum cofactor or multiple sulfite oxidase deficiency. In urine, sulfocysteine and elevated levels of AASA are measured.

Metabolic investigations should be undertaken simultaneously in parallel with therapeutic interventions. Initial seizure management should follow standard protocols. Severe infantile epileptic encephalopathy is one indication for CSF analyses testing neurotransmitter and glycine CSF/plasma ratio, allowing the diagnosis of defects in the metabolism of biogenic amines and GABA transaminase deficiency and nonketotic hyperglycinemia (Hoffmann et al. 1998; Ng et al. 2015; Coughlin 2nd and Swanson 2017).

Pyridoxine

Pyridoxine is administered i.v. Start with a single dose of 100 mg of pyridoxine, and if the patient is nonresponsive within 10 min, the dose should be increased and repeated up to 200 mg total before concluding about pyridoxine nonresponsiveness. High doses of pyridoxine can cause severe apnea so it is recommended to be administered in an ICU setting (Bass et al. 1996; Grillo et al. 2001). If there is uncertainty about at least a partial response, pyridoxine should be continued with 5–15 mg/kg/day (up to 30 mg/kg/day) for 7 days before final conclusions are made. Patients with mutations in antiquitin (*ALDH7A1*) encoding aminoadipic acid semialdehyde dehydrogenase accumulate piperideine-6-carboxylate which inactivates pyridoxal phosphate. They have elevated urine aminoadipic semialdehyde and elevated pipecolic acid in blood, CSF, and urine. If antiquitin deficiency is confirmed, dietary lysine restriction combined with arginine supplementation should be considered (Coughlin et al. 2015).

Pyridoxal Phosphate

Pyridoxal phosphate 30 mg/kg/day in 3 doses orally for 3 days can be tried and is effective for patients with pyridoxamine 5′-phosphate oxidase (*PNPO*) deficiency. These patients cannot convert pyridoxine or pyridoxamine to pyridoxal phosphate and so develop intracellular pyridoxal phosphate deficiency treatable only with pyridoxal phosphate.

Patients with congenital hypophosphatasia (*TNSALP*) with characteristic biochemical abnormalities including low alkaline phosphatase and phosphate and high calcium respond to either pyridoxine or pyridoxal phosphate.

Folinic Acid

If the response to pyridoxine is negative or doubtful, folinic acid can be administered with 5 mg/kg/day in 3 doses intravenously or orally for 3 days. Primary cerebral folate deficiency results from defects of the blood-brain barrier folate transporter systems and inborn errors of folate metabolism. Secondary cerebral folate deficiency is frequently observed in other IEMs including mitochondrial cytopathies (Pope et al. 2019).

Postmortem Investigations

In the event of death when metabolic disease is suspected, it is important to store adequate amounts of biological fluids and tissues for further diagnostic workup. In the case of sudden infant death syndrome (SIDS), it is important to recognize that defects of fatty acid β-oxidation may be responsible. In most cases, autopsy reveals an excess of fat droplets in the liver or heart, even in the absence of steatosis.

Should there be the suspicion of an underlying metabolic disease in a deceased child, it is critical to collect the following samples (Marín-Valencia et al. 2010):

Sample/storage
Urine (−20°)
Amino acids, organic acids, tubulopathy markers
Blood (−20°)
DNA, uric acid, amino acids
Dried blood spots (room temperature)
Acylcarnitine profile
CSF sample (−70°)
Neurotransmitters, amino acids
Skin biopsy (fibroblasts, culture medium at room temperature)
Enzyme analysis, DNA

Liver or muscle biopsies need to be considered in special circumstances, for example, if there is the suspicion of an underlying mitochondrial disorder. Those samples (and this also applies for plasma amino acid samples) must be taken as soon as possible postmortem to ensure reliable results. The samples need to be stored at −70 °C immediately.

Nosology of Inborn Errors of Metabolism

12

Carlos R. Ferreira

Contents

Abstract

Inborn errors of metabolism (IEMs) have existed since prehistoric times. As an example, a mummy named Harwa, dating from approximately 1,500 B.C. and currently exhibited at the Field Museum of Natural History in Chicago, was found to have arthropathy, black articular surfaces, and accumulation of homogentisic acid, consistent with alkaptonuria. Alkaptonuria also became the first condition identified as a metabolic disease, in 1902. This chapter briefly traces the historical development of classification systems for IEMs, starting with Garrod's tetrad in 1908, and culminating with the establishment of the International Classification of Inherited Metabolic Disorders (ICIMD), a global effort to unify classification systems of metabolic disease, in 2021.

Inborn errors of metabolism (IEMs) have existed since prehistoric times. As an example, a mummy named Harwa, dating from approximately 1500 B.C. and currently exhibited at the Field Museum of Natural History in Chicago, was found to have arthropathy, black articular surfaces, and accumulation of homogentisic acid, consistent with alkaptonuria (Stenn et al. 1977). Alkaptonuria also represents the first human disease to which Mendel's concepts of heredity were applied and the first condition identified as a metabolic disease (Garrod 1902). In the words of Sir Archibald Garrod in his classic 1902 paper, alkaptonuria "is rather of the nature of an alternative course of metabolism"; he went on to write that this view of alkaptonuria as "an alternative mode of metabolism will obviously gain considerably in weight if it can be shown that it is not an isolated example of a chemical abnormality, but that there are other conditions which may reasonably be placed in the same category." Indeed, by the time of his seminal Croonian Lectures delivered to the Royal College of Physicians in 1908, he had identified four conditions (alkaptonuria, albinism, cystinuria, and pentosuria, now known as Garrod's tetrad) that were explained by this alternative mode of metabolism (Garrod 1908a, b, c, d). He coined the term "inborn errors of metabolism" to describe this altered metabolic course; his Croonian lectures were in fact collected as a book in 1909 under the title *Inborn Errors of Metabolism* (Garrod 1909). By the time the second edition of his book appeared in 1923, he included two additional IEMs, congenital porphyrinuria and congenital steatorrhea (Garrod 1923), for a total of six IEMs (or what could be named "Garrod's hexad").

Various IEMs were described over the next several decades, but it wasn't perhaps until the appearance of the first edition of *The Metabolic Basis of Inherited Disease* in 1960 that a formal classification of IEMs was attempted. In that book, the following classifications were outlined (Stanbury et al. 1960):

- Disorders of carbohydrate metabolism: diabetes mellitus, glycogen deposition diseases, pentosuria, galactosemia, fructosuria, and hyperbilirubinemia
- Disorders of amino acid metabolism: familial goiter, alkaptonuria, phenylketonuria, albinism, tyrosinosis, primary hyperoxaluria and oxalosis, and maple syrup urine disease

https://doi.org/10.1007/978-3-030-67727-5_12

- Disorders of lipid metabolism: essential familial hyperlipidemia, Niemann-Pick disease, Tay-Sachs disease, and Gaucher disease
- Disorders of steroid metabolism: the adrenogenital syndrome
- Diseases of purine and pyrimidine metabolism: gout, orotic aciduria, xanthinuria, and beta-aminoisobutyric aciduria
- Disorders of metal metabolism: Wilson disease, hemochromatosis, periodic paralysis, adynamia episodica hereditaria, and pseudohypoparathyroidism
- Disorders of porphyrin metabolism: the porphyrias
- Disorders blood and blood-forming tissues: hereditary spherocytosis, hemoglobinopathies and thalassemia, drug-induced hemolytic anemia (primaquine sensitivity), hereditary methemoglobinemias, and disorders of blood-clotting factors
- Disorders of renal tubular transport: familial hypophosphatemia and vitamin D-resistant rickets, Fanconi syndrome, renal glycosuria, glycinuria, renal tubular acidosis, vasopressin-resistant diabetes insipidus, and Hartnup disease
- Disorders of plasma enzymes or proteins: hypophosphatasia, acatalasia, and hereditary hypoproteinemias

Other classification systems were developed over the next following decades, including one dividing IEMs into four main groups according to mechanism of disease: disorders of transport; disorders of storage, scavenge, and secretion; disorders of synthesis; and disorders of intermediary metabolism (Sinclair 1982). A clinical classification of IEMs has also been established, dividing them into two large categories: category 1, including disorders involving only one system, presenting uniform symptoms (such as a bleeding tendency in coagulation factor defects or hemolytic anemia in defects of glycolysis), and category 2, including diseases with systemic consequences, which in turn can be subdivided into three groups—(1) disorders of complex molecules, such as lysosomal disorders, peroxisomal disorders, or congenital disorders of glycosylation; (2) intoxication disorders, such as urea cycle defects, organic acidemias, or aminoacidopathies; and (3) energy deficiency disorders, such as disorders of gluconeogenesis, glycogen storage disorders, and fatty acid oxidation defects (Saudubray and Charpentier 2014).

One of the most comprehensive attempts at a classification of IEMs was established by the Society for the Study of Inborn Errors of Metabolism (SSIEM) and is accessible via their website (http://www.ssiem.org/resources/IEC.asp). This hierarchical classification was last updated in 2012 and appeared in print in 2014 in the prior edition of this book (Zschocke 2014). It includes 487 IEMs in 86 disease groups and classifies IEMs according to the specific biochemical pathway involved.

A recently proposed nosology was published in March 2018, including 1015 well-established IEMs in 130 groups (Ferreira et al. 2019). Additionally, it included 111 IEMs described as provisional, either because their molecular basis had not been elucidated, because only a few patients had been described in decades-old reports, or because only individual families had been reported. There is a precedent for including such provisional disorders in a classification system; for example, by the time of the publication of the first edition of *The Metabolic Basis of Inherited Disease*, orotic aciduria and tyrosinosis had only been described in one patient each but were considered plausible IEMs (Stanbury et al. 1960). Just as these two conditions were eventually found to represent bona fide IEMs, it is very likely that the majority of IEMs currently considered provisional will be well-established in the future.

The current book will follow the classification system established in the aforementioned nosology. An overview of the 9 categories and 130 groups represented in the nosology is outlined in Table 12.1.

Table 12.1 Overview of the nosology of IEMs

(A)	**Disorders of nitrogen-containing compounds**
1.	Disorders of pyrimidine metabolism
2.	Disorders of purine metabolism
3.	Disorders of nucleotide metabolism
4.	Disorders of creatine metabolism
5.	Disorders of choline metabolism
6.	Disorders of glutathione metabolism
7.	Disorders of ammonia detoxification
8.	Disorders of amino acid transport
9.	Aminoacylase deficiencies
10.	Disorders of monoamine metabolism
11.	Disorders of phenylalanine and tetrahydrobiopterin metabolism
12.	Disorders of tyrosine metabolism
13.	Disorders of sulfur amino acid and sulfide metabolism
14.	Disorders of branched-chain amino acid metabolism
15.	Disorders of lysine metabolism
16.	Disorders of proline and ornithine metabolism
17.	Disorders of β- and γ-amino acids
18.	Disorders of histidine metabolism
19.	Disorders of tryptophan metabolism
20.	Disorders of glutamate metabolism
21.	Disorder of glutamine metabolism
22.	Disorder of asparagine metabolism
23.	Disorders of serine metabolism
24.	Disorders of glycine metabolism
(B)	**Disorders of vitamins, cofactors, metals, and minerals**
25.	Disorders of lipoic acid and iron-sulfur metabolism
26.	Disorders of cobalamin metabolism
27.	Disorders of folate metabolism
28.	Disorders of biotin metabolism
29.	Disorders of thiamine metabolism
30.	Disorders of riboflavin metabolism
31.	Disorders of niacin and NAD metabolism
32.	Disorders of pantothenate metabolism
33.	Disorders of pyridoxine metabolism

Table 12.1 (continued)

34.	Disorder of vitamin C metabolism
35.	Disorders of vitamin A metabolism
36.	Disorders of vitamin D metabolism
37.	Disorder of vitamin E metabolism
38.	Disorders of vitamin K metabolism
39.	Disorders of molybdenum metabolism
40.	Disorders of copper metabolism
41.	Disorders of iron metabolism
42.	Disorders of manganese metabolism
43.	Disorders of zinc metabolism
44.	Disorders of selenium metabolism
45.	Disorders of magnesium metabolism
(C)	**Disorders of carbohydrates**
46.	Disorders of carbohydrate transport and absorption
47.	Disorders of galactose metabolism
48.	Disorders of fructose metabolism
49.	Disorders of the pentose phosphate pathway and polyol metabolism
50.	Disorders of insulin secretion and signaling
51.	Glycogen storage diseases
52.	Disorders of gluconeogenesis
53.	Disorders of glycolysis

The nosology of IEMs is regularly updated via IEMbase, a knowledgebase of IEMs (www.iembase.org/nosology) (Lee et al. 2018). In 14 months since the publication of this nosology, there have been 74 novel IEMs added, plus 30 new provisional IEMs (Fig. 12.1). Table 12.2 summarizes the current number of IEMs according to category, while Table 12.3 summarizes the inheritance pattern of well-established IEMs.

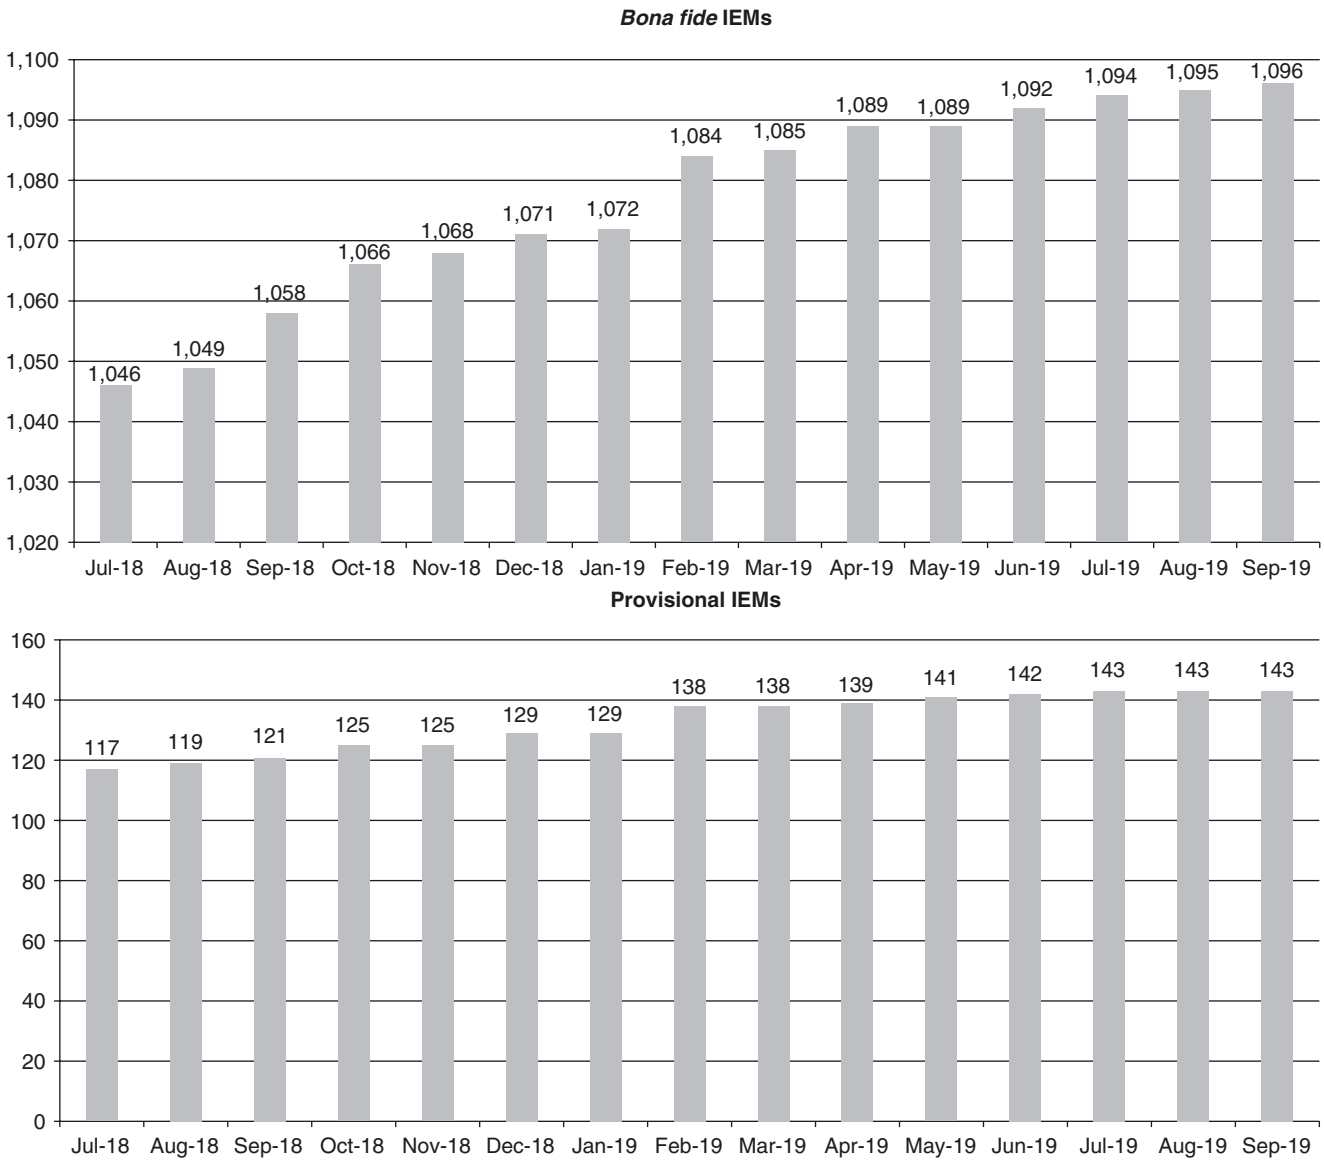

Fig. 12.1 IEMs added since inception of the nosology

Table 12.2 IEMs by the number

Final total	**1096**	**143**	**1239**

Table 12.3 Inheritance of bona fide IEMs

Inheritance	Count
Autosomal dominant	184
Autosomal recessive	878
X-linked	57
Digenic	2
Mitochondrial	37
Somatic	3

A simplification of the nosology of IEMs has been proposed since the time of its publication, with the explicit purpose of making it more useful from a clinical diagnostic perspective. This simplified classification divides IEMs as follows: (1) disorders of small molecules (accumulation and deficiency), (2) disorders of complex molecules (accumulation, deficiency, and cell processing/trafficking defects), and (3) energy defects (membrane carriers, cytoplasmic energy defects, and mitochondrial defects) (Saudubray et al. 2019).

Finally, given the presence of more than one classification approach currently in place, a unified approach was being actively developed at the time of writing of this book by a group of several experts in their respective IEM groups. This unified system was named the "International Classification of Inherited Metabolic Diseases" (ICIMD) and sought the ratification of the different metabolic societies worldwide prior to its implementation. At the time of publication in January 2021, the ICIMD included 1450 IEMs (Ferreira et al. 2021). As with the prior nosology of IEMs, the ICIMD will be continuously updated via IEMbase and a dedicated website (www.icimd.org). Thus, the classification of IEMs has been dynamic since its origins and represents an area of active development that will benefit from regular curation and updates via electronic databases.

Disorders of Nitrogen-Containing Compounds

Purine and Pyrimidine Disorders

13

Jörgen Bierau and Ivan Šebesta

Contents

Summary

Genetic defects of purine and pyrimidine metabolism represent a diverse group of disorders with serious or life-threatening symptoms. Compared to other groups of disorders, the identification of these disorders had a late and slow start. Xanthinuria was the first genetic metabolic purine disorder recognised and was described as the cause of renal stones in 1954, and the genetic basis for the Lesch-Nyhan syndrome accompanied by gout in childhood and adolescence with serious neurological impairment was recognised in 1967. The number of enzyme defects identified since then has increased rapidly and now totals 33. Not surprisingly, knowledge at the clinical level has been unable to keep the pace, a problem compounded by the broad spectrum of presentation and genetic heterogeneity. Clinical presentations may involve renal, musculoskeletal, neurological, immunological and haematological systems. Although these disorders are generally paediatric problems, some disorders can manifest themselves in patients at any age from birth to advanced adulthood. These disorders are frequently misdiagnosed, not because the diagnosis is complicated and difficult to establish, but rather because of a lack of awareness, particularly in adults where such defects are increas-

ingly being recognised. Although some conditions are relatively benign, others can have serious consequences. The fact that approximately 50% of the subjects remain asymptomatic in some disorders such as hereditary xanthinuria and hereditary hypouricaemia poses an additional serious problem for effective diagnosis and causes inaccuracy in incidence estimation of these conditions. Currently, there appear to be few laboratories worldwide providing the necessary comprehensive diagnostic services for detailed purine and pyrimidine investigations. Recent advances alert physicians to the broad spectrum of clinical presentation. The proper identification and detection of new cases will not only help a number of (un)fortunate patients but will almost certainly lead to the illumination of the still unknown pathogenesis of these disorders.

Introduction

Purines and pyrimidines are closely related heterocyclic compounds, consisting of a single six-membered ring for pyrimidines or a nine-membered imidazole-pyrimidine for purines. The purine and pyrimidine ring structures are called bases. When the base is covalently bound to a ribose or 2-deoxyribose, the structure is called a nucleoside, and when the ribose moiety is phosphorylated, it is called a nucleotide. As far as our knowledge extends, purines and pyrimidines are present in all living creatures. Not only are they the building blocks of the genetic code in the form of DNA and RNA, they also fulfil numerous roles in biological processes, including energy transport, glycan synthesis and lipid biosynthesis, cofactor biosynthesis, signal transduction and cell cycle progression both in the intracellular and extracellular matrices. Considering this, purine and pyrimidine metabolism can be regarded to be the central connecting hub for many metabolic routes. The regulation and cellular organisation of purine and pyrimidine metabolism are complex and governed, among other factors, by the cell cycle, DNA damage and higher organisational protein structures such as the purinosome and replisome. It is therefore easy to comprehend that the metabolism of these compounds is a complex and tightly regulated interplay of numerous processes and that any disturbance herein may have a wide array of clinical consequences.

The disorders covered in this chapter are the defects in de novo biosynthesis, interconversion, breakdown and salvage (reutilisation) of purine and pyrimidine bases, nucleosides and nucleotides. Disorders of nucleic acid editing and signal transduction are outside the scope of this chapter. Some disorders that are defects of purine and pyrimidine metabolism are covered in other chapters and from a clinical perspective better at their place in that chapter. These disorders include molybdenum cofactor deficiency, adenosine kinase deficiency (ADK) and mitochondrial DNA depletion syndromes caused by deoxyguanosine kinase (DGUOK), ribonucleotide reductase (RRM2B) and thymidine kinase 2 (TK2) deficiencies. More often than not, these disorders have no (or not yet known) biomarkers directly identifying them as defects of purine and pyrimidine metabolism. Other undeniable disorders of purine and pyrimidine metabolism disorders are covered in other chapters as well as in this chapter. These disorders include thymidine phosphorylase deficiency and the pyrimidine degradation defects.

At present, approximately 33 inborn errors of metabolism giving rise to a clinical presentation or which are of pharmacogenetic consequence are known. Since the last revision of this book (Bierau and Sebesta 2014), new defects have been discovered, i.e. CAD deficiency (Koch et al. 2017), dihydroorotate dehydrogenase deficiency (DHODH) (Rainger et al. 2012), adenosine kinase deficiency (Bjursell et al. 2011) and ITPA encephalopathy (Kevelam et al. 2015). Two excellent comprehensive reviews separately covering purine and pyrimidine disorders have been published (Balasubramaniam et al. 2014a, b).

As purines and pyrimidines play many important roles in cell metabolism, the clinical presentation of these disorders is extremely diverse. There are two important conditions for the early and effective diagnosis of these genetic defects: The first one is availability of proper analytical methods (as mentioned in the next paragraph), and the second one is the appropriate identification which is closely related to the awareness of these conditions. There is no fear of misdiagnosis in newborn screening because all patients are investigated. However, in the so called selective screening (for purine and pyrimidine disorders), where the indication is in many cases based on positive family history and suspicious clinical signs, it is still possible that some patients will not be investigated as they are not sent to specialised laboratories because of the lack of awareness. Therefore diagnostic flowcharts will help for proper diagnosis. In general, there is not one presenting clinical sign that irrefutably makes a clinical diagnosis (Simmonds and Van Gennip 2003; van Gennip et al. 2006). However, some conditions have clear clinical signs, and, when present, they are very clear indications for analysis of purines and pyrimidines. Examples hereof are signs such as self-mutilation (Micheli et al. 2011), severe combined immunodeficiency disease, hereditary urolithiasis and juvenile gout particularly in women (Sebesta 2012). Additional clear indications for assessment of purine metabolism are the findings of hyperuricaemia or hypouricaemia in a routine laboratory workup. Our experience shows that purine

metabolic workup is effective in subjects with the so-called 'unexplained hyperuricaemia or hypouricaemia', which means that frequent secondary causes of high or low levels of uric acid in blood were excluded. This selection, made in particular by general practitioners, helps quite a lot for effective diagnosis. The most frequent secondary causes of hyperuricaemia include excessive dietary purine intake, decreased renal function and myeloproliferative diseases. It is important to emphasise that secondary causes of hypouricaemia such as Wilson's disease, Fanconi syndrome, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), heavy metal poisoning, liver diseases, medication with uricosuric agents, etc. should be excluded before sending samples or subjects for laboratory tests of purine metabolism (Sebesta et al. 2018). In most other cases, the constellation of symptoms is not very conclusive (Assmann et al. 2006), and one should have a liberal policy concerning selective screening purine and pyrimidine metabolites in body fluids. Adult medicine is also of considerable importance. An example hereof is MNGIE syndrome caused by deficiency of thymidine phosphorylase (Hirano et al. 2006). Another example is the pharmacogenetic significance of the pyrimidine degradation defects, in general, and dihydropyrimidine dehydrogenase, in particular (van Kuilenburg 2004), and the purine-metabolising enzymes thiopurine methyltransferase (Weinshilboum et al. 1999).

The laboratory approach to detect defect in purine and pyrimidine metabolism is rapidly changing with current rate technological advances. There is a clear shift towards holistic genomic approaches, which has the advantage that whereas previously these defects were often ignored, they are now included in gene panels and packages. Confirmation and classical selective metabolic screening still rely on the quantification of purines and pyrimidines in body fluids and enzymology. State of the art is LC-MS/MS analysis, which allows comprehensive screening of purines and pyrimidines and is far more powerful than (U)HPLC-UV-based methodology (Monostori et al. 2019). Urine is the preferred body fluid, as all biomarkers can be excreted in the urine. In plasma, levels are much lower than urine, and this matrix is extremely sensitive to artefacts and misguiding shifts in metabolite levels. The arrival of metabolomics adds to the holistic approach of genomics and will play a role in the near future diagnostics of purine and pyrimidine defects. Undoubtedly, new biomarkers will be identified broadening diagnostic possibilities.

Nomenclature

	Disease name	Alternative disease name	Disease abbreviation	Gene symbol	Chromosomal localisation	Mode of inheritance	Affected protein	Disease OMIM#
13.1	CAD trifunctional protein deficiency	Epileptic encephalopathy, early infantile, 50	CAD-CDG	*CAD*	2p23.3	AR	Carbamoyl phosphate synthetase, aspartate transcarbamoylase and dihydroorotase trifunctional protein (CPSase/ATCase/ DHOase)	114010
13.2	Dihydroorotate dehydrogenase deficiency	Postaxial acrofacial dysostosis Miller syndrome Genée-Wiedemann syndrome	POADS	*DHODH*	16q22	AR	Dihydroorotate dehydrogenase	12664

Diagnostic Flowchart

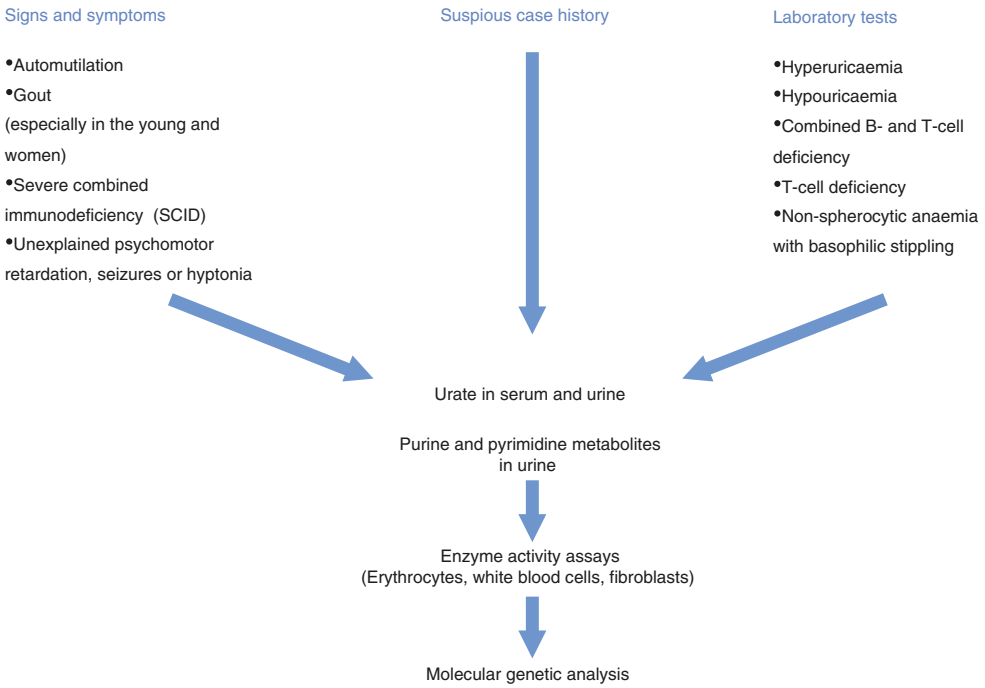

Fig. 13.3 The justification for detailed purine and pyrimidine investigations includes three aspects: (**a**) clinical signs and symptoms (some are very characteristic such as self-mutilation or gout in young people and women or SCID (severe combined immunodeficiency) syndrome; others are shown in the information of the specific diseases), (**b**) a case history suspicious of an inborn error of metabolism and (**c**) characteristic laboratory tests. If a patient meets these criteria, the first steps are measurement of uric acid in body fluid and purine and pyrimidine metabolites in urine. It is highly recommended to estimate both plasma and urine concentrations at once to be able to assess the excretion and confirm or exclude overproduction/hypoexcretion of uric acid. The exclusion of secondary causes of hyperuricaemia/hypouricaemia (such as nephropathy, tissue breakdown, Fanconi syndrome and uricosuric drugs) is very important. Confirmation of diagnosis consists of enzyme assay and finally molecular genetic analysis

Specimen Collection

This section is taken from the ERNDIM advisory document for the analysis of purines and pyrimidines (see Online Databases and Resources section for reference).

Urine

Many laboratories use urine portions for diagnostic purposes, and the traditionally 24-h urine collection or overnight collection has more or less become obsolete. No preservatives are added to the urine sample; freezing the sample as soon as possible is often enough.

If a 24-h urine collection is desired, proceed as follows: during the collection period, the urine aliquots are kept refrigerated (4 °C), and after completion, the urine is sent to the laboratory in a well-isolated package and stored in the refrigerator for max. 1 week at 4 °C until analysis or stored frozen at −20 °C when analysis is carried out after more than 1 week but within 2 months. For longer periods, storage at −80 °C is recommended.

Dipstick tests for nitrite and pH should be carried out directly after receipt of the urine in order to check for bacterial contamination. In addition, qualitative tests for glucose, reducing substances, sulphite and ketone bodies should be performed. Analysis should not be performed in severely bacterially contaminated samples (pH > 7 and/or nitrite is positive).

Plasma

The analysis of purines and pyrimidine can be performed in plasma obtained from blood anticoagulated with heparin as well as EDTA. This can be adjusted according to local protocols. In the case of capillary blood, clean and disinfect the skin thoroughly before taking the blood sample to avoid contamination from the skin surface. An absolute prerequisite is that the sample is absolutely fresh, and there should preferably be no or as little delay as possible between drawing of the blood and freezing the plasma sample. Plasma samples should be stored at −20 °C or at −80 °C if stored for a prolonged period. Plasma samples should be deproteinised before most types of analysis.

CSF

Please refer to your own hospital protocol for the lumbar puncture procedure.

CSF samples should be deproteinised before analysis. CSF samples should be stored at −80 °C.

Prenatal Diagnosis and DNA Analysis

Providing a table listing all disorders and materials in which molecular analysis can be performed is obsolete because of the modern sequencing techniques. All genes and their chromosomal localisations are listed above. In essence, any material from which DNA can be extracted is suitable for molecular analysis. There are good and reliable databases to be found on the Internet.

Treatment Summary

The Management of Purine and Pyrimidine Disorders

In the treatment of purine and pyrimidine disorders, patients and physicians need to be aware of several precautions: the dosage of allopurinol in overproduction hyperuricaemia (HPRT, PRPS) is higher than in primary gout and therefore should be reduced in the cases of renal insufficiency (risk of xanthine nephropathy!) (van Gennip et al. 2006). There is a risk of myopathy and neurotoxicity with colchicine prophylaxis in gouty patients with renal impairment and in patients receiving statins, so renal function should be assessed before prescribing colchicine or non-steroidal anti-inflammatory drugs (NSAIDs) (Nuki et al. 2017).

Administration of fluorinated pyrimidine analogues in dihydropyrimidine dehydrogenase deficiency can be catastrophic; in thiopurine methyltransferase deficiency, there may be enhanced toxicity of mercaptopurines.

Specific treatment is available for a small number of other purine and pyrimidine disorders at present. The reason is that, in many cases, our understanding of pathogenesis how a particular point defect in a gene produces these relatively new disorders is still incomplete and requires further studies.

The Management of Hyperuricaemia

Genetic defects with hyperuricaemia and gout represent the most frequent disorders of purine metabolism (Becker 2001). The incidence of hyperuricaemia and gout is increasing. Population-based studies have estimated an incidence of up to 21% for hyperuricaemia and 1–4% for gout (Kuo et al. 2015).

The Importance of Controlling Hyperuricaemia

Hyperuricaemia is the main underlying cause of gout. In addition, several studies suggest that chronic hyperuricaemia is related to the pathogenesis of multifactorial disorders such as hypertension, metabolic syndrome, chronic heart failure and chronic kidney disease (Mazzali et al. 2010; Teng et al. 2012). A recent study revealed that hyperuricaemia was a strong independent risk factor for major cardiovascular events and should be included in cardiovascular prevention strategies. Whether hypouricaemic drugs can reduce cardiovascular disease risk warrants further studies (Capuano et al. 2017). Therefore, it is important to emphasise rapid diagnosis and treatment of asymptomatic hyperuricaemia, considered as a multifactorial pathological condition very closely related to cardiovascular and renal complications. Control of hyperuricaemia should be more important to paediatricians than formerly thought. It is important to raise awareness among general practitioners to test uric acid concentrations in blood and urine more often, especially in patients with one or more risk factors for cardiovascular and renal impairment (Bove et al. 2017).

The Management of Gout

Recent updated recommendations of European League Against Rheumatism (EULAR) emphasise three main principles for the efficient management of gout: Firstly, every patient with gout should be fully informed about the pathophysiology of the disease, effective treatments and associated comorbidities. Secondly, every patient with gout should receive advice regarding lifestyle changes. Alcohol, especially beer, spirits and sugar-sweetened drinks, should

be excluded. Avoidance of excessive intake of meat, legumes, seafood and fructose-containing foods should be recommended. Low-fat dairy products and diets high in dietary fibre should be encouraged. Weight reduction and regular exercise should be advised. Thirdly, every patient with gout should be systematically examined for associated comorbidities including hyperlipidaemia, hypertension, obesity, coronary heart disease, peripheral artery disease and renal impairment. Detection of chronic kidney disease is notably required. The measurement of the estimated glomerular filtration rate (eGFR) at the time of diagnosis of gout is recommended. The subsequent monitoring of eGFR should follow in parallel with measurements of uric acid concentrations in blood and urine (Richette et al. 2017; Nuki et al. 2017).

The main principle of the management of gout with pharmacotherapy is the need to reduce serum uric acid concentrations to below a target of 0.30 or 0.36 mmol/L depending on whether it is tophaceous or non-tophaceous, respectively (Robinson PC 2018). Urate-lowering therapy (ULT) should be discussed from the first presentation of the disease. Allopurinol is recommended as the first choice of ULT. Its dosage should be adjusted according to renal function. If it is not possible to achieve uric acid target concentration in blood, then febuxostat, uricosuric or combining a xanthine oxidase inhibitor with a uricosuric should be recommended (Richette et al. 2017; Nuki et al. 2017). Febuxostat has an excellent safety and tolerability profile also in patients with moderate renal impairment, because of its hepatic metabolism. It was also shown that its serum uric acid-lowering efficacy is greater than of allopurinol in patients with hyperuricaemia with or without chronic kidney disease (Bove et al. 2017). The use of xanthine oxidase inhibitors is recommended for the overproduction-type hyperuricaemia, while uricosuric agents are recommended for the underexcretion type. However, when uricosuric drugs are used, urinary output must be sustained, and, in addition, alkalinisation of the urine to prevent urolithiasis must be considered (Becker 2001).

It is important to note that all uric acid-lowering therapies should be started at low dose and titrated upwards until the target value is achieved. The recommendations for the treatment of flare are colchicine, nonsteroidal anti-inflammatory drugs (NSAIDs), oral or intra-articular steroids or a combination. In patients with flare and contraindications to colchicine, NSAIDs and corticosteroids, an interleukin-1 blocker should be considered. For patients with refractory gout, pegloticase is recommended (Richette et al. 2017; Nuki et al. 2017).

Recent study suggests that febuxostat may positively affect cardiovascular mortality in comparison with allopurinol in elderly patients with mild-to-moderate heart failure. This finding deserves further evaluation in the future (Cicero et al. 2019).

Disorders of Nucleotide Metabolism

14

Min Ae Lee-Kirsch, Victoria Tüngler, Simona Orcesi, and Davide Tonduti

Contents

Summary

Nucleotides are the building blocks of nucleic acids including deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), both of which are essential biomolecules within virtually all forms of life. While DNA carries the genetic information required for building and maintaining an organism, RNA serves as an intermediary template for protein translation. Nucleic acids derived from pathogens, such as viruses, also represent important molecular patterns that can be sensed by pattern recognition receptors of the innate immune system as danger signals. Engagement of these nucleic acid-sensing receptors initiates activation of signaling cascades in the host immune cells leading to production and secretion of type I interferon (IFN) and other cytokines. The aim of the ensuing antiviral immune response is to eliminate infected cells and to restrict viral spread. As nucleic acid sensors have only limited capacity to differentiate between nonself- and self-DNA or RNA, a type I IFN response can also be initiated by endogenous nucleic acids. Such inappropriate activation of type I IFN can be detrimental to the host by promoting autoinflammation and a loss of immune tolerance leading to autoimmunity. Type I IFN activation induced by immune recognition of self-nucleic acids represents a central pathogenetic mechanism underlying disorders of nucleic acid metabolism and nucleic acid-sensing also referred to as type I interferonopathies.

Nucleotides play fundamental roles in cell metabolism. They provide energy in the form of nucleoside triphosphates, function as second messenger in cell signaling, and act as cofactors of enzymatic reactions. Perturbations in

adenosine homeostasis leading to downregulation of pyrophosphate (PPi), a key inhibitor of hydroxyapatite growth, underlie disorders of early arterial calcification. The lysosomal equilibrative nucleoside transporter 3 (ENT3) regulates intracellular nucleoside pools and thereby influences the availability of ATP and GTP, synthesis of DNA and RNA, and other metabolic pathways. Its general role in cell homeostasis likely accounts for the pleiotropy of ENT3 deficiency. Activation-induced cytidine deaminase (AID) and uracil-DNA glycosylase (UNG) mediate somatic hypermutation and class-switch recombination at the immunoglobulin gene loci, which represent key events during formation of protective antibodies by B cells. Malfunction of these pathways impedes antibody formation resulting in profound susceptibility to bacterial infections.

Introduction

Disorders of nucleotide metabolisms can be broadly divided into disorders of nucleic acid metabolism and nucleic acid-sensing, disorders relating to nucleotide transport and metabolism, and disorders of immunoglobulin hypermutation and class-switching. Given the extraordinary functional diversity of pathways regulating nucleotide metabolism, the phenotypes of the associated disorders comprise a broad and diverse spectrum of clinical presentations.

Disorders of Nucleic Acid Metabolism and Nucleic Acid-Sensing

Aicardi-Goutières Syndrome

Aicardi-Goutières syndrome (AGS) is a systemic inflammatory disorder primarily affecting the brain and skin. It is characterized by inappropriate activation of the antiviral type I IFN axis and represents the prototypic type I interferonopathy (Lee-Kirsch 2017). Type I interferonopathies comprise a heterogenous group of disorders caused by perturbations of the innate immune system associated with an abnormal activation of type I IFN.

AGS is caused by mutations in seven distinct genes encoding 3′ repair exonuclease (*TREX1*, AGS1), the three subunits of ribonuclease H2 (*RNASEH2B*, AGS2; *RNASEH2C*, AGS3; *RNASEH2A*, AGS4), sterile alpha motif (SAM) and HD-domain containing protein (*SAMHD1*, AGS5); RNA-specific adenosine deaminase (*ADAR*, AGS6), and interferon-induced helicase C domain-containing protein 1 (*IFIH1*, AGS7). All AGS-causing genes function in pathways affecting the metabolism or the immune recognition of intracellular nucleic acids including DNA and RNA (Lee-Kirsch 2017; Schlee and Hartmann 2016) (Fig. 14.1). Inheritance of AGS1 to AGS6 is predominantly autosomal recessive resulting in a loss of function of the underlying gene, although rare cases of heterozygous de novo mutations with presumably dominant negative effect have been described for *TREX1* and *ADAR*. In contrast, AGS7 is caused by heterozygous gain-of-function mutations in *IFIH1* that either occur de novo or are inherited as autosomal dominant trait with reduced penetrance (Crow et al. 2015).

AGS usually begins during the first year of life with a peak between the third and sixth month. Following a period of normal psychomotor development, infants commonly present with a subacute encephalitic-like phase characterized by irritability, unexplained fevers, dystonic movements, truncal hypotonia, as well as sleeping and feeding difficulties. After a few weeks to months, the clinical picture enters a plateau phase characterized by progressive microcephaly, spastic-dystonic tetraplegia with exaggerated startle reactions, and severe developmental delay. Children frequently present abnormal eye movements or poor visual performance, and some patients experience epilepsy. Both a neonatal and a late onset of symptoms beyond the first year of life have been described. Likewise, intrafamilial phenotypic variability can be high with one sibling presenting with severe neurological impairment and the other with only mild spasticity and normal intellect (Vogt et al. 2013; Tüngler et al. 2014). The major neuroradiological findings include leukoencephalopathy, basal ganglia calcification, and cerebral atrophy. Thus, the clinical phenotype of AGS resembles congenital viral infection. In addition, some patients develop signs that are also observed in patients with the autoimmune disorder systemic lupus erythematosus including arthritis, hepatic disease, thrombocytopenia, lymphopenia, antinuclear antibodies, as well as cold-induced erythematous skin lesions, also referred to as chilblain lesions (Ramantani et al. 2010, 2011; Cuadrado et al. 2015). Elevated liver function tests and thrombocytopenia occur more commonly in cases with neonatal onset.

Cerebrospinal fluid (CSF) lymphocytosis and increased levels of IFN-α in CSF are observed during the encephalitic phase but tend to gradually decrease over time (Goutieres et al. 1998). In the absence of lymphocytosis or IFN-α in CSF, elevated CSF pterins may be a less specific sign of CNS inflammation (Blau et al. 2003). In contrast, chronic upregulation of interferon-stimulated genes in peripheral blood cells, the so-called interferon signature, can be measured in most patients persistently throughout the course of the disease and reflects the underlying intrinsic systemic inflammation (Rice et al. 2013). The interferon signature therefore represents a more robust diagnostic tool.

Other AGS-Related Phenotypes

In general, the different AGS subtypes cannot be distinguished based on clinical grounds alone. However, certain clinical signs appear to be more specific for distinct AGS subtypes. Cerebral vasculopathy with early-onset strokes has

been described in patients with AGS1 (*TREX1*) and AGS5 (*SAMHD1*); the latter may also present with a moyamoya-like phenotype (Xin et al. 2011; Yamashiro et al. 2013). Bilateral striatal degeneration has been observed in patients with AGS6 (*ADAR)* (Livingston et al. 2014). Magnetic resonance imaging (MRI) shows symmetrical signal changes with swelling followed by shrinkage of the corpus striatum. Patients present with subacute onset of dystonia, commonly triggered by infections. Dyschromatosis symmetrica hereditaria is a rare manifestation of autosomal dominant *ADAR* mutations found in the Japanese population. It is characterized by childhood onset of hypopigmented and hyperpigmented lesions, particularly on the extremities and not associated with AGS (Hayashi and Suzuki 2013). Isolated spastic paraparesis has been observed in patients with AGS2 (*RNASEH2B)*, AGS6 (*ADAR1)*, and AGS7 (*IFIH1*) who present with slowly progressive lower limb spasticity, normal cognitive function, and normal head growth. Usually, brain MRI is unremarkable (Crow et al. 2014). Overall, there is emerging evidence for a phenotypic continuum between AGS and other AGS-related phenotypes and other type I interferonopathies.

Familial Chilblain Lupus

Familial chilblain lupus is a monogenic form of cutaneous lupus erythematosus with onset in early childhood. It is characterized by cold-induced bluish-red skin lesions in acral locations such as fingers, toes, nose, cheeks, and ears (Lee-Kirsch et al. 2006). Patients exhibit an interferon signature in blood indicating constitutive type I IFN activation. Some patients develop arthralgia, antinuclear antibodies, immune complexes, or lymphopenia. Histological findings include perivascular inflammatory infiltrates with increased mucin, deposits of immunoglobulins or complement, and increased expression of type I IFN-induced myxovirus resistance protein 1 (Mx1) (Gunther et al. 2013). Familial chilblain lupus is caused by heterozygous *TREX* mutations (CHBL1) (Rice et al. 2007; Lee-Kirsch et al. 2007). In addition, two families with familial chilblain lupus each segregating a heterozygous mutation in *SAMHD1* (CHBL2) or in *STING* have been reported (Ravenscroft et al. 2011; König et al. 2017).

Retinal Vasculopathy with Leukodystrophy

Retinal vasculopathy with cerebral leukodystrophy (RVCL) is an autosomal dominant disorder with onset in adolescence or early adulthood. Patients present with progressive loss of vision, cerebrovascular disease, and dementia. Some patients also develop migraine, glomerulopathy, or Raynaud's disease. RVCL is caused by heterozygous *TREX1* mutations that lead to C-terminal truncations of TREX1 with preservation of the N-terminal DNase domain (Richards et al. 2007).

Singleton-Merten Syndrome Type 1 and Type 2

Singleton-Merten syndrome (SGMRT) is characterized by progressive calcifications of large vessels, dental anomalies with periodontal disease and alveolar bone loss, as well as skeletal abnormalities. Patients may also suffer from psoriasis, glaucoma, and recurrent infections. Singleton-Merten syndrome is caused by heterozygous gain-of-function mutations in interferon-induced helicase C domain-containing protein 1 (*IFIH1*, SGMRT1) or dead box polypeptide 58 (*DDX58*, SGMRT2) which encode the cytosolic dsRNA sensors, melanoma differentiation-associated gene 5 (MDA5), and retinoic acid-inducible gene I (RIGI), respectively (Rutsch et al. 2015; Jang et al. 2015).

STING-Associated Vasculopathy with Onset in Infancy

STING-associated vasculopathy with onset in infancy (SAVI) is an autoinflammatory vasculopathy characterized by ulcerating acral skin lesions, recurrent fever, and interstitial lung disease (Liu et al. 2014). Similar to patients with AGS or chilblain lupus, skin lesions in SAVI patients are aggravated by cold. Some patients demonstrate variable or transient autoantibody titers. SAVI is caused by heterozygous de novo mutations in transmembrane protein 173 (*TMEM173*), encoding stimulator of interferon genes (STING), the key adaptor signaling molecule of the cyclic GMP-AMP synthase (cGAS)-dependent DNA-sensing pathway (Fig. 14.1). Mutations result in a gain of function leading to constitutive activation of type I IFN. In addition, a family with SAVI and lupus-like features segregating a dominant *STING* mutation was reported (Jeremiah et al. 2014).

RNASET2 Deficiency

Cystic leukoencephalopathy without megalencephaly is caused by biallelic mutations in ribonuclease T2 (*RNASET2*), which has been implicated in the degradation of ribosomal self RNA, thereby modulating host immune responses (Henneke et al. 2009; Haud et al. 2011). It is characterized by bilateral anterior temporal cysts and white matter disease, a phenotype overlapping with congenital cytomegalovirus infection and AGS.

OAS1 Deficiency

Deficiency in 2′,5′-oligoadenylate synthetase 1 (OAS1) causes infantile-onset pulmonary alveolar proteinosis with hypogammaglobulinemia, which is characterized by progressive respiratory failure with consolidations on lung imaging and recurrent respiratory viral infection. On bronchoalveolar lavage, small and non-foamy alveolar macrophages are seen. OAS1 is a member of the 2–5A synthetase family essential for innate immune responses to viral infection. Reported heterozygous *OAS1* mutations occurred de

novo or were transmitted to offspring by a mother who carried the mutation as mosaic (Cho et al. 2018).

Disorders of Nucleotide Transport and Metabolism

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum (PXE) is a connective tissue disorder characterized by progressive calcification of elastic fibers involving the skin, the eye, and the cardiovascular system. Typical skin lesions are yellowish papules on flexural surfaces. Retinal changes include peau d'orange and angioid streaks caused by calcification and dehiscence of Bruch's membrane, resulting in neovascularization with subsequent visual impairment. Adult patients may develop cardiovascular disease due to premature atherosclerosis. PXE is caused by autosomal recessive mutations in *ABCC6* (ATP-binding cassette, subfamily C, member 6) which belongs to the multidrug resistance-associated protein subfamily of ATP-binding cassette transmembrane transporters (Bergen et al. 2000; Struk et al. 2000). In rare cases, autosomal dominant inheritance has been described.

Generalized Arterial Calcification of Infancy Type 1 and Type 2

General arterial calcification of infancy (GACI) is characterized by calcification of the internal elastic lamina and fibrotic myointimal proliferation of muscular arteries resulting in arterial stenosis (Nitschke et al. 2012). It is often fatal within the first 6 months of life because of myocardial ischemia leading to heart failure. Radiographic findings include diffuse vascular and periarticular soft tissue calcification. Some patients also develop hypophosphatemic rickets due to reduced renal tubular phosphate reabsorption (Rutsch et al. 2008). The majority of cases is caused by autosomal recessive mutations in *ENPP1* (ectonucleotide pyrophosphatase/phosphodiesterase 1, GACI type 1), which converts ATP to AMP and pyrophosphate, an essential physiologic inhibitor of calcification (Fig. 14.2). GACI type 2 is due to biallelic mutations in *ABCC6*. It is usually not associated with pseudoxanthoma due to early death caused by cardiovascular disease. However, GACI patients with *ENPP1* mutations who survive early childhood may develop signs of pseudoxanthoma. It is thought that ABCC6 interferes with ENPP1-associated metabolic pathways, possibly by modulating extracellular ATP concentrations.

Cole Disease

Cole disease is characterized by congenital or early-onset punctate palmoplantar keratoderma with hypopigmented macules over the arms and legs. Some patients develop calcific tendinopathy. An autosomal dominant form due to mutations in *ENPP1*, which affect cysteine residues in the somatomedin B-like 2 domain, has been described in three families (Eytan et al. 2013). In addition, a recessive and more severe form of Cole disease due to homozygosity of the p.Cys120Arg allele has been reported in three families (Chourabi et al. 2018).

NT5E Deficiency

Deficiency of ecto-5′-nucleotidase (NT5E) has been described in three families (St Hilaire et al. 2011). This autosomal recessive disorder is characterized by arterial and periarticular calcifications with onset in early adulthood.

SLC29A1 Deficiency

Lack of the equilibrative nucleoside transporter 1 (ENT1, SLC29A1) results in the Augustine-null blood type and ectopic mineralization (Daniels et al. 2015). It represents an ill-defined clinical entity.

SLC29A3 Deficiency

Autosomal recessive deficiency of the equilibrative nucleoside transporter 3 (ENT3, SLC29A3) underlies histiocytosis-lymphadenopathy plus syndrome, which encompasses a spectrum of disorders previously thought to be distinct: Faisalabad histiocytosis, sinus histiocytosis with massive lymphadenopathy, Rosai-Dorfman disease, H syndrome, and pigmented hypertrichosis with insulin-dependent diabetes mellitus syndrome (Molho-Pessach et al. 2014). In addition to histiocytosis and lymphadenopathy, recurrent fever, hepatosplenomegaly, skin manifestations, hormone deficiencies, joint contractures, or deafness can occur. Lysosomal ENT3 regulates cell homeostasis by controlling nucleoside availability and is required for T-cell survival upon activation (Wei et al. 2018).

Disorders of Immunoglobulin Class-Switching and Hypermutation

Hyper-IgM Syndrome Type 2 and Type 5

Deficiencies in the nucleic acid-modifying enzymes, activation-induced cytidine deaminase (AID), and uracil-DNA glycosylase (UNG) cause the primary immunodeficiency disorders hyper-IgM syndrome type 2 and type 5 (Revy et al. 2000; Imai et al. 2003). Both enzymes play a central role in B cells, which function in the humoral arm of the adaptive immune system by secreting antibodies or immunoglobulin (Ig). Production of protective antibodies by activated B cells is accomplished by two processes of diversification, somatic hypermutation (SHM) and class-switch recombination (CSR) (Lee et al. 2004; Stavnezer et al. 2008). SHM introduces mutations into the variable region of Ig genes, which encodes the antigen-binding site of the Ig receptor. Repeated rounds of mutation and selec-

tion generate high-affinity antibodies. CSR, on the other hand, involves the constant region of the Ig locus and replaces the constant region of the primary IgM antibody with the constant region of other isotypes including IgA, IgG, or IgE via deletional DNA recombination. Recombination occurs between DNA double-strand breaks introduced at defined regions (switch region) upstream of the sequences encoding the constant regions of IgA, IgG, and IgE, respectively. This process improves the ability of an Ig to remove a pathogen by augmenting its effector functions without changing its antigen specificity. SHM and CSR are initiated by AID, which converts cytosines within Ig variable regions or switch regions to uracil by deamination (Fig. 14.3). Subsequent removal of uracil by UNG and nicking by apurinic endonuclease (APE) result in DNA single-strand breaks. These DNA lesions are either processed by error-prone DNA repair, to yield mutations during SHR, or converted to DNA double-strand breaks, to initiate CSR (Lee et al. 2004; Stavnezer et al. 2008; Fear 2013). Deficiencies in AID or UNG abrogate SHM and CSR, leading to recurrent bacterial infections due to the inability to mount efficient antibody responses (Revy et al. 2000; Imai et al. 2003). Patients typically exhibit normal to increased IgM; absent IgG, IgA, and IgE; as well as lymphoid hyperplasia caused by the presence of giant germinal centers.

Nomenclature

	Disease name	Alternative disease name	Disease abbreviation	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	Disease OMIM#
14.1	3′ Repair exonuclease 1 deficiency	Aicardi-Goutières syndrome type 1	AGS1	*TREX1*	3p21.31	AR[a]	3-prime repair exonuclease 1	225750

Metabolic Pathways

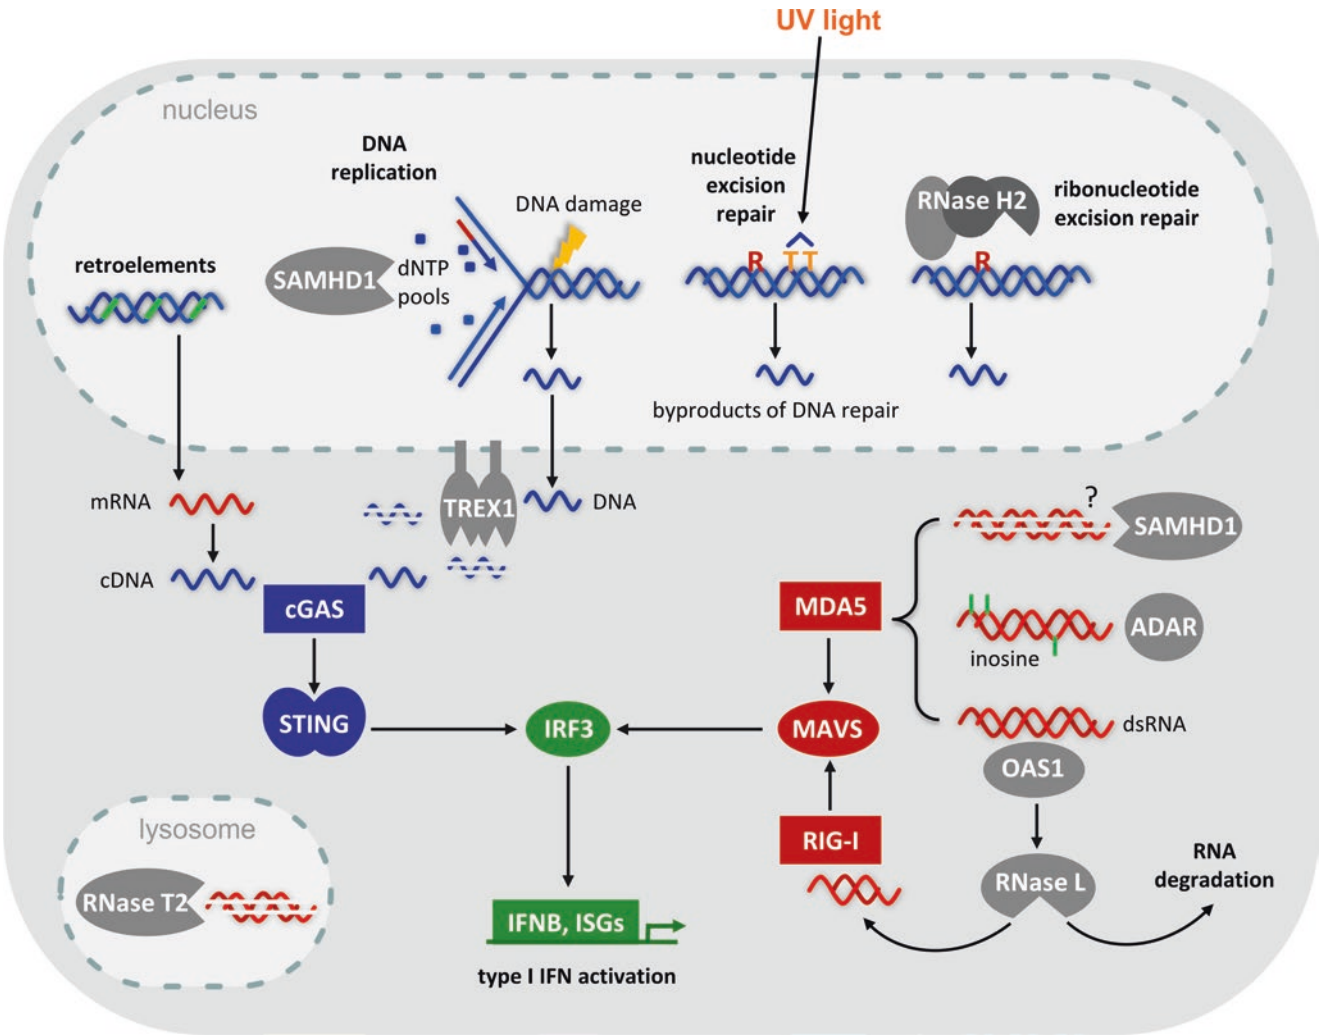

Fig. 14.1 Pathways of nucleic acid metabolism and innate immune sensing. TREX1 is a cytosolic deoxyribonuclease anchored in the outer nuclear membrane that degrades ssDNA derived from DNA repair or reverse transcription of endogenous retroelements. A lack of TREX1 causes DNA accumulation, within both the nucleus and the cytosol. Within the cytosol, ssDNA metabolites with stem loops or dsDNA are sensed by the DNA sensor cGAS which signals via STING (encoded by *TMEM173*) to induce type I IFN production. Activating mutations in STING cause constitutive type I IFN signaling in the absence of cGAS activation. The heterotrimeric RNase H2 maintains genome integrity by removing ribonucleotides misincorporated during DNA replication. The presence of ribonucleotides in genomic DNA enhances photodimerization of adjacent pyrimidines, which are repaired by nucleotide excision repair. A lack of RNase H2 promotes DNA damage, leading to enhanced formation of DNA repair metabolites. SAMHD1 degrades deoxynucleoside triphosphates (dNTP), thereby controlling the dNTP pool required for DNA synthesis. Loss of SAMHD1 function induces cell cycle arrest and DNA damage. DNA byproducts derived from DNA repair cause cGAS-mediated type I IFN activation. SAMHD1 has also ribonuclease activity, suggesting that a loss of SAMHD1 may lead to RNA accumulation. ADAR modifies dsRNA through deamination of adenosine to inosine, thereby preventing recognition of dsRNA by the RNA sensor MDA5 (encoded by *IFIH1*). Upon binding to dsRNA, OAS1 synthesizes 2′–5′-linked oligoadenylates using ATP as substrate, which in turn activate RNase L. This leads to RNA degradation and formation of short RNA fragments that act as ligand for RIG-I (encoded by *DDX58*), another cytosolic RNA sensor. Both RNA sensors, MDA5 and RIG-I, signal via mitochondrial antiviral signaling (MAVS) to activate type I IFN. Activation of either the DNA-sensing pathway led by cGAS or the RNA-sensing pathways led by MDA5 and RIG-I result in phosphorylation of the transcription factor interferon regulatory factor 3 (IRF3) which induces expression of the *IFNB* gene and numerous interferon-stimulated genes (ISG). Activating mutations in RIG-I and MDA5 increases receptor affinity resulting in constitutive type I IFN signaling. RNase T2 degrades ribosomal RNA in lysosomes. A lack of RNase T2 causes RNA accumulation which may activate RNA sensors

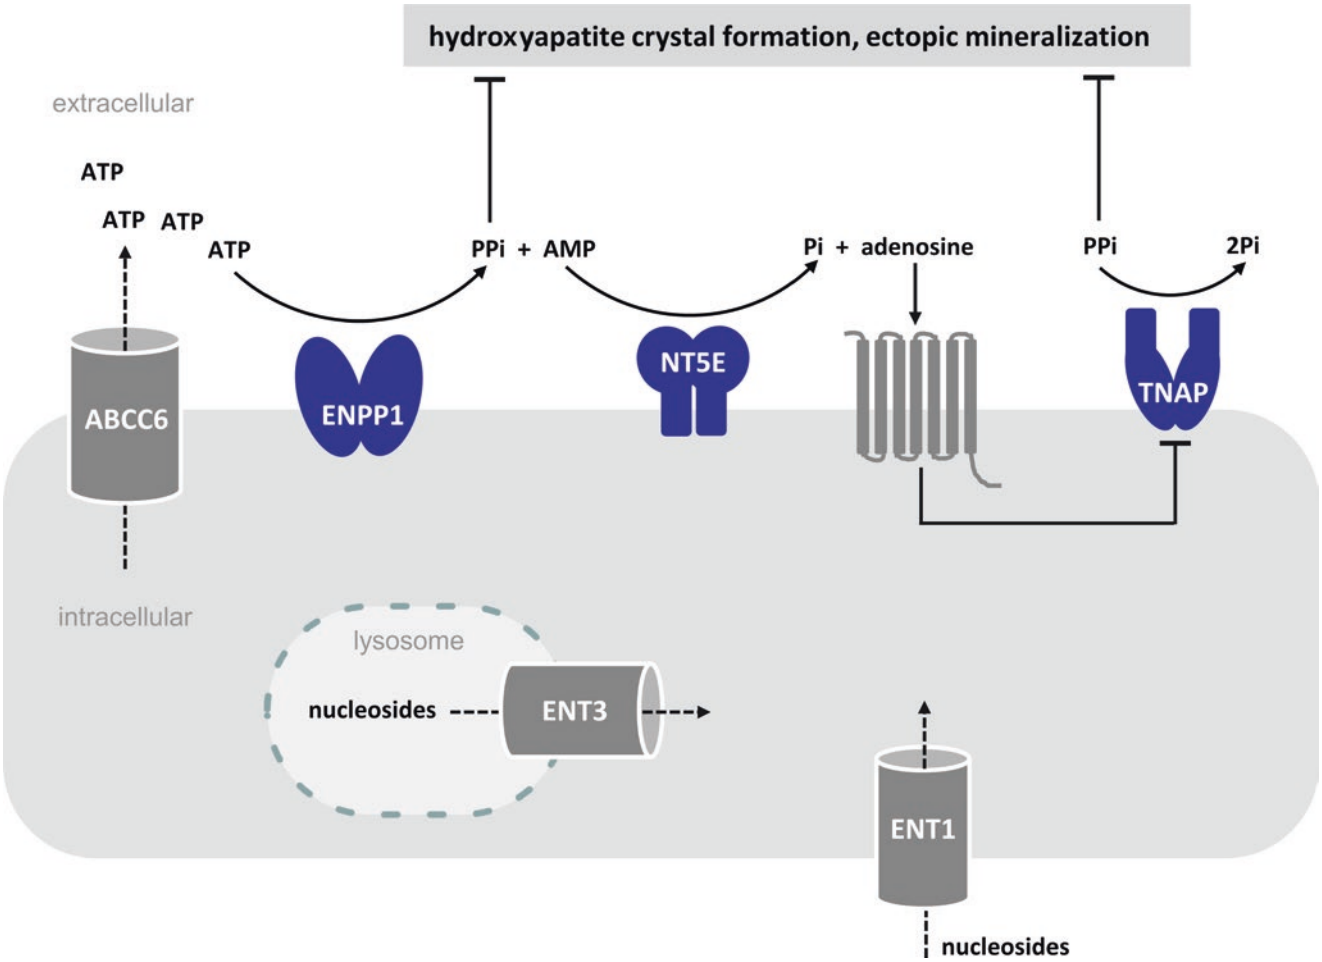

Fig. 14.2 Disorders of nucleotide transport and metabolism associated with ectopic mineralization or immune homeostasis. Pyrophosphate (PPi)-regulating enzymes in concert with the nucleotides ATP and AMP along with the nucleoside adenosine regulate ectopic mineralization by inhibition of PPi-dependent hydroxyapatite crystal formation. ABCC6 mediates the release of ATP from the liver into the extracellular space. In the periphery, ATP is converted into the mineralization inhibitor pyrophosphate (PPi) and AMP by ENPP1. Loss of function of either ABCC6 or ENPP1 results in reduced PPi formation, leading to unabated ectopic mineralization. AMP is converted to adenosine and inorganic phosphate (Pi) by NT5E. Adenosine maintains adequate PPi levels by inhibiting tissue-nonspecific alkaline phosphatase (TNAP) which hydrolyzes PPi, through adenosine receptor-mediated signaling. A lack of NT5E causes ectopic mineralization due to decreased adenosine, which in turn decreases PPi by enhancing TNAP activity. The nucleoside transporter ENT1 has been implicated in this pathway by interfering with extracellular adenosine availability. In contrast, ENT3 regulates cell homeostasis by coordinating lysosomal function with intracellular nucleoside availability, particularly in T cells. The clinical presentation of ENT3 deficiency is highly variable and involves multiple organ systems with signs of immune dysregulation

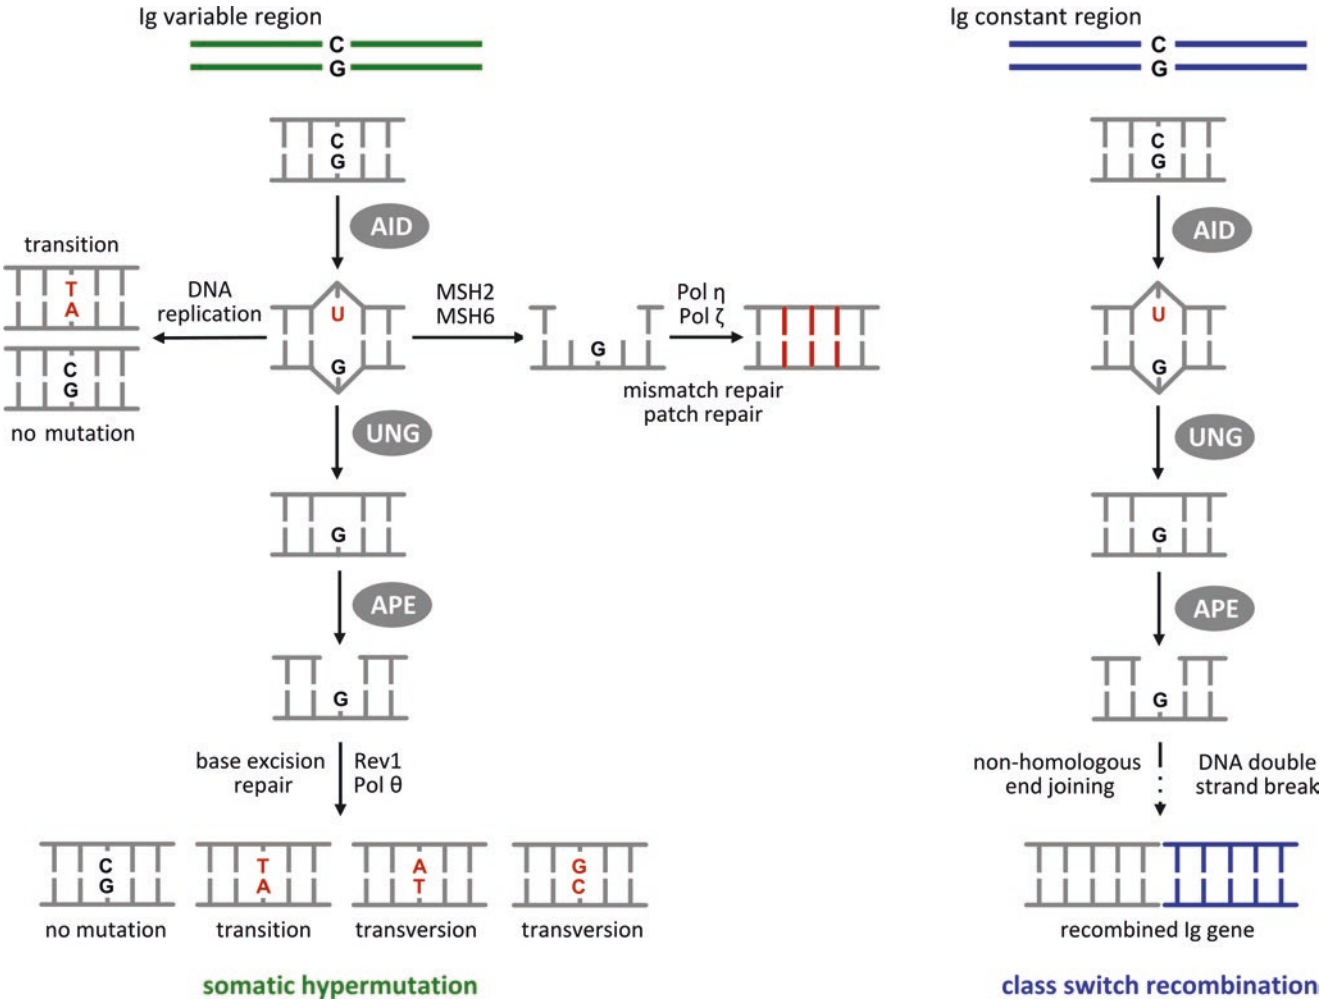

Fig. 14.3 Somatic hypermutation and class-switch recombination of immunoglobulin genes. AID initiates SHR (left) by deamination of cytosine (C) to uracil (U) within the variable region of the Ig genes which determines antigen specificity and affinity of the Ig receptor. Different DNA repair pathways are then utilized in the resolution of AID-mediated DNA lesions. If DNA replication occurs before resolution of the C/U mismatch, uracil is used as template resulting in a C to T transition in one daughter cell, or the mismatch is repaired. Alternatively, uracil is recognized by UNG which creates an abasic site that is subsequently converted into a nick by apurinic endonuclease (APE) as the first step of base excision repair (BER). Following replication by error-prone translesion synthesis polymerases (Rev1 or Pol θ), transitions or transversions can occur. Resolution of the uracil mismatch may also occur via the mismatch repair pathway. Bases surrounding the initial U lesion are removed and replaced in an error-prone manner through the action of Pol η and Pol ζ, leading to the spreading of mutations away from the initial site of AID action. CSR (right) also begins with AID creating a uracil at specific G-rich tandem repeated DNA sequences, the so-called switch regions, which direct deletional DNA recombination within the Ig constant regions. Following UNG-mediated uracil removal and nicking by APE, DNA double-strand breaks occur through factors of the BER pathway. Directed recombination is completed by nonhomologous end joining

Signs and Symptoms

Diagnosis

Genetic Testing

Genetic testing by symptom-driven sequencing of a larger group of genes (panel sequencing) or by whole-exome sequencing based on next-generation sequencing has facilitated the diagnosis of rare genetic disorders. This approach is particularly useful in patients presenting with leukodystrophy, autoinflammation, or immunodeficiency, all of which comprise a broad range of differential diagnoses. While both routine and special laboratory testing (Table 14.24) may aid in the differential diagnosis, generally for all diseases discussed in this chapter, the definite diagnosis is made by providing evidence for causative mutations in a specific gene by molecular genetic analysis. Confirmation of a specific diagnosis by genetic testing will also allow prenatal diagnosis.

Specific Laboratory Investigations

Table 14.24 Specific laboratory tests, which are helpful in the diagnostic workup of a patient suspected of a given disorder

Disorder	Test	Material	Preconditions, handling
AGS, CHBL, SAVI	Interferon signature, upregulation of IFN-stimulated genes	Blood drawn into heparin tubes or PAX tubes	If heparin blood is used, samples should be processed within 24 h
AGS	IFN-α in CSF	CSF	CSF must be shipped on dry ice to special laboratory
AGS	Pterins in CSF	CSF	CSF must be shipped on dry ice to special laboratory
OAS1 deficiency	Alveolar macrophage morphology	Bronchoalveolar lavage	
PXE	Elastin fibers in skin with Verhoeff-van Gieson staining	Skin biopsy	Formalin-fixed, paraffin-embedded sections
PXE	Calcium deposits in skin with von Kossa staining	Skin biopsy	Formalin-fixed, paraffin-embedded sections

Treatment

Familial Chilblain Lupus, STING-Associated Vasculopathy, and Aicardi-Goutières Syndrome

Emerging evidence indicates that an immunomodulatory intervention targeting the type I IFN axis using Janus kinase (JAK) inhibitors might be of therapeutic value (Bienias et al. 2018). JAK inhibitors such as ruxolitinib, baricitinib, and tofacitinib block signaling at the IFN receptor. Clinical improvement and suppression of the interferon signature have been demonstrated in patients with TREX1- and STING-associated familial chilblain lupus (König et al. 2017; Zimmermann et al. 2019). Improvement of skin lesion has also been observed in children with SAVI treated with ruxolitinib, tofacitinib, or baricitinib (Seo et al. 2017; Frémond et al. 2016; Sanchez et al. 2018). However, pulmonary symptoms did not consistently respond to treatment. While patients with AGS treated with ruxolitinib or baricitinib also respond with suppression of type I IFN activation and some clinical amelioration (Tüngler et al. 2016; Vanderver et al. 2020), improvement of neurological function depends on preexisting neurological damage. Given the progressive nature of AGS, a timely diagnosis is important as early therapeutic intervention can possibly ameliorate or prevent further brain damage. Although JAK inhibition represents an effective therapeutic strategy in patients with type I interferonopathies, future controlled clinical trials are required to fully assess the therapeutic effects as well as the side effects of JAK inhibitors in these patients.

OAS1 Deficiency

Immunoglobulin replacement therapy can improve pulmonary function. Hematopoietic stem cell transplantation is considered curative treatment (Cho et al. 2018).

Generalized Arterial Calcification of Infancy Type 1 and Type 2

In addition to symptomatic treatment with angiotensin-converting enzyme inhibitors and hydralazine, treatment with bisphosphonates can improve survival (Rutsch et al. 2008).

Hyper-IgM Syndrome Type 2 and Type 5

Regular treatment with immunoglobulin replacement therapy markedly reduces the frequency of bacterial infections and the likelihood of developing lymphoid hyperplasia. Sometimes prophylactic antibiotic therapy will be recommended for individuals who develop complications of chronic infection such as bronchiectasis.

Summary

Reduced creatine levels in the brain and in body fluids/tissues are the common denominator of primary creatine disorders (cerebral creatine deficiency syndromes types 1–3: X-linked creatine transporter (CrT/*SLC6A8*) deficiency, GAMT/*GAMT* deficiency, AGAT/*GATM* deficiency). Characteristic clinical features include developmental delay/intellectual disability; speech impairment and behavioral problems, combined with epilepsy; and movement disorders. Arginine:glycine amidinotransferase aggregation syndrome is a newly described genetic cause of renal Fanconi syndrome and kidney failure caused by aggregation of certain fully penetrant heterozygous *GATM* missense variants. OAT/*OAT* deficiency is a secondary creatine deficiency syndrome leading to chorioretinal degeneration. Diagnostic markers, besides brain creatine deficiency, include high or low levels of guanidinoacetate for GAMT and AGAT deficiency, a high urinary creatine excretion for CrT deficiency, and high plasma ornithine levels for OAT deficiency. Treatments comprise substitution of creatine (AGAT deficiency) combined with L-ornithine (GAMT deficiency) and arginine restricted diet (GAMT and OAT deficiency). Creatine and substrates for intracerebral creatine synthesis (L-arginine and L-glycine) have limited therapeutic effects in CrT deficiency. Improved outcomes after early recognition have prompted the implementation of GAMT newborn screening in various juridictions.

Introduction

Creatine is synthesized by two enzymatic reactions: (1) the formation of guanidinoacetate (GAA) from arginine and glycine by L-arginine:glycine amidinotransferase (AGAT/*GATM*) and (2) the methylation of GAA by *S*-adenosyl-L-methionine:*N*-guanidinoacetate methyltransferase (GAMT/*GAMT*). The liver, pancreas, and kidney are the main sites of creatine synthesis. Creatine is transported into cells via an X-linked Na^+/Cl^--dependent creatine transporter, CrT/*SLC6A8*. While blood-brain barrier expresses CrT allowing the brain to take up creatine, this transport from periphery has a low efficacy, and CNS must supply parts of its needs in creatine through endogenous synthesis, by expression of AGAT and GAMT (Hanna-El-Daher and Braissant 2016). Creatine plays a major role in storage and transmission of high-energy phosphates (ATP), via reversible conversion into phosphocreatine, catalyzed by creatine kinases. Creatine may also play a role in neurotransmission. Intracellular creatine and phosphocreatine are nonenzymatically converted into creatinine, which is excreted in urine. The daily creatinine excretion is directly proportional to total body creatine content. Creatine synthesis is regulated via AGAT activity. Because AGAT is inhibited by high concentrations of L-ornithine, the hyperornithinemia in ornithine aminotransferase (OAT) deficiency is associated with secondary creatine deficiency.

Nomenclature

No.	Disorder name	Alternative disorder names	Disorder abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM #
15.1	Arginine:glycine amidinotransferase deficiency	Glycine amidinotransferase deficiency	AGAT	*GATM*	15q15.3	Arginine:glycine amidinotransferase	612718
15.2	Guanidinoacetate methyltransferase deficiency	–	GAMT	*GAMT*	19p13.3	Guanidinoacetate methyltransferase	612736
15.3	Creatine transporter deficiency	X-linked creatine deficiency syndrome, CrT, or SLC6A8 deficiency	CrT, SLC6A8, CTD	*SLC6A8*	Xp28	SLC6A8 transporter (CrT, creatine transporter)	300352
15.4	Arginine:glycine amidinotransferase aggregation syndrome	AD GATM renal Fanconi syndrome	AGAT AS	*GATM*	15q15.3	Arginine:glycine amidinotransferase	
15.5	Ornithine aminotransferase deficiency	Gyrate atrophy of the choroid and retina	OAT, GACR	*OAT*	10q26.13	Ornithine aminotransferase	258870

Primary Creatine Deficiencies/AGAT, GAMT, and CrT Deficiencies

Primary creatine deficiencies comprise two autosomal recessive inborn errors of creatine synthesis, AGAT (**15.1**) and GAMT (**15.2**) deficiencies, and one X-linked defect of creatine transport, CrT (**15.3**) deficiency (Mercimek-Mahmutoglu and Salomons 2009). The main affected tissue in primary creatine deficiencies is the brain, which presents as a strongly decreased or absent peak of creatine as measured by proton magnetic resonance spectroscopy (^{1}H-MRS). Developmental delay and intellectual disability are their common clinical presentation. Speech impairment is most prominent even in patients with mild/moderate intellectual disability. Many patients have autistic behavior and/or various degrees of epilepsy ranging from occasional to pharmaco-resistant seizures. Additional manifestations include failure to thrive, low muscular mass, muscular hypotonia, and movement disorders (mainly extrapyramidal). Myopathy and proximal muscle weakness are an additional feature in AGAT deficiency. Pathological signal intensities of the basal ganglia have mainly been described in patients with GAMT deficiency. Approximately 120 patients are known with GAMT deficiency, and less than 20 patients are known with AGAT deficiency. CrT deficiency may represent a major cause of X-linked intellectual disability accounting for 1–2% in males with intellectual disabilities (Rosenberg et al. 2004). Detailed clinical features are described in series of cases with AGAT, GAMT, and CrT (Stöckler-Ipsiroglu et al. 2014, 2015; van de Kamp et al. 2013).

Arginine: Glycine Amidinotransferase Aggregation Syndrome

AGAT aggregation syndrome is a newly described genetic cause of renal Fanconi syndrome and kidney failure caused by mitochondrial aggregation of fully penetrant heterozygous *GATM* missense variants (Fanconi renotubular syndrome type 1). Four previously unreported heterozygous missense variants of evolutionary conserved amino acid residues in *GATM* (p.P320S, p.T336A, p.T336I, p.P341L) have been identified in these patients. Patients with this autosomal dominant disorders develop renal Fanconi syndrome with glucosuria, hyperphosphaturia, generalized hyperaminoaciduria, low molecular weight proteinuria, and metabolic acidosis. Debilitating rickets or bone deformities have not been described in these patients (Reichold et al. 2018).

OAT Deficiency

OAT deficiency is a secondary creatine deficiency. Hyperornithinemia-associated gyrate atrophy of the choroid and retina is an inherited metabolic eye disease, caused by autosomal recessive deficiency of the L-ornithine:2-oxoacid aminotransferase (OAT) (**15.5**) (Valle and Simell 1995). Clinical features include progressive chorioretinal degeneration with myopia, night blindness, and loss of peripheral vision starting late in the first decade, proceeding to tunnel vision and eventually leading to blindness in the third and fourth decade. In addition to the ocular findings, some patients present systemic abnormalities. Most patients have normal intelligence. MRI findings include degenerative lesions in the white matter and premature atrophic changes. Tubular aggregates and selected atrophy of the type II fibers of skeletal muscle do not cause muscle weakness, although muscle performance of affected patients may be impaired when speed or acute strength is required.

OAT is a mitochondrial matrix enzyme that requires pyridoxal phosphate (vitamin B_6) for the reversible conversion of ornithine and 2-oxoglutarate to Δ1-pyrroline-5-carboxylate and glutamate. In its deficiency, the accumulation of ornithine causes secondary creatine deficiency through inhibition of AGAT activity, the rate-limiting step in endogenous creatine synthesis (Näntö-Salonen et al. 1999).

The pathways of creatine synthesis and transport are shown in Fig. 15.1.

Diagnosis

AGAT, GAMT, CrT Deficiencies

Primary creatine disorders may account for a high proportion of undiagnosed and potentially treatable genetic intellectual disability syndromes in children and adults (Stöckler-Ipsiroglu and van Karnebeek 2014). Therefore, selective screening for these disorders should be included in the investigation of this population. Cerebral creatine deficiency as detected by ^{1}H-MRS is the common biochemical hallmark of AGAT, GAMT, and CrT deficiencies. Biochemical indicators include the following metabolites in urine, blood, and CSF. Increased levels of GAA in body fluids are pathognomonic for GAMT deficiency, whereas GAA levels are reduced in AGAT deficiency. Increased urinary creatine and decreased creatinine excretion, resulting in an increased urinary creatine-to-creatinine ratio, are associated with CrT deficiency (Sharer et al. 2017). Heterozygous females may also be affected clinically, but it appears that urinary creatine/creatinine ratio and cerebral creatine levels are not reliable diagnostic markers in females (van de Kamp et al. 2011). Diagnosis of AGAT deficiency is particularly challenging as determination of urinary GAA excretion is lacking sensitivity. Determination of GAA in blood seems to be more sensitive (Stöckler-Ipsiroglu et al. 2015). In an increasing number of cases, next-generation sequencing has provided the primary diagnosis, while determination of characteristic metabolites and enzyme activities is used for disease confirmation. Assays have been developed for the determination of AGAT, GAMT, and CrT activities in fibroblasts and white blood cells (Verhoeven et al. 2003; Berends et al. 2017; Joncquel-Chevalier Curt et al. 2018).

Based on most favorable outcomes in early-diagnosed patients, newborn screening for GAMT deficiency has been implemented in several legislations (Sinclair et al. 2016; Pasquali et al. 2014). A second-tier LC-MS/MS assay for guanidinoacetate quantification from bloodspots removes the interference seen in the first-tier standard flow injection assay, thus greatly improving the performance of the assay.

Functional and in silico analyses of *GAMT* variants reported in public databases revealed *GAMT* carrier estimates of 1 in 372 and 1 in 812, respectively, and a calculated disease frequency of 1 in 550,000 and 1 in 2,640,000 (Desroches et al. 2015). The rarity of the condition may explain why, after screening of over one million newborns world-wide, the 1st case has only been identified this beginning of 2021.

Arginine: Glycine Amidinotransferase Aggregation Syndrome

Extrarenal metabolic abnormalities such as creatine and GAA deficiency are not expected to occur in this condition. The diagnosis is confined to *GATM* DNA testing. Electron microscopy and immunofluorescence staining showing intramitochondrial filaments formed by AGAT aggregates may give a first hint (Reichold et al. 2018).

OAT Deficiency

The biochemical hallmark of OAT deficiency is marked hyperornithinemia. The most important laboratory test in this disease is therefore the amino acid analysis in plasma. In patients, plasma ornithine ranges from 400 to 1400 μmol/L (normal less than 80 to 90 μmol/L). The combination of elevated plasma ornithine and characteristic ocular findings is highly specific for the disease. Ornithine is also increased in the CSF and urine. Pathologic urinary excretion of ornithine and other dibasic amino acids (arginine, lysine, cystine) typically occurs at plasma ornithine concentrations greater than 600 μmol/L. In plasma, lysine and creatine may be decreased. In urine, creatine, creatinine, and GAA are usually decreased. Investigation by in vivo ^{1}H-MRS reveals a decreased concentration of creatine and phosphocreatine in the brain and muscle. DNA testing can be performed to confirm the diagnosis. Enzyme analysis is feasible in stimulated lymphocytes but provides only sparse additional information and is not offered for routine analysis by clinical laboratories. Prenatal diagnosis is potentially possible by ornithine aminotransferase activity measurement in amniotic fluid cells or chorionic villi or by DNA testing if the genetic variant is known in the index case.

The differential diagnosis of disorders of creatine metabolism is shown in Fig. 15.2.

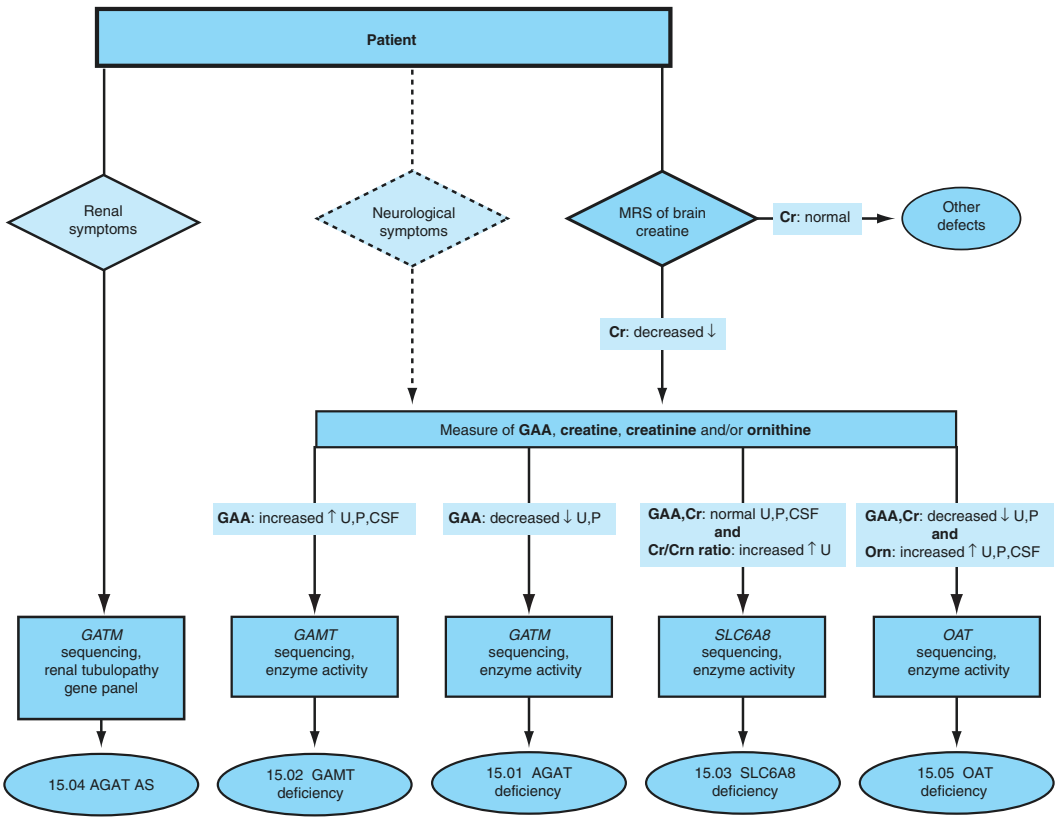

Fig. 15.2 Differential diagnosis of disorders of creatine metabolism

Treatments

GAMT, AGAT, CrT Deficiencies

In GAMT and AGAT deficiencies, correction of cerebral creatine deficiency is achieved via long-term supplementation of high dosages of creatine (given as creatine monohydrate). Clinically in AGAT deficiency, this is associated with significant improvement of myopathy, limited improvement of cognitive function in older patients, and normal development in patients treated at an early age (Stöckler-Ipsiroglu et al. 2015). In GAMT deficiency, creatine supplementation is combined with pharmacological doses of L-ornithine and/or dietary arginine restriction with the aim to reduce guanidinoacetate accumulation (Schulze et al. 2001). Treatment results in improvement of seizures and movement disorders but has limited effects on cognition and behaviors in late-treated patients, while presymptomatic/early treatment appears to completely prevent all these manifestations (Stöckler-Ipsiroglu et al. 2014; Khaikin et al. 2018). Sodium benzoate has been proposed as an additional approach to reduce the production of GAA via conjugation with glycine to form hippuric acid; however, its clinical efficacy is inconclusive (Viau et al. 2013; Mercimek-Mahmutoglu et al. 2014).

In CrT deficiency, while females may benefit from creatine supplementation, treatment of male patients even with high dosages of creatine is not effective due to the absence of functional CrT. Various combinations of L-arginine, L-glycine, and *S*-adenosyl-methionine (serving as precursors for intracerebral creatine synthesis) have also been employed. While some neurological and behavioral improvements associated with these treatments were observed in a few cases, in many others, the clinical benefit was inconclusive (Bruun et al. 2018; Dunbar et al. 2014; Valayannopoulos et al. 2012; van de Kamp et al. 2012). Creatine analogues and small molecule chaperone therapies are currently under preclinical investigation as treatment options.

Arginine: Glycine Amidinotransferase Aggregation Syndrome

It has been proposed that reduction of renal *GATM* mRNA expression via creatine supplementation may retard the formation of deleterious mitochondrial deposits (Reichold et al. 2018).

OAT Deficiency

Permanent reduction of plasma ornithine below 200 μmol/L slows or stops the chorioretinal degeneration. A small proportion of patients respond to pharmacological doses of vitamin B_6. Mainstay of treatment is substrate deprivation with a diet that consists of arginine restriction and arginine-free amino acid supplements. Additional experimental approaches include augmentation of renal ornithine excretion by administration of pharmacological doses of L-lysine (Elpeleg and Korman 2001) or the non-metabolizable amino acid α-aminoisobutyric acid and proline supplementation. Since no form of therapy is unequivocally effective, combined treatment approaches seem necessary. Creatine administration improves the histologic abnormalities in muscle, but does not halt the progress of chorioretinal degeneration.

An algorithm for the assessment of Vitamin B6 responsiveness is shown in Fig. 15.3.

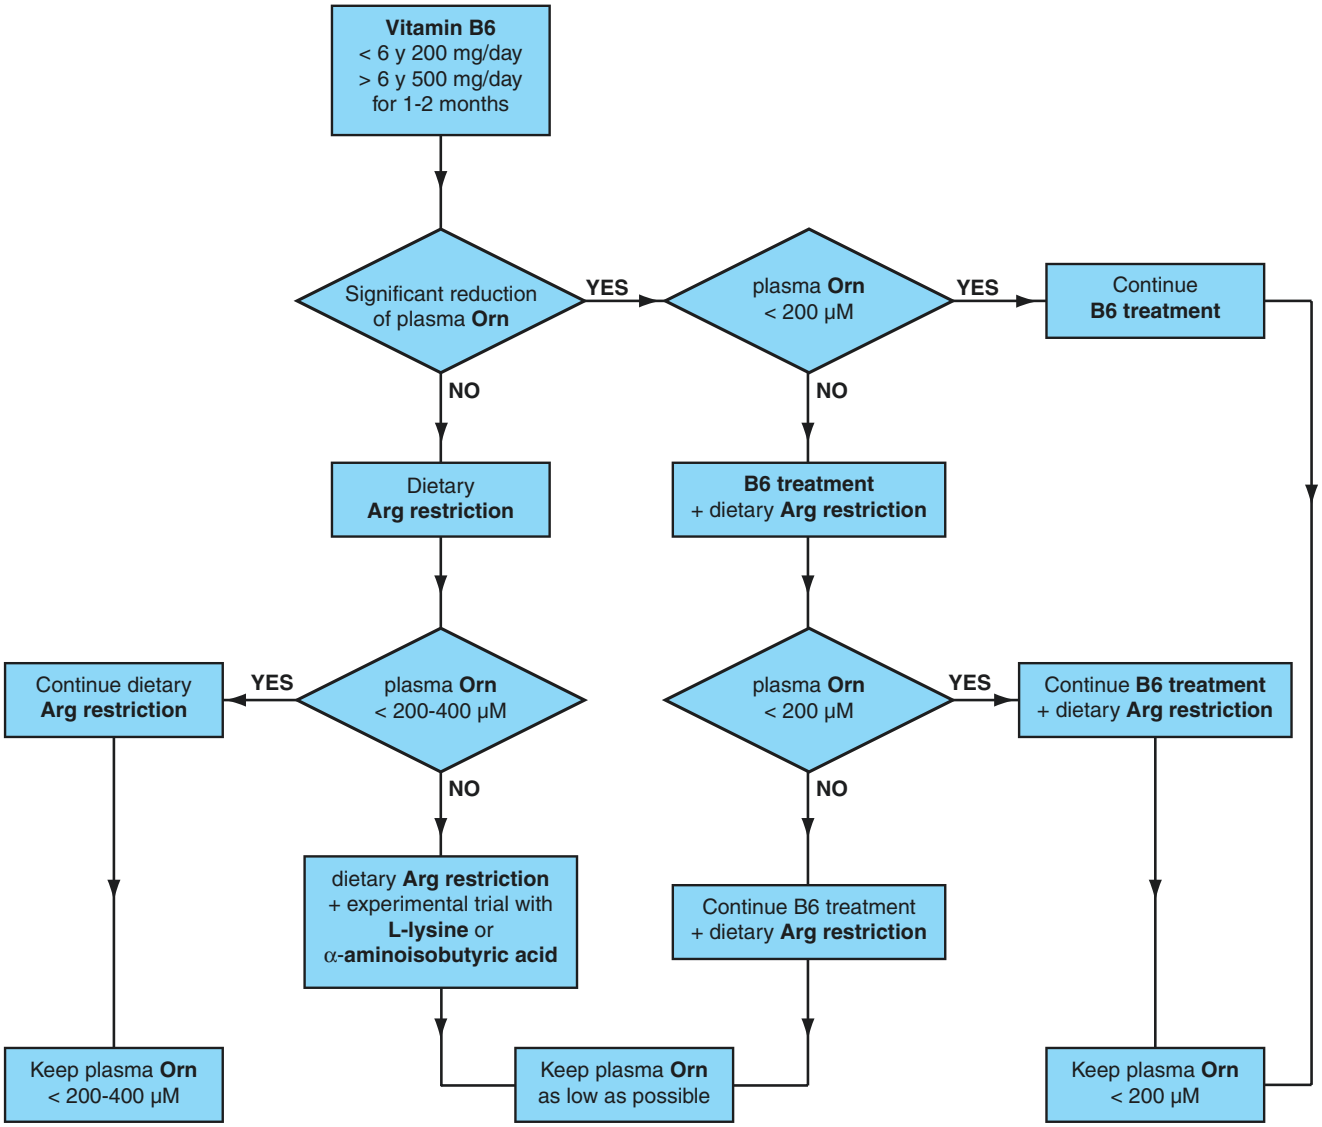

Fig. 15.3 Algorithm for the assessment of vitamin B6 responsiveness in OAT deficiency

Prenatal Diagnosis

Disorder	Method/analytes	Material	Timing semester
15.1	AGAT/GATM activity	Cultured amniotic cells	II
	DNA testing	Chorionic villi, cultured amniotic cells	I, II
15.2	GAMT activity	Cultured amniotic cells	II
	DNA testing	Chorionic villi, cultured amniotic cells Amniotic fluid	I, II II
15.3	CrT/SLC6A8 activity	Cultured amniotic cells	II
	DNA testing	Chorionic villi, cultured amniotic cells	I, II
15.4	AGAT/GATM DNA testing	Cultured amniotic cells Chorionic villi, cultured amniotic cells	II I,II
15.5	OAT activity	Cultured amniotic cells	II
	DNA testing	Chorionic villi, cultured amniotic cells	I, II

So far, prenatal diagnosis has been documented for disorders 15.1, 15.2, and 15.5, but not for 15.3 and 15.4

AGAT AS AGAT aggregation syndrome
[a]*Method*: GC-MS. *Reference*: Struys et al. (2008)
[b]*Method*: LC-MS/MS. *Reference*: Cheillan et al. (2006)
[c]*Method*: HPLC, fluorescence. *Reference*: Schulze A. Own observation in three patients
[d]Please note: Plasma ornithine may not be elevated in neonates and in the first months of life

Standard Treatment

No./symbol	Age	Medication/diet	Dosage [mg/kg per day]	Doses per day
15.1 AGAT	All ages	Creatine monohydrate	200–400[a]	3–6
15.2 GAMT	All ages	Creatine monohydrate	400	3–6
		L-Ornithine aspartate		3–6
	All ages	Low dose	100[b]	
	Children Adults	High dose	800[b] 400[b]	
	All ages	Sodium benzoate	100	3
		L-Arginine intake	15–25[c]	3–5 daily meals
		Essential amino acid mixture (arginine free)	0.2–0.7 g essential amino acids/kg	3–5 daily meals
15.5 OAT Vitamin B6 responsive form[d]	<14 years >14 years	Pyridoxine hydrochloride Diet (see below) Pyridoxine hydrochloride Diet (see below)	40–200[e] 40–500[e]	2 2
15.5 OAT Vitamin B6 nonresponsive form[d]	All ages	Arginine-restricted diet (see below)		

[a]Lower dosages of creatine monohydrate might be sufficient for restoration of the cerebral creatine pool in AGAT deficiency due to the absence of GAA accumulation and no subsequent competitive inhibition of creatine uptake
[b]Aim of low-dose substitution is to provide sufficient amounts of ornithine to the urea cycle (target plasma ornithine concentration 100–200 µmol/L) in case of an arginine-restricted diet. Aim of high-dose substitution is the competitive AGAT inhibition with high intracellular ornithine concentrations (K_m = 300 µmol/L)
[c]Corresponds to 0.4–0.7 g/kg natural protein. Essential amino acid mixture supplement is necessary in order to meet age-dependent physiological amino acid/protein requirements
[d]Target plasma ornithine concentration <200 µmol/L
[e]15–20 mg/day might be as effective in some patients as higher dosage (Weleber and Kennaway 1981)

Beware/Pitfalls

- In individuals supplemented with creatine, intake of high doses (20 g/day in adults) has been associated with weight gain (due to intracellular edema), muscle cramps, and impairment of renal function.
- Creatine monohydrate is freely available in drug stores, and attention has to be paid to the purity of the various products. In particular, after chemical synthesis from sarcosine and cyanamide, contamination with dicyanamide, which liberates HCN in the acidic conditions of the stomach, may occur as a result of incomplete purification.
- Higher doses of ornithine are preferably given as a formulation of ornithine aspartate, rather than ornithine HCl since the latter can lead to metabolic acidosis.
- Acute respiratory failure after institution of vitamin B6 is reported in a few neonates with severe seizure disorder.
- Peripheral neuropathy is associated with long-term ingestion of high-dosage vitamin B6 (>1000 mg/day).

Dietary Treatment

Age	Protein requirement [g/kg/day]	Natural protein [g/kg/day][a]	Arginine-free essential AAM	
			Type[b]	Protein equivalent[c] [g/day]
Infants	1.1–2.7	0.4	1	2–5
Children	1.0–1.7	0.3–0.5	2	10–25
Adults	0.8	0.25	2	30–75

[a]According to Dewey et al. (1996)
[b]Type 1, infantile formula; type 2, childhood formula
[c]Spread as evenly as possible through the 24 h

Beware/Pitfalls

Overtreatment through protein restriction.

Alternative Therapies/Experimental Trials

No./ symbol	Age	Medication/ diet	Dosage mg/kg per day	Dosages per day	Literature
15.3 CrT	All ages	Creatine monohydrate	100–400	3–6	Valayannopoulos et al. (2012); van de Kamp et al. (2012); Mercimek-Mahmutoglu et al. (2010); Jaggumantri et al. (2015); Schjelderup et al. (2021)
	All ages	L-Arginine	400	3	
	All ages	L-Glycine	150	3	
	All ages	*S*-Adenosyl methionine	100	2	
	All ages	Betaine	50–250	3	
15.5 OAT	Adults	Creatine monohydrate	1.5–2 g per day (1–1.5 g/m²/day)	2–3	Heinänen et al. (1999)
	Adults	L-Lysine	10–15 g per day (5 g/m²/day)	5[a]	Peltola et al. (2000); Elpeleg and Korman (2001)
	Adults	α-Aminoiso butyric acid	0.1	5[a]	Valle et al. (1981)
	All ages	L-Proline	65–488	3	Hayasaka et al. (1985)

[a]Spread within the diet as evenly as possible through the 24 h

Beware/Pitfalls

In CrT deficiency, creatine administration might be efficient in females but less in males.

In OAT deficiency, creatine administration corrects skeletal muscle abnormalities but not progress of ophthalmologic abnormalities.

Studies of the long-term efficacy of these approaches have not been reported or the results are inconclusive.

Disorder of Glutathione Metabolism

16

Verena Peters and Johannes Zschocke

Contents

Summary

Glutathione (GSH), a tripeptide composed of glutamate, cysteine, and glycine, prevents damage caused by reactive oxygen species and is metabolized via the γ-glutamyl cycle. The reduction of glutathione disulfide (GSSG) to the sulfhydryl from glutathione (GSH) is catalyzed by glutathione reductase. Several enzymes involved in the glutathione pathway, such as γ-glutamylcysteine synthetase (GCLC), glutathione synthetase (GSS), glutathione peroxidase 4 (GPX4), and glutathione reductase (GSR), are regulated, at least in part, by Nrf2 through its activation of the Nrf2-antioxidant response element. GPX4 catalyzes the reduction of hydrogen peroxide and lipid hydroperoxides at the expense of GSH.

Defects have been described in all those enzymes, except for the γ-glutamyl cyclotransferase (GGCT). The disorders are inherited in autosomal recessive, Nrf2 superactivity in an autosomal dominant manner. The most frequent disorder in human is the glutathione synthetase (GSS) deficiency, which is often associated with hemolytic anemia, a clinical feature also present in γ-glutamylcysteine (GCLC) deficiency. The severe form of glutathione synthetase (GSS) deficiency is associated with 5-oxoprolinuria, metabolic acidosis, central nervous system damage, and recurrent bacterial infections. 5-Oxoprolinuria can also be

caused by mutations in 5-oxoprolinase (OPLAH), a quite rare disease presenting with a high clinical variability. γ-Glutamyl transpeptidase (GCLC) deficiency has been found in patients with CNS involvement and glutathionuria. Dipeptidase (DPEP) deficiency has been described only in one patient with mental retardation, mild motor impairment, and partial deafness. The main clinical features of glutathione reductase (GSR) deficiency are favism and cataract. Diseases associated with glutathione peroxidase 4 (GPX4) are often associated with Sedaghatian-type spondylometaphyseal dysplasia, and Nrf2 superactivity is a multisystem disorder characterized by hypohomocysteinemia, failure to thrive, immunodeficiency, and neurodevelopmental abnormalities.

Diagnosis is made by measuring the concentration of different metabolites in the γ-glutamyl cycle and homocysteine, enzyme activity, and/or mutation analysis. Treatment aims are mainly to prevent hemolytic crises and correction of acidosis.

Introduction

The tripeptide glutathione (γ-glutamyl-cysteinylglycine, GSH) is the major nonprotein thiol and is present in millimolar concentrations in most mammalian cells. GSH is involved in several fundamental biological functions, including detoxification, scavenging of free radicals, redox reactions, biosynthesis of DNA, proteins, and leukotrienes, neurotransmission, as well as regulation in the cell cycle (Forman et al. 2009). The ratio of reduced (GSH) and oxidized glutathione (GSSG) is used as a measure of cellular oxidative stress. Disorders of glutathione metabolism are associated with a wide range of clinical features reflecting different pathophysiological functions:

- Deficiencies of enzyme involved in the biosynthesis and regeneration of GSH (γ-glutamylcysteine synthetase, glutathione synthetase, and glutathione reductase) are associated with hemolytic anemia due to reduced redox potential in red blood cells, as well as neurological and other symptoms.
- Deficiencies of enzymes involved in the breakdown of GSH (γ-glutamyl transpeptidase, γ-glutamyl cyclotransferase, and 5-oxoprolinase) may show biochemical abnormalities but are associated with no or inconsistent clinical abnormalities or have not been identified as such.
- Other disorders affecting GSH metabolism include superactivity of the Nrf2-antioxidant response element which activates transcription of a range of antioxidant enzymes involved in GSH biosynthesis and glutathione peroxidase 4 deficiency which causes Sedaghatian-type spondylometaphyseal dysplasia presumably due to impaired regeneration of lipid hydroperoxides.

γ-Glutamylcysteine synthetase (GCLC) deficiency has been described in very few patients. It is associated with hemolytic anemia and can have a mild non-neurological phenotype or a more severe phenotype with neurological manifestations which is similar to GSS deficiency (Almusafri et al. 2017; Ferguson and Bridge 2016).

Glutathione synthetase (GSS) deficiency is the most frequently diagnosed disorder of human glutathione metabolism with more than 70 patients described worldwide (Shi et al. 1996; Signolet et al. 2016; Soylu Ustkoyuncu et al. 2018). Mildly affected patients show hemolytic anemia as their only clinical symptom. Moderately affected patients show additionally metabolic acidosis (without ketosis or hypoglycemia), and severely affected patients also develop progressive neurological symptoms, such as intellectual disability, seizures, or spasticity, and may develop recurrent bacterial infections caused by defective granulocyte function. Several patients died in early life due to acidosis and electrolyte imbalances (Ristoff and Larsson 2007). About 30 different mutations have been described so far. The type of mutation involved can, to some extent, predict a mild versus a more severe phenotype (Njalsson 2005). The diagnosis of GCLC and GSS deficiencies is mainly based on low glutathione levels and low activities of the enzymes in red blood cells or fibroblasts or the presence of mutations in the genes.

Glutathione regeneration is catalyzed by glutathione reductase by reducing GSSG to GSH. **Hereditary glutathione reductase (GSR) deficiency** was first described in 1976 (van Zwieten et al. 2014). GSR is a flavoprotein, and dietary riboflavin deficiency causes a secondary GSR deficiency. In contrast to disorders in the synthesis of glutathione, the clinical outcome of glutathione reductase deficiency seems to be less severe, mainly presenting with hemolytic anemia, favism, and cataract and one patient with severe neonatal jaundice (Kamerbeek et al. 2007).

The initial degradative step of GSH is catalyzed by γ-glutamyl transpeptidase (GGT). There are two known active GGT isoenzymes encoded by different genes, *GGT1* and *GGT5*, which have different expression patterns (Heisterkamp et al. 2008). Both are membrane-bound extracellular enzymes that hydrolyze the γ-glutamyl bond and transfer the γ-glutamyl group to an acceptor, e.g., an amino acid. GSH is resistant to intracellular breakdown as both GGT isoforms are extracellular, and no other enzyme can degrade GSH. Standard GGT biochemical assays measure

the GGT1 transpeptidation reaction with an artificial substrate. Only eight patients with **γ-glutamyl transpeptidase (GGT1) deficiency** have been reported in the literature (Darin et al. 2018). The diagnosis is based on the finding of increased levels of GSH in urine and plasma and lowered enzyme activity levels. The exact genetic alteration has only been described for two siblings with glutathionuria (Darin et al. 2018). Most of the described patients have had central nervous system involvement, but causality has not been proven. Abnormalities of leukotriene metabolism have been reported in patients with GGT deficiency (see chapter on leukotriene metabolism).

Two genetic defects in the γ-glutamyl cycle have been described as causes of persistent 5-oxoprolinuria: either GSS deficiency or by **5-oxoprolinase (OPLAH) deficiency**. At least 20 mutations in *OPLAH* have been reported to date (Calpena et al. 2015; Sass et al. 2016). 5-Oxoprolinuria appears not to cause clinical symptoms and has also been observed in patients with defects in other inborn errors of metabolism, homocystinuria, type 2 diabetes, or drug metabolism as well as in other contexts (Ristoff and Larsson 2007). Further, it is considered as a worsening factor of hyperammonemic encephalopathy (Rousseau et al. 2017).

Cysteinylglycine is cleaved into cysteine and glycine by one of possibly several dipeptidases. A tentative **deficiency of cysteinylglycine dipeptidase** has been described in one patient so far, based on increased urinary cysteinylglycine and decreased activity of plasma dipeptidase. The dipeptidase also converts leukotriene D4 to leukotriene E4. Clinically, the patient presented mental retardation, mild motor impairment, and partial deafness (Mayatepek et al. 2004, 2005) (see chapter on leukotriene metabolism). Cysteine is extremely unstable and rapidly auto-oxidizes to cystine extracellularly, which can generate potentially toxic oxygen free radicals.

Glutathione peroxidase 4 (GPX4) catalyzes the reduction of hydrogen peroxide and organic and lipid hydroperoxides and therefore protects cells against oxidative damage. GPX4 is a selenoprotein (Sneddon et al. 2003), and loss of the gene (Gpx4) causes massive lipid peroxidation. **Diseases associated with GPX4** include Sedaghatian-type spondylometaphyseal dysplasia (Smith et al. 2014) and neurodegeneration (Cardoso et al. 2017). Sedaghatian-type spondylometaphyseal dysplasia is characterized by severe metaphyseal chondrodysplasia with mild limb shortening, platyspondyly, cardiac conduction defects, and central nervous system abnormalities.

The regulation of GSH synthesis is under tight control involving key enzymes including γ-glutamylcysteine synthetase, glutathione synthetase, and glutathione reductase. More importantly, these enzymes are all regulated, at least in part, by Nrf2 through its activation of the Nrf2-antioxidant response element (ARE; Abdul-Aziz et al. 2015). **Nrf2 superactivity** has been described in four patients presenting failure to thrive, immunodeficiency, and neurological symptoms (Huppke et al. 2017). Missense mutations were identified in the *NFE2L2* gene, leading to an altered cytosolic redox balance. All four patients described so far display a similar phenotype with several prominent features including developmental delay, failure to thrive, immunodeficiency, leukoencephalopathy, and hypohomocysteinemia. Hypohomocysteinemia together with elevated activity of glucose-6-phosphate dehydrogenase allows early diagnosis (Harvey et al. 2009).

Nomenclature

	Disorders of glutathione metabolism	Alternative name	Abbreviation	Gene	Chromosomal localization	Mode of inheritance	Affected protein	Omim

Metabolic Pathway

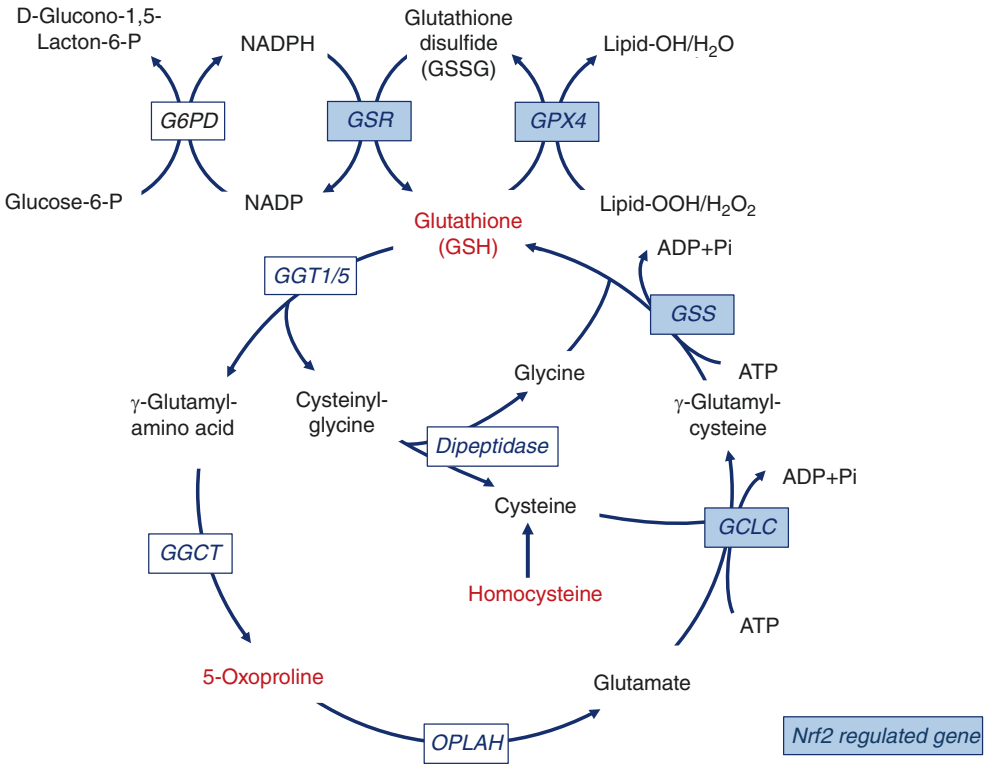

Fig. 16.1 The γ-glutamyl cycle for the biosynthesis and degradation of glutathione including known metabolic defects: γ-glutamylcysteine synthetase (GCLC), glutathione synthetase (GSS), γ-glutamyl transpeptidase deficiency (GGT1), 5-oxoprolinase (OPLAH), and dipeptidase. The reduction of glutathione disulfide (GSSG) to glutathione (GSH) is catalyzed by glutathione reductase (GSR), and peroxidase 4 (GPX4) catalyzes the reduction of hydrogen peroxide and lipid hydroperoxides at the expense of GSH. γ-Glutamylcysteine synthetase (GCLC), glutathione synthetase (GSS), peroxidase 4 (GPX4), and glutathione reductase (GSR) are regulated, at least in part, by Nrf2 through its activation of the Nrf2-antioxidant response element. No defects have been described or the γ-glutamyl cyclotransferase (GGCT). Glucose-6-phosphate dehydrogenase (G6PD) converts glucose-6-phosphate into 6-phosphoglucono-δ-lactone. Blood glutathione and homocysteine and urinary 5-oxoproline concentrations are important diagnostic markers

Diagnostic Flowchart

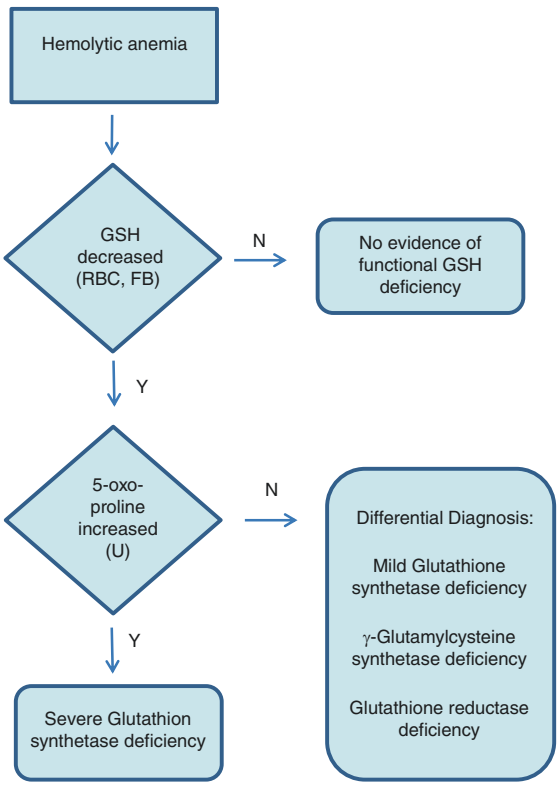

Fig. 16.2 Biochemical diagnostic flowchart for disorders of the γ-glutamyl cycle presenting with hemolytic anemia

Specimen Collection

Test	Material	Handling	Pitfalls
Glutathione	RBC, B, FB	Frozen (−20 °C)	The artificial oxidation of the sulfhydryl (SH) group of GSH, occurring during sample manipulation, may cause inconsistent values
γ-Glutamylcysteine synthetase	RBC, LYM, FB	Frozen (−20 °C)	
Glutathione synthetase	RBC, LYM, FB	Frozen (−20 °C)	
γ-Glutamyl transpeptidase	RBC, FB, P	Frozen (−20 °C)	
γ-Glutamyl cyclotransferase	RBC, LYM, FB	Frozen (−20 °C)	
5-Oxoprolinase	WBC, FB	Frozen (−20 °C)	
Glutathione reductase	LYM, RBC, tissue extracts	Cells in culture (room temperature)	
Glutathione peroxidase 4	RBC, P, cell extracts	Cells in culture (room temperature)	
5-Oxoproline	U	Frozen (−20 °C)	Excretion of 5-oxoproline has also been observed in patients with defects in other inborn errors of metabolism, homocystinuria, OCT deficiency, cystinosis, or type 2 diabetes or in patients receiving certain drugs (vigabatrin, paracetamol)
Homocysteine	P	Frozen (−20 °C)	
Glucose-6-phosphate dehydrogenase	RBC	Erythrocytes from EDTA blood	
Mutation analysis	FB, WBC, CV, AFC	Cells in culture (room temperature)	Prenatal diagnosis is greatly facilitated if the mutant allele in the specific family is known

Treatment Summary

Defects with decreased glutathione levels should avoid drugs that lead to oxidative stress. Also supplementation with antioxidants might be beneficial, but no studies have been made. The clinical goal of management of glutathione synthetase deficiency is the correction acidosis with bicarbonate, THAM, or sodium citrate. Early treatment with vitamin E (10 mg/kg/day) and vitamin C (100 mg/kg/day) has been shown to improve the condition (Ristoff and Larsson 2007; Soylu Ustkoyuncu et al. 2018). *N*-Acetylcysteine used to be recommended since it increases intracellular glutathione levels. However, cysteine has been shown to also accumulate, and since high cysteine levels have neurotoxic effects, treatment with *N*-acetylcysteine is no longer recommended (Ristoff and Larsson 2007). Patients with glutathione synthetase or γ-glutamylcysteine synthetase deficiency should avoid drugs that can induce hemolytic crisis in patients with glucose-6-*P*-dehydrogenase deficiency, e.g., phenobarbital, acetylsalicylic acid, and sulfonamides. Daily oral treatment of Nrf2 superactivity in one patient with 50 mg luteolin and 200 mg ascorbic acid reduced the frequency of infections (Huppke et al. 2017). No specific treatment has been proposed for γ-glutamyl transpeptidase, 5-oxoprolinase, dipeptidase, glutathione peroxidase 4, and glutathione reductase deficiency.

Standard Treatment

Disorder	Treatment/diet	Dosage (mg/kg/day)
γ-Glutamyl transpeptidase deficiency	No treatment has been recommended	
5-Oxoprolinase deficiency	No treatment has been recommended	
γ-Glutamylcysteine synthetase deficiency	Avoid drugs and foods known to precipitate hemolytic crisis in patients with glucose-6-phosphate dehydrogenase deficiency, e.g., phenobarbital, acetylsalicylic acid, sulfonamides	
	Early supplementation with:	
	Vitamin C	100
	Vitamin E	10
Glutathione synthetase deficiency	Avoid drugs and foods known to precipitate hemolytic crisis in patients with glucose-6-phosphate dehydrogenase deficiency	
	Early supplementation with:	
	Vitamin C	100
	Vitamin E	10
	Early supplementation with vitamin C and vitamin E. Correction of acidosis (bicarbonate, citrate, or THAM)	

Disorder	Treatment/diet	Dosage (mg/kg/day)
	Avoid drugs and foods known to precipitate hemolytic crisis in patients with glucose-6-phosphate dehydrogenase deficiency. Early supplementation with vitamin C and vitamin E. Correction of acidosis (bicarbonate, citrate, or THAM)	
Dipeptidase deficiency	No treatment has been recommended	
Glutathione reductase deficiency	No treatment has been recommended	
Glutathione peroxidase 4 deficiency	No treatment has been recommended	

Experimental Treatment

Disorder	Treatment/diet	Dosage
Nrf2 superactivity	Supplementation with luteolin[a]	50 mg/day
	And ascorbic acid [a]	200 mg/day

[a]Treatment of one patient with luteolin and ascorbic acid had no side effects but seemed to reduce the frequency of infections and increased muscle strength and endurance and general school performance (Huppke et al. 2017)

Follow-Up and Monitoring

Disorder	Clinical investigations	Laboratory investigations
γ-Glutamyl transpeptidase deficiency	Neurological investigations	
5-Oxoprolinase deficiency	Neurological investigations	Acid-base balance
γ-Glutamylcysteine synthetase deficiency	Neurological investigations	Hb, reticulocytes
Glutathione synthetase deficiency	Neurological investigations	Acid-base balance
	Eye examination (retinal pigmentations, corneal opacities)	Hb, reticulocytes

Disorders of Ammonia Detoxification

17

Johannes Häberle and Vicente Rubio

Contents

Summary

Ammonia, a product of protein catabolism, is detoxified in the liver by the urea cycle in a process that involves mitochondria and cytosol and that is carried out by six enzymes and two mitochondrial amino acid antiporters. Deficiencies in these enzymes and antiporters hamper ammonia detoxification and can cause *primary hyperammonemia*, a life- and cognition-threatening situation that can occur at any age and that can develop within hours from imbalance between ammonia production and detoxification, as in newborns with urea cycle defects following delivery. Hyperammonemia manifestations are generally unspecific and are mainly neurological, gastrointestinal, or psychiatric. Their hallmark is an unexplained change in consciousness and neurological status; indeed, hyperammonemia should be immediately excluded in any unexplained encephalopathy. Acute hyperammonemia is an emergency requiring urgent establishment of anabolism and avoidance of protein catabolism with rapid initiation (except in citrin deficiency, very rare in the West but not in the Orient) of parenteral glucose infusion and protein restriction. Additional urgent measures include dialysis to remove ammonia, and administration of carbamylglutamate and either L-arginine or L-citrulline, to try to enhance residual urea cycle function, and of the nitrogen scavengers sodium benzoate and/or sodium phenylacetate (or its

precursor, phenylbutyrate), to excrete nitrogen without use of the urea cycle. Liver transplantation is curative, correcting hepatic urea cycle function. Prognosis of acute hyperammonemia, still poor, is improving with increasing healthcare professionals' awareness.

As urea cycle operation needs substrates (ammonia, aspartate, ATP, bicarbonate, ornithine, glutamate, and acetyl coenzyme A), it can be hampered by substrate depletion or by toxic metabolites, as in *secondary hyperammonemias*. This chapter, in addition to focusing on defects of core urea cycle catalysts, will deal with other genetic conditions that may hamper the supply of ornithine, bicarbonate, glutamate, or ATP and other conditions with an impact on ammonia levels such as glutamine synthetase deficiency and glutamate dehydrogenase superactivity.

Introduction

Ammonia, the nitrogenous waste product of protein catabolism, crosses biological membranes and reaches the brain, where it is a potent neurotoxin. It causes brain edema possibly because of increased ammonia-dependent glutamine synthesis/accumulation in glial cells, with concomitant osmotically mediated water influx. Oxidative damage may also contribute to ammonia neurotoxicity (Häussinger and Görg 2010). The effects of hyperammonemia are mainly dependent on its duration and severity. Thus, it is essential to control arterial blood ammonia levels within narrow ranges (<100 μmol/L in newborns; <50 μmol/L beyond the neonatal period; Colombo et al. 1984). This is achieved by liver conversion of most of the ammonia to urea for urinary excretion, using for this conversion the urea cycle.

Periportal hepatocytes are the only cells having all the enzymes of the urea cycle (Fig. 17.1) (Grisolia et al. 1976). They extract ammonia from the portal blood (much richer in ammonia than peripheral blood) or produce it from glutamine by glutaminase (Häussinger 1990b) or from glutamate by oxidative deamination catalyzed by glutamate dehydrogenase (Fig. 17.1). In an ATP-consuming process, one molecule of each ammonia and bicarbonate enters the urea cycle inside the mitochondria of periportal hepatocytes, where the first two steps of the urea cycle, catalyzed by carbamoyl phosphate synthetase I (CPS1) and ornithine transcarbamylase (OTC), take place. The remaining three urea cycle steps, catalyzed by argininosuccinate synthetase (ASS), argininosuccinate lyase (ASL), and arginase (ARG1), are cytosolic. ASS incorporates, in an ATP-using reaction, the second ammonia molecule of urea, which is donated by aspartate (Fig. 17.1), with release by ASL of fumarate, which is reconverted to aspartate by incorporation of another ammonia molecule, to be used again by ASS. This involves the shuttling of intermediates in and out of the mitochondria and involving citrin, a liver-specific aspartate-glutamate/H^+ mitochondrial antiporter that delivers mitochondrial aspartate to ASS. Overall, urea production from ammonia requires the concerted action of five enzymes and of two mitochondrial transporters (citrin and the ornithine/citrulline mitochondrial antiporter) (Fig. 17.1). Defects in these enzymes and transporters as well as in *N*-acetylglutamate synthase (NAGS), the enzyme that produces the essential activator of CPS1, *N*-acetylglutamate (Tables 17.1, 17.2, 17.3, 17.4, 17.5, 17.6, 17.7 and 17.8), cause *primary hyperammonemia*. Symptoms of hyperammonemia dominate the presentations of CPS1 and OTC deficiencies, while hyperammonemia becomes less prominent more downstream in the cycle, particularly with ARG1 deficiency. Except OTC deficiency, which exhibits X-linked inheritance, all these defects present autosomal recessive inheritance.

This chapter covers, too, inborn errors in which ammonia detoxification can be impaired secondarily, largely by deficiency of urea cycle substrates (ammonia, aspartate, ATP, bicarbonate, ornithine, glutamate, and acetyl coenzyme A) (Häberle 2011). In the deficiency of carbonic anhydrase VA (CAVA; the specific form of carbonic anhydrase expressed in liver mitochondria) (Table 17.9), there is lack of intramitochondrial bicarbonate resulting in functional CPS1 deficiency. In lysinuric protein intolerance (LPI) (Table 17.10), citrulline, arginine, and ornithine are lost in the urine, impairing flux through the urea cycle. In pyrroline-5-carboxylate synthetase (P5CS) deficiency, the endogenous supply of ornithine is compromised (as well as proline synthesis; P5CS catalyzes the first step of both ornithine and proline synthesis). Depending on the mutation, P5CS deficiency presents dominant or recessive inheritance and can manifest (Tables 17.11, 17.12, and 17.13) as an early onset neurocutaneous syndrome or a later onset complicated spastic paraplegia with (recessive) or without (dominant) mental disability (Marco-Marin et al. 2020). Ornithine aminotransferase (OAT) deficiency can lead to neonatal or early infantile hyperammonemia (Table 17.14), reflecting the role of OAT in ornithine synthesis. The autoso-

mal dominant inherited hyperinsulinism-hyperammonemia (HIHA) syndrome (Table 17.15) results from gain-of-function mutations affecting glutamate dehydrogenase (GLUD) that cause nonregulated glutamate deamination. Following conversion of most of the portal blood ammonia to urea by periportal hepatocytes, perivenous hepatocytes further decrease the ammonia level of the liver-exiting blood by making glutamine with glutamine synthetase (GS) (Häussinger 1990a). GS deficiency is an ultra-rare condition included in this chapter because it presents moderate hyperammonemia (Table 17.16) although the urea cycle functions normally. Hyperammonemia due to impaired aspartate availability for ASS function is observed in patients of type B pyruvate carboxylase (PC) deficiency (Table 17.17). Finally, transmembrane protein 70 (TMEM70) deficiency is also included here because hyperammonemia is a manifestation of this complex condition in which oxidative phosphorylation complex V is defective, causing hypertrophic cardiomyopathy (Table 17.18).

When ammonia production exceeds urea synthesis, as in the inborn errors of the urea cycle, blood ammonia levels escalate and can reach in few hours even millimolar concentrations. The *clinical consequences of hyperammonemia* develop in parallel, with rapid escalation towards coma, rendering time crucial in the management of these patients. In about half of the patients, urea cycle disorders present within 2–3 days from birth with somnolence and lethargy accompanied by vomiting, temperature instability, and seizures, with rapid progression to coma (Brusilow and Horwich 2001; Leonard and Morris 2002). The other half of the patients exhibit later presentation (Summar et al. 2008) that can be as severe as in newborns. Indeed, urea cycle disorders can manifest at any age.

Diagnosis of the underlying disorder relies on studies of metabolites (Fig. 17.2) followed by molecular genetic (or sometimes enzymatic) confirmation.

Treatment of acute hyperammonemia aims at immediate lowering of the ammonia levels by (1) preventing protein catabolism and establishing anabolism by starting parenteral high-dose glucose infusion and stopping protein intake; (2) administering iv. the nitrogen scavengers sodium benzoate and/or sodium phenylacetate to eliminate nitrogen by alternative pathways that circumvent the urea cycle (benzoate conjugates with glycine, yielding hippurate that is excreted in the urine; the same happens for glutamine with phenylacetate, of which phenylbutyrate is a precursor) (Batshaw et al. 2001); (3) stimulating residual urea cycle function by giving, depending on the disorder, L-arginine and/or L-citrulline (these are urea cycle intermediates; Fig. 17.1) and, in NAGS deficiency and in patients with unclear diagnosis, by giving intragastrically *N*-carbamylglutamate (a commercial *N*-acetylglutamate analog that is effective orally (Rubio and Grisolia 1981)) and (4) preparing extracorporeal dialysis to rapidly lower ammonia. Chronic treatment for primary urea cycle disorders includes protein restriction (Leonard 2001; Singh 2007); supplementation of essential amino acids, trace elements, and vitamins; and oral use of nitrogen scavengers and of L-arginine or L-citrulline or, in NAGS deficiency, of *N*-carbamylglutamate. The only definitive cure of most of these conditions is liver transplantation, strongly recommended for patients with neonatal onset (Leonard and McKiernan 2004). Chronic treatment for most conditions that affect the urea cycle indirectly follows the same principles but may require additional action.

Prognosis is still bleak, particularly in cases with prolonged, severe, or recurrent episodes of metabolic decompensation (Gropman and Batshaw 2004; Gropman et al. 2007), since the duration and frequency of comatose episodes determine the severity of neurological sequelae (Picca et al. 2001). However, prognosis can be improved by earlier recognition of new patients and earlier specific therapy (Nassogne et al. 2005). Hopefully, enhanced awareness will lead to more widely available diagnosis, earlier start of specific therapy including dialysis, and hence better prognosis, while increased access to liver transplantation should expand the reach of curative therapy. New therapies, some of which still experimental, including gene therapy or editing, chemical chaperoning, nonsense mutation therapeutics, and enzyme substitution will hopefully soon reach clinical practice.

Nomenclature

Metabolic Pathways

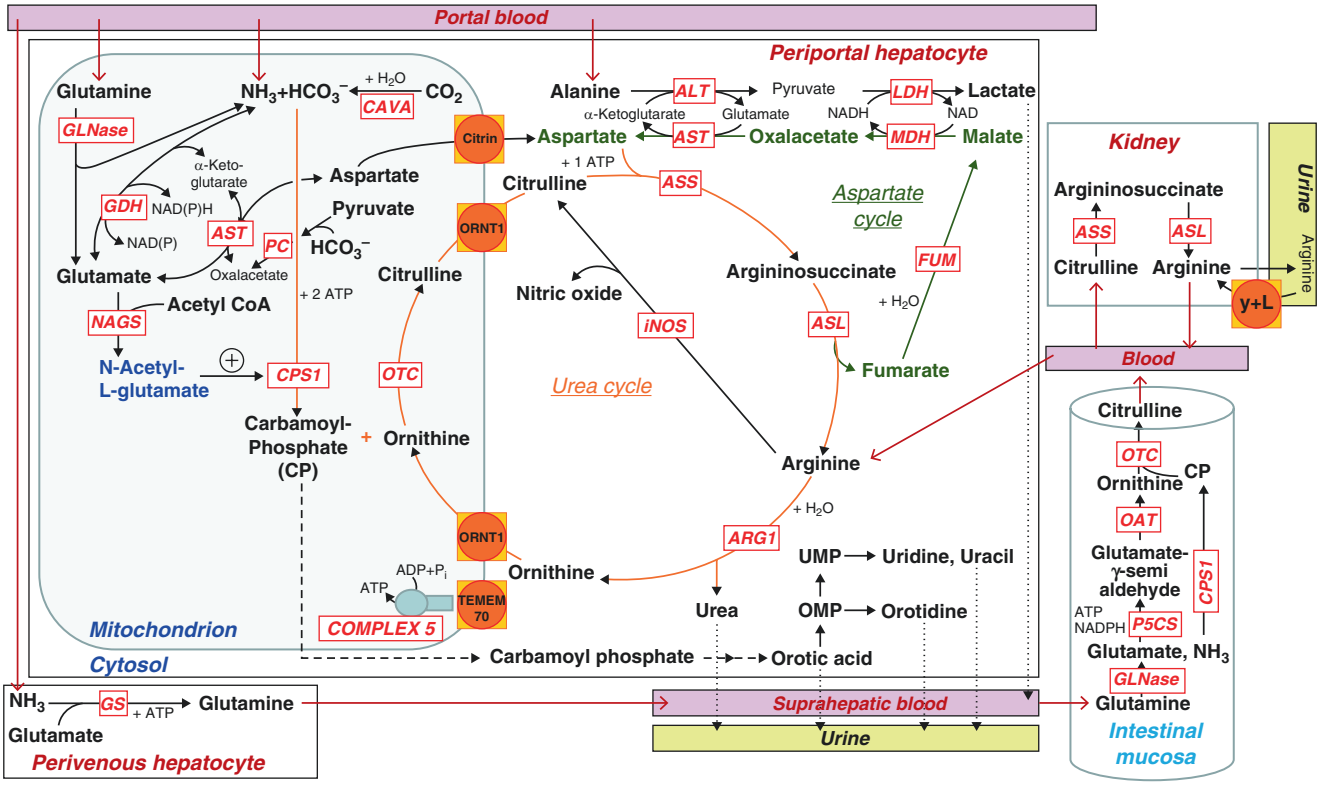

Fig. 17.1 The urea cycle and associated pathways. The central larger rectangle represents a periportal hepatocyte with the urea cycle and some ancillary reaction within it. For simplicity, not all the substrates and products of each reaction are shown. The main nitrogen-containing compounds taken by urea-synthesizing periportal hepatocytes include ammonia, glutamine, and other amino acids of which alanine is shown as the paradigm. Glutaminase (*GLNase*) and glutamate dehydrogenase (*GDH*) can supply ammonia from glutamine and glutamate, respectively, for entry into the urea cycle at the *CPS1* step. The various transaminases (of which alanine aminotransferase, *ALT*, is shown as the paradigm), coupled to aspartic transaminase (*AST*), provide the other N atom of urea as the aspartate used in the *ASS* reaction. Aspartate can also be provided by exporting it from mitochondria by citrin (in exchange for glutamate and a proton, not shown for simplicity). The fumarate produced in the *ASL* reaction is recycled and reconverted to aspartate in the "aspartate cycle," which combines the actions of fumarase (*FUM*), malate dehydrogenase (*MDH*), and *AST*. This cycle can be carried out in the cytosol if there is an adequate cytosolic supply of NAD as when utilizing alanine (thanks to the conversion of alanine-derived pyruvate to lactate by lactate dehydrogenase, *LDH*). However, if there is little cytosolic NAD supply, the malate produced by fumarase enters the mitochondria (in exchange for α-ketoglutarate), where it is converted to aspartate, which is then exported to the cytosol via citrin (for simplicity, this variant of the aspartate cycle is not shown). For convenience, the mitochondrial ornithine/citrulline antiporter (ORNT1) has been illustrated transporting separately ornithine and citrulline, although it exchanges ornithine for citrulline. A double-lined arrow next to an encircled plus sign indicates allosteric activation of *CPS1* by *N*-acetyl-L-glutamate (in blue). The reactions of pyruvate carboxylase (*PC*) in the context of mitochondrial aspartate production and of carbonic anhydrase type 5 (*CAVA*) supplying bicarbonate to CPS1 are also schematized in the mitochondria. TMEM70 is also shown in the mitochondrial membrane together with the respiratory complex *5* that is built if TMEM70 is functional, schematizing the role of this complex in mitochondrial ATP synthesis. At the bottom of the figure, in a smaller rectangle symbolizing a perivenous hepatocyte, glutamine synthesis by glutamine synthetase (*GS*) is schematized as a "polishing" reaction that converts to glutamine the small amounts of ammonia that have not been used up by periportal hepatocytes to make urea. "De novo" ornithine and citrulline synthesis from glutamate by Δ^1-pyrroline-5-carboxylate synthetase (*P5CS*) and δ-ornithine aminotransferase (*OAT*) is shown on the right, within a cylinder that symbolizes the small intestine, showing also the conversion by the kidney to arginine of the citrulline exported by the intestine to blood, illustrating the fact that this arginine ultimately provides the ornithine used by the liver to make urea. Not shown is the role of the *P5CS* reaction in proline synthesis, since it is also the first step of proline synthesis, where the glutamate semialdehyde cyclizes spontaneously to pyrroline carboxylate, which is then reduced by a reductase to give proline. This reaction occurs in most tissues but not in the intestine. Also shown in the kidney is y^+L, the system that reabsorbs dibasic amino acids and that does not work properly in LPI. The figure of the periportal hepatocyte also shows nitric oxide synthase (i*NOS* in the case of hepatocytes) in its position across the cytosolic part of the urea cycle. In macrophages and vascular cells, a reduced cycle involving ASS, ASL, and NOS appears to be operative. NAD(P) and NAD(P)H denote that *GDH* can use both NAD and NADP (and its reduced forms); *OMP* orotidine monophosphate, *UMP* uridine monophosphate. (This figure summarizes information from many sources, all of which cannot be listed because of space constraints. A summary of much knowledge is provided in Grisolia et al. (1976), with more recent data from Häussinger (1990b) and Mori et al. (1998). Data for the citrin transporter is reviewed in Imamura et al. (2003) and Mutoh et al. (2008))

[b]Argininosuccinate is converted spontaneously to its two anhydrides particularly in the urine, depending on the pH and storage conditions of the sample. Modern methods of amino acid analysis identify ASA and its two anhydrides. ASA levels are generally higher in CSF than in plasma

	Total protein (plasma)	↓↓	↓	n	n	n
	Tyrosine (plasma)	↑	↑	n	n	↑

Two forms, neonatal and later form, are distinguished. The neonatal form is dominated by intrahepatic cholestasis and jaundice, generally waning out with carbohydrate-devoid formula. The adult form is dominated by the symptoms and signs of hyperammonemia. Both forms are caused by mutations in the same gene

Table 17.9 Carbonic anhydrase VA deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Autonomic system	**Temperature instability**	+	±			
CNS	**Coma**	+	±			
	Encephalopathy	+	±			
Digestive	**Feeding difficulties**	+	±			
	Vomiting	+	±			
Metabolic	**Hypoglycemia**	+	±			
Laboratory findings	2-Oxoglutaric acid (urine)	n-↑	n-↑			
	3-Hydroxybutyric acid (urine, plasma)	n-↑	n-↑			
	3-Hydroxyisovaleric acid (urine)	n-↑	n-↑			
	3-Hydroxypropionic acid (urine)	n-↑	n-↑			
	3-Methylcrotonylglycine (urine)	n-↑	n-↑			
	Acetoacetate (urine, plasma)	n-↑	n-↑			
	Adipic acid (urine)	n-↑	n-↑			
	Ammonia (blood and plasma)	↑↑	↑			
	Arginine (plasma)	↓-n	↓-n			
	Citrulline (plasma)	↓-n	↓-n			
	Fumaric acid (urine)	n-↑	n-↑			
	Glucose (plasma)	↓	↓			
	Glutamine (plasma)	n-↑↑↑	n-↑

Orotidine	<5.0	<1.3	<0.6
Uracil	10–50	10–50	10–50

	Urine (mmol/mol creatinine)				
Age	<7 days	8 days–4 months	5 months–2 years	3–10 years	>10 years
Homocitrulline	<135	<15	<4	<11	<8

	Cerebrospinal fluid (μmol/L)	
Age	<1 year	>1 year
Glutamine[c]	390–824	352–680

Except the values for ammonia, cerebrospinal fluid, and urinary homocitrulline, these reference values are from the Metabolic Diseases Unit of the Vall d'Hebrón Hospital of Barcelona (Drs. J.A. Arranz and E. Riudor)

[a]Preanalytical problems: tourniquet, convulsions, or very heavy resistance. Cooling of the blood and prompt cell removal and ammonia analysis are essential

[b]Cells should be separated soon, since erythrocyte arginase can hydrolyze the arginine and increase the ornithine. Hemolysis must be avoided

[c]Glutamine is unstable on standing unless plasma, CSF, or urine is frozen

Pathological Values Table

Disorder	Ammonia (P)	Citrulline[a] (P)	Arginine[b] (P)	Glutamine (P)	Ornithine (P)	Proline (P)	ASA (U)	Orotic acid (U)	Homocitrulline[c] (U)	Lactate (P)	Insulin (P)

Ammonia is determined most often enzymatically using glutamate dehydrogenase. Bedside ammonia determination uses a reflectometric method. Amino acids can be determined in different ways, although the classical method is based on ion exchange chromatography with post-column derivatization with ninhydrin and colorimetric detection

Def. deficiency, *nd* not detectable, *ASA* argininosuccinate

[a]Watermelon contains citrulline, and its consumption in high amount was reported to increase citrulline levels. Take also into account the possibility that citrulline may have been administered therapeutically to the patient

[b]Exclude arginine load or take into account the possibility that arginine may have been administered therapeutically to the patient

[c]Exclude canned food or milk as a source of the homocitrulline

[d]Normal urinary level of orotic acid has been found in some neonatal onset OTC-deficient patients

[e]Sampling should be done in a fasting state; sampling during fasting is crucial not only for proline but for all the PACO (proline, arginine, citrulline, and ornithine) amino acids

Diagnostic Flowchart

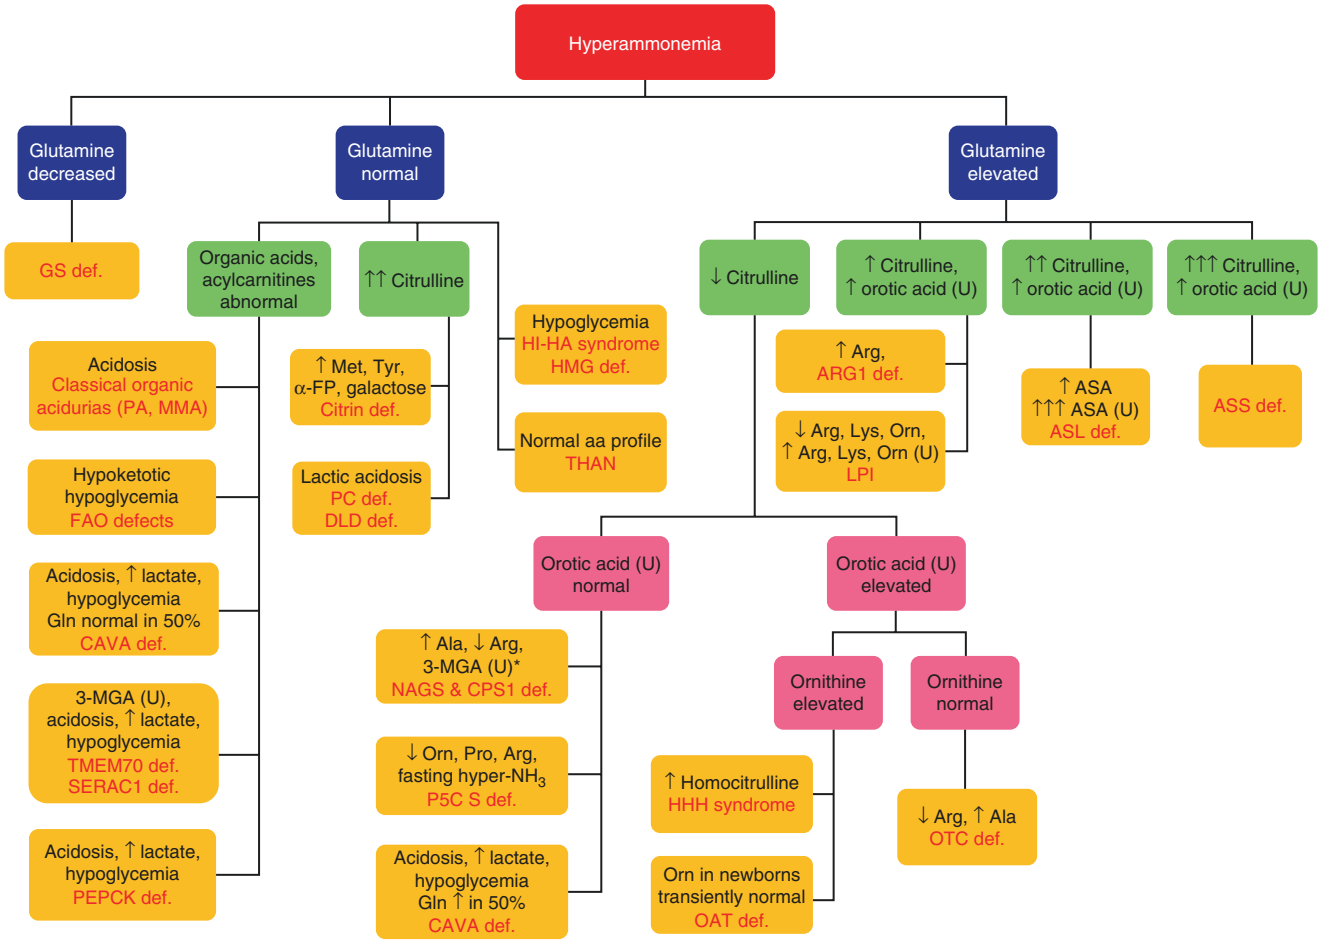

Fig. 17.2 This diagnostic flowchart describes the typical situation for each disorder; however, some patients will present with different biochemical findings. For this reason, the flowchart should guide diagnosis but must not be taken for absolute exclusion of a disorder. Unless indicated with a (*U*) (urine), the figure refers to plasma levels. Abbreviations not defined in the disease table: *α-FP* α-fetoprotein, *Ala* alanine, *ASA* argininosuccinic acid, *Arg* arginine, *Def.* deficiency, *DLD* dihydrolipoamide dehydrogenase, *FAO* fatty acid oxidation, *Gln* glutamine, *HMG* 3-hydroxy-3-methylglutaryl-CoA lyase, *Met* methionine, *3-MGA* 3-methylglutaconic acid, *MMA* methylmalonic aciduria, *Orn* ornithine, *PA* propionic acidemia, *Pro* proline, *SERAC1* serine active site-containing protein 1, *THAN* transient hyperammonemia of the newborn, *Tyr* tyrosine, *, this asterisk indicates that 3-MGA was only found in few CPS1D patients but not yet in NAGSD. (The figure was adapted from Häberle et al. (2012))

Specimen Collection

Table 17.19 Overview on methods and required samples for enzyme and mutation analysis

	Metabolites
For all disorders	Ammonia in plasma (arterial blood preferable; use tourniquets minimally; do not request muscular contractions; refrigerate blood and process at 4 °C; assay within 30 min of blood drawing)
	Amino acids in plasma (for routine analysis, draw blood 3–4 h after a meal; use Na heparin; harvest plasma promptly; avoid hemolysis; freeze plasma if analysis is to be delayed, particularly since glutamine is unstable; ASA may not be seen in certain amino acid analyzers; in these cases it can be converted first to its anhydrides by heating; watermelon contains citrulline and can increase its level)
	Orotic acid in urine (if urine is refrigerated or frozen, it can precipitate out; heat urine at 37 °C until precipitate dissolved)
	Drug levels (benzoate, phenylacetate) in serum if monitoring is required
ASL deficiency	Argininosuccinate in urine (make certain that method detects ASA)
HHH syndrome	Homocitrulline in the urine
LPI	Amino acids in urine: arginine, lysine, ornithine, and cystine (the latter being normal in LPI)
HIHA syndrome	Insulin in serum

	Mutation analysis
For all disorders	DNA
	RNA (preferred for CPS1 genetics)

	Enzyme analysis	
Disorder	Method	Sample
NAGS deficiency	Stable isotope dilution assay with GC/MS	Liver[a]
CPS1 deficiency	Colorimetric[b] or isotopic OTC-coupled assay	**Liver**[a], small intestine
OTC deficiency	Colorimetric assay[b]	**Liver**[a,c], small intestine[c]
ASS deficiency	Radiometric assay (cultured fibroblasts)	**Skin fibroblasts**, kidney, liver[a]
	Isotopically labeled citrulline incorporation[d] (cultured fibroblasts)	
	Colorimetric ASL-arginase-coupled assay (liver)	
ASL deficiency	Colorimetric, arginase-coupled assay (erythrocytes, liver, kidney)	**Skin fibroblasts**, red blood cells[e], liver[a], kidney
	Isotopically labeled citrulline incorporation[d] (cultured fibroblasts)	
ARG1 deficiency	Colorimetric assay	**Red blood cells**, liver[a]
HHH syndrome	Isotopically labeled ornithine incorporation[d]	**Skin fibroblasts**, liver[a]
Citrin deficiency	Transport activity assayed radiometrically in liposomes incorporating the recombinant transporter expressed in *Escherichia coli*	Artificial liposomes
P5CS deficiency	Incorporation of isotopically labeled glutamate into protein proline[d] can support the diagnosis[f]	Skin fibroblasts
OAT deficiency	Isotopically labeled ornithine incorporation[d]	Skin fibroblasts
PC deficiency	Radiometric assay	Skin fibroblasts

Table adapted from Häberle et al. (2012)
Bold: first choice if analysis in more than one tissue is possible
[a]Needle biopsy (>10 mg) sufficient either for NAGS assay or for assay of the other five urea cycle enzymes
Liver tissue should be snap frozen and kept at −80 °C (or below this temperature) until analysis
[b]Treatment with carbamylglutamate might interfere with some colorimetric assays of citrulline, but zero time controls can be used to subtract high blank values
[c]Reliable in males but less so in females due to X-mosaicism in all tissues
[d]Incorporation assays can be considered indirect *in vivo* enzyme assays since the amount of labeled precursor incorporated can be limited by deficiency in one of the enzymatic steps of the route that leads to such incorporation
[e]Caution: conflicting results
[f]Limited experience

Prenatal Diagnosis Table and Sample Requirements

Table 17.20 Recommended analyses and sample requirements for prenatal diagnosis

Disorder	Tests recommended
NAGS deficiency	Mutation analysis on DNA from CVS or AFC[a]
CPS1 deficiency	**Mutation analysis on DNA from CVS or AFC**
	Enzyme analysis, late fetal liver biopsy[b]
OTC deficiency	**Mutation analysis on DNA from CVS or AFC**[c]
	Enzyme analysis, late fetal liver biopsy[b,d]
ASS deficiency	**Mutation analysis on DNA from CVS or AFC**
	Citrulline in amniotic fluid
	Enzyme assays or indirect labeled citrulline incorporation assays using intact or cultured CVS or cultured AFC[e]
ASL deficiency	**Mutation analysis on DNA from CVS or AFC**
	Argininosuccinate and its anhydrides in amniotic fluid
	Enzyme assays or indirect labeled citrulline incorporation assays using intact or cultured CVS or cultured AFC[e]
ARG1 deficiency	**Mutation analysis on DNA from CVS**
	Enzyme assay in fetal blood erythrocytes (mid-gestation sampling)
HHH syndrome	**Mutation analysis on DNA from CVS or AFC**
	Enzyme assay in CVS or cultured AFC
Citrin deficiency	**Mutation analysis on DNA from CVS or AFC**
CAVA deficiency	**Mutation analysis on DNA from CVS or AFC**
LPI	**Mutation analysis on DNA from CVS or AFC**
P5CS deficiency	**Mutation analysis on DNA from CVS or AFC**
OAT deficiency	**Mutation analysis on DNA from CVS or AFC**
HIHA syndrome	**Mutation analysis on DNA from CVS or AFC**
GS deficiency	**Mutation analysis on DNA from CVS or AFC**
PC deficiency	**Mutation analysis on DNA from CVS or AFC**
	Enzyme assay in CVS or cultured AFC
TMEM70 deficiency	**Mutation analysis on DNA from CVS or AFC**

Table adapted from Häberle et al. (2012)
CVS chorionic villous sampling, *AFC* amniotic fluid cells
Bold: first choice
[a]In case of a request for prenatal testing, it should be kept in mind that NAGSD is a treatable disorder
[b]Described in single patients but not widely available and very limited experience
[c]In the female fetus, the genotype is only able to exclude *OTC* mutations. Because of the lyonization, it has no predictive value for the resulting phenotype if affected
[d]Interpretation not clear in females due to lyonization, which results in mosaicism for the expression of the X-chromosome
[e]Carried out in few laboratories

DNA Testing

Mutation analysis is feasible in all disorders described in this chapter. In all disorders, DNA from peripheral blood leukocytes can be used for PCR and direct sequencing; due to the size of the *CPS1* gene and the frequent occurrence of intronic changes, some labs prefer using RNA from stimulated lymphocytes or from cultured fibroblasts for mutation analysis. See also the table in Sect. 17.8.

Treatment

Summary

Acute symptomatic hyperammonemia is always an emergency that must be promptly treated (Häberle 2011). Treatment aims at minimizing ammonia production by preventing protein breakdown and at the same time increasing ammonia removal. Dietary protein should be withheld immediately but not for longer than 24–48 h (give thereafter at least essential amino acids). Except in citrin deficiency, in which carbohydrates are contraindicated, high-dose intravenous glucose (with or without insulin) should be given to supply high energy and to prevent endogenous protein catabolism. The nitrogen scavengers sodium benzoate and sodium phenylacetate/phenylbutyrate (or glycerol phenylbutyrate) are given to increase urinary nitrogen excretion bypassing the urea cycle, being excreted as conjugates of glycine and glutamine, respectively (Batshaw et al. 2001; Enns 2010). Administration of L-arginine (oral or intravenous) or L-citrulline (oral) enhances residual urea cycle function and urinary excretion of urea cycle intermediates (Brusilow 1984). Carbamylglutamate administration (oral) restores CPS1 function in NAGS deficiency. Nitrogen scavenger drugs and L-arginine are given at the beginning of treatment of acute hyperammonemia as boluses followed by continuous infusions.

A central venous line is desirable for administration of high glucose concentrations especially if parenteral nutrition is needed for more than 1 or 2 days, also facilitating fluid management and continuous supply of nitrogen scavengers and L-arginine.

If there is severe hyperammonemia with significant associated neurological symptoms, extracorporeal detoxification should be performed to remove ammonia, by either venovenous hemodiafiltration (infants and children) or hemodialysis (adults) (Picca et al. 2001).

Except in citrin deficiency, which is treated with high-protein, low-carbohydrate diet and L-arginine and pyruvate supplementation (Imamura et al. 2003; Mutoh et al. 2008), and in NAGS deficiency, which only requires oral carbamylglutamate, chronic treatment of all other primary urea cycle defects requires lifelong protein restriction, use of scavenger drugs and of L-arginine/L-citrulline, and preparation to cope with catabolic situations. Liver transplantation provides a definitive cure for all urea cycle disorders and for citrin deficiency.

In the case of CAVA deficiency, management of acute hyperammonemia follows the above. LPI is a more complex disorder, with currently mainly symptomatic treatment for its many complications; management of acute hyperammonemia is rarely required. For prevention of hyperammonemia, see below standard management table. In OAT deficiency, hyperammonemia is only described in patients of very young age. Management of acute hyperammonemia in PC and in TMEM70 deficiencies follows the principles of the primary urea cycle disorders.

Emergency Treatment Table and Medication Requirements

Table 17.21 Dosages of drugs to be used in acute hyperammonemia and acute decompensations

Disorder[a]	Sodium benzoate (to be given IV in glucose 10%)	Sodium PBA/sodium phenylacetate (to be given IV in glucose 10%)	L-Arginine hydrochloride (to be given IV in glucose 10%)	*N*-carbamylglutamate (only available as oral/enteral drug)
NAGS deficiency	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]; >20 kg body weight: 5.5 g/m^2/day	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]; >20 kg body weight: 5.5 g/m^2/day	250 mg/kg (1.2 mmol/kg) as bolus in 90–120 min, then maintenance 250 mg/kg/day (1.2 mmol/kg/day)	100 mg/kg bolus per nasogastric tube, then 25–62.5 mg/kg every 6 h
CPS1 deficiency and OTC deficiency	Same	Same	Same	–
ASS deficiency	Same	Same	Same	–
ASL deficiency[c]	Same	Same	200–400 mg/kg (1–2 mmol/kg) as bolus in 90–120 min, then maintenance 200–400 mg/kg/day (1–2 mmol/kg/day)	–
ARG1 deficiency[d]	Same	–	AVOID	–
HHH syndrome	Same	Same	–	–
Citrin deficiency[e]	Same	Same	10–15 g/day[f]	–
CAVA deficiency	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]; >20 kg bw 5.5 g/m^2/day	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]	250 mg/kg (1.2 mmol/kg) as bolus in 90–120 min, then maintenance 250 mg/kg/day (1.2 mmol/kg/day)	100 mg/kg bolus per nasogastric tube, then 25–62.5 mg/kg every 6 h
LPI[g]	Same	Same	Same	–
P5CS deficiency	Few patients reported with frank hyperammonemia. Arginine or protein feeding should be effective[g]			
OAT deficiency[h]	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]; >20 kg bw 5.5 g/m^2/day	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]	250 mg/kg (1.2 mmol/kg) as bolus in 90–120 min, then maintenance 250 mg/kg/day (1.2 mmol/kg/day)	–
HIHA syndrome	Not applicable			
GS deficiency	Not applicable			
PC deficiency	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]; >20 kg bw 5.5 g/m^2/day	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[b]	250 mg/kg (1.2 mmol/kg) as bolus in 90–120 min, then maintenance 250 mg/kg/day (1.2 mmol/kg/day)	–
TMEM70 deficiency	Same	Same	Same	–

Table adapted from Häberle et al. (2012)

Maximal daily drug dosages: sodium benzoate 12 g/day, sodium PBA 12 g/day, L-arginine 12 g/day (15 g/day in citrin deficiency)

Note: The doses indicated can be used at the start of treatment but must be adapted depending on plasma ammonia and amino acids

Sodium benzoate and sodium PBA/phenylacetate should be given in parallel in severe acute decompensation. In less severe cases, a stepwise approach with initial sodium benzoate and if hyperammonemia persists or worsens, the addition of sodium PBA/phenylacetate can be chosen

[a]In undiagnosed patients, consider additional use of carnitine 100 mg/kg IV, hydroxycobalamin 1 mg IM/IV, and biotin 10 mg IV/PO

[b]If on hemodialysis/hemodiafiltration, maintenance doses should be increased by 50% without exceeding the top limit given

[c]In ASL deficiency, L-arginine therapy for acute decompensations might be sufficient for some patients

[d]The risk for acute hyperammonemic decompensation is low in ARG1 deficiency

[e]Glucose or other carbohydrates should not be administered (mannitol is allowed) and protein should not be restricted

[f]Limited data in literature; dose of arginine according to Imamura et al. (2003)

[g]Rarely presentation with acute hyperammonemia

[h]Only in neonates and young infants

Standard Treatment Table and Medication Requirements

Table 17.22 Dosages of drugs to be used per orally for long-term treatment

Disorder	Diet	Sodium benzoate[a] (mg/kg/day)	Sodium PBA (g) or glycerol PBA (mL)[a,b]	L-Arginine[a] (hydrochloride and/or free base) (mg/kg/day)	L-Citrulline[a] (mg/kg/day)	Carbamylglutamate[a] (mg/kg/day)
NAGS deficiency	Normal	–	–	–	–	10–100
CPS1 deficiency	Protein-restricted	Up to 250[c,d] max. 12 g/day	Sodium PBA: <20 kg, up to 0.25 g/kg/day[c,d] >20 kg, 5 g/m²/day max. 12 g/day or glycerol PBA: Dosages in mL equal dosage in g of sodium PBA times 0.85	<20 kg, 100–200[c] mg/kg/day or 0.5–1 mmol/kg/day >20 kg, 2.5–6 g/m²/day max. 6 g/day	100–200[e] Max. 6 g/day	–
OTC deficiency	Protein-restricted	Same	Same	Same as for CPS1 deficiency	100–200[e] Max. 6 g/day	–
ASS deficiency	Protein-restricted	Same	Same	<20 kg, 100–300[c,d] mg/kg/day or 0.5–1.5 mmol/kg/day >20 kg, 2.5–6 g/m²/day[d] max. 8 g/day	–	–
ASL deficiency	Protein-restricted	Same	Same	Same as for ASS deficiency	–	–
ARG1 deficiency	Protein-restricted	Same	Same	AVOID	–	–
HHH syndrome	Protein-restricted	Same	Same	<20 kg, 100–200[c] mg/kg/day >20 kg, 2.5–6 g/m²/day max. 6 g/day	100–250[e] Max. 6 g/day	–
Citrin deficiency	Low-carbohydrate and protein-rich	For children: fat-soluble vitamins and use of lactose-free formula				
		For adults: L-arginine (5–10 g/day), sodium pyruvate (4–9 g/day), medium chain triglycerides oil (45 mL/day); liver transplantation				
CAVA deficiency	Protein-restricted (in neonates during crisis)	No reports on long-term drug treatment available				
LPI	Protein-restricted	L-citrulline 100 mg/kg/day in 4 doses Sodium benzoate and/or sodium phenylbutyrate 100–250 mg/kg/day				
P5CS deficiency	Normal	Consider ornithine and/or arginine supplementation and perhaps also proline supplementation				
OAT deficiency	Protein-restricted, especially low-ornithine	Not applicable				
HIHA syndrome	Normal	Diazoxide (for treatment of hyperinsulinism)				

(continued)

Table 17.22 (continued)

Disorder	Diet	Sodium benzoate[a] (mg/kg/day)	Sodium PBA (g) or glycerol PBA (mL)[a,b]	L-Arginine[a] (hydrochloride and/or free base) (mg/kg/day)	L-Citrulline[a] (mg/kg/day)	Carbamylglutamate[a] (mg/kg/day)
GS deficiency	Normal	No treatment available (consider oral/enteral use of glutamine and of nicotinamide)				
PC deficiency	Protein-restricted	Not applicable				
TMEM70 deficiency	Normal	Not applicable				

Table adapted from Häberle et al. (2012)

All medications should be divided into three to four doses daily taken with meals and distributed as far as possible throughout the day. Food intake and protein intake are also recommended to be divided in frequent small meals, considering a light evening snack to minimize night fasting catabolism

[a]1 g equal 6.94 mmol sodium benzoate; 5.37 mmol sodium PBA; 4.75 mmol arginine hydrochloride; 5.74 mmol arginine base; 5.71 mmol citrulline; 5.32 mmol carbamylglutamate, respectively. 1 mL glycerol phenylbutyrate delivers 6.22 mmol of phenylbutyrate

[b]PBA is the second-choice drug for long-term treatment and should be given in patients not responsive to benzoate alone (according to Häberle et al. (2019))

[c]Serum/plasma levels of benzoate/PBA and plasma levels of arginine should be monitored

[d]In some patients, higher doses are needed, according to expert advice

[e]If citrulline is given, there is usually no need for concomitant use of L-arginine

Summary

Disorders associated with the malfunction of amino acid transporters mainly affect the function of the intestine, kidney, brain, and liver. Mutations of brain amino acid transporters, for example, alter neuronal excitability (e.g., episodic ataxia due to SLC1A3 (EAAT1) defect and hyperekplexia due to SLC6A5 (GLYT2) deficiency) or brain development (SLC1A1 (EAAT3), SLC3A2/SLC7A5 (CD98hc/LAT1), and SLC1A4 (ASCT1) deficiencies). Mutations of renal and intestinal amino acid transporters SLC3A1/SLC7A9 (rBAT/$b^{0,+}$AT) and SLC1A1 (EAAT3) cause renal problems (cystinuria and dicarboxylic aminoaciduria, respectively) and malabsorption that can affect

whole-body homoeostasis (Hartnup disorder SLC6A19 (B^0AT1), lysinuric protein intolerance SLC3A2/SLC7A7 (CD98hc/y^+LAT1), and hyperdibasic aminoaciduria type 1). Mutations in the neuronal system A amino acid transporter SLC38A8 (SNAT8) cause eye developmental and visual defects. Inborn errors associated with mitochondrial SLC25 family members such as SLC25A12 (neuronal- and muscle-specific mitochondrial aspartate/glutamate transporter 1; AGC1) (global cerebral hypomyelination), SLC25A13 (aspartate/glutamate transporter 2) (citrin deficiency), SLC25A15 (ornithine-citrulline carrier 2) (homocitrullinuria, hyperornithinemia, and hyperammonemia syndrome), and SLC25A22 (mitochondrial glutamate/H+ symporter 1, GC1) (neonatal myoclonic epilepsy) will be dealt within Chap. 43 (defects of mitochondrial carriers).

Introduction

Amino acid transporters are essential for the absorption of amino acids from nutrition, mediating the interorgan and intercellular transfer of amino acids and the transport of amino acids between cellular compartments (Bröer and Palacín 2011). To date, 11 SLC families are known to comprise amino acid transporters. Defects due to mutations in amino acid transporters in six of these families affecting renal tubular reabsorption (Fig. 18.1) and intestinal absorption, neurotransmitter reuptake in the synapse (Fig. 18.2), and development of organs are considered in this chapter: (1) Mutations in the members of the glutamate transporter family SLC1A1 (EAAT3) and SLC1A3 (EAAT1) cause the primary inherited aminoaciduria named dicarboxylic aminoaciduria and episodic ataxia type 6, respectively (Bailey et al. 2011; Jen et al. 2005). (2 and 3) Mutations in the heteromeric amino acid transporters (HAT) SLC3A1/SLC7A9 (rBAT/$b^{0,+}$AT) and SLC3A2/SLC7A7 (CD98hc/y^+LAT1) cause the primary inherited aminoacidurias cystinuria and lysinuric protein intolerance (LPI), respectively (Borsani et al. 1999; Calonge et al. 1994; Feliubadaló et al. 1999; Torrents et al. 1999). Moreover, mutations in SLC3A1/SLC7A5 (CD98hc/LAT1) cause autism spectrum disorder (ASD) (Tărlungeanu et al. 2016) and in SLC3A1/SLC7A8 (CD98hc/LAT2) contribute to age-related hearing loss (ARHL) (Guarch et al. 2018). In cystinuria, mutations are found in either of the two subunits (SLC3A1 or SLC7A9) (Chillarón et al. 2010), whereas in LPI, ASD, and ARHL, mutations are only present in the light subunit SLC7A7, SLC7A5, or SLC7A8, respectively. (4) Mutations in SLC6A5 (neuronal glycine transporter GLYT2), member of the neurotransmitter branch of the neurotransmitter transporter family, cause hyperekplexia (Rees et al. 2006). Mutations in the members of the metabolic branch of this family SLC6A19 (sodium-dependent neutral amino acid transporter B^0AT) and SLC1A4 (sodium-dependent small neutral amino acid exchanger ASCT1) cause the primary inherited aminoaciduria named Hartnup disorder (Kleta et al. 2004; Seow et al. 2004) and brain (Damseh et al. 2015; Heimer et al. 2015; Srour et al. 2015), respectively. (5) Mutations in SLC36A2 (proton-dependent glycine, proline, and hydroxyproline transporter PAT2) cause hyperglycinuria and iminoglycinuria with the modulation of variants in SLC6A20 (system IMINO transporter) (Bröer et al. 2008). (6) Mutations in SLC38A8 (neuronal sodium-dependent system A transporter SNAT8) cause eye and visual defects (Perez et al. 2014; Poulter et al. 2013). Finally, one case with mutations in SLC7A2 (cationic amino acid transporter CAT2) with increased plasma concentration of arginine has been described with not yet associated pathology (Yahyaoui et al. 2019), and for the lysine malabsorption syndrome (Omura et al. 1976), dibasic aminoaciduria type I (Kihara et al. 1973), and the methionine malabsorption syndrome (Hooft et al. 1965; Smith and Strang 1958), only one or two families transmitting each disease have been described and the associated genes are unknown.

The principal biochemical and structural characteristics of these amino acid transporters have been reviewed elsewhere (Bröer and Palacín 2011). SLC1 family members (glutamate/aspartate transporters named EAAT for excitatory amino acid transporters 1–5) mediate high-affinity sodium- and potassium-dependent uptake of glutamate and aspartate in mammalian cells. SLC1A1 (EAAT3) is expressed in the apical membrane of epithelial cells of the kidney proximal convoluted tubule (Fig. 18.1) and the small intestine and in neurons of the brain cortex, particularly in the hippocampus, the basal ganglia, and the olfactory bulb. SLC1A3 (EAAT1) is found in astrocytes throughout the brain (Fig. 18.2). It is the main glutamate transporter in the cerebellum, inner ear, circumventricular organs, and retina. Expression in peripheral organs is limited (Zhou and Danbolt 2013). ASCT1 (SLC1A4) is a sodium-activated exchanger of the L-isomers of alanine, serine, cysteine, and threonine with a chloride channel activity that is thermodynamically uncoupled from amino acid transport (Zerangue and Kavanaugh 1996). ASCT1 also transports the co-agonist of NMDA glutamate receptors D-serine, and being expressed in astrocytes has been suggested to play a key role on the signaling of these receptors (Kaplan et al. 2018) (Fig. 18.2). Structural knowledge on SLC1 transporters is based on crystal structures of bacterial homologues (Reyes et al. 2009) and human EAAT1 (Canul-Tec et al. 2017).

HAT are composed of a heavy subunit (SLC3 family) and a light subunit (LAT branch of the SLC7 family), which are linked by a conserved disulfide bridge (Fig. 18.1). Both subunits are required to form functional transporters at the cell

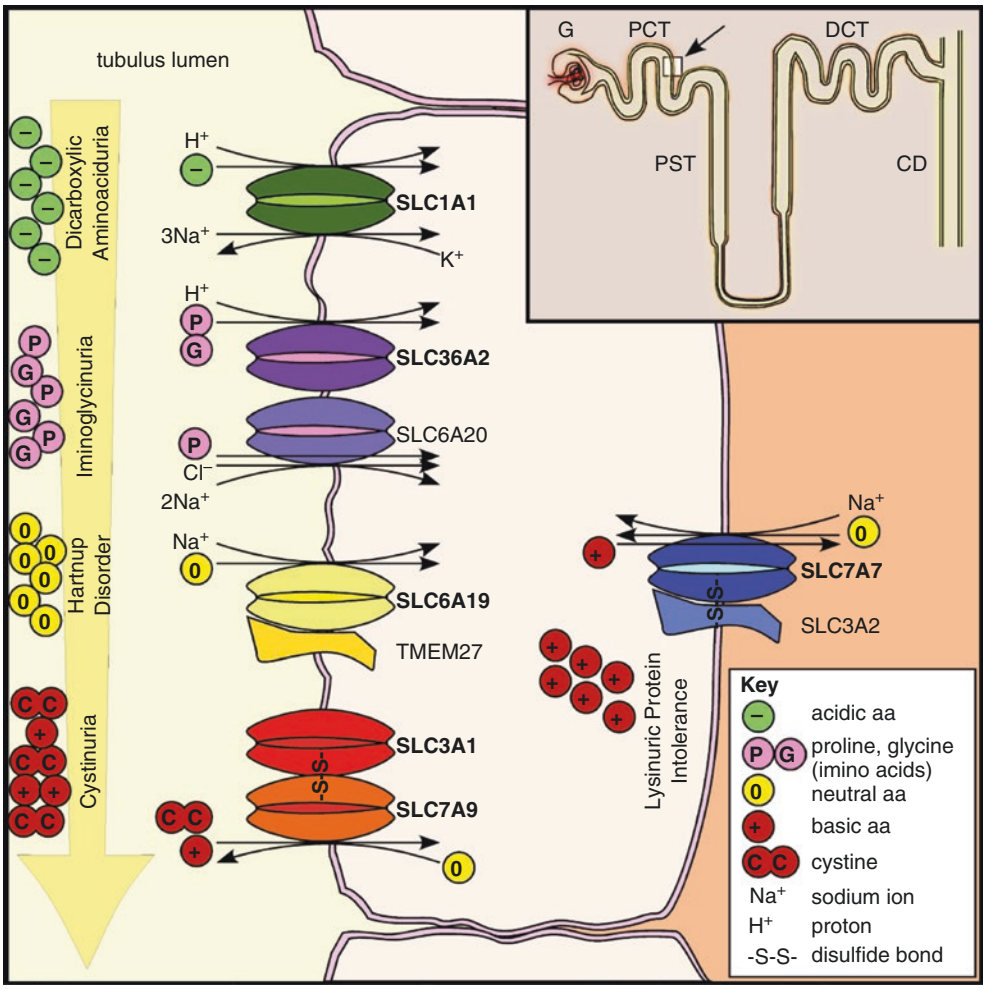

Fig. 18.1 Principal epithelial transporters involved in amino acid reabsorption, which are mutated in human aminoacidurias. A nephron is depicted (inset), showing the glomerulus (G), proximal convoluted tubule (PCT), proximal straight tubule (PST), distal convoluted tubule (DCT), and collecting duct (CD). A cross section of the proximal convoluted tubule (white square indicated with an arrow) is represented in the main diagram. Four of the aminoacidurias, including dicarboxylic aminoaciduria, iminoglycinuria (and hyperglycinuria), Hartnup disorder, and cystinuria, manifest at the apical surface of the renal tubule, while lysinuric protein intolerance manifests at the basolateral surface (see text for details). The major transporters involved in each aminoaciduria are in bold. Iminoglycinuria results from complete inactivation of SLC36A2, a proline and glycine transporter, or from additional modifying mutations in the high-affinity proline transporter SLC6A20 when SLC36A2 is not completely inactivated (Bröer et al. 2008). Iminoglycinuria is a benign condition with no associated pathology. Mutations in the neutral amino acid transporter, SLC6A19, are responsible for Hartnup disorder (Kleta et al. 2004; Seow et al. 2004). The neutral amino acid transport defect can also be exacerbated by a kidney-specific loss of heterodimerization of mutant SLC6A19 with TMEM27 (Kowalczuk et al. 2008). Finally, no mutations have been identified in SLC3A2, coding for the ancillary protein of y^+LAT1 (SLC7A7) in patients with LPI (Bröer and Palacín 2011). Renal amino acid transporters not depicted in the scheme because have not been related to aminoacidurias: (1) SLC3A1/SLC7A13 is expressed in the apical membrane of PST epithelial cells and exchanges cystine and dicarboxylic amino acids (Nagamori et al. 2016), (2) the neutral amino acid exchanger SLC3A2/SLC7A8 and the uniport of aromatic amino acids SLC16A10 are expressed in the basolateral membrane of the PCT epithelial cells where cooperate in the renal reabsorption of neutral amino acids (Vilches et al. 2018). Figure extracted from Bailey et al. (2011)

surface. HAT are amino acid exchangers. Transporter SLC3A1/SLC7A9 (rBAT/$b^{0,+}$AT) is expressed in the apical membrane of epithelial cells of the kidney proximal convoluted tubule and the small intestine (Calonge et al. 1994; Feliubadaló et al. 1999) and transporter SLC3A1/SLC7A13 (rBAT/AGT1) in the kidney proximal straight tubule (Nagamori et al. 2016) (Fig. 18.1). rBAT/$b^{0,+}$AT participates in renal and intestinal (re)absorption of cysteine and cationic amino acids, and rBAT/AGT1 putatively in renal reabsorption of cysteine. Transporter SLC3A2/SLC7A7 (CD98hc/y^+LAT1) is mainly expressed in the basolateral plasma membrane of the epithelial cells of the kidney proximal convoluted tubule (Fig. 18.1) and the small intestine, with a role in (re)absorption of cationic amino acids, and in white blood cells (Borsani et al. 1999; Torrents et al. 1999). Transporter SLC3A2/SLC7A5 (CD98hc/LAT1), which exchanges large

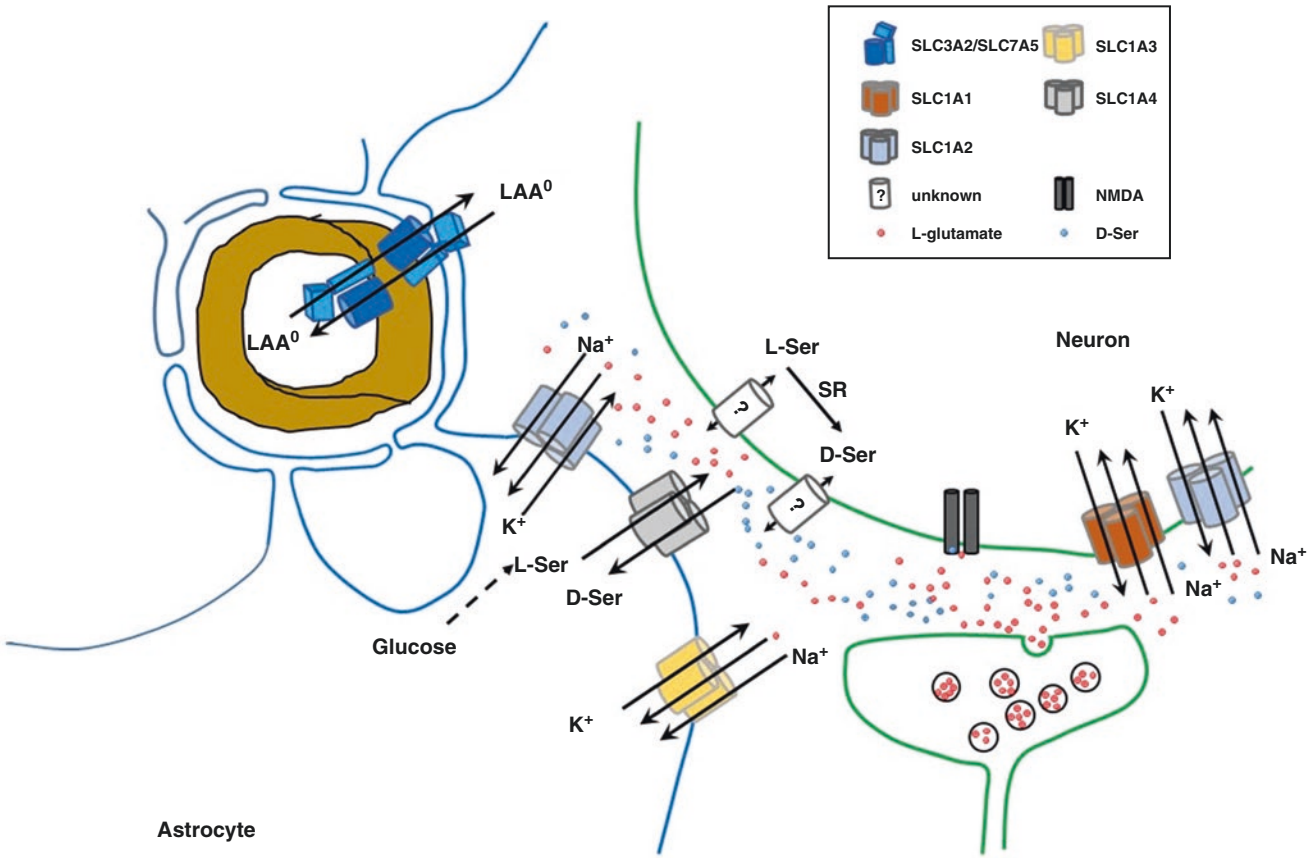

Fig. 18.2 SLC3A2/SLC7A5 transporter in the blood-brain barrier and principal transporters involved in glutamatergic synapsis with NMDA glutamate receptors. The large neutral amino acid (LAA^0) exchanger CD98hc/LAT1 heterodimer is expressed in the endothelial cells (brown) of the blood-brain barrier and mediates access of essential branched chain amino acids to the central nervous system to support proper development. The Na^+- and K^+-coupled glutamate transporters SLC1A3 (astrocytes), SLC1A1 (neurons), and SLC1A2 (astrocytes and neurons) terminate transmission by active uptake of glutamate from the synaptic cleft in glutamatergic synapses (Zhou and Danbolt 2013). SLC1A4 exchanges L-serine (L-Ser) and D-serine (D-Ser) across the plasma membrane of astrocytes. This is a key element of the "Serine shuttle" that allows that the L-serine synthetized in the astrocytes from glucose is transferred to neurons to produce D-serine, by serine racemase (SR), that acts as a co-agonist of NMDA glutamate receptors (Kaplan et al. 2018). Loss-of-function mutations in SLC7A5 and ASCT1 cause, among other alterations, microcephaly. Loss-of-function mutations in SLC1A1 cause dicarboxylic aminoaciduria with mental retardation and in SLC1A3 cause episodic ataxia. L- and D-serine transporters in neurons and the blood-brain barrier are not depicted here

neutral amino acids, is expressed in the endothelial cells of the blood-brain barrier (Fig. 18.2). Loss-of-function in mouse causes dramatic increase of histidine and depletion of branched chain amino acids in cerebral spinal fluid (Tărlungeanu et al. 2016). Transporter SLC3A2/SLC7A8 (CD98hc/LAT2) has a broad tissue expression, including the basolateral membrane of renal and small intestinal epithelial cells where has a role on renal reabsorption of neutral amino acids (Vilches et al. 2018), and in fibrocytes of the cochlea where supports proper aging of the organ (Guarch et al. 2018). SLC7A2 (CAT2) is a member of the other branch of the SLC7 family, the cationic amino acid transporters (CATs). LATs are exchangers with different amino acid substrate profiles, whereas CATs mediate transport of cationic amino acids in favor of chemical and electrical gradients (see Fotiadis et al. 2013, for a review). The structure of the human heteromeric CD98hc/LAT1 complex has been elucidated (Lee et al. 2019; Yan et al. 2019), as well as that of bacterial homologues of LATs (Errasti-Murugarren et al. 2019) and CATs (Jungnickel et al. 2018) transporters.

The SLC6 family comprises 20 members in humans that can be grouped into four subfamilies, namely, the monoamine transporter branch, the GABA (γ-aminobutyric acid) transporter branch, and the amino acid transporter branches I and II. SLC6A5 (GLYT2) and SLC6A19 (B^0AT1) belong to the two latter subfamilies and mediate reuptake of glycine in synapses and the uptake of neutral amino acids in epithelial cells, respectively. GLYT2 is mainly found in the spinal cord where it terminates inhibitory neurotransmission. B^0AT1 is found in the apical membrane of kidney proximal tubular epithelial cells (Fig. 18.1) and enterocytes of the small intestine. Structural understanding of this family is derived from the bacterial transporter LeuT, for which structures are available in all conformations (Penmatsa and

Gouaux 2014), the dopamine transporter from *Drosophila* (Penmatsa et al. 2013), and the human serotonin transporter (Coleman et al. 2016).

Finally, transporters of the SLC38 family are found in all cell types of the body. They mediate sodium-dependent net uptake (system A) and sodium- and proton-dependent influx and efflux (system N) of amino acids (see Bröer 2014, for a review). SLC38A8 (SNAT8) is a system A transporter for L-glutamine, L-alanine, L-arginine, L-histidine, and L-aspartate. In mouse, SNAT8 is expressed in adult and fetal brain and in spinal cord and shows weaker expression in other tissues. Protein SNAT8 is present throughout the neuronal retina, with stronger staining in the inner and outer plexiform layers and photoreceptor layer (Perez et al. 2014) and in all neurons, both excitatory and inhibitory, in mouse brain (Hägglund et al. 2015). Structural understanding of this family has been obtained through the crystal structure of the lysosomal member SLC38A9 from zebrafish (Lei et al. 2018).

Nomenclature

No.	Disorders of amino acid transport	Alternative name	Abbreviation	Inheritance	Gene symbol	Chromosomal localization	Affected protein	OMIM no.
18.1	Hartnup disorder		HD	AR	*SLC6A19*	5p15.33	Sodium-dependent neutral amino acid transporter (B^0AT1)	234500
18.2	Iminoglycinuria		IG	AR (or digenic)	*SLC36A2* (±*SLC6A20*)	5q33.1 (3p21.31)	Proton amino acid transporter (PAT2) (system imino transporter SIT)	242600
18.3	Hyperglycinuria		HG	AD	SLC36A2	5q33.1	Proton amino acid transporter (PAT2)	138500
18.4	Cystinuria type A		Cystinuria A	AR	*SLC3A1* (1)	2p16.3	Amino acid transport system b(0,+) composed by rBAT (SLC3A1) and $b^{0,+}AT$ (SLC7A9) and the cysteine/dicarboxylic amino acid exchanger composed by rBAT (SLC3A) and AGT1 (SLC7A13)[a]	220100
18.5	Cystinuria type B		Cystinuria B	AD, AR	*SLC7A9*	19q12	Amino acid transport system b(0,+) composed by rBAT (SLC3A1) and $b^{0,+}AT$ (SLC7A9)	220100
18.6	Lysinuric protein intolerance	Dibasic aminoaciduria type 2	LPI	AR	*SLC7A7*	14q11.2	Amino acid transport system y^+L (CD98hc/y^+LAT1) (SLC3A2/SLC7A7)[b]	222700
18.7	Dicarboxylic aminoaciduria		DA	AR	*SLC1A1*	9p24	Neuronal/epithelial high-affinity glutamate transporter, excitatory amino acid transporter 3 (EAAT3)	222730
18.8	Lysine malabsorption syndrome							247950
18.9	Dibasic aminoaciduria type 1			AD				222690
18.10	Methionine malabsorption syndrome	Oasthouse disease; Smith-Strang disease; methioninuria						250900

(continued)

No.	Disorders of amino acid transport	Alternative name	Abbreviation	Inheritance	Gene symbol	Chromosomal localization	Affected protein	OMIM no.
18.11	Cationic amino acid transporter 2 deficiency			AR	SLC7A2	8p22	Cationic amino acid transporter 2 (CAT2)	601872
18.12	Large neutral amino acid transporter deficiency	SLC7A5 deficiency		AR	*SLC7A5*	16q24.2	Amino acid exchanger L composed by CD98hc (SLC3A2) and LAT1 (SLC7A5)	600182
18.13	Neuronal system A amino acid transporter deficiency	Foveal hypoplasia type 2 with or without optic nerve misrouting and/or anterior segment dysgenesis		AR	*SLC38A8*	16q23.3	Neuronal sodium-dependent system A amino acid transporter SNAT8	609218
18.14	Glutamate aspartate transporter deficiency	EAAT1 deficiency; episodic ataxia type 6	EA6	AD	*SLC1A3*	5p13	Glutamate/aspartate transporter (GLAST); excitatory amino acid transporter 1 (EAAT1)	612656
18.15	ASCT1 transporter deficiency	Spastic tetraplegia, thin corpus callosum, and progressive microcephaly		AR	*SLC1A4*	2p14	Glutamate/neutral amino acid transporter ASCT1	616657
18.16	Hyperekplexia due to glycine transporter GLYT2 defect	Startle disease, familial		AR	*SLC6A5*	11p15.1	Neuronal glycine transporter GLYT2	614618

[a]Different recessive contiguous gene deletion syndromes involving PREPL and a variable combination of SLC3A1 (hypotonia-cystinuria syndrome), CAMKMT (atypical hypotonia-cystinuria syndrome), and PPM1B (2p21 deletion syndrome) have been described (Régal et al. 2018)
[b]CD98hc (SLC3A2) is also named 4F2hc

Signs and Symptoms

Table 18.1 Hartnup disorder

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Table 18.10 Methionine malabsorption syndrome

System	Symptoms and biomarkers	Neonatal (birth–1 month)[a]	Infancy (1–18 months)[a,b]	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Convulsions	+	+	+	+	
	Intellectual disability	+	+	+	+	
Digestive	Diarrhea	+	+	+	+	
Hair	White hair	+	+	+	±	
Respiratory	Hypernoea (attacks)	+	+	+	+	
Other	Oasthouse smell (U)	+	+	+	+	
Laboratory findings	3-Hydroxybutyric acid (U)	↑	↑	↑		
	Branched chain amino acids (U)[c]	↑	↑	↑		
	Methionine (U)[c]	↑	↑	↑		
	Serine (U)	↑	↑	↑		

[a]A neonatal girl was first described with the "oasthouse disease" with hyperexcretion in urine of α-hydroxybutyric acid and amino acids (phenylalanine, tyrosine, and methionine) and a suspected phenylketonuria (PKU) mimicked condition (Smith and Strang 1958). A toddler girl presented similar symptoms but without PKU signs (Hooft et al. 1968, 1965). Methionine malabsorption was demonstrated in this patient
[b]Methionine-poor diet introduced at 2 years of age improved all the signs and symptoms with the exception of mental retardation
[c]The indicated aminoaciduria was not detected in the second patient (Hooft et al. 1968, 1965)

Table 18.11 Cationic amino acid transporter 2 deficiency

System	Symptoms and biomarkers[a]	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Other	No clinical symptoms					
Laboratory findings	Arginine (P)	↑	↑	↑		
	Arginine/ornithine ratio (P)	n				
	Arginine, lysine, ornithine (U)	↑	↑	↑		
	Asymmetric dimethylarginine (P, U)	n		n		
	Guanidinoacetate (U)	↑		n		
	Lysine (P)	↑	↑	↑		
	NO (nitrate/nitrite)	n		n		
	Ornithine (P)	n	n	n		
	Symmetric dimethylarginine (U)	↑		n		

[a]Only a 4-year-old boy has been reported (Yahyaoui et al. 2019). After identifying hyperargininemia in newborn screening (dried blood spot) and diagnosis (1 month old), the infant is on protein-restricted diet of 2 g/kg/day with PFD1 formula 30 g/day to control amino acid levels. He has been asymptomatic and presents normal psychomotor development

Table 18.12 Large neutral amino acid transporter deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	**Autism spectrum disorder**		++	++	++	++
	Developmental delay	++	++			
	Microcephaly	++	++	++		
	Motor delay	–	++	++		
Laboratory findings	Branched chain amino acid levels (CSF)	+	+	+	+	+

Table 18.13 Neuronal system A amino acid transporter deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)	Characteristic
Eye	Anterior segment dysgenesis[a]					±	
	Defective visual acuity		+			+	
	Foveal hypoplasia		+			+	
	Nystagmus[b]		+			+	
	Ocular albinism		–			–	
	Optic nerve decussation defects[a]					+	
	Refractive errors[b]					±	
Other	Albinism		–			–	

Fifteen patients from seven families of diverse origin and nine patients from three families of Jews Indian (Mumbai region) ancestry have been reported by Perez et al. (2014) and Poulter et al. (2013), respectively

[a]Optic nerve decussation defects (misrouting in the optic chiasm) and dysgenesis of the anterior segment of the eye have only been characterized in Poulter et al. (2013)

[b]Nystagmus and refractive errors have only been characterized in Perez et al. (2014)

Table 18.14 Glutamate aspartate transporter deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Other	Sudden infant death	±	±			

Metabolic Pathways (See Figs. 18.1 and 18.2)

Metabolites Important for Diagnosis

Hartnup disorder Metabolites important for diagnosis: neutral amino acids in the urine (glycine is usually normal).

Iminoglycinuria Metabolites important for diagnosis: glycine, proline, hydroxyproline in urine.

Hyperglycinuria Metabolites important for diagnosis: glycine in urine (proline and hydroxyproline are normal).

Cystinuria A and Cystinuria B Due to mutations in SLC3A1 (rBAT) or SLC7A9 (b0,+AT), respectively. Metabolites important for diagnosis: cystine, lysine, arginine, and ornithine in urine.

Lysinuric protein intolerance Metabolites important for diagnosis: dibasic amino acids in the plasma (decreased) and urine (increased) and orotic acid in urine (increased).

Dicarboxylic aminoaciduria Metabolites important for diagnosis: glutamate and aspartate in the urine.

Lysine malabsorption syndrome Metabolites important for diagnosis: Lys, Arg, Orn in urine and plasma.

Dibasic aminoaciduria type I Metabolites important for diagnosis: lysine, arginine, and ornithine in urine.

Methionine malabsorption syndrome Metabolites important for diagnosis: α-hydroxybutyrate (oasthouse smell), Met, BCAA, and Ser in urine and feces.

Cationic amino acid transporter 2 deficiency Metabolites important for diagnosis: Arg, Lys, ornithine, and guanidinoacetic acid.

Large neutral amino acid transporter LAT1 deficiency Metabolites important for diagnosis: not identified, but branched chain amino acid levels are expected to be below reference values in patients.

Neuronal system A SNAT8 transporter deficiency Metabolites important for diagnosis: not identified.

Episodic ataxia due to EAAT1 defect Metabolites important for diagnosis: not identified.

ASCT1 transporter deficiency Metabolites important for diagnosis: not identified.

Hyperekplexia due to GLYT2 deficiency Metabolites important for diagnosis: not identified.

Reference Values

Urine amino acid levels (mmol/mol creatinine) (5–95 percentile limits) measured by amino acid analyzer.

Amino acid	Neonatal	Infancy	Childhood	Adolescence	Adulthood
	Fasting	Fasting	Fasting	Fasting	Fasting
Alanine	75–244	36–206	33–130	17–92	16–68
Arginine	<14	<11	<9	<6	<5

Pathological Values

Hartnup disorder Altered urine amino acid levels (lower and upper values in mmol/mol creatinine) in adults with HD (Potter et al. 2002).

Amino acid	Patients HD
Alanine	384–1436
Glutamate	15–29
Glutamine	515–2010
Glycine	159–708
Histidine	325–653
Isoleucine	14–194
Leucine	16–200
Lysine	2–88
Methionine	5–51
Phenylalanine	12–122
Serine	546–842
Threonine	233–665
Tyrosine	2–281
Valine	43–566

Urine samples obtained by random collection. Glutamate and lysine are usually slightly elevated, but no in all HD patients

Iminoglycinuria Altered urine amino acid levels (lower and upper values in mmol/mol creatinine) in adults with IG (Bröer et al. 2008).

Amino acid	Patients IG
Glycine	576–1965
Proline	33–1000
Hydroxyproline	35–250

Hyperglycinuria Altered urine amino acid levels (lower and upper values in mmol/mol creatinine) in adults with HG (Bröer et al. 2008).

Amino acid	Patients HG
Glycine	174–632

Cystinuria A and B Altered urine amino acid levels (5–95 percentile limits in mmol/mol creatinine) in cystinuria (Font-Llitjós et al. 2005).

Amino acid	Controls[a]	Cystinuria patients[b]	Type B carriers[c]
Cystine	3–12	73–385	15–152
Lysine	4–56	300–1315	56–507
Arginine	<5	26–946	0–38
Ornithine	1–8	66–389	2–59

Urine samples randomly collected (morning or 24 h) from 83 controls and 34 patients and 127 type B carriers of any age
[a]Controls were relatives of cystinuria patients without mutations in SLC3A1 and SLC7A9
[b]Patients with two mutated SLC3A1 alleles (cystinuria type A); similar ranges of values were obtained from the urine of patients with cystinuria type B (two mutated SLC7A9 alleles)
[c]Values from cystinuria type B carriers ($b^{0,+}$AT heterozygotes) are also shown

Lysinuric protein intolerance Altered amino acid plasma concentration (mM) in 20 patients (the range of lower-upper values is shown) (Simell 2001). Altered urine excretion values (mmol/mol creatinine) of amino acids and orotic acid after overnight fasting in one LPI patient (provided by R. Artuch from Gómez et al. 2006). Reference values for urine orotic acid excretion (1.2–6.9 mmol/mol creatinine).

Amino acid	Plasma	Urine
Alanine	0.42–1.02	116
Arginine	0.01–0.06	661
Citrulline	0.14–0.53	53
Glutamine	3.64–7.16	149
Glycine	0.39–0.53	240
Lysine	0.03–0.18	1040
Ornithine	<0.08	112
Carbamoyl phosphate metabolite		
Orotic acid	–	30

Dicarboxylic aminoaciduria Altered urine amino acid levels (lower and upper values in mmol/mol creatinine) in DA (Bailey et al. 2011).

Amino acid	Reference values		Patients DA	
	Infancy	Adulthood	Infancy	Adulthood
Aspartate	<26	<15	50	46–51
Glutamate	<63	<36	1225	1052–1377

Urine samples obtained by random collection

Lysine malabsorption syndrome Cationic amino acids and cystine urine levels (mmol/mol creatinine) in the only patient identified (Omura et al. 1976). The normal range reported in this publication is also shown.

Amino acid	Normal range values	Reported patient
Lysine	19–100	1414
Arginine	Trace-13	13
Ornithine	Trace-21	27
Cystine	Trace-14	13

Dibasic aminoaciduria type I Altered urine amino acid levels (range of values in six determinations within 2 years) of the only identified patient with hyperdibasic aminoaciduria type I (mmol/mol creatinine) (Kihara et al. 1973).

Amino acid	Controls[a]	Patient
Cystine	3	22–45
Lysine	12	400–803
Arginine	2	11–56
Ornithine	9	21–83

[a]Control reference values in the Pacific State Hospital (California, USA) at the time of the study

Methionine malabsorption syndrome Metabolite important for diagnosis: α-hydroxybutyrate (oasthouse smell) in urine and feces (Hooft et al. 1968, 1965). To our knowledge, quantitative determination of α-hydroxybutyrate in urine and feces before methionine-poor diet was introduced in the patient has not been reported. Under methionine-poor diet, no α-hydroxybutyrate is detected in urine and feces (Hooft et al. 1968).

Cationic amino acid transporter 2 deficiency Metabolites important for diagnosis in plasma and urine in the unique patient described (Yahyaoui et al. 2019).

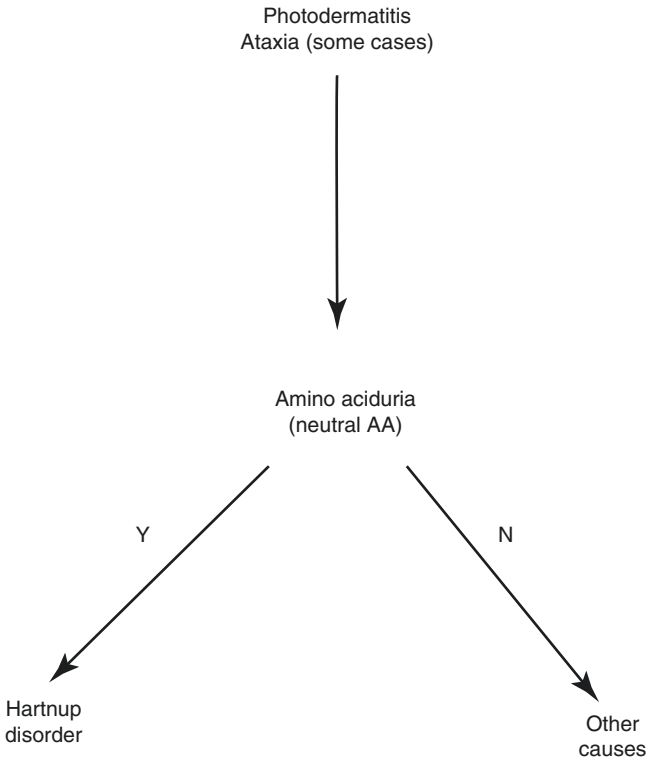
	Reference values	Patients DA	
Plasma (μM)	Infancy	Neonate	Infant[a]
Lysine	199–209	599	392
Arginine	34–88	312	261
Ornithine	1–25	177	121
Urine (mmol/mol creatinine)			
Lysine	25–191	1005	632
Arginine	1–19	94	350
Ornithine	1–25	42	108
Guac[b]	11–168	380	82
ADMA[b]	4.7–12	50	26

[a]Analysis performed at 2 years of age. Currently, the child receives a protein-controlled diet of 1.2 g/kg/day with protein- and amino-acid-free infant formula (PFD1), 30 g/day, and is asymptomatic
[b]*Guac* guadinoacetic acid, *ADMA* asymmetric dimethylarginine

Large neutral amino acid transporter LAT1 deficiency No pathological values of amino acids in the cerebral spinal fluid of patients are available. According to *Slc7a5* knockout mice amino acid levels in cerebral spinal fluid (Tărlungeanu et al. 2016), branched chain amino acids in cerebral spinal fluid are expected to be below reference values in patients.

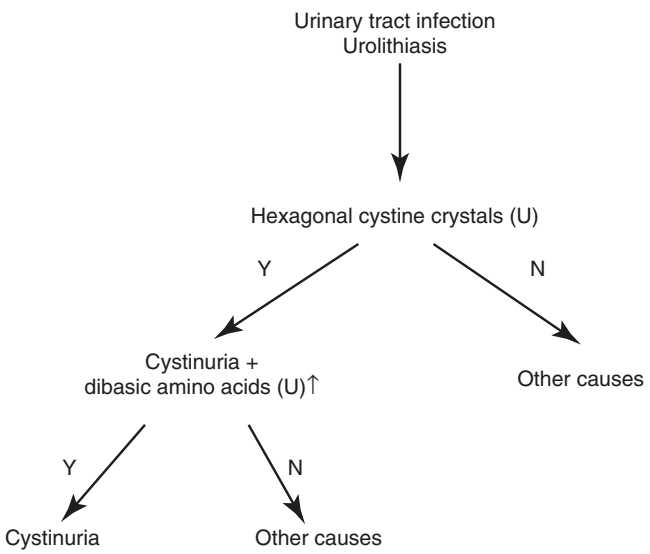
Diagnostic Flowcharts

Hartnup disorder



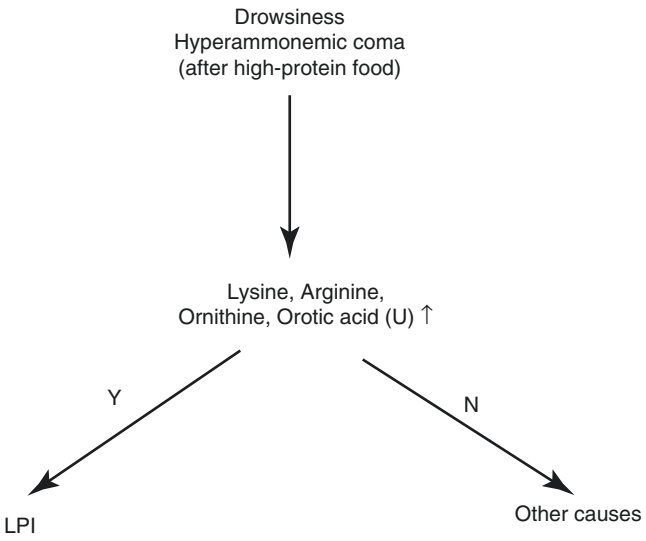
Iminoglycinuria and hyperglycinuria are considered benign and no diagnostic flowchart required. Accidental identification through urine amino acid analysis.

Cystinuria



If patients are presented with neonatal seizures, hypotonia, developmental delay, and/or facial dysmorphism, the very rare hypotonia-cystinuria syndrome (OMIM 606407) due to homozygous deletion on chromosome 2p21 should be discarded.

Lysinuric protein intolerance



Dicarboxylic aminoaciduria Usually detected retrospectively, consider in cases of obsessive-compulsive disorder. Mental retardation most likely diagnosed due to ascertainment bias.

Lysine malabsorption syndrome The principal differences between the described patient with lysine malabsorption syndrome and LPI patients are (1) absence of hyperammonemia or protein intolerance and (2) isolate lysninuria (i.e., without argininuria and ornithinuria).

The principal differences between the described patient with lysine malabsorption syndrome and the patient with dibasic aminoaciduria type I are isolate lysninuria without argininuria and ornithinuria.

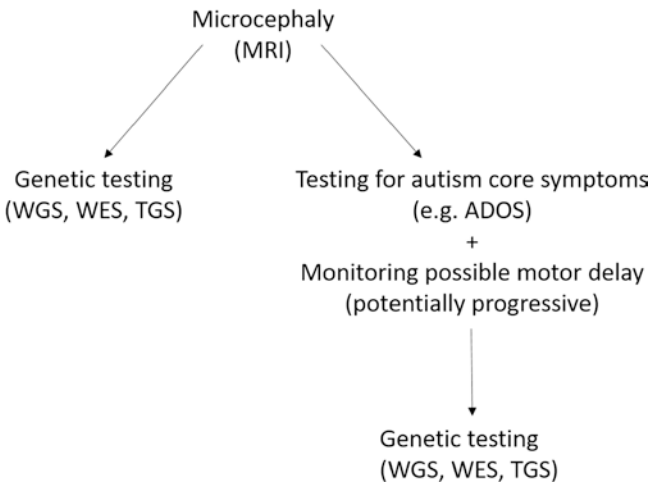
Dibasic aminoaciduria type I The principal differences between the described patient with hyperdibasic aminoaciduria type I and LPI patients are (1) absence of hyperammonemia or protein intolerance and (2) moderate hyperdibasic aminoaciduria in the obligated heterozygotes (e.g., parents) in the former.

Methionine malabsorption syndrome The presence of α-hydroxybutyrate in urine and feces with a typical oasthouse smell is a paradigmatic characteristic of this syndrome.

Cationic amino acid transporter 2 deficiency The characteristic biochemical profile includes high plasma and urine arginine, ornithine, and lysine levels. Newborn screening centers should know of this disorder since it can be detected in arginase 1 deficiency screening (OMIM 207800).

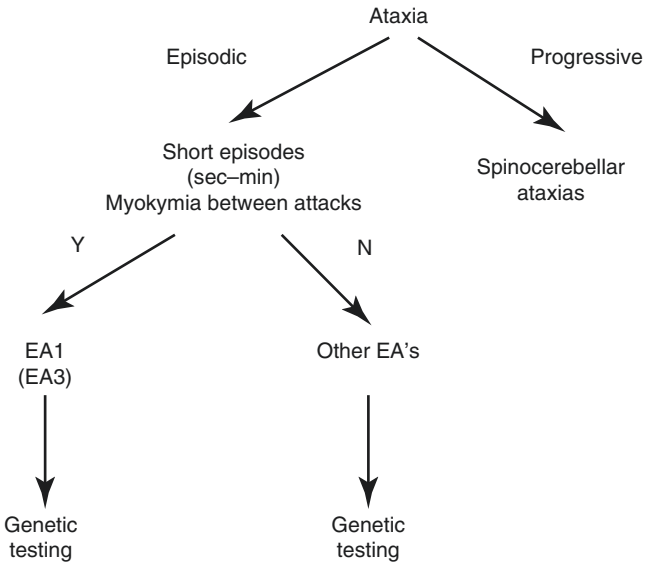
At present, it is unclear whether this defect is benign or the early establishment of a low-protein diet from the first month of life may have prevented or delayed the onset of symptoms.

Large neutral amino acid transporter LAT1 deficiency Diagnostic flowchart for diagnosing large neutral amino acid transporter deficiency. MRI, magnetic resonance imaging; WGS, whole genome sequencing; WES, whole exome sequencing; TGS, targeted genome sequencing; ADOS, Autism Diagnostic Observation Schedule.



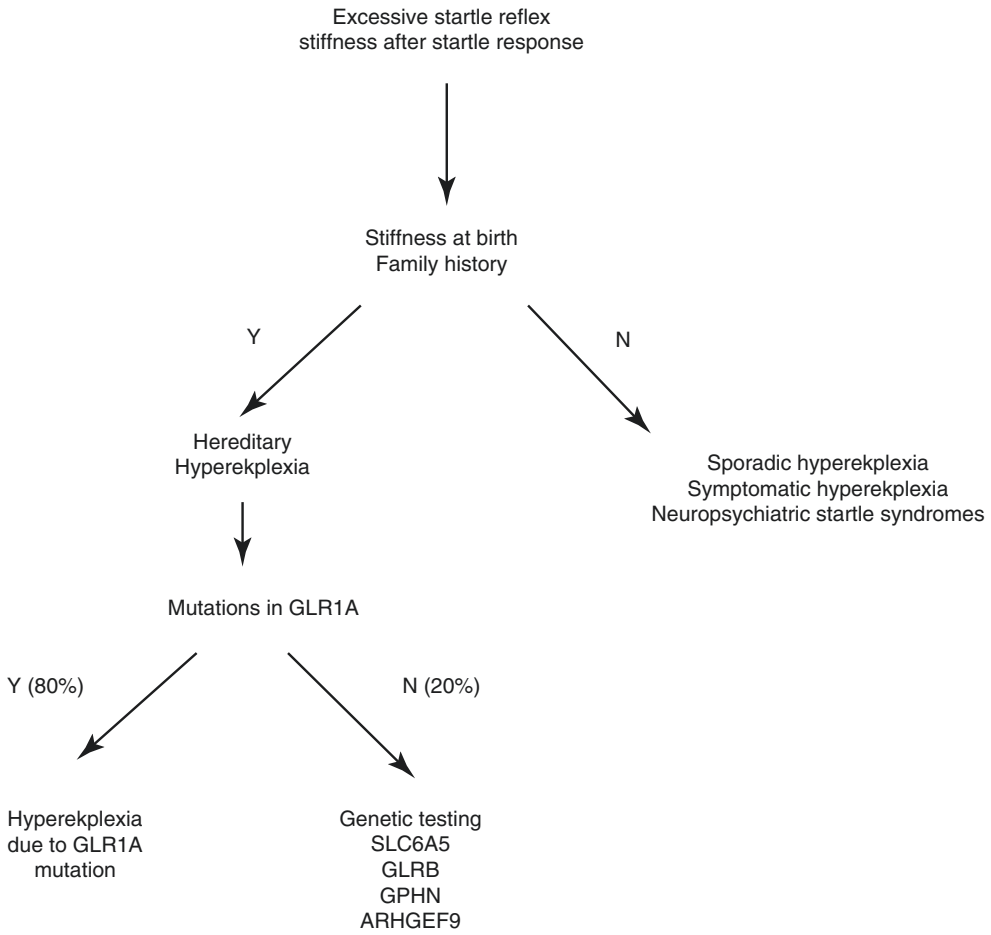
Neuronal system A amino acid transporter deficiency Defective SNAT8 (SLC38A8) cause isolated foveal hypoplasia nystagmus and optic nerve misrouting without albinism. Foveal hypoplasia has been identified in association with optic nerve misrouting in cases of ocular (MIM 300500) or oculocutaneous (MIM 203100, OMIM 606952 and 300808) albinism (reviewed) (Perez et al. 2014; Poulter et al. 2013).

Episodic ataxia due to EAAT1 defect



ASCT1 transporter deficiency CNS and musculoskeletal symptoms are alike to those of L-serine biosynthesis disorders (developmental delay and intellectual disability, microcephaly, seizures, and dysmyelination) (i.e., OMIM references 601815, 610992, and 614023) (Damseh et al. 2015; Heimer et al. 2015; Srour et al. 2015, for a review).

Hyperekplexia



Specimen Collection

Aminoacidurias Standard urine sample collected for 24 h or as single sample where amino acid concentration is referred to creatinine amount.

Large neutral amino acid transporter deficiency, neuronal system A amino acid transporter deficiency, episodic ataxia, ASCT1 and transporter deficiency, and startle disease due to glycine transporter GLYT2 defect, not applicable.

Prenatal Diagnosis

Prenatal diagnosis is not recommended in cystinuria, dicarboxylic aminoaciduria, Hartnup disorder, and lysinuric protein intolerance. For at-risk pregnancies of episodic ataxia type 6, if mutations have been identified in the family, DNA sequence analysis can be performed by a research laboratory. In Ashkenazi Jewish populations, due to a relatively high carrier rate of ASCT1 (SLC1A4) mutations, mainly c.766G>A, p.(E256K), DNA sequence prenatal diagnosis can be performed for risk pregnancies. If SLC7A5 mutations causing large neutral amino acid transporter deficiency are known in the family, prenatal genetic testing or DNA sequencing of the parents can be used for prenatal diagnosis.

Neonatal Diagnosis

Expanded newborn screening for amino acid disorders using tandem mass spectrometry includes the possibility to determine arginine levels in dried blood sample specimen to detect possible patients of hyperargininemia in cationic amino acid transporter 2 deficiency, and oasthouse smell might facilitate identification of methionine malabsorption syndrome. Early diagnosis would facilitate protein-deficient diet or methionine-deficient diet in these diseases, respectively.

DNA Testing

DNA testing can be performed but is not necessary for diagnosis of cystinuria, dicarboxylic aminoaciduria and Hartnup disorder, iminoglycinuria, and hyperglycinuria. In cystinuria, if one mutated allele is already identified in one of the two cystinuria genes (SLC3A1 or SLC7A9), the second mutated allele most probably will be identified in the same gene because digenic inheritance in cystinuria has not been demonstrated. A small proportion (~4%) of carriers of one mutated allele (mainly SLC7A9 heterozygotes) present with cystine lithiasis. LPI: Neonatal DNA screenings for the unique mutation present in Finland (Finnish mutation 1181-2A→T) and a northern part of Iwate (Japan) (mutation R410X) with an incidence in the population of 1:60,000 have been established due to the benefits of an early therapy. DNA testing for common forms of hyperekplexia and episodic ataxia type 6 is available. For the cases associated with SLC6A5 and SLC1A3, respectively, sequencing is only available through research laboratories.

DNA sequencing by specialized laboratories will be necessary for diagnosis in the following cases: (1) SLC7A2 (CAT2) and arginase 1 in cases of hyperargininemia at birth, (2) SLC38A8 (SNAT8) in isolated foveal hypoplasia, (3) SLC1A4 (ASCT1) in the suspicious of central nervous system symptoms due to serine synthesis defects, and (4) large neutral amino acid transporter deficiency if microcephaly is present. In this latter case, skin biopsies for fibroblast primary cultures can be collected to monitor SLC7A5 transporter function via transporter assays.

Treatment Summary

Methods to reverse the defect in transport that causes the disorders discussed in this chapter have not been developed. Photodermatitis in Hartnup disorder is treated with oral nicotinamide. Treatment and management of cystinuria in children and adults relate to the prevention of stone formation by reducing the absolute amount and increasing the solubility of the poorly soluble cystine that is excreted in the urine by dietary measures and alkalization of urine. If these conservative approaches fail, thiol-chelating drugs that reduce cystine to more soluble cysteine adducts are used. The goal is to maintain cystine urine concentration below 1 mmol/L (~250 mg/L) and excretion below <100 μmol per mmol of creatinine (Chillarón et al. 2010; Knoll et al. 2005). For LPI, they are two main directions of therapy (Sebastio et al. 2011). The first is aimed to reduce the risk of hyperammonemia (low-protein diet and L-citrulline supplementation (to refill urea cycle intermediates) or administration of ammonium scavengers (e.g., sodium benzoate)). The second is aimed at the specific treatment of the severe complications. Treatment is not required for dicarboxylic aminoaciduria, iminoglycinuria, and hyperglycinuria.

Acetazolamide should be tried in any patient with episodic ataxia type 6, but not all are responsive. Clonazepam is used to treat hyperekplexia. Low-protein diet and methionine restricted diet were implemented in the unique cases of cationic amino acid transporter 2 deficiency and methionine malabsorption syndrome, respectively (Hooft et al. 1968; Yahyaoui et al. 2019).

No treatment has been implemented for large neutral amino acid transporter deficiency and neuronal system A transporter deficiency. Serine supplementation could be envisaged as a treatment for ASCT1 transporter deficiency, but this has not been implemented even in mouse models.

Emergency Treatment

Cystinuria type A and type B

Urological interventions are often indicated for the management of cystine stones >5 mm in diameter (Chillarón et al. 2010). The almost noninvasive extracorporeal shock wave lithotripsy should be the treatment of choice at least in children (Knoll et al. 2005).

Pitfalls: Some cystine stones have crystalline structures (e.g., smooth appearance or low degree of radio-opacity), which make them resistant to extracorporeal shock wave lithotripsy. Ureteroscopy and percutaneous nephrostolithotomy may be preferable in these patients to remove the stones.

Episodic ataxia due to EAAT1 defect

Antiepileptic drugs: carbamazepine (up 1600 mg/day), sulthiamine (50–200 mg/day), and diphenylhydantoin (150–300 mg/day).

Dangers/Pitfalls: Drugs should be used with caution due to significant side effects.

Hyperekplexia due to GLYT2 defect

Sudden infant death due to apnea (stiffness of respiratory muscles) can occur in cases of hyperekplexia. This can be prevented by the Vigevano maneuver (flexing of head and limbs toward the trunk) (Vigevano et al. 1989).

Standard Treatment

Cystinuria type A and type B

Objective	Strategy	Neonatal	Infancy	Childhood	Adolescence	Adulthood
Decrease in cystine excretion	Dietary sodium intake (upper limit; g/24 h) (Metabolic Nephropathy Work group 2011)	–	–	2	2	2
	Animal protein intake (g/kg BW • 24 h)	–	–	–	<1	<1
Decrease in urine cystine concentration	Fluid intake (L/24 h)	0.5–1	2	3–4	4	4–5
Increase in cystine solubility in urine	Urine alkalization (pH 7.5) Potassium citrate (mmol/24 h) (divided in 2–3 doses/day)	–	10–20	10–60	10–60	40–90
	Tiopronin[1] (mg/kg BW • 24 h)[2]	–	–	20–40	20–40	45–60

[a]Alternative treatment with tiopronin (α-mercaptopropionylglycine) produces adducts with cysteine that increase the solubility of cysteine 50-fold. This treatment is recomended to do not exceed 1.2 g/24 h (2021)

Dangers/Pitfalls

A high nocturnal fluid intake will delay the achievement of urinary control in childhood. At least two nocturnal fluid intakes are recommended, but good compliance is difficult to achieve in adolescents and adults.

Potassium citrate administration is recommended in three doses (one-quarter of the daily dose in the morning, one-quarter at lunchtime, and half in the evening), which is recommended to monitor urine pH (>7.5) with indicator paper three times per day to adjust treatment.

The incidence of adverse effects is similar for both agents (tiopronin—fever, proteinuria, and hyperlipidemia; D-penicillamine—rash, fever, immune-complex-mediated glomerulonephritis, leucopenia, thrombocytopenia, and taste loss) but is slightly lower with tiopronin. Monitoring of liver enzymes, complete blood cell count, and urinary protein excretion should be performed regularly while patients are on tiopronin or D-penicillamine therapy.

Hartnup disorder Oral nicotinamide treatment (50–100 mg/day) may prevent or resolve photodermatitis in Hartnup disorder.

Lysinuric protein intolerance

Objective	Strategy	Neonatal	Infancy	Childhood	Adolescence	Adulthood
Prevention of hyperammonemia	Low-protein diet (upper limit; g/kg BW • 24 h)	–	–	0.8–1.5	0.8–1.5	0.5–0.8
	Citrulline supplementation (mg/kg BW • 24 h) (in 4 divided doses)	–	–	100	100	100
	Sodium benzoate (mg/kg BW • 24 h) (in 4 divided doses)	–	–	100–250	100–250	100–250
	L-Carnitine (mg/kg BW • 24 h) (in 2 or more divided doses)[a]	–	–	25–50	25–50	25–50
Additional treatments	hGH (for patients with GH deficiency)	–	–	Careful evaluation for patients with severe growth retardation and delayed bone age		–
	L-Lysine (mg/kg BW • 24 h) (in presence of marked hypolysinemia)	–	–	10–40	10–40	10–40
	Statins (to treat combined hyperlipidemia)	–	–	Standard protocols		
Severe complications	Pulmonary alveolar proteinosis (PAP)	–	Bronchoalveolar lavage in specialized center. Immunosuppressors			
	Chronic renal disease	–	–	–	Standard guidelines under the direction of specialist	
	Hemophagocytic lymphohistiocytosis	–	–	Standard guidelines under the direction of specialist		

[a]Hypocarnitinemia, which strongly correlates with renal insufficiency, low-protein diet, and the use of ammonia scavenger drugs, might present in LPI. Therefore, L-carnitine is supplemented after measurement of plasma carnitine levels (Sebastio et al. 2011)

Dangers/Pitfalls

Urinary orotic acid can be used to monitor the protein tolerance and the urea cycle functioning but is not totally reliable.

Nutritional deficiency due to the low-protein diet might require supplementation of calcium, vitamin D, iron, and zinc.

Recurrent fatal pulmonary alveolar proteinosis after heart-lung transplantation in a child highlighted that this complication of LPI is caused by factors external to the lung, most likely macrophages (Santamaria et al. 2004).

Pulmonary alveolar proteinosis (PAP) of different origins is usually treated by whole lung lavage or granulocyte-macrophage colony-stimulating factor (GM-CSF) administration. GM-CSF is a hematopoietic growth factor known to stimulate stem cells to proliferate into granulocytes or monocytes, promote differentiation of monocytes into alveolar macrophages, increase the catabolism within alveolar macrophages, and increase the innate immune potential of neutrophils. Although GM-CSF may have therapeutic advantage in certain types of PAP, it may not be suitable for treating LPI-associated PAP because of the tendency of LPI alveolar macrophages to form granulomas (Douda et al. 2009).

Episodic ataxia type 6 due to EAAT3 defect Typical treatment is acetazolamide (125–1000 mg/day) (Pessia 2010). Acetazolamide is a carboanhydrase inhibitor and particularly effective in episodic ataxia type 2 caused by mutations in the calcium channel gene CACNA1A (Jen et al. 2007). Whether bicarbonate homeostasis is deranged in episodic ataxias is unclear.

4-Aminopyridine treatment has been shown to be effective in patients with EA (Jen et al. 2007).

Dangers/Pitfalls. Not all cases of EA are responsive to acetazolamide.

Hyperekplexia Clonazepam is used to treat hyperekplexia. Initial dose is 0.5 mg twice/day, which can be increased to 2 mg twice a day. Clonazepam modulates the $GABA_A$ receptor, making it more sensitive to GABA. $GABA_A$ receptors and glycine receptors have an overlapping distribution in the brain. Clonazepam is a muscle relaxant counteracting the muscle stiffness observed in hyperekplexia.

Dangers/Pitfalls. Hyperekplexia can be misdiagnosed as seizures, but commonly used anticonvulsants are ineffective. The effectiveness of valproic acid, clobazam, and fluoxetine has been reported in a few sporadic cases of unknown genetic etiology (Zhou et al. 2002), but has not been tested in controlled studies.

Experimental Treatment

Cystinuria Real-time atomic force microscopy has been used to identify cystine derivatives (L-cystine dimethyl ester and L-cystine methyl ester) that bind to the surface and reduce the growth of cystine microcrystals in vitro (Rimer et al. 2010). Proof of principle of their antilithiasic activity in vivo is yet lacking.

Lysinuric protein intolerance Therapy with bisphosphonates (alendronate 10 mg/kg body weight • 24 h) has been proposed for severe osteoporosis in LPI (Gómez et al. 2006), but a standardized protocol is lacking.

Episodic ataxia due to EAAT1 defect See emergency treatment.

Acknowledgments The authors thank Dr. Christian Lueck (Canberra Hospital) for clarification of differential diagnosis in cases of episodic ataxia. The authors thank Dr. Rafael Artuch (Hospital San Joan de Deu, Barcelona) for reference values of plasma amino acid concentration. The authors also thank Lisa Kraus (Institute of Science and Technology-Austria) and Dr. Susanna Bodoy (IRB-Barcelona) that helped in preparing tables and bibliography.

Disorders of Monoamine Metabolism

19

Thomas Opladen and Georg F. Hoffmann

Contents

Summary

Neurotransmitters include the catecholamines (dopamine, norepinephrine, and epinephrine) and the indoleamines (serotonin and melatonin). They are chemical messengers, which mediate, amplify, or modulate synaptic transmission between neurons in the brain. Consequently, neurotransmitters are involved in central brain functions including control of movements and behavior, neuronal excitation and inhibition, the regulation of body temperature, pain threshold, memory, and a host of other processes. Inherited deficiencies of monoamine neurotransmitters encompass defects of biosynthesis and catabolism, as well as defects of transporters. They result in a wide variety of clinical signs and symptoms. This chapter will focus on primary disorders of serotonin and dopamine metabolism. Described defects are deficiencies of tyrosine hydroxylase (TH), aromatic L-amino acid decarboxylase (AADC), dopamine β-hydroxylase (DβH), monoamine oxidase A, as well as

the hereditary dopamine transporter deficiency syndrome (DTDS) and the brain dopamine-serotonin vesicular transport (VMAT2) disease.

Neurotransmitter disorders are important to recognize because early diagnosis and prompt therapeutic intervention seem to improve motor and cognitive outcome. The disease predominantly starts during infancy and early childhood. The specific clinical presentation of neurotransmitter diseases is determined by the type and severity of the underlying disorder. The clinical phenotype is not characteristic but can mimic that of other neurological disorders. Although detailed clinical history and physical examination are essential, the diagnosis is almost exclusively based on the quantitative determination of monoamines or their metabolites in cerebrospinal fluid (CSF). The additional determination of pterin metabolites is needed for the differentiation from deficiencies of BH_4 metabolism. Every diagnosis must be confirmed by molecular testing. The aim of treatment is to restore neurotransmitter homeostasis. Bypassing the metabolic block using levodopa/decarboxylase inhibitor together with dopamine agonists has led to remarkable clinical improvement in TH deficiency. In patients with AADC deficiency, treatment options are limited and in many cases not satisfactory. Patients with DβH deficiency benefit from droxidopa administration. While patients with VMAT2 defects benefit from treatment with a dopamine receptor agonist, no specific treatment with sustained effect for MAO-A deficiency or dopamine transporter deficiency syndrome has been described.

Introduction

The umbrella term "neurotransmitter" subsumes different types of chemical substances involved in synaptic transmission from cell to cell within the central (CNS) and peripheral nervous system (PNS). Neurotransmitters are synthesized in the neuron and stored within vesicles, are essential for intercellular communication, and lay the foundation of basic and complex biological functions, including muscular movement as well as neuropsychological development (Kurian et al. 2011a). Neurotransmitters can be grouped according to their chemical structure into amino acid transmitters (glycine, glutamate, and γ-aminobutyric acid (GABA)), monoamines transmitters (with the subgroup of catecholamines norepinephrine, epinephrine, and dopamine as well as serotonin), and neuropeptides, classified as short proteins or polypeptides (e.g., the hypothalamic hormones oxytocin and vasopressin or orexins) (Brennenstuhl et al. 2019). Inherited defects of neurotransmitter synthesis, breakdown, and transport have become recognized as a cause of early onset, severe, and progressive encephalopathies.

This chapter will focus on primary disorders of serotonin and dopamine (monoamine neurotransmitter) metabolism. Described defects in monoamine metabolism include deficiencies of tyrosine hydroxylase (TH) (EC 1.14.16.2) (Bartholome and Ludecke 1998; Ludecke and Bartholome 1995), aromatic L-amino acid decarboxylase (AADC) (EC 4.1.1.28) (Hyland et al. 1992), dopamine *β*-hydroxylase (D*β*H) (EC 1.14.17.1) (Man in 't Veld et al. 1987; Robertson et al. 1986), monoamine oxidase (MAO) (EC 1.4.3.4) (Brunner et al. 1993a), as well as the recently characterized hereditary dopamine transporter deficiency syndrome (Kurian et al. 2011b) and the brain dopamine-serotonin vesicular transport disease (Rilstone et al. 2013).

The diseases predominantly have their onset during infancy and early childhood. The clinical presentation is determined by the type and severity of the underlying disorder. The phenotype is not characteristic and can be mistaken for other neurological disease entities (Kurian et al. 2011a). Important neurological symptoms are developmental delay, central and peripheral hypotonia, hypo- or hyperkinesia, mixed pyramidal and extrapyramidal motor disorders, epilepsy, and oculogyric crises. Cognitive function is mostly less severely affected (Assmann et al. 2003; Brun et al. 2010; Willemsen et al. 2010).

Identical clinical pictures may result from abnormalities of tetrahydrobiopterin (BH_4) metabolism (see Chap. 20). But in contrast to patients with BH_4 deficiencies where hyperphenylalaninemia in newborn screening can guide an early way to diagnosis, hyperphenylalaninemia is always missing in neurotransmitter disorders. Recently, an option for newborn screening for AADC deficiency using the determination of 3-*O*-methyldopa (3OMD) was published (Brennenstuhl 2020). However, this investigation is still limited to very few laboratories. Hence, the diagnosis is depending on a diagnostic lumbar puncture, more explicitly the quantitative determination of monoamine metabolites and pterin species in cerebrospinal fluid (CSF) (Hoffmann et al. 1998). Apart from a strictly standardized sampling protocol, neurotransmitter analysis requires special logistics and transport as well as demanding laboratory techniques, adequately established age-related reference values, and finally experienced interpretation in the clinical context (Brautigam et al. 2002; Bräutigam et al. 1998). It is therefore performed in a limited number of specialized laboratories worldwide. As a consequence, only small numbers of patients have been diagnosed, and a substantial number is suspected to remain undiagnosed. A generalized deficiency of dopaminergic transmission can be recognized by raised levels of prolactin in blood. However, this is not a diagnostic test because of insufficient

sensitivity as well as specificity. In addition, prolactin levels can change in response to stress. To obtain reliable values, three determinations should be done hourly in a resting relaxed patient. If these are in agreement, the value is to be trusted.

Tyrosine hydroxylase (TH) catalyzes the conversion of L-tyrosine to L-dopa. It is the rate-limiting step in the biosynthesis of dopamine, norepinephrine, and epinephrine. The first committed defect, autosomal recessively inherited TH deficiency (DYT5b, DYT/PARK-TH), is therefore characterized by decreased concentrations of homovanillic acid (HVA) in CSF in combination with normal 5-hydroxyindoleacetic acid (5-HIAA). TH deficiency is associated with a broad phenotypic spectrum. According to the severity of the neurological symptoms and the concentrations of the monoamine in CSF, patients were delineated into two clinical phenotypes: an infantile onset, progressive, hypokinetic-rigid syndrome with dystonia (type A, less severe) and a complex encephalopathy with neonatal onset (type B). However, both phenotypes overlap substantially to a continuum of symptomatology and clinical severity (Willemsen et al. 2010).

Aromatic L-amino acid decarboxylase (AADC) is required for the synthesis of both serotonin and the catecholamines. Therefore, the clinical phenotype of autosomal recessively inherited AADC deficiency is caused by a severe combined deficiency of serotonin and catecholamines and characterized by oculogyric crises, dystonia, and severe neurological dysfunction in addition to vegetative symptoms (Brun et al. 2010; Pons et al. 2004; Swoboda et al. 2003). Biochemically, the deficiency leads to low levels of all neurotransmitters and accumulation of 3-*O*-methyldopa, 5-hydroxytryptophan, and L-dopa in CSF, plasma, and urine.

The aim of treatment in TH and AADC deficiencies is to restore neurotransmitter homeostasis. Bypassing the metabolic block using levodopa/decarboxylase inhibitor (carbidopa or benserazide) together (if required) with dopamine agonists leads to a good to excellent clinical response in most TH-deficient patients. AADC-deficient patients received dopamine receptor agonists, monoamine oxidase inhibitors, anticholinergics, and selective serotonin reuptake inhibitors often in conjunction with vitamin B_6 (cofactor for AADC). For the treatment of AADC-D, a consensus guideline was recently published. Nevertheless, the treatment response is often disappointing (Wassenberg et al. 2017), and significant clinical improvement was only observed in attenuated clinical manifestations (Brun et al. 2010). Recently, it has been shown that gene therapy approaches in AADC deficiency improve motor and mental function as well as brain white matter tracts (Kojima et al. 2019; Tseng et al. 2019).

Dopamine *β*-hydroxylase (D*β*H) catalyzes the conversion of dopamine to norepinephrine presynaptic secretory vesicles. D*β*H deficiency represents a very rare disease with 20 cases worldwide (Brennenstuhl et al. 2019). Autosomal recessive D*β*H deficiency is characterized by primary autonomic failure with complete absence of norepinephrine and epinephrine in plasma in combination with increased levels of dopamine. Serum D*β*H activity is low (Man in 't Veld et al. 1987; Robertson et al. 1986). The initial symptoms can be seen during the perinatal period with hypotension, muscle hypotonia, hypothermia and hypoglycemia, delayed eye opening, and ptosis. Children exhibit a reduced ability to exercise because blood pressure cannot adapt adequately which results in syncopes. Symptoms usually progressively worsen during early adulthood with severe orthostatic hypotension and also eyelid ptosis, nasal stuffiness, and retrograde ejaculation (Senard and Rouet 2006). Treatment is mainly supportive with the aim to relieve orthostatic symptoms. Oral administration of droxidopa (or L-threo-3,4-dihydroxyphenylserine), a synthetic amino acid precursor of norepinephrine which can cross the blood-brain barrier and can be utilized to generate dopamine, has been shown to improve orthostatic hypotension. Very few pathogenic *DBH* mutations have been identified. Variations in the *DBH* gene were further reported in patients with Gilles de la Tourette syndrome, ADHD, and schizophrenia (Haavik et al. 2008).

X chromosome-linked monoamine oxidase (MAO) catalyzes the oxidative deamination of a wide variety of monoamines including dopamine, serotonin, and the catecholamines. Two forms of the enzyme are classified as MAO-A and MAO-B depending on their sensitivity to inhibitors and affinity for substrates. MAO-A prefers serotonin, norepinephrine, and dopamine MAO-B phenylethylamine. While isolated MAO-B deficiency reveals no relevant clinical phenotype, MAO-A deficiency leads conceptually to accumulation of the monoamine neurotransmitters in CSF, while levels of their metabolites in body fluids and compartments are decreased (Brunner et al. 1993a). Male patients presented with mild mental retardation and a tendency toward stereotyped hand movements, as well as behavioral problems with repeated occurrences of aggression (Brunner et al. 1993b). In addition, chronic episodes of flushing, diarrhea, headaches, and psychiatric problems have been reported (Cheung and Earl 2001). Combined deletion of *MAO-A* and *MAO-B* was described in a male patient with severe developmental delay, intermittent hypotonia, and stereotypical hand movements (Whibley et al. 2010). Up to now, no effective treatment for MAO-A deficiency is available. Dietary intervention of avoiding foods rich in amines and cyproheptadine hydrochloride and sertraline hydrochloride have been used with uncertain or with no effect.

In addition to enzyme deficiencies, two transporter defects are known to cause disorders of biogenic amines. The autosomal recessive SLC6A3-related dopamine transporter defi-

ciency syndrome (DTDS) typically presents in infancy and atypically later in childhood, adolescence, or adulthood (Assmann et al. 2004; Kurian et al. 2009; Ng et al. 2014). After initial nonspecific clinical symptoms (including delayed motor development with axial hypotonia), patients with early onset DTDS develop a variable hyperkinetic movement disorder with predominantly choreatic and dystonic features. Over time, hyperkinetic features shift toward parkinsonian symptoms such as tremor, bradykinesia, and hypomimia. In some patients, oculogyric crises occur. Neurodevelopmental milestones are hardly achieved; however, cognitive impairment is usually mild compared with motor deficiencies (Kurian et al. 2011b). The atypical later-onset DTDS can develop during childhood or adulthood after normal psychomotor development in infancy and early childhood (Ng et al. 2014). Symptoms include parkinsonism-dystonia with tremor, progressive bradykinesia, variable tone, and dystonic posturing.

Characteristic biochemical findings are elevated HVA in CSF and raised HVA/5-HIAA ratio in CSF (>4.0; Norm range: 1.0–4.0). All known patients have a homozygous or compound heterozygous mutations in the *SLC6A3* gene. There is no causative treatment available. Treatment attempts include dopamine agonists (e.g., pramipexole) or anticholinergic drugs, such as trihexyphenidyl to control dystonia, benzodiazepines or chloral hydrate to relief chorea, dyskinesia and improve sleep as well as supportive treatment with physiotherapy and/or focal botulinum toxin (Yildiz et al. 2017).

The second transporter defect was identified in eight children from one consanguineous family showing clinical symptoms of deficiencies of dopamine, serotonin, epinephrine, and norepinephrine without detectable deficit of neurotransmitters in CSF. A mutation in *SLC18A2* gene encoding the vesicular monoamine transporter 2 (VMAT2) protein was identified, leading to a defective monoamine loading into synaptic vesicles (Rilstone et al. 2013). While normal CSF monoamine metabolites are not suitable for diagnosis, patients show elevated homovanillic acid and 5-hydroxyindoleacetic acid concentration in urine and present low total serotonin levels in blood (Rath et al. 2017). The use of dopamine receptor agonists resulted in an improvement of movement disorders, while L-dopa/carbidopa worsened the clinical presentation (Ng et al. 2015).

Nomenclature

No.	Disease name	Alternative disease name	Disease abbreviation	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	OMIM no.

Prenatal Diagnosis

	Material	Timing
TH	**Chorionic villi** **Amniotic fluid cells** (if mutations are known)	I. Trimester
AADC	**Chorionic villi** **Amniotic fluid cells** (if mutations are known) Liver biopsy for enzyme analysis (2. trimester)	I. Trimester
DßH	–	–
MAO-A	–	–
DTDS	**Chorionic villi** **Amniotic fluid cells** (if mutations are known)	I. Trimester
VMAT2	**Chorionic villi** **Amniotic fluid cells** (if mutations are known)	I. Trimester

DNA Testing

	Tissue	Methodology
TH	Genomic DNA (and from c**ultures of skin fibroblasts, lymphoblasts, lymphocytes)**	PCR/SSCP sequencing
AADC	Genomic DNA (and from c**ultures of skin fibroblasts, lymphoblasts, lymphocytes)**	PCR sequencing
DßH	Genomic DNA	PCR sequencing
MAO-A	Cultured fibroblasts	PCR sequencing
DTDS	Genomic DNA (and from c**ultures of skin fibroblasts, lymphoblasts, lymphocytes)**	PCR sequencing
VMAT2	Genomic DNA (and from c**ultures of skin fibroblasts, lymphoblasts, lymphocytes)**	PCR sequencing

Treatment

Treatment in TH deficiency is aimed at correction of the shortage of neurotransmitters. Bypassing the metabolic block using levodopa/carbidopa only or together with dopamine agonists usually leads to a good to excellent clinical response in most TH-deficient patients. In addition to L-dopa, inhibitors of dopamine degradation such as selegiline can be used. Despite appropriate treatment, long-term cognitive development can be subnormal in these patients (Willemsen et al. 2010).

AADC-deficient patients have received dopamine receptor agonists, monoamine oxidase inhibitors, anticholinergics, and selective serotonin reuptake inhibitors in conjunction with vitamin B_6 (cofactor for AADC). Therapy is usually initiated with one of the dopamine agonists (bromocriptine or pergolide), sometimes in combination with low-dose pyridoxine. In a second step, a monoamine oxidase inhibitor is added (e.g., selegiline). All other medications are added only if the initial treatment protocol fails to improve neurological symptoms. Treatment should be carefully evaluated for at least 3 months and be discontinued in case of no or questionable positive effects. L-Dopa treatment has been successful in three siblings with mutations affecting the L-dopa binding (Wassenberg et al. 2017). In general, response to treatment in AADC patients is variable, and outcome appears to be better in less severely affected patients and males than females. Gene therapy approaches are promising new treatment options in AADC deficiency leading to improved motor and mental function as well as brain white matter tracts (Kojima et al. 2019; Tseng et al. 2019).

Since orthostatic hypotension is the main symptom in patients with dopamine β-hydroxylase (DβH), treatment focuses on this aspect. Droxidopa, a synthetic amino acid precursor of norepinephrine, can cross the blood-brain barrier and can by using the AADC generate dopamine, improving orthostatic hypotension.

Up to now, no effective treatment for MAO-A deficiency is available. Dietary intervention by avoiding foods rich in amines as well as cyproheptadine hydrochloride and sertraline hydrochloride supplementation have been used with uncertain or with no effect.

Various drug treatment strategies and surgical interventions like deep brain stimulators had only little, temporary, or even no effect on the clinical symptoms of DTDS-deficient patients (Kurian et al. 2011b).

In brain dopamine-serotonin vesicular transport disease, treatment was initially started with levodopa leading to a worsening of the movement disorder. In contrast, subsequent treatment with direct dopamine agonists was followed by immediate ambulation, near-complete correction of the movement disorder, and resumption of development (Rilstone et al. 2013).

Emergency Treatment

Dangers and Pitfalls

1. Besides the neurological picture, patients with TH and AADC deficiency developed additional non-neurological symptoms, especially autonomic symptoms including hypoglycemia due to catecholamine deficiency (Manegold et al. 2009).
2. Lack of catecholamines may also render patients susceptible to sudden cardiac arrest, especially when patients are exposed to stressful situations. Therefore, clinical admission and close cardiac monitoring during acute illness and/or for any medical intervention is inevitable (Wassenberg et al. 2017).
3. Use glucose infusion during acute illness and/or during any medical intervention.

Standard Treatment

	Medication	Dosage (mg/kg/day)	Dose/day (*n*)
TH	Levodopa (L-dopa)	(0.5) 1–10	2–6
	Carbidopa	10–25% of L-dopa	2–6
AADC	Pramipexole	5–10 **µg/kg/day!**	3
	Bromocriptine	0.1–0.5	3
	Selegiline	0.1–0.3	2–3
	Pyridoxine (B_6)	50–200 **mg/day!**	2
	Tranylcypromine	0.1–0.5	2
	Trihexyphenidyl	0.1–0.5	3
	Levodopa (L-dopa)[a]	1–15	3
DβH	Droxidopa	250–500	2–3
DTDS	Pramipexole	5–10 **µg/kg/day!**	3
	Bromocriptine	0.1–0.5	3
	Selegiline	0.1–0.3	2–3
VMAT2	Pramipexole	Not known	Not known

Please note: The dosages given are the range which is usually applied. In individual patients, some adaptations and variations depending on the clinical picture are needed

[a]L-Dopa treatment should be limited to AADC-deficient patients with proven variants at the L-dopa binding site (Wassenberg et al. 2017)

Dangers/Pitfalls

1. L-Dopa/carbidopa/5-hydroxytryptophan therapy should be introduced slowly and increased in steps of not more than 1 mg/kg over days or weeks.
2. Changes in dopamine receptor density can cause difficulties with treatment. Receptor hypersensitivity in early diagnosed, severe cases means that treatment with cocareldopa should start at very low doses (0.25–0.5 mg levodopa/kg per day) given frequently up to 6 times a day. Receptor downregulation in late-diagnosed severe forms means that treatment with cocareldopa in the maximally tolerated dose up to 10 mg levodopa/kg per day should be maintained for as much as 6 months before deciding it is unhelpful.
3. L-Dopa/carbidopa/5-hydroxytryptophan therapy may reduce CSF folate (5′-methyltetrohydrofolate in CSF is the major transport species for the brain folate pool and is utilized by the single carbon transfer pathway to methylate L-dopa to 3-*O*-methyl-dopa). Determine 5-methyltetrahydrofolate in CSF. Consider folinic acid (5-formyltetra-hydrofolate) substitution (10–20 mg/day). This may occur "naturally" in AADC deficiency, again requiring folate supplementation (Surtees and Hyland 1990).
4. In AADC deficiency dopamine agonists can produce dyskinesia and increased irritability, and the dose needs to be carefully titrated.
5. The dose of trihexyphenidyl should start at 1 or 2 mg three times a day. The dose is then increased by 1 or 2 mg/day each week until one of three possibilities occur: (1) the child's condition improves; (2) troublesome side-effects occur (dry eyes or mouth, or gastrointestinal disturbance most commonly); or (3) a limit of 10 mg/kg/day is reached.

Experimental Treatment

To date, there are only very few reports on prenatal treatment in cases with confirmed disorders of monoamine metabolism, and most of them concentrate on disorders in tetrahydrobiopterin metabolism (Bruggemann et al. 2012; Kuseyri et al. 2018). Assuming that adequate catecholamine maintenance is essential for embryonic (synaptic) development, it has been suggested that early administration of L-dopa with a decarboxylase inhibitor can improve long-term outcome of the fetus (Bruggemann et al. 2012).

In addition, the conclusion of a recent study on pregnancy management and outcome in patients with four different tetrahydrobiopterin disorders stating that these patients require an intensive clinical and biochemical supervision by a multidisciplinary team before, during, and after the pregnancy holds also true for patients with disorders of monoamine metabolism (Kuseyri et al. 2018).

	Medication	Dosage (mg/kg/day)	Dose/day (*n*)
MAO-A	Sertraline hydrochloride		
	Cyproheptadine		
DTDS	Ropinirole?	2–6	2–6
	Levodopa (L-dopa)?	2–6	2–6

Dangers/Pitfalls

1. Adjunctive treatment with a M AO-B inhibitor such as selegeline, COMT inhibitor such as entacapone, and dopamine agonists such as bromocriptine may be necessary in TH. When introducing a MAO-B inhibitor or a COMT inhibitor, L-dopa should be reduced by approximately 50–30%.
2. Pyridoxine is a natural cofactor of AADC. In most patients, no sustained clinical or biochemical effect is achieved. In one family, in whom kinetic studies showed the mutation to decrease the binding affinity for the substrate, an improvement was achieved by combined therapy of L-dopa, without carbidopa, and pyridoxine.
3. Sertraline hydrochloride should be introduced slowly because of the risk of causing the serotonin syndrome.

Summary

Most countries now identify hyperphenylalaninemia (HPA) immediately after birth through national neonatal screening programs. Rapid identification of HPA allows timely diagnosis of the underlying enzyme defect and application of appropriate therapy: every patient with confirmed HPA who receives appropriate dietary intervention is potentially a child saved from a lifetime of mental retardation. Pharmacological treatment with tetrahydrobiopterin (BH4; sapropterin) and an enzyme substitution therapy with phenylalanine ammonia lyase (PAL; pegvaliase) are recently introduced in some groups of patients with phenylalanine hydroxylase (PAH) deficiency. Approximately 1–2% of cases of HPA detected by screening of neonates will have a disorder of BH4 metabolism (higher in countries with frequent consanguineous marriages). It is important to test for the presence of BH4 deficiency in patients with even mild elevation of blood Phe. Analysis of pterins (neopterin, biopterin, and primapterin) in blood or urine and measurement of dihydropteridine reductase (DHPR) should be carried out on all patients. Some patients with autosomal dominant GTP cyclohydrolase I (GTPCH) deficiency and patients with sepiapterin reductase (SR) deficiency may present with normal blood Phe in the newborn period, however. Measurement of monoamine neurotransmitter metabolites in cerebrospinal fluid adds importantly to the diagnosis of different forms (severe vs. mild) of BH4 deficiencies. Molecular diagnostics for the PAH co-chaperone DNAJC12 variants are mandatory in all patients in which deficiencies of PAH and BH4 are genetically excluded.

Introduction

Hyperphenylalaninemia (HPA) is a condition caused primarily by genetically based defects in Phe metabolism. HPA is usually caused by a deficiency of the hepatic phenylalanine-4-hydroxylase (PAH), by one of the enzymes involved in its cofactor tetrahydrobiopterin (BH4) biosynthesis (GTP cyclohydrolase I, GTPCH; and 6-pyruvoyl-tetrahydropterin synthase, PTPS) or regeneration (dihydropteridine reductase, DHPR; and pterin carbinolamine-4α-dehydratase, PCD) (Blau et al. 2010), or by the DNAJC12 co-chaperon of the PAH (Anikster et al. 2017). BH4 is known to be the natural cofactor and co-substrate for PAH, tyrosine-3-hydroxylase, and tryptophan-5-hydroxylase as well as all three isoforms of nitric oxide synthase (NOS) (Werner et al. 2011). Tyrosine-3-hydroxylase and tryptophan-5-hydroxylase are the two rate-limiting enzymes in the biosynthesis of the neurotransmitters dopamine and serotonin. Thus, with two exceptions (see below), any cofactor defect will result in a deficiency of biogenic amines accompanied by HPA (Burlina and Blau 2014). Because phenylalanine is a competitive inhibitor of the uptake of tyrosine and tryptophan across the blood-brain barrier and of the hydroxylases of tyrosine and tryptophan in the CNS, depletion of catecholamines and serotonin occurs in untreated patients with PAH deficiency. Both groups of HPA (PAH and BH4 deficiency) are heterogeneous disorders varying from severe, e.g., classical phenylketonuria (PKU), to mild, and benign forms (van Spronsen et al. 2017). Because of the different clinical and biochemical severities in patients with BH4 deficiencies, the terms "severe" or "mild" will be used based upon the type of treatment and involvement of the CNS. For the BH4 defects, symptoms may manifest during the first weeks of life but usually are noted within the first half year of life. Birth is generally uneventful, except for an increased incidence of prematurity and lower birth weights in severe PTPS deficiency (Opladen et al. 2012).

Two disorders of BH4 metabolism may present without HPA. These are autosomal dominant GTPCH deficiency (also addressed as Segawa disease, dopa-responsive dystonia (DRD), DYT5a, DYT/PARK-GCH1) (Segawa 2011) and sepiapterin reductase (SR) (DYT/PARK-SPR) deficiency (Friedman et al. 2012). While DRD is caused by mutations in the *GCH1* gene and is inherited in an autosomal dominant manner, SR deficiency is inherited in an autosomal recessive trait. Both diseases result in severe biogenic amines deficiencies (Brennenstuhl et al. 2019) but appear to decrease PAH activity in a less meaningful way so that it does not result in HPA. DRD usually presents with a dystonic gait and diurnal variation. A wide phenotypic spectrum of *GCH1* variants has been reported ranging from dystonia to "Parkinsonian" symptoms such as tremor, bradykinesia, and impaired fine motor skills. Symptoms can show a circadian fluctuation with worsening during the day and improvement of the symptoms after sleep.

In SR deficiency, the early phenotype includes axial hypotonia, developmental delay of motor functions, and psychiatric symptoms such as increased irritability, behavioral problems, and oculogyric crises (Friedman et al. 2012). Later, the phenotype changes toward dystonia with apparent circadian rhythm. Recently, endocrinological disturbances such as hypoglycemia and growth-hormone deficiency were identified as early symptoms of dopamine depletion in SR deficiency (Zielonka et al. 2015).

Recently, variants in DNAJC12, a co-chaperone of the HSP40/DNAJ family, type III, were described to lead to mild HPA, central biogenic amines deficiency, dystonia, intellectual disability, and parkinsonism, thereby defining a new entity of HPA without PAH or BH4 deficiency (Anikster et al. 2017). DNAJC12 interacts with PAH, TH, and the TPHs, which indicates that DNAJC12 is a specific co-chaperone for the aromatic amino acid hydroxylases that contributes to the maintenance of their intracellular stability (Jung-Kc et al. 2019).

A diagnosis of HPA is usually based upon the confirmation of an elevated blood phenylalanine level obtained on a normal diet, following a positive newborn screening test. Normal breast milk or formula feeding for only 24 h is sufficient to raise the baby's blood phenylalanine sufficiently to trigger a positive test level (>120 μmol/L), while severe illness may also cause HPA even without nutritional intake. In general, an infant will be found to have a positive screening test after 12 h postnatal if the phenylalanine-to-tyrosine ratio rather than the phenylalanine concentration is used. The tandem mass spectrometer (TMS) is today the method of choice for newborn screening. Based on the fact that patients diagnosed early have better outcome, it is logical—although not proven—that detection as early as possible is essential in order to introduce appropriate treatment to not only prevent mental retardation but to guarantee the best optimal mental development.

In PAH and BH4 deficiencies, factors like a relatively high phenylalanine intake in relation to current growth velocity or catabolic situations may be responsible for high phenylalanine concentrations in blood. Once HPA has been detected, a sequence of quantitative tests (see Sect. 20.8) enables the differentiation between variants, i.e., classical PKU (usually the patients with the most severe PAH deficiency), BH4-responsive PKU, BH4 deficiencies, and the DNAJC12 variant. Because the last two forms are actually a group of diseases that may be detected because of HPA, but not simply and routinely identified by neonatal mass screening, selective screening for a BH4 deficiency and DNAJC12 is essential in every newborn with even slightly elevated phenylalanine levels. Differential testing for BH4 deficiencies should be done in all newborns with plasma phenylalanine levels >120 μmol/L (2 mg/dL), as well as in older infants and children with neurological signs and symptoms. DNAJC12 should be genotyped in HPA patients in which deficiencies of PAH and BH4 are excluded (Blau et al. 2018).

Since the two forms of BH4 deficiency presenting *without* HPA (DRD and SR deficiency) cannot be recognized through the newborn screening for PKU, investigation of neurotransmitter metabolites and pterins in CSF is essential in patients with delay in mental development and neurological issues, especially concerning tonus regulation. In patients with DRD, a phenylalanine loading test, a trial with L-dopa, DNA testing, and enzyme activity measurement in cytokine-stimulated fibroblasts are confirmatory for the diagnosis. SR deficiency can be definitely diagnosed by pterins analysis in CSF and urine and by DNA testing, but a phenylalanine-loading test can be indicative as well.

For patients with PAH deficiency, three different treatments are available: diet, chaperone therapy with BH4, and enzyme replacement therapy (Blau and Longo 2015). Future treatment options for lowering the blood phenylalanine in PKU, like gene replacement or repair or manipulation of microbioma are under development (Lichter-Konecki and Vockley 2019) while other strategies such as large neutral amino acids targeting the brain more directly are also under development. In BH4 deficiencies, the goal is to reduce phenylalanine by supplementation with BH4 and to normalize brain neurotransmitters by normalizing blood—and by that brain—phenylalanine but especially by giving the precursors of the neurotransmitters knowing that they will pass the blood-brain barrier oral administration of dopamine and serotonin precursors (L-dopa/carbidopa and 5-hydroxytryptophan, respectively). In instances where the standard treatment approach is not beneficial, drugs like selegiline, entacapone, pramipexole, and rotigotine should be considered (Burlina and Blau 2014; Opladen et al. 2012). In this respect, it should be taken into account that some patients with PAH deficiency, historically only treated by diet, can be treated with BH4 (sapropterin dihydrochloride). At the same time, in patients with DHPR deficiency, in whom historically the HPA was treated with BH4, the diet restricting phenylalanine intake is the treatment of choice, as BH4 administration may result in BH2 accumulation and the BH4/BH2 ratio may then become less optimal. DNAJC12-deficient patients can be treated by oral administration of BH4, dopamine, and serotonin precursors (Straniero et al. 2017), but some patients with a milder phenotype do well on BH4 alone (van Spronsen et al. 2017).

Late introduction of treatment in all the patients called above leads to irreversible brain damage. In contrast to early and continuously treated patients with PAH deficiency, some patients with BH4 deficiencies (DHPR and severe form of PTPS) show progressive neurological deterioration despite treatment. An international working group on neurotransmitter-related disorders (iNTD) focused primarily on epidemiology, diagnosis, and treatment of these disorders is now systematically collecting data for improving the understanding of these disorders (Opladen et al. 2016).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene	Chromosomal location	Mode of inheritance	Affected protein	OMIM
20.1	Phenylalanine hydroxylase deficiency	Classic PKU	cPKU	*PAH*	12q22-24.1	AR	Phenylalanine hydroxylase	261600

Loading Tests

Loading Test with BH4 (Sapropterin Dihydrochloride) to Diagnose BH4-Responsive PAH Deficiency

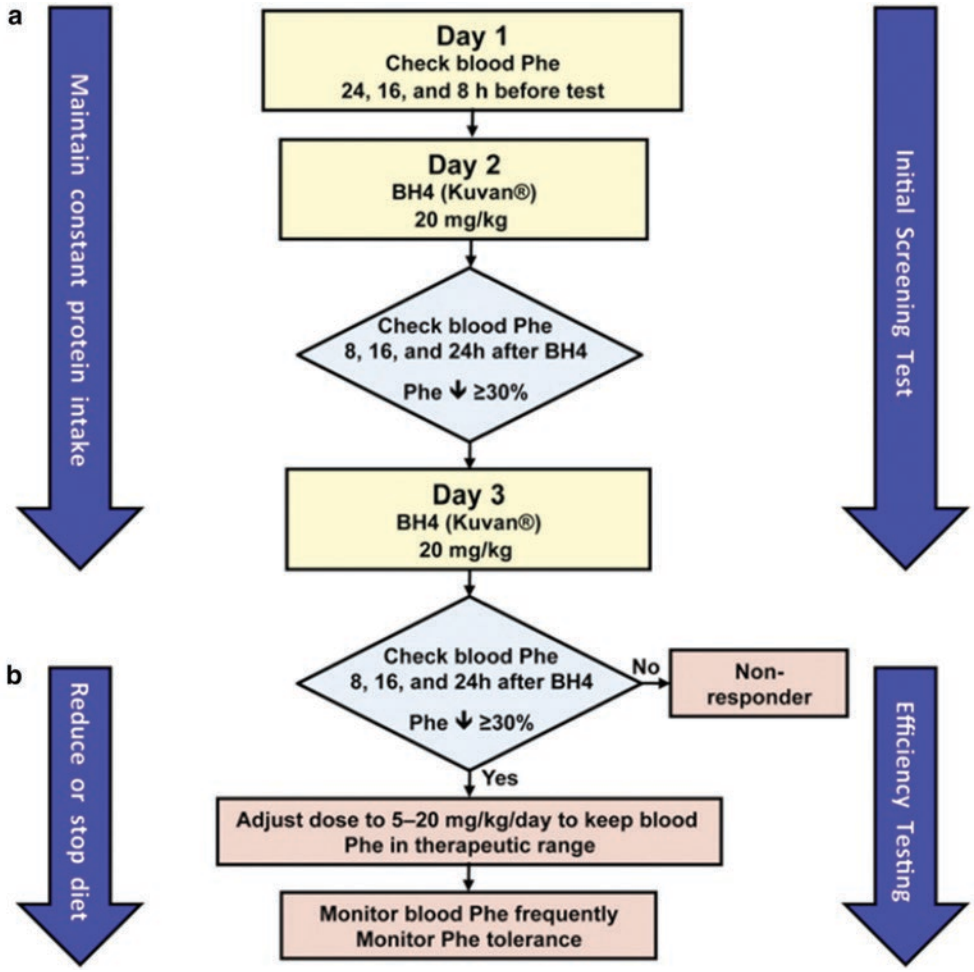

Fig. 20.2 Suggested European guidelines algorithms for the BH4 (sapropterin dihydrochloride) challenge, screening, and initiating treatment in BH4-responsive PKU patients. (**a**) Initial screening test with blood phenylalanine monitoring on the first day and BH4 (sapropterin dihydrochloride) administration (20 mg/kg) on two following days. (**b**) Efficiency testing in BH4-responsive patients over several weeks with BH4 doses adjusted individually according to phenylalanine tolerance and therapeutic blood phenylalanine levels. Combined phenylalanine (100 mg/kg) and BH4 (20 mg/kg) loading test is sometimes difficult to interpret and is therefore not recommended (Blau et al. 2011). It is of importance to note that this BH4 loading test in neonates must be done over a period of 24 h (blood samples at 4, 6, 8, 12, and 24 h after sapropterin administration) and is useful to differentiate BH4 deficiencies from PAH deficiency (Muntau et al. 2019), rather than proving BH4 responsiveness

Diagnostic Flowcharts

Differential Diagnosis of HPAs

Screening for a BH_4 deficiency should be done in all newborns and children with even slight HPA (plasma Phe >120 µmol/L) as well as in older children without HPA but with neurological symptoms suggestive of a neurotransmitter deficiency.

The following protocol is suggested:

1. Analysis of pterins in DBS or urine
2. Measurement of DHPR activity in DBS
3. Analysis of phenylalanine and tyrosine in serum or plasma or DBS before and during > not after a BH_4 challenge
4. DNA testing

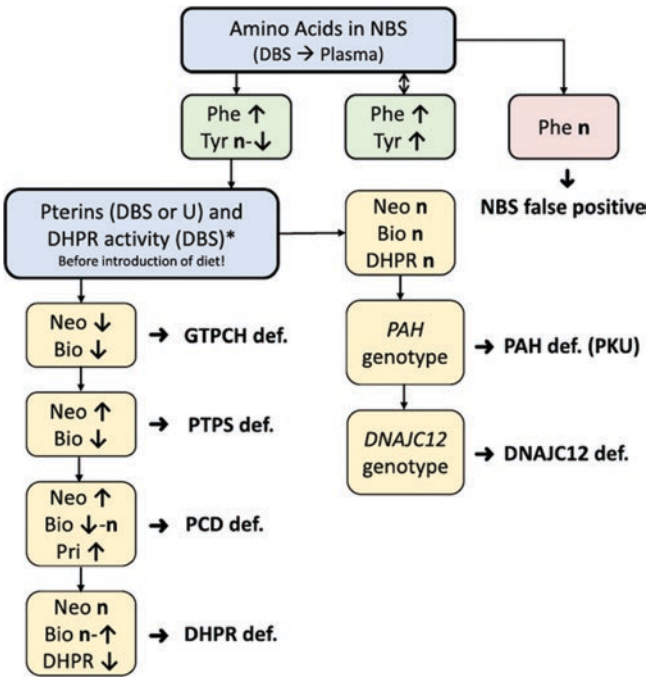

Fig. 20.3 Diagnostic flowchart for the laboratory diagnosis of PKU, BH4, and DNAJC12 deficiencies. Dried blood spots (DBS) or random urine (U) can be used for the differential diagnosis, and depending on the profile of neopterin (Neo), biopterin (Bio), and primapterin (Pri) and dihydropteridine reductase (DHPR) activity in DBS, diagnosis of following BH4 deficiencies can be established: GTP cyclohydrolase I (GTPCH) deficiency (low or no detectable neopterin and biopterin), 6-pyruvoyl-tetrahydropterin synthase (PTPS) deficiency (high neopterin and low or no detectable biopterin), dihydropteridine reductase (DHPR) deficiency (normal neopterin and normal or elevated biopterin and no DHPR activity), pterin-4α-carbinolamine dehydratase (PCD) deficiency (elevated neopterin, low-normal biopterin, and elevated primapterin), and DNAJC12 (normal pterins and PAH genotype) (modified from Blau et al. (Blau et al. 2018))

The first two tests are essential and will allow the differentiation between all variants with BH_4 deficiencies.

With some limitations (DHPR def.), the BH_4 loading test (for 24 h) is an additional useful diagnostic tool for the rapid discrimination between classical PKU and biopterin variants (Muntau et al. 2019). This test is particularly useful for identifying the BH_4-responsive PAH deficiency. For the interpretation and determination of the various disorders based upon loading tests, see "Pathological Values and Differential Diagnosis."

Interpretation of the Phenylalanine Loading Test in Patients with DRD

Fig. 20.5 Diagnostic algorithm for patients with a possible disorder of neurotransmitter metabolism. Sepiapterin reductase (SR) deficiency and other disorders of neurotransmitter metabolism should be considered in patients with (1) developmental delay with hypotonia, (2) suspect but unexplained cerebral palsy (CP) or CP with atypical features, and (3) uncharacterized L-dopa-responsive motor disorders. (1) In a patient with developmental delay and hypotonia, if oculogyric crises, diurnal fluctuation, sleep disturbance, or extrapyramidal or autonomic signs exist, a disorder of neurotransmitter biosynthesis is likely and cerebrospinal fluid (CSF) analysis should be done. If no other signs are present, CSF analysis should be considered if standard workup for hypotonia is unrevealing. If CSF analysis is abnormal, then mutational screening and/or measurement of enzymatic activity can be targeted to confirm the specific disorder suggested by the pattern of CSF abnormalities. If CSF evaluation is impractical, alternative evaluation may include L-dopa trial and/or phenylalanine load. If negative, CSF analysis must still be done to exclude a disorder of neurotransmitter metabolism. If L-dopa trial and/or phenylalanine loading are positive, CSF analysis will allow targeted mutational screening; however, one should keep in mind that phenylalanine load can be positive in heterozygote carriers for PKU. Alternatively, CSF analysis may be skipped, and broad mutational screening undertaken. Mutational and gene dosage screening may be time-consuming and costly, and false negatives may still occur. Therefore, this alternative evaluation route should be reserved for cases in which CSF analysis is not available or is declined, or in which other clinical features lead to suspicion of a specific diagnosis. (2) In a patient with unexplained CP or CP with atypical features, a disorder of neurotransmitter metabolism should be considered and diagnostic algorithm, as outlined above, should be followed. Atypical or unexplained features suggesting need for further metabolic investigation in a child with possible CP include lack of adequate antecedent, nondiagnostic magnetic resonance imaging, progressive symptoms, familial occurrence, episodic encephalopathy, and features not expected in the CPs such as diurnal variation, sleep disturbance, autonomic symptoms, or oculogyric crises. (3) All patients with an L-dopa-responsive motor disorder should be evaluated for a disorder of neurotransmitter metabolism. CSF analysis (after discontinuation of L-dopa therapy for at least 10 days) is the recommended first step. If L-dopa withdrawal is impractical, the results of CSF analyses may still be informative if either pterins or 5-hydroxyindoleacetic acid levels are abnormal. Alternatively, molecular investigations can be done, guided either by results of phenylalanine loading test or clinical symptoms with caveats as noted above. CSF analysis should consist of homovanillic acid, 5-hydroxyindoleacetic acid (5-HIAA), pterins (neopterin, biopterin, and sepiapterin), and 5-methyltetrahydrofolate

Prenatal Diagnosis

Prenatal diagnosis is only relevant for GTPCH, PTPS, DHPR, and SR deficiencies. Generally, the first choice of method for each of these is mutation analysis in chorionic villous material provided that disease causing mutations and their parental origin has been confirmed. Alternatively, enzyme assay in cultured amniocytes can be performed in some diseases.

DNA Analysis

All genes (*GCH1*, *PTS*, *QDPR*, *PCBD1*, *SPR*, *DNAJC12*) in this chapter are known, and mutation analysis of genomic DNA isolated from peripheral blood, chorionic villi, amniocytes, or other cells is feasible. Sanger sequencing of individual genes or next generation sequencing of gene panels are used. For mutations suspected to affect splicing, mRNA analysis in appropriate tissues may be necessary.

A locus-specific PNDdb database (http://www.biopku.org/home/pnddb.asp) lists all reported variants.

Treatment

PKU patients due to a PAH deficiency present with HPA (20.1; see below). In PAH deficiency, European guidelines to optimize PKU care have been released. The main goal of treatment is to reduce or normalize blood phenylalanine levels without causing deficiencies of other amino acids and other nutrients that are usually received by intake of natural intake (Belanger-Quintana et al. 2011). This can be done by introduction of the low-phenylalanine (or low-natural protein) diet. In some patients, administration of the synthetic cofactor BH4 can decrease or even replace the necessity of the diet. In such cases, it is important to be sure that patients use normal amounts of natural protein of high biological value not causing deficiencies of amino acids (van Wegberg et al. 2017).

Untreated blood phenylalanine concentrations determine management of patients with PKU. No intervention is required if the blood phenylalanine concentration is less than 360 μmol/L. Treatment is recommended up to the age of 12 years if the phenylalanine blood concentration is between 360 and 600 μmol/L, and lifelong treatment is recommended if the concentration is more than 600 μmol/L. For women trying to conceive and during pregnancy (maternal PKU), untreated phenylalanine blood concentrations of more than 360 μmol/L need to be reduced. Treatment target concentrations are as follows: 120–360 μmol/L for individuals aged 0–12 years and for maternal PKU, and 120–600 μmol/L for nonpregnant individuals older than 12 years (van Wegberg et al. 2017).

One should be aware that there are individuals with "severe" PKU mutations that have escaped severe mental retardation despite high blood phenylalanine levels and very poor dietary control (van Vliet et al. 2019). One explanation for this phenomenon is that they have near normal brain phenylalanine levels, despite high blood phenylalanine levels. A number of studies have now demonstrated considerably variability in blood vs. brain phenylalanine levels in PKU patients, although this can partly be explained by technical issues with measuring the phenylalanine content in brain. Outcome in PKU appears to be related to both blood and brain phenylalanine levels. This, in all probability, will assume greater importance in making decisions about the strictness and duration of dietary control in the future. It has also been shown that the brain phenylalanine levels of heterozygotes (parents) for PKU are higher than usually seen in PKU patients under very strict dietary control. This would suggest that control levels would probably be higher and safer than are now generally recommended although the neurocognitive functioning of the parents has never been officially studied (Burlina et al. 2019).

In BH4 deficiencies (20.2–20.7; see below), the mode of treatment depends on the type of disease, may differ with the patient's age, and the policies in various countries and centers (Opladen et al. 2012) In addition, patients with HPA due to a cofactor defect need more strict blood phenylalanine control and additional supplementations with the neurotransmitter precursors L-dopa and 5-hydroxytryptophan in combination with the peripheral decarboxylase inhibitor carbidopa. Patients with dihydropteridine reductase deficiency (DHPR, 20.4) need additional folinic acid substitution. In patients revealing levodopa-induced peak-dose dyskinesia, slow-release forms of drugs can be used and reaching the upper therapeutic limits of L-dopa may be an indication for the use of MAO and/or COMT inhibitors.

Patients with dopa-responsive dystonia (DRD, dominant GTPCH cyclohydrolase I deficiency, 20.6) and sepiapterin reductase deficiency (SR, 20.7) respond to low-dosage L-dopa/carbidopa therapy, and patients with SR deficiency need additional supplementation with 5-hydroxytryptophan and probably also BH4 (Friedman et al. 2012).

Prognosis and outcome strongly depend on the age when the diagnosis is made and treatment introduced but also on the type of mutation (Jäggi et al. 2008). Patients with DNAJC12 (20.8) can be treated by oral administration of sapropterin dihydrochloride, dopamine, and serotonin precursors (Straniero et al. 2017).

Recommendations for treatment and monitoring are not completely uniform worldwide. Therefore, where possible and necessary, recommendations have been combined and ranges of values indicating lower and upper limits are reported.

20.1: Phenylalanine hydroxylase deficiency (PKU)

Age (in years)	Protein requirement g/kg BW/day[a]	Target blood Phe µmol/L		Minimum frequency of blood Phe measurement (usually home sampling)[b]	Minimum frequency of outpatient visits[b]
		Europe[b]	USA[c]		
0–1	1.14–1.77	120–360	120–360	Weekly	Every 2 months
1–2	0.97–1.14	120–360	120–360	Fortnightly	Twice per year
2–4	0.90–0.97	120–360	120–360	Fortnightly	Twice per year
4–6	0.85–0.90	120–360	120–360	Fortnightly	Twice per year
6–10	0.90–0.92	120–360	120–360	Fortnightly	Twice per year
10–12	0.89–0.91	120–360	120–360	Fortnightly	Twice per year
12–15	0.85–0.90	120–600	120–360	Monthly	Twice per year
>16	0.8	120–600	120–360	Monthly	Once per year
Pregnancy wish	0.8	120–360	120–360	Weekly	Not advised on
Pregnancy	0.8[d]	120–360	120–360	Twice weekly	Once per trimester

[a]Based on WHO 2007, in which the European PKU guidelines by van Wegberg et al. (van Wegberg et al. 2017) advise to multiply the "protein" intake from amino acid supplements by 1.4 (40% added) since the bioavailability of amino acids mixtures is not equivalent to natural protein
[b]According to the European guidelines for PKU (van Wegberg et al. 2017)
[c]According to the US consensus for PKU (Vockley et al. 2014)
[d]For trimesters 1, 2, and 3, an additional total protein intake is advised as 1, 10, and 31 g. This is usually achieved by increasing the natural protein as the Phe allowance can be increased

Treatment and monitoring only necessary for pregnant women with blood phenylalanine levels >360 µmol/L (see below).

Tetrahydrobiopterin (BH4)-Responsive PKU/HPA

The treatment trial starts with at 20 mg/kg BW of BH4 per kg body weight and natural protein intake is increased, the BH4 dose should be adjusted, within blood phenylalanine concentrations maintained in the target (20.1) (van Spronsen et al. 2017

Beware/Pitfalls

1. Patients are on an unrestricted (i.e., protein-rich) diet.
2. BH_4 may significantly reduce plasma and CSF tyrosine levels. Consider nutrition and tyrosine supplementation.
3. L-Dopa/carbidopa/5-hydroxytryptophan therapy should be introduced slowly but continuously increased according to the clinical picture in steps of 1 mg/kg/day per week. 5-Hydroxytryptophan may not be tolerated due to gastrointestinal side effect. In this case, monotherapy with L-dopa/carbidopa may be sufficient.
4. L-Dopa/carbidopa/5-hydroxytryptophan therapy may reduce CSF folates (CH_3-group trapping by L-dopa to 3-*O*-methyldopa). Determine 5-methyltetrahydrofolate in CSF. Consider folinic acid (5-formyltetrahydrofolate, leucovorin) substitution (10–20 mg/day).

20.2: GTP cyclohydrolase I deficiency and 20.3: 6-Pyruvoyl-tetrahydropterin synthase deficiency (severe form)

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Dosages per day
20.2 20.3.1	GTPCH PTPS (severe)	Newborn	L-Dopa Carbidopa 5-Hydroxytryptophan Tetrahydrobiopterin (BH4)	1–3 10–25%[a] 1–2 5–10	3–6 3–6 3–6 3
		<1–2 years	L-Dopa Carbidopa 5-Hydroxytryptophan Tetrahydrobiopterin (BH4)	4–7 10–25%[a] 3–5 5–10	3–6 3–6 3–6 2
		>1–2 years	L-Dopa Carbidopa 5-Hydroxytryptophan Tetrahydrobiopterin (BH4)	8–15 10–25%[a] 6–9 5–10	3–6 3–6 3–6 2

[a]Percentage compared to L-dopa).

5. Drugs like trimethoprim-sulfamethazole or methotrexate may induce hyperphenylalaninemia by inhibiting DHPR.

20.3: 6-Pyruvoyl-tetrahydropterin synthase deficiency (mild form)

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Dosages per day
20.3.2	PTPS (mild)	All ages	Tetrahydrobiopterin (BH4; sapropterin dihydrochloride)	5–10	2

Beware/Pitfalls

1. Patients are on an unrestricted (i.e., protein-rich) diet.
2. BH4 may significantly reduce plasma and CSF tyrosine levels. Monitor and consider tyrosine supplementation.
3. Drugs like trimethoprim-sulfamethoxazoles or methotrexate may induce hyperphenylalaninemia by inhibiting DHPR.

20.4: Dihydropteridine reductase deficiency

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Doses per day
20.4	DHPR	Newborn	l-Dopa Carbidopa 5-Hydroxytryptophan Folinic acid Diet (see 20.1 PKU)	1–3 10–25%[a] 1–2 15–20 mg/day	3–6 3–6 3–6 1–2
		<1–2 years	l-Dopa Carbidopa 5-Hydroxytryptophan Folinic acid Diet (see 20.1 PKU)	4–7 10–25%[a] 3–5 15–20 mg/day	3–6 3–6 3–6 1–2
		>1–2 years	l-Dopa Carbidopa 5-Hydroxytryptophan Folinic acid Diet (see 20.1 PKU)	8–15 10–25%[a] 6–9 15–20 mg/day	3–6 3–6 3–6 1–2

[a]Percentage compared to l-dopa

Beware/Pitfalls

1. Patients are on low-Phe diet (see 20.1); however, blood Phe levels should be close to normal. These patients are more sensitive to high Phe levels than other PKU.
2. L-Dopa/carbidopa/5-hydroxytryptophan therapy should be introduced slowly but continuously increased according to the clinical picture in steps of 1 mg/kg/day per week. 5-Hydroxytryptophan may not be tolerated due to gastrointestinal side effect. In this case, monotherapy with L-dopa/carbidopa may be sufficient.
3. Drugs like trimethoprim-sulfamethoxazoles or methotrexate may induce hyperphenylalaninemia by inhibiting DHPR.

20.5: Pterin-4α-carbinolamine dehydratase deficiency

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Doses per day
20.5	PCD	Newborn	Tetrahydrobiopterin (BH4; sapropterin dihydrochloride)	5–10	2
		>1 year	No treatment		

Beware/Pitfalls

1. Patients are on an unrestricted (i.e., protein-rich) diet.
2. BH4 may significantly reduce plasma and CSF tyrosine levels. Consider tyrosine supplementation.
3. Drugs like trimethoprim-sulfametazole or methotrexate may induce hyperphenylalaninemia by inhibiting DHPR.

20.6: Dopa-responsive dystonia/autosomal dominant GTPCH deficiency

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Doses per day
20.6	DRD	Newborn	l-Dopa Carbidopa	1–3 10–25%[a]	3–4 3–4
		>1 year	l-Dopa Carbidopa	4–12 10–25%[a]	3–4 3–4

[a]Percentage compared to L-dopa

Beware/Pitfalls

1. L-Dopa/carbidopa therapy should be introduced slowly but continuously increased according to the clinical picture in steps of 1 mg/kg/day per week.

20.7: Sepiapterin reductase deficiency

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Doses per day
20.7	SR	Newborn	l-Dopa Carbidopa 5-Hydroxytryptophan	1–3 10–25%[a] 1–2	3–4 3–4 3–4
		>1 year	l-Dopa Carbidopa 5-Hydroxytryptophan	4–10 10–25%[a] 3–9	3–4 3–4 3–4

[a]Percentage compared to l-dopa

20.8: DNAJC12

No.	Symbol	Age	Medication/diet	Dosage (mg/kg/day)	Doses per day
20.8	DNAJC12	All ages	Tetrahydrobiopterin (BH4; sapropterin dihydrochloride)	20	2
			l-Dopa Carbidopa 5-Hydroxytryptophan	4–10 10–25%* 3–9	3–4 3–4 3–4

Beware/Pitfalls

1. L-Dopa/carbidopa/5-hydroxytryptophan therapy should be introduced slowly and increased in steps of not more than 10 mg/day.

Alternative Therapies/Experimental Trials

No.	Deficiency symbol	Age	Medication	Dosage (mg/kg/day)	Dosages per day
20.1	BH4-responsive PKU	>4 years	Tetrahydrobiopterin (BH4; sapropterin dihydrochloride)[a]	10–20	1–2
20.3–20.5	GTPCH, PTPS, DHPR	All ages	Deprenyl[b] Entacapone[c]	0.1–0.3 ~30	3–4 1–2
20.7	SR	All ages	Deprenyl[b] Sertraline[d] Melatonin[e] Bromocriptine	0.07–0.14 0.71–2.14 0.01–0.03 Not reported	3–4 2–3 1–2 Not reported

[a]Tetrahydrobiopterin (BH_4; sapropterin dihydrochloride, Kuvan®) treatment has been recently introduced as a standard therapy for children with phenylalanine hydroxylase deficiency that showed a decrease of Phe levels after BH_4 loading (see above)
[b]MAO-B inhibitor (selegiline)
[c]COMT inhibitor
[d]Serotonin reuptake inhibitor
[e]Product of serotonin metabolism

Beware/Pitfalls

1. Administration of MAO-B or COMT inhibitors allows a 30% reduction of the daily dosage of neurotransmitter precursors.

Follow-Up/Monitoring

PAH Deficiency

Age	Biochemical monitoring Phe and Tyr	Clinical monitoring[a]	Intellectual and personality development
0–3 months	Weekly	1–3 monthly	
4–12 months	Weekly	1–3 monthly	X
1–2 years	Weekly	2–6 monthly	
2–3 years	Weekly	2–6 monthly	X
4–6 years	Fortnightly	3–6 monthly	X
7–9 years	Fortnightly	6 monthly	
10–12 years	Monthly	6 monthly	X
13–15 years	Monthly	6 monthly	X
Adolescents/adults	Monthly	6–12 monthly	X
Maternal PKU	Weekly[b]	Bimonthly[c]	

[a]Nutrient intake, body growth, general health, as well as laboratory tests: blood count, calcium, phosphate, magnesium, iron, liver and kidney function tests, alkaline phosphatase, total protein, albumin, prealbumin, cholesterol, triglycerides, vitamins
[b]Plasma AA, albumin, cholesterol, ferritin, folate, vitamin B12
[c]Nutrient intake including micronutrients, body growth, general health

Standard Protocol for Intercurrent Illness

The best possible intake of fluid, energy, and Phe-free amino acid mixtures (AAM), with special attention for higher need of energy, while taking AAM in these periods may be a real.

BH_4 Deficiencies

Plasma Phe and Tyr are monitored in all forms of HPA, CSF investigations only in disorders affecting BH_4 metabolism with and without HPA (20.2–20.7).

Test	Age	Frequency	Comments
Phe and Tyr (blood)	1–3 years	Weekly to fortnightly	Phe levels: 40–240 (360) µmol/L[a]
	4–10 years	Fortnightly to monthly	
	11–16 years	Monthly	Phe levels: 40–900 µmol/L[a]
	>16 years	Every 2–3 months	Phe levels: 40–1200 µmol/L[a]
Neopterin Biopterin 5HIAA HVA Folates (CSF)[b]	<1 months	Fortnightly	Close to normal range
	1 month–1 year	Every 4–8 weeks	Close to normal range
	<1 year	Monthly to yearly	Close to normal range

[a]In DHPR-deficient patients, Phe levels should be close to 240–360 µmol/L at all ages

[b]Lumbar puncture in the morning before medication. Discard first 0.5 mL and collect the next 1–2 mL (−80 °C)

Summary

Inherited disorders of tyrosine catabolism have been identified at five of the six enzymatic steps. Under normal conditions tyrosine concentrations are regulated by its synthetic enzyme (phenylalanine hydroxylase) and especially the first catabolic enzyme (tyrosine aminotransferase). Acquired or inherited deficiency of the second catabolic enzyme (4-hydroxyphenylpyruvate dioxygenase) also results in hypertyrosinemia. Tyrosine is mainly degraded in the liver but to a minor extent also in the kidney. In tyrosinemia type I, the primary defect is

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_21

in the last enzyme of the pathway, accumulation of toxic metabolites are seen, and the hypertyrosinemia results from secondary deficiency of 4-hydroxyphenylpyruvate dioxygenase, which also is found in severe liver disease in general and in the immature liver. Generally, there is no common phenotype to the different disorders of tyrosine degradation. The occurrence of corneal and skin lesions, as seen in tyrosinemia type II, is a direct effect of high tissue tyrosine. Cognitive impairment is common in tyrosinemia type II, probably common in type III, and increasingly reported in type I. The liver and kidney diseases of tyrosinemia type I are caused by accumulation of toxic metabolites (fumarylacetoacetate and its derivatives) and can be prevented by an inhibitor (nitisinone) of tyrosine degradation at the level of 4-hydroxyphenylpyruvate dioxygenase. Whether maleylacetoacetate hydrolase that essentially gives the same metabolic features as tyrosinemia type I results in clinical features is unclear. In alkaptonuria there is no increase in tyrosine level, and the degradation of tyrosine proceeds at a normal rate to produce homogentisate. Upon oxidation, homogentisate forms reactive intermediates and pigment, which is deposited in various tissues particularly in joints and connective tissue. In hawkinsinuria, a very rare condition, data suggest that an aberrant metabolism of 4-hydroxyphenylpyruvate in some cases may lead to failure to thrive, acidosis, and excretion of a characteristic metabolite pattern.

Introduction

Hypertyrosinemia in the newborn is usually not due to inborn errors of tyrosine (Tyr) metabolism but rather to immaturity of 4-hydroxyphenylpyruvate dioxygenase (4HPD). This is called transient tyrosinemia of the premature newborn. At any age, liver dysfunction of any cause or postprandial sampling can give mildly increased Tyr levels.

Sustained isolated hypertyrosinemia is strongly suggestive of an inborn error of tyrosine degradation.

The phenotype of tyrosinemia type I (TT1) is variable, and the severity of the disease varies with age at the onset of symptoms (van Spronsen et al. 1994). Newborns detected by neonatal screening by succinylacetone (SA) in blood are clinically asymptomatic, but plasma alpha-fetoprotein (AFP) usually is already increased suggesting prenatal damage to the liver and most children have mild prolongation of coagulation tests. In non-screened patients, the most common presentation is severe liver disease or failure between 2 and 4 months of age, often preceded by a period of nonspecific failure to thrive. Typically, there is a pronounced coagulopathy with highly increased prothrombin time and sometimes thrombocytopenia, with a disproportionately moderate increase in transaminases and normal ammonia and almost normal bilirubin. Plasma AFP can be extremely high. Sepsis is not uncommon. There may be early signs of hypophosphatemic rickets secondary to renal tubulopathy. Plasma Tyr and methionine show moderate to marked increases. In later presenting patients, laboratory signs of tubulopathy and liver disease may be more impressive than the subtle clinical picture, while clinically rickets, porphyria-like neurologic crisis characterized by pain in the limbs and sometimes by paralysis resembling Guillain-Barré, or hepatic noduli that can develop into liver cancer (hepatocellular carcinoma or hepatoblastoma) can be a presenting symptom.

In comparison with the previous edition of this book (Holme and Mithcell 2014), developmental delay in TT1 is increasingly reported and in early diagnosed patients may represent an important clinical feature (van Ginkel et al. 2017a, b), with possible relations to high concentrations of Tyr and to low concentrations of phenylalanine (Phe), showing the importance—as well as the complexity—of adequate dietary management of these patients. If real eye problems (as in tyrosinemia type 2, TT2) are seen, it is believed to be related to higher Tyr concentrations rather than nitisinone itself.

So far, some patients with (mildly) increased SA concentrations appear to have a deficiency of maleylacetoacetate isomerase (MAAI) rather than FAH (Fig. 21.1), also showing that these patients do not have liver or renal failure (Yang et al. 2017).

TT2 is characterized by eye lesions (painful recurrent corneal lesions, frequently with dendritic morphology, that may be diagnosed as herpetic keratitis if the diagnosis is not suspected), skin disease (hyperkeratosis at the pressure points of palms, finger pads, and soles of the feet), and/or developmental delay or intellectual deficiency. The disorder usually presents during infancy but may become manifest at any age. Tyr concentration is grossly elevated in an otherwise normal amino acid profile.

In asymptomatic patients referred for hypertyrosinemia, discovered by neonatal screening or in the course of an investigation for another problem, it is urgent to eliminate type I disease by showing normal liver function and normal SA. After

this, the distinction between TT2 and tyrosinemia type 3 (TT3) may be difficult as Tyr level in TT2 tends to be higher, but shows considerably overlap, while organic acids with increased 4HP point at TT3. Since the concentration of blood tyrosine may be normal in some TT1, SA is the recommended biomarker to screen TTI at birth to avoid false-negative results (Stinton et al. 2017). If SA is increased, normal liver functions point at MAAI rather than FAH deficiency.

To obtain a specific diagnosis in chronically hypertyrosinemic patients without skin or eye signs, molecular testing is the approach of choice also because enzyme studies of both TT2 and TT3 require liver tissue. Today, the dietary measures are similar, but knowing the precise diagnosis also in relation to its treatment is important.

TT3 patients have been detected because of high plasma Tyr levels in an otherwise normal amino acid profile, performed in the investigation of neurological symptoms and in mental retardation or neonatal screening programs. Eye or skin lesions have not been reported, while mental retardation and epilepsy as well as vision and language problems have (Blundell et al. 2018).

Hawkinsinuria (HAWK): This rare and incompletely understood disorder is characterized by failure to thrive and acidosis in some, but clearly not all—biochemically affected—infants. No symptoms have been reported after infancy. Autosomal dominant transmission is described. Organic acids (identification of hawkinsin (2-cystenyl-1, 4-dihydroxycyclohexenylacetate)) rather than the just slightly increased Tyr in plasma will result in its diagnosis. After infancy, 4-hydroxycyclohexylacetate appears in urine in addition to hawkinsin. The condition has responded to restriction of dietary protein as well as *N*-acetyl-L-cysteine pointing at glutathione depletion (Gomez-Ospina et al. 2016).

Alkaptonuria (AKU): The earliest physical sign of AKU is abnormal darkening of urine on standing. This sign is frequently overlooked by parents and often not explored by physicians. It should lead to investigation of the excretion of homogentisate. The finding is most likely to be noticed in diapers and is typically not detectable in older patients who live in areas with modern plumbing. Symptoms like patchy grayish pigmentation of the sclera, a blue-gray aspect to the cartilage of the ear, and arthritis, most often in the hip and knee, do not appear until early adulthood, while aortic valve leakage and aorta aneurysm are problems of late adulthood. Periods of acute inflammation may resemble rheumatoid arthritis. The arthritis may be severe and disabling in middle-aged adults. Ankylosis of the lumbosacral region is common. The specific diagnosis may be suggested by radiologists who note reduced intervertebral spacing in the lumbar spine, with calcification of the intervertebral disc and marked degenerative changes in the shoulder and hip joints. Diagnosis is confirmed by identification of homogentisate in urine, often present in millimolar amounts, and DNA mutations found in the gene for 4HPD. Nitisinone has proven to be effective in preventing the formation of homogentisate (Ranganath et al. 2018). Questions to be answered are how early nitisinone needs to be started to prevent these long-term consequences and the strictness of dietary treatment.

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM no.
21.1	Tyrosinemia type I	Hepatorenal Tyrosinemia Hereditary Tyrosinemia type I Fumarylacetoacetase deficiency	TT1	*FAH*	15q25.1	Fumarylacetoacetase	276700

	Tyrosine (DBS, plasma)	(↑)	↑	↑	↑	↑	↑
	Phenylalanine (DBS, plasma)	n	n				

Succinylacetone is measured rapidly in order to exclude tyrosinemia type I. As measuring succinylacetone is now not that difficult anymore, measuring the decreased activity of porphobilinogen synthase activity in RBC or increased concentrations of delta-aminolevulinic acid strictly speaking is not needed anymore. Of note, increased excretion of phenolic tyrosine metabolites is present in sustained hypertyrosinemia of any cause and is of no differential diagnostic value

[a]Be aware of the risks on mental development as a result of too low Phe concentrations

[b]Lower risk in patients identified at newborn screening and treated early

[c]Higher risk in patients treated with NTBC and noncompliant with dietary treatment

[d]Succinylacetone and/or succinyl acetoacetate and/or 4-oxo-6-hydroxyheptonoate (U).

21.6	Maleylacetoacetate isomerase deficiency	Normal	Normal	Normal	0.2–1.2	ND	ND	ND	ND	ND

Increased tyrosine concentration is caused by inborn or acquired deficiency of the first two enzymes of the tyrosine degradation pathway (the increased tyrosine concentration of TT1 is caused by secondary inhibition of 4-hydroxyphenylpyruvate dioxygenase by liver disease in general)

Diagnostic Flowchart in Hypertyrosinemias
(Fig. 21.2)

Fig. 21.2 Clinical and biochemical signs suggestive of hereditary tyrosinemias. *Plasma succinylacetone concentrations up to 1282 nmol/L have been reported in maleylacetoacetate isomerase deficiency

Clinical situation	Symptoms and signs	Diagnosis
Neonatal screening (Succinylacetone)	Asymptomatic Mild coagulopathy	Tyrosinemia type I if succinylacetone more than mildly increased*
	Asymptomatic No coagulopathy or liver abnormalities	Maleylacetoacetate isomerase deficiency if succinylacetone is only mildly increased*
Neonatal screening (hypertyrosinaemia)	Transaminases (±) A-Fetoprotein (+) Prothrombine time (±) Porphobilinogen synthase deficiency (+) Succinylacetone (+)	Tyrosinemia type I (tyr(P) 120-1300 µmol/L)
↘ Persistent	No liver disease Succinylcetone (-)	Tyrosinemia type II (tyr(P) 800-2000 µmol/L) Tyrosinemia type III (tyr(P) 500-1300 µmol/L) ↓ Mutation analysis (Rarely, liver enzyme assay)
Failure to thrive	Signs of liver disease (+) Succinylacetone (+)	Tyrosinemia type I
	Acidosis (+) Hawkinsin (+) 5-oxoproline (+)	Hawkinsinuria
Liver disease	Prothrombin time (+) Transaminases (±) α-Fetoprotein (+) Bilirubin (normal-100 µmol/L) Succinylacetone (U)(+)	Tyrosinemia type I
Rickets	Hypophosphatemia (+) Alkaline phosphatase (+) General aminoaciduria (+) Complete Fanconi syndrome (+) Signs of liver disease (+) Succinylacetone (U)(+)	Tyrosinemia type I
Mental retardation	Eye and/or skin symptoms (+) No other symptoms	Tyrosinemia type II Tyrosinemia type II or III

*plasma succinylacetone concentrations up to 1282 nmol/l have been reported in Maleylacetoacetate isomerase deficiency.

Specimen Collection

Test	Material	Handling	Pitfalls
Phe (Blood)	Plasma	Ambient temp	Liver disease, any cause; false negatives in treated patients
	Blood spot	Ambient temp	Variation possible due to various technical issues There are known differences with plasma >20%
Tyr (Blood)	Plasma	Ambient temp	Liver disease, any cause; false negatives in dietary treated patients
	Blood spot	Ambient temp	Variation possible due to various technical issues Not that many studies on differences with plasma
Met (P)	Plasma	Ambient temp	Liver disease, any cause
4-Hydroxyphenylpyruvate, 4-Hydroxyphenyllactate and 4-Hydroxyphenylacetate	Urine	Ambient temp	Nonspecific elevations in liver disease of any cause. Urinary levels highly variable with diet and not generally useful for patient follow-up
Succinylacetone (Blood)	Plasma	Ambient temp	Slight increase in severe liver disease; possible false positive on dichloroacetate, treatment
	Blood spot	Ambient temp	So far, succinylacetone so far seems not easy to be compared to plasma
Porphobilinogen synthase (RBC)	Heparinized blood	Ambient temp	May be close to normal in TT1 Primary deficiency of porphobilinogen synthase
Succinylacetone (U)	Urine	Ambient temp (Frozen −20 °C)	False negatives possible in dilute urine specimens with some techniques
Hawkinsin	Urine	Frozen −20 °C	Failure to recognize hawkinsin and related metabolites if the specific diagnosis is not suggested on requisition
Homogentisate	Urine	Frozen −20 °C	–
FAH activity	Fibroblasts Lymphocytes Liver	Ambient temp Frozen (−70 °C) Frozen (−70 °C)	False positive: pseudo-deficiency. False negative: back mutation with significant FAH activity in revertant areas (common in liver) Insensitivity: very low normal activity in most available extrahepatic tissues renders enzymatic diagnosis difficult
TAT activity	Liver	Frozen (−70 °C)	False positive: highly regulated enzyme with wide normal range of activity depending on physiological state
HPD activity	Liver	Frozen (−70 °C)	False positive: secondary deficiency in cirrhotic liver Late maturation prenatally; may be low in premature infants

In general plasma and urine are stored frozen until assay. Experiences of the laboratory of the late Prof Holme learned that untreated blood and urine samples retain acceptable quality if transported at ambient temperature by same day or overnight courier

Prenatal Diagnosis

DNA analysis is the preferred method for prenatal diagnosis of all diseases of tyrosine degradation. The pathogenic variation of each biological parent must be known before proposing this technique. Molecular diagnosis can be performed on cells obtained directly or by culture after amniocentesis, from chorionic villus samples or at the preimplantation stage. Measurement of SA in amniotic fluid is an acceptable approach to diagnosis of TT1 for couples in whom the causal DNA variations are not known.

DNA Testing

DNA analysis is available for all diseases of tyrosine degradation. Standard molecular diagnostic procedures can be applied, using genomic DNA of any source. If the patient comes from a background with a known ethnic founder effect or if the pathogenic variation for which he or she is at risk is known, this can be tested directly. Otherwise, exome sequencing and, if necessary, deletion/duplication analysis are the methods of choice.

Treatment and Monitoring Summary

Diet Therapy

In all forms of hypertyrosinemia but MAAI, a mainstay of treatment is dietary restriction of the intake of Tyr and its precursor Phe, plus provision of adequate amounts of other nutrients in a form that is palatable as much as possible. Close supervision is necessary in order to avoid dietary deficiencies. Compliance is an important long-term issue, especially because hypertyrosinemia itself does not directly confer a sense of discomfort. In TT1, expert consensus, without clear data, suggested that plasma Tyr should be maintained below 400 or 500 μmol/L (De Laet et al. 2013; Chinsky et al. 2017). In TT2 and TT3, the ideal levels of plasma Tyr are even less established. Eye and skin lesions have rarely been seen in TT2 patients with plasma Tyr level <800 μmol/L, suggesting that levels should be maintained below this level. However, the repeated observation of developmental delay in many TT2 patients suggests that a lower level, perhaps 400–500 μmol/L, may be more appropriate. The increasing number of studies on intellectual and executive functions as well as social abilities in TT1 has delineated that there might not only be a relation with blood Tyr but also with blood Phe concentrations (van Vliet et al. 2015; van Ginkel et al. 2017a, b) pointing at effects of low Phe and high Tyr concentrations.

The Place of Liver Transplantation in the Era Without Nitisinone and the Era with Nitisinone

In the era that only dietary treatment was available and nitisinone was not, liver transplantation was the only definitive answer to both the oncological and metabolic problem in TT1 (van Spronsen et al. 1994). This completely changed with nitisinone.

Patients presenting with liver failure usually respond favorably to nitisinone, liver transplantation only being necessary in those patients in which the liver does not respond within some 5 days or when liver failure progresses as can be seen by the increase of ammonia and bilirubin. This implies that nitisinone is an emergency treatment in infants with unexplained liver failure till TT1 has been excluded. Nitisinone is available only for oral administration. In acutely ill patients with suspected and proven TT1, all efforts should be made to administer nitisinone immediately, even not preventing from use when samples for the proof of TT1 have not yet been taken as high SA will remain present for some hours after the first dose.

The other indication for liver transplantation that still may exist is the development of liver cancer. While liver disease, acute porphyria, and renal tubulopathy are not reported anymore on adequate use of nitisinone, liver cancer can be an issue. The older the patient is at start of nitisinone, the higher the risk of pre-malignancy development in the liver till diagnosis resulting in hepatocellular carcinoma (HCC) or hepatoblastoma at presentation or later in life (Mayorandan et al. 2014; van Ginkel et al. 2017b). Patients with an AFP that does not show a normalization of AFP within some 1–2 years of nitisinone are considered to be at risk for later development of liver cancer (Koelink et al. 2006), while patients with an AFP that starts to rise again after its decrease (often not have completely normalized by optimal nitisinone use) and patients with a new nodule seen at ultrasound under nitisinone should be considered to have liver cancer necessitating immediate referral to the liver transplantation team.

Patients who have had a donor liver still show mild increased SA in both blood and urine. It has therefore been advocated to continue nitisinone after liver transplantation. However, to our knowledge, none of the patients without receiving nitisinone after liver transplantation has developed any renal cancer that theoretically could be hypothesized. At the same time, these experiments with nitisinone after liver transplantation revealed that the dose of nitisinone to diminish the SA in blood and urine in a "healthy liver" is only a fraction of the dose needed in the diseased liver in TT1 patients but at the same time may result in still higher blood Tyr concentrations, resembling the situation in AKU (Milan et al. 2017).

TT1-Nitisinone Treatment

Nitisinone combined with dietary therapy is the medical treatment of choice for patients with TT1 since 1992 (Lindstedt et al. 1992). To date, no instance of liver cancer has occurred in patients detected by neonatal screening and treated with nitisinone rapidly thereafter (Larochelle et al. 2012). Late-treated patients are at greater risk of liver cancer, but no acute episodes of liver failure or neurological crises occurred during nitisinone treatment.

Starting nitisinone in infants with liver failure is an adventure. At the one hand, these patients may still deteriorate the first days before nitisinone start to show its clinical effect (usually within 3 days), and in these patients 2 mg/kg/day might be needed. Nitisinone may increase the already increased Tyr concentrations, but the need for natural protein for anabolism probably is of more importance accepting the higher Tyr concentrations for some days if the liver accepts that amount of nitrogen load without increasing ammonia. In

that respect, attention should be paid to give clotting factors rather than fresh frozen plasma in case of too high risk of bleeding.

Starting nitisinone in patients presenting with acute intermittent porphyria caused by TT1 can also show to be very efficacious still necessitating the promotion of anabolism.

Nitisinone has a long half-life in healthy adults of 54 h, permitting once daily administration. However, the healthy situation cannot be transferred to the TT1 patient that easily as can be learned from two issues. First of all, the experiment with nitisinone in patients having or had liver transplantation learned that nitisinone metabolism is different in a healthy compared to a diseased liver. Second, a recent study showed that dividing the total daily dose into two daily doses results in better reduction of SA if compared to taking the total dose in one daily dose (Kienstra et al. 2018). That study also showed that nitisinone levels of >35 μmol/L may suffice to suppress blood SA levels to <0.6 μmol/L. The lack of total depression of SA presumably reflects a state of increased liver cancer risk. It is important to monitor dose and compliance both clinically and by repeated laboratory measurements. Therefore, the use of home sampling methods to frequently monitor not only blood Phe and Tyr but also NTBC and SA is of clinical importance. If that is not provided by the own institutional laboratory, it is advised to collaborate with metabolic institutions that provide this service.

Monitoring TT1 probably can be split into the situation with diagnosis of neonatal screening and clinical presentation, the last group of patients not only having a higher risk of liver cancer when presented after 2–3 months of age (Holme and Lindstedt 1998; Larochelle et al. 2012), but tubular function also needing longer to return to normal than the patients found by newborn screening (Maiorana et al. 2014; Maiorana and Dionisi-Vici 2017).

Therefore, in patients with clinical presentation after 2 months of age, the authors of this chapter would advise a frequency of AFP of four times a year and twice yearly ultrasound and only performing MRI (with contrast) in case of some lesion found with ultrasound if performed by an experienced radiologist, only performing yearly studies on the kidney (tubular and glomerular) when patients show some issues at diagnosis having returned to normal. In case of newborn screening, patients do even need less regular follow-up with AFP and ultrasound (twice yearly and once yearly, respectively), while kidney function measurements are only needed on clinical indication. Both groups of patients will continue to show some very mild abnormalities in prothrombin time, but this seems to be without any clinical relevance.

Instead, increased attention should be given to neurocognitive function and psychosocial development, and both parents and school teams should be aware of the risk of delay in development and behavioral issues, while research is needed in larger series to explore the adequate target concentrations of both Phe and Tyr. This at itself points to the importance of centers of expertise to centralize the experience and learn from that much faster than is being done now.

For all such patients, developmental assessment should be regularly performed, and plasma Phe and Tyr concentrations should be monitored regularly in order that evidence-based conclusions regarding development and metabolic control can be attained in the future. If developmental delay or behavioral issues are present, appropriate educational help is needed.

TT2 and TT3

These patients are offered dietary treatment as above. Cutaneous and ocular complications are usually rapidly reversed when dietary control of plasma Tyr is achieved. Symptomatic treatment can provide some immediate benefit.

It is reasonable to consider that the development delay seen in some TT2 and TT3 patients may be related to increased levels of plasma Tyr. Controlled trials in large numbers of patients are not available at present because of the rarity of these conditions and the lack of consistent documentation of outcome. This again not only asks for international cooperation in research but also for expert centers that can see as many of these patients as possible to increase and disseminate the expertise. This issue should be discussed with patients and families, and treatment should be offered accordingly. The authors treat patients with these conditions in a similar fashion to the recommendations for nitisinone-treated TT1 patients (De Laet et al. 2013).

Alkaptonuria (AKU)

Currently most treatment of AKU is still symptomatic, concentrating upon the relief of the symptoms of arthritis and joint pain. Nitisinone results in a marked reduction in homogentisate excretion at small doses of nitisinone (Milan et al. 2017). As these small doses of nitisinone for AKU imply hypertyrosinemia, dietary restriction of Phe and Tyr seems essential again. Results of long-term studies as presently undertaken will be needed to show the effect of adequate reduction of homogentisate in order to prevent the major complications of AKU. However, these studies are performed in adults not knowing whether starting nitisinone (with dietary) treatment already in infancy or childhood is more effective.

Hawkinsinuria (HAWK)

Reported patients have become asymptomatic after infancy. Patients should be given symptomatic treatment for acidosis. Temporary dietary restriction of Phe and Tyr could be considered in symptomatic patients.

Maleylacetoacetate Isomerase Deficiency (MAAI)

Reported patients are without symptoms, signs being found with mildly increased SA concentrations at newborn screening for TT1. These patients do not seem to need treatment (Yang et al. 2017).

Comments

There are six defined inborn errors of tyrosine metabolism: TT1, TT2, TT3, HAWK, AKU, and MAAI. The most common and serious of these disorders is TT1. For this disease efficient drug treatment is available with nitisinone, based on inhibition of Tyr degradation at a level prior to the formation of hepatotoxic metabolites. Early institution of nitisinone therapy is desirable, before complications occur. SA is the most sensitive and specific marker for neonatal screening of TT1, and this is now increasingly practiced in newborn screening programs. The outcome in TT1 patients detected by neonatal screening and treated early with nitisinone is very promising to date (Larochelle et al. 2012; Mayorandan et al. 2014), but attention should be focused on neurocognitive and psychosocial development in addition to liver and kidney function and porphyria-like symptoms. For TT2, dietary control of Tyr levels can prevent skin and ocular complications. Controlled dietary restriction of Phe and Tyr is a reasonable approach to all defects in the catabolism of Tyr except MAAI. Expanded newborn screening with SA efficiently detect TT1 and possibly also MAAI depending on the cut-off at newborn screening, but the other inborn errors of Tyr degradation are generally not detected by newborn screening, and a high index of suspicion by clinicians and diagnostic laboratory personnel is necessary to ensure early diagnosis and treatment.

Summary

The conversion of methionine to inorganic sulfate involves the formation of homocysteine encompassing transmethylation followed by transsulfuration. Several inherited enzyme deficiencies within this pathway have been described. Those causing hypermethioninemia may be confused with the many known secondary causes of increased methionine demanding diagnostic expediency. Most of the disorders have been described in small numbers of patients so that the full clinical spectrum of these is not known. Exceptions are methionine adenosyltransferase (MAT) I/III deficiency and cystathionine ß-synthase deficiency which causes classical homocystinuria, characterized primarily by an increased risk of thrombosis and embolism, lens dislocation, and other connective tissue involvement and cognitive impairment. While methionine adenosyltransferase I/III deficiency is only symptomatic in some patients causing different neurological problems and glycine *N*-methyltransferase deficiency affects liver function, other diseases causing hypermethioninemias may be associated with a multisystem disease of varying severity and progression. MAT II deficiency can be associated with thoracic aortic aneurysms in some heterozygotes for *MAT2* mutations. Methanethiol oxidase deficiency causes cabbage-like breath odor (extraoral halitosis). The association of mercaptopyruvate sulfur transferase deficiency with cognitive impairment, as the only disease characteristic, is questionable. Isolated sulfite oxidase deficiency is characterized by refractory convulsions in early infancy, brain atrophy, severe psychomotor retardation, and lens dislocation. Ethylmalonic encephalopathy is a severe disorder manifesting with seizures, developmental delay and cognitive impairment, orthostatic acrocyanosis and petechia due to vasodilation, failure to thrive, and chronic hemorrhagic diarrhea. Measurement of plasma and urine amino acids and total homocysteine can detect many of the disorders described in this chapter, while other tests are necessary for others. Confirmatory tests are enzyme assays and/or mutation analysis. Treatment combines one or more of dietary restriction of precursors, substitution of essential products, pharmacologic doses of cofactors, and binding and removing of harmful metabolites. Early diagnosis and early treatment favor better outcome.

Introduction

Sulfur-containing amino acids include methionine, homocysteine, cystathionine, cysteine, and taurine. This chapter deals with inherited deficiencies of enzymes in the transmethylation and transsulfuration pathways that convert sulfur from methionine via homocysteine and cysteine to sulfate, including sulfide metabolism (Fig. 22.1). Since adenosine kinase deficiency also disrupts the methionine cycle, it is included in this chapter.

Most disorders described in this chapter are inherited as autosomal recessive traits. Exceptions are autosomal dominant forms of methionine adenosyltransferase (MAT) II deficiency and a subgroup of MAT I/III deficiency, caused by mutations with dominant negative effect on the wild-type allele (Chamberlin et al. 1997).

Pathophysiology of disorders of sulfur-containing amino acids is complex and only partly understood (Kožich et al. 2016). In disorders associated with hypermethioninemia, very high concentrations can be harmful themselves, primarily for the brain. In MAT I/III deficiency, low adenosylmethionine (AdoMet) and subsequent deficient methylation could be contributing factors. There are several hypotheses of how *MAT2A* loss-of-function mutations could lead to aortic disease, and it is possible that they require a second "hit" (Guo et al. 2015). Methionine can be also transaminated yielding methanethiol; deficiency of methanethiol oxidase results in accumulation of malodorous molecules such as methanethiol and dimethylsulfide. In *S*-adenosylhomocysteine (AdoHcy) hydrolase deficiency, high concentrations of AdoHcy inhibit numerous methyltransferases with very variable clinical consequences. Several putative pathogenetic mechanisms of adenosine kinase deficiency are related to increased adenosine and its various toxic effects. Another mechanism could be inhibition of numerous methyltransferases caused by secondary elevation of *S*-adenosylhomocysteine. The latter mechanism could also be important in classical homocystinuria, where a major pathogenetic mechanism seems to be elevation of homocysteine with its adverse effect on coagulation, vessels and secondary to vascular changes in many tissues, and possibly the decreased production of cysteine manifesting in connective tissue including lens zonular fibers. Clinical consequences of sulfite oxidase deficiency are likely due to toxic effects of sulfite, *S*-sulfocysteine, and thiosulfate on the brain and connective tissue. Patients with ethylmalonic encephalopathy accumulate a large amount of hydrogen sulfide, which leads directly to vasodilation and to secondary inhibition of cytochrome c-oxidase with subsequent impairment of short-chain fatty oxidation with typical metabolite changes and of oxidative phosphorylation with lactic acidosis.

Clinical presentation can occur at any age and varies widely in its severity.

MAT I/III deficiency is asymptomatic in all individuals with the autosomal dominant disease, while about half of the patients with the autosomal recessive form have developed neurological symptoms (Chien et al. 2015). Hypermethioninemia, the biochemical hallmark of this

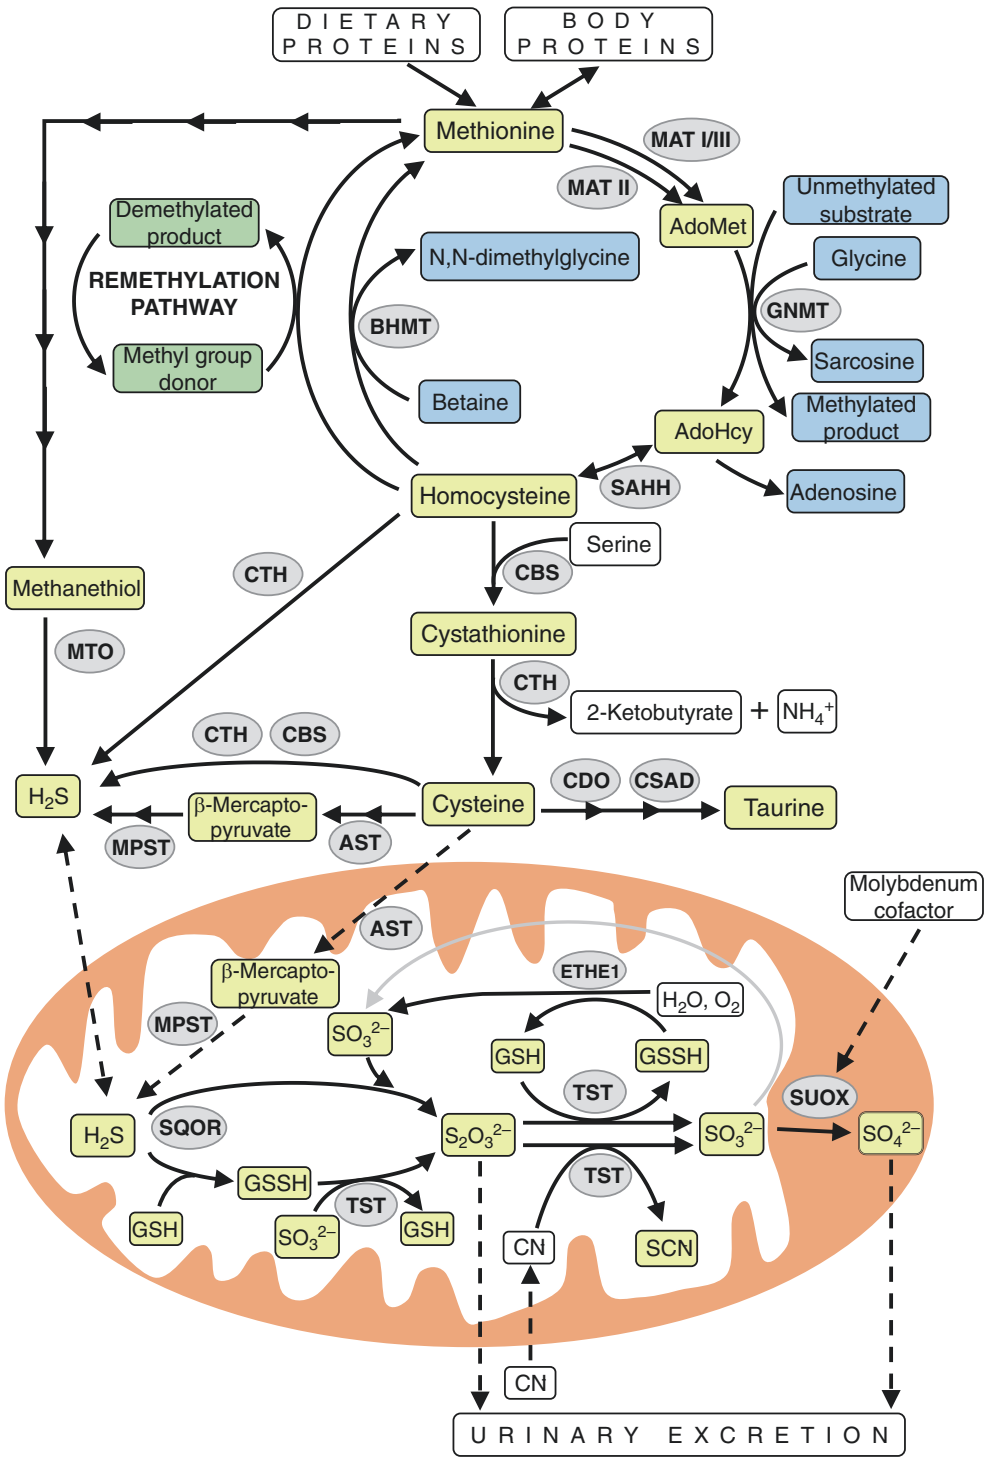

Fig. 22.1 Metabolism of sulfur amino acids and of hydrogen sulfide. Methionine is converted to cysteine via a series of reactions involving the following enzymes: *MATI/III* methionine adenosyltransferase I/III, *MATII* methionine adenosyltransferase II, *GNMT* glycine *N*-methyltransferase, *SAHH* *S*-adenosylhomocysteine hydrolase, *BHMT* betaine homocysteine methyltransferase, *CBS* cystathionine beta-synthase, *CTH* cystathionine gamma-lyase, *AdoMet* *S*-adenosylmethionine, *AdoHcy* *S*-adenosylhomocysteine. Cysteine serves as the major precursor for synthesis of hydrogen sulfide catalyzed by CBS, CTH, aspartate aminotransferase (AST), and mercaptopyruvate sulfurtransferase (MPST); hydrogen sulfide may be also synthesized by methanethiol oxidase (MTO). Another route of cysteine oxidation to taurine is catalyzed by cysteine dioxygenase (CDO) and cysteine sulfinic acid decarboxylase (CSAD). Mitochondrial oxidation of hydrogen sulfide requires the following enzymes: *SQOR* sulfide:quinone oxidoreductase, *ETHE1* persulfide dioxygenase, *TST* thiosulfate transferase, *SUOX* sulfite oxidase, *GSH* glutathione, *GSSH* glutathione persulfide

disease, if severe, is itself associated with increased risk of various neurological problems (Braverman et al. 2005). The most characteristic brain imaging changes are demyelination with edema of subcortical and deep white matter, more pronounced in dorsal brain stem and resulting in separation of myelin layers—the so-called vacuolating myelinopathy (Braverman et al. 2005). Neurological abnormalities tend to occur in patients with plasma methionine concentrations generally above 800 μmol/L, whereas they have been rare in subjects with lower levels (Chien et al. 2015).

MAT II deficiency is only a risk factor for developing thoracic aortic aneurysms in some heterozygotes for *MAT2A* mutations.

Glycine N-methyltransferase (GNMT) deficiency (Mudd et al. 2001) has been so far described in only five children. The only clinical sign was mild hepatomegaly present in two

siblings. The patients have remained clinically well during follow-up (Barić et al. 2017). Their aminotransferase activities ranged from borderline to fivefold increase. Plasma methionine can reach potentially damaging values (see MAT I/III deficiency).

S-adenosylhomocysteine hydrolase deficiency (Barić et al. 2004) has been proven and reported so far in ten patients. Two sibs had fetal hydrops, liver synthetic failure, and muscular hypotonia leading to respiratory failure and death in early infancy. They also showed brain abnormalities including cerebellar and pontine hypoplasia, hypoplastic corpus callosum, and hypomyelination. Muscle disease with high creatine kinase was present also in other patients with a milder phenotype. They also had, in various combinations, developmental delay, behavioral abnormalities, myelination delay, strabismus, coagulopathy, and liver disease. One patient had hepatocellular carcinoma, and there is some evidence that this disease carries increased risk for this malignancy.

Adenosine kinase deficiency has been described so far in 19 patients. All had severe developmental delay, hypotonia, and frontal bossing. The majority had hypertelorism, failure to thrive, epilepsy, macrocephaly, neonatal jaundice, and liver disease with elevated aminotransferases. About half of patients had cardiac anomalies (Staufner et al. 2016; Alhusani et al. 2019).

Cystathionine beta-synthase (CBS) deficiency is clinically variable and characterized primarily by an increased risk of thrombosis—predominantly in venous beds—and pulmonary embolism and in more severe forms by osteoporosis, lenticular myopia and lens dislocation, developmental delay, and cognitive impairment (Mudd et al. 1985). About half of patients are pyridoxine responsive with a less severe disease (Morris et al. 2017).

Cystathionase deficiency is considered a benign condition (Kraus et al. 2009) although it was originally described in patients with psychomotor retardation and other neurological findings.

Methanethiol oxidase (MTO) deficiency has been described in only five patients with cabbage-like breath odor (extraoral halitosis) due to accumulation of methanethiol and dimethylsulfide (Pol et al. 2018).

Isolated sulfite oxidase deficiency is characterized by refractory convulsions starting in the neonatal or early infantile period, severe psychomotor retardation, brain imaging findings resembling hypoxic-ischemic encephalopathy with development of cysts, and early death. Lens dislocation occurs usually after the neonatal period. Milder and late-onset cases have been reported (Claerhout et al. 2018; Bindu et al. 2017, see Online resources).

Persulfide dioxygenase (PDO) deficiency or ethylmalonic encephalopathy (ETHE1) is a severe disorder manifesting in seizures, developmental delay and cognitive impairment, orthostatic acrocyanosis and petechia due to vasodilation, failure to thrive, and chronic hemorrhagic diarrhea (Di Meo et al. 2017, see Online resources).

Mercaptopyruvate sulfur transferase (MPST) deficiency and/or excretion of the mercaptolactate has been reported in two patients with mental retardation (Ampola et al. 1969); however, subsequently no association with cognitive impairment was reported.

Nomenclature

No.	Disorder	Alternative name	Abbreviation of the disease/ deficiency	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	OMIM No.	Subtype
22.1	Methionine adenosyltransferase I/III deficiency	MAT deficiency	MAT I/III	*MAT1A*	10q22	AR	Methionine adenosyltransferase I/III	250850	Potentially symptomatic form

[a]Inheritance of this risk factor with incomplete penetrance is autosomal dominant

Metabolic Pathway

Metabolism of sulfur amino acids is summarized in Fig. 22.1. Methionine and homocysteine are linked by the remethylation cycle (see Chap. 28 for details) and the transsulfuration pathway. The essential amino acid methionine is derived from the diet or catabolism of proteins. Methionine is first converted to *S*-adenosylmethionine by two methionine *S*-adenosyltransferases, the ubiquitously expressed MATII and liver-expressed MATI/III encoded by *MAT2A* and *MAT1A* genes, respectively. *S*-adenosylmethionine (AdoMet) is the methyl-group donor in a wide range of transmethylation reactions including DNA methylation, creatine, and neurotransmitter synthesis, and surplus amounts are converted to sarcosine by glycine *N*-methyltransferase. The transfer of methyl groups from AdoMet yields *S*-adenosylhomocysteine, which is a strong inhibitor of transmethylation reactions and must be cleaved to adenosine and homocysteine by *S*-adenosylhomocysteine hydrolase. Depending on a number of factors, about half of available homocysteine is recycled into methionine by the folate and cobalamin-dependent remethylation cycle, while the other half is channeled into the transsulfuration pathway. In the latter series of reactions, homocysteine is condensed with serine to form cystathionine via a reaction catalyzed by the pyridoxal phosphate-requiring cystathionine ß-synthase. Cystathionine is cleaved to cysteine, α-ketobutyrate, and ammonia by another pyridoxal phosphate-dependent enzyme, γ-cystathionase. Cysteine is an important precursor for the synthesis of glutathione and taurine and the major source for endogenous production of the signaling molecule hydrogen sulfide. The sulfur atom of cysteine can be fully oxidized to sulfate via two major pathways. Cysteine can be converted to cysteine sulfinic acid by cysteine dioxygenase followed by transamination with α-oxoglutarate yielding pyruvate and sulfite, although cysteine sulfinate can be also decarboxylated and give rise to hypotaurine and finally to taurine. The other pathway utilizes cysteine for the synthesis of the gasotransmitter hydrogen sulfide by catalysis of CBS, CTH, MPST, and cysteinyl-tRNA synthetase; hydrogen sulfide exists in a dynamic equilibrium of dissolved gas, hydrosulfide, and various organic and inorganic polysulfides. Oxidation of hydrogen sulfide occurs in mitochondria and starts with persulfidation of GSH by sulfide:quinone oxidoreductase, followed by release of sulfite under the catalysis of ETHE1. Sulfite is finally oxidized by the molybdenum cofactor-containing sulfite oxidase to the ultimate oxidation product sulfate.

Signs and Symptoms

Table 22.1 Methionine adenosyltransferase I/III deficiency (AR and AD[a] forms)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Sarcosine	0.6–2.5 (not age stratified)			
S-adenosylmethionine	0.03–0.16 (not age stratified)			
S-adenosylhomocysteine	0.015–0.06 (not age stratified)			
Cystathionine (by sensitive GC-MS or LC-MS/MS assays)	0.08–0.5 (up to 1 in neonates)			
Methionine-to-cystathionine ratio	40–200 (not age stratified)			
Thiosulfate	0.4–0.7 (not age stratified)			
Sulfite	0.2–0.5 (not age stratified)			
Free sulfide (hydrogen sulfide)	0.15–0.3 (not age stratified)			
Dimethylsulfide (blood)	<0.007 (not age stratified)			
Dimethylsulfoxide (blood)	<1 (not age stratified)			
Lactate (blood)	Reference ranges for lactate in blood are shown in Chap. 42 of this book			
Dried blood spots (μmol/L blood)				
Methionine	7–40 (not age stratified)			
Methionine/phenylalanine	0.15–0.6			
Total homocysteine	2.5–9		5.5–9	8–13
Methionine-to-total homocysteine ratio	2–4 (not age stratified)			
Reference ranges for acylcarnitines in dried blood spots are shown in Chap. 5 of this book				
Urinary amino acids (mmol/mol creatinine)				
Methionine	7–29	5–20	3–17	2–16
Cystathionine	Usually below detection limit (not age stratified)			
Homocystine	0.2–3.7 (not age stratified)			
Reference ranges for organic acids in urine are shown in Chap. 4 of this book				
Urinary special assays (mmol/mol creatinine)				
Total cysteine	10–50 (not age stratified)			
Total homocysteine	1–4 (not age stratified)			
Thiosulfate	0.8–2.5 (not age stratified)			
Sulfite	0.03–0.15 (not age stratified)			
S-sulfocysteine	0.3–1 (not age stratified)			
Simple tests in urine (qualitative test)				
Nitroprusside test	Negative (not age stratified)			
Exhaled air (ppb)				
Dimethylsulfide	1–19 (not age stratified)			
Methanethiol	0.01–0.24 (not age stratified)			

[a]Table shows typical values from literature (Duran et al. 2008, Chap. 2 of this book) and authors' laboratories; due to the lack of harmonization and the use of different analytical platforms for many of the metabolites listed, these reference ranges are not universally applicable. Therefore, it is important to use the reference ranges given by the laboratory which issued the results. Reference ranges can be also found in the Human Metabolome Database (see Sect. 22.17 Online Resources)

[a]Pathological values may vary in different age groups and disease forms; for details, see Tables 22.1–22.11
[b]There are no specific biochemical abnormalities in individuals with thoracic aortic aneurysms who are heterozygotes for *MAT2A* mutations. Therefore, related column is not provided
[c]Normal values are denoted by "n" only when particularly important for differential diagnosis. Blank cells indicate that the metabolite is within reference range or that data are not available
[d]Nitroprusside test has limited reliability due to false-negative results

Diagnostic Flowcharts

Since most of the mentioned diseases are at least partly treatable if diagnosed early and may have rapid course, the *diagnostic work-up* in suspected cases should also be rapid. Suspicion should be raised in all patients having unexplained neurological symptoms, muscle disease, liver disease, lens dislocation and other marfanoid features, orthostatic acrocyanosis, or any other symptom attributable to diseases from this group or unexplained hypermethioninemia and/or hyperhomocysteinemia or hypohomocysteinemia (see Sect. 22.4). Measurement of plasma total homocysteine and amino acids (methionine, taurine, and *S*-sulfocysteine) and special tests for sarcosine, cystathionine, *S*-adenosylmethionine, and *S*-adenosylhomocysteine should be sufficient as the first step to detect all diseases from this group; sulfite and thiosulfate analysis is necessary for diagnosing disorders in the distal part of transsulfuration pathway (for differential diagnosis of hypermethioninemia and hypo- and hyperhomocysteinemia, see Diagnostic flowcharts, Figs. 22.2 and 22.3).

It is useful to keep in mind that in MAT I/III deficiency homocysteine can be sufficiently elevated to mimic CBS deficiency, probably due to less than normal stimulation of CBS by low AdoMet and inhibition of betaine-homocysteine methyltransferase, N^5-*methyltetrahydrofolate-homocysteine* methyltransferase and cystathionine gamma-lyase by methionine, in particular in patients with very high methionine values (Stabler et al. 2002). Mild elevations of tHcy, which can be diagnostically misleading, have also been described in other methylation defects and in CTH deficiency.

Pyridoxine responsiveness test in CBS deficiency. This test is performed in patients with CBS deficiency to assess pyridoxine responsiveness. Recent guidelines recommended standard tests in patients detected symptomatically using 10 mg/kg/day pyridoxine (maximum of 500 mg/day) for 6 weeks; the plasma tHcy concentration should be measured at least twice before treatment and twice on treatment (by the end of weeks 2 and 6). The test should be done on normal protein intake, folate supplements should be given, and vitamin B_{12} deficiency should be corrected prior to testing. Classification of pyridoxine responsiveness is as follows: full responsiveness, plasma tHcy levels below 50 μmol/L; extreme responsiveness, tHcy below 50 μmol/L on pyridoxine doses <1 mg/kg/day; partial responsiveness, tHcy falls >20% of pre-test average but above 50 μmol/L; and non-responsiveness, tHcy falls by <20% (Morris et al. 2017).

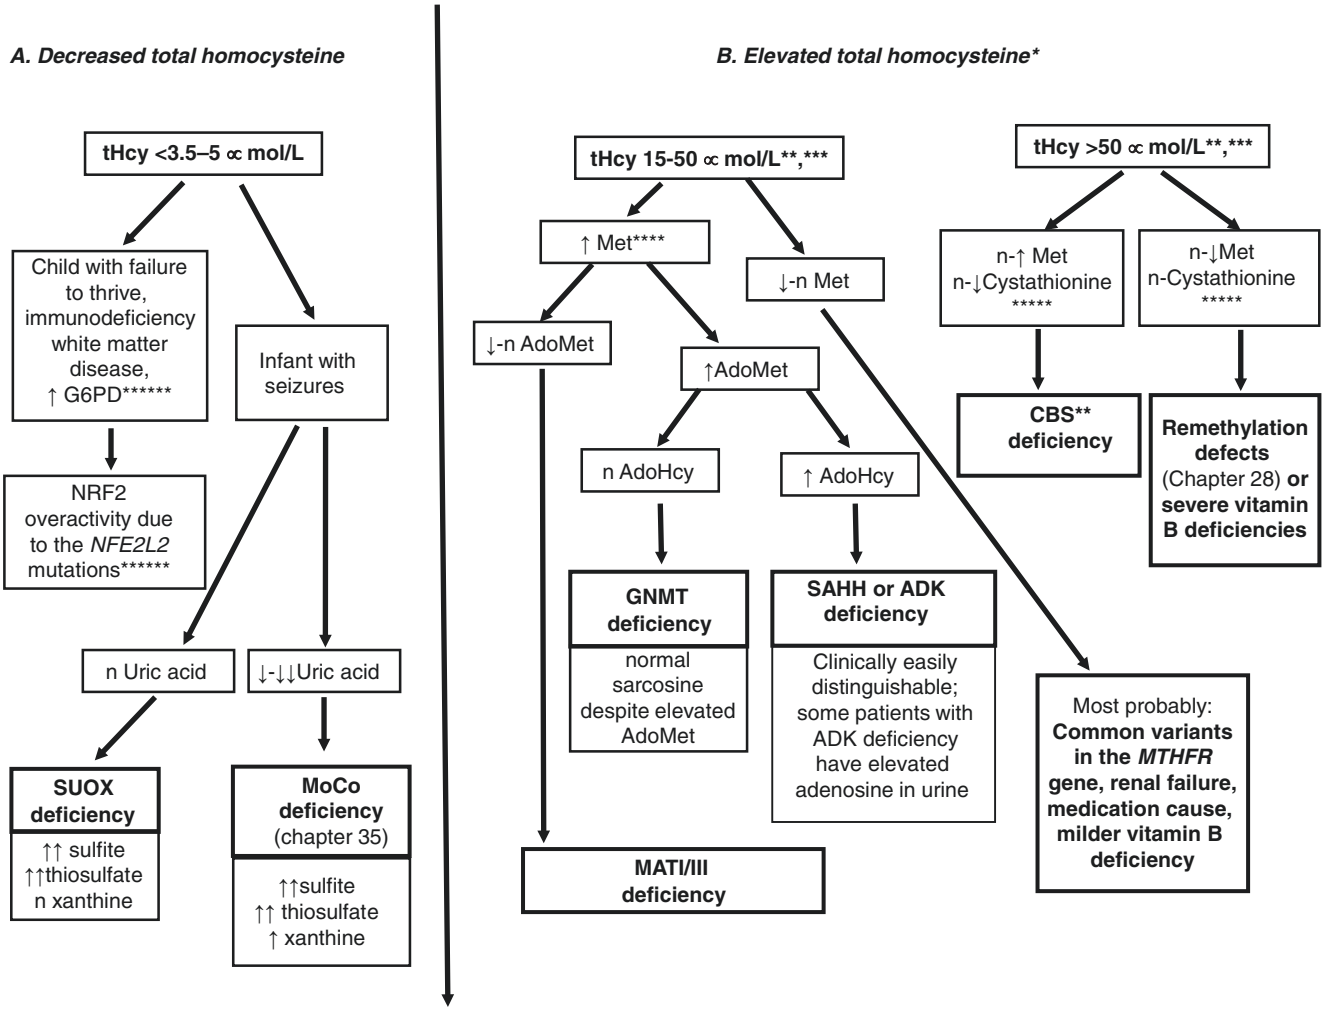

Fig. 22.2 Diagnostic flowchart for hypo- (**a**) and hyperhomocysteinemia (**b**). * tHcy range of 5–15 μmol/L is used here as reference range for all ages; actually, in children the upper limit of reference range is lower (see Reference Values). ** In non-treated CBS deficiency, tHcy is usually significantly >50 μmol/L but may be lower in mild cases, in particular when on vitamin supplementation (even non-pharmacological doses of pyridoxine). *** In non-CBS hypermethioninemias, tHcy is usually normal or only mildly elevated, and values of about 50 μmol/L are exceptionally seen. **** In ADK and SAHH deficiency, plasma methionine concentrations can occasionally be normal, for instance, in SAHH deficiency in early infancy during lower methionine intake and higher needs for growth. ***** Cystathionine for differential diagnosis of hyperhomocysteinemia cannot be detected by amino acid analyzers and must be determined by sensitive GC-MS or LC-MS/MS assay. ****** This disease has been reported in only few patients (for details, see Chap. 16), and all abnormalities are not necessarily present in all patients. Mild hypohomocysteinemia (below 3.5–5 μmol/L) is sometimes seen without association with a particular disease. *ADK* adenosine kinase, *AdoHcy* *S*-adenosylhomocysteine, *AdoMet* *S*-adenosylmethionine, *CBS* cystathionine beta synthase, *GNMT* glycine *N*-methyltransferase, *G6PD* glucose-6-phosphate dehydrogenase, *MAT I/III* methionine adenosyltransferase I/III, *Met* methionine, *MoCo* molybdenum cofactor, *MTHFR* methylenetetrahydrofolate reductase, *NFE2L2* nuclear factor, erythroid 2 like 2, *NRF2* nuclear factor-erythroid 2-related factor 2, *SAHH* *S*-adenosylhomocysteine hydrolase, *SUOX* sulfite oxidase, *tHcy* plasma total homocysteine

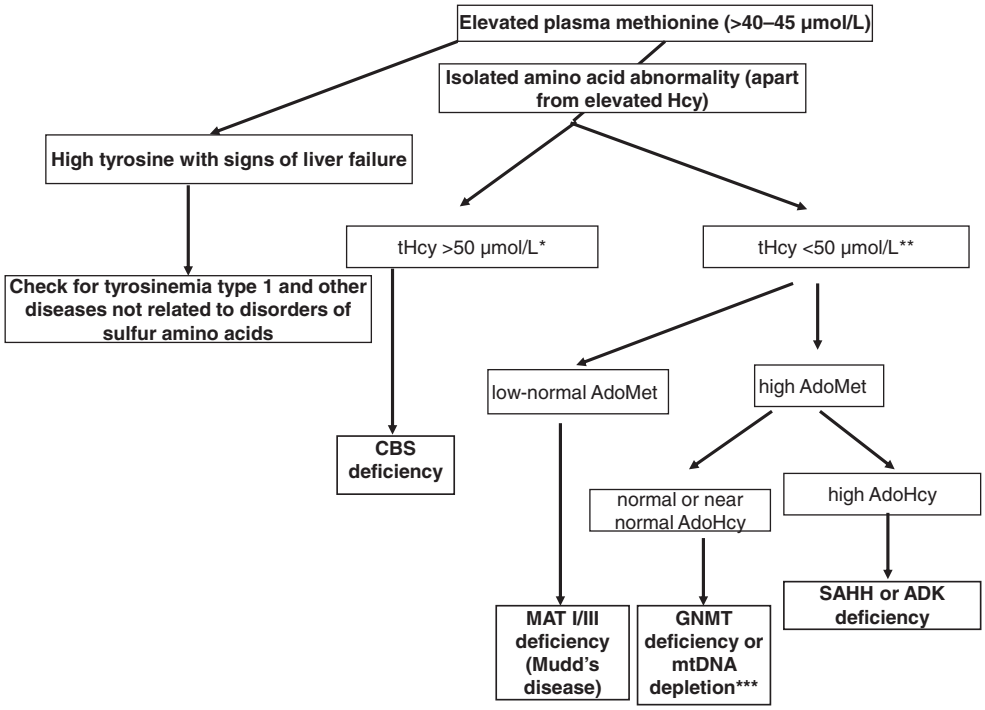

Fig. 22.3 Diagnostic flowchart in patients with hypermethioninemia. *In untreated CBS deficiency, tHcy is usually >50 µmol/L but may be lower in mild cases, in particular when on vitamin supplementation (non-pharmacological doses). **In non-CBS deficiency hypermethioninemias, tHcy is usually normal or only mildly elevated, and values of about 50 µmol/L are rarely seen. ***Tyrosine can be elevated. *ADK* adenosine kinase, *AdoHcy* *S*-adenosylhomocysteine, *AdoMet* *S*-adenosylmethionine, *CBS* cystathionine beta synthase, *GNMT* glycine *N*-methyltransferase, *MAT I/III* methionine adenosyltransferase I/III, *mtDNA* mitochondrial DNA, *SAHH* *S*-adenosylhomocysteine hydrolase, *tHcy* plasma total homocysteine

Loading Test

Increase of plasma dimethylsulfone and dimethylsulfoxide in methionine loading test in patients suspected to suffer from extraoral halitosis due to methanethiol oxidase deficiency can point to the cause of the disease. The methionine loading test became obsolete in diagnosis of sulfur-containing amino acids disorders.

Specimen Collection

Overview on required samples for metabolite, enzyme, and mutation analysis

Disorder	Metabolite: sample
	Amino acids (including taurine): plasma or serum[a] and urine
	Organic acids: urine
	Acylcarnitines: dried blood spots and plasma/serum
	Special assays
CBS, CTH, SUOX	Total homocysteine and total cysteine: plasma[b] and urine
MATI/III, GNMT, ADK, CBS	*S*-adenosylmethionine: plasma[c], whole blood
MATI/III, GNMT, ADK, CBS	*S*-adenosylhomocysteine: plasma[c], whole blood
SUOX, ETHE	Thiosulfate: plasma and urine[d,e]
SUOX, ETHE	Sulfite: plasma and urine[d,e]
SUOX, ETHE	Free sulfide (hydrogen sulfide): plasma[d]
MTO	Methanethiol and dimethylsulfide in exhaled air
CBS	Methionine, Met/Phe and tHcy in dried blood spots
	Other assays: plasma, blood or urine (may require special sampling conditions, consult the laboratory)
	Enzyme assays[f]: specimen
MAT I/III	Liver[g]
GNMT	Liver[g]
SAHH	Cultured fibroblasts, erythrocytes, liver
ADK	Not available
CBS	Cultured fibroblasts and plasma[a]
CTH	Liver[g]
SUOX	Cultured fibroblasts
ETHE1	Not available
MPST	Erythrocytes
MTO	Erythrocytes

Disorder	Metabolite: sample
	Mutation analysis
All disorders	DNA

[a]Blood for plasma amino acids analysis should be sampled after 3–4 h fasting. For taurine determination only plasma should be used and handled as in [b]. Rapid deproteinization is essential for determination of non-protein bound homocysteine (this analysis is considered obsolete and should be replaced by total homocysteine determination)
[b]Samples should be immediately placed into ice/water slush, separation of plasma within 60 min since collection is essential
[c]EDTA blood on ice, immediate separation of plasma and deproteinization (within 30 min since collection)
[d]Plasma: only lithium heparin plasma should be collected, samples should be immediately placed into ice/water slush, separation of plasma within 15 min since collection, and immediate freezing prior to analysis at −85 °C is essential
[e]Urine: only freshly collected urine should be used for analysis, immediate freezing prior to analysis at −85 °C is essential
[f]In general, enzymatic work-up as a first step is advised. In some cases (common mutation or small gene), mutation analysis as first step
[g]Liver biopsy is not routinely justified

Prenatal Diagnosis

Prenatal diagnosis is only relevant for SAHH, ADK, CBS, ETHE1, and SUOX deficiencies. Generally the first choice of method for each of these is mutation analysis in chorionic villous material provided that disease-causing mutations and their parental origin have been confirmed. Alternatively, enzyme assay in cultured amniocytes can be performed in some diseases.

DNA Testing

All genes in this chapter are known, and mutation analysis of genomic DNA isolated from peripheral blood, chorionic villi, amniocytes, or other cells is feasible. Sanger sequencing of individual genes or next-generation sequencing of gene panels are used. For mutations suspected to affect splicing, mRNA analysis in appropriate tissues may be necessary.

Treatment Summary

The general treatment goal for disorders of sulfur amino acid and hydrogen sulfide metabolism is correcting biochemical abnormalities in order to suppress their adverse effects. This causal treatment primarily consists in various combinations of high doses of cofactors, low-protein or low-methionine or low-cysteine diet, and supplementation of metabolites behind the enzymatic block. Betaine is an additional means to decrease homocysteine concentration.

In *MAT I/III deficiency*, methionine restriction is indicated in symptomatic patients and those with brain imaging changes. It is justified also in asymptomatic patients with severe deficiency and plasma methionine >500–800 μmol/L. AdoMet supplementation may be necessary. It seems that *GNMT deficiency*, *cystathionase deficiency*, and *autosomal dominant MATI/III deficiency* do not require treatment. In *AdoHcy hydrolase deficiency*, low-methionine diet can decrease plasma AdoMet and AdoHcy, with a positive effect on methylation and clinical and biochemical abnormalities (Barić et al. 2005). Phosphatidylcholine, creatine, and cysteine supplementation may be useful. Liver transplantation seemed beneficial in one patient with short follow-up. *CBS-deficient* patients are treated with varying doses of pyridoxine if responsive in the pyridoxine test. Folate and cobalamin should be added to avoid vitamin depletion and stimulate homocysteine remethylation. Betaine and/or a low-methionine diet (sometimes with methionine-free/cystine-enriched amino acid mixture) may also be needed in partial responders but necessary in pyridoxine nonresponsive patients. In *isolated sulfite oxidase deficiency*, partial success with low-protein diet combined with methionine- and cysteine-free amino acid mixture has been reported only in late-onset patients (Touati et al. 2000). Low methionine diet may ameliorate the liver phenotype in *adenosine kinase deficiency.* For *MATII deficiency and mercaptopyruvate sulfurtransferase deficiency*, no successful causal treatment has been reported. In *ethylmalonic encephalopathy*, metronidazole and *N*-acetylcysteine may reduce some symptoms. Early liver transplantation may be an option to reverse otherwise unfavorable outcome. In *MTO deficiency*, metronidazole can reduce methanethiol production by gut bacteria.

Emergency Treatment

Methionine Adenosyltransferase I/III Deficiency (AR and ADa forms)

If unexplained neurological signs are present with very high methionine level, discontinuance of methionine intake for 1–3 days followed by low-methionine diet until symptoms disappear, in combination with AdoMet supplementation (for instance, at a dose of 400 mg twice daily, Surtees et al.

1991), seems to be indicated. See also the comment [b] below the standard treatment table.

S-Adenosylhomocysteine Hydrolase Deficiency

Severe cases, such as those presenting with fetal hydrops, insufficiency of liver synthetic function, and severe muscular hypotonia leading to respiratory insufficiency, may potentially benefit from strict methionine restriction and choline and cysteine supplementation in combination with vigorous symptomatic treatment.

Ethylmalonic Encephalopathy

Continuous renal replacement therapy may help to reestablish metabolic control during acute metabolic decompensations in patients on chronic treatment with *N*-acetylcysteine and metronidazole (Kitzler et al. 2019).

For other disorders from this group, emergency situations amenable to specific disease-related emergency treatment are not likely. A diet low in protein and an amino acid mixture without cystine and methionine may be helpful in mild sulfite oxidase deficiency.

Standard Treatment

Disease	Comment	Medication/diet	Dosage[a]	Goals
22.1 MAT I/III deficiency	For the autosomal dominant form of the disease, treatment does not seem to be indicated For the autosomal recessive form, if plasma methionine concentrations are above risky level (clear risk above 800 µmol/L, existing risk above 500–600 µmol/L), a methionine-restricted diet is recommended If the mean plasma methionine is below 500–600 µmol/L, treatment does not seem to be indicated	Low-methionine diet	In infancy ~15–20 mg of methionine/kg/day; later less as expressed in mg/kg/day and according to clinical and biochemical parameters	Disappearance/prevention of clinical symptoms Normalization of brain imaging findings The aim of the diet is to maintain methionine levels around 500–600 µmol/L, even in asymptomatic individuals It should be borne in mind that lowering plasma methionine below 500 µmol/L in patients with some residual MAT I/III activity may further limit the flux through MAT I/III and further decrease the availability of AdoMet (Mudd et al. 2001)
	AdoMet supplementation, especially if methionine intake is limited, may be necessary	*S*-adenosylmethionine	2–3 × 400 mg daily per os[b]	Clinical improvement, normalization of plasma and/or CSF AdoMet; normalization of hyperhomocysteinemia
22.2 Methionine adenosyltransferase II deficiency	No causal treatment; surgery and other measures according to risk assessment of thoracic aorta aneurysm development			
22.3 GNMT deficiency	There is no evidence that therapy is necessary; low-methionine diet can correct biochemical abnormalities. It may be indicated when plasma methionine reaches values above 500–600 µmol/L, which may be risky regardless of cause	Low-methionine diet	In infancy ~15–20 mg of methionine/kg/day; later less as expressed in mg/kg/day and according to clinical and biochemical parameters	Correction of biochemical abnormalities and potential neurological problems due to high hypermethioninemia
22.4 AHCY deficiency	Due to small number of patients, these recommendations are based only on pathogenetic hypotheses and limited clinical experience Liver transplantation seemed beneficial in one patient with a short follow-up	Low-methionine diet	In infancy natural protein intake containing ~10–20 mg/kg/day of methionine, depending on the severity of the disease and biochemical findings, in combination with methionine-free amino acid mixture to meet needs for proteins	Clinical improvement and decrease of AdoMet and AdoHcy as close to normal values as possible, while avoiding protein malnutrition

Disease	Comment	Medication/diet	Dosage[a]	Goals
		Phosphatidylcholine	3 × 600–1200 mg/day	Avoidance of possible phosphatidylcholine and choline deficiency
		N-acetylcysteine	3 × 100–200 mg/day	Avoidance of possible glutathione deficiency
		Creatine (may be useful theoretically)	3–5 g/day	Avoidance of possible creatine deficiency
22.5 ADK deficiency	Low methionine diet should be considered as a therapeutic option, since it ameliorates the liver phenotype clinically and biochemically. Positive effect on the neurological outcome has only been reported in a single case. Diazoxide is recommended for recurrent hypoglycemia when it is due to hyperinsulinism (Barić et al. 2017)	Low methionine diet	Daily intake of 15–20 mg of methionine per kg of body weight in infants and small children; later less as expressed in mg/kg/day and according to clinical and biochemical parameters	Improvement of clinical and biochemical indices of liver disease
22.6 CBS deficiency[c]	*Test of pyridoxine responsiveness* should be done on normal protein intake at the beginning of the treatment (for details, see above) Before test possible folate and cobalamin deficiency should be corrected to assure proper assessment of the test results	A. Pyridoxine responders and partial responders		**Clinical targets:** For early diagnosed patients, prevention of all the complications of CBS deficiency while maintaining normal growth and nutrition For late-diagnosed patients, prevention of further complications, especially thromboembolic disease **Biochemical targets**: Maintenance of tHcy concentration as close to normal as possible. In fully responsive patients, standard doses can lead to tHcy levels below 50 µmol/L (and sometimes within the normal range in extreme responsive patients). Some patients who are partially responsive to pyridoxine may be able to achieve a tHcy level below 50 µmol/L if they are also on a low-Met diet; for others it is not a realistic goal. Excessive methionine restriction, with plasma methionine concentrations that are sometimes below the normal range, may impair growth and neurodevelopmental progress in children. In pyridoxine unresponsive patients, it is recommended to keep tHcy levels at least below 100 µmol/L, but this may need revision when very long-term data become available (Morris et al. 2017). Plasma methionine levels in patients treated with betaine should be kept below 800 µmol/L (it is probably safer below 500–600 µmol/L)
		Pyridoxine	The pyridoxine dose should be the lowest that achieves the biochemical targets. Recommended doses are up to 10 mg/kg/day divided into 1–3 doses; doses above 500 mg/day should be avoided	
		Folate[d]	Optimal dose is not known; up to 1 mg/day is probably sufficient if folate deficiency is not present	
		Hydroxocobalamin	Vitamin B_{12} should be monitored and supplemented if deficient	
		Low-methionine diet (for partially responsive patients only)	The degree of methionine or natural protein restriction required varies and is determined for each patient according to their plasma tHcy, methionine, and other parameters	
		Betaine (for partially responsive patients only)	Patients' responses to betaine are variable and optimal doses have to be individualized. For children, the initial betaine dose is 50 mg/kg twice daily. For adults, the starting dose is 3 g twice a day. The dose and frequency are adjusted according to response. There is unlikely to be any benefit in exceeding a dose of 150–200 mg/kg/day	

Disease	Comment	Medication/diet	Dosage[a]	Goals
	Guidelines for protein intake in methionine-restricted diet are very approximate. Diet must be adjusted, in combination with other measures, to achieve therapeutic goal, if possible, but should not jeopardize the patient; therefore strict monitoring of growth and nutritional indices (including aromatic and branched chain amino acids) is necessary	B. Pyridoxine nonresponders		
		There is no evidence that long-term pyridoxine is beneficial if there is no biochemical response in a properly conducted test (Morris et al. 2017)		
		Folate[d]	Optimal dose is not known; less than 1 mg/day is probably sufficient if folate deficiency is not present	
	In nearly all CBS-deficient patients, high remethylation activity may lead to folate and/or cobalamin depletion; therefore, folate and cobalamin should be added to the therapy	Cobalamin	Vitamin B_{12} should be monitored and supplemented if deficient	
		Low-methionine diet	Patients may require only isolated mild protein/methionine restriction or more severe restriction combined with amino acid mixture administration. The combined intake of low natural protein and methionine-free/cystine-enriched amino acid mixture (total protein equivalent) should follow the WHO/FAO recommendations (Joint FAO/WHO/UNU Expert Consultation on Protein and Amino Acid Requirements in Human Nutrition 2007). Methionine intake in natural protein depends on age and should be adjusted to maintain plasma tHcy levels <100 μmol/L while avoiding protein over-restriction. This can be typically achieved by prescribing 0.4–1.0 g natural protein/kg/day; however, higher or lower intake may be needed. If diet is based on calculation of methionine intake, appropriate amount may be between 4 and 10 mg/kg/day, with higher needs in infancy, particularly early infancy	
		Betaine	See pyridoxine responders	

Disease	Comment	Medication/diet	Dosage[a]	Goals
22.7 CTH deficiency	The disorder seems benign and therapy unnecessary			
22.8 Methanethiol oxidase deficiency	There is no standard treatment for this recently described disease, and options provided are based on pathogenesis (low methionine diet, metronidazole) and short trial in a single patient (metronidazole), respectively (Pol et al. 2018). Although an effect is expected from metronidazole, it is not recommended as prophylactic treatment	Metronidazole Low-protein/low methionine diet	Metronidazole: children 20–30 mg/kg/day three times daily; adults 400 mg three times daily (doses provided here are those usually used for anaerobic infections and for this indication may depend on the effect, occasion, and duration of the therapy/prophylaxis) Low-protein/low methionine diet can be considered but should not be over-restrictive so that methionine intake carefully adjusted to avoid harmful effects	To minimize the malodor while avoiding side effects
22.9 Isolated SUOX deficiency	The treatment has been useful only in milder forms of the disease. The diet must be carefully monitored to avoid protein malnutrition. Thiamine and pyridoxine can be added to avoid thiamine and pyridoxal-5-phosphate deficiency due to sulfite accumulation	Low-methionine and low-cysteine diet	Dependent on age and biochemical markers of the disease and protein status	Clinical improvement, decrease of toxic metabolites (*S*-sulfocysteine, thiosulfate), to limit excitotoxicity (dextromethorphan)
		Dextromethorphan (NMDA receptor antagonist)	Dextromethorphan: 12.5 mg/kg daily (dosage reported in patient with molybdenum cofactor deficiency; largely variable dosage has been reported in nonketotic hyperglycinemia)	
22.10 Ethylmalonic encephalopathy	Metronidazole and *N*-acetylcysteine may improve metabolic abnormalities (decrease H_2S accumulation and the sulfur atom from H_2S, respectively), reduce some symptoms, and slow disease progression	Metronidazole *N*-acetylcysteine	Metronidazole 25–50 mg/kg/day three times daily *N*-acetylcysteine 50–100 mg/kg/day in 2–3 doses	Decrease of H_2S accumulation and assimilation of the sulfur atom from H_2S, respectively, reducing some symptoms and slowing disease progression
22.11 Mercaptopyruvate sulfurtransferase deficiency	This condition could be benign	Not reported	–	–

[a]With the exception of CBS deficiency, given doses are arbitrary and frequently not evaluated in a sufficient number of patients for each given indication; therefore, they must be adjusted individually according to the diagnosis, patients' needs, and results of clinical and biochemical monitoring. A common problem is finding a proper balance between the wish to achieve desired therapeutic goals and avoidance of potentially serious side effects of higher doses than recommended/tested

[b]The dosage and route are only for approximate orientation. Information about AdoMet treatment in children is very limited. In adults daily doses from 50 mg to 3 g have been used. Intramuscular and intravenous forms of the drug do exist and should be considered in every patient individually

[c]Besides specific measures listed in table for CBS deficiency, other risk factors for thromboembolism should be checked and, if needed, treated. Dehydration and immobilization should be avoided to reduce the risk of thromboembolic disease. Patients who are poorly controlled or have had a vascular event may need additional treatment with anti-platelet drugs or anticoagulants. Surgery and anesthesia pose an additional risk of thrombosis. Biochemical control should be optimized before elective procedures. Standard anti-thrombotic measures such as elastic stockings, pneumatic leg compression systems, and early mobilization should be followed during and after surgery. Low molecular weight heparin is recommended in cases of prolonged immobilization. Nitrous oxide increases Hcy concentrations and should be avoided. Standard measures for preventing thrombosis are recommended for travel (Morris et al. 2017). Theoretically, phosphatidylcholine and creatine may inhibit transfer of methyl groups and thereby diminish the production of *S*-adenosylhomocysteine and homocysteine

[d]Folinate is probably generally a better option than folate, but folate should be satisfactory in most cases, except in those where parenteral use is necessary (folinate is available for parenteral use and folate is not)

Warning Boxes/Pitfalls

1. In patients treated with low-methionine diet, careful clinical and biochemical monitoring is necessary to avoid consequences of protein malnutrition.
2. Long-term folate therapy in high doses may be associated with increased cancer risk.
3. There is a high risk of peripheral neuropathy following long-term treatment with pyridoxine doses above 900 mg/day, but it has not been found in patients treated with less than 500 mg/day. In children, the safe dose is likely to depend on body weight; there are few data but last guidelines suggest using doses up to 10 mg/kg/day, with a maximum of 500 mg/day (Morris et al. 2017).
4. A major potential problem of betaine therapy in CBS deficiency and other disorders with both elevated tHcy and methionine is potential increase of methionine to the concentrations that may be toxic for the brain, leading to cerebral edema and other consequences of excessive hypermethioninemia described above.
5. Accidental inhalation of betaine in powder form can cause pulmonary problems.

Experimental Treatment

For *CBS deficiency,* molecular chaperones have been investigated in proof of principle studies, while enzyme replacement therapy is in phase I/II of a clinical trial.

For *ethylmalonic encephalopathy*, early liver transplantation may be an option to reverse otherwise poor outcome (Dionisi-Vici et al. 2016). Diet restricted in sulfur-containing amino acids may contribute to better outcome in patients detected by newborn screening, particularly if liver transplantation would be proven as an option. In some patients, improvement in some symptoms has been observed with ubiquinone and/or riboflavin.

Follow-Up and Monitoring

Recommendations given in the table are only approximate guidelines and should be adjusted individually according to age, severity of the disease, compliance, and other factors.

Disease	Clinical follow-up and monitoring	Biochemical follow-up and monitoring
22.1 MAT I/III deficiency	Both for untreated patients and those on therapy: any neurological sign or symptom should be considered as a possible sign of the disease and reason for further clinical (including brain imaging) and metabolic evaluation. Therefore, neurological and cognitive evaluation should be performed regularly in all patients with the risk of grossly elevated plasma methionine (clear risk above 800 μmol/L and existing risk above 500–600 μmol/L). In these patients neurological testing should take place about once every 2–3 months in infants and every 6–12 months later in life. If indicated, brain MRI should be performed (Chien et al. 2015). For patients on low-methionine diet, additionally, signs of protein malnutrition should be regularly looked for	In untreated patients without symptoms, checking of methionine, AdoMet, and total homocysteine (tHcy) is justified. The frequency depends on the severity of enzyme deficiency and mode of inheritance. The autosomal dominant form of MAT I/III deficiency is considered benign and does not require regular biochemical monitoring. In patients with the autosomal recessive form of the disease with severe enzyme deficiency and previous plasma methionine close to 500 μmol/L or more, or abnormal tHcy values, checking should be more frequent (i.e., in infancy every 3 months, later every 3–12 months and after significant changes in dietary methionine intake). In patients with the autosomal recessive form and mild enzyme deficiency, if highest plasma methionine values, which should be checked after normal and high protein intake, are not close to 500 μmol/L, only sporadic checking of plasma methionine is indicated, i.e., when symptoms attributable to MAT I/III deficiency appear. In patients on low-methionine diet, regular monitoring of protein status and plasma amino acids is indicated (in infancy at least every 3 months, later every 6–12 months and after significant changes in dietary methionine intake). In hyperhomocysteinemic patients in similar intervals, tHcy should be measured and thrombophilia screen should be performed at least once

Disease	Clinical follow-up and monitoring	Biochemical follow-up and monitoring
22.2 MAT II deficiency	In individuals with *MAT2* mutations, regular cardiac evaluation by ultrasound and if needed other methods to check for possible development of thoracic aorta dilatation are indicated	Not possible due to the lack of biochemical markers
22.3 GNMT deficiency	In GNMT-deficient patients tending to have very high plasma methionine levels which have been related to central nervous system complications (see MAT I/III deficiency above), regular neurological and cognitive testing is justified. [a]Yearly liver ultrasound seems justified	Due to possible hypermethioninemia-related problems, plasma methionine checking in regular intervals is recommended (in infancy every 3 months, if indicated even more frequently, later every 6–12 months or depending on previous values). Liver function tests, alpha-fetoprotein[a]
22.4 AHCY deficiency	Careful evaluation of all body systems, particularly of the nervous system and development, muscles, liver, and coagulation. In infancy every 1–3 months, if indicated even more frequently, later every 3–6 months. This includes imaging studies, particularly regular liver imaging	Careful biochemical monitoring is mandatory to control both disease development and treatment to avoid their complications. The following tests are indicated: protein status, amino acids, AdoMet, AdoHcy, liver function tests, creatine kinase, alpha-fetoprotein, coagulation tests, liver imaging, while others depend on the clinical situation. Follow-up intervals depend on age and clinical course. In infancy this could be every 1–3 months, if indicated even more frequently, later every 3–6 months
22.5 ADK deficiency	Careful clinical evaluation with regular follow-up visits depending on age and severity is recommended (intervals ranging from 1 month to 1 year), including regular monitoring of psychomotor development and neurological examination and regular liver imaging Since epilepsy is often present in ADK deficiency, regular electroencephalography is recommended. In one patient retinal dystrophy was diagnosed; thus ophthalmological examination on a regular basis should be considered. Because of an increased incidence of cardiac defects, echocardiography should be performed in all patients and followed up accordingly. Several patients presented with cholelithiasis; thus abdominal ultrasound should be performed in cases of unexplained pain (colic)	Assays of protein status, plasma amino acids, tHcy, AdoMet, AdoHcy, adenosine in urine and/or dried blood spot, serum aminotransferases, total and direct bilirubin, ammonia, blood glucose, uric acid, coagulation tests, and alpha-fetoprotein are relevant. Regular blood glucose profiles should be performed, depending on the presence and treatment of recurrent hypoglycemia. A full blood count should be included in the regular monitoring to check for megaloblastic anemia
22.6 CBS deficiency	The adequate frequency of monitoring depends on the severity of the disorder, treatment, compliance, age, status of the patient, and previous complications (e.g., thrombosis). Approximate schedule could be the following: Neurological and, depending on age, developmental or mental evaluation in infancy every 3 months, later every 6–12 months. Ophthalmology examination yearly. Bone mineral density once in 1–3 years. Vascular status every 6–12 months, depending on the severity of the disease and clinical course	Plasma amino acids and total homocysteine in infancy every 1–3 months, if indicated even more frequently, later every 3–6 months. If tHcy is monitored in dried blood spots, this test may be done more frequently. In patients on low-methionine diet protein status in the same intervals. Unless on supplementation, serum cobalamin and folate every 3–6 months. Thrombophilia screening should be considered once. Lipids first time at age 2–3 years, afterward, if normal, every 2–3 years, if not every 3 months alongside therapy
22.7 CTH deficiency	Not necessary	
22.8 MTO deficiency	Malodor can be monitored clinically. Possible related psychological burden may need psychologist's evaluation	If metronidazole is used, caution should be taken because of possible side effects. If low-protein/low methionine diet is used, protein status should be checked to avoid methionine deficiency and/or protein malnutrition
22.9 Isolated SUOX deficiency	General and, particularly, neurological (including EEG and imaging) and developmental evaluation in infancy every 1–3 months, later every 3–6 months, if indicated more frequently. Ophthalmology every 6 months, if indicated, more frequently	If on diet, protein status, amino acids, *S*-sulfocysteine, thiosulfate, sulfite in infancy every 1–3 months, if indicated more frequently, later every 3–6 months

Disease	Clinical follow-up and monitoring	Biochemical follow-up and monitoring
22.10 Ethylmalonic encephalopathy	General and, particularly, neurological (including EEG and imaging) and developmental evaluation in infancy every 1–3 months, later every 3–6 months, if indicated more frequently. Nutritional evaluation	Blood count according to blood losses in stool. Specific markers of the disease activity include lactate, plasma and urinary thiosulfate and sulfite, urinary ethylmalonate, and plasma C4- and C5-acylcarnitines. The frequency of monitoring depends on clinical condition and is more frequent in crises and/or following active treatment attempts, like liver transplantation. Otherwise it can be carried out in parallel with clinical evaluation, every 1–3 months in infancy, later every 3–6 months, if indicated more frequently
22.11 Mercaptopyruvate sulfurtransferase deficiency	If the disease is associated with intellectual disability, regular cognitive assessment seems justified	There is no evidence that intervention in this very rare disorder is needed or effective. Specific markers would be beta-mercaptolactate cysteine disulfide (urine), mercaptopyruvate, and mercaptolactate. It is questionable if this would have practical meaning

[a]In mice, in the long term significant liver disease may take place, including hepatocellular carcinoma; therefore, liver ultrasound and liver tumor markers checking may be justified

Contents

Summary

Disorders in the catabolic pathways of the branched-chain amino acids (BCAA) leucine, isoleucine, and valine encompass diverse organic and amino acidurias. Clinical severity may range from asymptomatic findings in some to life-threatening episodes and multi-organ involvement in others. Several of these defects may reflect a complex pathogenesis related to mitochondrial dysfunction, particularly the 3-methylglutaconic acidurias. As a general rule, treatment includes (1) dietary restriction of the precursor BCAA along with optimal nutritional supply, (2) adjunct therapy (e.g., with L-carnitine, appropriate cofactors, other conjugating compounds), and (3) rapid intervention for acute metabolic decompensation including

home preventative measures strictly following a written sick-day protocol. Late complications of these diseases must be anticipated, such as liver disease, cardiomyopathy, and renal failure. In asymptomatic screened individuals, instructions regarding risks for metabolic stress and fasting avoidance, along with clinical monitoring, represent appropriate prophylactic interventions.

Introduction

The catabolic pathways of branched-chain amino acids (BCAA), namely, leucine, isoleucine, and valine, consist of multiple steps including transamination, oxidative decarboxylation, and dehydrogenation. Due to irreversible steps early in metabolism, elevated levels of these amino acids do not occur in those disorders that result from blocks in the pathways distal to the site of maple syrup urine disease (MSUD). Rather, they are associated with organic acidemia and aciduria. Severe forms of these disorders usually present as acute, overwhelming neurological deterioration in the neonatal period if not detected through newborn screening. Milder variants may be episodic and not become symptomatic until late childhood or even adult life. Moreover, some patients are asymptomatic and identified only through family studies or newborn screening. Some disorders of BCAA metabolism are exceedingly rare, and the clinical experience in managing these cases is still being defined.

Branched-Chain Amino Acid (BCAA) Transferase (BCAT1 and BCAT2) Deficiency: The existence of this disorder in humans remains in question. There is some evidence that transamination of valine and transamination of leucine and isoleucine may be affected differentially. Early reports have described patients with hyperleucine-isoleucinemia and hypervalinemia, attributed to a defect of branched-chain amino acid transamination, who presented with failure to thrive and mental retardation (Reddi et al. 1977).

Maple syrup urine disease (MSUD) results from deficient activity of the branched-chain α-ketoacid dehydrogenase complex (BCKDC). During episodes of metabolic decompensation, the BCAA and their corresponding branched-chain α-ketoacids (BCKA) accumulate excessively. The pathophysiology of MSUD is thought to be related primarily to leucine. The enzyme complex BCKDC consists of three catalytic components (E1, E2, and E3) encoded by four different genetic loci. Whereas mutations in all four of the catalytic loci have been associated with clinical disease (MSUD 1a, 1b, 2, 3, respectively), *BCKDHA* and *BCKDHB* are the most frequently involved genes.

Five *clinical forms* of MSUD exist, differentiated by the amount of residual enzymatic activity, age and severity of onset, and responsiveness to thiamine. These include *classic*, *intermediate*, *intermittent*, and *thiamine-responsive* MSUD, in addition to *E3* (lipoamide dehydrogenase) *deficiency*. The latter associates with combined deficiencies of the pyruvate dehydrogenase complex and 2-oxoglutarate dehydrogenase complexes, which share the E3 component with BCKDC. The former is exceedingly rare and doubts exist concerning its reality. The activity of the complex BCKDC is tightly regulated, in particular by phosphorylation under the control of a specific kinase (BCKDHK) and a phosphatase. BCKDC phosphatase deficiency is responsible for a mild form of MSUD, while the kinase deficiency leads to persistently reduced BCAA body fluid levels associated with developmental delay, microcephaly, and autism (Novarino et al. 2012).

Isovaleric acidemia (IVA) results from deficient activity of isovaleryl-CoA dehydrogenase, ranging from acute neonatal to an intermittent or chronic presentation. Asymptomatic individuals with only subtle biochemical abnormalities are detected through newborn screening (Ensenauer et al. 2004, 2011; Vockley and Ensenauer 2006). In patients with a severe phenotype, the odor of "sweaty feet" may be detected during metabolic crisis, associated with marked ketoacidosis, bone marrow suppression, and hyperammonemia.

3-*Methylcrotonyl-CoA carboxylase (3MCCC) deficiency (MCCD)* also features a highly variable phenotype, from severe presentation to asymptomatic in patients detected via newborn screening or family association studies (Gibson et al. 1998). Thus far there are no reliable markers to identify the few individuals at risk for clinical symptoms. A more recent study performed whole exome sequencing in individuals exhibiting nonspecific phenotypes attributed to MCCD and showed that such signs were likely not due to mutations in the MCC enzyme but from rare homozygous mutations in other disease genes. These findings suggest that MCCD should be viewed largely as an asymptomatic condition (Shepard et al. 2015). Appropriate testing (urinary organic acids, acylcarnitine profile, and eventually mutation analysis/enzymatic assay) is necessary to differentiate 3MCCC deficiency from the multiple carboxylase deficiencies due to defects in biotin metabolism.

3-Methylglutaconic aciduria occurs in multiple forms. Only type I (MGA1), associated with reduced activity of 3-methylglutaconyl-CoA hydratase, is a disorder of the leucine degradation pathway. Barth (MGA2) syndrome is an X-linked multi-system disorder with cardiomyopathy, myopathy, neutropenia, and 3-methylglutaconic aciduria. Costeff syndrome (MGA3) is characterized by optic atrophy and

neurological symptoms. MEGDEL syndrome is a recessive disorder featuring sensorineural deafness and encephalopathy with neuroradiological evidence of Leigh disease. Neonatal mitochondrial encephalocardiomyopathy is caused by isolated mitochondrial ATP synthase deficiency, associated with mutation in the TMEM 70 gene. 3-Methylglutaconic aciduria type IV refers to conditions in which the primary etiologies remain to be elucidated. Most of the time and for yet understood reasons, MGA is a biomarker in the setting of mitochondrial respiratory chain disorders (Wortmann et al. 2013). For more details on the mitochondrial etiologies of MGA.

3-Hydroxy-3-methylglutaric acidemia (*HMG-CoA lyase deficiency)* is a dual defect in leucine degradation and ketogenesis that often presents with neonatal hypoketotic hypoglycemia, metabolic acidosis, and hyperammonemia (Gibson et al. 1988). Milder forms of the disorder, including presentation in adulthood, have also been reported. Overwhelming metabolic decompensation and organic aciduria are associated with a characteristic absence of ketone bodies, a hallmark of this disorder.

2-Methylbutyrylglycinuria or 2-methylbutyryl-CoA dehydrogenase (MBD) deficiency is a defect in isoleucine degradation caused by mutations in the short/branched-chain acyl-CoA dehydrogenase (*ACADSB*) (Andresen et al. 2000). Diverse clinical symptoms such as hypotonia, mental retardation, autistic features, hypoglycemia, or metabolic acidosis have been reported, but most individuals (especially those identified by newborn screening) have remained asymptomatic (Gibson et al. 2000; Sass et al. 2008). A founder mutation in the Hmong Chinese population has been described (Alfardan et al. 2010).

2-Methyl-3-hydroxybutyryl-CoA dehydrogenase (MHBD) deficiency (or 17beta-hydroxysteroid dehydrogenase type 10 [HSD10] deficiency) was first reported in a 2-year-old boy with neurodegenerative symptoms (Zschocke et al. 2000). This defect was also documented in a female patient who was less severely affected, suggesting skewed X-inactivation (Perez-Cerda et al. 2005). Additional patients delineated a clinical spectrum from severe neurological disease to isolated ketoacidosis mimicking beta-ketothiolase deficiency (Fukao et al. 2014). The disease-causing gene, HSD17B10, encodes 17beta-hydroxysteroid dehydrogenase type 10 (HSD10), the latter essential for structural and functional integrity of mitochondria (Rauschenberger et al. 2010; Oerum et al. 2017).

Beta-ketothiolase deficiency (alpha-methylacetoacetic aciduria, 3-oxothiolase deficiency, *methylacetoacetyl-coenzyme A thiolase [MAT] deficiency)* is a defect of ketone body utilization and isoleucine catabolism. It is caused by mutations in the *ACAT1* gene and presents with recurrent episodes of fasting metabolic ketoacidosis with or without hypoglycemia (Grünert et al. 2017). A subset of ACAT1-deficient patients may exhibit chronic movement disorder and basal ganglia abnormalities on neuroimaging independent of ketoacidotic episodes (Paquay et al. 2017).

Isobutyryl-CoA dehydrogenase deficiency (IBD deficiency) is a disorder of valine degradation. The original patient presented with anemia and dilated cardiomyopathy, probably related to secondary carnitine deficiency (Roe et al. 1998). Thus far, more individuals have been described who are mostly asymptomatic, largely identified via newborn screening (Koeberl et al. 2003; Sass et al. 2004; Oglesbee et al. 2007).

Short-chain enoyl-CoA hydratase or crotonase deficiency (SCEH/ECHS1 deficiency) is a disorder of both valine degradation and short-chain fatty acid oxidation (Peters et al. 2014). Pathogenesis is thought to be ascribed mainly to the former. Clinical presentation includes infantile-onset severe developmental delay with regression and seizures, with elevated plasma lactate and brain MRI abnormalities consistent with Leigh-like disease. In urine, 2,3-dihydroxy-2-methylbutyric acid and *N*-acetyl-*S*-(2-carboxypropyl)cysteine, the metabolites of acrylyl-CoA and methacrylyl-CoA, are the most specific markers of the disease (Fitzsimons et al. 2018; Sharpe and McKenzie 2018); other unspecific markers such as 3-methylglutaconic can be found. Molecular studies revealed variants in the *ECHS1* gene.

3-Hydroxyisobutyryl-CoA deacylase deficiency (or methacrylic aciduria) has been confirmed in a few patients with variants in the *HIBCH* gene (Tan et al. 2018). They presented with failure to thrive, developmental delay, and neurological symptoms in infancy with neuroradiological findings compatible with Leigh-like disease. Unusual cysteine and cysteamine conjugates of methacrylic acid were detected in urine. With the exception of 3-hydroxyisobutyryl carnitine, the metabolite abnormalities are essentially the same as those observed in ECHS1 patients. In fibroblasts from the initial patients, 3-hydroxyisobutyryl-CoA hydrolase activity was deficient (Loupatty et al. 2007).

3-Hydroxyisobutyric aciduria may be caused by a primary defect of 3-hydroxyisobutyrate dehydrogenase, active in valine metabolism, or via secondary inhibition of 3-hydroxyisobutyrate dehydrogenase in selected respiratory chain defects (Loupatty et al. 2006). The clinical phenotype is variable, but the majority of patients reported in the literature presented with dysmorphic features, neurodevelopmental symptoms, ketoacidotic episodes, and lactic acidemia.

Methylmalonate semialdehyde dehydrogenase (MMSDH) deficiency is a rare disorder of the valine catabolic pathway

associated with variable clinical and biochemical phenotype from vomiting and dehydration (Chambliss et al. 2000) to neurodevelopmental disease with delayed myelination (Marcadier et al. 2013). To date four patients were reported with mutations in *ALDH6A1* encoding for MMSDH.

Isoleucine and valine share the propionate pathway for their terminal steps of catabolism, and *propionic acidemia* (PA, propionyl-CoA carboxylase deficiency) and *methylmalonic acidemia* (MMA, methylmalonyl-CoA mutase deficiency) are disorders of propionate degradation derived in part from the catabolism of isoleucine and valine, as well as other propionate precursors (threonine, methionine, odd-chain fatty acids, and cholesterol). MMA and PA usually present with life-threatening episodes of ketoacidosis, hyperammonemia, encephalopathy, and hematological manifestations. Late complications of these disorders include renal failure (particularly in MMA), pancreatitis, liver disease, cardiomyopathy (particularly in PA), long QT syndrome (particularly in PA), basal ganglion infarction, optic neuropathy, or impaired hearing ability (Grünert et al. 2013; Tuncel et al. 2018). Secondary mitochondrial respiratory chain deficiencies have been demonstrated in both disorders (De Keyzer et al. 2009). In addition to the primary deficiencies of propionyl-CoA carboxylase (PCCA and PCCB) and methylmalonyl-CoA mutase (MMUT), secondary defects of these enzymes can be associated with genetic disorders in the metabolism of their respective cofactors, i.e., biotin and cobalamin.

Methylmalonic aciduria due to methylmalonyl-CoA epimerase deficiency is a rare recessive disorder identified through moderate methylmalonic accumulation in urine. The clinical significance and biochemical characteristics of this rare condition have been incompletely defined. Some patients may present with an acute decompensation and other with progressive neurological symptoms (Waters et al. 2016). At least two patients were also affected by a second inherited disorder, a sepiapterin reductase deficiency (Mazzuca et al. 2015); the link between the two disorders is not understood.

Malonic aciduria (MA) is caused by malonyl-CoA decarboxylase deficiency leading to a block in fatty acid metabolism. Patients present with cardiomyopathy, developmental delay, short stature, seizures, hypoglycemia, and metabolic acidosis (Salomons et al. 2007).

Combined malonic and methylmalonic aciduria (CMAMMA) is a rare recessive disorder caused by a defect in the *ACSF3* gene, which encodes an acyl-CoA synthetase. Initial CMAMMA patients were reported with developmental delay, seizures, cognitive decline, cardiomyopathy, and metabolic acidosis (Sloan et al. 2011). More recently, a significant number of asymptomatic CMAMMA patients from Quebec identified through urine newborn screening have been reported (Levtova et al. 2019).

Diagnostic Flowchart

A positive newborn screening test for elevated leucine should be confirmed by quantitative plasma amino acid analysis and usually is seen only in MSUD. High-risk newborns require an early newborn screening, e.g., at day 1 of life, along with preventative dietary intervention. Abnormal blood acylcarnitine species may be seen in the other disorders in this pathway, and making the correct diagnosis depends on analysis of urinary organic acids by combined gas chromatography/mass spectrometry (GCMS). Further diagnostic information is obtained through analysis of urinary acylglycines. Essentially, the detection of unusual body odor (maple syrup, sweaty feet), acidosis, ketosis, elevated ammonia, hypoglycemia, or carnitine deficiency suggests that urine organic acid analysis should be performed. Patients with many of these disorders may be asymptomatic at birth and are identified only on the basis of an abnormal newborn screening using tandem mass spectrometry. In patients not screened as newborns, non-specific symptoms such as failure to thrive or developmental delay should trigger a metabolic evaluation that may identify a diagnostic metabolite. Blood acylcarnitines and urinary organic acid profiling are again essential for the correct differential diagnosis followed by confirmatory analysis. The disorders of isoleucine and valine metabolism are also detected in a sequential process that begins with the evaluation of the symptoms and signs displayed by the patient (selective metabolic screening) or in some countries on newborn screening. Clinical chemistry is helpful in the assessment of ketogenesis by urinary tests for ketone bodies or quantification of 3-hydroxybutyrate and acetoacetate in the blood. Electrolytes, blood gases, and pH provide evidence of acidosis, and it is important to test for hyperammonemia. Analysis of plasma amino acids and blood acylcarnitines is helpful. In virtually all instances, the definitive diagnosis will come from organic acid analysis of the urine, followed by further molecular testing. Enzymatic testing is not a first-line analysis and should be reserved to unsolved cases.

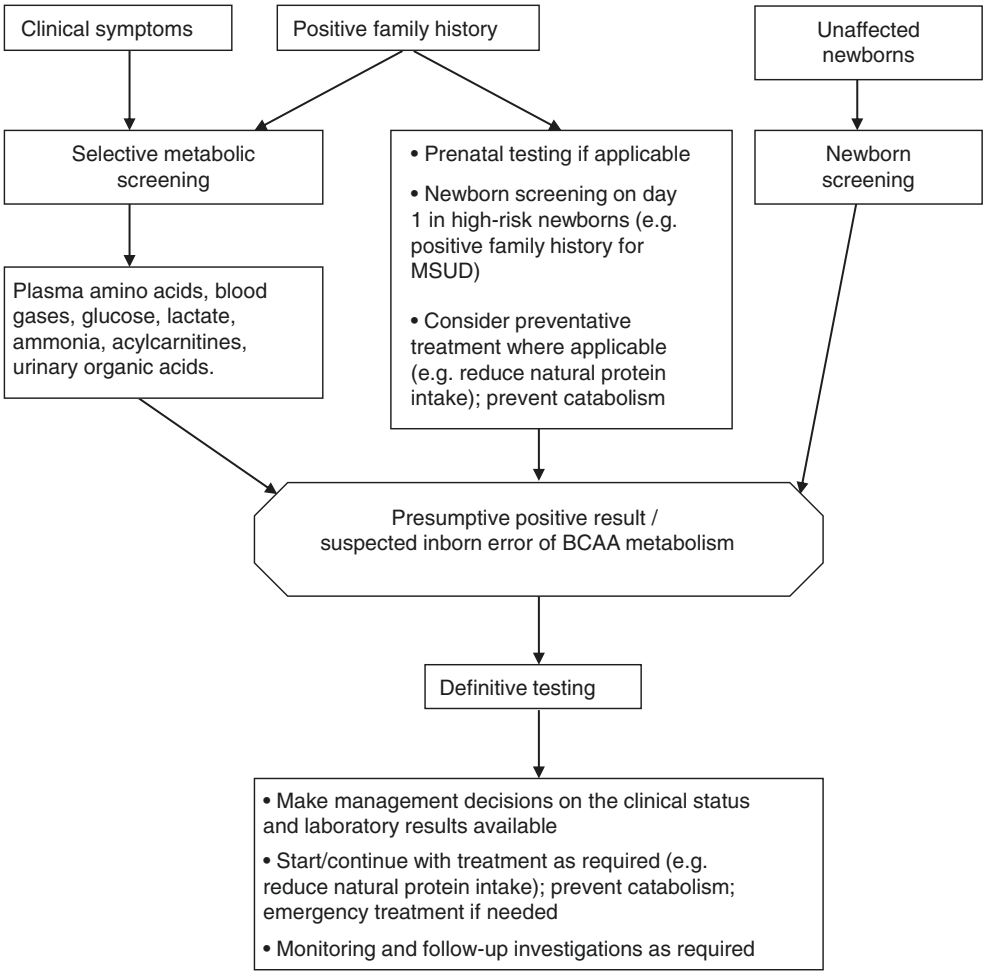

Fig. 23.2 Diagnostic flowchart

Reference Values

- Urine/spot tests

	2,4-Dinitrophenylhydrazine (DNPH) test	Ferric chloride test
Normal	No precipitate	No color change

- Plasma quantitative amino acids (μmol/L)
  (Ion exchange column chromatography or high-performance liquid chromatography, HPLC)

Age	Valine	Isoleucine	Leucine	Alloisoleucine
Newborn[a]	86–220	23–95	48–180	0
Child	64–320	30–105	59–180	0
Adult	99–286	30–108	61–162	0

Age	Glycine	Methionine	Threonine
Newborn[a]	220–500	6–40	60–200
Child	130–400	9–45	60–200
Adult	120–550	9–59	43–130

[a]The national standards and local reference ranges for newborn screening or selective screening tests should be used

- Organic acids in urine (mmol/mol creatinine), blood plasma or serum (μmol/L), or dried blood spots (DBS, μmol/L)
  (Gas chromatography (GC)/mass spectrometry, GC/MS)

Age	Urine 2-oxoiso-caproic acid	Urine 2-oxo-3-methyl-valeric acid	Urine 2-oxoiso-valeric acid	Urine 2-hydroxy-isovaleric acid	Urine 2-hydroxy-isocaproic acid	Urine 2-hydroxy-3-methyl-valeric acid	Urine lactate	Venous blood lactate (mmol/L)
All	<2	<2	<2	<2	<2	<2	<197	<2.2

Age	Plasma/serum isovaleric acid	DBS isovaleryl-glycine	Urine isovalery-glycine	Urine 3-hydroxy-isovaleric acid	Urine 4-hydroxy-isovaleric acid	Urine isovaleryl-glucuronide	Urine 3-methyl-crotonyl-glycine	Urine 3-methyl-glutaconic acid	Urine 3-methyl-glutaric acid	Urine 3-hydroxy-3-methyl glutaric acid
All	<10	<0.5	<10	<16	<2	ND	<2	<6	<7	<36

Age	Urine 3-hydroxy-propionate	DBS 3-hydroxy-propionate	Urine methyl-citrate	Urine propionyl-glycine	Urine 2-methyl-butyryl-glycine	Urine methyl-malonate	DBS methyl-malonate	Urine 2-methyl-3-hydroxy butyrate	Urine 3-hydroxy-isobutyrate	Urine 2-methyl-acetoacetate
All	<2	ND	<2	<2	<2	<2	<0.4	<12	<24	<2

Age	Urine 2-methyl-butyryl-glycine	Urine 2-ethyl-hydra-crylic acid	Urine 2-methyl-3-hydroxy butyrate	Urine tiglyl-glycine	Urine isobutyryl-glycine	Urine *S*-2-carboxy-propyl-cysteamine and *S*-2-carboxy-propylcysteine	Urine 3-hydroxy-isobutyrate
All	<2	<2	<11	<2	<3.8	ND	<33

Age	Urine 3-hydroxy-propionate	DBS 3-hydroxy-propionate	Urine methyl-citrate	Urine tiglyl-glycine	Urine propionyl-glycine	Urine methyl-malonate	DBS methyl-malonate	Plasma/serum methyl-malonate	Urine malonic acid
All	<10	ND	<8	<2	<2	<2	<0.4	<0.2	<5

- Acylcarnitines in dried blood spots (DBS, µmol/L) (Tandem mass spectrometry)[a]

Age	Free carnitine (C0)	C3-/ propionyl-carnitine	C3-DC/ malonyl-carnitine	C4-/ butyryl-carnitine + isobutyryl-carnitine	C4-DC-/ methyl-malonyl-carnitine	C4-OH-/3-OH-isobutyryl-carnitine	C5-/isovaleryl-/2-methyl-butyryl-carnitine	C5:1-/pentanoyl-/ tiglyl-carnitine	C5-OH-/3-hydroxy-isovaleryl-/2-methyl-3-OH-butyryl-carnitine
All[b]	10–60	<3.60	<0.20	<0.50	<0.54	<0.39	<0.20	<0.03	<0.36

[a]The national standards and local reference ranges for newborn screening or selective screening tests should be used
[b]Of note, acylcarnitine reference values are age-dependent (see special literature)

Pathological Values

- Urine/spot tests

Disorder	2,4-Dinitrophenylhydrazine (DNPH) test[a]	Ferric chloride test[a]
23.2 Maple syrup disease (MSUD)	Yellow precipitate	Greenish-gray color

[a]This test has historical importance but has since been replaced (e.g., through newborn screening or selective metabolic screening using tandem mass spectrometry)

- Plasma quantitative amino acids (μmol/L)
  (Ion exchange column chromatography or high-performance liquid chromatography, HPLC)

Disorder	Valine	Isoleucine	Leucine	Alloisoleucine	% Normal activity of BCKD[a] complex
23.1 BCAT deficiency	220–1500	Increased	Increased	–	Normal
23.2–23.4 MSUD					
Clinical forms:					
Classic	To 7550	To 4800	To 10,800	≥5–970	0–2
Intermediate[a]	To 1000	To 1000	To 2000	2–220	3–30
Intermittent[a]	To 1000	To 1000	To 4000	2–220	3–30
Thiamin-responsive	To 1000	To 1000	To 5000	Present	2–40

[a]Levels may only be abnormal during acute episodes of ketoacidosis in the intermittent/intermediate form

- Comments/Additions
  1. Leucine, isoleucine, and valine are usually not elevated in metabolic defects distal from the BCKD complex as this complex catalyzes an irreversible enzymic reaction.
  2. Secondary findings, such as elevated plasma glycine and alanine concentrations, are not listed separately.

- Organic acids in urine (mmol/mol creatinine), blood plasma or serum (μmol/L) or dried blood spots (DBS, μmol/L)

23.18–23.19 MMA[c]	↓-n	↑			↑				
23.20 CMAMMA	↓-n	n		↑					
23.21 MA	↓-n			↑					

[a]Levels may only be abnormal in patients with variant forms during metabolic decompensation
[b]Acylcarnitine concentration may increase following L-carnitine supplementation
[c]Molar ratios should be applied for diagnostic purposes, e.g., C3/acetylcarnitine (C2) and C3/C0

Specimen Collection

Tests	Sample requirements
Urine	5–10 mL, random, fresh or frozen without preservatives and shipped frozen (packed in dry-ice) or lyophilized and shipped at room temperature with original volume specified or shipped as fresh sample with 1–2 drops of chloroform for preservation.
Amino acids	Test urinary amino acids, e.g., in patients with hyperammonemia or kidney dysfunction, otherwise plasma sample preferred
Organic acids	
Carnitine (free/total)	
Acylglycines	
2,4-Dinitrophenylhydrazine (DNPH) test	Fresh or frozen random
	This test has historical importance but has since been replaced
	May give false-negative results
	Usually positive if blood leucine is greater than 800 μmol/L
	May be positive in other conditions with oxoacids
	False positives with methenamine and radio-opaque contrast material
Ferric chloride test	Fresh or frozen random
	This test has historical importance but has since been replaced
	Turned colors to various abnormal urinary metabolites
Plasma	Plasma, 0.5–1.0 mL for each determination from heparinized or EDTA blood (or serum) supernatant from clinical centrifugation (within 20 min), fresh or promptly frozen and shipped frozen (packed with dry-ice) or lyophilized and shipped at room temperature with original volume specified. For quantitative amino acids: random or semi-fasting conditions (i.e., 4 hrs)
Amino acids	Plasma ketone body concentration changes with fasting over time, check glucose simultaneously
Organic acids	
Carnitine (free/total)	
Acylcarnitine profile	
Organic acids (such as methylmalonic acid) ketone bodies	
Dried blood spots	Drops of whole blood correctly collected on filter paper.
Acylcarnitine profile	It is important neither to overload nor to dilute the sample.
Amino acids	Blood spots should dry completely before storage or transportation (at room temperature)
Organic acids (such as methylmalonic acid)	
Cerebrospinal fluid	0.5–1 mL for each investigation (standard plastic lumbar puncture tube), fresh or frozen and shipped frozen (packed with dry-ice). Check plasma amino acids simultaneously
Amino acids	

Prenatal Diagnosis[a]

Disorder		Type of analysis[a]	Timing, trimester
23.1	BCAA aminotransferase deficiency		
23.2	Maple syrup disease	Molecular analysis	I, II
23.2			
23.2

23.16	Methylmalonate semialdehyde dehydrogenase deficiency[a]		
23.17	Propionic acidemia (propionyl-CoA carboxylase α subunit deficiency)		
23.17	Propionic acidemia (propionyl-CoA carboxylase β subunit deficiency)		
23.18	Methylmalonyl-CoA epimerase deficiency		
23.19	Methylmalonic aciduria due to methylmalonyl-CoA mutase deficiency		
23.20	Combined malonic and methylmalonic aciduria[a]		
23.21	Malonic aciduria		
23.22	Mitochondrial acetoacetyl-CoA thiolase deficiency		
23.23	Large neutral amino acid transporter deficiency[a]		

[a]Very limited evidence

Treatment Summary

The mainstay of treatment for all of the disorders is to limit intake of the affected amino acid(s) while preventing catabolism. With severe forms of the disorders, special medical foods (devoid of all or some BCAA, as required for the different conditions) are needed to allow for adequate caloric, protein, and other nutrient intake. In MSUD and IVA, the medical food is Leu-free. This Leu-free medical food should always be used for all of the MSUD patients. Milder IVA forms may only require a moderately reduced natural protein intake without medical food. Further, in PA and MMA, the use of the amino acid medical food devoid of Met, Thr, Val, and Ile is controversial (Manoli et al. 2016). The amount of natural protein tolerated is determined by monitoring parameters such as growth, control of acidosis, excretion of abnormal metabolites, and blood amino acid levels. The least restrictive dietary approach should be taken in order to avoid over-treatment and nutritional deficiencies. Emergency treatment includes promotion of anabolism using a special high-calorie diet, transient stop of natural protein intake or of the precursor amino acids, carefully adjusted IV treatment including adequate amounts of IV dextrose, correction of acidosis, detoxification, prevention of brain edema, and emergency hemodialysis in case of coma/encephalopathy with severe hyperammonemia or profound metabolic acidosis in classic forms of the disorders. Carnitine is used in a quantity of conditions to support excretion of organic acids as carnitine adducts, thus sparing coenzyme A and preserving the function of the Krebs cycle. Hyperammonemia may occur, particularly in PA and MMA, but conjugating agents are typically not indicated for therapy as ammonia normalizes with reversal of the primary metabolic derangement. *N*-carbamylglutamate may be useful in the setting of acute hyperammonemia in PA and MMA. If severe, hemodialysis may be indicated. The chronic treatment of severe forms of the disorders, particularly of PA and MMA, is also challenging. Late complications must be anticipated, including neurologic complications, renal failure (particularly in MMA), or cardiomyopathy (particularly in PA). Liver transplantation (PA and MMA) and combined liver/kidney transplantation (MMA) have been applied in a number of cases, and there is substantial evidence of benefits. Novel therapies such as mRNA (An et al. 2017) are currently under evaluation in MMA and PA patients.

Emergency Treatment

- **Branched-chain aminotransferase 2 deficiency**
  - The existence of this disorder in humans is not established.
- **Branched-chain ketoacid dehydrogenase E1α deficiency**
- **Branched-chain ketoacid dehydrogenase E1β deficiency**
- **Dihydrolipoyl transacylase deficiency**
- **Branched-chain ketoacid dehydrogenase phosphatase deficiency**
  - Emergency treatment table (includes management of ill neonates)

Objective	Treatment
1. Correct dehydration	Normal saline bolus as clinically indicated. Start IV dextrose 10–12.5% at 1–1.5 times maintenance; add NaCl and KCl depending on renal output and serum electrolyte levels. Plan rehydration over a 48 h period to prevent cerebral edema. Do not use hypoosmolar solutions
2. Maintain normal plasma sodium and osmolality levels. High risk for SIADH	(a) Check plasma sodium (aim for 140–145 mEq/L with minimal fluctuation) and plasma osmolality (290–300 mosm/L) regularly; monitor intake and output, body weight; urine osmolality (≤300–400 mosm/L), urine electrolytes and output (2–4 mL/kg/h) (b) Give 3% NaCl, dosage carefully calculated to replace deficit if hyponatremic. May also need furosemide 0.50 (0.25–1) mg/kg per dose every 6–8 h if plasma osmolality falls (c) Limit free water intake, observe for fluid overload due to excessive vasopressin production (d) Monitor for signs of increased intracranial pressure
3. Correct hyperglycemia (blood glucose >200 mg/dL) induced by IV fluids	Regular insulin drip, e.g., 0.05–0.1 units/kg per hour until blood glucose is controlled
4. Re-establish anabolism	(a) BCAA-free formula and/or IV fluids to provide total caloric intake of 120–150% of maintenance or give step 1 sick-day diet by PO or NG/G-tube (see table Protocol for intercurrent illness)[a] (b) Add intralipid i.v. 1.5–2 g/kg/day (c) Add back natural protein beginning with, e.g., 100 mg of leucine per day after 24 h; total protein including BCAA-free supplements 2.5–3.5 g/kg per day
5. Reduce persistently elevated leucine levels or encephalopathy	(a) Hemodialysis (HD) or hemofiltration (HF) in encephalopathic patients if intensified treatment (measure 1–4) is insufficient over a period of 2–4 h (b) Expect rate of decrease in plasma leucine levels >750 μmol/L per 24 h

[a]Isoleucine and valine levels should be high during crisis, at over 400–600 μM, to suppress entry of leucine into the brain. Isoleucine and valine usually need to be added early (after 24 h) into treatment (e.g., 40–100 mg/kg per day each). Leucine is reintroduced when its plasma level falls close to the normal range (e.g., total daily dose of 100 mg of leucine per day when plasma level below 400 μmol/L, 200 mg per day when level below 300 μmol/L; provide in total 2.0–2.5 g/kg per day of protein equivalent). Aim at target ratios of approximately 1:2:2 for plasma leucine, isoleucine, and valine, respectively

- **Comments/Additions**
  1. Stop all natural protein sources initially but add back leucine restricted source after 24 h to re-establish protein anabolism.
  2. Monitor laboratory studies including blood glucose, electrolytes, lactate, osmolality, plasma amino acids, urinary organic acids, and dipstick for ketones as indicated by the clinical history and examination.
  3. Patients with the E3 subunit deficiency may experience severe lactic acidosis and abnormal blood glucose.
  4. Thiamine 10 mg/kg per day (50–500 mg per day) may be given until genotype is known but is usually of low/no benefit.

- **Protocol for intercurrent illness**

Treatment	Branched-chain amino acid-free special medical food	Natural food leucine intake
First 24 h	1.2–1.5 times usual daily amount with additional isoleucine and valine[a]	None
24–48 h	1.2–1.5 times usual daily amount with additional isoleucine and valine[a]	None to half usual dietary intake
>48 h or when well	Usual daily amount	Gradual increase to usual full dietary intake

[a]Additions of isoleucine and valine should be increased during sick days. Goal is to keep levels of isoleucine and valine between 150–350 and 200–400 μM, respectively, when the patient is well and at over 400–600 μM when ill

- **Comments/Additions**
  1. Families/individuals should start sick-day formula (to decrease leucine intake, increase isoleucine and valine intake, and suppress catabolism) with the onset of intercurrent illness or symptoms related to loss of metabolic control. Fluids without calories or electrolytes should be avoided or intake minimized.
  2. If the patient is unable to take in oral fluids and has persistent vomiting, or the clinical condition deteriorates, they should proceed urgently to an experienced emergency care facility.

- **Dihydrolipoamide dehydrogenase deficiency**

  – Management may be adapted according to the three mitochondrial enzyme complex deficiencies that can be observed. See table for disorder 23.2, (MSUD) for the branched-chain ketoacid dehydrogenase deficiency and for the PDH complex: ketogenic diet, trial of dichloroacetate (DCA), and thiamine supplementation. Management of the primarily liver presentation (recurrent Reye-like liver failure) typically involves supportive therapy during times of acute liver injury or failure, including nutritional support, IV glucose for hypoglycemia, correction of metabolic acidosis, correction of coagulopathy, and avoidance of liver-toxic medications. Riboflavin should be used in the myopathic form of the disease.

- **Branched-chain ketoacid dehydrogenase kinase deficiency**

  – BCAA supplementation could be proposed in an attempt to prevent irreversible brain damage.

- **Isovaleric acidemia**
- **3-Methylcrotonylglycinuria type 1**[a]
- **3-Methylcrotonylglycinuria type 2**[a]
- **3-Methylglutaconic aciduria type 1**[b]
- **Hydroxymethylglutaric aciduria**[c]
- Emergency treatment table (includes management of ill neonates)

Objective	Treatment
1. Treat dehydration	Normal saline bolus as clinically indicated. Start IV dextrose 10–12.5% at 1–1.5 times maintenance; add NaCl and KCl depending on renal output and serum electrolyte levels
2. Correct acidosis	Usually corrects with re-establishment of anabolic state. In extremis, give 1–2 mEq/kg of Na bicarbonate
3. Correct hyperglycemia (blood glucose >200 mg/dL) induced by IV fluids	Regular insulin drip, e.g., 0.05 units/kg per hour until blood glucose is controlled
4. Re-establish anabolism	(a) Leucine-free formula or IV fluids (plus low-fat in HMGCL deficiency/disorder 23.9) with caloric intake 120–150% of maintenance (b) Can add intralipids for additional calories except for HMGCL deficiency (disorder 23.9)
6. Metabolite conjugation	Carnitine: 100 mg/kg per day in 3 divided doses IV or PO Glycine (IVA only): usual daily dose (e.g., 250 mg/kg per day) in sick-day enteral formula or TPN

[a]Most patients do not become acutely ill
[b]Treatment is mainly symptomatic
[c]Patients with HMGCL (disorder 23.9) usually present with acute hypoketotic or nonketotic hypoglycemia and dehydration may be underestimated. Give IV glucose bolus (e.g., 2 mL/kg of dextrose 10%) in a hypoglycemic patient

- **Comments/Additions**
  1. Stop all natural protein sources initially. Begin to add back leucine restricted protein after 24 h and complete protein after 48 h.
  2. Monitor laboratory studies including blood glucose, electrolytes, pH, blood gases, ammonia, lactate, plasma amino acids, urinary organic acids, acylcarni-

tine profile, liver function tests, CK, and any other laboratory tests indicated by the clinical history and examination.

- **Protocol for intercurrent illness: initial measures**

Treatment	Leucine-free special medical food[a]	Natural food leucine intake	L-carnitine (mg/kg/day)
First 24 h	1.2–1.5 times usual daily amount	None	100
24–48 h	1.2–1.5 times usual daily amount	None to half usual dietary intake	100
>48 h or when well	Usual daily amount	Gradual increase to usual full dietary intake	100

[a]Leucine-free and low fat for HMGCL (disorder 23.15)

- **Comments/Additions**
  1. Families/individuals should start sick-day formula (to decrease leucine intake and suppress catabolism). Start carnitine if not used routinely. Fluids without calories or electrolytes should be avoided or intake minimized.
  2. In patients with HMGCL deficiency (disorder 23.15), prompt administration of carbohydrates/IV dextrose is mandatory. IV lipids are contraindicated. Monitor urine ketones, which will become positive with loss of metabolic control or inadequate caloric intake except in patients who are unable to produce ketones.
  3. If the patient is unable to take in oral fluids and has persistent vomiting, or the clinical condition deteriorates, they should proceed urgently to an experienced emergency care facility.

- **Isoleucine catabolic pathway:**
  - **2-Methylbutyrylglycinuria**[1a]
  - **2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency**
  - **β-ketothiolase deficiency**
- **Valine catabolic pathway:**
  - **Isobutyryl-CoA dehydrogenase deficiency**[1]
  - **Crotonase deficiency**
  - **3-Hydroxyisobutyryl-CoA deacylase deficiency**
  - **3-Hydroxyisobutyrate dehydrogenase deficiency**
  - **Methylmalonate semialdehyde dehydrogenase deficiency**

Treatment is similar to the leucine pathway disorders except that isoleucine or valine reduced concentration formulae are required. Check carnitine status and add L-carnitine as required (e.g., 50–100 mg/kg per day). In patients with beta-ketothiolase deficiency (disorder 23.22), oral or IV carbohydrate administration is most effective in suppressing ketogenesis; metabolic acidosis should be treated cautiously to prevent hypernatremia and paradoxical CNS acidosis. Treatment mostly relies on preventative measures: avoidance of fasting. Risk of acute metabolic decompensation in SBCAD and IBD deficiencies appears to be small and chronic dietary therapy is likely not necessary.

- **Propionic academia (α-subunit)**
- **Propionic acidemia (β-subunit)**
- **Methylmalonic aciduria due to methylmalonyl-CoA epimerase deficiency**[a]
- **Methylmalonic aciduria due to methylmalonyl-CoA mutase deficiency**

- Emergency treatment table (includes management of ill neonates):

Objective	Treatment
1. Treat dehydration	Normal saline bolus as clinically indicated. Start IV dextrose 10–12.5% at 1–1.5 times maintenance; add NaCl and KCl depending on renal output and serum electrolyte levels. Plan rehydration over a 48 h period to prevent cerebral edema.
2. Correct acidosis	Usually corrects with re-establishment of anabolic state. In extremis, give 1–2 mEq/kg of Na bicarbonate.
3. Correct hyperglycemia (blood glucose >200 mg/dL)	If lactate <3 mM: regular insulin drip, e.g., 0.05–0.1 units/kg per hour until blood glucose is controlled. But if lactate >3 mM, consider to reduce glucose intake first
4. Re-establish anabolism	(b) If able to feed enterally, use Ile-/Met-/Thr-/Val-free formula to provide total caloric intake of 120–150% of maintenance (c) Adjust IV treatment as required (peripheral/central line) (d) 20% fat emulsion, rate 1–3 g/kg/day IV (e) If NPO use lowered Ile/Met/Thr/Val-free TPN
6. Metabolite conjugation and reduction	(b) L-carnitine 100 mg/kg per day IV or PO/NG[a] (c) Add metronidazole PO or NG for intermittent treatment (10 mg/kg per day for 1 week) (d) Urgently consider HD/HF in encephalopathic patients or if blood ammonia is ≥300–400 μM or in case of persistent severe acidosis, particularly if intensified treatment is insufficient over a period of 2–4 h
7. Enhance residual enzyme activity	Cobalamin-responsive MMA: 1 mg hydroxocobalamin/dose IM daily[b,c]

[1]Patients not usually acutely ill

Objective	Treatment
10. Other	(b) Treat infections effectively. Note that neutropenia and thrombocytopenia are frequent findings during metabolic crisis (c) Monitor for further complications (e.g., cerebral edema, acute pancreatitis)

[a]Most patients do not become acutely ill
[b]Higher doses of L-carnitine have also been used (200–400 mg/kg per day). It is reasonable to increase the IV dose, e.g., when the patient undergoes HD/HF
[c]Each patient with MMA should be tested for B12 responsiveness by a trial of parenteral hydroxocobalamin in a dose of 1 mg/day. In those who respond, therapy is continued but the oral route may be used. Cyanocobalamin may be used if hydroxocobalamin is not available
[d]In PA, biotin responsiveness is doubtful. Biotin supplementation (10 mg daily) is therefore rarely beneficial
[e]*N*-carbamylglutamate may be started as a bridge, e.g., while waiting for HD/HF. In undiagnosed patients presenting with hyperammonemia, sodium benzoate/phenylacetate may be given but should be stopped once PA or MMA has been diagnosed

- **Comments/Additions**
  1. Stop all natural protein sources initially, and then reintroduce restricted natural protein by 24 h (0.2–0.5 g/kg/day), and begin addition of complete protein by 48 h with escalation to normal intake thereafter. Use additional Ile-/Met-/Thr-/Val-free formula for adequate amino acid supply.
  2. Laboratory studies including blood gases, pH, ammonia, blood glucose, lactate, electrolytes, osmolality, plasma amino acids, acylcarnitines, ALT, AST, coagulation screen, CK, full blood count, urinary ketones, and urinary organic acids and any other laboratory tests indicated by the clinical history and examination.
  3. A few patients with methylmalonic aciduria due to methylmalonyl-CoA epimerase deficiency have been described with an associated sepiapterin reductase deficiency without knowing the mechanism that links the two disorders. Sepiapterin reductase deficiency should be treated as specified in Chapter.

- **Protocol for intercurrent illness: initial measures**

Treatment	Ile-/Met-/Thr-/Val-free special medical food	Natural food protein intake
First 24 h	1.2–1.5 times usual daily amount	None
24–48 h	1.2–1.5 times usual daily amount	None to half usual dietary intake
>48 h or when well	Usual daily amount	Gradual increase to usual full dietary intake

- **Combined malonic aciduria and methylmalonic aciduria**
- **Malonic aciduria**
- **Emergency treatment table (includes management of ill neonates)**[a]

Objective	Treatment
1. Treat hypoglycemia	Give IV glucose bolus (e.g., 2 mL/kg of dextrose 10%); start IV dextrose 10–12.5% at maintenance and add NaCl and KCl depending on serum electrolyte levels
2. Metabolite conjugation	Carnitine: 100 mg/kg per day in 3 divided doses IV or PO
3. Correct acidosis	Usually corrects with re-establishment of anabolic state. In extremis, give 1–2 mEq/kg of Na bicarbonate
4. Other	(a) Monitor cardiac function (b) Monitor for further complications (e.g., lactic acidemia, seizures)

[a]There is limited experience in managing this condition

- **Comments/Additions**
  1. If the patient is feeding orally, increase the amount of calories from carbohydrate relative to fat, introduce MCT fat, and prevent fasting.
  2. Laboratory studies including blood gases, pH, blood glucose, lactate, electrolytes, full blood count, osmolality, CK, ALT, AST, acylcarnitines, cholesterol, ketones, and urinary organic acids and any other laboratory tests indicated by the clinical history and examination.

Chronic Treatment

- **Branched-chain aminotransferase 2 deficiency**
  - The existence of this disorder in humans remains in question.
- **Branched-chain ketoacid dehydrogenase E1α deficiency**
- **Branched-chain ketoacid dehydrogenase E1β deficiency**
- **Dihydrolipoyl transacylase deficiency**
- **E3 deficiency**
- **Branched-chain ketoacid dehydrogenase phosphatase deficiency**

- Standard treatment table

No.	Disease/symbol	Age	Medication/diet	Dosage	Target plasma levels
23.2 23.2 23.2	MSUD—Severe forms (MSUD 1a, 1b, 2)	All ages	Lowered BCAA diet[a] Isoleucine and valine supplements[b]	See table below Adjusted to blood levels	Leucine 100–300 μM Isoleucine 150–350 μM Valine 200–400 μM[c]
			NaCl[d] Thiamine[e]	3–5 mEq/kg/day 50–300 mg/day	Within normal limits
23.2 23.2 23.4	MSUD—Milder forms (1a, 2, BCKDH phosphatase)	All ages	Reduced natural protein diet[f] Multivitamin with minerals Thiamine[e]	See table below As required 50–300 mg/day	See above (severe forms)
23.2	MSUD—Thiamine-responsive forms (2)	All ages	Reduced natural protein diet[f] Multivitamin with minerals Thiamine	See table below As required 10 mg/kg/day (50–500 mg/day)	See above (severe forms)
23.3	MSUD 3 (combined dehydrogenase deficiency; E3 deficiency)	All ages	See above (severe forms)[g]		See above (severe forms)

[a]Special medical food devoid of the branched-chain amino acids and enriched with micronutrients (see table Nutritional treatment for patients with maple syrup urine disease)
[b]Typically as 10 mg/mL solutions
[c]Target ratios of approximately 1:2:2 for leucine, isoleucine, and valine, respectively
[d]Calculate the amount present in the diet and add supplements to meet the recommended intake
[e]Thiamine given until molecular genotype known. Not given in patients with the Mennonite mutation Y393N
[f]Protein intake of approximately 1.5–2.0 g/kg/day in young infants and 0.6–1.5 g/kg/day in older children and adults
[g]Attempts at treatment with diet and co-factors have been unsuccessful in some patients in preventing CNS deterioration; usually not thiamine-responsive

- **Comments/Additions**
  1. Intake of whole protein and supplements of individual amino acids is adjusted based on plasma quantitative amino acids levels and individual needs to meet the target levels.
  2. All patients with MSUD 1a, MSUD 1b, and MSUD 2 should be given a trial of thiamine therapy for at least 3 weeks or until the molecular genotype is known. Patients homozygous for the Y393N Mennonite mutation are not thiamine-responsive.

- Standard nutritional treatment for patients with maple syrup urine disease[a]

Age	Total protein requirement[b] (g/kg/day)	Leucine tolerance[c] (mg/kg/day)	Isoleucine intake (mg/kg/day)	Valine intake (mg/kg/day)	Energy requirement[d] (kcal/kg/day)
Neonates	2.7–3.5	40–100	30–90	40–95	100–145
Infants	2.5–3.2	35–75	20–70	30–80	80–135
Young children	1.8–2.6	20–65	10–30	20–50	60–130
Older children and adults	1.4–1.8	5–50	5–30	15–30	35–70

[a]Modified from Strauss et al. (2010), Acosta and Yannicelli (2001), and Marriage (2010). These recommendations are only a guide and must be individualized for each patient, based on the severity of their disorder, actual needs, and blood quantitative amino acid levels
[b]Includes protein intake from special medical foods devoid of BCAA plus that from natural whole protein sources
[c]Leucine (mg/kcal ratio of 0.5–0.8 for neonates, 0.4–0.6 for infants; ratio of 0.25:0.30 in children and older)
[d]Lipids should comprise 40–50% of total calories. Formula concentrations over 24 kcal/oz. may result in loose stools, diarrhea, and dehydration

- **Isovaleric acidemia**
- Standard treatment table

No.	Symbol	Age	Medication/diet	Dosage	Target plasma levels
23.6	IVA—Severe forms	All ages	Lowered leucine diet[a]	See tables below	Leucine 50–180 μM, or normal range for laboratory
			L-Carnitine	100 mg/kg/day in 3 doses[b]	Normal to high normal range for free carnitine
			Glycine	250 (150–300) mg/kg/day in 3 doses[c]	Glycine 200–400 μM

No.	Symbol	Age	Medication/diet	Dosage	Target plasma levels
23.6	IVA-Mild forms	All ages	Reduced natural protein diet[d] Multivitamin with minerals L-Carnitine	See tables below As required 30–100 mg/kg/day in 3 doses[b]	Normal free carnitine
			Glycine	150–250 mg/kg/day in 3 doses[d,e]	Glycine 200–400 μM

[a]Special medical food devoid of leucine and enriched with micronutrients may be needed for severe forms of the disorder. Patients with milder forms of the disorder will only require a reduced natural protein intake. The least restrictive diet sufficient to maintain metabolic control should be used
[b]Calculate the amount present in the special medical food or protein-free product and add supplements to meet the recommended intake
[c]Glycine is often omitted from chronic therapy. If used, it is added to the daily special formula as weighed dry powder or 100 mg/mL solution
[d]Natural protein intake of approximately 1.5–2.0 g/kg per day in young infants and 0.6–1.5 g/kg per day in older children and adults. Patients with a mild IVA form and the missense mutation 932C>T (A282V) usually do not require protein restriction
[e]Patients with a mild IVA form may not require glycine supplements

- Standard nutritional treatment for patients with isovaleric acidemia[a]

Age	Protein requirement[a] (g/kg/day)	Leucine intake[b] from whole natural protein (mg/kg/day)	Energy requirement[c] (kcal/kg/day)
Neonates	2.5–3.5	65–150	95–145
Infants	2.0–3.0	50–140	80–135
Young children	1.5–2.0	40–90	60–130
Older children and adults	1.1–1.8	30–60	35–70

[a]Includes protein intake from special medical food devoid of leucine plus that from natural whole protein sources
[b]These figures reflect leucine intake if special medical foods devoid of leucine are used and may be too low for some actively growing infants and children
[c]Formula concentrations over 24 Kcal/oz. may result in loose stools, diarrhea, and dehydration
[d]Modified from Acosta and Yannicelli (2001) and Marriage (2010). These recommendations are only a guide and must be individualized for each patient, based on the severity of their disorder. Patients with milder forms of the disorder will tolerate a higher leucine intake and may only require a reduced natural protein diet

- **Comments/Additions**
  1. Although leucine is the precursor amino acid for the disorder, it is the organic acids that are toxic to the patients and not the leucine per se as with MSUD. Monitoring leucine levels gives an indication as to whether there is sufficient intake of natural protein to support growth, losses, and tissue repair, but it does not rise in catabolism. The plasma leucine range of 50–150 μM, however, may be too low for some growing infants and children. Many affected patients are able to tolerate a near-normal leucine intake and may be treated with a lowered natural protein diet, without selective leucine restriction. The least restrictive dietary approach allowing metabolic control should be used in order to avoid over-treatment and leucine deficiency.

- **3-Methylcrotonylglycinuria type 1**
- **3-Methylcrotonylglycinuria type 2**
- Standard Treatment Table

No.	Symbol	Age	Medication/diet	Dosage	Target plasma levels
23.9	3MCCC1 3MCCC2	All ages	Lowered leucine diet[a]	See tables for IVA/disorder 23.2	Leucine 50–180 μM, or normal range for laboratory
			L-Carnitine	50–100 mg/kg per day in 2–3 doses[b]	Normal free carnitine

[a]Special medical food devoid of leucine may be needed for severe forms of the disorder. Patients with milder forms of the disorder will only require a reduced natural protein intake. The least restrictive diet should be used. Glycine is usually not given, though it might be considered in severe cases (175–250 mg/kg per day) as it increases 3-methylcrotonylglycine excretion
[b]Calculate the amount present in the special medical food if used and add supplements to meet the recommended intake

- **Comments/Additions**
  1. Special medical food devoid of leucine and enriched with micronutrients may be needed for severe forms of the disorder. Patients with milder forms of the disorder will only require a reduced natural protein intake. The least restrictive diet allowing metabolic control should be used.
  2. Patients are not responsive to biotin therapy.
  3. Asymptomatic individuals may not need dietary restrictions or L-carnitine but may occasionally need blood and urine monitoring.

- **3-Methylglutaconic aciduria, type 1**
- Standard treatment table

No.	Symbol	Age	Medication/diet	Dosage	Target plasma levels
23.10	3MG1	All ages	L-Carnitine	100 mg/kg per day in 3 doses[a]	Normal free carnitine
			Lowered leucine diet[b]	See tables for IVA/disorder 23.6	Leucine 50–180 μM, or normal range for laboratory

[a]Calculate the amount present in the special medical food if used and add supplements to this to meet the recommended intake
[b]No dietary regimen has been therapeutically proven. Special medical food devoid of leucine may be used for severe forms of the disorder. Patients with milder forms of the disorder might require a reduced natural protein intake. The least restrictive diet allowing metabolic control should be used

- **Comments/Additions**
  1. See comment 1 for Isovaleric acidemia.

- **Hydroxymethylglutaric aciduria**
- Standard treatment table

No.	Symbol	Age	Medication/diet	Dosage	Target plasma levels
23.15	HMGCL	All ages	Lowered leucine and fat, high carbohydrate diet[a]	See tables for IVA/disorder 7.3 Of note, fat is limited to 20–25% of total daily caloric intake	Leucine 50–180 μM, or normal range for laboratory
			L-Carnitine	100 mg/kg/day in 3 doses	Normal free carnitine

[a]Special medical food devoid of leucine may be needed for severe forms of the disorder. Patients with milder forms of the disorder will only require a reduced natural protein intake and low-fat diet. Avoid fasting. The least restrictive diet that allows metabolic control should be used

- Comments**/Additions**
  1. See comment 1 for Isovaleric acidemia.
  2. In addition to leucine restriction, daily caloric intake of fat is limited to 20–25% of total caloric intake per day. Use a leucine-free product that contains carbohydrates and other nutrients, but no or very low fat.
  3. Avoid fasting. Overnight drip nasogastric or gastrostomy feedings may be needed.
  4. Uncooked cornstarch added to the special metabolic formula may be used to prevent hypoglycemia.

- **2-Methylbutyrylglycinuria**
- **2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency**
- **α-Methylacetoacetic aciduria**
- **Isobutyryl-CoA dehydrogenase deficiency**
- **Crotonase deficiency**
- **3-Hydroxyisobutyryl-CoA deacylase deficiency**
- **3-Hydroxyisobutyrate dehydrogenase deficiency**
- **Methylmalonate semialdehyde dehydrogenase deficiency**
- Standard nutritional treatment for patients with disorders limited to isoleucine or valine[a]

Age	Isoleucine intake[b]	Valine intake	Natural protein requirement[d] (g/kg/day)	Total protein requirement (g/kg/day)	Energy requirement (kcal/kg/day)
Neonates	90–150 mg/kg/day	65–110 mg/kg/day	1.5–2.5	2.8–3.5	95–145
Infants	50–115 mg/kg/day	40–90 mg/kg/day	1.2–2.0	2.5–3.2	80–135
Young children	630–1250 mg per day	600–1100 mg per day	0.8–1.5	1.8–2.6	60–130
Older children and adults	965–1900 mg per day	900–2015 mg per day	0.5–1.4	1.4–1.8	35–70

[a]Modified from Yanicelli (2010). These recommendations are only a guide and must be individualized for each patient, based on the severity of their disorder, actual needs, and blood quantitative amino acid levels
[b]The targets relating to isoleucine curtailment would apply to MBD deficiency (disorder 23.8), to MHBD deficiency (disorder 23.14), and in principle to beta-ketothiolase deficiency (disorder 23.22)
[c]The targets relating to valine curtailment would apply to MMSDH deficiency (disorder 23.16), to HIBDH deficiency (disorder 23.13), to IBD deficiency (disorder 23.7), and in principle to HIBCH deficiency (disorder 23.12)
[d]In addition to the natural protein intake, special medical food (devoid of Ile or Val as appropriate) provides adequate total protein intake. The least restrictive diet should be used. These are approximate therapeutic strategies, and individual patient's requirements may vary substantially. Also, for a given patient, variations must be anticipated in relationship to growth rate, physical activity, intercurrent illness, etc.
[e]Monitor carnitine status and add L-carnitine as required (e.g., 50–100 mg/kg per day)
[f]In beta-ketothiolase deficiency (disorder 23.22): avoid fasting and high-fat intake; carbohydrate-rich meals and frequent feeding have been effective to avoid ketonuria

- **Propionic academia (α-subunit)**
- **Propionic acidemia (β-subunit)**
- **Methylmalonic aciduria due to methylmalonyl-CoA epimerase deficiency (the need for dietary treatment of this condition remains questionable)**
- **Methylmalonic aciduria due to methylmalonyl-CoA mutase deficiency**

- Standard treatment table

No.	Symbol	Age	Medication/diet	Dosage	Target plasma levels
23.17	PA	All ages	Lowered Ile/Val/Met/Thr diet[a]	See table below	Low normal to normal range of age for laboratory for Ile/Val/Met/Thr[b]; normal ammonia; normal acid-base status
			l-Carnitine	100 mg/kg/day in 3 doses	Normal to high normal range for free carnitine
			Metronidazole	10 mg/kg per day for intermittent treatment PO[c,d]	
23.19	MMA	All ages	Lowered Ile/Val/Met/Thr diet[a]	See table below	Low normal to normal range of age for laboratory for Ile/Val/Met/Thr[b]; normal plasma ammonia; normal acid-base status
			l-Carnitine	100 mg/kg/day in 3 doses	Normal to high normal range for free carnitine
			In cobalamin-responsive MMA: hydroxocobalamin	1 mg per day IM[e]	
			Metronidazole	10 mg/kg per day for intermittent treatment PO[c]	
			In renal failure: symptomatic therapy	As required	

This plan must be individualized for each patient, based on the severity and type of their disorder

[a]Individualize depending upon tolerance to protein, growth, and nutritional adequacy, guided by parameters in table Standard nutritional treatment for propionic acidemia and methylmalonic acidemia. Benefits from lowered Ile/Val/Met/Thr medical food is controversial (Manoli et al. 2016)

[b]Provide an adequate intake; prevent deficiencies

[c]Short-course or intermittent treatment (e.g., 1 week per month; >6 months)

[d]In PA, biotin responsiveness is doubtful and supplementation rarely beneficial

[e]Each patient with MMA should be tested for B12 responsiveness by a trial of parenteral hydroxocobalamin in a dose of 1 mg/day IM. In those that respond (decrease in urinary MMA excretion by ≥50%), therapy is continued, but the oral route may be used and the dose may be adjusted. Cyanocobalamin may be used if hydroxocobalamin is not available

- Standard nutritional treatment for propionic acidemia and methylmalonic acidemia[a]

Age	Isoleucine intake	Methionine intake	Threonine intake	Valine intake	Natural protein requirement[b]	Total protein requirement[c]	Energy requirement[d]
Neonates	60–110 mg/kg/day	20–50 mg/kg/day	50–125 mg/kg/day	60–105 mg/kg/day	1.2–1.8 g/kg/day	2.7–3.5 g/kg/day	125–145 kcal/kg/day
Infants	40–90 mg/kg/day	15–40 mg/kg/day	20–75 mg/kg/day	40–80 mg/kg/day	0.8–1.5 g/kg/day	2.5–3.2 g/kg/day	115–140 kcal/kg/day
Young children	485–735 mg per day	275–390 mg per day	415–600 mg per day	550–830 mg per day	0.7–1.2 g/kg/day	1.8–2.6 g/kg/day	900–1800 kcal per day
Older children and adults	630–1470 mg per day	360–950 mg per day	540–1455 mg per day	720–2000 mg per day	0.5–0.8 g/kg/day	1.4–1.7 g/kg/day	1500–3200 kcal per day

[a]Modified from Yanicelli (2010). These recommendations are only a guide and must be individualized for each patient, based on the severity of their disorder, actual needs, and blood quantitative amino acid levels

[b]In addition to the whole protein, specialized formulas (devoid of Ile/Met/Thr/Val) are needed. Of note, individual patient's requirements may vary substantially

[c]Includes protein intake from special medical foods devoid of Ile/Met/Thr/Val plus that from natural whole protein sources. Total protein recommendation is higher when the majority of protein is supplied by free amino acids (Ile−/Met-/Thr-/Val-free formula). However, patients with hyperammonemia or MMA patients with renal impairment require carefully adjusted protein amounts

[d]Energy requirement is usually lower during well state compared with unwell state in patients

- **Combined malonic aciduria and methylmalonic aciduria**
- **Malonic aciduria**

- Standard treatment table[a]

No.	Symbol	Age	Medication/diet	Dosage[a]	Target plasma levels
23.19	MMA	All ages	High carbohydrate and low long-chain triglycerides (LCT) fat diet; medium chain triglycerides (MCT) fat supplements	Dietary fat may comprise 30–50% LCT and 50–70% MCT	Normal blood glucose, normal essential fatty acids, normal cholesterol
			l-Carnitine	100 mg/kg/day in 3 doses	Normal free carnitine
23.20	CMAMMA	All ages	High carbohydrate and low long-chain triglycerides (LCT) fat diet; medium chain triglycerides (MCT) fat supplements; moderate restriction of natural protein	Dietary fat may comprise 30–50% LCT and 50–70% MCT	Normal blood glucose, normal essential fatty acids, normal cholesterol
			l-Carnitine	100 mg/kg/day in 2–3 doses	Normal free carnitine

[a]There are no established treatment recommendations and dosage may vary considerably
[b]Little information published and effectiveness of treatment has yet to be determined
[c]Check whether metabolite levels are responsive to (moderate) protein restriction in patients with combined malonic aciduria and methylmalonic aciduria (disorder 23.20)

- **Comments/Additions**
  1. Avoid fasting to prevent hypoglycemia.
  2. The management of a patient with cardiomyopathy should be done in consultation with a cardiologist; a beta blocker or angiotensin-converting enzyme inhibitor or other medications might be given depending on individual needs.
  3. Cholesterol supplementation should be given in patients with reduced cholesterol levels.

Experimental Treatment

Disorder no.	Symbol	Substance
23.2	MSUD 1a MSUD 1b MSUD 2 MSUD 1a	Coenzyme Q10 (5 mg/kg/day; electron carrier of the respiratory chain with antioxidant properties; in addition to standard therapy during crisis)[a] Phenylbutyrate (500 mg/kg/day; to activate E1α/BCKDC enzyme activity; in addition to standard therapy)
23.17	PA	Citric acid (as K-Na-hydrogen citrate, 80–120 mg/kg/day PO; might improve TCA cycle flux; in addition to standard therapy during crisis with lactic acidosis)[c]

Disorders of Beta and Gamma Amino Acids

24

Phillip L. Pearl and Lance Rodan

Contents

Summary

Disorders of beta amino acid synthesis, specifically dihydropyrimidine dehydrogenase, dihydropyrimidinase, and beta-ureidopropionase deficiency, manifest with neurodevelopmental impairment including epilepsy, sensitivity to fluropyrimidine chemotherapeutics, and abnormal urine pyrimidines on diagnostic testing. Of the disorders of beta amino acid degradation, hyper-beta-alaninemia and methylmalonate semialdehyde dehydrogenase deficiency have neurological phenotypes. In contrast, beta-aminoisobutyric aciduria is asymptomatic. Carnosinase deficiency leads to homocarnosinosis, with elevated urinary carnosine and CSF homocarnosine, although a phenotype has not been confirmed. The disorders of gamma amino acid metabolism are manifest by impaired GABA degradation in GABA transaminase deficiency and the more common succinic semialdehyde dehydrogenase (SSADH) deficiency. GABA transaminase deficiency leads to an early-onset epileptic encephalopathy associated with choreoathetosis, hypersomnolence, and sometimes growth acceleration, the latter attributed to GABA-mediated enhancing effects on growth hormone production. SSADH typically has the phenotype of a nonprogressive neurodevelopmental disorder with profound effects on expressive language, mild hypotonia and ataxia, and later development of epilepsy. There are other cases with prominent choreoathetosis and sometimes regression associated with systemic illnesses in infancy. GABA transporter deficiency may manifest as myoclonic-atonic epilepsy. There are a variety of GABA receptor subunit deficiencies, each with a handful of affected patients identified, and mostly manifest as early infantile or childhood *epileptic* encephalopathy.

Introduction

Beta and gamma amino acids are non-essential, non-proteinogenic amino acids containing an amine group attached to a beta or gamma carbon atom, respectively. The beta and gamma amino acids serve diverse cellular functions in humans, including an important role in the nervous system. They are present in both free and dipeptide forms. The free-form beta amino acids include beta-alanine, beta-aminoisobutyrate, and beta-leucine, and dipeptides include carnosine and anserine. The only gamma amino acid in humans is gamma aminobutyric acid (GABA), which exists in both free form and as the dipeptide homocarnosine (Pearl et al. 2019).

Beta-Alanine

β-alanine is produced through the degradation of the pyrimidine base uracil. Free-form beta-alanine acts as a neurotransmitter/neuromodulator in the central nervous system and as a precursor for pantothenic acid, which is required for synthesis of Coenzyme A. Beta-alanine is catabolized to acetyl-CoA, which can be used for anaplerosis and for synthesis of ketone bodies, fatty acids, and other compounds.

Beta-Aminoisobutyrate

Beta-aminoisobutyrate exists in two enantiomers in humans: an R-enantiomer derived from catabolism of the pyrimidine base thymine and an S-enantiomer derived from valine catabolism. In plasma, the S-enantiomer is the predominant form due to active renal reabsorption, whereas in urine the R-enantiomer is the predominant form, eliminated by renal filtration and tubular secretion. It has been suggested that there may be non-enzymatic interconversion between these enantiomers. The functions of beta-aminoisobutyrate have not been fully elucidated. It may play a role as a myokine involved in the browning of white fat through a PPARalpha-mediated mechanism. In addition, beta-aminoisobutyrate is a structural analogue of gamma aminobutyric acid (GABA) and glycine and may play a role in neurotransmission. Beta-aminoisobutyrate is catabolized to the anaplerotic metabolite propionyl-CoA.

Beta-Leucine

Beta-leucine is converted to alpha-leucine in a reversible reaction catalyzed by the B12-dependent enzyme leucine 2,3-aminomutase. The biological role of beta-leucine has not been established. Beta-leucine accounts for a very small percentage of the total leucine pool in tissues, other than in the testes where it accounts for approximately one-third. Elevated beta-leucine is a biomarker of vitamin B12 deficiency.

Gamma-Aminobutyric Acid (GABA)

GABA is synthesized through decarboxylation of the amino acid glutamate via the enzyme glutamic acid decarboxylase (GAD) and to a lesser degree through metabolism of the polyamine putrescine. GABA is the principal inhibitory neurotransmitter in the human central nervous system. It facilitates neuronal inhibition by binding to specific transmembrane GABA receptors. There are two classes of receptors: GABA-A and GABA-B receptors. GABA-A receptors are ligand-activated chloride channels, and GABA-B receptors are metabotropic, G protein-coupled receptors that activate potassium channels. GABA is catabolized to the Krebs cycle intermediate succinate.

Beta and Gamma Amino Acid Dipeptides

β-alanine and GABA both occur as imidazole dipeptides. The β-alanine dipeptides include carnosine (β-alanyl-L-histidine) and anserine (β-alanyl-1-methyl-L-histidine). Carnosine is synthesized endogenously through the enzyme carnosine synthetase. Most carnosine obtained from the diet is excreted intact in urine. Carnosine contains the largest pool of beta-alanine in humans. Carnosine is primarily stored within skeletal muscle and central nervous system. In skeletal muscle, it acts as an intracellular buffer and antioxidant during glycolysis. In the central nervous system, it may play a role as a neurotransmitter. Carnosine is hydrolyzed to its constituent amino acids, beta-alanine and histidine, by carnosine dipeptidase. Anserine is not a constituent of human tissue and is obtained solely from dietary sources. It is hydrolyzed to beta-alanine and 1-methylhistidine by carnosine dipeptidase (Pearl et al. 2019).

GABA exists as the dipeptide homocarnosine (β-aminobutyryl-L-histidine). It is synthesized through the enzyme carnosine synthetase. Homocarnosine is found only in the brain. The function of homocarnosine has not been established. It is hydrolyzed to its constituent amino acids by the enzyme carnosine dipeptidase.

Nomenclature

No.	Disorder	Alternate disease name	Disease abbreviation	Gene symbol	Chromosome localization	Mode of inheritance	Altered protein	OMIM #
24.1	Dihydropyrimidine dehydrogenase deficiency	Thymine-uraciluria		DPYD	1p21.3	AR	Dihydropyrimidine dehydrogenase	274270; 612779

Metabolic Pathways and Disorders

Disorders of Beta Amino Acid Synthesis

Beta-alanine and beta-aminoisobutyrate are synthesized in the liver and kidney through the degradation of the pyrimidine bases, uracil and thymine, respectively, in three sequential steps utilizing enzymes shared by both pathways.

Dihydropyrimidine Dehydrogenase Deficiency

Dihydropyrimidine dehydrogenase is the first and rate-limiting enzyme of the pyrimidine degradation pathway. It catalyzes the reduction of uracil to 5,6-dihydrouracil and thymine to 5,6-dihydrothymine. Dihydropyrimidine dehydrogenase is ubiquitously expressed. It is encoded by the DPYD gene.

Dihydropyrimidine dehydrogenase deficiency is an autosomal recessive disorder resulting from mutations in the DPYD gene. More than 75 patients have been reported to date (Fang et al. 2019). It has incomplete penetrance and variable expressivity. Affected individuals variably present with developmental delays, hypotonia, autism, epilepsy, growth restriction, microcephaly, dysmorphic features, and ophthalmological abnormalities. There may be nonspecific MRI abnormalities including cerebral volume loss, white matter abnormalities, and abnormalities of corpus callosum (Chen et al. 2014). In contrast, some individuals with DPYD gene mutations and classic biochemical abnormalities may remain entirely asymptomatic, suggesting a role of modifier genes or environmental factors. Individuals with dihydropyrimidine dehydrogenase deficiency are unable to normally metabolize fluoropyrimidine chemotherapy medications, 5-fluorouracil and capecitabine, resulting in drug toxicity if they are unknowingly treated. Clinical manifestations include myelosuppression, diarrhea, mucositis, stomatitis, neurotoxicity, and potentially death. Heterozygous carriers for dihydropyrimidine dehydrogenase deficiency may also have adverse reactions to these medications. Biochemical diagnosis is established through measurement of urine pyrimidines, demonstrating accumulation of uracil and thymine. These abnormalities may also be detected in blood and CSF. Treatment of dihydropyrimidine dehydrogenase deficiency is supportive, aimed at managing neurological manifestations and avoiding medications in the fluoropyrimidine category.

Dihydropyrimidinase Deficiency

In the second step of pyrimidine degradation, dihydropyrimidinase catalyzes the hydrolytic ring opening of the dihydropyrimidines, 5,6-dihydrouracil and 5,6-dihydrothymine, to *N*-carbamyl-beta-alanine and *N*-carbamyl-beta-aminoisobutyric acid, respectively. The enzyme is primarily expressed in the liver and kidneys. It is encoded by the DPYS gene.

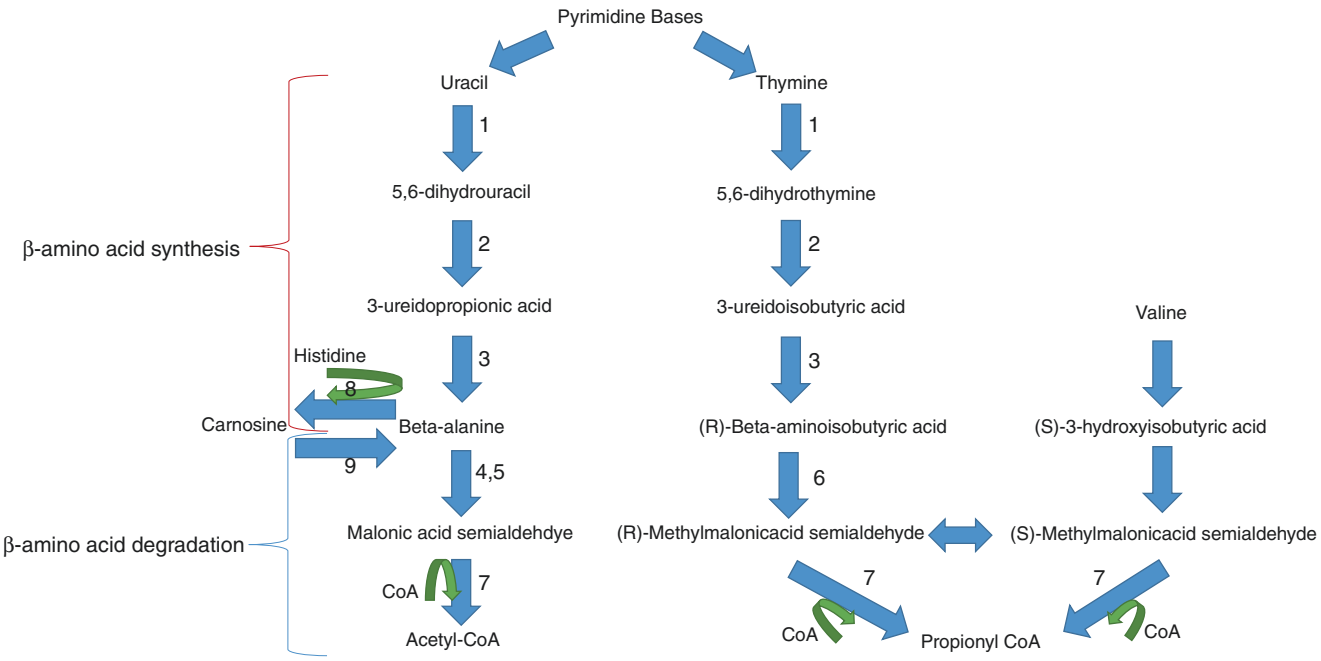

Fig. 24.1 Beta amino acid metabolism. (1) Dihydropyrimidine dehydrogenase. (2) Dihydropyrimidinase. (3) Beta-ureidopropionase. (4) β-alanine-α-ketoglutarate transaminase. (5) β-alanine-pyruvate transaminase. (6) β-aminoisobutyrate-pyruvate transaminase. (7) Methylmalonate semialdehyde dehydrogenase. (8) Carnosine synthetase. (9) Carnosinase

Dihydropyrimidinase deficiency is an autosomal recessive disorder resulting from mutations in the DPYS gene. Approximately 30 patients with confirmed dihydropyrimidinase deficiency have been reported to date (Nakahima et al. 2017). Similar to dihydropyrimidine dehydrogenase deficiency, dihydropyrimidinase deficiency has incomplete penetrance and variable expressivity. Affected individuals variably present with developmental delay, epilepsy, growth restriction, and dysmorphic features. Autism has been rarely reported. Some affected individuals may be asymptomatic (Nakahima et al. 2017). Similar to dihydropyrimidine dehydrogenase deficiency, this disorder may be associated with adverse reactions to the fluropyrimidine chemotherapies. Neuroimaging may variably demonstrate cerebral atrophy and white matter abnormalities (Nakahima et al. 2017). Biochemical diagnosis is established through measurement of urine pyrimidines, demonstrating accumulation of 5,6-dihydrouracil and 5,6-dihydrothymine. A similar profile may be detected in plasma and cerebrospinal fluid. Enzyme activity can be measured in liver biopsy. Treatment of dihydropyrimidinase deficiency is supportive.

Beta-Ureidopropionase Deficiency

In the third step of pyrimidine degradation, beta-ureidopropionase catalyzes the conversion of *N*-carbamyl-beta-alanine and *N*-carbamyl-beta-aminoisobutyric acid to beta-alanine and beta-aminoisobutyric acid, respectively. The enzyme is primarily expressed in the liver and kidneys. It is encoded by the UPB1 gene.

Beta-ureidopropionase deficiency is an autosomal recessive disorder resulting from biallelic variants in the UPB1 gene. Approximately 40 patients have been reported to date (Fang et al. 2019). Similar to other defects in pyrimidine degradation, the clinical presentation is variable, ranging from asymptomatic individuals to individuals affected with a severe neurodevelopmental disorder associated with developmental delay, hypotonia, dystonia, epilepsy, autism, microcephaly, growth restriction, dysmorphic features, optic atrophy, retinal pigmentary abnormalities, and gastrointestinal dysmotility. Individuals with beta-ureidopropionase deficiency and carriers also appear to be at increased risk of fluoropyrimidine-related toxicity. Neuroimaging is inconsistent, and various abnormalities have been described, including cortical malformations, atrophy, cerebellar and brainstem dysplasia, and white matter abnormalities. Biochemical diagnosis is established through measurement of urine pyrimidines, demonstrating highly elevated levels of *N*-carbamyl-beta-alanine and *N*-carbamyl-beta-aminoisobutyric acid and moderately elevated levels of 5,6-dihydrouracil and 5,6-dihydrothymine. A similar profile may be detected in plasma and cerebrospinal fluid. Enzyme activity can be measured in liver biopsy. Treatment of beta-ureidopropionase deficiency remains supportive. Treatment with ß-alanine is not effective.

Disorders of Beta Amino Acid Degradation

Hyper-Beta-Alaninemia

Beta-alanine is catabolized in two sequential steps. Beta-alanine is first transaminated in the liver by either beta-alanine-alpha-ketoglutarate transaminase (AKT) or beta-alanine-pyruvate transaminase to malonate semialdehyde (beta-ketopropionate). In the second step, malonate semialdehyde is oxidized by methylmalonate semialdehyde dehydrogenase to acetyl-CoA.

Hyper-beta-alaninemia was first described in 1966. It has been reported in two individuals to date, one of which also carried a clinical diagnosis of Cohen syndrome (Higgins et al. 1994). Reported clinical features include epilepsy, encephalopathy, lethargy, and hypotonia. The molecular basis has not yet been established. It is hypothesized to result from deficiency of beta-alanine transaminase activity, either beta-alanine pyruvate aminotransferase or beta-alanine alpha ketoglutarate aminotransferase. The biochemical features of hyper-beta-alaninemia have been induced experimentally in vitro by administration of aminooxyacetate, an inhibitor of aminotransferases. In addition, one of the reported individuals with hyper-beta-alaninemia was found to have reduced beta-alanyl-alpha-ketoglutarate transaminase (AKT) activity in cultured skin fibroblasts. Biochemical evaluation in this disorder demonstrates elevations of plasma and urine beta-alanine, as well as elevated urine levels of GABA and beta-aminoisobutyrate. The mechanism of neurotoxicity has not yet been elucidated, although it has been suggested that it may result from increased oxidative stress, depletion of taurine, and mitochondrial damage. In the index case, pyridoxine supplementation resulted in biochemical but not clinical improvement. Dietary modifications, pantothenic acid supplementation, and antibiotic therapy were also not found to be beneficial (Scriver et al. 1966). In the second case, pyridoxine supplementation resulted in both biochemical correction and clinical improvement. Pyridoxine is a precursor of the transaminase cofactor.

Beta-Aminoisobutyric Aciduria

Similar to beta-alanine, beta-aminoisobutyric acid is catabolized into two sequential steps. It is first deaminated by beta-aminoisobutyrate aminotransferases to methylmalonate semialdehyde and then oxidized by methylmalonate semialdehyde dehydrogenase to propionyl-CoA.

Beta-aminoisobutyric aciduria is considered a benign biochemical variant and occurs at a high frequency in certain

populations: 5–10% in Caucasians and 40–95% in Asian populations. The disorder results from deficiency of hepatic D-beta-aminoisobutyrate:pyruvate aminotransferase, encoded by the AGXT2 gene. Inheritance is autosomal recessive, with incomplete penetrance. Individuals with beta-aminoisobutyric aciduria excrete large amounts of (R) beta-aminoisobutyric acid in their urine but have no clinical symptoms (Pearl et al. 2019).

Methylmalonate Semialdehyde Dehydrogenase Deficiency

Methylmalonate semialdehyde dehydrogenase is involved in the second step of both beta-alanine and beta-aminoisobutyrate degradation. It is also involved in the valine catabolic pathway. It is a member of the aldehyde dehydrogenase superfamily but uniquely requires CoA as a substrate. It is located in the mitochondrial matrix.

Methylmalonate semialdehyde dehydrogenase deficiency is an autosomal recessive disorder resulting from mutations in the ALDH6A1 gene. Four patients have been reported to date. This disorder presents with variable developmental delays, microcephaly, dysmorphic features, epilepsy, ophthalmological abnormalities, hypotonia, and dystonia. Imaging may demonstrate delayed myelination and thinning of the corpus callosum. Metabolic evaluation variably demonstrates metabolic acidosis and increased urinary excretion of 3-hydroxyisobutyric acid, beta-aminoisobutyric acid, beta-alanine, 3-hydroxypropionate, lactate, and methylmalonic acid. Management is supportive (Marcadier et al. 2013).

Disorders of Beta and Gamma Amino Acid Dipeptide Metabolism

Serum Carnosinase Deficiency and Homocarnosinosis

Both carnosine and homocarnosine are hydrolyzed to their constituent amino acids by the enzyme carnosine dipeptidase (also known as carnosinase). There are separate serum and tissue forms, encoded by different genes. The serum form is encoded by the CNDP1 gene. Deficiency of serum carnosine dipeptidase was initially reported in association with two distinct disorders, serum carnosinase deficiency and homocarnosinosis. It is now appreciated that these likely represent the same biochemical defect. Biochemical features include increased urinary excretion of carnosine and elevated levels of CSF homocarnosine. While about half of the patients with this biochemical finding have been reported to present with neurological disease (spasticity, retinal degeneration, epilepsy), the association between this biochemical finding and clinical disease has not been firmly established. Multiple cases of asymptomatic family members with serum carnosinase deficiency have been ascertained after diagnosis of symptomatic probands (Pearl et al. 2019). Further, the index family with homocarnosinosis was determined to have had SPG11 gene-related hereditary spastic paraplegia as the likely cause of their symptoms (Sjaastad et al. 2018).

Disorders of Gamma Amino Acids

GABA Transaminase Deficiency

Gamma transaminase (GABA-T), or ABAT (4-aminobutyrate aminotransferase), converts GABA to succinic semialdehyde, leading to the oxidative metabolism of GABA through the Krebs cycle. If GABA-T is absent, there is a resultant accumulation of GABA and beta-alanine, homocarnosine, and the GABA ketone, 2-pyrrolidinone. GABA-T deficiency is caused by biallelic pathogenic variants in the ABAT gene (OMIM 613163). While initially characterized as an early-onset epileptic encephalopathy with mortality within the first 2 years of life, an expanded phenotypic spectrum has been identified with further case series, including survival into adulthood (Hegde et al. 2019).

The typical presentation is neonatal or early infantile-onset encephalopathy along with hypotonia, hypersomnolence, epilepsy, choreoathetosis, and in some cases, accelerated linear growth. EEG recordings manifest burst-suppression, modified hypsarrhythmia, multifocal spikes, or generalized spike-wave. MRI demonstrates cerebral atrophy, thalamic lesions, and increased diffusion-weighted signal intensity involving the internal and external capsules and cerebral white matter (Ichikawa et al. 2019). MR spectroscopy may be helpful in demonstrating elevated GABA levels (Ichikawa et al. 2019). There is no specific treatment. Flumazenil, a GABA-A benzodiazepine receptor antagonist, has been utilized with variable effects (Koenig et al. 2017).

Succinic Semialdehyde Dehydrogenase (SSADH) Deficiency

GABA is normally deaminated to succinic semialdehyde, itself an unstable intermediate, by GABA-T and then converted to succinic acid via SSADH. Deficiency of SSADH

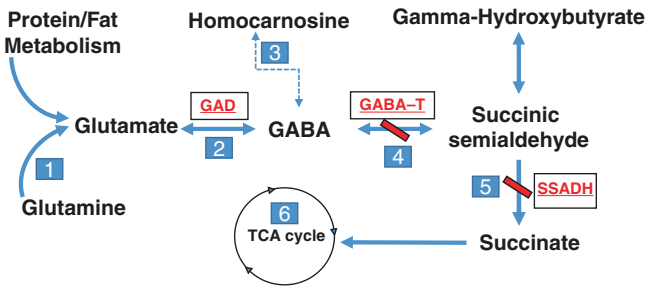

Fig. 24.2 GABA metabolism. (1) Glutaminase. (2) Glutamic acid decarboxylase. (3) Homocarnosinase/carnosinase. (4) GABA transaminase. (5) Succinic semialdehyde dehydrogenase. (6) Tricarboxylic acid cycle

leads to the pathological accumulation of gamma-hydroxybutyrate (GHB) as well as D-2-hydroxyglutaric acid and 4,5-dihydroxyhexanoic acid (DHHA). SSADH deficiency is caused by inactivating variants of the ALDH5A1 gene and is an autosomal recessively inherited disorder (OMIM 271980). The true prevalence is unknown, although at least 350 patients have been estimated to have been diagnosed based on laboratory experience, and 182 confirmed cases from 40 countries had been published as of 2016 based on a literature review along with our database (Attri et al. 2017). The true prevalence is likely underestimated, given the nonspecific neurologic phenotype, absence of systemic abnormalities or neurodegenerative course in most cases, potential for misdiagnosis, and increasing number of cases diagnosed with more widespread use of next-generation sequencing. The typical presentation is that of a relatively static encephalopathy with hypotonia and developmental delay having onset in the first 2 years, with subsequent manifestations being intellectual deficiency, severe expressive language impairment, mild ataxia, and a neuropsychiatric profile characterized by ADHD and sometimes aggression and autistic behavior in childhood with increasingly incapacitating anxiety and obsessive-compulsive disorder in adulthood (DiBacco et al. 2018). About half of patients develop epilepsy, and there appears to be a risk for SUDEP (sudden unexplained death in epilepsy patients) in as high as 10–15% of the adult cohort with otherwise normal or nearly normal life expectancy (Lapalme-Remis et al. 2015).

The diagnosis is made by elevation of 4-hydroxybutyric acid (GHB) which is detected on urine organic acids as the most common metabolic pathway to clinical suspicion, although more clinicians are recently using targeted gene sequencing panels with nonspecific neurologic phenotypes or whole exome sequencing and arriving at the diagnosis. GHB is elevated in all physiologic body fluids, owing to impaired GABA degradation by SSADH. SSADH deficiency was first described in two patients with high levels of GHB found in blood, urine, and cerebrospinal fluid in 1983 (Gibson et al. 1983), followed by purification of mammalian SSADH, molecular cloning of ALDH5A1 gene and identification of mutations (Chambliss et al. 1998), and elaboration of the phenotype (Pearl et al. 2007).

A murine genetic degradation model has led to extensive therapeutic insight, leading to translational trials demonstrating downregulation of GABA(A) and (B) receptor activity in both clinical studies and animal models (Reis et al. 2012; Pearl et al. 2009a). Additional clinical studies have indicated sleep disturbances and polysomnographic abnormalities consistent with decreased stage REM, consistent with a hyper-GABA'ergic effect, as well as clinical trials that have either shown no definite benefit or are in progress (Pearl et al. 2009b, 2014). A natural history study is currently underway, along with the international working group on neurotransmitter related diseases (iNTD) and sponsored by the National Institute of Child Health and Development (NICHD) of the National Institutes of Health (NIH) (www.clinicaltrials.gov).

GABA Transporter Deficiency

The GABA transporter that removes GABA from the synaptic cleft is coded by the solute carrier gene SLC6A1, which maps to chromosomal locus 3p25-p24. Mutations in the transporter were reported to cause epilepsy of the myoclonic-atonic type in seven individuals, with six mutations characterized by two truncations and four missense alterations (Carvill et al. 2015). Interestingly, Slc6a1-knockout mice develop spike-wave discharges characteristic of absence seizures. A large cohort of 24 patients with pathogenic SLC6A1 variants were reported to have the phenotype of myoclonic atonic epilepsy (MAE) along with language delay plus mild or moderate intellectual deficiency before epilepsy onset (Johannesen et al. 2018). Excellent clinical response to the ketogenic diet has been reported, which is well known to occur in a subset of patients with the syndrome of MAE, or myoclonic atonic epilepsy of Doose (Palmer et al. 2016).

GABA Receptor Subunit Deficiencies

GABA type A receptors are composed of five homologous, variable subunits that form a central channel that functions as a chloride ion pore. Each subunit has a long, variable extracellular region, four transmembrane domains, and a variable cytoplasmic region. Zinc ions play a critical role in regulating GABA-A receptors via an allosteric mechanism dependent on the subunit receptor composition. There are distinct binding sites for benzodiazepines and neurosteroids. A number of GABA type A receptor subunit deficiencies have been described, each in a handful or less of patients. The associated nomenclature and clinical disorders are shown in Nomenclature Table.

In contrast to the ionotropic GABA-A receptors, metabotropic GABA type B receptors' inhibitory properties are mediated through G protein-coupled second messenger systems which regulate potassium conductance. The GABA-B receptor R2 subunit is encoded by the gene GABBR2, with cytogenetic location 9q22.33. Pathogenic variants have been associated with an early infantile epileptic encephalopathy as well as a neurodevelopmental disorder with speech impairment and loss of purposeful hand skills (Hamdan et al. 2017; Lopes et al. 2016).

Specimen Collection

Table 24.20 Specimen collection and interpretation pitfalls

Metabolite	Material	Handling	Pitfalls
Amino acids	Urine	First morning urine preferred. Keep refrigerated in short term (24 h). Freeze at −20 °C for up to 1 month	
Neurotransmitters	CSF	Freeze immediately; store at −80 °C	
Organic acids	Urine	Freeze at −20 °C	
Organic acids	Plasma	Obtained from blood anticoagulated with heparin Plasma samples should be stored at −20 °C or at −80 °C	
Purines and pyrimidines panel	Urine	24 h collection is preferred, but random urine specimen can be used. During the collection period, the urine aliquots are kept refrigerated (4 °C), and after completion stored frozen at −20 °C for 1 week to 2 months. If storing longer than 2 months, storage at −80 °C is recommended	Need aged matched reference range
Purines and pyrimidines panel	Plasma	Obtained from blood anticoagulated with heparin, as well as EDTA. Plasma samples should be stored at −20 °C or at −80 °C	Need aged matched reference range
GABA	Serum	Freeze immediately; store at −80 °C	Vigabatrin ↑
GABA	CSF	Freeze immediately; store at −80 °C	Vigabatrin ↑ Hyperprolinemia Immaturity of transporter or polymorphism in transporter
4-Hydroxybutyric acid	Urine	First morning urine preferred. Keep refrigerated in short term (24 h). Freeze at −20 °C for up to 1 month	Treatment with 4-hydroxybutyric acid ↑ Vigabatrin ↓
4-Hydroxybutyric acid	CSF	Freeze at −20 °C	Treatment with 4-hydroxybutyric acid ↑ Vigabatrin ↓

Diagnosis

Diagnosis of the disorders of beta and gamma amino acids may follow clinical suspicion, although the phenotypes are nonspecific and generally involve early infantile onset epileptic encephalopathies, although can also manifest as autism spectrum, neurodevelopmental disability with profound language impairment, and extrapyramidal syndromes, e.g., choreoathetosis or dystonia. Urine organic acids are often useful as a laboratory screening tool. More specific metabolic analytes are identified in Table 24.21 (Diagnosis) and include urine purines and pyrimidines and potentially CSF GABA. Enzyme assays are available for some conditions. Generally, mutation analysis, whether through targeted screening or whole exome sequencing, is used to establish the diagnosis.

Table 24.21 Diagnosis

No.	Disorder	Prenatal diagnosis	Diagnosis
24.1	Dihydropyrimidine dehydrogenase deficiency	Mutation analysis	Urine purines and pyrimidines panel: elevated uracil and thymine Mutation analysis
24.2	Dihydropyrimidinase deficiency	Mutation analysis	Urine purines and pyrimidines panel: elevated dihydrouracil and dihydrothymine Enzyme assay of liver biopsy Mutation analysis
24.3	Beta-ureidopropionase deficiency	Mutation analysis	Urine purines and pyrimidines panel: elevated *N*-Carbamyl-β-alanine and *N*-carbamyl-β-aminoisobutyric acid Enzyme assay of liver biopsy Mutation analysis
24.4	Hyper-β-aminoisobutyric aciduria	Mutation analysis	Beta-aminoisobutyric acid (urine) Mutation analysis
24.5	Hyper-β-alaninemia		Beta-aminoisobutyric acid (urine)
24.6	GABA transaminase deficiency	Mutation analysis	Neurotransmitters CSF: elevated GABA Mutation analysis
24.7	Succinic semialdehyde dehydrogenase deficiency	Metabolite: 4-hydroxybutyric acid in amniotic fluid Enzyme assay in CVS or cultured amniocytes Mutation analysis	Urine organic acids: elevated 4-hydroxybutyric acid Mutation analysis
24.8	GABA transporter deficiency	Mutation analysis	Mutation analysis
24.9	GABA type A receptor α1 subunit deficiency	Mutation analysis	Mutation analysis

24.17	Serum carnosinase deficiency/ homocarnosinosis	Enzyme assay	Neurotransmitters CSF: elevated GABA, elevated homocarnosinase Mutation analysis
24.18	Methylmalonate semialdehyde dehydrogenase deficiency	Molecular analysis WBC, FB or other suitable cells or tissue samples may be used	Mutation analysis Molecular analysis WBC, FB, or other suitable cells or tissue samples may be used

Treatment Summary

The treatment of the disorders of beta and gamma amino acids is supportive and largely consists of antiseizure medications and, when indicated, anxiolytics and psychoactive medications. The chemotherapeutic 5-fluorouracil and related compounds should be avoided in the beta amino acid synthesis deficiencies of dihydropyrimidine dehydrogenase, dihydropyrimidinase, and beta-ureidopropionase. Valproate is generally contraindicated in SSADH deficiency because it can inhibit any residual enzymatic activity. Targeted therapy is not currently available, including enzyme replacement or gene therapy. Attempts have been made for more specific therapies such as flumazenil as a benzodiazepine receptor antagonist of the GABA(A) receptor in GABA transaminase deficiency, and there may be a role for the cofactor pyridoxine in hyper-beta-alaninemia (cf Table 24.22).

Table 24.22 Treatment

No.	Disorder	Emergency treatment	Long-term treatment	Experimental treatment
24.1	Dihydropyrimidine dehydrogenase deficiency	Supportive	No specific treatment The use of 5-halogenated pyrimidines (5-fluorouracil) should be avoided at any time	None
24.2	Dihydropyrimidinase deficiency	Supportive	No specific treatment The use of 5-halogenated pyrimidines (5-fluorouracil) should be avoided at any time	None
24.3	Beta-ureidopropionase deficiency	Supportive	No specific treatment The use of 5-halogenated pyrimidines (5-fluorouracil) should be avoided at any time	None
24.4	Hyper-β-aminoisobutyric aciduria	No treatment needed	No treatment needed	None
24.5	Hyper-β-alaninemia	Supportive	10–100 mg/day of pyridoxine may be beneficial	None
24.6	GABA transaminase deficiency	Supportive	No specific treatment Supportive	Flumazenil
24.7	Succinic semialdehyde dehydrogenase deficiency	Supportive	No specific treatment Supportive	SGS-742 Phase 2 Clinical Trial (GABA B receptor antagonist)
24.8	GABA transporter deficiency	Supportive	Ketogenic diet has been beneficial	None
24.9	GABA type A receptor α1 subunit deficiency	Supportive	No specific treatment Supportive	None
24.10	GABA type A receptor α6 subunit deficiency	Supportive	No specific treatment Supportive	None
24.11	GABA type A receptor β1 subunit deficiency	Supportive	No specific treatment Supportive	None
24.12	GABA type A receptor β2 subunit deficiency	Supportive	No specific treatment Supportive	None
24.13	GABA type A receptor β3 subunit deficiency	Supportive	No specific treatment Supportive	None
24.14	GABA type A receptor γ2 subunit deficiency	Supportive	No specific treatment Supportive	None
24.15	GABA type A receptor δ subunit deficiency	Supportive	No specific treatment Supportive	None
24.16	GABA type B receptor subunit 2 deficiency	Supportive	No specific treatment Supportive	None
24.17	Serum carnosinase deficiency/ homocarnosinosis	Supportive	Vegetarian diet Supportive	None
24.18	Methylmalonate semialdehyde dehydrogenase deficiency	Supportive	Supportive	None

Follow-Up and Monitoring

Clinical follow-up at regular intervals is indicated in these chronic disorders, including electroencephalography with associated seizure disorders and neuroimaging for baseline and then later studies depending upon the clinical course. Serial testing of metabolic analytes has an unknown role in these disorders.

Amino Acid Synthesis Deficiencies

25

Contents

Summary

In recent years the list of disorders affecting amino acid synthesis has grown rapidly. Not only the number of defects has increased, but also the associated clinical phenotypes have expanded spectacular, the latter mainly due to the advances of next-generation sequencing diagnostics.

An important reason for the contribution of NGS in the diagnosis of amino acid synthesis disorders is the fact that the biochemical diagnosis of some of these synthesis disorders can be quite challenging, synthesis defects may present with low values of amino acids, or their concentrations can even be completely normal. Defects in the synthesis pathways of serine metabolism, glutamine, glutamate, proline, and asparagine have been reported, and all pose specific challenges to a biochemical diagnosis. An exception to this are the disorders of pyrroline-5-carboxylate (P5C) synthesis where ornithine or proline is strongly elevated and easily detected by plasma amino acid analysis. Finally, Snyder-Robinson, a defect in the synthesis of the polyamine spermine, is discussed here as well, and molecular testing is advised for this disorder as well.

Although the amino acid synthesis defects in this chapter are not all in related metabolic pathways, they do share some clinical features. In children the central nervous system is primarily affected, giving rise to (congenital) microcephaly, early-onset seizures, and mental retardation to a variable degree. The brain abnormalities can be accompanied by skin disorders such as cutis laxa in proline defects, collodion-like skin and ichthyosis in serine deficiency, necrolytic erythema in glutamine deficiency, and difficult to classify skin abnormalities in glutaminase hyperactivity. In adults with serine or proline disorders, several forms of polyneuropathy with or without intellectual disability appear to be the major presenting symptom. An exception to this is ornithine aminotransferase deficiency which primarily affects the choroid and retina and Snyder-Robinson syndrome in which mental retardation is accompanied by seizures, dysmorphic features, and severe osteoporosis.

Introduction

By tradition the biochemical analysis of elevated levels of amino acids or their degradation products in body fluids has been the cornerstone in diagnosing inborn errors of metabolism. In 1996 (Jaeken et al. 1996), for the first time, defects in the pathway of serine synthesis were reported and identified through low concentrations of amino acids. Since then defects in the synthesis pathways of serine, proline, glutamine, glutamate, and asparagine have all been reported. In this chapter the defects in the synthesis of pyrroline-5-carboxylate (P5C) are discussed as well, namely, ornithine aminotransferase (OAT) deficiency and hyperprolinemia type I and II as well as Snyder-Robinson syndrome, a defect in the synthesis of the polyamine spermine (Fig. 25.1).

Some of these disorders present with low values of amino acids, for instance, serine and glutamine deficiency, whereas in others amino acid concentrations are variable or completely normal (proline and asparagine synthesis defects) or highly elevated as in OAT deficiency, hyperprolinemia type I and II, and glutaminase deficiency. Only the latter disorders are easily diagnosed through elevated concentrations of an amino acid, namely, ornithine, glutamine, or proline (Fig. 25.2).

With the discovery of these amino disorders, it became evident that they can give rise to a whole spectrum of clinical symptoms ranging from lethal developmental defects to late-onset adult neurologic disease. The disorders do have some clinical features in common as well. In children the brain is primarily affected, giving rise to (congenital) microcephaly, early-onset seizures, and mental retardation to a variable degree. These neurological symptoms can be accompanied by skin disorders such as cutis laxa in proline defects, collodion-like skin and ichthyosis in serine deficiency, necrolytic erythema in glutamine deficiency, and difficult to classify skin abnormalities in glutaminase hyperactivity. On brain MRI hypomyelination can be seen in serine, proline, mild glutamine, glutaminase hyperactivity, and asparagine deficiency, whereas structural abnormalities are present in severe serine, glutamine, and glutaminase deficiency as well as in proline deficiency. The adulthood-onset phenotypes of serine and proline synthesis defects have a different presentation with several forms of polyneuropathy with or without intellectual disability.

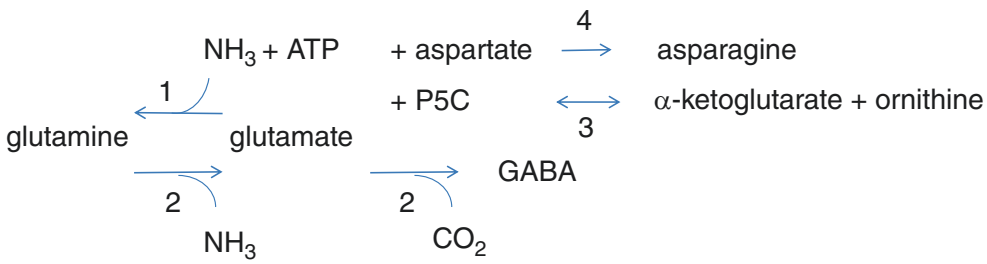

Fig. 25.2 Glutamine, glutamate and asparagine synthesis. (1) Glutamine synthetase, (2) glutaminase, (3) ornthine aminotransferase, (4) asparagine synthetase

Serine Deficiency

L-serine is synthesized in three steps from the glycolytic intermediate phosphoglycerate, and defects in any of these three enzymes give rise to identical clinical phenotypes. Serine deficiency is associated with a wide spectrum of clinical presentations ranging from Neu-Laxova syndrome, a lethal fetal developmental defect, to adult-onset neuropathy (Acuna-Hidalgo et al. 2014; van der Crabben et al. 2013). The majority of patients present as infants with congenital microcephaly, severe psychomotor retardation, spastic paraplegia, and intractable seizures. On MRI extensive developmental defects are seen in Neu-Laxova syndrome with lissencephaly, absence of corpus callosum, and hypoplasia of pons and cerebellum, whereas in infantile cases hypomyelination is the major finding on MRI. In juvenile and adulthood presentations, normal MRIs are found.

Glutamine Deficiency

Glutamine deficiency appears to be an ultra-rare disorder among the synthesis defects and is caused by a deficiency of glutamine synthetase. Only four patients have been reported so far. The first two patients reported were severely affected and presented as newborns with respiratory failure, hypotonia, absence of spontaneous movement, and generalized seizures and died soon after birth (Häberle et al. 2005). The children also suffered from necrolytic skin abnormalities. The two other patients reported had a somewhat milder phenotype with psychomotor retardation and intractable seizures. In only one of them episodic necrolytic skin abnormalities were also present. MRI showed structural abnormalities in severe cases and hypomyelination in a milder case (Häberle et al. 2012).

Glutaminase Deficiency and Hyperactivity

Very recently both a deficiency and hyperactivity of glutaminase were reported, an enzyme that regulates the synthesis of glutamate from glutamine and plays an important role in brain homeostasis of glutamate, ammonia, and GABA.

Although very little patients were reported so far, glutaminase deficiency apparently also causes a spectrum of symptoms ranging from severe hypotonia, respiratory insufficiency, and early-onset intractable seizures to infantile presentation with motor and speech delay evolving into progressive ataxia (Rumping et al. 2019a; van Kuilenburg et al. 2019). On MRI simplified gyration and white matter abnormalities were present in early-onset presentation, and cerebellar atrophy may be seen during follow-up of the infantile presentation.

The case with glutaminase hyperactivity presented with congenital cataracts and developed hypotonia, significant developmental delay, behavioral abnormalities, and specific skin abnormalities (Tessadori et al. 2019b). Low glutamate and high glutamine were present on MRS, but CSF and plasma analyses were unremarkable. High glutamine and low glutamate excretion was observed in urine, but with some samples being close to the levels of reference samples.

Disorders of Proline and P5C Synthesis

In contrast to most metabolic disorders are the proline synthesis defects mostly known by their gene symbols and usually not classified according to the corresponding enzymes. The proline defects are pyrroline-5-carboxylate synthase (P5CS or *ALDH18A1*) deficiency, pyrroline-5-carboxylate reductase 1 (*PYCR1*) deficiency, and pyrroline-5-carboxylate reductase 2 (*PYCR2*) deficiency.

The phenotypes of P5CS deficiency and PYCR1 deficiency are overlapping, and most patients have prominent cutis laxa and therefore classified as autosomal recessive cutis laxa syndromes. The cutis laxa can be associated with microcephaly, progeroid features, mental retardation, hypotonia, seizures, joint laxity (intrauterine), growth retardation, cataract, and corneal abnormalities (Baumgartner et al. 2000; Reversade et al. 2009; Skidmore et al. 2011; Zampatti et al. 2012). In some patients movement disorders such as tremor and dystonia were reported as well. On MRI, hypomyelination with a thin corpus callosum can be seen as well as cerebellar abnormalities. Adults with P5CS deficiency present with late-onset spastic paraparesis, a phenotype very different from that in children (Coutelier et al. 2015).

PYCR2 deficiency was first classified as hypomyelinating leukodystrophy-10 reported with secondary microcephaly and hypomyelination (Nakayama et al. 2015). In subsequent reports the phenotype (Zaki et al. 2016) expanded to that of a lethal neurodegenerative disorder with microcephaly, severe failure to thrive, profound psychomotor retardation, dysmorphism, ataxia and hyperkinetic movement disorders, seizures, and spastic tetraplegia. The MRI findings can be more variable with regard to the white matter abnormalities, and many patients had extensive cortical atrophy and thin corpus callosum.

The two forms of hyperprolinemia can be regarded as a synthesis disorder of P5C, the intermediate metabolite in proline and ornithine metabolism. The clinical significance of a deficiency of proline dehydrogenase causing hyperprolinemia type I is still unclear; at present it is considered a risk factor for schizophrenia, but associations with autism and neurological symptoms such as seizures have been suggested. In hyperprolinemia type I, elevated proline is often an incidental finding, but it is important to realize this can be caused by a deletion of 22q11 (DiGeorge syndrome), the region that contains proline dehydrogenase. In contrast, in hyperprolinemia type II, drug-resistant seizures typically starting in the first year of life are the major clinical symptoms. The seizures are pyridoxine responsive, and when the disorder is not treated in time developmental delay can occur.

Ornithine aminotransferase (OAT) deficiency or gyrate atrophy of the retina and choroidea is also a disorder of P5C synthesis; OAT is a pyridoxal phosphate-dependent enzyme and converts ornithine into P5C. A deficiency of OAT causes a progressive disorder of the retina and choroid resulting in myopia in childhood, impaired night vision in adolescence and young adulthood, and progressive retinopathy in adulthood ultimately leading to blindness. In rare cases newborns can present with hyperammonemia identical to a urea cycle defect (Cleary et al. 2005). Developmental outcomes are not systematically investigated in this disorder, but developmental delay and learning these disabilities were observed in OAT deficiency patients, in combination with a significant reduced creatine peak on MR spectroscopy (Valayannopoulos et al. 2009) (Fig. 25.3).

Asparagine Synthetase Deficiency

Asparagine synthetase catalyzes the transfer of ammonia from glutamine to aspartic acid to form asparagine. A deficiency causes an epileptic encephalopathy with intractable seizures, progressive (congenital) microcephaly, severe developmental disabilities, axial hypotonia, and spastic tetraplegia (Ruzzo et al. 2013). In many patients abnormal gyration patterns are seen on MRI with decreased cerebral volume, thin corpus callosum, and ventriculomegaly. In patients for whom follow-up was reported, it showed that, similar to PYCR2 deficiency, it is a slowly progressive disorder with progressive microcephaly and MRI abnormalities.

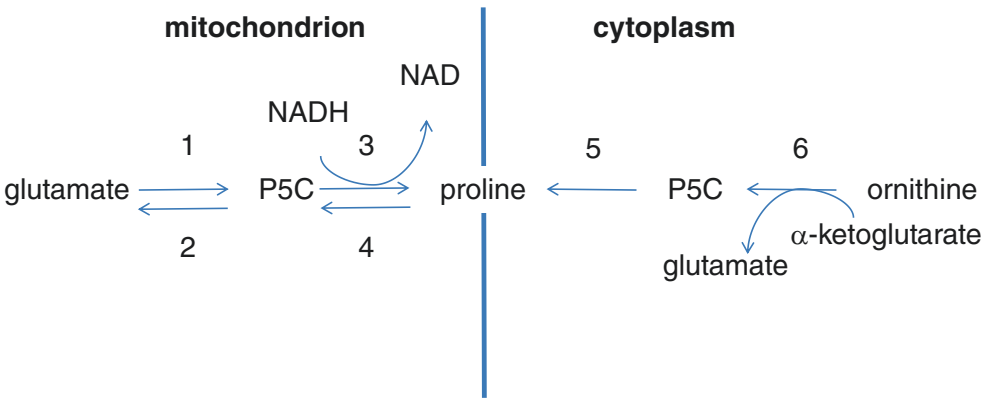

Fig. 25.3 Proline and P5C synthesis. (1) P5C synthase, (2) P5C dehydrogenase, (3) PYCR1 and PYCR2, (4) proline dehydrogenase, (5) PYCRL, (6) ornthine aminotransferase. *P5C* Δ^1-pyrroline-5-carboxylate, pyrroline-5-carboxylate reductase (PYCR, three isoforms 1, 2 and L)

Snyder-Robinson Syndrome (SRS)

This X-linked disorder is caused by a deficiency of spermine synthase, which converts spermidine into spermine, a primary synthesis route for polyamines that starts with L-ornithine (Li et al. 2017). Affected males present with profound mental retardation, hypotonia, asthenic body built, dysmorphic features, and seizures. In addition they have early onset osteoporosis starting in the first decade of life, leading to fractures in the absence of trauma. In rare cases the phenotype can be present in females as well.

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM
25.1	3-Phosphoglycerate dehydrogenase deficiency	Serine deficiency	3-PGDH	*PHGDH*	1p12	Phosphoglycerate dehydrogenase	606879, 256520
25.2	3-Phosphoserine aminotransferase deficiency	Serine deficiency	PSAT	*PSAT1*	9q21.2	Phosphoserine aminotransferase	172480, 616038

Diagnosis of Amino Acid Synthesis Disorders

In most of the amino acid synthesis disorders discussed here, molecular diagnostic techniques are preferred over biochemical testing. An exception to this are OAT deficiency, glutaminase deficiency, and hyperprolinemia type I and II where elevated concentrations of ornithine, glutamine, and proline are easily detected in plasma. In the other disorders, pitfalls in biochemical testing hamper the use of it, either because of preanalytical confounders (non-fasted plasma samples in serine deficiency or near-normal glutamine in milder glutamine synthetase deficiency), inconsistent findings in patients (P5CS deficiency and asparagine synthase), or the fact that no abnormalities can be detected at all in body fluids (PYCR1, PYCR2, and SRS). One must be aware of the fact that heterozygous mutations can cause a phenotype in these disorders either because of dominant negative effects on dimerization of protein complexes (*ALDH18A1*) or gain of function (*GLS*). Unfortunately the lack of easily available functional assays may cause difficulties in interpreting variants of unknown significance (VUS) in the genes involved.

Treatment

Of all the synthesis defects, serine deficiency appears most amendable for therapy (van der Crabben et al. 2013). Except for Neu-Laxova syndrome, therapy with L-serine has been successfully applied, and even in the severe infantile form seizures can be treated. However, to prevent psychomotor retardation, patients must be treated during pregnancy on within the first month of life (de Koning et al. 2004). In the other disorders, reports of treatment are anecdotal, but it is very likely that, for instance, in glutamine deficiency similar to serine deficiency, treatment with L-glutamine and nicotinamide must start early to treat seizures and prevent psychomotor retardation. In OAT deficiency treatment consists of

protein restriction, pyridoxine, and creatine monohydrate, the latter because there is evidence of low creatine on MRS (Valayannopoulos et al. 2009).

Of course in all disorders discussed, symptomatic treatment of associated findings is warranted, for instance, treatment of seizures or osteoporosis.

Follow-Up and Monitoring

Monitoring L-serine therapy in serine deficiency would require repeated lumbar punctures, but normalization of CSF serine occurs with the dosages recommended. Therefore, we would advise follow-up based on clinical response, for instance, on improvement of well-being and drop in seizure frequency, albeit that improvement in EEG patterns can take months. For glutamine deficiency clinical follow-up is recommended as well; in the case treated with high dosages of L-glutamine, therapy resulted in partial correction of CSF glutamine, but in a significant improvement of EEG abnormalities. Follow-up on clinical findings may be more important than monitoring correction of CSF deficiency of the amino acid (Häberle et al. 2012).

In OAT deficiency lowering ornithine concentrations delays the progression of the retinal abnormalities in most patients, and this can be done by arginine/protein restriction, but the diet is difficult to adhere to. Plasma values should be at least below 400–500 μmol/L (Kaiser-Kupfer et al. 2004). In a minority of patients, this can be achieved by pyridoxine therapy alone. Beware of the fact that long-term treatment with high-dose pyridoxine can cause polyneuropathy, and this should be monitored as well. It is unsure whether creatine therapy in this disorder does result in reduced risk for retinopathy but likely results in better brain and muscular function.

In all disorders discussed here, potential complications of the defects should be monitored at regular intervals during clinical follow-up.

Contents

Summary

Glycine is broken down by the glycine cleavage enzyme, which is composed of the P-protein, T-protein, H-protein, and L-protein. Its deficient activity causes accumulation of glycine in all tissues, including the brain, which defines nonketotic hyperglycinemia (NKH). It is caused by mutations in the genes *GLDC* encoding the P-protein and *AMT* encoding the T-protein. Children with the severe phenotype have two mutations without residual activity and present in the first days to weeks of life with transient apnea, coma, hypotonia, hiccups, burst-suppression pattern, and myoclonic epilepsy. Patients have very limited or no developmental progress and develop intractable multifocal epilepsy, axial hypotonia and peripheral spasticity, cortical blindness, and poor feeding. In childhood they can develop scoliosis, hip dysplasia, and poor airway maintenance resulting in pneumonia. Children with the attenuated form have at least one mutation with residual

enzyme activity. Many children also present in the neonatal period, but some present in infancy or later. Patients make variable developmental progress, have little or no spasticity, chorea, and pronounced hyperactivity, episodic lethargy, or ataxia. Patients have no seizures or seizures that are controlled with treatment. Infants with NKH have a diagnostic pattern of diffusion restriction in the posterior limb of the internal capsule, anterior brain stem tracts, posterior tegmental tracts, and cerebellar white matter. Hypoplastic corpus callosum is frequent. Specific treatment of NKH includes reduction of glycine with sodium benzoate and use of dextromethorphan to reduce neurotransmission at the NMDA receptor. This treatment improves developmental outcome when initiated early in attenuated NKH patients. In severe NKH, treatment can improve alertness and seizure control in patients without changing the lack of development.

The glycine transporter GLYT1 encoded by the gene *SLC6A9* provides uptake of glycine at the cell membrane in astrocytes. Patients with mutations in this gene present with prolonged apnea requiring ventilation or hypotonia developing into spasticity with axial hypotonia. Reported congenital anomalies include hydrops, polyhydramnios, and arthrogryposis. Patients also develop excessive startles and hyperekplexia. They have mildly elevated glycine in cerebrospinal fluid (CSF) but not in blood. There is no specific treatment.

Primary differential diagnosis for the disorders with elevated glycine in the CSF includes disorders of the cofactors pyridoxal-phosphate and lipoate, medication interference by valproate, and loss of the integrity of the blood brain barrier such as in hypoxic-ischemic injury.

Introduction

The primary enzyme in the catabolism of glycine is the glycine cleavage enzyme (GCE). The GCE is located in hepatocytes and in astrocytes and consists of four proteins (P, T, H, and L) and has two cofactors lipoate and pyridoxal phosphate.

Nonketotic Hyperglycinemia

Disorders caused by pathogenic mutations in the genes encoding for P-protein (*GLDC* gene) and for T-protein (*AMT* gene) cause nonketotic hyperglycinemia (NKH). This condition is phenotypically distinguished into the severe form and an attenuated form based on severity of outcome (Swanson et al. 2015; Hennermann et al. 2012). Patients with the severe form have two mutations without residual activity, whereas patients with the attenuated form have at least one mutation with some residual activity (Swanson et al. 2015).

Patients with the severe form present in the first month of life with neonatal epileptic encephalopathy. Patients can have hiccups in utero, and at birth, rare patients have club feet or cleft palate (Hennermann et al. 2012). In the first days of life, neonates develop a comatose episode with myoclonia, hiccups, and often a burst-suppression pattern on EEG. Up to 85% of severe patients have apnea requiring ventilation which spontaneously resolves by the end of the first month (Hennermann et al. 2012; Hoover-Fong et al. 2004). Over the next year, they lack any developmental progress and develop treatment-resistant epilepsy, progressive peripheral spasticity with axial hypotonia, cortical blindness, and poor swallowing requiring gastric tube feeding. Long-term complications include the development of scoliosis, hip dysplasia, and poor airway maintenance (Ramirez et al. 2012).

Most patients with the attenuated form present in the neonatal period essentially similar to the severe form at that age, but some patients may present later in life with developmental delays or epilepsy (Swanson et al. 2015; Hennermann et al. 2012; Hoover-Fong et al. 2004). Patients with the attenuated form are divided based on severity into poor, intermediate, and good outcome categories (Swanson et al. 2015). Patients with attenuated poor outcome still develop epilepsy which is usually treatable with antiepileptics, have moderate spasticity, and make some limited developmental progress. They usually only use sign language. Patients with the attenuated intermediate phenotype have a developmental quotient (DQ) of 20–50, often are very hyperactive, and can have choreatic movements, intermittent ataxia, and intermittent episodes of lethargy. If they have epilepsy, it is readily treatable. Receptive language is fair but expressive language is poor. Patients with the attenuated good outcome category make substantial developmental progress (DQ > 50). They tend to have pronounced hyperactivity, clumsy walk and movements, and some developmental delays but do not have epilepsy. They too can have intermittent episodes of lethargy.

On brain MRI, all NKH patients in the neonatal period and early infancy have a recognizable pattern of diffusion restriction of the posterior limb of the internal capsule, the corticospinal tract into the brain stem, the posterior tegmental tracts, and the cerebellar white matter (Stence et al. 2019) (Fig. 26.1). This evolves over time and is less recognizable in late infancy. The corpus callosum is thin and shortened and, in severe NKH, does not grow over time. In severe NKH, there is gradual development of atrophy. A few patients with severe NKH develop hydrocephalus often with a large retrocerebellar cystic area (Hoover-Fong et al. 2004; Van Hove et al. 2000).

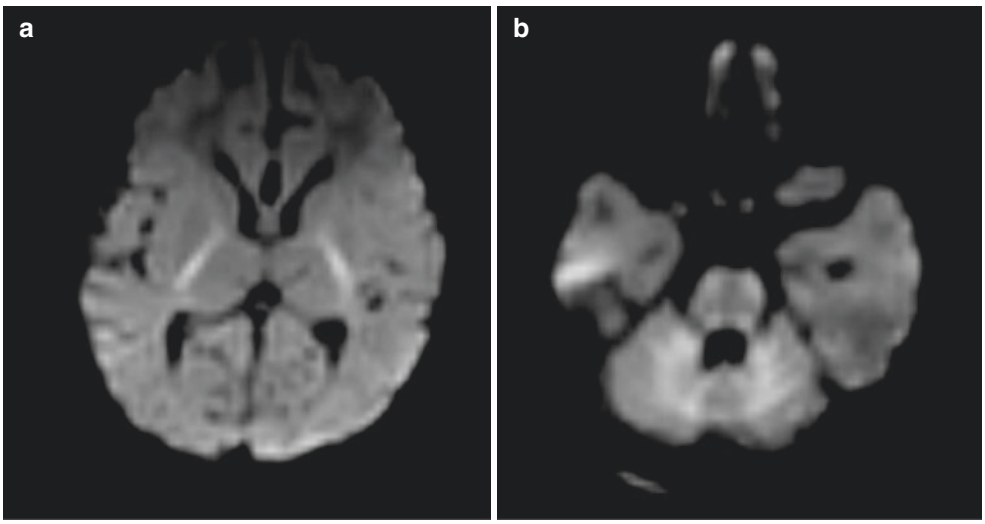

Fig. 26.1 Brain MRI of a neonate with nonketotic hyperglycinemia
Legend: Diffusion weighted images of a neonate with NKH showing diffusion restriction (**a**) at the level of the posterior limb of the internal capsule and (**b**) in the anterior part of the brain stem, the posterior tegmental tracts, and the white matter of the cerebellum. Reproduced with permission from GeneReviews®, University of Washington, Seattle (Van Hove et al. 2002)

Plasma glycine is often but not always elevated. CSF glycine is always elevated with the elevation related to outcome, as a high CSF glycine is predictive of severe NKH (Swanson et al. 2015). The ratio of CSF-plasma glycine is elevated, and a low ratio is predictive of attenuated NKH (Swanson et al. 2015). Mutations are identified either in the *GLDC* gene in 80% of cases or in the *AMT* gene in 20% of cases (Coughlin II et al. 2017). It is unclear if any rare cases of *GCSH* mutations exist. Exonic copy number variants are common in *GLDC*.

The primary differential diagnosis involves the disorders of the synthesis and metabolism of the co-factors pyridoxalphosphate (PLP) and lipoate (Coughlin II et al. 2017; Van Hove et al. 2002; Wilson et al. 2019). Particularly, some patients with lipoate deficiency have presented biochemically similarly to patients with nonketotic hyperglycinemia (Baker et al. 2014). Some patients with PLP disorders have presented symptomatically similar to nonketotic hyperglycinemia and can have elevated CSF glycine (Wilson et al. 2019). Some patients with perinatal hypoxic ischemic injury can present with a transient comatose episode with elevated CSF glycine likely due to blood-brain barrier dysfunction (Aburahma et al. 2011). This resolves over time resulting in normalization of the biochemistry and often symptoms, and was historically called transient nonketotic hyperglycinemia (Aburahma et al. 2011; Aliefendioğlu et al. 2003). None of these differential diagnostic conditions has the full typical pattern of diffusion restriction on brain MRI, which can rapidly guide to the correct diagnosis (Stence et al. 2019). A peak of increased glycine, more in severe than in attenuated NKH patients, is noticeable on brain magnetic resonance spectroscopy (MRS) best recognizable in intermediate or long echo times (Stence et al. 2019).

Glycine Transporter Defect (GLYT1, SLC6A9)

The glycine transporter GLYT1 is responsible for the transport of glycine into the astrocyte where it becomes accessible to the glycine cleavage enzyme. Its absence results in increased brain glycine (Kurolap et al. 2016).

Patients with the glycine transporter defect presented in the neonatal period (Kurolap et al. 2016; Alfadhel et al. 2016; Kurolap et al. 2017). Prenatal findings may include hydrops, polyhydramnios, and arthrogryposis (Kurolap et al. 2016; Alfadhel et al. 2016). In the neonatal period, they have severe hypotonia and poor breathing requiring prolonged ventilation, which they can only be weaned off after months. They can be encephalopathic and unresponsive. They have profound hypotonia and lack of almost all developmental progress. They have joint laxity or arthrogryposis, particularly club feet. They develop severe global developmental delays, axial hypotonia with peripheral spasticity, and contractures, some present since birth. They have sudden startle-like movements to any stimuli, but no seizures and are not accompanied by epileptic elements on EEG, and may represent hyperekplexia movements, which tends to resolve in late infancy.

They have normal levels of plasma glycine but mildly elevated levels of CSF glycine with an elevated CSF-plasma glycine ratio. Brain imaging can show ventriculomegaly, optic atrophy, thin or normal corpus callosum, and white matter abnormalities. Some have abnormal signal in the basal ganglia. A polyneuropathy and abnormal visual and auditory evoked potentials were reported. Many children have died in infancy (Kurolap et al. 2017).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene	Chromosomal location	Mode of inheritance	Affected protein	Disease OMIM#
26.1	Nonketotic hyperglycinemia	Severe nonketotic hyperglycinemia	NKH	*GLDC* *AMT* *GCSH*	9p24.1 3p21.31 16q23.2	AR	P-protein T-protein H-protein	605899
26.2	Nonketotic hyperglycinemia	Attenuated nonketotic hyperglycinemia	NKH	*GLDC* *AMT* *GCSH*	9p24.1 3p21.31 16q23.2	AR	P-protein T-protein H-protein	605899
26.3	Glycine transporter GLYT1 encephalopathy	Glycine encephalopathy with normal serum glycine	–	*SLC6A9*	1p34.1	AR	GLYT1-protein	617301

Subtypes

- Severe nonketotic hyperglycinemia
- Attenuated nonketotic hyperglycinemia
  - Attenuated poor nonketotic hyperglycinemia
  - Attenuated intermediate nonketotic hyperglycinemia
  - Attenuated good nonketotic hyperglycinemia

Metabolic Pathways

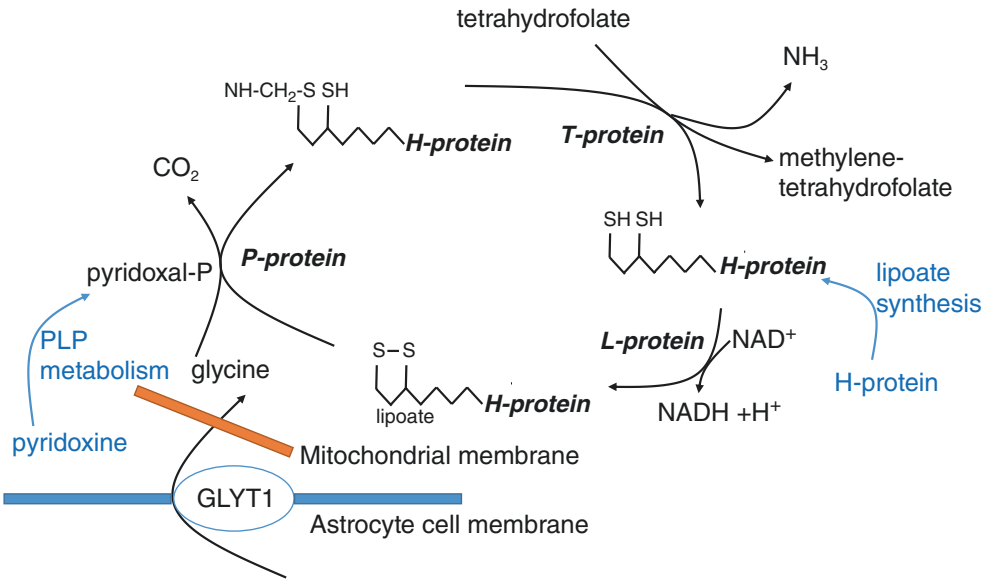

Fig. 26.2 Metabolic pathways of glycine metabolism
Legend: Glycine is metabolized by the P-protein with pyridoxal-phosphate as cofactor. The T-protein transfers the methyl group to tetrahydrofolate synthesizing methylene-tetrahydrofolate. The L-protein reoxidizes the lipoate group, which is carried by the H-protein. The lipoate cofactor is synthesized on the H-protein in a multistep process

Diagnostic Flowchart

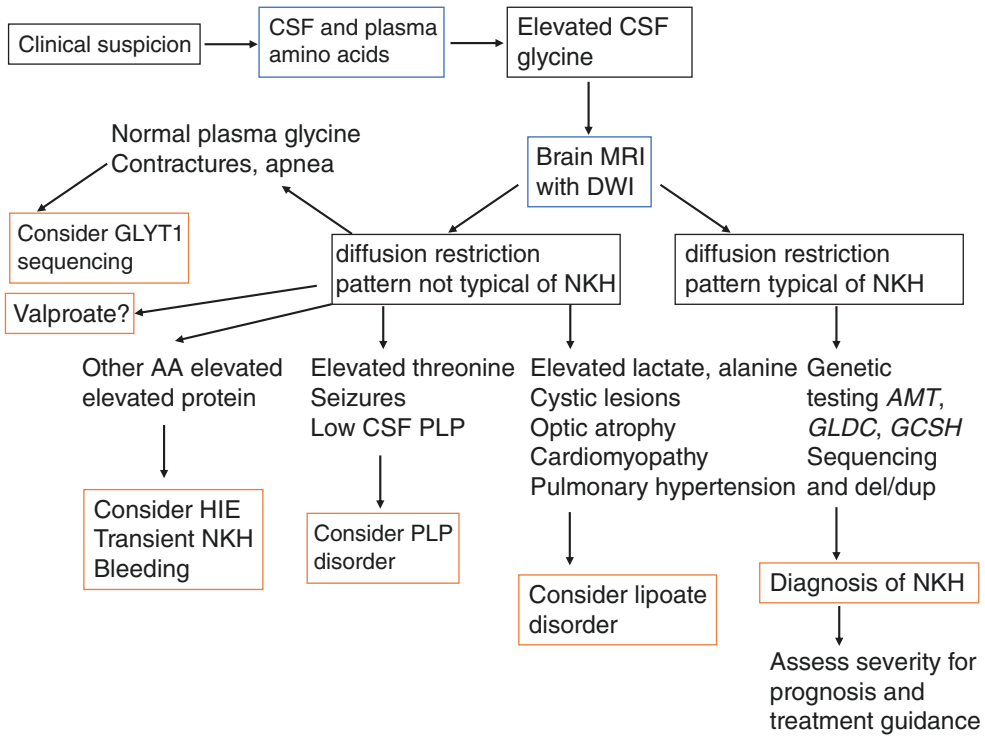

Fig. 26.3 Diagnostic flowchart for children <3 months of age Legend: Upon clinical suspicion, CSF amino acids are obtained. A brain magnetic resonance imaging (MRI) with diffusion weighted images (DWI) is obtained when elevated CSF glycine is found. If a pattern of diffusion restriction typical of nonketotic hyperglycinemia (NKH) is identified, then molecular testing for genes of NKH can provide a confirmed diagnosis. If the pattern is not present or is different, then alternative diagnoses should be considered, such as GLYT1 disorder, valproate use, hypoxic ischemic injury (HIE) with blood-brain barrier damage, a disorder of pyridoxal-phosphate (PLP), or a disorder or lipoate synthesis and metabolism

Reference Values

Parameter	Control values <6 months	>6 months
Plasma glycine in μM	125–450	125–350
CSF glycine in μM	3–20	3–12
CSF-plasma glycine ratio	<0.02	<0.02

Pathological Values

Parameter	Severe NKH	Attenuated NKH	GLYT1
Plasma glycine in μM	1133 (342–2363)	822 (342–1590)	228; 275
CSF glycine in μM	228 (40–510)	99 (41–230)	25 (21–31)
CSF-plasma glycine ratio	0.22 (0.09–0.45)	0.13 (0.04–0.22)	0.07; 0.08

Values from: Swanson et al. (2015), Kurolap et al. (2016), and Alfadhel et al. (2016)

Loading Tests

A glycine loading test shows higher glycine levels and lack of an expected rise in serine (von Wendt et al. 1978). A glycine breath test using ^{13}C-glycine shows lack of increase in $^{13}CO_2$ exhalation (Kure et al. 2006).

Specimen Collection

Plasma glycine: Obtain plasma glycine at least 3–4 h after a meal. It is elevated with the following: (1) valproate; (2) diet low in essential amino acids and increase in non-essential amino acids or kwashiorkor; (3) disorders of vitamin B6 pyridoxal phosphate including pyridoxine-dependent epilepsy due to mutations in *ALDH7A1*, pyridox(am)ine oxidase deficiency (*PNPO*), and pyridoxal binding protein PLPBP (*PROSC*); (4) severe liver failure, in particular with disseminated neonatal

herpes infection; (5) exogenous loading with large amounts of glycine (e.g., certain immunoglobulins in a glycine buffer); (6) disorders of lipoate synthesis; and (7) newborns identified on newborn screening with very elevated glycine levels who remain asymptomatic; the cause is currently unknown.

CSF glycine: CSF glycine must be obtained on a clean tap (Korman and Gutman 2002). We recommend measuring all amino acids. The CSF glycine is increased in the following: (1) blood contamination or serum contamination (including at the level of the puncture or from intracranial bleeding)—look for elevated CSF protein and for elevation of CSF branched chain amino acids as an indicator; (2) use of valproate and to a small extent certain other anticonvulsants such as vigabatrin; (3) breakthrough of the blood-brain barrier, e.g., after hypoxic-ischemic injury (look for elevated branched chain amino acids); (4) mild elevation in certain neurological conditions such as vanishing white matter disease; mild elevations in disorders affecting the formation of pyridoxal-phosphate (pyridoxine-dependent epilepsy ALDH7A1, pyridox(am)ine oxidase deficiency (*PNPO*), and pyridoxal binding protein PLPBP (*PROSC*)); and (5) disorders affecting lipoate synthesis.

CSF-plasma glycine ratio: This ratio is calculated from a simultaneously obtained plasma and CSF glycine value. The ratio is increased in the same circumstances where CSF glycine is elevated.

Prenatal Diagnosis

Prenatal diagnosis is almost always done by molecular analysis. This is possible in chorionic villus biopsy or amniocentesis. Preimplantation genetic diagnosis has also been successfully accomplished. For molecular diagnosis, the pathogenic variants in the family should be known, which is best performed prior to pregnancy. When only a single pathogenic variant is known, then intragenic linkage using intragenic single nucleotide polymorphisms can be done.

If the mutation is not known, then enzyme assays on chorionic villus biopsy are possible. A false-negative rate of at least 1% can occur, more commonly so in attenuated NKH or in NKH due to defects in the T-protein (Hennermann et al. 2012; Applegarth et al. 2000).

DNA Testing Table and Sample Requirements

DNA testing can be done on blood or on any tissue.

Testing in *GLDC* requires sequencing, which can be either Sanger sequencing or next-generation sequencing. Copy number alternations occur in 20% of the alleles. These can be identified by gene-targeted microarray, by multiplex ligation-dependent probe amplification (MLPA), by quantitative PCR, or in some cases by next-generation sequencing at sufficient read depth. Rare, very long deletions have been identified by fluorescent in situ hybridization (FISH) or genome-wide microarray.

Testing in *AMT* requires sequencing, which can be either Sanger sequencing or next-generation sequencing. Care must be taken to include the 5′ UTR region as pathogenic mutations in this region have been reported (Coughlin II et al. 2017). Thus far, intragenic copy number alterations in this gene have not yet been reported, but labs often test for them using gene-targeted microarray or in some cases next-generation sequencing at sufficient read depth.

Testing in *GCSH* requires sequencing, which can be either Sanger sequencing or next-generation sequencing. No proven pathogenic mutation in *GCSH* has been reported. Large deletions encompassing the entire GCSH gene have been identified by fluorescent in situ hybridization (FISH) or genome-wide microarray.

Testing in *SLC6A9* requires sequencing, which can be either Sanger sequencing or next-generation sequencing. Limited information about the span of mutations in this condition has been reported thus far.

Treatment Summary

Current treatment of nonketotic hyperglycinemia is based on decreasing glycine levels and by blocking the effect of the stimulation of glycine on the NMDA receptor (Van Hove et al. 2002).

Benzoate treatment is used to decrease plasma glycine levels. Benzoate is activated to benzoyl-Coenzyme A, which then conjugates with glycine to hippurate using glycine-N-acyltransferase, an enzyme only present in the liver and kidney, and hippurate is then excreted in urine. The dose of benzoate is increased and individually tailored to such an extent that glycine levels remain in a targeted treatment range of 120 to 300 μmol/L when obtained 1–2 h after a dose of benzoate. In infancy, very regular monitoring of plasma glycine levels is necessary for a safe and effective treatment. Patients with severe NKH require a higher dose (500–750 mg/kg/day) than patients with attenuated NKH (250–550 mg/kg/day) (Van Hove et al. 2005). Medication dosing should be divided in no less than three samples per day, more in infants, starting with six doses in neonates. Gastric irritation is common, and antacids, preferably proton pump inhibitors, are indicated (Hennermann et al. 2012). Some infants can have low carnitine levels which may require substitution (Van Hove et al. 1995). Overdosing of benzoate begins with nausea, vomiting, and hypocalcemia,

but if severe can be very toxic and lethal. The contribution of dietary glycine to the overall metabolism of glycine is limited (Van Hove et al. 2005). Some reduction in glycine levels can be achieved through a glycine-restricted diet, but this is usually reserved for severe NKH already treated with high doses of benzoate. Dietary glycine restriction alone has no effect. A ketogenic diet, often initiated for anticonvulsant properties, strongly reduces glycine levels, and benzoate dosing should be appropriately reduced to avoid toxicity (Cusmaiu et al. 2012).

Blocking overstimulation of the NMDA receptor has been done with partial antagonists dextromethorphan or ketamine. High doses of dextromethorphan are used starting at 10 mg/kg/day in an infant, 5 mg/kg/day in a child, and 3 mg/kg/day in an adolescent or adult. Dosing is divided in three or four doses, but for the slow release version, twice daily dosing is possible. Pharmacogenomic differences in the metabolism of dextromethorphan at CYP2D6 and CYP3A4 should be taken into account, as for poor metabolizers the dose should be sharply reduced.

The clinical effect of the combination treatment of lowering plasma glycine levels with benzoate and of dextromethorphan has resulted in improvement in attenuated NKH in cognitive outcome and epilepsy when initiated in very early infancy (Bjoraker et al. 2016). In severe NKH, it results in improvements in alertness, breathing, and seizure control but does not prevent lack of development, therapy-resistant epilepsy, or spasticity (Hennermann et al. 2012). The role of dextromethorphan is very limited in severe NKH, whereas in some children with attenuated NKH, it can improve chorea and attentiveness (Van Hove et al. 2002). Benzoate treatment in attenuated NKH prevents episodic neurological depression. Up to 80% of neonatal presenting NKH patients have transient apnea, and the utility of intensive care treatment should be reviewed. Some families have elected to withdraw intensive care support during this time (Boneh et al. 2008). After resumption of breathing, some untreated infants may die in the next 2 years, but many survive long term (Hoover-Fong et al. 2004).

Seizure control is difficult in severe NKH. First-line treatment for neonates with myoclonic epilepsy treatment are benzodiazepine class medications in particular clobazam, with phenobarbital second. Later seizures respond variably to medications. Valproate, which inhibits the glycine cleavage enzyme, and vigabatrin should be avoided as severe neurological regressions have been reported. Ketogenic diet has variable success on infantile spasms but rarely controls the hypsarrhythmic background (Cusmaiu et al. 2012). Older patients with difficult to control seizures have responded to vagal nerve stimulator.

Symptomatic treatment in severe NKH includes placement of a gastric tube to enable feeding, monitoring, and as needed surgical treatment for scoliosis and hip dislocation (Hennermann et al. 2012; Hoover-Fong et al. 2004; Ramirez et al. 2012). Maintaining good airway management is essential for older children with severe NKH.

Treatment of GLYT1 deficiency is symptomatic. Treatment with sodium benzoate and dextromethorphan has no effect. Ventilatory support may need to be continued for several months, but most infants can eventually be weaned. Hyperekplexia responds to benzodiazepines. Tone management is important and physical therapy is usually indicated, and most children require gastrostomy feeding (Kurolap et al. 2017; Alfallaj and Alfadhel 2019).

Experimental Treatment

Treatment with increased co-factors can sometimes improve activity. Treatment of patients with missense mutations in GLDC have occasionally responded to treatment with pyridoxal phosphate with increased cognitive abilities. However, in most no effect is seen, and occasional worsening of chorea and behavior is known. Treatment of patients with missense mutations in AMT has occasionally appeared to improve to treatment with folinic acid.

Follow-Up and Monitoring

It is essential that patients treated with benzoate have regular plasma glycine levels monitored, and medication dosage should be adjusted frequently in infancy. Glycine levels should be obtained 1–2 h after a dose of benzoate. Occasional monitoring of carnitine levels is appropriate in benzoate-treated infants. The changing epileptic propensity in infancy requires frequent neurological and, as indicated, EEG monitoring. Older children with severe NKH should be monitored for orthopedic problems and for airway management.

Contents

Summary

Iron-sulfur (Fe-S) clusters are one of the most ancient, ubiquitous, and versatile classes of metal cofactors found in nature. In contrast to its simple structure, the biogenesis of Fe-S clusters is an extremely complex process. It involves a large number of proteins necessary for assembly, maturation, and delivery of Fe-S to their target proteins, including subunits of the mitochondrial respiratory chain complexes I, II, and III, aconitase, heme biosynthesis, and lipoic acid synthase (LIAS). Lipoic acid (LA) is an essential cofactor required for the activity of five multienzyme complexes (the 2-oxoacid dehydrogenase complexes and the glycine cleavage system) that play a central role in the mitochondrial energy metabolism. Four well-defined clinical entities, Friedreich ataxia, myopathy with lactic acidosis and exercise intolerance (ISCU), X-linked sideroblastic anemia with ataxia (ABCB7), and sideroblastic anemia associated with particular mutations in GLRX5, were the first-described diseases related to Fe-S cluster biosynthesis or transport defects. However, the progress in the knowledge of these diseases started when two parallel and independent studies identified mutations in the genes encoding for the Fe-S cluster proteins NFU1 and BOLA3, in patients with a fatal mitochondrial encephalopathy, lactic acidemia, hyperglycinemia, and deficiencies in the activity of LA-dependent enzymes. Later on, new diseases with similar clinical and biochemical characteristics were described. LA supplementation has been speculated as a potential treatment for patients with lipoic acid deficiency, but eukaryotic cells cannot use exogenously supplied LA. Therefore, for the moment, no specific treatment is available. This chapter focuses on the diagnosis and clinical description of 17 diseases due to lipoic acid and iron sulfur cluster biogenesis defects.

Introduction

Iron-sulfur (Fe-S) clusters are one of the most ancient, ubiquitous, and versatile classes of metal cofactors found in nature. Proteins that contain Fe-S clusters constitute one of the largest protein families that are localized within mitochondria, cytosol, and nucleus (Stehling et al. 2014). The biogenesis of Fe-S clusters is performed by two main protein machineries, the mitochondrial iron-sulfur cluster (ISC) assembly system and the cytosolic iron-sulfur protein assembly (CIA) machinery. The most common stoichiometric species of Fe-S include [2Fe-2S], [3Fe-4S], and [4Fe-4S] (Lill et al. 2012). The biogenesis is Fe-S is a complex process and involves a large number of proteins necessary for assembly, maturation, and delivery of Fe-S clusters to their target proteins, including subunits of the mitochondrial respiratory chain; complexes I,II, and III; aconitase; heme biosynthesis; and lipoic acid synthase (Stehling et al. 2014). As indicated in Fig. 27.1, de novo synthesis of [2Fe-2S] cluster is accomplished on the scaffold protein, ISCU. Ferrous iron is imported into the mitochondria through the MFRN1 transporter and with the participation of FXN is delivered to ISCU. The sulfur required for Fe-S synthesis is provided by the conversion of a cysteine to alanine, a reaction catalyzed by the NFS1-ISD11 desulfurase complex. Then, the coordinated action of FDX1, FDX2, and FDXR allows the final assembly of the [2Fe-2S] cluster on the ISCU scaffold protein. After that, the [2Fe-2S] cluster is released from the scaffold protein by the action of a chaperone system (HSCB, GRPEL1, HSPA9) and GLXR5 protein. On the other hand, the [2Fe-2S] cluster can be directly used for the assembly of [2Fe–2S] proteins (such as complex III subunits), or exported to the cytosol through the ABCB7 transporter to take part in the CIA machinery, or delivered to the IBA57-ISCA1-ISCA2 complex for maturation to [4Fe–4S] clusters. The mature [4Fe–4S] clusters are specifically delivered to target proteins by the action of late-acting factors, such as NFU1 and BOLA3. These proteins are required for the proper assembly of mitochondrial respiratory chain complexes I and II as well as for lipoic acid synthase (LIAS) activity, the enzyme responsible of lipoic acid (LA) synthesis. LA is an essential cofactor required for the activity of five multienzymatic complexes that play a central role in the mitochondrial energy metabolism: the 2-oxoacid dehydrogenase complexes (pyruvate dehydrogenase, 2-ketoglutarate dehydrogenase, 2-oxoadipate dehydrogenase, and branched-chain ketoacid dehydrogenase) and the glycine cleavage system (GCS). The activity of these enzymes depends exclusively on de novo intramitochondrial LA synthesis, which requires the appropriate function of LIAS, LIPT1, and LIPT2. In addition, the mitochondrial fatty acid synthesis (mtFASII) and the biogenesis of iron-sulfur (Fe-S) clusters are also essential for LA synthesis (Tort et al. 2016). Therefore, it is not surprising that mutations in genes involved in LA biosynthesis could potentially lead to multiple and severe defects of the mitochondrial energy metabolism.

Nomenclature

No.	Disease name	Alternative disease name	Disease abbreviation	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	Disease OMIM
27.1	Lipoyltransferase 2 deficiency	Neonatal severe encephalopathy with lactic acidosis and brain abnormalities	NELABA	*LIPT2*	11q13.4	AR	Lipoyl(octanoyl)transferase 2 (LIPT2)	617668

27.17	HSPA9 deficiency	Sideroblastic anemia type 4;	SIDBA4	*HSPA9*	5q31.2	AR	Heat shock 70 kDa protein 9 (Mortalin) (HSPA9)	182170
27.17	HSPA9 deficiency	Epiphyseal, vertebral, ear, nose, plus associated malformations (EVEN-plus) syndrome	EVPLS	*HSPA9*	5q31.2	AR	Heat shock 70 kDa protein 9 (Mortalin) (HSPA9)	616854

Metabolic Pathway

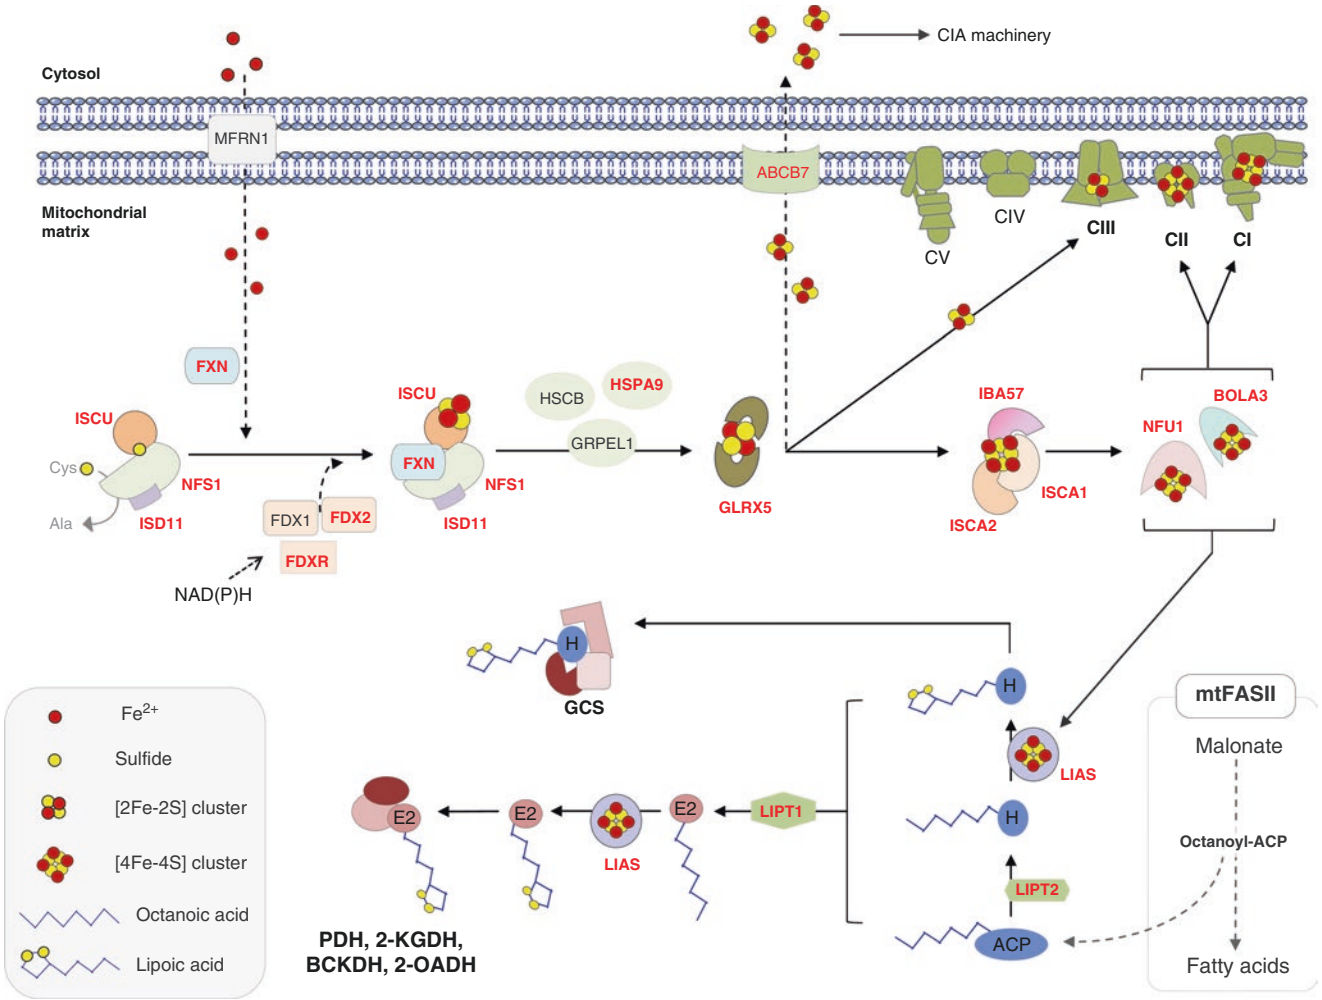

Fig. 27.1 Fe-S Clusters and Lipoic Acid Synthesis Pathways
The synthesis of Fe-S is orchestrated by a complex molecular machinery and consists of three main steps: (1) iron import into the mitochondria and assembly of the [2Fe–2S] clusters on the ISCU scaffold protein, (2) maturation of the [2Fe–2S] clusters, and (3) delivery of the [2Fe–2S] and [4Fe–4S] clusters to their target proteins, by the action of late-acting factors. During this process Fe-S clusters can also be specifically exported to the cytosol to be incorporated to the cytosolic and nuclear proteins, through CIA machinery. Fe-S clusters are essential for the activity of a wide variety of enzymes, including several subunits of the mitochondrial respiratory chain complexes I, II, and III and also for other processes such as LA synthesis, a reaction catalyzed by LIAS. LA is synthetized in a multistep process that, in addition to Fe-S cluster biogenesis, requires the proper function of the mtFASII, a complex biochemical pathway that synthesizes saturated fatty acids from mevalonate. Octanoic acid bound to ACP is transferred to the H protein of the GCS by the action LIPT2. The octanoylated H protein is the substrate for the insertion of two sulfur atoms at C-6 and C-8 positions by LIAS. LIPT1 is responsible for the octanoylation and the subsequent lipoylation of the E2 subunits of the 2-oxoacid dehydrogenase complexes (PDH, 2-KGDH, BCKDH, and 2-OADH)
Fe-S cluster and lipoic acid metabolism enzymes associated with human disease are highlighted in red color
CIA, cytosolic iron-sulfur cluster assembly; CI-V, mitochondrial respiratory chain complexes I–V; mtFASII, mitochondrial fatty acid synthesis pathway; ACP, acyl-carrier protein; LIAS, lipoic acid synthase; LIPT1, lipoyltransferase 1; LIPT2, lipoyl(octanoyl) transferase 2; PDH, pyruvate dehydrogenase; BCKDH, branched-chain ketoacid dehydrogenase; 2-KGDH, 2-ketoglutarate dehydrogenase; 2-OADH, 2-oxoadipate dehydrogenase; GCS, glycine cleavage system

Four well-defined clinical entities, Friedreich ataxia (FXN) (Table 27.16), myopathy with lactic acidosis and exercise intolerance (ISCU) (Table 27.10), X-linked sideroblastic anemia with ataxia (ABCB7) (Table 27.11), and sideroblastic anemia associated with particular mutations in GLRX5 (Table 27.6), were the first-described diseases related to Fe-S cluster biosynthesis or transport defects. In addition, patients with mutations in HSPA9 also presenting two well-defined phenotypes consisting in sideroblastic anemia (Schmitz-Abe et al. 2015) or EVEN-plus syndrome (Royer-Bertrand et al. 2015) (Table 27.17) were described later on. In these cases diagnosis goes directly from the clinical suspicion to molecular studies.

The progress in the knowledge of these diseases started in 2011 when two parallel and independent studies identified mutations in the genes encoding for the Fe-S cluster proteins NFU1 and BOLA3 (Tables 27.4 and 27.5) in patients with a fatal mitochondrial encephalopathy with lactic acidosis, hyperglycinemia, and deficient activities of LA-dependent enzymes (Navarro-Sastre et al. 2011; Cameron et al. 2011).

Later on, six new diseases, LIPT2, LIAS (Tables 27.1 and 27.2), GLRX5, IBA57, ISCA1, and ISCA2 (Tables 27.6, 27.7, 27.8, and 27.9), with very close clinical and biochemical phenotype to NFU1 and BOLA3 were described. It is important to remark that patients with mutations in GLRX5 can present two different phenotypes: the abovementioned sideroblastic anemia into adulthood or progressive spasticity and MRI abnormalities consistent with leukodystrophy in childhood (Table 27.6). These two phenotypes are mutation dependent. In fact, it has been demonstrated that GLRX5 protein is multifunctional and defects of the different amino acids of the protein will lead to distinct effects downstream Fe-S biosynthesis (Baker et al. 2014; Lui et al. 2016).

Neonatal encephalopathy with lactic acidosis and normal glycine was observed in a patient with mutation in *LIPT1* (Table 27.3) (Tort et al. 2014). This could be explained by the fact that LIPT1 is required for lipoylation, and subsequent activation, of the 2-oxoacid dehydrogenases but is not involved in the regulation of the GCS. On the other hand, other diseases, ISCU (Table 27.10) FDX2 (Table 27.12), ISD11, and NFS1 (Tables 27.14 and 27.15), presenting also with lactic acidosis but normal glycine completed the spectrum of mitochondrial encephalopathies associated with LA and Fe-S cluster disorders.

It is interesting that patients carrying mutations in *ISCU* and *FDX2* had a similar clinical phenotype showing late-onset presentation, even into adulthood, with myopathy, rhabdomyolysis, and myoglobinuria. In addition, the recent report of patients with normal lactate, hearing loss, and visual impairment in childhood, associated with *FDXR* mutations (Table 27.13) highlight the wide clinical and biochemical heterogeneity of mitochondrial disorders related to Fe-S metabolism (Peng et al., 2017; Paul et al. 2017; Slone et al. 2018).

To summarize, the clinical suspicion is always the first step for the diagnosis. As mentioned above, in the well-defined clinical syndromes, the diagnosis goes from the clinical suspicion to molecular studies, but for other diseases the analysis of both LA- and Fe-S cluster-dependent pathways is very useful to direct the defect. With few exceptions, high lactate is a common finding of these diseases (Figs. 27.2 and 27.3). Glycine elevation, due to the defective lipoylation of the H-protein of GCS, is observed in all patients with defects in LA synthesis (LIAS, LIPT2, NFU1, BOLA3, IBA57, GLRX5, and ISCA2). In contrast, glycine levels remained unaltered in individuals with mutations in *LIPT1*, *FDX1L*, *LYRM4* (ISD11 protein), *FDXR*, and *NFS1*. On the other hand, analysis of LA levels is also a useful parameter. This analysis is performed using a specific antibody that recognizes the lipoylated forms of the E2 subunits of 2-oxoacid dehydrogenase complexes as well as the lipoylated H-protein of the GCS. This approach is

mainly used as a research resource. Nevertheless, the fact that this antibody does not react against non-lipoylated proteins provides an efficient and cost-effective tool to identify lipoylation defects. Another useful parameter is the measurement of the respiratory chain activities, which are frequently altered in the patients with defects in biosynthesis, maturation, and delivery of Fe-S clusters but are unaltered in other defects (Figs. 27.2 and 27.3) (Tort et al. 2016; Mayr et al. 2014).

The *inheritance* of these diseases is autosomal recessive, except for ABCB7 that is X-linked and ISCU that can be autosomal recessive or dominant (Olsson et al. 2008; Mochel et al. 2008; Legati et al. 2017).

Concerning *frequency*, apart from the high number of reported patients with Friedreich ataxia, the first-described Fe-S cluster disorder (Campuzano et al. 1996), the most frequently described disease is NFU1, with more than 70 reported patients. It is remarkable that 27 patients with the recently described FDXR deficiency have already been reported (Peng et al., 2017; Paul et al. 2017; Slone et al. 2018).

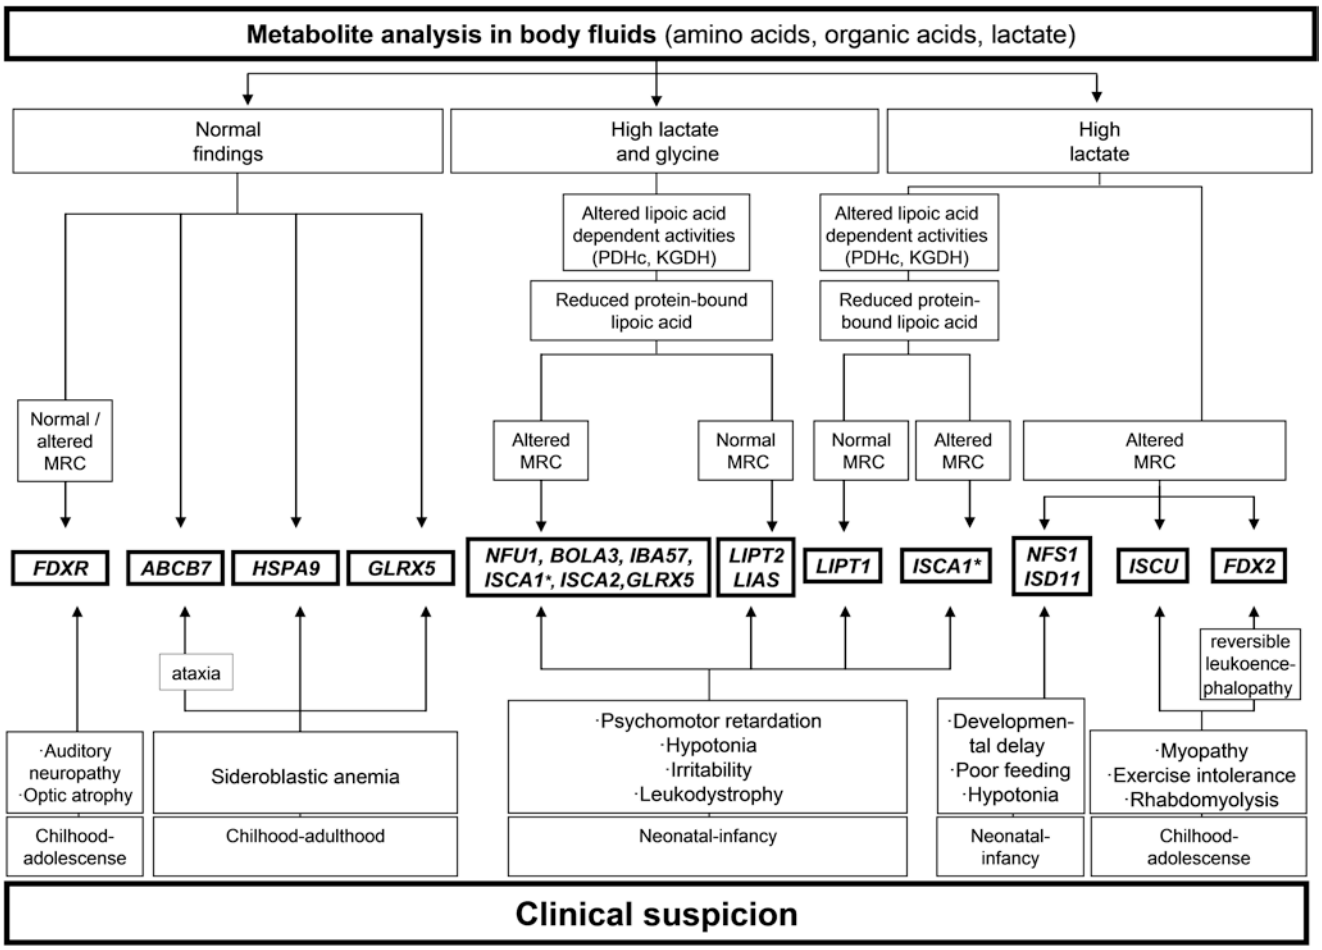
Diagnostic Flowchart



* Glycine elevation has not been documented in ISCA1 patients. ISCA1 is involved in a protein complex together with IBA57 and ISCA2, both deficiencies presenting with hyperglycinemia. Therefore, hyperglycinemia can not be excluded in this disease.

Fig. 27.2 Diagnostic flowchart

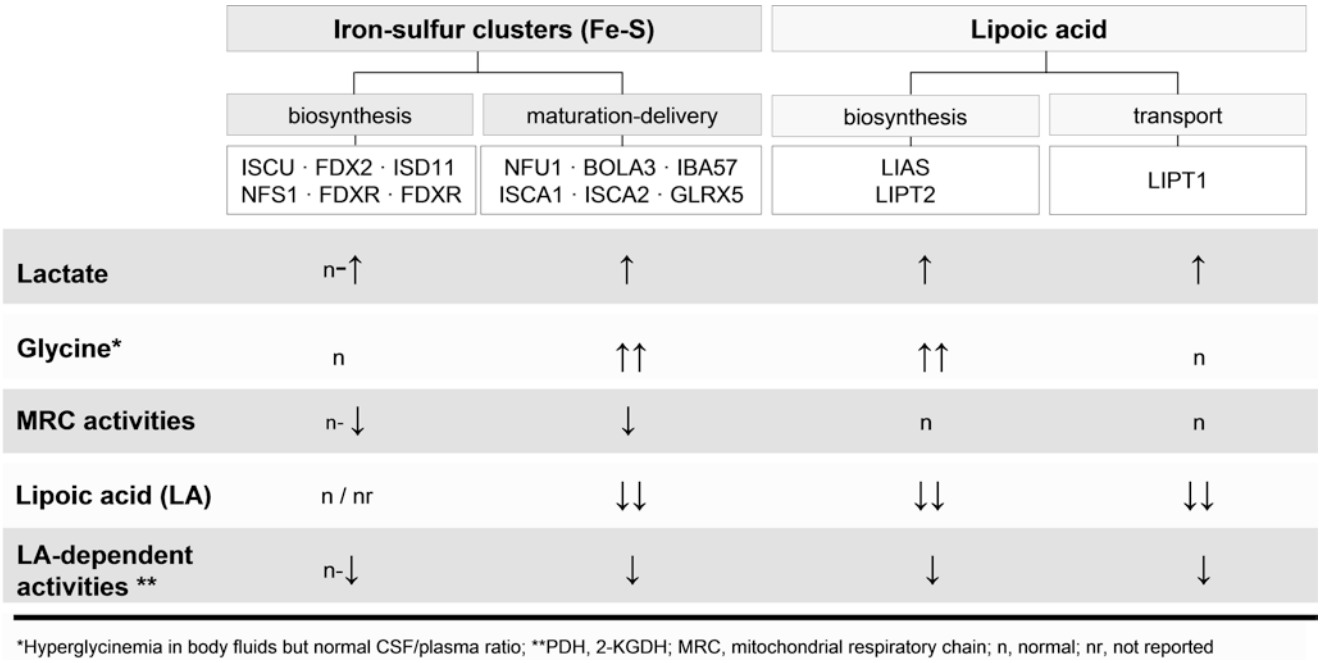


Fig. 27.3 Biochemical characteristics of lipoic acid and Fe-S protein disorders

Genetic Diagnosis

To reach the genetic diagnosis, the use of whole exome or targeted exome sequencing is strongly recommended. In this context, accurate clinical and biochemical characterization of patients will be determinant for the interpretation of genetic data and to narrow down the potential disease-causing mutations identified in each case. Therefore, this combined strategy is a good approach to reach a final diagnosis.

Treatment

LA supplementation has been speculated as a potential treatment for patients with LA deficiency, but eukaryotic cells cannot use exogenously supplied LA. In fact it has been demonstrated that endogenous production of LA was essential for mouse development as LIAS knock-out mice died during early embryonic development and supplementation with LA to the heterozygous mothers during pregnancy did not revert the prenatal death of LIAS knock-out mice (Yi and Maeda 2005). Therefore, at present, no specific treatment for these patients is available.

Specimen Collection

Enzymatic activities		
	Method	Sample
PDH	$^{14}CO2$ production from [1-^{14}C]-labeled pyruvate after activation with Ca^{++} and Mg^{++} and addition of carnitine and cytochrome C	Skin fibroblasts, muscle biopsy
MRC	Spectrophotometric determinations or BN-PAGE (in gel activity)	Skin fibroblasts, muscle biopsy
Protein-bound lipoic acid[a]	Western blot (SDS-PAGE)	Skin fibroblasts, muscle biopsy, liver necropsy
	Immunofluorescence	Skin fibroblasts
Genetic analysis		
	Method	**Sample**
Identification of disease-causing mutations	Whole exome sequencing/ targeted exome sequencing	Genomic DNA

PDH Pyruvate dehydrogenase, *MRC* Mitochondrial respiratory chain

Disorders of Vitamins, Cofactors, Metals and Minerals

Disorders of Cobalamin Metabolism

28

Matthias R. Baumgartner and D. Sean Froese

Contents

Summary

Vitamin B_{12} (Cbl) is needed for just two metabolic reactions in man, the methylation of homocysteine to methionine (cofactor methyl-Cbl) and the conversion of methylmalonyl-CoA to succinyl-CoA (cofactor adenosyl-Cbl). A complex sequence of processes is required to convert dietary Cbl to its cofactors and to correctly deliver them to the target enzymes. A wide range of acquired or hereditary disorders of absorption, transport and intracellular processing of Cbl are known, resulting in combined methylmalonic aciduria and homocystinuria or each in isolation. Seventeen distinct genetic disorders have been identified involving transcription factors, carrier proteins, receptors, membrane proteins, molecular chaperones and enzymes, and the genes have been characterised for each of these, although the exact function of some of the proteins remains to be elucidated. Main clinical hallmarks of these disorders are haematological and neurological disease of varying severity. Diagnosis centres on measurement of the two precursors of the Cbl enzymes, methylmalonic acid and homocysteine, together with

measurements of other parameters such as total vitamin B_{12}, holotranscobalamin, 3-hydroxypropionic acid and methylcitric acid, C3-acylcarnitine and methionine. Absorption and transport defects respond well to treatment with Cbl. Intracellular processing defects also respond to Cbl, but biochemical and clinical abnormalities may not fully resolve, and long-term outcome can be poor. Prenatal diagnosis can be reliably performed in those disorders where this is indicated.

Introduction

Vitamin B_{12} (cobalamin, Cbl) is a complex molecule with a cobalt-containing corrin ring. It is derived almost exclusively from animal sources, secondary to production by microorganisms. Cbl is needed for just two metabolic reactions in man, methylation of homocysteine to methionine and conversion of methylmalonyl-CoA to succinyl-CoA (Fig. 28.1). Deficiency of Cbl, inability to absorb Cbl normally or inability to process Cbl to its two active cofactors can result in elevated circulating and urinary levels of the precursors methylmalonic acid (MMA) and homocysteine which are useful diagnostic markers for Cbl disorders.

In children, causes of Cbl deficiency fall into three categories: (1) dietary deficiency, (2) abnormal absorption and transport and inborn errors of cellular uptake and (3) inborn errors of intracellular processing. While the first category is an acquired form of Cbl deficiency, the two latter categories represent mostly inherited disorders (Watkins and Rosenblatt 2017).

Abnormal Cbl absorption and transport may result from hereditary causes such as absent or abnormal intrinsic factor (IF), defective ileal receptors or deficient transport into cells or from a wide range of nonhereditary absorption disorders such as surgery involving the stomach or terminal ileum, decreased Cbl release from food protein, competi-

tion for Cbl in the ileum or loss of the ileal absorptive surface. Cbl malabsorption (or juvenile Cbl deficiency, JCD) is a potentially fatal condition that is mostly hereditary in nature in children since the classic adult form of autoimmune pernicious anaemia is rare in early life. Two main forms of inherited JCD exist: intrinsic factor deficiency (IFD) and Imerslund-Najman-Gräsbeck syndrome (IGS), also known as juvenile/hereditary megaloblastic anaemia, MGA1 or juvenile pernicious anaemia with proteinuria. IFD is caused by mutations in the gastric IF gene (*GIF*, (Tanner et al. 2005)). In IGS, deleterious mutations in the genes encoding the ileal Cbl receptor cubilin (*CUBN*, (Aminoff et al. 1999)) or its facilitator amnionless (*AMN*, (Tanner et al. 2003)) cause malabsorption of Cbl. Both proteins are involved in intestinal absorption and renal tubular reabsorption and form the heterodimer named CUBAM that accomplishes the internalisation of the IF-Cbl complex (Fyfe et al. 2004).

Conversion of Cbl to its active cofactors, methylcobalamin (MeCbl) and adenosylcobalamin (AdoCbl), requires a series of biochemical modifications that have been classified as Cbl complementation groups A–J, each of which represents a distinct autosomal recessive genetic disease (Fig. 28.1).

Patients belonging to the complementation groups *cblF*, *cblJ*, *cblC* and one form of *cblD* have combined deficiencies of AdoCbl and MeCbl synthesis and are thus characterised by both methylmalonic aciduria (MMAuria) and elevated total homocysteine (tHcy) which is often associated with low plasma methionine and *S*-adenosylmethionine (SAM). The *cblF* defect is a rare disorder described in less than 20 unrelated families. The gene responsible for the defect (*LMBRD1*) encodes a lysosomal membrane protein that is thought to act as an accessory protein for lysosomal export of Cbl (Rutsch et al. 2009; Fettelschoss et al. 2017). The *cblJ* defect has been described in only six unrelated patients with a biochemical phenotype similar to *cblF*. The gene responsible for the defect, *ABCD4*, encodes a presumed ABC transporter that interacts with and is targeted to the lysosome by the cblF protein (Fettelschoss et al. 2017; Coelho et al. 2012). *cblC* disease is the most frequent inborn error of Cbl metabolism with over 500 patients known in the Western world, a number that may be doubled when accounting for recent publications from mainland China (Liu et al. 2018; Hu et al. 2018). The gene responsible for *cblC*, designated *MMACHC* for MMAuria *cblC* type with homocystinuria, is thought to be a porter that carries out targeted delivery of Cbl from the lysosome to other Cbl-related proteins but also functions as a decyanase and dealkylase (Lerner-Ellis et al. 2006; Hannibal et al. 2009; Kim et al. 2008). Loss of expression of *MMACHC* due to mutation of the gene *PRDX1*, which results in epigenetic silencing of *MMACHC*, has recently been described in the heterozygous state combined with genetic *MMACHC* mutation in three patients with *cblC* disease (Gueant et al. 2018). Alternatively, loss of *MMACHC* expression due to mutation of the transcriptional co-regulator *HCFC1* (sometimes termed *cblX* disease) (Yu et al. 2013) or its interacting transcription factors *THAP11* (also called Ronin) (Quintana et al. 2017) and *ZNF143* (Pupavac et al. 2016) has been described in 19, 1 and 1 patient, respectively. The *cblD* defect has only recently been elucidated, over 30 years after the first description of the complementation group in two siblings. Approximately 20 patients are known worldwide (Coelho et al. 2008; Parini et al. 2013; Stucki et al. 2012). The *cblD* defect is remarkable in that mutations in the same gene (*MMADHC* for MMAuria, *cblD* type, with homocystinuria) cause three distinct biochemical phenotypes: (1) deficient synthesis of both Cbl coenzymes causing combined MMAuria and homocystinuria (*cblD*-MMA/HC) associated with truncating mutations in the middle part of the gene, (2) deficiency of MeCbl synthesis causing isolated homocystinuria (*cblD*-HC) associated with missense mutations in the C-terminal part and (3) deficient synthesis of AdoCbl causing isolated MMAuria (*cblD*-MMA), associated with truncating mutations in the N-terminal region (Fig. 28.1).

The *cblD-HC*, *cblE* and *cblG* defects are associated with deficient methionine synthesis associated with elevated tHcy, low methionine and SAM in plasma with normal MMA. The *cblE* defect is caused by deficiency of methionine synthase reductase (*MTRR*), which is required for the activation of the methionine synthase apoenzyme by reductive methylation (Fig. 28.1). The *cblG* defect is caused by deficient activity of the methionine synthase apoenzyme (*MTR*) itself. The genes for both defects have been described (Watkins and Rosenblatt 2017).

MMAurias are a heterogeneous group of inborn errors of metabolism biochemically characterised by the accumulation of MMA in body fluids and tissues. They result from deficiency of the mitochondrial enzyme methylmalonyl-CoA mutase (*MMUT*) or by a defect in the synthesis of its cofactor AdoCbl (*cblA*, *cblB* and *cblD-MMA*) (Fig. 28.1). MMUT deficiencies are further subdivided into defects without (mut^0) and with residual activity (mut^-). The conversion of L-methylmalonyl-CoA to succinyl-CoA, catalysed by MMUT, links the final catabolic pathways of branched-chain amino acids, odd-chain fatty acids and cholesterol to the Krebs cycle (Fowler et al. 2008). In the final step of AdoCbl synthesis in the mitochondrion, adenosyltransferase encoded by the *cblB* locus (*MMAB*) converts cob(II)alamin to AdoCbl and transfers the product directly to MMUT, in a process gated by the protein encoded by the *cblA* locus (*MMAA*) (Banerjee et al. 2009; Plessl et al. 2017).

Metabolic Pathway

Cobalamin and its metabolism are shown in Fig. 28.1. Cbl is released from food proteins in the acidity of the stomach and binds to haptocorrin (HC), produced in saliva and in the stomach. In the duodenum, pancreatic enzymes degrade the Cbl-HC complexes releasing free Cbl which forms a complex with intrinsic factor (IF) from gastric parietal cells. The Cbl-IF factor complex is taken up by epithelial cells in the terminal ileum via specific receptor-mediated endocytosis. Free Cbl then enters the portal circulation bound to transcobalamin (TC) and is transported to tissues where the Cbl-TC complex binds to the TC receptor and is internalised (Nielsen et al. 2012). In the cell, conversion of Cbl to its active cofactors, methylcobalamin (MeCbl) and adenosylcobalamin (AdoCbl), requires a series of biochemical modifications that have been classified as Cbl complementation groups A–J (Fig. 28.1).

Signs and Symptoms

The characteristic hallmark of Cbl disorders is haematologic abnormalities with megaloblastic anaemia, hypersegmentation of neutrophils and (pan)cytopenia. However, these symptoms may only manifest late or not at all. In most disorders, the phenotypes encompass a spectrum ranging from early-onset to late-onset clinical forms. The clinical presentation and characteristic laboratory findings of each disease are summarised in Tables 28.1, 28.2 and 28.3, 28.4, 28.5, 28.6, 28.7, 28.8, 28.9, 28.10, and 28.11; 28.12, 28.13 and 28.14; 28.15, 28.16, and 28.17; and 28.18, 28.19 and 28.20.

Absorption and Transport Disorders

In disorders of Cbl absorption and transport, the symptoms are usually indistinguishable from those caused by dietary deficiency of vitamin B_{12}. Unspecific clinical signs and symptoms may already arise in the first months of life including failure to thrive (weight and head circumference), developmental regression, irritability, apathy, anorexia and refusal of solid foods (Whitehead 2006). Clinically, Imerslund-Najman-Gräsbeck syndrome (IGS) and intrinsic factor deficiency (IFD) overlap considerably; mild, Cbl-resistant proteinuria (not obligatory) in IGS may help to distinguish the two disorders. While patients with IGS and IFD usually present between age 1 and 10 (Tables 28.1, 28.2 and 28.3), those with transcobalamin (TC) deficiency present much earlier, mainly in the first weeks to months of life (Table 28.5). Although haptocorrin deficiency has been associated with low serum Cbl levels, there is no evidence that these low levels result in clinical manifestation of Cbl deficiency (Table 28.4) (Watkins and Rosenblatt 2017). Nine patients with defects in the TC receptor have come to medical attention, mostly as the result of positive newborn screening results for MMAuria (Hannah-Shmouni et al. 2018). Homocysteine was also elevated in most patients (Table 28.6). Eight of the nine patients have remained asymptomatic, with the ninth suffering from bilateral central retinal artery occlusions (Karth et al. 2012). The long-term effects of this condition are yet to be unravelled.

Intracellular Disorders

Although disorders of intracellular Cbl metabolism share many clinical features with the forms of Cbl deficiency due to abnormal absorption and transport, some clinical manifestations are unique. Symptoms are generally more severe, and in most cases there is only a partial or no response to parenteral hydroxo-Cbl treatment (Watkins et al. 2016).

Patients with combined deficiency of MeCbl and AdoCbl synthesis (*cblC*, *cblD*, *cblF*, *cblJ*) usually present within the first year of life with poor feeding, failure to thrive, developmental delay, megaloblastic anaemia and (pan)cytopenia (Tables 28.7, 28.8, 28.9, 28.10 and 28.11). In *cblF* and *cblJ*, low birth weight, minor facial abnormalities and congenital heart defects have been reported as well, while most *cblJ* patients have been reported to have skin hyperpigmentation and grey hair. In *cblC* patients, at least two distinct pheno-

[a]Few patients described, none beyond infancy

types differentiated by age of onset have been delineated and are related to specific mutations in *MMACHC* (Lerner-Ellis et al. 2009). Early-onset patients present in the first year of life with feeding problems, failure to thrive, neurological symptoms including muscular hypotonia, developmental delay and seizures (Fischer et al. 2014; Huemer et al. 2018) and more rarely with atypical haemolytic uremic syndrome and pulmonary hypertension (Beck et al. 2017). These patients may develop multisystem pathology, which mainly presents as persistent failure to thrive, cognitive dysfunction and eye disease, which is resistant to therapy (Fischer et al. 2014; Huemer et al. 2018). In contrast, a few *cblC* patients have come to clinical attention after the first year of life and have presented as late as in the fourth decade (Thauvin-Robinet et al. 2008). Clinical findings in this group are mainly neurologic and include gait abnormalities, confusion, disorientation, psychosis and dementia (Fischer et al. 2014; Huemer et al. 2018). Macrocytic anaemia is found in less than half of these patients. Only three patients with epimutation of *MMACHC* due to genetic mutation of *PRDX1* have so far been described, and these were consistent with early onset *cblC* disease (Gueant et al. 2018). Alternatively, 19 patients with mutation of *HCFC1* (Yu et al. 2013; Gerard et al. 2015; Koufaris et al. 2016) and one patient each with mutation of *ZNF143* (Pupavac et al. 2016) and *THAP11* (Quintana et al. 2017) have presented in the first months of life with a somewhat similar clinical presentation to early-onset *cblC* patients (Tables 28.12, 28.13 and 28.14). However, in these patients the metabolic abnormalities were milder, while the neurological presentation more severe and often included intractable seizures and severe intellectual disability.

The clinical features of the isolated homocystinuria defects (*cblE*, *cblG*, *cblD*-HC) include poor feeding and vomiting with failure to thrive, megaloblastic anaemia, and neurological disease including developmental delay, cerebral atrophy, hypotonia or hypertonia, ataxia, neonatal seizures, nystagmus and visual disturbances (Huemer et al. 2015; Huemer et al. 2017) (Tables 28.15, 28.16 and 28.17). Most patients are symptomatic in the first year of life, but isolated cases with later onset and minimal findings have also been reported (Vilaseca et al. 2003).

The majority of patients with isolated MMAuria (*cblA*, *cblB*, *cblD*-MMA and *mut*) present during the newborn period or infancy with metabolic crises, often precipitated by catabolic stress, e.g. induced by febrile illness. Symptoms include vomiting, dehydration, tachypnea, lethargy, failure to thrive, developmental delay, hypotonia and encephalopathy (Tables 28.18, 28.19 and 28.20). Long-term complications include chronic renal failure, developmental delay, metabolic stroke, extrapyramidal movement disorder and optic neuropathy (Baumgartner et al. 2014; Kolker et al. 2015). Patients with mut^0 and *cblB* defects tend to have earlier onset of symptoms and a higher frequency of complications and deaths than those with mut^- and *cblA* defects (Horster et al. 2007).

Diagnosis

Haematologic investigations and measurement of serum Cbl can be helpful. Cbl levels below 125 pmol/L are almost always indicative of Cbl deficiency. However, symptomatic patients with low-normal Cbl that are responsive to Cbl treatment have been reported. Accumulating evidence indicates that plasma measurements of the biologically active Cbl holotranscobalamin may be superior to serum Cbl, and these are being introduced increasingly into the clinical setting (Nexo and Hoffmann-Lucke 2011). However, both markers may be normal in patients with TC deficiency and inborn errors of intracellular Cbl metabolism. In these disorders, measurement of the two metabolic markers MMA and tHcy, which are sensitive indicators of Cbl deficiency, is indicated. Limitations are the specificity of tHcy which is also increased in folate deficiency and the complexity and cost of the assay for MMA. Further studies are usually required to determine the cause of Cbl deficiency, e.g. mutation analysis and/or tests for investigating Cbl absorption or enzymatic and genetic complementation studies in defects of Cbl metabolism. These tests should be performed in laboratories with specific expertise.

Reference Values

Analyte	Infant	Child	Adolescent	Adult
	<1 year	1–12 years	12–18 years	>18 years

28.20 cblB	

CVS Chorionic villous sampling
[a]First choice if disease causing mutations and their parental origin confirmed

Treatment

In patients with defects of Cbl absorption and transport, treatment with relatively small amounts of Cbl, administered by injection to circumvent the barrier of the intestinal mucosa, generally results in rapid resolution of biochemical abnormalities and symptoms of deficiency. The conventional therapy is 1000 µg of parenteral cyano-Cbl or hydroxo-Cbl daily for 1 week, followed by 100–1000 µg cyano-Cbl weekly for 1 month and monthly thereafter. This therapy is believed to replete and sustain body Cbl stores.

Treatment of diseases caused by defects of intracellular processing of Cbl usually requires very large doses of cofactor, i.e. 1000 µg or even more of parenteral hydroxo-Cbl several times weekly (Watkins and Rosenblatt 2017). In patients with combined MMA and Hcy (cblC, cblD, cblF, cblJ) and in those with isolated Hcy (cblE, cblG, cblD-HC), treatment with parenteral hydroxo-Cbl, betaine, folinic acid/methylfolinic acid and theoretically methionine usually corrects the haematologic abnormalities and improves but usually does not completely correct the biochemical abnormalities. Moreover, neurological symptoms respond only partially, and severe neurological deficits, including eye disease, often persist. Treatment of isolated MMAurias consists of dietary restriction of protein, carnitine supplementation and, in Cbl-responsive patients, parenteral hydroxo-Cbl. While most patients with *cblA* will respond even to oral hydroxo-Cbl, only about one third of *cblB* patients and even fewer patients with *mut* will do so (Matsui et al. 1983). Thus, it is important to reliably classify these patients and identify those who genuinely benefit from hydroxo-Cbl treatment using a standardised test (Fowler et al. 2008).

Drugs and Dosages to be Used in Acute Presentation of Suspected Disorders of Vitamin B_{12} Metabolism

Emergency and standard treatment tables and medication requirements. Acute presentation

Disorder	Hydroxo-Cbl (CN-Cbl less effective)	Folic or folinic acid (never give without Cbl)	L-Carnitine	L-Arginine hydrochloride (to be given IV in glucose 10%)	Sodium benzoate (to be given IV in glucose 10%)
All disorders	1–5 mg/day i.m., i.v. or s.c.	Folic acid: 15 mg/kg/day (i.v. in three doses) Folinic acid (preferred, if available): 3 mg/kg/day (i.v. in one dose)	50–100 mg/kg/day[a]	–	–
Disorders with MMA only (cblA, cblB, cblD-MMA)[b]	Same	Optional	50–200 mg/kg/day i.v.	250 mg/kg (1.2 mmol/kg) as bolus in 90–120 min, then maintenance 250 mg/kg/day (1.2 mmol/kg/day)	250 mg/kg as bolus in 90–120 min, then maintenance 250–500 mg/kg/day[c] >20 kg bw: 5.5 g/m²/day

[a]Optional
[b]For more details see methylmalonyl-CoA mutase deficiency in Chap. 23 (disorder **23.23**)
[c]If on haemodialysis/haemodiafiltration, doses should be increased to 350 mg/kg/day (maintenance dose)

Dosages of drugs to be used for long-term treatment

Disorder	Hydroxo-Cbl (Cyano-Cbl generally less effective)	Folinic/folic acid (never give without Cbl)	L-Carnitine	Diet	Betaine
28.1 IFD 28.2 and 28.3 IGS	1 mg i.m. or s.c. every 1–3 months	Folic acid up to 10 mg 4× daily	–	–	–
28.4 HCD	–	–	–	–	–
28.5 TCD	0.5–1 mg p.o. 2× weekly or 1 mg i.m. 1× weekly	Folic acid up to 10 mg 4× daily	–	–	–
28.6 TCR		–	–	–	–
28.7 cblF 28.8 cblJ 28.9 cblC 28.10 epi-cblC 28.11 cblD-MMA/HC	1 mg i.m. or s.c. daily[a]	Folinic acid 15 mg/day[b]	50 mg/kg/day[b]	Moderate protein restriction[b]	Up to 250 mg/kg/day
28.12 HCFC1 28.13 ZNF143 28.14 THAP11					
28.15 cblD-HC 28.16 cblE 28.17 cblG	1 mg i.m. or s.c. daily	Folinic acid 15 mg/day[b]	–	–	Up to 250 mg/kg/day
28.18 cblD-MMA[c] 28.19 cblA 28.20 cblB	1 mg i.m. or s.c. 1–7× weekly[d]	–	50–100 mg/kg/day	Protein restriction and supplementation of precursor-free amino acid mixture[b]	–

[a]In cblC OHCbl should be titrated individually based on metabolic response; up to 20 mg OHCbl daily have been used; even with such doses tHcy mostly cannot be normalised; levels between 40 and 60 µmol/L are typicaslly reached in infantile-onset cblC. In some late-onset patients, tHcy has been normalised
[b]Optional
[c]See also methylmalonyl-CoA mutase deficiency in Chap. 23 (disorder **23.23**)
[d]Cbl responsiveness should be carefully tested starting with 1–2 mg OHCbl i.m. or s.c. for several days followed by titrating cobalamin dosage against methylmalonate excretion and clinical status in cobalamin-responsive patients

Experimental Treatment

In the cblC defect, prenatal diagnosis and treatment of the affected foetus by administration of hydroxo-Cbl i.m. in the mother have been reported (Huemer et al. 2005; Trefz et al. 2016). Furthermore, attempts to treat this disorder with antioxidants and creatine have been made. In the cblA and cblB defects, transplantation of the kidney and/or the liver has been reported. It must be borne in mind that such treatment does not prevent neurological damage such as metabolic stroke.

Disorders of Folate Metabolism and Transport

29

Robert Steinfeld and Nenad Blau

Contents

Summary

Folates play an essential role in one-carbon methyl transfer reactions, mediating several biological processes including DNA synthesis, regulation of gene expression through methylation and formylation reactions, embryonic central nervous system development, synthesis and breakdown of amino acids, and synthesis of thymidines, purines, and neurotransmitters (Blount et al. 1997; Linhart et al. 2009; Ghoshal et al. 2006; Pogribny et al. 2008; Fournier et al. 2002). In mammals, folates are mostly derived from exogenous sources as folate is stored in the liver for few months.

The biologically active folate derivative is 5,6,7,8-tetrahydrofolate (THF). Dietary folate is absorbed in the intestine via the proton-coupled folate transporter (PCFT). In the cytoplasm, interconversion of 5,10-methylene-THF and 5,10-methenyl-THF, interconversion of 5,10-methenyl-THF and 10-formyl-THF, and reaction of THF with formate to synthesize 10-formyl-THF are mediated by the MTHFD1 gene that encodes a trifunctional protein. Metabolism of 5,10-methylene-THF to 5-methyl-THF in the liver is catalyzed by methylene-THF reductase (MTHFR). 5-Methyl-THF is then widely distributed in the bloodstream. The transport of 5-methyl-THF inside the cells is mediated by different transport systems that include the proton-coupled folate transporter (PCFT), the reduced folate carrier 1 (RFC1), and the two GPI-anchored receptors, folate receptor alpha (FRα) and beta (FRβ) (Matherly and Goldman 2003). The physiological form of folate, 5-methyl-THF, is actively transported to the central nervous system by FRα-mediated endocytosis in choroid epithelial cells, reaching a higher concentration in the cerebrospinal

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_29

fluid when compared to the serum. FRα is a high-affinity low-capacity receptor that functions at a nanomolar range of extracellular folate concentrations (Weitman et al. 1992). Glutamate formiminotransferase-cyclodeaminase (FTCD) is a bifunctional enzyme that catalyzes the folate-dependent degradation of N-formimino-L-glutamic acid (FIGLU) to form 5,10-methenyltetrahydrofolate, glutamate, and ammonia, the final two reactions of the pathway responsible for the degradation of L-histidine. Thus far, seven different inherited disorders of folate metabolism are known which lead to folate deficiency including hereditary folate malabsorption, folate receptor alpha deficiency, 5,10-methylenete-THF reductase deficiency, 5,10-methenyl-THF synthetase deficiency, dihydrofolate reductase deficiency, and 5,10-methylenete-THF dehydrogenase deficiency (Watkins et al. 2011; Watkins and Rosenblatt 2012). Reduced folate carrier deficiency presenting with recurrent megaloblastic anemia has been reported very recently in a single patient carrying a homozygous deletion of the Phe212 residue (Svaton et al. 2020). Glutamate formimino transferase deficiency is considered as a non-disease, despite being former characterized by megaloblastic anemia, mental retardation and elevated urine FIGLU following a histidine load (Hilton et al. 2003). Mitochondrial 10-formyltetrahydrofolate dehydrogenase, encoded by *ALDH1L2*, affects mitochondrial pool of metabolites relevant to beta-oxidation of fatty acids and presents with neuro-ichthyotic syndrome (Sarret et al. 2019). For more details on FIGLU-uria, see Chap. 71.

Introduction

Hereditary folate malabsorption is an autosomal recessive condition where infants present at 2–6 months of age with clinical features suggestive of megaloblastic anemia, failure to thrive, diarrhea, frequent infections, mucositis, immune deficiency, and neurological features including epilepsy, developmental delay, and intellectual disability due to a defect in the uptake of folates from the intestine and the blood-brain barrier of the choroid plexus. Folate levels on both serum and cerebrospinal fluid are low (see Table 29.1). This condition is caused by variants in the *SLC46A1* gene that maps to 17q11.2 and encodes the PCFT (Qiu et al. 2006). Several variants have been reported including missense, nonsense, and splice site variants, and it has been demonstrated that they affect folate transport in an in vitro system (Qiu et al. 2006). The therapy of this condition has involved the parenteral administration of folate. However, oral therapy has been successfully implemented in some cases (Watkins et al. 2011). Folate receptor alpha deficiency is an autosomal recessive condition caused by loss of function variants in the *FOLR1* gene encoding the folate receptor alpha that leads to impaired transport of folate to the CNS (see Table 29.2). The patients initially described exhibit null variants causing severe cerebral folate deficiency (CFD) (Steinfeld et al. 2009). These patients have an initial period of normal development until the age of 2 years, and they eventually exhibit psychomotor decline, progressive movement disturbance, white matter disease, and epilepsy (Steinfeld et al. 2009; Cario et al. 2009). Myoclonic-astatic seizures have been described in the most affected patients, and the epilepsy in these patients seems to be drug refractory (Steinfeld et al. 2009; Cario et al. 2009) although a case associated with progressive myoclonic epilepsy has responded to high dose of folinic acid supplementation (Perez-Duenas et al. 2011). These patients have almost undetectable levels of cerebrospinal fluid (CSF) 5-methyl-THF. MR-based in vivo metabolite analysis indicates depletion of white matter choline and inositol. Folinic acid therapy restores glial choline and inositol contents, CSF 5-methyl-THF and ameliorates symptoms in these patients. Folate receptor alpha deficiency caused by a homozygous p.(Arg204*) variant in the *FOLR1* gene has been described in a patient with congenital deafness, labyrinthine aplasia, microtia, and microdontia (LAMM) syndrome (Dill et al. 2011). Folinic acid treatment helped to regain consciousness, but the epilepsy was controlled with pyridoxal 5′-phosphate.

Methylenete-THF reductase (MTHFR) deficiency is an autosomal recessive condition caused by variants in the *MTHFR* gene that maps to 1p36.22 (Goyette et al. 1994). This condition represents the most common of the known inborn errors of folate metabolism with more than 160 subjects identified (Huemer et al. 2019). Methylene-THF reductase mediates the conversion of 5,10-methylene-THF to 5-methyl-THF. Biochemically, patients with this condition have hyperhomocysteinemia with low or low-normal methionine levels, reflecting decreased activity of methionine synthase. Clinical features of this disorder include developmental delay, intellectual disability, neurological and psychiatric features, thrombotic events, and serious disease leading to death (Strauss et al. 2007) (see Table 29.3). Severe MTHFR deficiency should be a diagnostic consideration in infantile epileptic encephalopathy and infantile communicating hydrocephalus (Prasad et al.

2011; Baethmann et al. 2000). Microcephaly and developmental regression become noticeable following the onset of seizures. Patients with this condition do not exhibit megaloblastic anemia. Other subjects may present later in childhood with developmental delay and other neurological manifestations. The striking changes of demyelination do not necessarily reflect an effect from the vascular lesions, suggesting the participation of other factors such as inadequate methionine synthesis, a deficiency of *S*-adenosylmethionine or accumulation of toxic intermediates from the elevated levels of homocysteine (Prasad et al. 2011). Among different therapeutic strategies, the best outcome has been seen with betaine-homocysteine methyltransferase that converts homocysteine to methionine without requiring folate when started prenatally or soon after birth (Strauss et al. 2007). MTHFR deficiency can be pre-clinically diagnosed through the newborn screening for total homocysteine (Huemer et al. 2019).

Dihydrofolate reductase (DHFR) deficiency is a rare inborn error of folate metabolism (Cario et al. 2011; Banka et al. 2011) (see Table 29.4). DHFR is a key enzyme in folate metabolism and an important target of several pharmacological compounds. Three individuals from two families were described, who presented with megaloblastic anemia and/or pancytopenia, severe CFD, and cerebral tetrahydrobiopterin deficiency due to a germline missense variant in *DHFR*, leading to profound enzymatic deficiency. Cerebral folate levels, anemia, and pancytopenia were corrected by treatment with folinic acid. These individuals presented in the first weeks of life with epilepsy, developmental delay, and cerebral and cerebellar atrophy (Banka et al. 2011). Individuals from a third family presented at 2–11 years, and two exhibited atypical childhood absence epilepsy (Cario et al. 2011). All of these subjects were homozygous for variants in the *DHFR* gene that maps to 5q14.1. Therapy with folinic acid has corrected the biochemical abnormalities. However, in some cases, the epilepsy became persistent when the treatment with folinic acid was not given in a consistent basis (Cario et al. 2011).

Variants in the *MTHFD1* gene mapping to 14q23.3 have been identified by exome sequencing in an infant who presented at 2 months of age with megaloblastic anemia, atypical hemolytic uremic syndrome, and severe combined immunodeficiency (see Table 29.5). The *MTHFD1* gene encodes the trifunctional enzyme that mediates the 5,10-methylene-THF dehydrogenase, 5,10-methenyl-THF cyclohydrolase, and 10-formyl-THF synthetase reactions (Watkins and Rosenblatt 2012). Homocysteine and methylmalonic acid were increased. In vitro studies demonstrated decreased synthesis of methylcobalamin, required for the activity of methionine synthase. Serum folate was normal (Keller et al. 2013; Bidla et al. 2020).

Several patients with *MTHFS* variants and with frequent seizures and cerebral hypomyelination, unresponsive to folinic acid administration, were reported with very low CSF 5MTHF (see Table 29.6). All other biochemical parameters were normal, and there were no signs of anemia. MTHFS converts 5-formyl-THF to 5,10-methenyl-THF, thus making folinic acid not a therapeutic option. CFD may be associated with autistic features in a subset of children with developmental regression, intellectual disability, epilepsy, dyskinesia, and autism (Moretti et al. 2008; Rodan et al. 2018) (see Table 29.7).

A single patient presenting with a folate-dependent megaloblastic anemia, hyperhomocysteinemia, low total vitamin B12 levels, and normal serum folates due to a homozygous Phe212 deletion in the *SLC19A1* gene responded well to treatment with cyanocobalamin and folate (Svaton et al. 2020).

Two phenotypes of the glutamate formimino transferase deficiency, a severe and a mild form, have been described with their genetic basis not yet fully elucidated (Hilton et al. 2003).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM No.
29.1	Hereditary folate malabsorption	Proton-coupled folate transporter (PCFT) deficiency	HFM	*SLC46A1*	17q11.2	SLC46A1 transporter	229050

Prenatal Diagnosis and DNA Testing

No data available for prenatal diagnosis. DNA testing possible for disorders 29.1–29.8.

Treatment

Drugs and dosages to be used in acute/chronic presentations of suspected disorders of folate transport and metabolism

Disorder	Folinic acid/folic acid	Betaine	Hydroxocobalamin/ cyanocobalamin	Methionine	Vitamin B6
29.1 Hereditary folate malabsorption	Folinic acid parenterally (intravenous in acute presentation and intramuscular for chronic treatment) 4 mg/day				
29.2 Folate receptor alpha deficiency	Folinic acid orally 2–5 mg/kg/day. 100 mg intravenously or once a week have been used concomitantly with 5 mg per kilo per day of oral folinic acid. Preliminary results indicate that intrathecal administration may be more efficient than oral administration. However, no doses have been reported (Grapp et al. 2012)				
29.3 5,10-methylene-THF reductase deficiency	Folinic acid orally 15 mg/day	Betaine orally 100–250 mg/kg/day in neonates and infants. In children and adults, 6–9 g/day in three divided doses with a maximum daily dose of up to 20 g/day	Hydroxocobalamin 0.5–1 mg orally or 1 mg IM monthly	Methionine orally 40–50 mg/kg/day	Vitamin B6 orally 100–250 mg/day
29.4 5,10-methylene-THF dehydrogenase deficiency	L-methyl-THF 3 mg compounded with 35 mg of pyridoxal 5′-phosphate and 2 mg of methylcobalamin given orally once a day				

Disorder	Folinic acid/folic acid	Betaine	Hydroxocobalamin/ cyanocobalamin	Methionine	Vitamin B6
29.5 Dihydrofolate reductase deficiency	Folinic acid orally 1 mg/kg/ day				
29.6	No treatment needed				
29.7 5,10-Methenyl-THF synthetase deficiency	L-methyl-THF 3 mg compounded with 35 mg of pyridoxal 5′-phosphate and 2 mg of methylcobalamin given orally once a day				
29.8 Reduced folate carrier deficiency	Folic acid 10 mg/day		Cyanocobalamin i.m. 1000 µg twice a week		

Folic acid *should not* be used to treat these disorders since it is not a physiologic form of folate and binds in an irreversible way to folate receptor alpha, inhibiting the binding of 5-methylTHF and blocking the transport of folate across the choroid plexus. In addition, folate has to be converted by a series of enzymatic reactions to the biological active 5MTHF

Hereditary Folate Malabsorption

Folic acid should not be used to treat hereditary folate malabsorption. Folic acid is the most common pharmacologic form of folate and very stable. However, it is not a physiologic form of folate. It binds in an irreversibly way to folate receptors and may block these receptors from transporting folate across the choroid plexus (Kamen and Smith 2004). 5-Formyltetrahydrofolate (5-formyl-THF), also known as folinic acid (Ca-Folinate), is a racemic and stable form of folate that is found in human tissues and can be used in oral and parenteral formulations. The active L-isomer may also be used for parenteral administration. The active isomer, L-5-methyltetrahydrofolate (L-5MTHF), is the principal folate in the diet, the form that is absorbed in the intestine and circulating in the blood. It is available commercially but only for oral and not parenteral supplementation. No controlled studies have been conducted in order to provide guidelines for optimal treatment. The required dose of reduced folate seems to vary among patients. The dose of reduced folate needed to improve the neurological features is much higher than that needed to improve the hematological problems. Dosing should be done and guided by its effect on reaching normal age ranges for trough CSF 5MTHF concentrations. Oral doses of 150–200 mg of 5-formyl-THF have been associated with good clinical outcomes (Geller et al. 2002). An appropriate starting dose of a reduced folate in an infant could be 50 mg or 10–15 mg/kg given daily as a single dose. Appropriate dosing of a reduced folate should be tailored to achieve a normal CSF 5MTHF concentration for age. The parenteral dose used to achieve adequate blood folate levels is lower than the oral dose. The hematological abnormalities have corrected with intramuscular injections of 1.0 mg/day of 5-formyl-THF. Nevertheless, the normalization of CSF 5MTHF levels requires higher reduced folate doses. Dosing should be adjusted in each individual to achieve a CSF 5MTHF level normal for age (Grapp et al. 2012).

Folate Receptor Alpha Deficiency

Since this is a rare autosomal recessive disorder, no controlled studies have been conducted in order to provide guidelines for optimal treatment. It has been presumed that alternative or residual transport pathways into the central nervous system can be used by increasing the plasma 5MTHF concentrations. Thus, most patients have been treated with folinic acid at oral doses of 2–5 mg per kg/body weight daily. Folic acid should not be used to treat folate receptor alpha deficiency since it is not a physiologic form of folate (Kamen and Smith 2004). In addition, folate has to be converted by a series of enzymatic reactions to the biological active 5MTHF. 5-formyl-THF is a racemic and stable form of folate found in human tissues. It can be used in oral formulation. The active L-isomer (Isovorin) may also be used for oral administration. Most patients benefit from this treatment and respond within 2–6 months of therapy with reduced frequency of seizures, almost complete normalization of neurological status, improved motor skills, and increase of the CSF 5MTHF concentration in the CSF (Steinfeld et al. 2009; Cario et al. 2009; Grapp et al. 2012). In addition, after 6 months of treatment, the white matter choline and inositol signals normalized, and signs of remyelination were observed on brain MRI (Steinfeld et al. 2009). In one additional case of folate receptor alpha deficiency, a trial with 30 mg/day of folinic acid at the age of 26 months controlled the seizures completely in 1 month and ameliorated the myoclonic jerks and choreic movements presented by the patient (Perez-Duenas et al. 2010). In few patients, alternative routes of folinic acid supplementation (intravenous and/or intrathe-

cal) have been tried, and the results indicate better treatment efficacy (Grapp et al. 2012).

Methylenetetrahydrofolate Reductase Deficiency

The aim of the treatment is the decrease of homocysteine levels by using the compound betaine (Huemer et al. 2019). Betaine is a substrate of the enzyme betaine-homocysteine S-methyltransferase (BHMT) that catalyzes remethylation of homocysteine to methionine in kidney and liver causing hypermethioninemia in these patients. Betaine is administered orally, and treatment is begun with 100 mg/kg/day. Doses may range from 100 to 250 mg/kg/day in neonates and infants. In children and adults, doses can range to 6–9 g/day in two to six divided doses, and the total daily dose can be increased up to 20 g/day (Prasad et al. 2011). Since the expression of BHMT is low in the central nervous system, it is not surprising to find out that the best therapeutic outcome with betaine has been observed when started prenatally or soon after birth with restoration of plasma SAM levels and attainment of normal brain growth and development (Strauss et al. 2007). Frequent dosing of orally administered betaine (six divided doses) normalized total plasma homocysteine levels in one infant with MTHFR deficiency (Ucar et al. 2010). Supplementation with methionine (40–50 mg/kg/day), folinic acid (5–30 mg/day), vitamin B6 (100–250 mg/day), and vitamin B12 (0.5–1 mg/day orally) may be contemplated based on the fact that they play a role as cofactors in different enzymatic reactions of the folate utilization pathway that ultimately leads to the synthesis of 5MTHF (Schiff et al. 2011).

Methylene-THF Dehydrogenase Deficiency

No treatment was initially reported in the only patient identified with this particular inborn error of metabolism (Watkins and Rosenblatt 2012). However, the treatment was subsequently reported as consisting of 3 mg of L-methyl-THF compounded with 35 mg of pyridoxal 5′-phosphate and 2 mg of methyl-cobalamin given orally once a day. This treatment provided partial immune reconstitution (Keller et al. 2013).

Dihydrofolate Reductase Deficiency

Therapy with 1 mg/kg per day of folinic acid corrects the biochemical abnormalities including cerebral 5MTHF levels, total red blood cell folate levels, anemia, and pancytopenia (Cario et al. 2011). The treatment can also improve school performance and control the epilepsy; however, irregular treatment with folinic acid is associated with recurrence of epilepsy of enzymatic (Cario et al. 2011). In another report, treatment with 10–30 mg of daily folinic acid corrected the cerebral 5MTHF level and improved the anemia and the seizure control (Banka et al. 2011).

Glutamate Formimino Transferase Deficiency

No treatment required.

Methenyl-THF Synthetase Deficiency

No treatment has been reported so far.

Reduced Folate Carrier Deficiency

A combined therapy with cyanocobalamin (1000 mg, i.m.) and folic acid (10 mg/day) seems to be beneficial in a single patient.

Mitochondrial 10-formyltetrahydrofolate Dehydrogenase Deficiency

No treatment has been reported so far.

Disorders of Biotin Metabolism

30

Bruce A. Barshop

Contents

Summary

Disorders in the processing of biotin present with deficiencies of the biotin-dependent carboxylases, i.e., multiple carboxylase deficiency. The biochemical and clinical abnormalities reflect those observed in individual, isolated defects of three mitochondrial carboxylases: methylcrotonyl-CoA carboxylase, propionyl-CoA carboxylase, and pyruvate carboxylase. Dietary deficiency of biotin is very rare in general, but may occur with prolonged insufficiency or with a defect of absorption and transport. Multiple carboxylase deficiency is caused by defects in holocarboxylase synthetase or in biotinidase. Treatment of biotinidase deficiency with biotin supplementation is highly effective in reversing the abnormalities, and that is usually also the case for the treatment of holocarboxylase deficiency, though there may be some variability of response.

Introduction

Biotin is a vitamin cofactor used in carboxylation reactions which fix CO_2 from bicarbonate to substrates, to generate carboxylic acid moieties; in fact each biotin-dependent reaction in human metabolism converts a carboxylic acid (or CoA ester) to a dicarboxylic acid (or CoA ester).

In its active form, biotin is covalently bound to lysine in the active site of a carboxylase holoenzyme. Utilization of biotin requires its transfer to the correct lysine residue of the carboxylase apoenzyme to generate the active holoenzyme, a reaction carried out by holocarboxylase synthetase (HCS). Ingested biotin may be free, or as most often ingested, protein-bound, in the form of the lysine conjugate (biocytin). Absorption and cellular uptake of free biotin involves the transporter SLC5A6 (also known as the sodium-dependent multivitamin transporter, SMVT) which mediates biotin, pantothenic acid, and lipoate uptake in a variety of cellular systems (Prasad and Ganapathy 2000). Recovery of protein-bound biotin from dietary sources, and retention of biotin from endogenous carboxylase proteins as they are proteolyzed, requires cleavage of biocytin, a reaction catalyzed by the enzyme biotinidase. Biotinidase deficiency or HCS deficiency (HCSD) causes a functional defect in all the carboxylases, termed multiple carboxylase deficiency (MCD).

HCS is a complex enzyme which activates biotin to form D-biotinyl-5′-adenylate and then catalyzes the covalent attachment of the biotin to an active site ε-amino group of a lysine residue of a newly synthesized apocarboxylase protein, converting it into an active holocarboxylase enzyme.

There are four biotin-dependent enzymes in human metabolism (Fig. 30.1). Acetyl-CoA carboxylase (ACC) is used to generate malonyl-CoA which is important in initiation of the synthesis of fatty acids and regulation of their oxidation. ACC is present in two isomers, one of which (ACC1) is cytoplasmic and the other of which (ACC2) is associated with the endomembrane system (including primarily the cytosolic side of the outer mitochondrial membrane). There are as yet no known disorders due to defects in ACC, but the other three carboxylases, which are all localized to the mitochondrial matrix, each have a disease state associated with its deficiency. These include methylcrotonyl-CoA carboxylase (two subunits, MCCC1 and MCCC2), propionyl-CoA carboxylase (two subunits, PCCA and PCCB), and pyruvate carboxylase (PC).

The first patient ascertained with MCD had HCSD and was described in 1971 by Gompertz et al. as having an abnormality of leucine metabolism due to identification of 3-methylcrotonylglycine and 3-hydroxyisovaleric acid in the urine. A defect in 3-methylcrotonyl-CoA carboxylase was documented by Gompertz et al. in 1973. When methylcitric and hydroxypropionic acids were also found to be increased in the same patient in 1977 by Sweetman et al., enzymatic analysis revealed defective activity of propionyl-CoA carboxylase in addition. The third mitochondrial carboxylase, pyruvate carboxylase, was also shown to be defective in 1979, and the disorder was then renamed multiple carboxylase deficiency (Saunders et al. 1979).

Nomenclature

#	Disorder	Alternative name	Abbr	Gene symbol	Chromosomal location	Affected protein	Mode of inheritance	OMIM
30.1	Biotinidase deficiency	Late-onset multiple carboxylase deficiency	BTDD	*BTD*	3p25.1	Biotinidase	AR	253260

Biotinidase Deficiency

Biotinidase deficiency presents with a median age of 3 months (Wolf et al. 1983), but it may present in the second decade of life (Wolf et al. 1998). In earlier literature biotinidase deficiency was referred to as the later infantile form of multiple carboxylase deficiency (Wolf et al. 1983) to distinguish it from the usual neonatal presentation of holocarboxylase synthetase deficiency. It is also possible for adults with profound biotinidase deficiency to remain asymptomatic, although those individuals would be predicted to be at ongoing risk for symptoms to arise at times of intercurrent infection or other stress. Such individuals have been ascertained because of abnormal results on newborn screening of their babies (Wolf et al. 1997).

The cutaneous lesions tend to be patchy, in contrast to the total body eruption seen in holocarboxylase synthetase deficiency, or there may be severe generalized involvement of the skin with redness and desquamation. Concomitant mucocutaneous candidiasis is common. The alopecia may be progressive to alopecia totalis but is usually less than total.

Neurological manifestations of biotinidase deficiency (Wolf 2011) tend to be indolent and significant. Ataxia is a prominent feature and may interfere with walking. Seizures are common and may be the only obvious symptom; they may be general or myoclonic or may present as infantile spasms. There may be developmental delay and neurodevelopmental regression. Stridorous breathing and apnea have been reported in some patients, may be a presenting sign, and may be expected to resolve with biotin treatment. The untreated disease may be fatal.

Visual and auditory neurosensory abnormalities have been reported in a considerable number of patients, often as late complications. Loss of visual function is associated with optic atrophy and appears to be encountered only in patients for whom diagnosis and treatment is delayed (Wolf 2011). Neurosensory hearing loss seems to follow the same pattern (Wolf 2011). Many of the neurological features of disease disappear in response to treatment with biotin, as do the cutaneous and metabolic features; but sensorineural abnormalities involving the optic and auditory nerves are among those which are not reversible once they have appeared and neurologic signs may persist if there is a long delay instituting treatment (Ferreira et al. 2017).

Holocarboxylase Synthetase Deficiency

Patients with HCS deficiency generally present in the first days or months of life with overwhelming illness identical to those of propionic acidemia or other classic organic acidemia. The age of onset of clinical symptoms generally has generally been before 6 weeks of life, but it is clear that patients with an abnormal holocarboxylase synthetase can present at any age from 1 day to 6 years of age (Suormala et al. 1997).

In the acute episode of illness, the infant has massive ketosis and metabolic acidosis with an anion gap. There may be tachypnea or Kussmaul breathing, and blood ammonia may be elevated. The episode may progress to dehydration and deep coma, and a number of patients have died of this disease; the initial episode may be lethal within hours of birth (Sweetman et al. 1982). Cutaneous features are an integral part of the untreated disease, though some patients have died before the development of skin lesions, and now patients are being treated before the development of cutaneous lesions. An erythematous eruption may involve the entire body, with bright red, scaly, or desquamative lesions. Complicating monilial infection is common. Varying degrees of alopecia are seen, including alopecia totalis, with absence

of eyelashes, eyebrows, and lanugo, as well as the hair of the head. There may be persistent vomiting and failure to thrive. Neurological abnormalities appear to be related to the effects of the initial or subsequent episodes of illness, which might include decreased brain perfusion and hyperammonemia; with treatment and while compensated, the neurological function is otherwise expected to be normal, and the neurological examination may be normal despite a hyperammonemic episode (Dabbagh et al. 1994). Muscular hypotonia and hypertonia have been described, as have more severe forms of dystonia and movement disorders, including athetosis and opisthotonus. There may be electroencephalographic abnormalities and abnormal findings on cranial computed tomography or magnetic resonance imaging, particularly involving the white matter. Subependymal cysts were observed in one infant and reported to disappear following 6 months of treatment (Squires et al. 1997), and subependymal cysts were also observed in seven Samoan infants who had severe disease, incomplete responsiveness to biotin, and early life-threatening metabolic events (Wilson et al. 2005), as well as a Samoan infant in an earlier series, who had a poor dermatological response to biotin (Sweetman et al. 1982).

The biochemical hallmark of this disease is the excretion of 3-hydroxyisovaleric acid and 3-methylcrotonylglycine, plus elevated quantities of lactic acid in blood and urine. The first clinical chemical clue to the disease may be the discovery of lactic acidemia. Organic acid analysis during an acute acidosis also reveals methylcitric and 3-hydroxypropionic acids and may also include tiglylglycine (Sweetman et al. 1982). The excretion of 3-hydroxyisovaleric acid is almost always greater than that of 3-methylcrotonylglycine and may be as high as 200 times normal (Sweetman et al. 1977).

Biotin Transporter Defect

Using whole genome-scanning, a child was found to have mutations in the SLC5A6 gene (Subramanian et al. 2017). The proband, identified at 15 months of age, presented with failure to thrive, developmental delay, microcephaly, generalized atrophy and thin corpus callosum on MRI, variable immunodeficiency, gastroesophageal reflux, and osteoporosis and pathologic bone fractures. The patient responded clinically to supplemental administration of biotin, pantothenic acid, and lipoate (Subramanian et al. 2017), but interestingly was said to have normal organic acids and other metabolic testing. It may be that another patient reported earlier (Mardach et al. 2002) had this or a similar defect, although the phenotype was slightly different (encephalopathy during episode of viral gastroenteritis at 18 months, findings of biotin-dependent MCD with normal activities of BTD and HCS, but moderately reduced rate of biotin uptake in vitro), and no mutations were found in SLC5A6.

This entity is distinct from the so-called biotin-thiamine-dependent basal ganglion, first described as a biotin-responsive entity, but subsequently proven to be caused by a defect in a thiamine transporter SLC19A3 (Zeng et al. 2005). The reported effect of biotin is presumed to be due to increased expression of the SLC19A3 gene in response to biotin (Leon-Del-Rio 2019). This entity is discussed in Chap. 31 (Disorders of Thiamine).

Diagnosis

Biotinidase deficiency is diagnosed by enzyme assay. It is generally conducted as a fluorometric assay and routinely performed on bloodspots in newborn screening programs worldwide (Heard et al. 1986); serum or plasma samples may be assayed also, and that is usually done for confirmation. The enzyme defect can be demonstrated whether the patient takes biotin or not, and the objective is to make the diagnosis prior to other biochemical changes. In the event of delayed treatment, the first biochemical changes generally include elevation of blood lactate and urine 3-hydroxyisovalerate and 3-methylcrotonylglycine. The diagnostic findings of holocarboxylase synthetase deficiency are similar in terms of organic acid changes, but enzymatic confirmation is more complicated. The assay may involve formation of acid-precipitable radiolabel from $H^{14}CO_2$ in the presence of apocarboxylases prepared from biotin-deficient rats (Burri et al. 1981), but that is a difficult assay to validate to clinical standards. Presumptive diagnosis may be made in fibroblast cultures which are grown in biotin-depleted media to check the activities of carboxylases. A practical solution may be to use p67, a peptide comprising the 67 C-terminal amino acids of propionyl-CoA carboxylase, as the substrate (Rios-Avila et al. 2011). Molecular methodology to document DNA mutations is possible as a primary diagnostic step, but in the present era of newborn screening, molecular studies are more often recommended to confirm an enzymatic diagnosis. Similarly, for diagnosis of SLC5A6 defects, it might in principle be possible to perform assay of biotin uptake in biopsies as in experimental cell culture systems (Subramanian et al. 2017), but that is not practical in general, and it is disconcerting that urine organic acids were reportedly normal in the sole reported case (Subramanian et al. 2017).

Reference Values

Compound	Fluid	Method	Age/gender	Reference range
3-Hydroxyisovaleric acid	Urine	GC-MS	All	0–58 mmol/mol creatinine
3-Methylcrotonylglycine	Urine	GC-MS	All	0–2 mmol/mol creatinine
Lactic acid	Blood, CSF	Enzymatic	All	0.5–1.5 mmol/L
Lactic acid	Urine	GC-MS or enzymatic	All	10–200 mmol/mol creatinine
Methylcitric acid	Urine	GC-MS	All	0–5 mmol/mol creatinine
3-Hydroxypropionic acid	Urine	GC-MS	All	0–24 mmol/mol creatinine
Tiglylglycine	Urine	GC-MS	All	0–2 mmol/mol creatinine

Specimen Collection

Test	Material	Handling	Pitfalls
Organic acids	Urine	Preservative-free, frozen	Results may be uninformative if responsive patient being treated. Sample thawing, bacterial contamination
Lactic acid	Serum	Prompt separation, freezing	Tourniquet/agitation effects. Delayed processing, thawing
Carboxylase assays	Whole blood	Yellow-top tube, room temp	Results may be uninformative if responsive patient being treated. Freezing, temp extremes or delays in shipping.
	Fibroblasts	Skin biopsy, plates to reference lab	Temperature extremes or delays in shipping. Bacterial or mycoplasma contamination.

Prenatal Diagnosis

Though feasibility of prenatal diagnosis of biotinidase deficiency by enzymatic assay activity in amniocytes was demonstrated as early as 1984, prenatal diagnosis is rarely undertaken, probably because outcome is expected to be favorable with treatment. Prenatal testing of amniocytes and chorionic villi has yielded evidence of normal fetuses and heterozygotes. If disease-causing mutations have been identified in the family, it is recommended to use DNA-based methods if prenatal diagnosis is desired. In holocarboxylase synthetase deficiency, amniotic fluid at 16 weeks of gestation showed methylcitrate and 3-hydroxyisovalerate to be only slightly elevated, but enzyme assay was diagnostic in amniocytes and may also be applied to chorionic villi. Given the complexity of the enzyme assay for HCS, molecular analysis affords advantages. Prenatal diagnosis of SLC5A6 dysfunction has never been performed, but there are special concerns, since unlike other forms of MCD, systemic biotin deficiency may be present prenatally in a biotin transporter defect and features such as structural brain abnormalities may reflect early effects on fetal development and organogenesis.

Treatment

Supplementation with pharmacologic doses of biotin is the cornerstone of therapy. Doses of 5–20 mg daily are generally used. In most cases, patients respond quickly, and most symptoms are reversible; when dosage is inadequate or is stopped due to error or noncompliance, symptoms may reappear. Currently, dosage of biotin in the range of 5–10 mg per day appears to be adequate and effective during childhood (Wolf 2010). Usually the dose is not changed, so with growth, the body mass-normalized dosage tends to decrease. To assure that the dosage is adequate and that the patient is in compliance, some have monitored urinary organic acids (3-hydroxyisovleric and 3-methylcrotonylglycine) and/or plasma acylcarnitines (C5OH-carnitine) (Wolf 2010). There is some concern arising from anecdotal reports of several females with biotinidase deficiency who have begun to lose hair when entering puberty, with reversal when the dose is increased to 15–20 mg from 10 mg.

Supplementation must be in the form of free biotin in biotinidase deficiency (as opposed to some formulations marketed in the health food industry which are derived from yeast extracts and are composed of biocytin). The dosage is determined only by the body's requirements for biotin, since the supplemented biotin does not interact directly with the biotinidase enzyme. In HCSD, however, there is a direct interaction at the biotin binding site of the enzyme, so the effectiveness may be determined by the concentration of biotin. A few cases have been encountered which have been incompletely responsive or unresponsive to biotin (Wilson et al. 2005; Santer et al. 2003), and those have proven to correspond to mutations outside of the biotin binding domain (exons 4–8), resulting in decreased Vmax. However, most cases of HCSD have been found to alterations in Km and relatively normal levels for Vmax, so those are all responsive to high doses of biotin (Bartlett et al. 1980).

Individuals with partial biotinidase deficiency (10%–30% of mean normal serum biotinidase activity) may not exhibit symptoms, but they are at risk of developing symptoms when stressed, such as during infection. Although it is uncommon for individuals with partial deficiency to develop symptoms, given the safety of biotin, it is recommended that they be treated with 1–10 mg oral biotin daily. Patients who are homozygous for the p.D444H biotinidase variant are expected to have approximately 45%–50% of mean normal serum biotinidase enzyme

activity (similar to heterozygotes for profound biotinidase deficiency mutations) and do not require biotin therapy (Wolf 2016).

As opposed to biotinidase and HCS deficiency, the rationale is not clear for using biotin to treat isolated deficiencies of the individual carboxylases (primary forms of propionic acidemia, 3-methylcrotonyl-CoA carboxylase deficiency, and pyruvate carboxylase deficiency). Since biotin is covalently bound to the apocarboxylases through the action of HCS, it is not easy to imagine a mutation in the apocarboxylase itself which would affect that process but which would also be remediated with higher biotin concentrations, since the reversible binding of biotin is supposed to be limited to its interaction with HCS. It is a common practice to conduct a trial of biotin in newly diagnosed cases of isolated carboxylase deficiency, and there is one mutation in methylcrotonyl-CoA carboxylase (R385S) which is reported to be biotin-responsive (Baumgartner et al. 2004), but a response to biotin supplementation is virtually never observed in isolated individual carboxylase deficiencies.

If there is an incomplete response to biotin in an individual case of HCSD, alteration of the diet may be indicated, to limit protein and provide supplements of carnitine (and possibly glycine) as appropriate, in the same manner that isolated carboxylase deficiencies are managed. In general, a complete response is expected with adequate amounts of biotin in most cases of HCSD and all cases of biotinidase deficiency; in such cases, dietary modification is not necessary.

Follow-Up and Monitoring

Ongoing monitoring is recommended, including annual ophthalmologic examination and auditory testing for profound biotinidase deficiency and every 2 years for partial biotinidase deficiency. The interval for follow-up in HCS deficiency should be individualized depending upon responsiveness to therapy.

Adequacy of treatment may be confirmed with periodic monitoring of urine organic acids, to look for an increase in 3-hydroxyisovalerate, 3-methylcrotonylglycine, and related metabolites. Even in cases where a complete response is documented, it is a common practice to monitor organic acids annually.

Raw eggs should be avoided because the undenatured egg white protein avidin tightly binds biotin and decreases its bioavailability. It has also been noted that there needs to be awareness that results of biotin-binding diagnostic bioassays can be compromised when patients are taking pharmacologic doses of biotin.

Contents

Summary

Thiamine or vitamin B1 is an essential water-soluble vitamin for which human body relies solely on external dietary intake. Once absorbed by two thiamine transporters, hTHTR1 and hTHTR2, the free thiamine is phosphorylated to the active form, thiamine pyrophosphate (TPP), by thiamine phosphokinase (TPK1). TPP acts as a cofactor for multiple enzymes in the cytosol, mitochondria, and peroxisomes. Thiamine-related diseases in humans are either primary or secondary. Four diseases were described so far related to primary thiamine metabolism dysfunction. Thiamine-responsive megaloblastic anemia syndrome or Rogers syndrome is caused by mutations in *SLC19A2*, encoding the first thiamine transporter and characterized by a triad of megaloblastic anemia, non-type 1 diabetes mellitus, and sensory neural hearing loss. Biotin-thiamine-responsive basal ganglia disease (BTBGD) is caused by mutations in the gene encoding for the second thiamine transporter (*SLC19A3*). The disease is classified into three phenotypes: classical childhood BTBGD, early infantile (< 3 months) Leigh-like/atypical infantile spasms, and adult Wernicke's-like encephalopathy. The subacute encephalopathy is usually provoked by a stressor. Thiamine pyrophosphokinase deficiency is caused by mutations in *TPK1* gene resulting in episodic encephalopathy with psychomotor developmental delay, ataxia, seizures, and dystonia. Mutations in *SLC25A19* are responsible for mitochondrial thiamine pyrophosphate carrier deficiency with two distinct phenotypes: Amish microcephaly and neuropathy and bilateral striatal necrosis. Thiamine metabolism disorders are considered generally among the treatable metabolic conditions. Clinicians should have a low threshold to start thiamine supplementation upon suspicion due to the huge difference in the outcome based on the time of treatment initiation.

Introduction

Thiamine or vitamin B1 is an essential water-soluble vitamin for which human body relies solely on external dietary intake. The main sources of dietary thiamin are meats, whole grains, nuts, and legumes. The limited stores and short half-life of thiamine necessitate a regular supply of the vitamin. The recommended daily intake of thiamine differs according to age, sex, pregnancy and lactation status, and carbohydrate intake. For females and males, it is recommended to take 1.1 mg/day and 1.2 mg/day, respectively (WHO and FAO 2005). As a hydrophilic micronutrient, thiamin is absorbed in the upper part of the small intestine in exchange with hydrogen at physiological concentrations. However, at high concentrations, it can be absorbed by passive diffusion (Brown 2014). The intestinal phosphatases convert the ingested phosphate attached thiamine to the free form, which is absorbed by two thiamine transporters, hTHTR1 and hTHTR2, encoded by *SLC19A2* and *SLC19A3* genes, respectively (Ganapathy et al. 2004). Once absorbed, the free thiamine is phosphorylated to the active form, thiamine pyrophosphate (TPP), by thiamine phosphokinase (TPK1). TPP acts as a cofactor for multiple enzymes in the cytosol, mitochondria, and peroxisomes. In the cytosol, TPP is required for the transketolase enzyme in the pentose phosphate pathway, to produce NADPH in addition to the ribose sugar needed for the DNA and RNA synthesis. Additionally, TPP is transported to the mitochondria through SLC25A19 (Kang and Samuels 2008), where it is utilized by pyruvate dehydrogenase complex to produce acetyl-CoA, which takes place in the citric acid cycle to produce energy. Furthermore, within the citric acid cycle, 2-oxoglutarate dehydrogenase complex converts alpha-ketoglutarate to succinate only in the presence of TPP as a cofactor. Branched-chain alpha-ketoacid dehydrogenase complex located in the inner membrane of the mitochondria catalyzes the branched chain amino acids, valine, leucine, and isoleucine, catabolism in the presence of TPP (Lonsdale 2006). The alpha oxidation of fatty acids takes place only in peroxisomes by the enzyme 2-hydroxy acyl-CoA lyase (HACL1), which requires TPP as a cofactor (Fraccascia et al. 2011).

Thiamine-related diseases in humans are either primary or secondary. Four diseases were described so far related to primary thiamine metabolism dysfunction, thiamine-responsive megaloblastic anemia syndrome or Rogers syndrome (SLC19A2), biotin-thiamine-responsive basal ganglia disease or thiamine metabolism dysfunction syndrome 2 (SLC19A3), thiamine pyrophosphokinase deficiency or thiamine metabolism dysfunction syndrome 5 (TPK1), and mitochondrial thiamine pyrophosphate carrier deficiency or bilateral striatal necrosis or Amish microcephaly (SLD25A19). Secondary causes of thiamine disorders are related to the nutritional deficiency of thiamine like beriberi and Wernicke's encephalopathy.

Thiamine-responsive megaloblastic anemia (TRMA) syndrome or Rogers syndrome is caused by homozygous or compound heterozygous mutations in *SLC19A2*, encoding the first thiamine transporter. The classic triad of the disease since its first description (Porter et al. 1969) includes megaloblastic anemia, non-type 1 diabetes mellitus, and sensory neural hearing loss. The hTHTR1 is the sole thiamine transporter in the marrow, beta cells of the pancreas, and the cochlear inner hair cells, which might explain the cardinal features of the disease (Bergmann et al. 2009). The age of onset of the symptoms ranges from infancy to adulthood, noting that deafness usually starts at a later age. Other reported associated symptoms include cardiac abnormalities like arrhythmia, atrial and ventricular septal defects, visual impairments particularly optic nerve atrophy and retinal dystrophy, neurological symptoms like seizures, and stroke-like symptoms. Short stature was also reported in multiple cases (Bergmann et al. 2009; Ricketts et al. 2006). The thiamine level can be normal or slightly reduced. Additionally, patients do not manifest lactic acidosis or organic aciduria (Ortigoza Escobar and Duenas 2016).

The dysfunction of the second thiamine transporter (hTHTR2) encoded by *SLC19A3* causes biotin-thiamine-responsive basal ganglia disease (BTBGD) or thiamine metabolism dysfunction syndrome type 2. The disease was first described by Ozand et al. in 1998, (Ozand et al. 1998) who reported ten cases mostly from Saudi Arabia presented with subacute encephalopathy and improved on biotin supplementation. Thereafter, more cases were reported, and the disease phenotypes were further delineated and classified into three main subtypes; classical childhood BTBGD, early infantile (<3 months) Leigh-like/atypical infantile spasms, and adult Wernicke's-like encephalopathy (Alfadhel and Tabarki 2018). The patients with classical phenotype present with subacute encephalopathy, usually triggered by a stressor like fever, vaccine, or trauma, with confusion, dysarthria and dysphagia, supranuclear facial nerve palsy, seizures, and external ophthalmoplegia, progressing to severe cogwheel rigidity, dystonia, and quadriparesis or even death if not treated. The second phenotype presents in early infantile life either in the form of Leigh-like syndrome with poor feeding, encephalopathy, and severe lactic acidosis (Perez-Duenas et al. 2013) or as atypical infantile spasm with poor outcome (Yamada et al. 2010). The third adult Wernicke's-like encephalopathy phenotype manifests with status epilepticus, diplopia, nystagmus, ptosis, ophthalmoplegia, and ataxia (Kono et al. 2009). The genotype-phenotype correlation is still not clear (Alfadhel and Tabarki 2018). Biochemically, patients may have lactic acidosis, elevated serum alanine, leucine, and isoleucine, in addition to the increase in the

excretion of α-Ketoglutarate in urine. Brain MRI findings vary according to the phenotype; bilateral symmetrical lesions in the basal ganglia in addition to the involvement of the thalami, cerebellum, and brain stem are characteristic in the classical phenotype (Kassem et al. 2014). In the early infantile phenotype, brain MRI may mimic the classical phenotype, but with restricted diffusion in various regions of the cortex and white matter (Yamada et al. 2010).

Thiamine pyrophosphokinase deficiency is caused by mutations in *TPK1* gene. This disease was the most recent thiamine metabolism disorder reported. Most of the patients present with episodic encephalopathy with psychomotor developmental delay, ataxia, seizures, and dystonia. So far, only nine patients were reported in the literature, only one of them presented with progressive (non-episodic) Leigh-like encephalopathy. The symptoms for most of the patients were provoked by a febrile illness. Investigations may show lactic acidosis and elevated α-Ketoglutarate in urine. The reported radiological findings in brain MRI include the involvement of the basal ganglia, thalamus in addition to white matter involvement in some patients (Banka et al. 2014; Fraser et al. 2014; Mayr et al. 2011).

Mutations in *SLC25A19* are responsible for mitochondrial thiamine pyrophosphate carrier deficiency with two distinct phenotypes: Amish microcephaly and neuropathy and bilateral striatal necrosis. Amish microcephaly was reported in Amish population with microcephaly evident as early as the 20th week of gestation. The patients showed severe frontal sloping and absent fontanels. Hepatomegaly, seizures, exaggerated startle reflex, and irritability were also reported. Most of the patients died in the first year of life. Biochemically, patients had lactic acidosis and marked elevation in α-Ketoglutarate in urine. Brain MRI might show an immature brain with absent gyri (lissencephaly) and cerebellar vermis hypoplasia. Viral infections were reported to provoke metabolic acidosis crises and worsening of the patients' conditions (Kelley et al. 2002). Sui, VM. et al. reported another case with similar genotype but with a more favorable outcome. They expanded the phenotype to include partial agenesis of the corpus callosum and neural tube defect (Siu et al. 2010). The second phenotype was reported in Arab patients by Spiegel et al. presented with episodic flaccid paralysis attacks starting at ages from 3 to 6 years. The attacks are usually preceded by a viral infection with near-complete recovery. However, patients suffered from slowly progressive polyneuropathy. The cognitive abilities of the patients were maintained. Brain MRI findings included bilateral caudate and putamen hyperintensity (Spiegel et al. 2009).

Nomenclature

No.	Disorder	Alternative name	Disease abbreviation	Gene symbol	Chromosomal location	Mode of inheritance	Affected protein	Disease OMIM#
31.1	Thiamine-responsive megaloblastic anemia	Rogers syndrome; thiamine metabolism dysfunction syndrome type 1	TRMA	*SLC19A2*	1q23.3	AR	THTR1 transporter	249270
31.2	Biotin-thiamine-responsive basal ganglia disease	Thiamine metabolism dysfunction syndrome type 2	BTBGD, THMD2, BBGD	*SLC19A3*	2q36.3	AR	THTR2 transporter	607483
31.3	Thiamine pyrophosphokinase deficiency	Thiamine metabolism dysfunction syndrome type 5	THMD5	*TPK1*	7q35	AR	Thiamine pyrophosphokinase	614458
31.4	Mitochondrial thiamine pyrophosphate carrier deficiency	Amish lethal microcephaly, thiamine metabolism dysfunction syndrome type 3 (severe)	MCPHA, THMD3	*SLC25A19*	17q25.1	AR	Mitochondrial thiamine pyrophosphate carrier	607196
		Bilateral striatal necrosis and progressive polyneuropathy, thiamine metabolism dysfunction syndrome type 4 (milder)	THMD4	*SLC25A19*	17q25.1	AR	Mitochondrial thiamine pyrophosphate carrier	613710

Metabolic Pathways

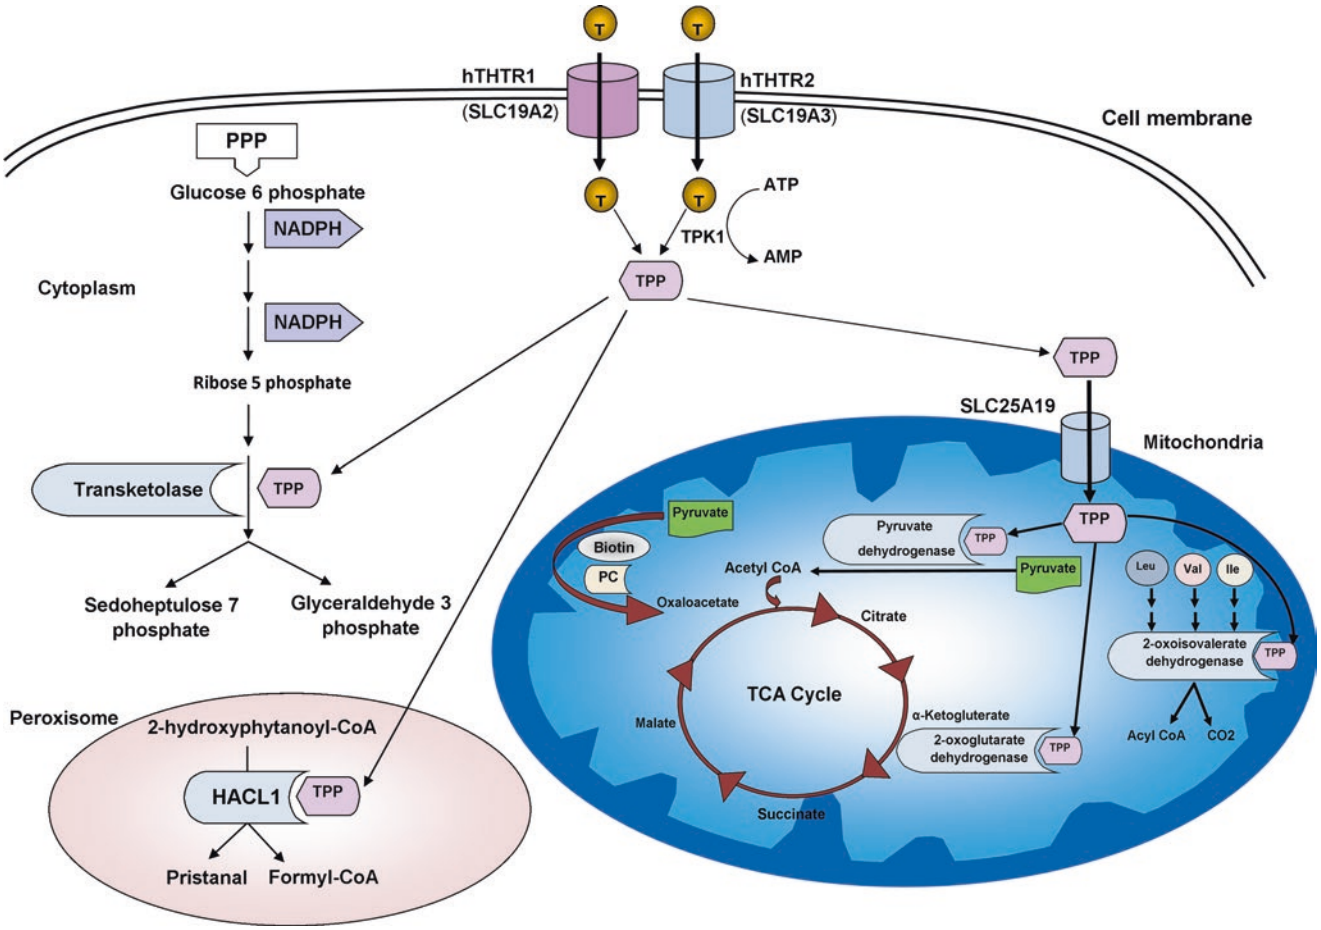

Fig. 31.1 Thiamine enters the cells through two transporters (hTHTR1 and hTHTR2). In the cytoplasm, thiamine undergoes phosphorylation to produce the active form (thiamine pyrophosphate (TPP)) by thiamine pyrophosphate kinase (TPK1). TPP is transported to the mitochondria by thiamine pyrophosphate carrier encoded by *SLC25A19*, where it acts as a cofactor for three main enzymes; pyruvate dehydrogenase, 2-oxoglutarate dehydrogenase (α ketoglutarate dehydrogenase), and 2-oxoisovalerate dehydrogenase (α-ketoacid dehydrogenase). In the cytoplasm, TPP acts as a cofactor for transketolase in the pentose phosphate pathway (PPP). In the peroxisomes, TPP acts as a cofactor with 2-hydroxy acyl-CoA lyase (HACL1) in the α-oxidation of fatty acids like phytanic acid

Diagnostic Flowchart

Molecular investigations are the mainstay in diagnosing thiamine metabolism disorders as the signs and symptoms are general and may not give a clue for the diagnosis. TRMA could be an exception, where the presentation with the classic triad of the syndrome might ease reaching the diagnosis. Although the phenotypes of BTBGD were described thoroughly in the literature, the unspecific presenting symptoms, which might mimic other diseases including mitochondrial diseases, and the lack of specific biomarkers, make the molecular test as the best initial diagnostic tool. The lactic acidosis and the elevation of the urine alpha ketoglutarate are not specific nor consistent in all patients with TPK1 deficiency and mitochondrial thiamine pyrophosphate carrier deficiency. However, the presence of marked microcephaly in addition to the biochemical findings should raise the suspicion of SLC25A19 gene mutation. Combining the clinical presentations, biochemical findings and the brain MRI could narrow the differential diagnosis.

Prenatal Diagnosis Table

In families with diagnosed patients, it is highly recommended to go for prenatal genetic testing in each pregnancy. No other prenatal tests or biomarkers could confirm the diagnosis of any thiamine metabolism disorder.

Treatment Summary

Given the fact that thiamine metabolism disorders are considered generally among the treatable metabolic conditions, clinicians should have a low threshold to start thiamine supplementation upon suspicion due to the huge difference in the outcome based on the time of treatment initiation, in addition to the safety of the medication (thiamine) in all age groups, as there were no significant adverse effects reported so far (Ortigoza-Escobar et al. 2016).

Thiamine supplementation was proven to improve the clinical features of TRMA patients. A prompt hematological

response was observed after thiamine supplementation mainly in thrombocytes and neutropenia; however, the sideroblasts and macrocytic anemia may persist. The need for insulin is reduced after thiamine treatment, and some patients were successfully off insulin. However, in the adolescence, they may develop insulin-dependent diabetes. On the other hand, thiamine did not improve the hearing loss, and the patients may benefit from cochlear implant. The thiamine dose for TRMA ranges from 1 to 4 mg/kg/day (Porter et al. 1969; Bergmann et al. 2009; Ricketts et al. 2006; Ortigoza-Escobar et al. 2016).

BTBGD patients usually recover immediately after thiamine and biotin supplementation; however, the level of neurological sequelae depends on the time of treatment initiation. It is recommended to give biotin and thiamine supplements for life as the discontinuation of the treatment might result in the recurrence of the encephalopathy and neurological deficit. The exact role of biotin in the management is still not fully understood; however, it might improve the expression of hTHTR2 and may bypass the oxaloacetate supply for the citric acid cycle through the pyruvate carboxylase (Alfadhel and Tabarki 2018; Ortigoza-Escobar et al. 2016). It is recommended to use biotin as an adjunct treatment with thiamine, which is considered the main treatment for this disease. The recommended doses of biotin range from 5 to 10 mg/kg/day and thiamine 10 to 40 mg/kg/day (Tabarki et al. 2015).

Most of the patients with TPK1 deficiency were treated using either thiamine alone or with other treatment modalities like mitochondrial cocktail and ketogenic diet. The thiamine doses used ranged from 100 up to 500 mg per day. Significant improvements were observed on the treated patients particularly the early diagnosed and treated patients. However, there was a limited benefit for late diagnosed patients (Banka et al. 2014; Fraser et al. 2014; Mayr et al. 2011). Banka et al. used the ketogenic diet for one of their patients before adding the thiamine, which resulted in severe metabolic acidosis and serious consequences on the patient. Hence they recommended not to use the ketogenic diet alone for TPK1 deficiency patients (Banka et al. 2014).

The first reported cases of Amish microcephaly did not receive any management and died early (Kelley et al. 2002). On the other hand, the case reported by Sui et al. was managed with low-protein, high-fat diet in addition to a vitamin cocktail including thiamin 50 mg per day, which resulted in resolving the lactic acidosis and improvement of the patient's condition (Siu et al. 2010). The polyneuropathy phenotype was managed by Spiegel et al. using high thiamine doses, which were not expected to improve the neurological impairment of the patients; however, it hopefully might prevent future deterioration (Spiegel et al. 2009).

Follow-Up and Monitoring

TRMA patients need annual monitoring for the complete blood count with differential and reticulocytes count. In addition to serum glucose and the glycosylated hemoglobin, hearing assessment, ophthalmology evaluation, and cardiac evaluation are also recommended.

A regular follow-up for BTBGD patients to monitor the compliance of treatment and to monitor any progression of the neurological symptoms. The prognosis depends on the age of onset and the age of establishing the diagnosis, the age of initiating the treatment, and the nature of the mutation.

The literature lacks long-term follow-up data for patients with TPK1 deficiency and mitochondrial thiamine pyrophosphate carrier deficiency (SLC25A19). However, it is recommended to keep all the patients on thiamine supplementation and to monitor the patients closely for any neurological deterioration. Additionally, serum lactic acid level and urine alpha ketoglutarate level urine should be monitored.

Disorders of Riboflavin Metabolism

32

Christine Vianey-Saban, Cécile Acquaviva,
and Annet M. Bosch

Contents

Summary

Riboflavin or vitamin B2, a water-soluble vitamin supplied by dairy products, is the precursor of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). FAD is the essential cofactor for the two electron transporters Electron Transfer Flavoprotein (ETF) and ETF-ubiQuinone Oxidoreductase (ETF-QO) involved in multiple acyl-CoA dehydrogenase deficiency (MADD). A genetic defect in ETF or in ETF-QO results in an impairment of mitochondrial fatty acid oxidation, branched-chain amino acids, lysine, and choline metabolisms. The clinical phenotype of MADD patients is highly variable, ranging from severe neonatal non-ketotic hypoglycaemia, cardiomyopathy, metabolic acidosis, sometimes associated with congenital abnormalities and a poor prognosis despite dietary and 3-hydroxybutyrate treatment, to muscle weakness or exercise intolerance in adulthood, which responds well to riboflavin.

FAD and FMN are the cofactors for at least 80 enzymes. Dietary depletion of riboflavin is rare in developed countries. The intestinal absorption and the uptake of riboflavin by the different organs are mediated by three riboflavin transporters: RFVT1 (*SLC52A1* gene), RFVT2 (*SLC52A2* gene), and RFVT3 (*SLC52A3* gene). In the cytoplasmic compartment, the conversion of riboflavin into FMN and FAD is catalysed by riboflavin kinase and FAD synthase (*FLAD1* gene). The uptake of FAD in mitochondria is mediated by the mitochondrial FAD transporter (MFT, *SLC25A32* gene). Genetic defects of RFVT2 or RFVT3 cause Riboflavin Transporter Deficiencies (RTD) type 2 and 3, which were formerly known as Brown-Vialetto-van Laere or Fazio-Londe syndrome. RTD patients may present from infancy into adulthood with progressive cranial neuropathy, muscle weakness, (sensory) ataxia, and respiratory insufficiency. FAD synthase deficiency is associated either with an early-onset severe hypotonia of poor prognosis or with a mild phenotype with muscle weakness and exercise intolerance. MFT-deficient patients present with exercise intolerance, muscle weakness, and vomiting during exercise, starting in infancy or adolescence, leading to a more severe neuromuscular phenotype without treatment. High-dose oral riboflavin supplementation (minimum 20 mg/kg/day) is life-saving in RTD patients and has to be tried in patients with the severe form of FAD synthase deficiency. Patients with late-onset FAD synthase and MTF deficiency respond dramatically to lower riboflavin doses (3 mg/kg/day).

Introduction

Riboflavin or vitamin B2 is a water-soluble vitamin. Milk and dairy products make the greatest contribution of its intake in Western diets. Meat, fish, and green vegetables are also good sources. Unknown amounts are generated by intestinal bacteria. Recommended intakes range from 0.4 mg/day in infancy to 1.8 mg/day in adult females during lactation. Riboflavin is degraded by light but is relatively heat-stable. Biochemical signs of depletion arise within only a few days of dietary deprivation. Poor riboflavin status interferes with iron handling and contributes to anaemia when iron intakes are low. Riboflavin depletion has been described as a risk factor for cancer, cardiovascular disease, and neurodegeneration.

Riboflavin is the precursor of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). FAD is the essential cofactor for the two electron transporters Electron Transfer Flavoprotein (ETF) and Electron Transfer Flavoprotein-ubiQuinone Oxidoreductase (ETF-QO), involved in multiple acyl-CoA dehydrogenase deficiency (MADD). Eleven ETF-dependent dehydrogenases have been identified, and this concerns five different metabolisms: (1) fatty acid oxidation (very long-chain acyl-CoA dehydrogenase, VLCAD; long-chain acyl-CoA dehydrogenase, LCAD; medium-chain acyl-CoA dehydrogenase, MCAD; and short-chain acyl-CoA dehydrogenase, SCAD), (2) branched-chain amino acid metabolism (isovaleryl-CoA dehydrogenase, 2-methylbutyryl-CoA dehydrogenase, and isobutyryl-CoA dehydrogenase), (3) lysine and tryptophan metabolism (glutaryl-CoA dehydrogenase), (4) choline metabolism (sarcosine dehydrogenase and dimethylglycine dehydrogenase), and (5) D-2-hydroxyglutarate dehydrogenase.

FAD and FMN are the cofactors for at least 80 other enzymes called flavoproteins. The majority of human flavoproteins are mitochondrial oxidoreductases. A number of them are involved in the biosynthesis of other cofactors such as coenzyme-A, coenzyme-Q (ubiquinone), heme, and pyridoxal 5′-phosphate, highlighting the involvement of riboflavin in the metabolism of folate, cobalamins, and other vitamins. In the nucleus, FAD-dependent oxidases play some role in epigenic events, controlling the expression of genes involved in energy metabolism.

A small amount of riboflavin is present in food as free riboflavin: most is present as FAD, and a smaller amount occurs as FMN, both non-covalently bound to enzymes. To be absorbed FMN and FAD have to be hydrolysed to riboflavin by non-specific phosphatases in the brush border membranes of enterocytes. Absorption takes place mainly in the proximal small intestine and partly in colon via carrier-mediated processes. Three riboflavin transporters have been identified almost 10 years ago, belonging to the SLC52 family of solute carriers: riboflavin transporter 1 (RFVT1, *SLC52A1* gene, Yonezawa et al. 2008), riboflavin transporter 2 (RFVT2, *SLC52A2* gene, Yao et al. 2010), and riboflavin transporter 3 (RFVT3, *SLC52A3* gene, Yamamoto et al. 2009). RFVT1 is a high-affinity transporter, located in the plasma membrane, mainly expressed in the small intestine, placenta, and kidney, but ubiquitous. It could play an important role in the homeostasis of riboflavin. *SLC52A1* gene is highly conserved among species, so likely an important gene for survival. RFVT2 is ubiquitously expressed, especially in the brain and salivary glands, but also in the intestine and kidney. RFVT3 plays a major role in intestinal absorption of riboflavin. Located at the apical membrane domain, it is highly expressed in ileum and jejunum, stomach, testis, pancreas, and prostate. It is efficient in acidic conditions and saturable but inhibited by FMN and FAD. Following intesti-

nal absorption, riboflavin may enter blood circulation as the free form or as FMN. Free riboflavin is transported in the plasma bound to albumin and some immunoglobulins, but most endogenous blood flavins are located in erythrocytes, mainly as enzyme-bound FAD (or FMN). That is why measurement of blood flavins has to be performed in whole blood. In tissues, most riboflavin is enzyme bound, such as FAD bound to succinate dehydrogenase.

The intracellular metabolism of riboflavin is not fully elucidated. The uptake of riboflavin by the different organs and tissues is mediated by all RFVTs, but not the uptake of FMN and FAD (Jin et al. 2017). In the cytoplasmic compartment, the conversion of riboflavin into its active cofactors FMN and FAD is catalysed by riboflavin kinase and FAD synthase. Riboflavin kinase also called flavokinase (EC 2.7.1.26, *RFK* gene) is a cytosolic enzyme which catalyses the phosphorylation of riboflavin to form flavin mononucleotide (FMN) in the presence of ATP and Mg(2+). FAD synthase FADS (EC 2.7.7.2, *FLAD1* gene) converts FMN to FAD in an ATP-dependent reaction. Two different isoforms have been identified: hFADS1, localised in mitochondria, and hFADS2, a soluble cytosolic isoform. FAD synthase is organised in two domains: the phosphoadenosine-5′-phosphosulfate (PAPS) reductase domain, also called FADS domain, which catalyses the synthesis of FAD and acts as a FAD chaperone for the delivery of FAD for the synthesis of flavoproteins, and the molybdenum-pterin-binding (MPTb) domain, which has a Co^{++} dependent FAD hydrolytic activity (Gianscapero et al. 2015). The uptake of FAD in mitochondria is mediated by the mitochondrial FAD transporter (MFT) (Spaan et al. 2005), previously identified as the human mitochondrial folate transporter: it facilitates the transport of FAD from the cytosol to the mitochondria or vice versa, therefore controlling the flavin homeostasis in the mitochondria. Little is known about the assembly of FAD (and FMN) to apoenzymes, the FAD cleavage and the flavoprotein turnover.

There is little or no storage of riboflavin in the body. Renal reabsorption, by possibly RFVT1 and RFVT2, is saturable. Any surplus is eliminated in urine, and this possibly explains why there is no toxicity to administrate high doses of riboflavin.

Multiple acyl-CoA dehydrogenase deficiency (MADD) has been identified more than 30 years ago (Frerman and Goodman 1985). It is sometimes called glutaric aciduria type 2, but this denomination is misleading, since glutaric acid excretion can be normal and therefore has to be abandoned. MADD is caused by a deficiency of either ETF (*ETFA* or *ETFB* genes) or of ETF-QO (*ETFDH* gene). Conversely, the inborn errors of riboflavin transport and intracellular metabolism have been identified much more recently. The association of Brown-Vialetto-Van Laere syndrome and Fazio Londe syndrome with RFVT2 and RFVT3 deficiency has been reported in 2010 (Green et al. 2010; Bosch et al. 2011), while deficiency of FAD synthase and of the mitochondrial FAD transporter (MFT) have been reported in 2016 (Olsen et al. 2016; Schiff et al. 2016). Regarding RFVT1 deficiency, two case reports were published of transient riboflavin deficiency in infants of mothers who harboured only one heterozygous mutation, in one case in combination with a maternal dietary riboflavin deficiency (Ho et al. 2011; Mosegaard et al. 2017) that can cause a transient MADD.

Multiple Acyl-CoA Dehydrogenase Deficiency

More than 500 patients have been reported with heterogeneous clinical presentation and have been classified into three groups: (1) severe neonatal form, associated with congenital abnormalities (polycystic kidneys, midface hypoplasia), (2) severe neonatal form without congenital abnormalities, both with a poor prognosis, and (3) late-onset milder phenotype. Neonates usually present with severe metabolic acidosis, hypoketotic hypoglycaemia, hyperammonaemia, hypotonia, and frequently cardiomyopathy. They usually have an unpleasant odour of sweaty feet, similar to that of isovaleric acidaemia. The prognosis is poor, leading to early death. Neonatal form can be due to mutations in *ETFA*, *ETFB*, or *ETFDH* genes. Milder phenotypes can present at any age. In infancy, symptoms are mainly acute decompensation with hypoglycaemia and acidosis triggered by fast or infections, and possibly cardiomyopathy, while in adolescence and adulthood, symptoms are chronic, dominated by exercise intolerance and muscle weakness (Grünert 2014; Béhin et al. 2016). The majority of late-onset MADD patients responds well to riboflavin and harbour mutations in the *ETFDH* gene. All patients present with an abnormal plasma/DBS acylcarnitine profile, with an increase in all chain-length acylcarnitines (C4 to C18) with or without glutarylcarnitine (C5DC), and an abnormal urinary organic acid profile, characterised by an increase of ethylmalonic acid (EMA), 2-hydroxyglutaric acid, glutaric acid, and acylglycine conjugates. In late-onset MADD, the biochemical abnormalities can be less obvious and normalise with riboflavin supplementation. When performed, most patients present a massive lipid storage myopathy.

Riboflavin Transporter Deficiency

The phenotype was previously known as the "Brown-Vialetto-van Laere syndrome" or "Fazio-Londe syndrome" which may have been a more heterogeneous group of patients before the possibility of a molecular diagnosis (Bosch et al. 2012). Patients may present at all ages. The youngest patients present within the first year of life, usually with a rapidly progressive life-threatening hypotonia, muscular weakness, bulbar palsy, and respiratory insufficiency resulting from muscle weakness and diaphragmatic paralysis. At older ages, symptoms of sensorimotor axial neuropathy and hearing loss are more prominent. Approximately 50% of patients demonstrate an abnormal plasma/DBS acylcarnitine profile when untreated, with an increase in short-, medium-, and long-chain acylcarnitines. Urinary organic acid profile may demonstrate increased ethylmalonic acid (EMA). Flavins in blood may be normal or low. Untreated patients all rapidly deteriorate with a limited life expectancy. Oral supplementation of riboflavin is life-saving, and most patients demonstrate striking improvement, while a minority only shows stabilisation of symptoms. Patients with riboflavin transporter deficiency type 2 (RFVT2) and type 3 (RFVT3) are reported to have similar phenotypes (Jaeger and Bosch 2016; O'Callaghan et al. 2019).

Disorders of Intracellular Riboflavin Metabolism

FAD Synthase Deficiency

Patients with FAD synthase deficiency present either an early-onset form with severe progressive generalised hypotonia in the neonatal period or early infancy, sometimes associated with cardiomyopathy, leading to respiratory failure or cardiac arrest and early death, or a late-onset form with exercise intolerance and muscle weakness in childhood or adolescence (Olsen et al. 2016; Auranen et al. 2017; Yıldız et al. 2018; García-Villoria et al. 2018; Muru et al. 2019). Conversely to transporter defects, no cranial and no peripheral neuropathy are present.

Although it was inconstant in one patient, all patients presented with abnormal plasma or dried blood spot (DBS) acylcarnitine profile, exhibiting an increase in short-, medium-, and long-chain acylcarnitines, like in MADD, even if this profile can be incomplete. Urinary organic acid profile was dominated by an increase in ethylmalonic acid (EMA), lactic acid, and, less constantly, glutaric acid, 2-hydroxyglutaric acid, and acylglycine derivatives. Increase of lactataemia and mild increase of CK, allowing differential diagnosis with congenital myopathies, were also reported. Blood flavin levels were decreased or normal. Interestingly, one patient with a severe phenotype was misdiagnosed as MCAD deficiency at newborn screening. Mutation analysis of the *FLAD1* gene (exome, gene panels, or Sanger sequencing) revealed that mutations in the FADS domain (FAD synthesis) are associated with the late-onset phenotype, while mutations in the MPTb domain (FAD cleavage) are associated with the severe early phenotype. When performed, a massive lipid storage myopathy, with faint SDH and/or COX staining, has been observed.

No clinical improvement was reported with riboflavin treatment in the early-onset form of the disease, although one patient presented a slight clinical improvement with high doses. This patient died of aspiration pneumonia (Yıldız et al. 2018). The prognosis is severe with death occurring before the first year of life. Conversely, the late-onset form is associated with a clear clinical improvement with low doses of riboflavin.

Mitochondrial FAD Transporter (MFT) Deficiency

The two published patients with MFT deficiency (Schiff et al. 2016; Hellebrekers et al. 2017) presented with exercise intolerance, muscle weakness, and vomiting during exercise, starting in infancy or adolescence, leading to a more severe neuromuscular phenotype with progressive dysarthria, swallowing difficulties, myoclonic jerks, and need of wheelchair around 50 years in one of them (Hellebrekers et al. 2017).

The acylcarnitine and organic acid profiles were "MADD-like", with additionally an increase of urinary dimethylglycine and sarcosine levels in one of them. Hyperlactataemia was also reported, but nothing is known about CK or flavin levels. The diagnosis has to be confirmed by mutation analysis of the *SLC25A32* gene. Both patients presented a massive lipid storage myopathy with ragged-red fibres, faint SDH, and/or COX staining and complex II deficiency (suggestive of mitochondrial myopathy) at muscle histology.

Treatment with low doses of riboflavin (30 mg/day and 3 mg/kg/day) resulted in a dramatic improvement of symptoms and a normalisation of biochemical biomarkers. Symptoms reappeared when B2 was stopped in one patient (Schiff et al. 2016).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Inheritance	Gene symbol	Chromosomal localisation	Affected protein	OMIM N°
32.1	Riboflavin transporter 2 deficiency	Brown-Vialetto-van Laere syndrome type 1	RFVT2 deficiency	AR	*SLC52A3*	20p13	Riboflavin transporter 2	613350
32.2	Riboflavin transporter 3 deficiency	Brown-Vialetto-van Laere syndrome type 2	RFVT3 deficiency	AR	*SLC52A2*	8q24.3	Riboflavin transporter 3	607882

Metabolic Pathways

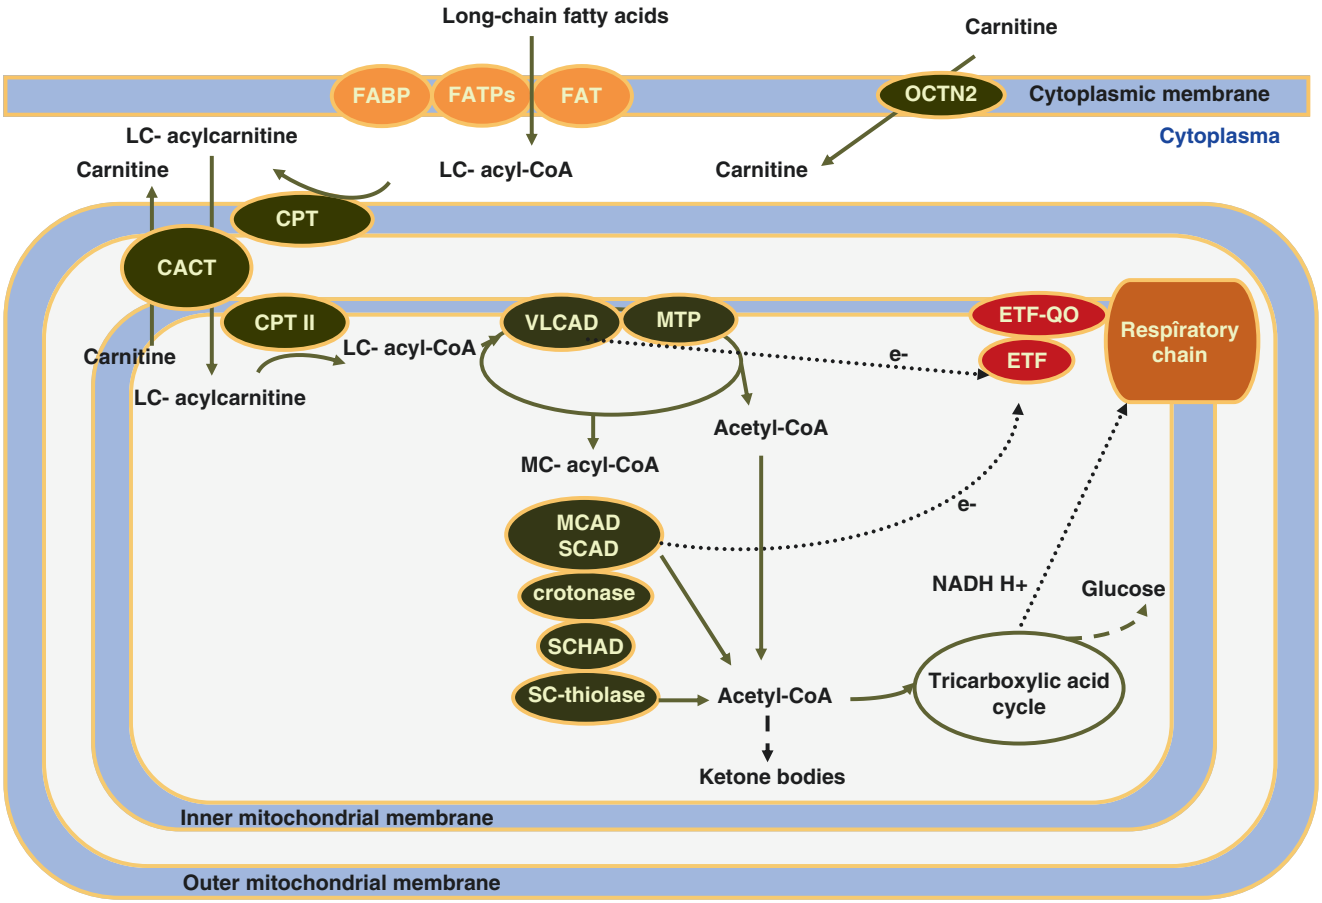

Fig. 32.1 Simplified scheme of mitochondrial fatty acid oxidation. ETF (Electron Transfer Flavoprotein) and ETF-QO (ETF-ubiQuinone Oxidoreductase) are the two electron transporters which transfer electrons from VLCAD (very long-chain acyl-CoA dehydrogenase), MCAD (medium-chain acyl-CoA dehydrogenase), and SCAD (short-chain acyl-CoA dehydrogenase) to coenzyme Q_{10} and then to complex II of the respiratory chain. ETF is a matrix soluble protein, while ETF-QO is linked to inner mitochondrial membrane

No signs and symptoms table has been issued for RFVT1 deficiency since the two described affected heterozygous mothers were asymptomatic and biochemical investigation was normal away from delivery.

Reference Values

Reference values for free carnitine and acylcarnitine species in plasma and dried blood spots are given in Chap. 5. Reference values for urinary organic acids are given in Chap. 4

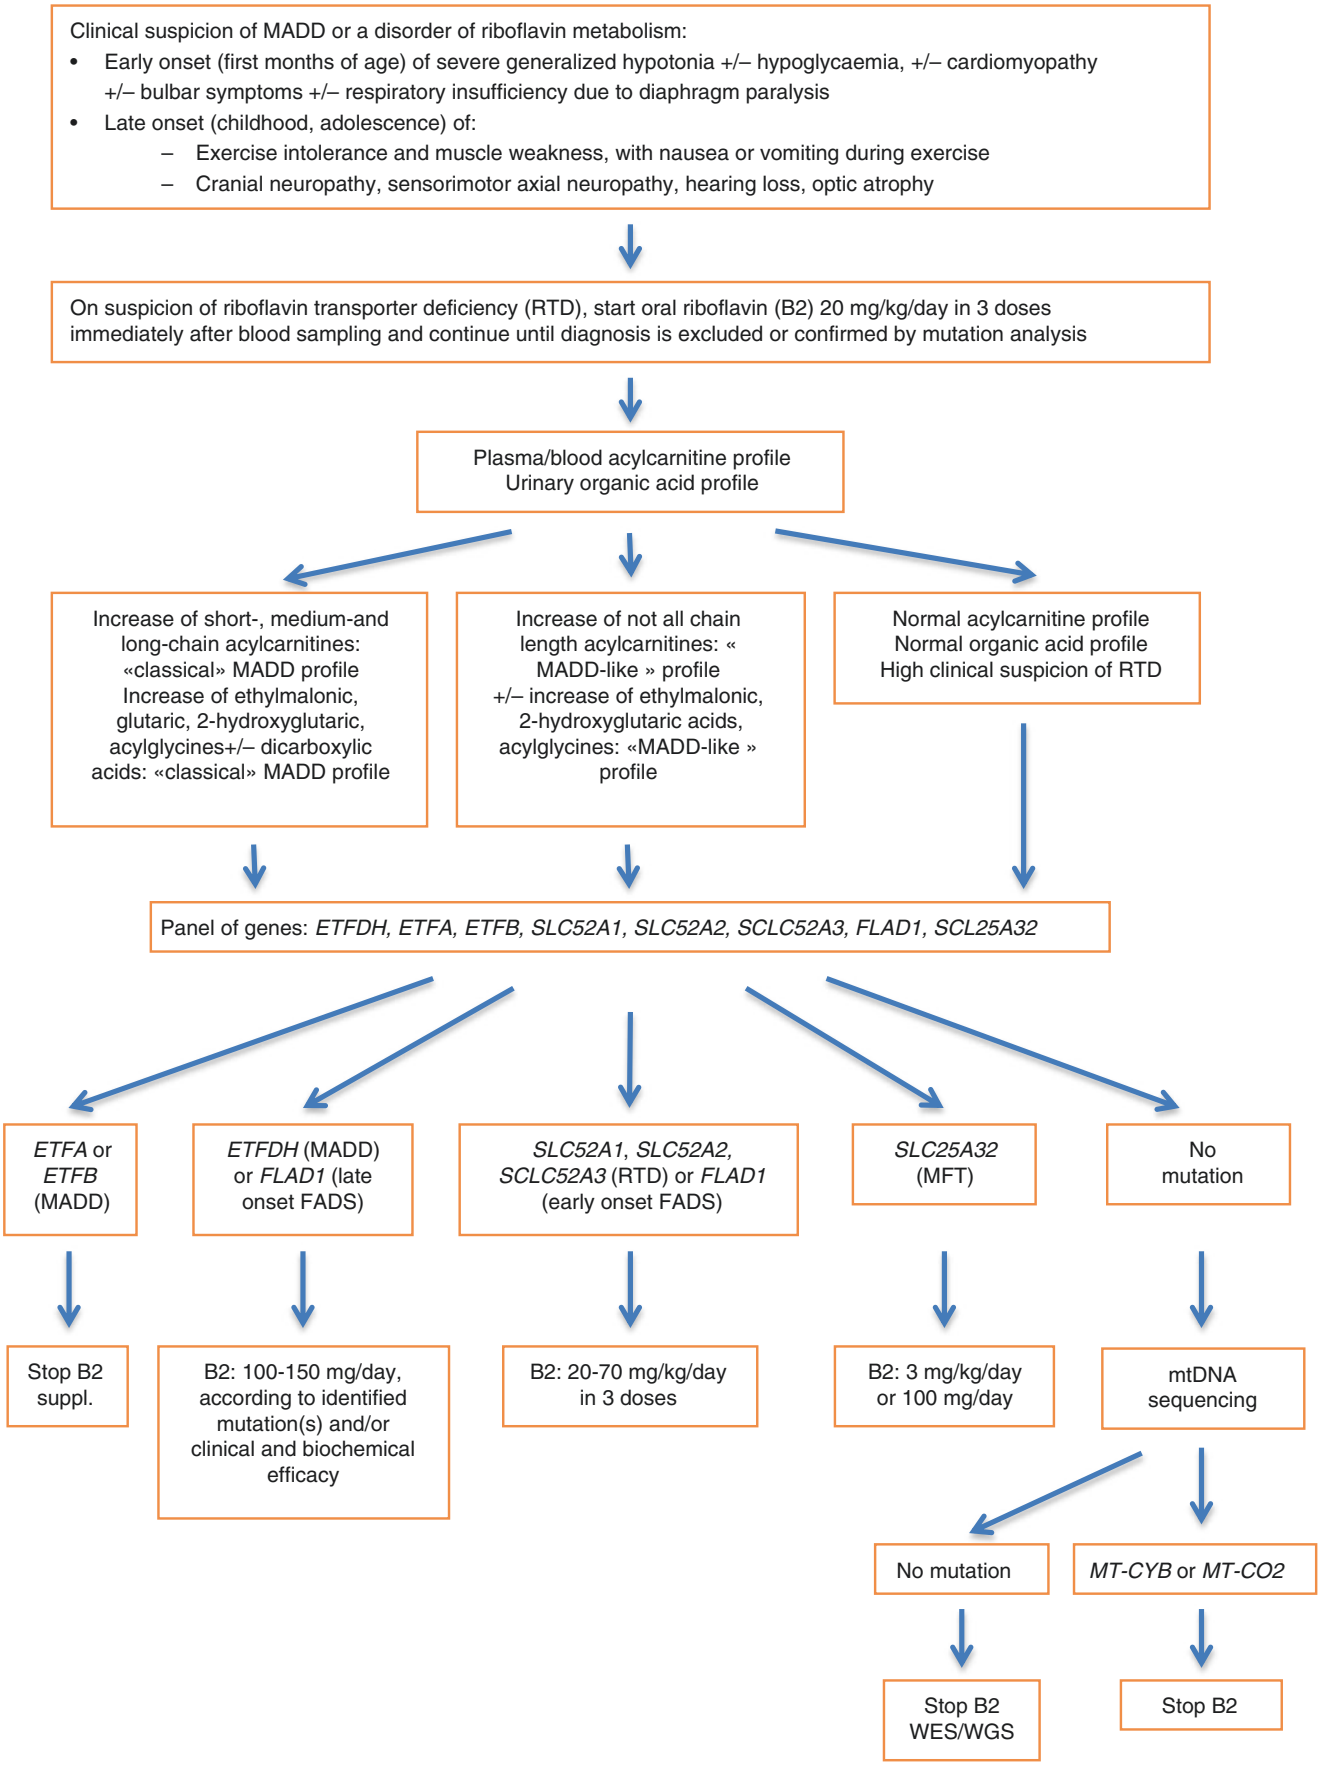
Compound	Plasma	Whole blood
Riboflavin	5–38 nmol/L	
FAD	57–170 nmol/L	174–471 nmol/L
FMN	4–14 nmol/L	
CK	♂ 46–171 U/L ♀ 34–145 U/L	

Pathological Values

Patients with MADD, FAD synthase, and MFT deficiency usually present with an abnormal plasma/DBS acylcarnitine profile, exhibiting an increase of all chain-length acylcarnitines (C4, C5, C6, C8, C10:1, C10, C12:1, C12, C14:1, C14, C16:1, C16, C18:1, C18) and, in the severe form of these diseases, glutarylcarnitine (C5DC), associated with a decrease in free carnitine levels. The concentrations of these acylcarnitines are highly variable and depend of the patient's status and of the severity of the disease. Their urinary organic acid profile is characterised by an increase of ethylmalonic acid, 2-hydroxyglutaric acid, and, most of the time but non constantly, glutaric acid, dicarboxylic acids, and acylglycine conjugates (isovalerylglycine, 2-methylbutyrylglycine, isobutyrylglycine, hexanoylglycine, suberylglycine). Plasma/DBS acylcarnitine and urinary organic acid profiles usually normalise after riboflavin supplementation, except for the severe form of MADD and FAD synthase. An increase of CK is often reported in acute episodes, as well as an increase of transaminases.

In RTD, the acylcarnitine profile and the urinary organic acid profile can be "MADD-like" or normal, and flavin levels can be decreased or normal. That is why the diagnosis relies on genetic studies.

Diagnostic Flowchart



This diagnosis flowchart shows how to reach a diagnosis. However, if the clinical picture is highly suggestive of MADD or of an inborn error of riboflavin metabolism, an **immediate treatment** with riboflavin has to be tried, directly after taking the first biological samples: minimum dose is 20 mg/kg/day in three doses in patients with neurological symptoms, while it can be lower (3 mg/kg/day) in patients with only muscular symptoms.

B2 Riboflavin, *FADS* FAD synthase, *MADD* Multiple acyl-CoA dehydrogenase deficiency, *MFT* Mitochondrial FAD transporter, *mtDNA* Mitochondrial DNA, *RTD* Riboflavin transporter defects, *WES* Whole exome sequencing, *WGS* Whole genome sequencing.

Specimen Collection

Test	Precondition	Material	Handling	Pitfalls
Acylcarnitines	During an acute episode (if any) Fasting state Before B2 supplementation	Plasma Dried blood spot (DBS)	Frozen (−20 °C): Plasma Room temperature: DBS	False negative: Possible normal profile in RTD, lack of diagnostic acylcarnitines when severe secondary carnitine deficiency False positive: Anoxia can induce a "MADD-like" profile
Carnitine	During an acute episode (if any) Fasting state Before B2 supplementation	Plasma Dried blood spot (DBS)	Frozen (−20 °C): Plasma Room temperature: DBS	False negative: Frequently normal in RTD
Organic acids	During an acute episode (if any) First morning urine sample, preferably Before B2 supplementation	Spot urine (no addition of preservatives)	Frozen (−20 °C)	False negative: Possible normal profile in RTD. Late-onset MADD and FAD synthase deficiency: Increase of only ethylmalonic and 2-hydroxyglutaric acids
Flavins (riboflavin, FAD, FMN)	Before B2 supplementation	EDTA plasma EDTA whole blood	Frozen (−20 °C) and protected from light: Plasma and whole blood	False negative: Can be normal in all disorders False positive: Decrease due to light degradation
Functional tests in lymphocytes	Before B2 supplementation	EDTA blood	Don't centrifuge Room temperature Has to reach the lab within 48 h	False negative: Can be normal in all disorders
Functional tests in cultured fibroblasts	–	Skin biopsy	Room temperature in culture medium	Cell culture medium depleted in riboflavin is necessary for RR-MADD and IEM of riboflavin metabolism
Molecular analysis	–	EDTA blood	Room temperature	Identification of only one heterozygous mutation does not rule out a diagnosis

Prenatal Diagnosis

Prenatal diagnosis is available for MADD and disorders of riboflavin metabolism. Mutation analysis in DNA extracted from chorionic villi or from amniocytes is the more reliable technique, provided that the index case's genotype has been determined. RTD deficiency can be diagnosed by mutation analysis only. Quantification of acylcarnitines and acylglycines in the supernatant of amniotic fluid can be used when an abnormal plasma acylcarnitine profile and an abnormal urinary organic acid profile have been observed in the index case, but only abnormal levels of short- and medium-chain acylcarnitines can be detected, since long-chain acylcarnitines are not excreted in urine and therefore are absent from amniotic fluid. Functional tests, such acylcarnitine profiling or fatty acid flux in cultured chorionic villi cells or amniocytes, can only be used in severe form of MADD.

Disorder	Prenatal diagnosis suggested	Reliability of mutation analysis	Reliability of acylcarnitines/acylglycines quantification in AF	Reliability of functional tests	Remarks
RFVT1	–	+	–	–	No patients with two mutations of *SLC52A1* gene have been identified. Heterozygous patients are asymptomatic
RFVT2	+	+	–	–	
RFVT3	+	+	–	–	
FADS early-onset form	+	+	±	–	Severe outcome
FADS late-onset form	–	+	–	–	Favourable outcome with riboflavin supplementation
MFT	–	+	±	–	Favourable outcome with riboflavin supplementation
MADD (ETF or ETF-QO) early-onset form	+	+	+	+	Severe outcome
MADD (ETF or ETF-QO) late onset form	±	+	±	±	Depend of the severity of the clinical phenotype
RR-MADD	–	+	–	–	Favourable outcome with riboflavin supplementation

DNA Testing

Multiple acyl-CoA dehydrogenase deficiency and all disorders in the transport or metabolism of riboflavin are inherited in an autosomal recessive pattern. Molecular genetic testing of all genes involved in these disorders can be performed in genomic DNA (from blood or any tissue) by Sanger methods or by MPS (massive parallel sequencing). No prevalent mutations have been identified, except three common riboflavin-responsive mutations in the *ETFDH* gene mainly found in the Chinese and Taiwanese population: c.250G>A; c.770G>A; and c.1227A>C (Xi et al. 2014).

Treatment

Summary

Early-onset forms of MADD are treated with an emergency regime, avoidance of fasting, and a diet restricted in fat. Late-onset forms of MADD may respond to riboflavin supplementation (3 mg/kg/day or 100–150 mg/day) (Grünert 2014).

On suspicion of RTD, supplementation of high-dose oral riboflavin (20–70 mg/kg/day in three doses) must be started immediately without awaiting a final diagnosis. Clinical improvement is observed in the majority of RTD patients, but sometimes it is not observed for months following the beginning of riboflavin supplementation. Supplementation with oral riboflavin has to be considered in all other disorders of riboflavin metabolism.

Emergency Treatment

Emergency treatment for early-onset forms of MADD is high-dose glucose infusion, in association with insulin when high doses of glucose are required, and carnitine supplementation in case of carnitine depletion. Late-onset MADD may demonstrate clinical improvement with riboflavin supplementation (Grünert 2014).

Immediate start of oral riboflavin supplementation on suspicion of RTD is life-saving, and supplementation needs to be continued until the diagnosis is confirmed or excluded by genetic analysis (O'Callaghan et al. 2019).

In FAD synthase deficiency, especially late onset, patients demonstrate riboflavin responsivity; however riboflavin supplementation should initially be started in all patients (Olsen et al. 2016).

In mitochondrial FAD transporter deficiency, riboflavin supplementation was highly effective in the two described patients (Schiff et al. 2016; Hellebrekers et al. 2017).

Standard Treatment

Early-onset forms of MADD are treated with an emergency regime, avoidance of fasting, and a diet restricted in fat. Due to the accumulation of carnitine conjugates, MADD patients are prone to carnitine deficiency, which may require oral carnitine supplementation (Grünert 2014).

Recommended doses of riboflavin supplementation depend of the disease. There is no literature report on effective dosing of riboflavin in MADD. Morris and Spiekekotter (2011) propose 100 mg/day, while Zschocke and Hoffmann

(2011) recommend 150 mg/day in the Vademecum Metabolicum. RTD patients have demonstrated strong clinical improvements on doses of 10–70 mg/kg/day in three doses (Jaeger and Bosch 2016). There is no evidence for riboflavin dosing in FAD synthase deficiency, but a high dose seems advisable. In two patients with mitochondrial FAD transporter deficiency, a striking effect of riboflavin supplementation has been reported with doses of 30 mg/day and 3 mg/kg/day, respectively.

Experimental Treatment

Long-term treatment of severe MADD patients with 3-hydroxybutyrate has been proposed, with clinical improvement in 70% of patients (reviewed by van Rijt et al. 2020). Prescribed doses ranged between 100 and 2600 mg/kg/day, divided in one to six daily doses. Cornelius et al. (2014) reported that CoQ_{10} treatment can decrease ROS production in fibroblasts from RR-MADD patients and may relieve oxidative stress. This suggests that late-onset MADD patients could benefit from a combined treatment of riboflavin and CoQ_{10}.

For RTD esterified derivatives of riboflavin may increase bioavailability (Manole et al. 2017). The effects of CoQ_{10} in RTD are presently unclear.

Follow-Up and Monitoring

The biological monitoring of patients with MADD, FAD synthase, and MFT deficiency usually associates CK, transaminases, plasma/blood acylcarnitine profile including free and total carnitine levels, and eventually urinary organic acids. Normalisation of these parameters after riboflavin supplementation is an indication of the efficacy of this treatment. General indices of nutrition in patients on a restricted diet (severe MADD), echocardiogram, liver ultrasound, and eventually nerve conduction studies should also be monitored. In adults, the monitoring is usually on an annual basis, whereas it has to be more frequent in younger patients.

In RTD patients with abnormal plasma/blood acylcarnitine profiles, or urinary organic acid profiles, or abnormal flavins, a rapid normalisation is seen after supplementation of riboflavin, and these parameters may be used for monitoring. Clinical follow-up by a neurologist, ophthalmologist, and ENT specialist is warranted. In case of hearing loss, cochlear implantates are reported to be effective (Anderson et al. 2019).

Disorders of Niacin, NAD, and Pantothenate Metabolism

33

Anna Ardissone, Daria Diodato, Ivano Di Meo, and Valeria Tiranti

Contents

Summary

Niacin or vitamin B3 and pantothenate or vitamin B5 are water-soluble vitamins acting as precursors of nicotinamide adenine dinucleotide (NAD) and Coenzyme A (CoA), respectively, two fundamental elements for every cell.

The niacin-derived coenzymes NAD and NADP carry out similar oxidation and reduction reactions: NADP is mainly involved in biosynthetic pathways, while NAD, in its reduced form NADH, supplies the mitochondrial electron transport chain with reducing equivalent and, in doing so, propels the oxidative phosphorylation.

Pantothenate-derived CoA is a crucial molecule for hundred of metabolic reactions, including, among others, the Krebs cycle and the oxidation and synthesis of fatty acids. Both coenzymes play crucial roles not only in metabolism and in maintaining mitochondrial functionality but also in complex mechanisms of signalling. Moreover, by modulating deacetylation (NAD) and acetylation (CoA) of histones and transcription factors, these coenzymes also regulate gene expression.

NAD biosynthetic pathways originate from four major molecules: (i) the amino acid tryptophan (Trp), (ii) nicotinic acid (NA), (iii) nicotinamide (NAM), and (iv) nicotinamide riboside (NR). Nicotinamide mononucleotide (NMN) generated from NAM and NR can also be a source of NAD.

CoA is instead synthesized through the sequential activity of five enzymatic reactions belonging to the same

metabolic pathway, in which pantothenate is the starting molecule.

Considering the vital roles of NAD and CoA, their deficiency either due to shortage of vitamins in the diet or to genetic causes impinging on the biochemical pathways responsible for their production and proper maintenance could give rise to human diseases.

We will discuss disorders of niacin and NAD separately from disorders of pantothenate for the sake of clarity even if it is clear that NAD and CoA play convergent roles in energetic metabolism and regulate common pathways.

Introduction

Disorders of Niacin and NAD Metabolism

Niacin is the term that defines both NAM and NA and is necessary to synthesize the two coenzymes NAD and NADP.

Tryptophan, NA, NAM, and NR are used to generate NAD through different metabolic pathways (Fig. 33.1): NAD synthesized from NA is known as Preiss-Handler pathway; tryptophan is the starting amino acid in the de novo synthesis (kynurenine pathway); the salvage pathway converts NR and NAM through two enzymatic steps into nicotinamide mononucleotide (NMN).

The best-known disorder due to niacin deficiency is pellagra that was endemic a century ago in rural areas and nowadays is present, in developed countries, as secondary effect to other disorders such as tuberculosis, malabsorption, and alcoholism. Distinctive features of pellagra include diarrhoea, peculiar pigmented skin rash, and dementia, which can be reversed by NAM and NA administration.

Disorders of niacin and NAD metabolism are also due to genetic causes affecting different genes coding for enzymes designed to synthesize NAD, synthesize and modify NADP, remove toxic metabolites, and transport tryptophan.

These disorders mainly impair brain functions and, in some instances, give rise to pellagra-like clinical manifestations.

Deficiency of nicotinamide mononucleotide adenylyl transferase 1 (*NMNAT1*), a central enzyme in the Preiss-Handler NAD biosynthetic pathway, catalysing the condensation of nicotinic acid mononucleotide (NaMN) with AMP (Zhang et al., 2003), leads to Leber congenital amaurosis (LCA), an early-onset neurodegenerative condition of the human retina causing congenital blindness (Koenekoop et al., 2012).

The mitochondrial kinase coded by the *NADK2* gene synthesizes NADP+ (Ohashi et al., 2012). Exome sequence investigation revealed the presence of a nonsense mutation in this gene in one subject with deficiency of 2,4-dienoyl-CoA reductase (DECR; OMIM#616034) (Houten et al., 2014) and early-onset encephalopathy, developmental delay, movement disorder, lactic acidosis, and premature death. Mitochondria derived from patient fibroblasts displayed reduction of NADP(H) level, and real-time measurement of oxygen consumption demonstrated a reduction of the respiratory rate with a parallel increase in extracellular acidification. In addition to decreased activity of DECR, laboratory tests also showed hyperlysinaemia due to impaired activity of alpha-aminoadipic semialdehyde synthase coded by the *AASS* gene (OMIM#605113).

The very severe phenotype observed in this patient could be ascribed not only to the combined deficiency of DECR and AASS, two NADP-dependent mitochondrial enzymes, but also to a global deficiency of additional NADP-dependent processes inside the mitochondria.

Recently and thanks to exome sequencing in subjects with complex clinical neurological presentations, new genes coding for proteins responsible for elimination of damaged metabolites have been identified.

Two genes belonging to the metabolite repair system denominated *NAXE* (Kremer et al., 2016) and *NAXD* (van Bergen et al., 2019) were found mutated in a childhood-onset lethal metabolic disorder with neurological involvement and in an early-onset encephalopathy with brain oedema and leucoencephalopathy, respectively.

The *NAXE* gene encodes an epimerase involved in the repair of NADHX and NADPHX, toxic compounds inhibiting several dehydrogenase activities. The epimerase catalyses the conversion of R-NAD(P)HX to S-NAD(P)HX so that S-NAD(P)HX can be reconverted to S-NAD(P)H by the dehydratase *NAXD*. In patient-derived fibroblasts, elevated concentrations of toxic compounds S-NADHX, R-NADHX, and cyclic NADHX were identified (Kremer et al., 2016; van Bergen et al., 2019).

Homozygous or compound heterozygous mutations in the gene *NNT*, coding for a pyridine nucleotide transhydrogenase protein located in the inner mitochondrial membrane, cause glucocorticoid deficiency type 4 with or without mineralocorticoid deficiency (Meimaridou et al., 2012; Yamaguchi et al., 2013; Hershkovitz et al., 2015; Weinberg-Shukron et al., 2015; Roucher-Boulez et al., 2016). This protein transfers a hydride ion between NAD, NAD(H), and NADP(H) (Zieger and Ware, 1997), and it contributes to functioning of the mitochondrial respiratory chain system playing a role in removing excess of reactive oxygen species in adrenal glands (Meimaridou et al., 2012).

Hartnup disorder is an autosomal recessive disorder due to defective transport of neutral amino acids across epithelial cells in renal proximal tubules and intestinal mucosa causing increased level of amino acids in urine. It is characterized by symptoms like pellagra, cerebellar ataxia, and neurological manifestation. The genetic cause of this disorder was identified in 2004 (Kleta et al. 2004) as due to mutation in the *SLC6A19* gene coding for a neutral amino acid transporter. One particular amino acid transported includes tryptophan, which is required to generate NAD, and this would be the reason for the clinical manifestations resembling pellagra.

Kynureninase and 3-hydroxyanthranilate 3,4-dioxygenase deficiencies are caused by mutations in the *KYNU* and *HAAO* genes, respectively, which code for enzymes involved in the kynurenine pathway leading to NAD cofactor production from tryptophan. A first missense mutation in *KYNU* gene was identified in 2007 (Christensen et al. 2007) in two brothers with no pathological phenotype except for increased level of xanthurenic acid, kynurenine, and 3-hydroxykynurenine in urine. In 2017 additional patients with a complicated multisystem syndrome were proved to carry out truncating mutations in *KYNU* and *HAAO* (Shi et al., 2017). In one affected patient analysis of plasma revealed the presence of high level of 3-hydroxykynurenine and low level of NAD, which was hypothesized to be responsible for the complicated clinical presentation characterized by vertebral, cardiac, renal, and limb defects (VCRL) observed in these patients.

Disorders of Pantothenate Metabolism

Coenzyme A is synthesized from pantothenate in a pathway composed of five enzymatic reactions (Fig. 33.1). CoA has a relevant role not only in bioenergetic metabolism but contributes to the synthesis of cholesterol, amino acids, phospholipids, fatty acids, and neurotransmitters. This multiplicity of activities impacts massively, even if not exclusively, on the structure and function of the brain.

While there are almost no reports describing deficiency of pantothenic acid due to nutritional deficits, mutations in genes coding for the first (PANK2) and last (COASY) enzymes of the CoA biosynthetic pathway are associated with neurodegenerative disorders hallmarked by iron accumulation in specific regions of the brain (NBIA). The pathogenic mechanisms linking iron accumulation to impaired CoA biosynthesis is still under investigation, but defective mitochondrial functionality seems to be one of the triggering causes of the disease as demonstrated in cellular and animal models (Orellana et al., 2016; Brunetti et al., 2012; Berti et al., 2015). Recently, mutations in *PPCS* gene coding for the second enzyme in the CoA synthetic pathway have been identified in a completely different clinical phenotype characterized by dilated cardiomyopathy and altered acylcarnitine profile (Iuso et al., 2018). It remains to be clarified why malfunctioning of enzymes belonging to the same metabolic pathway results in great clinical heterogeneity.

Mutations in *SLC25A42* coding for a mitochondrial CoA transporter were found in a patient with mitochondrial myopathy and delayed motor development (Shamseldin et al. 2016) and in additional cases presenting with encephalopathy and metabolic crisis (Almannai et al., 2018; Iuso et al., 2019). Instrumental investigations demonstrated increased serum lactate and basal ganglia lesions on MRI, in one case associated with iron deposition; muscle biopsy was performed in few cases and showed ragged-red-like fibers.

Nomenclature

No.	Disease name	Alternative disease name	Disease Abbreviation	Gene Symbol	Chromosomal localization	Mode of inheritance	Affected protein	Disease OMIM
33.1	Leber congenital amaurosis 9	Nicotinamide mononucleotide adenylyl transferase 1 deficiency	LCA9	*NMNAT1*	1p36.22	AR	Nicotinamide nucleotide adenylyltransferase 1	608553
33.2	Mitochondrial NAD kinase 2 deficiency	2,4-dienoyl-CoA reductase deficiency with hyperlysinemia	DECRD	*NADK2*	5p13.2	AR	2,4-dienoyl-CoA reductase	616034

33.8	3-hydroxyanthranilic acid 3,4-dioxygenase deficiency	Vertebral, cardiac, renal, and limb defects syndrome type 1	VCRL1	*HAAO*	2p21	AR	3-Hydroxyanthranilate 3,4-dioxygenase	617660
33.9	Pantothenate kinase 2 deficiency	Pantothenate kinase-associated neurodegeneration (PKAN); neurodegeneration with brain iron accumulation type 1	PKAN	*PANK2*	20p13	AR	Pantothenate kinase type	2234200
33.10	Phosphopantothenoylcysteine synthetase deficiency	Autosomal recessive dilated cardiomyopathy	CMD2C	*PPCS*	1p34.2	AR	Phosphopantothenoylcysteine synthetase	618189
33.11	Coenzyme A synthase deficiency	CoA synthase protein-associated neurodegeneration (CoPAN); neurodegeneration with brain iron accumulation type 6	COPAN	*COASY*	17q21.2	AR	Phosphopantetheine adenylytransferase/ dephosphocoenzyme A	615643
33.12	Mitochondrial coenzyme A transporter deficiency			*SLC25A42*	19p13.11	AR	Mitochondrial coenzyme A transporter	610823

Metabolic Pathway

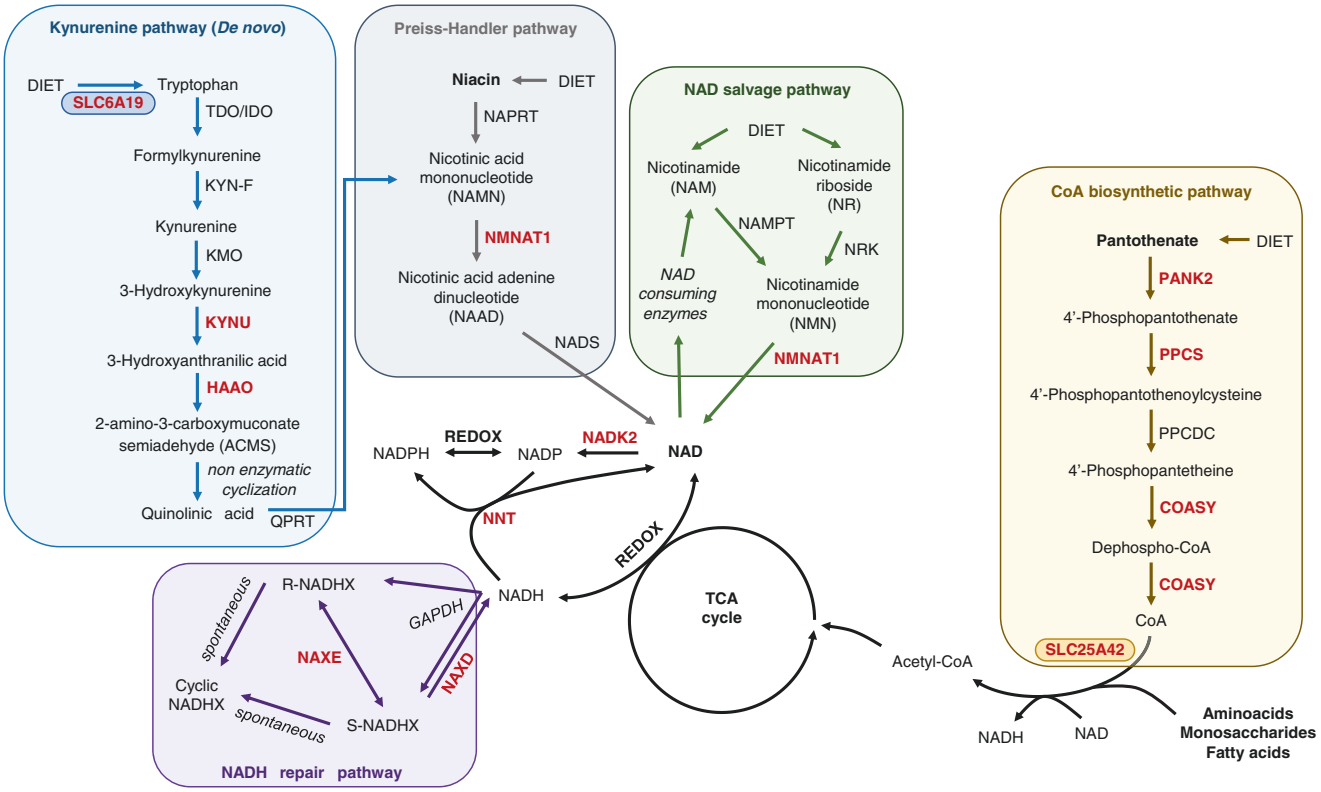

Fig. 33.1 Schematic representation of niacin, NAD, and pantothenate pathways and their interconnections

For simplicity, different pathways are grouped by different colors. Proteins mutated in human diseases are in red. NAD is synthesized through two main ways: it is produced either in a de novo pathway from amino acids or in salvage pathways by recycling preformed components such as nicotinamide (NAM) back to NAD. In the kynurenine (de novo) pathway (blue), a series of enzymatic and non-enzymatic reactions converts the amino acid tryptophan to nicotinic acid mononucleotide (NAMN), which is also produced in the Preiss-Handler pathway (grey) starting from niacin. NAMN is then converted to NAD by two further enzymatic reactions. NAD and its phosphorylated derivative NADP are reduced to NADH and NADPH by catabolic and anabolic redox reactions. In the NAD salvage pathway (green), NAM molecule, which is produced by NAD consuming enzymes such as sirtuins, Poly (ADP-ribose) polymerases (PARPs), CD38, and CD157, is recycled into nicotinamide mononucleotide (NMN), which in turn is re-converted to NAD. Hydrated forms of NADH and NADPH, called NADHX and NADPHX, respectively, can be formed spontaneously under acidic conditions or enzymatically by glyceraldehyde-3-phosphate dehydrogenase (GAPDH). NADHX and NADPHX, which are inhibitors of several dehydrogenases, are both converted back to NADH and NADPH by a series of enzymatic reactions in the repair pathway (purple)

In the CoA biosynthetic pathway (yellow), pantothenate is sequentially converted to CoA by a series of five enzymatic reactions. CoA is then used as an acyl group carrier and carbonyl-activating group in a multitude of biochemical transformations, including tricarboxylic acid (TCA) cycle and fatty acid metabolism. Enzymes: TDO tryptophan 2,3-dioxygenase, IDO indoleamine 2,3-dioxygenase, KYN-F kynurenine formamidase, KMO kynurenine 3-monoxygenase, KYNU kynunerinase, HAAO 3-hydroxyanthranilate 3,4-dioxygenase, QPRT nicotinate-nucleotide pyrophosphorylase, NAPRT nicotinate phosphoribosyltransferase, NMNAT1 nicotinamide mononucleotide adenyltransferase 1, NADS glutamine-dependent NAD(+) synthetase, NAMPT nicotinamide phosphoribosyltransferase, NRK nicotinamide riboside kinase, NADK2 NAD kinase 2, NNT nicotinamide nucleotide transhydrogenase, GAPDH glyceraldehyde-3-phosphate dehydrogenase, NAXE NAD(P)HX epimerase, NAXD NAD(P)HX dehydratase, PANK2 pantothenate kinase 2, PPCS phosphopantothenoylcysteine synthetase, PPCDC phosphopantothenoylcysteine decarboxylase, COASY coenzyme A synthetase. Transporters: SLC6A19 sodium-dependent neutral amino acid transporter B(0)AT1, SLC25A42 mitochondrial coenzyme A transporter

Signs and Symptoms

Prenatal Diagnosis

Disorder	Tests recommended
Nicotinamide mononucleotide adenylyl transferase 1 deficiency	Mutation analysis on DNA from CVS or AFC
Mitochondrial NAD kinase 2 deficiency	Mutation analysis on DNA from CVS or AFC
NAD(P)HX epimerase deficiency	Mutation analysis on DNA from CVS or AFC
NAD(P)HX dehydratase deficiency	Mutation analysis on DNA from CVS or AFC
Nicotinamide nucleotide transhydrogenase deficiency	Mutation analysis on DNA from CVS or AFC
Hartnup disorder	Mutation analysis on DNA from CVS or AFC
Kynureninase deficiency	Mutation analysis on DNA from CVS or AFC
3-Hydroxyanthranilic acid 3,4-dioxygenase deficiency	Mutation analysis on DNA from CVS or AFC
Pantothenate kinase 2 deficiency	Mutation analysis on DNA from CVS or AFC
Phosphopantothenoylcysteine synthetase deficiency	Mutation analysis on DNA from CVS or AFC
Coenzyme A synthase deficiency	Mutation analysis on DNA from CVS or AFC
Mitochondrial coenzyme A transporter deficiency	Mutation analysis on DNA from CVS or AFC

CVS Chorionic villous sampling, AFC Amniotic fluid cells

DNA Testing

Genetic investigation is performed for all the diseases described in this chapter, on DNA extracted from peripheral blood mononuclear cells (PBMC). PCR amplification and direct sequencing are carried out for mutation detection. In some laboratories, usage of genes panel followed by next-generation sequencing (NGS) is available.

Treatment

Summary

In disorders of pantothenate metabolism, pharmacologic and surgical interventions have focused on palliation of symptoms according to consensus clinical management guideline available for PKAN (Hogarth et al., 2017). Symptomatic treatment is aimed primarily at the dystonia, which can be profoundly debilitating to the affected individual and caregivers. Different treatments have been commonly used including oral baclofen, trihexyphenidyl, and clonazepam, intrathecal and intraventricular baclofen, and deep brain stimulation.

In SLC25A42-related disorders, affected individuals are prone to metabolic decompensations with relatively mild intercurrent illnesses and therefore should be managed to promote anabolism; in acute metabolic crisis management with intravenous fluids and bicarbonate infusion will prevent permanent neurological sequela (Almannai et al., 2018).

Experimental Treatment

Clinical and experimental studies are currently underway in disorders of pantothenate metabolism, and treatments will mainly target pathogenic mechanisms. The potential for iron chelation using deferiprone (an iron chelator that is able to cross the blood–brain barrier) to modify disease and improve clinical symptoms is highly topical at present. To date, good tolerability of deferiprone, with reduction of radiologically discernible brain iron, and clinical improvement in some PKAN patients was reported (Abbruzzese et al., 2011). Another pilot phase II trial showed that deferiprone was well tolerated in the nine PKAN patients who completed the study, with statistically significant reduction of iron in the pallida by MRI evaluation but disappointingly without clinical improvement of symptoms (Zorzi et al., 2011). An international randomized, double-blind, placebo-controlled trial of deferiprone was recently completed (Klopstock et al., 2019). In PKAN patients who have residual PANK2 activity, the possibility of using high-dose pantothenate therapy has been considered. Pantothenate is well tolerated with no known toxicity. The effect of pantothenate supplementation in PKAN is currently unknown although patients with atypical PKAN have anecdotally reported improvement in motor symptoms, speech, cognition, and general wellbeing while on treatment (Kurian and Hayflick 2013).

Oral pantethine supplementation as targeted treatmente aimed to bypass the deficient enzyme in the CoA synthesis pathway was proposed in two PPCS mutated patients and showed mild clinical and instrumental improvement in one of them (Iuso et al., 2018).

In NADK2 deficiency, low-lysine diet has been tried (Houten et al., 2014; Tort et al., 2016) with reported beneficial effect in one case in association with other cofactors (ubidecarenone, idebenone, vitamin E, creatine) (Tort et al., 2016). NADPH supplementation has been tried in a recently reported case with a milder phenotype with initial beneficial effect (Pomerantz et al., 2018). Treatment with nicotinic acid has been speculated for individuals with NAXE defect (Kremer et al., 2016). Oral nicotinamide treatment (50–100 mg/day) may prevent or resolve photodermatitis in Hartnup disorder.

Vitamin B_6-Dependent and Vitamin B_6-Responsive Disorders

34

Barbara Plecko and Eduard A. Struys

Contents

Summary

The importance of vitamin B_6 is evident by its role as the most abundant cofactor in human metabolism. A total of six different B_6 vitamers follow a complex pathway of absorption and transformation into the final active cofactor, pyridoxal 5′-phosphate (PLP), which catalyses over 100 reactions, mainly in amino acid and neurotransmitter metabolism. Over recent years, a number of genetic defects have been identified as the underlying cause of vitamin B_6-dependent epilepsies that need to be considered particularly in therapy-resistant seizures of unclear aetiology in the neonatal period, but also later in life. With diagnostic delay, these disorders can be fatal or may lead to irreversible brain damage. A standardised vitamin B_6 trial should be part of a protocol for neonatal seizures in every institution caring for the critically ill newborn. The underlying mechanisms of vitamin B_6-dependent epilepsies can be assigned to either reduced synthesis and recycling of PLP (pyridox(am)ine 5′-phosphate oxidase (PNPO) deficiency), reduced cellular uptake (congenital hypophosphatasia, HPP), inactivation of PLP by accumulating compounds (antiquitin deficiency and hyperprolinaemia type II) or disturbed intracellular PLP homeostasis (PLP-binding protein (formerly PROSC) deficiency). The disorders can be distinguished by specific biomarkers in urine, plasma or CSF and confirmed by molecular testing. Affected patients need a lifelong oral treatment with pyridoxine or pyridoxal 5′-phosphate,

and withdrawal will inevitably lead to seizure recurrence. Pyridoxine has less severe potential side effects compared to PLP and should be the preferred vitamer wherever possible. Add-on of folinic acid may be considered in case of partial response to pyridoxine or PLP. Lysine-restricted diet and high-dose arginine supplementation are being evaluated as add-on therapy in patients with ATQ deficiency. Due to autosomal recessive inheritance, recurrence risk for all disorders discussed here is 25% and intrauterine treatment with vitamin B_6 from early pregnancy may be considered in forthcoming pregnancies. Prenatal testing is available by molecular analysis.

Introduction

Vitamin B_6 is a water-soluble vitamin derived from various animal and plant food sources as well as intestinal bacterial flora in six different vitamers: pyridoxal, pyridoxine-glucoside, pyridoxamine and their 5′-phosphorylated esters. Pyridoxal 5′-phosphate is the only active cofactor and catalyses over 140 enzymatic reactions, mainly in amino acid metabolism (e.g. the glycine cleavage system, serine dehydratase, threonine dehydratase) as well as in neurotransmitter metabolism (e.g. GABA formation by glutamate decarboxylase; aromatic acid decarboxylase/AADC). The demand of vitamin B_6 is 0.1–0.3 mg/day during infancy and around 1.2–1.4 mg/day in adulthood. As cellular uptake and transport across the blood-brain barrier is only possible for free bases of vitamin B_6, phosphorylated vitamers undergo hydrolysation by intestinal phosphatases and tissue non-specific alkaline phosphatase (TNSALP), respectively (Fig. 34.1). The latter is attached to the cellular membrane by a PIGV anchor system. Within cells pyridoxine, pyridoxamine and pyridoxal undergo rephosphorylation by pyridoxal kinase with consecutive oxidation of pyridoxine 5′-phosphate and pyridoxamine 5′-phosphate into pyridoxal 5′-phosphate (PLP) by flavin mononucleotide-dependent pyridox(am)ine 5′-phosphate oxidase (PNPO), which can also recycle pyridoxamine monophosphate back to PLP (salvage pathway). Though the liver seems to play an important role in the formation of PLP, expression of PNPO has also been shown in human intestinal and muscle cells, as well as in neurons. Enzymes involved in PLP synthesis are regulated by a feedback mechanism to avoid toxic PLP concentrations. Recently the PLP-binding protein (PLPBP, formerly named PROSC) has been shown to be crucial for intracellular PLP homeostasis (Fig. 34.1).

The role of vitamin B_6 in epileptogenesis has been well recognised by the occurrence of seizures in nutritional deficiency as well as in genetic disorders. Nutritional vitamin B_6 deficiency is rare nowadays, eventually seen in children with severe chronic disease or on high dosages of the tuberculostatic isoniazid and cured by adequate vitamin supply.

In contrast, genetically determined vitamin B_6-dependent epilepsies are caused by inborn errors of metabolism that lead to reduced PLP availability (Wilson et al. 2019, Clayton 2006). To date, five different disorders are known that can be assigned to four different mechanisms:

- Reduced synthesis and recycling of PLP (pyridox(am)ine 5′-phosphate oxidase (PNPO) deficiency), MIM#610090
- Reduced cellular uptake of PLP (congenital hypophosphatasia, HPP, MIM#241500)
- Inactivation of PLP by accumulating compounds (antiquitin deficiency, MIM#266100 and hyperprolinaemia type II, MIM#239500)
- Disturbed intracellular PLP homeostasis (PLP-binding protein (PLPBP, formerly PROSC) deficiency, MIM#617290)

Seizures with resistance to common anticonvulsants occur as a consequence of imbalance in PLP-dependent neurotransmitter—as well as in cerebral amino acid metabolism. Prematurity, poor adaptation, abdominal distension, lactic acidosis and hypoglycaemia have been described as confounding factors in severe manifestations of PNPO, ATQ as well as PLPBP deficiency (Wilson et al. 2019). A standardised vitamin B_6 trial with the administration of 100 mg of pyridoxine i.v. followed by a 3-day trial with pyridoxine, 30 mg/kg/day in two single dosages is recommended for every neonate with therapy-resistant seizures of unclear aetiology. Specific biomarkers serve in the differentiation of these disorders and complement the diagnostic value of a vitamin B_6 trial. A variety of secondary biochemical findings has been described in patients with vitamin B_6-dependent epilepsies. These include lactic acidosis, elevated threonine and glycine in plasma or CSF and abnormal metabolites of biogenic amines in CSF, as low homovanillic acid, low hydroxyindoleacetic acid, increased 3-methoxytyrosine and high vanillactate in urine. These secondary findings are all explained by impaired function of PLP-dependent enzymes in amino acid or neurotransmitter metabolism. They are nevertheless inconsistent and non-specific and may be found in all circumstances of (cerebral) PLP depletion. While administration of PLP would serve all five disorders, pyridoxine is ineffective in most cases of classical PNPO deficiency as well as in severe PLPBP deficiency. In case of a positive treatment effect, pyridoxine or PLP therapy should be continued until results of biochemical and molecular testing are available.

Due to recent reports on attenuated phenotypes, administration of vitamin B_6 should also be considered in older patients with therapy-resistant epilepsy.

Antiquitin (ATQ) Deficiency

ATQ deficiency is the most prevalent form of pyridoxine-dependent epilepsy (PDE) and has an estimated incidence of 1:64.000 (Coughlin II et al. 2019). Patients with ATQ deficiency usually present with seizures soon after birth (Gospe 2017, Stockler et al. 2011). Seizures are myoclonic, tonic or clonic with variable EEG patterns (Schmitt et al. 2010). Cranial imaging may be normal or may show some grey and white matter atrophy, hydrocephalus, thin corpus callosum mega cisterna magna and also cortical dysplasia (Toldo et al. 2018). Seizures are typically refractory to common anticonvulsants with a high tendency towards status epilepticus (SE). Partial response to phenobarbitone is possible. About 30% of PDE patients suffer from birth asphyxia or may have signs of encephalopathy. Abdominal distension with bile-stained vomiting, elevated lactate or hypoglycaemia may be confusing confounders. Atypical presentations with onset of seizures beyond infancy, initial response to common anticonvulsants or response to extremely low dose of pyridoxine have been observed (van Karnebeek et al. 2016, Srinivasaraghavan et al. 2018).

The *antiquitin* gene is located on 5q31 and encodes alpha-aminoadipic semialdehyde dehydrogenase, an enzyme involved in the L-lysine degradation pathway (Figs. 34.2, 34.3, 34.4 and 34.5). The accumulating compound alpha-aminoadipic semialdehyde (AASA) is in equilibrium with L-Δ^1-piperideine-6-carboxylate (P6C). The latter inactivates pyridoxal 5′-phosphate by a so-called Knoevenagel condensation, leading to profound cerebral PLP deficiency (Mills et al. 2006, Footitt et al. 2011). Elevated AASA in urine serves as a specific biomarker for ATQ deficiency (Table 34.1), though it may also be elevated in molybdenum cofactor—or sulfite oxidase deficiency due to secondary inhibition of antiquitin by accumulating sulfite (Struys et al. 2012a, b). Pipecolic acid (PA) is an unspecific biomarker for ATQ deficiency and is found elevated in urine, plasma and CSF prior to pyridoxine treatment (Plecko et al. 2000, 2007), while urinary levels always normalise, and also plasma levels may normalise on pyridoxine therapy. 6-Oxo-pipecolate (6-oxo-PIP) was described as a potential novel biomarker in plasma, urine and CSF of four patients with ATQ deficiency, with stability at room temperature and measured by LC-MS/MS, but warrants confirmation in larger cohorts (Wempe et al. 2019). Recent labelled isotope studies in cultured human brain cells (Crowther et al. 2019) support data from studies in human fibroblast (Struys et al. 2014) and mice (Pena et al. 2017a, b) that PA is built via the saccharopine pathway by conversion of P6C. Diagnosis is confirmed by molecular analysis of the *ALDH7A1* gene also known as antiquitin, and to date a total of 165 different mutations have been described (Coughlin II et al. 2019).

In 2009, folinic acid-responsive seizures were found to be allelic to antiquitin deficiency (Gallagher et al. 2009). The effect may rely on overlapping cofactor functions of folinic acid and PLP. Add-on of folinic acid, 3–5 mg/kg/day, may be considered, if the initial response to pyridoxine is limited. Inheritance of ATQ deficiency is autosomal recessive with a 25% recurrence risk in forthcoming pregnancies. Patients, who never received pyridoxine experience high mortality, as shown by a considerable rate of deceased siblings diagnosed retrospectively as well as some patients who had been on folinic acid monotherapy. Outcome of patients with ATQ deficiency treated with pyridoxine is variable, and about 70% have some degree of cognitive impairment (Plecko et al. 2007; Mills et al. 2010; Bok et al. 2012). Normal IQ has been described in single patients despite prolonged status epilepticus (Kluger et al. 2008).

Hyperprolinaemia Type II (HP II)

This inborn error has first been described in Irish travellers, with primary generalised seizures in late infancy or childhood in 50% of affected individuals. Mental retardation may be present, but several individuals were reported with normal school performance (Flynn et al. 1989). A recent series reported on additional anxiety problems and hallucinations (van de Ven et al. 2014). In many patients, seizures are triggered by fever, are relatively benign and can be controlled by common anticonvulsants. Thus, several patients with this autosomal recessive disorder may remain undiagnosed.

HP II is caused by defective Δ^1-pyrroline 5-carboxylate dehydrogenase, leading to increased utilisation of PLP. In analogy to the pathophysiologic mechanism in ATQ deficiency, L-D1-pyrroline-5-carboxylate (P5C) inactivates PLP by a Knoevenagel condensation (Farrant et al. 2001). Patients show high proline on plasma amino acid analysis as well as elevated P5C in urine, plasma and CSF (Fig. 34.6).

Pyridoxal 5′- Phosphate (PLP)-Dependent Epilepsy (PNPO) Deficiency

Pyridoxal 5′-phosphate-dependent seizures were first described in 2002 (Kuo and Wang 2002). The clinical presentation is indistinguishable from ATQ deficiency except for a higher rate of prematurity seen in about 60% of cases

(Mills et al. 2005; Levtova et al. 2015). Again, about a third of patients have perinatal distress with low APGAR scores, requiring primary intubation in some. Patients typically present with neonatal myoclonic seizures up to 2 weeks of age, sometimes accompanied by roving eye movements and most often severely abnormal EEG (Mills et al. 2005; Hoffmann et al. 2007). One patient has been reported with infantile spasms, presenting at age 5 months (Mills et al. 2014). Recently, a patient with PNPO deficiency was reported with seizures that could initially be controlled by common anticonvulsants over a period of 3 years (Xue et al. 2017). Cranial imaging may be normal or show marked white matter changes. Patients with PNPO deficiency may suffer from anaemia, coagulopathy, renal dysfunction as well as failure to thrive. This broader range of symptoms and very high mortality rate in untreated patients is explained by systemic PLP deficiency. Many patients have deceased siblings with a history of neonatal epileptic encephalopathy and burst suppression EEG, falsely assigned to Ohtahara syndrome. Prognosis of patients with PNPO deficiency relies on early initiation of specific treatment and may result in normal outcome (Porri et al. 2014; Hatch et al. 2016). Seizures and EEG changes respond to pyridoxal 5′-phosphate (PLP) within hours or days. While first patients identified with classical PNPO deficiency had seizures that were resistant to pyridoxine, it became apparent that a subgroup of patients with PNPO mutations allowing residual enzyme activity may respond to pyridoxine and paradoxically have worsening of seizures upon PLP administration (Plecko et al. 2014; Mills et al. 2014).

Pyridoxal 5′-phosphate-dependent epilepsy is caused by autosomal recessive mutations in the *PNPO* gene (Mills et al. 2005). *PNPO* encodes pyridox(am)ine 5′-phosphate oxidase, an enzyme needed for the oxidation of pyridoxine and pyridoxamine into the only active vitamin B_6 cofactor, which is pyridoxal 5′-phosphate (PLP). This enzyme is expressed in all human cell types and, aside from PLP synthesis, is involved in the recycling of pyridoxamine monophosphate back to PLP (salvage pathway) as well as PLP trafficking within the cell.

Elevated pyridoxamine (Footitt et al. 2013; Ware et al. 2014) and, even more specific, an elevated pyridoxamine to pyridoxic acid ratio in plasma (and CSF) serve as reliable biomarkers for PNPO deficiency and can be determined while on treatment (Mathis et al. 2016). Elevated plasma glycine, threonine, elevated urinary vanillactate as well as abnormal biogenic amines are inconsistent secondary findings. Glycine elevation can be marked and may mislead clinicians to consider non-ketotic hypoglycaemia instead of going for a vitamin B_6 trial. Recently an LC-MS/MS-based assay for the measurement of PNPO activity in dried blood spots has been developed (Wilson et al. 2019).

Diagnosis has to be confirmed by molecular analysis of the *PNPO* gene; prenatal diagnosis is possible. Twenty seven different mutations have been identified to date (Wilson et al. 2019).

Congenital Hypophosphatasia

The main impact of congenital hypophosphatasia is poor bone mineralisation and early death due to respiratory insufficiency. Only patients with the severe, congenital, autosomal recessive form of this disease may present with therapy-resistant seizures from birth, even before skeletal signs become more prominent (Balasubramaniam et al. 2010, Baumgartner-Sigl et al. 2007). EEG is usually severely abnormal and may show a burst suppression pattern. While seizures are resistant to common anticonvulsants, a favourable response to oral or i.v. administration of pyridoxine has been reported in single cases (Nunes et al. 2002, Baumgartner-Sigl et al. 2007) while in other seizures were resistant to pyridoxine and the encephalopathy was fatal (de Roo et al. 2014). The recently licensed enzyme replacement therapy (ERT) is considered unlikely to alter CNS involvement, as ERT does not cross the blood-brain barrier.

The diagnostic hallmark of congenital hypophosphatasia is a markedly decreased concentration of alkaline phosphatase in plasma, while decreased phosphate and elevated calcium concentrations can be inconsistent. Tissue non-specific alkaline phosphatase (TNSALP) is a multifunctional enzyme that processes three substrates, namely, inorganic pyrophosphate, phosphoethanolamine and PLP for cellular uptake.

With respect to seizure aetiology, impaired TNSALP function leads to reduced intracellular availability of PLP, while plasma levels of PLP are (extremely) high. To date it is not well understood why patients do not show signs of systemic PLP deficiency, if there is toxicity of high extracellular PLP concentrations or if other mechanisms as morphologic changes in neurons as observed in a knock-out mouse model (Sebastián-Serrano et al. 2016) may contribute to human disease. Diagnosis is confirmed by molecular analysis of the *ALPL* gene.

Pyridoxal-Binding Protein (PLPBP) Formerly PROSC Deficiency

With the application of a standardised vitamin trial and new techniques in genetic testing, another genetic defect causing

vitamin B_6-dependent epilepsy has been unravelled by Darin et al. in 2016 in seven patients of four families. To date a total of 15 patients with PLPBP deficiency have been described (Darin et al. 2016, Plecko et al. 2017, Shiraku et al. 2018), all presenting with seizures from birth to 3 months of age. There is overlap with ATQ and PNPO deficiency according to seizure type as well as accompanying signs of prematurity or foetal distress, but within the cohort of PLPBP deficiency, four patients had microcephaly at birth and another four developed acquired microcephaly during the course of disease. Seven patients had a burst suppression pattern on EEG, while the remainder had diffuse slowing or (multi)focal discharges. Cranial MRI was normal in eight cases and in all other cases showed broad gyri, shallow sulcy, abnormal white matter and eventually also periventricular cysts. Ten patients were treated with pyridoxine, while five were receiving PLP at dosages ranging from a total of 100 mg to 450 mg/day. Nine were seizure-free aside from febrile breakthrough seizures, but only five patients were on vitamin B_6 monotherapy. Thirteen patients have intellectual impairment of variable degree, some of them with considerable delay of first vitamin B_6 administration.

In contrast to the aforementioned entities, PLPBP deficiency does not have a specific biomarker. Low PLP concentrations were found in CSF as unspecific clues to vitamin B_6-dependent epilepsies, but alterations of amino acids and biogenic amines were inconsistent.

PLPBP encodes for a protein with non-enzymatic function. It is most likely a key regulator of intracellular PLP homeostasis and important in protecting PLP from intracellular inactivation by phosphatases.

Diagnosis of PLPBP deficiency relies on genetic testing, either by gene panels for epileptic encephalopathies or by next-generation sequencing. A positive vitamin B_6 response to either pyridoxine or PLP but normal biomarkers for ATQ-PNPO as well as TNSALP deficiency may suggest PLPBP deficiency. So far a total of 14 pathogenic variants in PLPBP have been identified.

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localisation	Mode of inheritance	Affected protein	OMIM no.
34.1	Pyridoxine-dependent epilepsy (PDE)	Alpha-amino adipic semialdehyde (AASA) dehydrogenase deficiency	AASADHD	*ALDH7A1*	5q31	AR	Alpha-amino adipic semialdehyde dehydrogenase	266100
34.2	Pyridox(am)ine 5′-phosphate oxidase deficiency	Pyridoxal 5′-phosphate (PLP)-dependent seizures	PNPOD	*PNPO*	17q21.32	AR	Pyridox(am)ine 5′-phosphate oxidase	610090
34.3	Hyperprolinaemia type II	Pyrroline-5-carboxylate dehydrogenase deficiency	P5CDH	*ALDH4A1*	1p36.13	AR	Pyrroline-5-carboxylate dehydrogenase	239510
34.4	Congenital hypophosphatasia	Phosphoethanolaminuria	HOPS	*ALPL*	1p36.12	AR	Alkaline phosphatase	241500
34.5	PLP-binding protein deficiency	(Formerly PROSC deficiency)	PLPBP	*PLPBP*	8p11.23	AR	PLPBP	604430

Metabolic Pathways

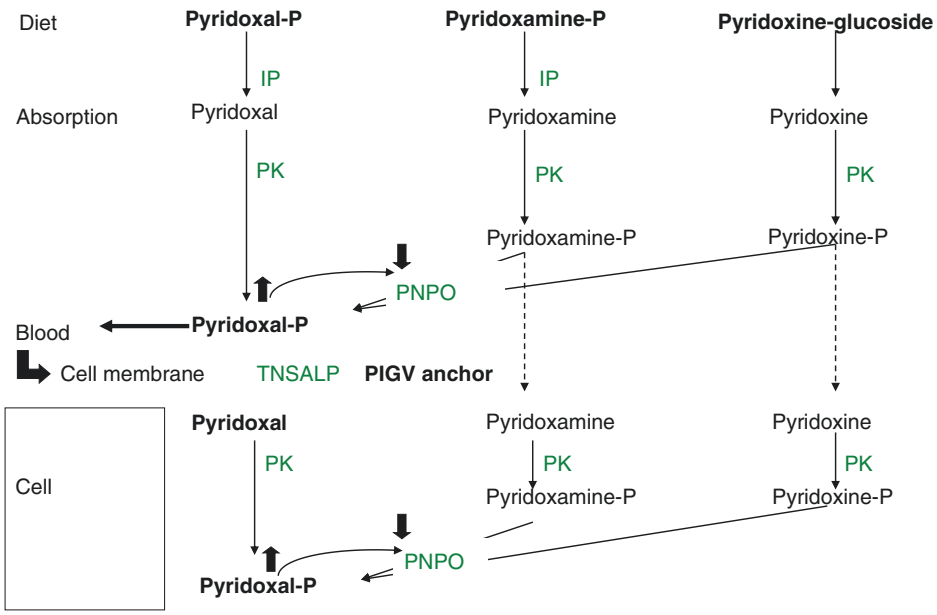

Fig. 34.1 Vitamin B_6 is absorbed in different vitamers that are dephosphorylated by intestinal alkaline phosphatases (IP). In the liver they are then rephosphorylated to their 5′-phosphate esters by phosphate kinase (PK), and pyridox(am)ine is consequently converted into pyridoxal 5′-phosphate (PLP) by pyridoxamine 5′-phosphate oxidase (PNPO) and partly released into circulation. For cellular uptake or transport across the blood-brain barrier, phosphorylated vitamers (mainly PLP) are hydrolysed by tissue non-specific alkaline phosphatase (TNSALP). Within the (brain) cell, rephosphorylation of PL as the major source and oxidation of pyridox(am)ine by PNPO provides PLP as the only active cofactor for intracellular enzyme reactions. Pyridoxal 5′-phosphate exhibits feedback inhibition upon PNPO activity. PLP-binding protein (PLPBP) has a non-enzymatic function and is considered a key regulator of intracellular PLP homeostasis

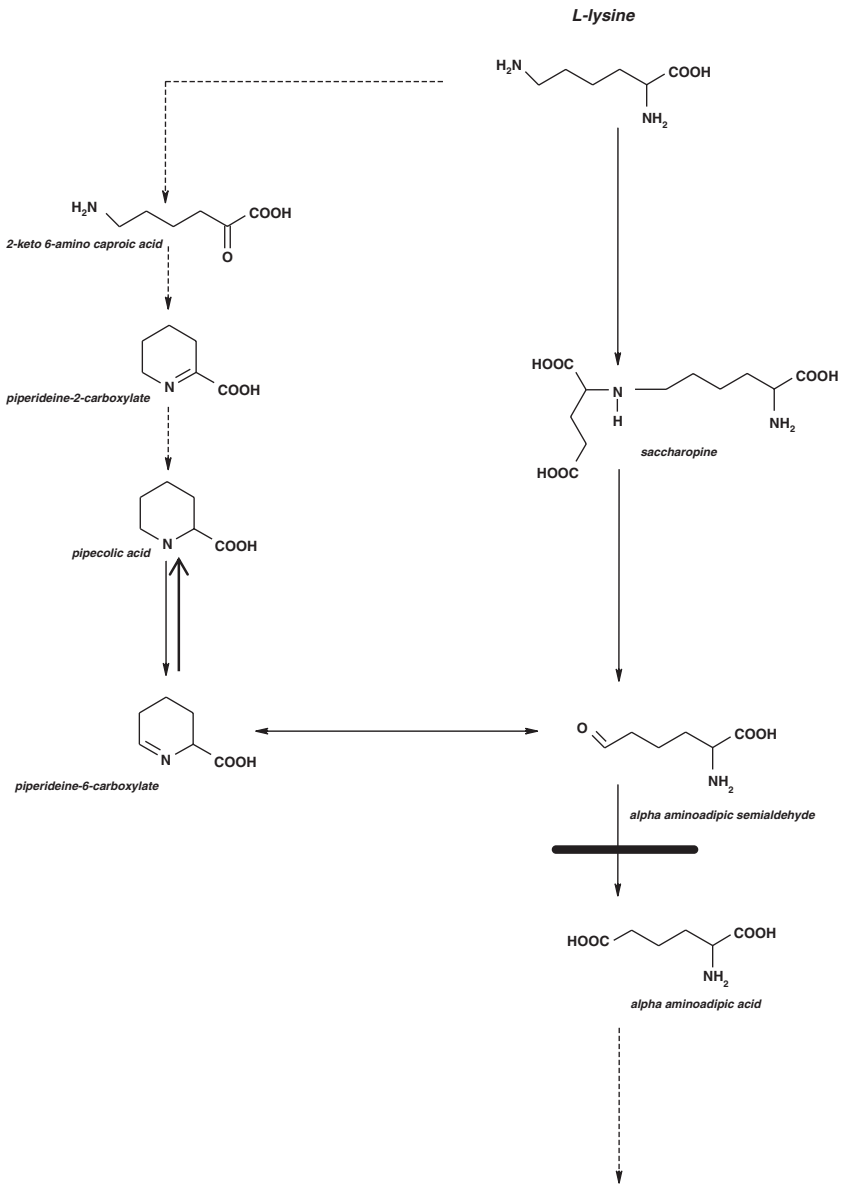

Fig. 34.2 Lysine degradation pathway. Antiquitin deficiency leads to accumulation of alpha-aminoadipic semialdehyde and piperideine-6-carboxylate and is accompanied by elevated pipecolic acid. It is now assumed that pipecolic acid is formed via the saccharopine pathway by conversion of piperideine-6-carboxylate. Piperideine-6-carboxylate inactivates PLP by a Knoevenagel condensation, leading to cerebral PLP deficiency

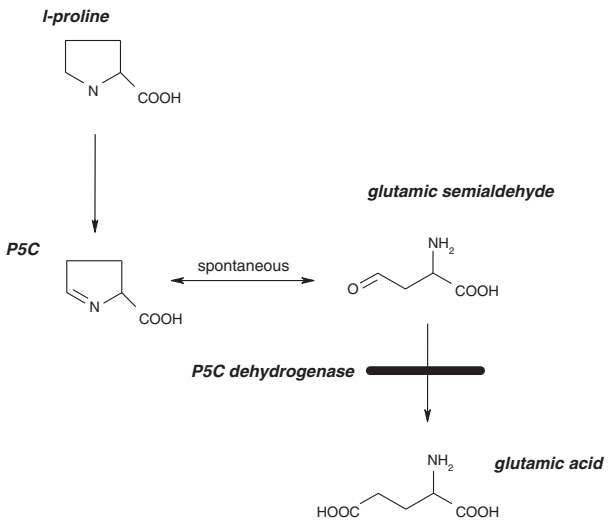
Fig. 34.3 Catabolism of L-proline. In hyperprolinaemia type II, deficiency of Δ^1-pyrroline-5-carboxylate (*P5C*) dehydrogenase leads to accumulation of glutamic acid γ semialdehyde and P5C. P5C inactivates PLP by a Knoevenagel condensation



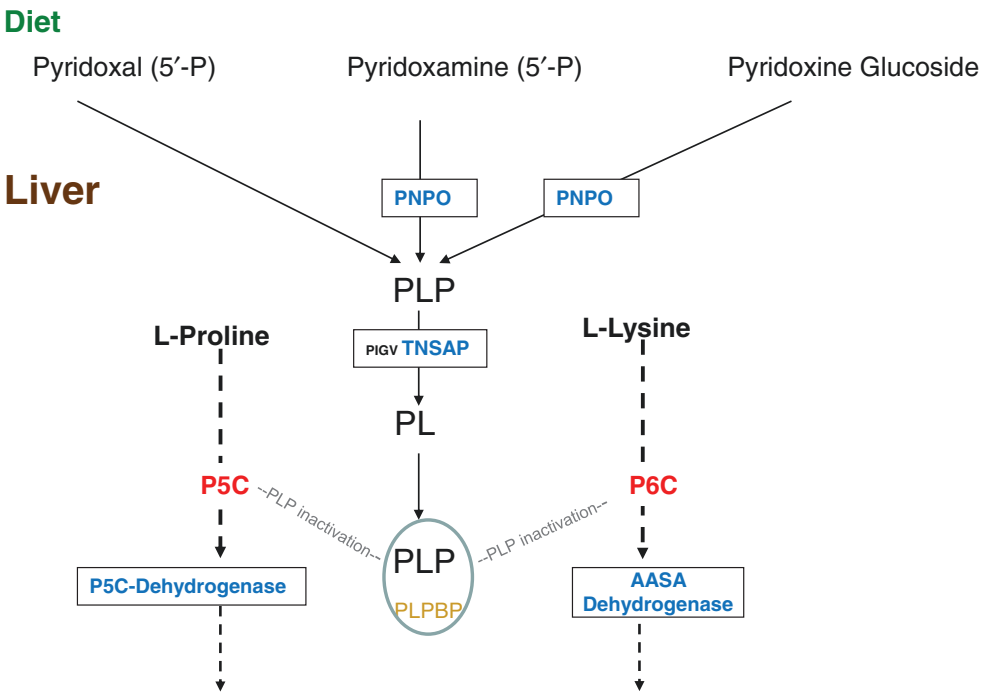


Fig. 34.4 Scheme illustrating all five inborn errors leading to vitamin B_6-dependent epilepsy. Two inborn errors within vitamin B_6 metabolism leading to reduced synthesis of pyridoxal 5′-phosphate (*PLP*): pyridox(am)ine 5′-phosphate oxidase (*PNPO*) deficiency and tissue non-specific alkaline phosphatase (*TNSALP*) deficiency in congenital hypophosphatasia, two inborn errors leading to inactivation of PLP by a Knoevenagel condensation, hyperprolinaemia type II (P5C dehydrogenase deficiency) and antiquitin (alpha-AASA dehydrogenase) deficiency and one inborn error with impaired intracellular PLP homeostasis, PLPBP deficiency

Specimen Collection

All specific biomarkers of inborn errors leading to vitamin B_6-dependent epilepsy can be determined on or off pyridoxine or PLP supplementation. Urine is the best material to test for AASA. As AASA and P6C are quite unstable, samples should be frozen immediately and kept at −20 °C until analysis (Struys et al. 2012a, b). AASA and P6C may be secondarily elevated in patients with molybdenum cofactor deficiency; therefore simultaneous determination of sulfocysteine prevents diagnostic error. Cerebrospinal fluid specimens should be free of blood contamination. In those with blood contamination, a centrifugal step at low speed can be performed to pellet the erythrocytes. For measurement of pyridoxamine and pyridoxic acid, blood samples should be centrifuged immediately and plasma as well as CSF samples be protected from light and stored at −80° until analysis (Albersen et al. 2012).

Prenatal Diagnosis

For all entities discussed in this chapter, prenatal diagnosis is feasible by molecular analysis of the respective gene in chorionic villi or amniotic fluid and should be accompanied by genetic counselling.

DNA Testing

DNA testing for all entities discussed in this chapter is available in specialised laboratories and some commercial institutions. In antiquitin deficiency, patients may harbour deletions and may need MLPA analysis in the presence of normal sequencing of the ALDH7A1 gene.

Treatment

Established Treatment Options

Figure 34.5 illustrates a standardised diagnostic and treatment algorithm that should be performed in every neonate with therapy-resistant seizures of unclear aetiology. Though the scheme suggests time lines, the duration of each individual step is at the discretion of the treating physician and should be adapted to individual scenarios. As severe apnoea may occur in responders along a first vitamin B_6 trial, resuscitation equipment should be at hand. In any case, determination of respective biomarkers should be performed in parallel and will help to differentiate among the different disorders. In the presence of diagnostic biomarkers, a diagnostic vitamin B_6 withdrawal is contraindicated. Patients with confirmed diagnoses will need a lifelong substitution with pharmacological doses of pyridoxine or PLP. While PLP is effective in all five inborn errors discussed in this chapter, pyridoxine may fail in most cases of PNPO deficiency as well as in severe PLPBP deficiency. The usual pyridoxine dose in a neonate is 100 mg i.v., followed by 30 mg/kg/day in two single i.v. or oral dosages over three consecutive days in order to also identify patients with ambiguous or delayed response. Simultaneous EEG recording with first administration is of no clear benefit (Bok et al. 2010a, b), but an EEG control should be performed at least at the end of the trial in order to verify any improvement regarding epileptic discharges or background activity. 90% of patients with ATQ deficiency will stay seizure-free on pyridoxine monotherapy, which is adapted to weight until a total daily dose of 200–300 mg of pyridoxine is reached. In case of febrile break-through seizures, the pyridoxine dose may be doubled for the first 3–5 days of future febrile illnesses. Long-term doses of pyridoxine above 200–300 mg/day should be avoided as they may lead to sensory (and at dosages above 1000 mg/day also to motor) neuropathy. Pyridoxine monotherapy should be tempted, once a clear pyridoxine effect has been observed. In case patients respond to pyridoxine, but are later identified to harbour pyridoxine-responsive PNPO mutations by molecular analysis, a switch to PLP therapy should only be performed if patients are not seizure-free and should be done at very low pace over several days, as PLP in some of these patients may aggravate seizures or even cause SE (Plecko et al. 2014).

In case pyridoxine fails, folinic acid may be added at 3–5 mg/kg/day given in two single dosages i.v. or orally, and neonates should be switched to PLP starting from 30 to 60 mg/kg/day in three to four single oral dosages. PLP is unlicensed outside of Asia and in most countries is only available as a chemical compound for oral administration. PNPO deficiency is more difficult to treat, as patients need shorter intervals with four (to six) single daily administrations and PLP dosages of 30 up to 60 mg/kg/day. Recently severe side effects of hepatopathy and liver cirrhosis were reported in single patients with PNPO deficiency under high-dose PLP treatment (Sudarsanam et al. 2014, Coman et al. 2016) so that the lowest effective dose of PLP should be used. PLP should be light protected and dissolved immediately before administration to avoid oxidation and build-up of potentially toxic compounds (Mohamed-Ahmed et al. 2017).

Recently a new subgroup of patients harbouring pyridoxine-responsive PNPO mutations has been described (Plecko et al. 2014, Mills et al. 2014). Interestingly these patients may have seizure aggravation upon PLP administration. The comparably higher incidence of antiquitin deficiency, the availability of pyridoxine as a licensed drug and the less severe side effects are in favour of pyridoxine as the first-line drug in standardised vitamin B_6 trials. As long-term administration of PLP has led to liver fibrosis in single patients with PNPO deficiency, pyridoxine may be the preferred vitamer wherever possible.

Experimental Therapies

Since 2012 dietary lysine restriction and high-dose arginine supplementation have emerged as additional treatment modalities for ATQ deficiency (van Karnebeek et al. 2012, 2014; Mercimek-Mahmutoglu et al. 2014; Coughlin 2nd et al. 2015, Yuzyuk et al. 2016) and were shown to decrease concentrations of potentially neurotoxic AASA in plasma, urine and CFS in a so far limited number of patients. While dietary lysine restriction is based on reduction of precursors, arginine supplementation is acting by competitive inhibition of lysine uptake in the gut and also at the blood-brain barrier. Early initiation of lysine restriction and arginine supplementation were associated with better outcomes. Robust long-term data on cognitive outcome are pending.

Intrauterine treatment with pyridoxine, 100 mg/day given from early pregnancy, may benefit offsprings of forthcoming pregnancies that are at risk for antiquitin deficiency (Bok et al. 2010a, b). In these offsprings, molecular and biochemical confirmation should be sought immediately after birth to prevent potential neuronal pyridoxine toxicity in unaffected newborns (Hartmann et al. 2011).

The rational would also argue for administration of low-dose PLP in pregnancies at risk for PNPO deficiency, but no data have been published so far.

As PNPO is a riboflavin-dependent enzyme, mutations with residual activity may benefit from the administration of riboflavin in addition to PLP, but so far no clinical experience on this hypothesis has been reported. For congenital hypophosphatasia, recombinant enzyme replacement therapy is available but may not be effective in preventing fatal encephalopathy observed in single cases.

Very recently animal models have been established for ATQ deficiency in zebrafish (Zabinyakov et al. 2017, Pena et al. 2017a, b), PNPO deficiency in drosophila (Chi et al. 2019) as well as PLPBP deficiency in zebrafish (Johnstone et al. 2019) and will give further insight into disease mechanisms and provide opportunities for new drug discovery .

Molybdenum Cofactor Disorders

35

Guenter Schwarz and Bernd C. Schwahn

Contents

Summary

Molybdenum (Mo) cofactor deficiency (MoCD) is characterized by neonatal-onset myoclonic epileptic encephalopathy and dystonia with cerebral MRI changes similar to hypoxic-ischemic lesions. The initial presentation is unspecific, and diagnosis is often delayed owing to the absence of easily accessible specific tests. Surviving children suffer from severe static cerebral palsy characterized by myoclonus, generalized seizures, dystonic movements, spasticity, and lack of developmental progress. After the neonatal period, the diagnosis can be ascertained by recognising a typical combination of facial dysmorphism, lens dislocation, and severe atrophy and cystic transformation of the brain or by untargeted genetic testing. Attenuated and atypical cases have been described.

The molecular cause of the disease is the loss of sulfite oxidase activity, one out of four molybdenum cofactor (Moco)-dependent enzymes. The resulting accumulation of toxic sulfite causes a secondary increase of metabolites

such as S-sulfocysteine and thiosulfate as well as a decrease in L-cystine. A second important Mo-dependent enzyme is xanthine oxidoreductase which catalyzes the conversion of hypoxanthine to xanthine and further to uric acid representing the final steps in purine catabolism. Moco is synthesized by a three-step biosynthetic pathway, which involves gene products of *MOCS1*, *MOCS2, MOCS3*, and *GPHN*. Depending on which synthetic step is compromised, MoCD is biochemically classified as type A, B, or C. This distinction is clinically relevant for patient management because the metabolic block in MoCD type A can be circumvented by administering the product of the impaired reaction, cyclic pyranopterin monophosphate (cPMP). A substitution therapy with cPMP is highly effective in reducing sulfite toxicity and restoring the biochemical homeostasis, but the clinical outcome critically depends on the degree of brain injury prior to the start of treatment. There is currently no specific treatment for MoCD type B or MoCD type C.

Introduction

Four molybdenum (Mo)-enzymes are known in humans, each catalyzing either catabolic or detoxifying reactions (Schwarz et al. 2009). Sulfite oxidase (SO) is localized in the intermembrane space of mitochondria and couples sulfite oxidation to the reduction of cytochrome c. The two cytosolic Mo-enzymes, xanthine oxidoreductase (XO) and aldehyde oxidase, are closely related Mo-iron-flavin enzymes catalyzing hydroxylation reactions of purines and other heterocyclic substrates, respectively (Schwarz et al. 2009). In these enzymes, Moco requires the addition of a terminal sulfido ligand, which is dependent on the Moco sulfurylase MOCOS (Ichida et al. 2001). The mitochondrial amidoxime-reducing component has been identified as a fourth vertebrate Mo-enzyme (Havemeyer et al. 2006) and reduces N-hydroxylated prodrugs as well as metabolites such as N-hydroxy-L-arginine.

Patients with isolated deficiencies in SO or xanthine oxidase (xanthinuria type I) are well-known in the field, while isolated deficiencies in aldehyde oxidase and the amidoxime-reducing component have not been reported yet. Mutations in *MOCOS* cause a deficiency of xanthine oxidase and aldehyde oxidase, named xanthinuria type II (see Sect. 35.4, Table 35.4).

Moco Biosynthesis

Moco biosynthesis is divided into three major steps based on the two intermediates cyclic pyranopterin monophosphate (cPMP) (Santamaria-Araujo et al. 2004) and molybdopterin (MPT) (Johnson et al. 1984) (Fig. 35.1). The first step in Moco biosynthesis, the conversion of GTP into cPMP, is catalyzed by two proteins encoded by the *MOCS1* gene. *MOCS1* expression undergoes alternative splicing with two different transcripts, one bicistronic and one monocistronic mRNA (Gray and Nicholls 2000). The bicistronic transcript encodes for two open reading frames, MOCS1A and MOCS1B (Reiss et al. 1998), of which only the first is translated yielding a functional MOCS1A protein. MOCS1A catalyzes the S-adenosyl-methionine and [4Fe-4S] cluster-dependent radical conversion of GTP to 3′ 8-cyclo-7,8 dihydro GTP. The second, monocistronic transcript, produces a MOCS1AB fusion protein that is targeted (independent of MOCS1A) to mitochondria and proteolytically cleaved to release a MOCS1B protein, which converts 3′ 8-cyclo-7,8 dihydro GTP to cPMP (Mayr et al. 2020).

The second step in Moco biosynthesis is catalyzed by MPT synthase, which converts cPMP into molybdopterin (MPT) and is encoded by the bicistronic *MOCS2* gene producing both subunits (MOCS2A and MOCS2B) by a ribosomal leaky scanning mechanism (Stallmeyer et al. 1999). *MOCS3* encodes for the Moco sulfurase (Matthies et al. 2004), which is required for the ATP-dependent thiolation of MOCS2A.

The third and final step in Moco synthesis involves the synthesis of MPT-AMP and subsequent molybdate-dependent hydrolysis of MPT-AMP releasing Moco. Both reactions are dependent on the *GPHN* gene, which encodes for a multi-domain cytosolic protein composed of an N-terminal G-domain (GPHN-G), a central domain, and a C-terminal E-domain (GPHN-E, Fig. 35.1). Besides Moco biosynthesis, gephyrin functions as cytosolic membrane-associated receptor clustering protein, being essential for the formation of inhibitory synapses (Fritschy et al. 2008).

Genetics of MoCD

MoCD is characterized by the simultaneous loss of all Mo-enzyme activities due to biallelic pathogenic variants in either *MOCS1*, *MOCS2*, *MOCS3*, or *GPHN* (Huijmans et al. 2017; Reiss and Hahnewald 2011), and prenatal diagnosis in carrier families has been established. In nearly all cases, disease-causing mutations result in a complete loss of enzyme function due to frame shifts, splice site and nonsense mutations, or missense mutations affecting highly conserved or invariant residues. Approximately 60% of all MoCD patients carry mutations in the *MOCS*1 gene (Reiss and Hahnewald 2011). Most of the remaining MoCD patients are affected in the *MOCS2* gene. Recently, the first patient with

a *MOCS*3 mutation has been reported (Huijmans et al. 2017) presenting residual SO activity and attenuated disease symptoms. Due to an additional function of MOCS3 in tRNA thiolation (Chowdhury et al. 2012), it is likely that a total loss of MOCS3 function is embryonic lethal. Only two cases with homozygous *GPHN* mutations have been described in the last two decades both representing severe disease manifestation and neonatal death due to a loss of both gephyrin functions, Moco synthesis, and synaptic inhibition (Reiss et al. 2001; Reiss et al. 2011). Homozygosity for private mutations is common, reflecting a low rate of spontaneous mutations and founder effects in consanguineous communities. In addition, heterozygous gephyrin mutations and deletions have been reported in various cases presenting with different forms of epilepsy (Dejanovic et al. 2015; Dejanovic et al. 2014).

Clinical Presentation

The three biochemically distinct forms of MoCD cannot clinically be reliably distinguished from each other or from isolated SO deficiency (ISOD; see 22.10), and all are childhood onset disorders. ISOD has been reported in more than 50 cases (Claerhout et al. 2018), whereas over 200 cases of MoCD have been described (Misko et al. 2020, Spiegel et al. submitted), and many more are known to metabolic clinicians. Children with MoCD present with a spectrum of clinical severity, with a clear majority being severely affected from the neonatal age. Affected newborns are usually born at term. They may initially appear healthy and have normal proportions including head circumference, although they can display typical minor dysmorphic facial features and may have solitary cerebral parenchymal cysts and a hypoplastic pons and cerebellum. The most common presentation of severe MoCD as first described in 1978 (Duran et al. 1978) is of early myoclonic encephalopathy, often starting within hours to days after birth with poor feeding, irritability, and a distressed facial expression and quickly progressing to myoclonic seizures, decreased consciousness, and apnea. The EEG can initially be normal, advancing to a generalized burst suppression pattern. After a period of 1–2 weeks, children may regain alertness but show persistent hyperexcitability, frequent myoclonus, tonic spasms, and focal seizures with eye deviation and facial flushing. Seizures are often refractive to anticonvulsants. Infants can display dystonic episodes with prominent limb hypertonia, spasticity and opisthotonus. Cerebral visual impairment and bulbar dysfunction and a lack of speech and motor development are common. A proportion of children develop lens dislocation after infancy. Nephrolithiasis has been reported. Mortality is high due to intercurrent lower respiratory tract infections and seizures, with a reported median survival between 2.4 (Spiegel et al., submitted) and 3.0 years (Mechler et al., 2015).

Neuroimaging usually demonstrates severe abnormalities. An early stage of generalized edema is quickly followed by features mimicking severe generalized hypoxic-ischemic encephalopathy (Vijayakumar et al. 2011), which evolves within a few weeks to a characteristic appearance including in decreasing frequency cortical atrophy and loss of white matter with cyst formation, hypoplastic corpus callosum, abnormal basal ganglia, hydrocephalus ex vacuo, dilated ventricles, cerebellar and brainstem hypoplasia, and mega cisterna magna (Arslanoglu et al. 2001; Bayram et al. 2013; Vijayakumar et al. 2011).

Increasingly, cases with symptom onset later in childhood and attenuated severity are being described. Occasionally, children present merely with dystonia and speech delay (Mayr et al., 2018, Scelsa et al. 2019), and the cranial imaging may only show changes to the basal ganglia or even appear normal (Del Rizzo et al. 2013, Spiegel et al., submitted). Attenuated disease probably reflects a slightly higher residual activity of SO, and the diagnosis is easily missed if specific diagnostic investigations are not undertaken. Secondary deterioration can occur with intercurrent illness.

Disease Mechanism

MoCD is clinically very similar to isolated SOX deficiency, implicating sulfite toxicity as a major underlying cause for neurotoxicity in MoCD patients. Sulfite is a strong reducing agent that attacks disulfide bonds in proteins and small molecules. As a highly abundant disulfide, cystine reacts with accumulating sulfite leading to the formation of S-sulfocysteine (SSC, Fig. 35.2) (Rupar et al. 1996). SSC accumulates in MoCD patients, and its excretion in urine is detectable shortly after birth and increases over the first few days of life (Veldman et al. 2010) supporting the view that sulfite is removed via placental clearance during pregnancy (Belaidi et al. 2012; Reiss et al. 2005). SSC is structurally similar to glutamate and able to bind to NMDA receptors (Olney et al. 1975). We have recently shown that SSC mediated excitotoxicity is NMDA-receptor dependent and causes Ca^{2+} influx, calpain activation, and inhibitory synapse depletion. Treatment with the NMDA receptor antagonist memantine was able to rescue neurodevelopmental deficits in a pharmacological model of MoCD in mice (Kumar et al. 2017). SSC formation results in L-cystine depletion in plasma (Barbot et al. 1995; Johnson and Duran 2001). Deficiency of L-cysteine, the precursor of GSH, might contribute to ferroptosis, a novel form of non-apoptotic cell death that involves glutathione-dependent clearance of lipid

peroxidation (Stockwell et al. 2017). MoCD patients have lowered plasma total homocysteine concentrations (Graf et al. 1998; Sass et al. 2003). The molecular cause has not been explored further, but probably reflects, similar to SSC formation, a sulfite-dependent liberation of protein-bound homocysteine as S-sulfohomocysteine. Additional pro-excitatory effects of sulfite might also contribute to the disease pathology given that a sulfite-dependent reduction of pyridoxal 5′-phosphate (PLP) in cerebrospinal fluid of MoCD patients has been reported (Footitt et al. 2011).

The primary route of cysteine catabolism proceeds via the oxidative catabolism (Bagley and Stipanuk 1994) that involves cysteine dioxygenase and aspartate aminotransferase. In addition, there is growing evidence for a significant role of the hydrogen sulfide (H_2S)-dependent degradation of cysteine. Formation of H_2S involves at least four enzymes (cystathionine γ-lyase, CSE, cystathionine β-synthase, CBS, and aspartate amino transferase together with 3-mercaptopyruvate sulfurtransferase, MSPT, Fig. 35.2) in three distinct pathways. As a signaling molecule (Abe and Kimura 1996), the half-life of H_2S is rather short, and one mode of action is the H_2S-dependent formation of cysteine persulfides, which have been shown to protect protein-bound cysteines from irreversible oxidation (Zivanovic et al. 2019). H_2S is further oxidized to sulfite and thiosulfate in mitochondria by three enzymatic reactions (Fig. 35.2) (Hildebrandt and Grieshaber 2008). First, the mitochondrial membrane flavoprotein sulfur quinone oxidoreductase (SQR) converts H_2S to a GSH-bound persulfide and transfers two electrons to the ubiquinone pool (Kabil and Banerjee 2010). Next, the glutathione persulfide is handed over either to a persulfide dioxygenase releasing sulfite. Alternatively, thiosulfate sulfur transferase transfers the glutathione persulfide to sulfite yielding thiosulfate (Hildebrandt and Grieshaber 2008).

MoCD and SOX deficiency are characterized by high levels of thiosulfate excretion, suggesting an increased sulfur flux via the H_2S pathway. A similar imbalance is seen in cysteine dioxygenase deficiency observed in the *CDO*$^{-/-}$ mice (Ueki et al. 2011). Finally, ethylmalonic encephalopathy (ETHE1 deficiency) is caused by genetic variants in persulfide dioxygenase leading to H_2S accumulation, respiratory chain deficiency, and massively increased thiosulfate excretion (Tiranti et al. 2009). Based on the collective accumulation of thiosulfate in MoCD, SOXD, and ETHE1 deficiency, a recent study identified similar principles of mitochondrial dysfunction in these disorders (Grings et al. 2019).

Nomenclature

No.	Disorder	Alt Name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM No.
35.1	Molybdenum cofactor deficiency A	MoCo deficiency, complementation group A	MoCD-A	*MOCS1*	6p21.3	MOCS1A, MOCS1AB	603707
35.2	Molybdenum cofactor deficiency B	MoCo deficiency, complementation group B	MoCD-B	*MOCS2*	5q11	MOCS2A MOCS2B	603708
35.3	Molybdenum cofactor deficiency C	MoCo deficiency, complementation group C	MoCD-C	*GPHN*	14q23.3	Gephyrin	603930
35.4	Molybdenum cofactor sulfurase deficiency	Xanthinuria type II	MCSD	*MOCOS*	18q12.2	MOCOS	613274

Metabolic Pathways

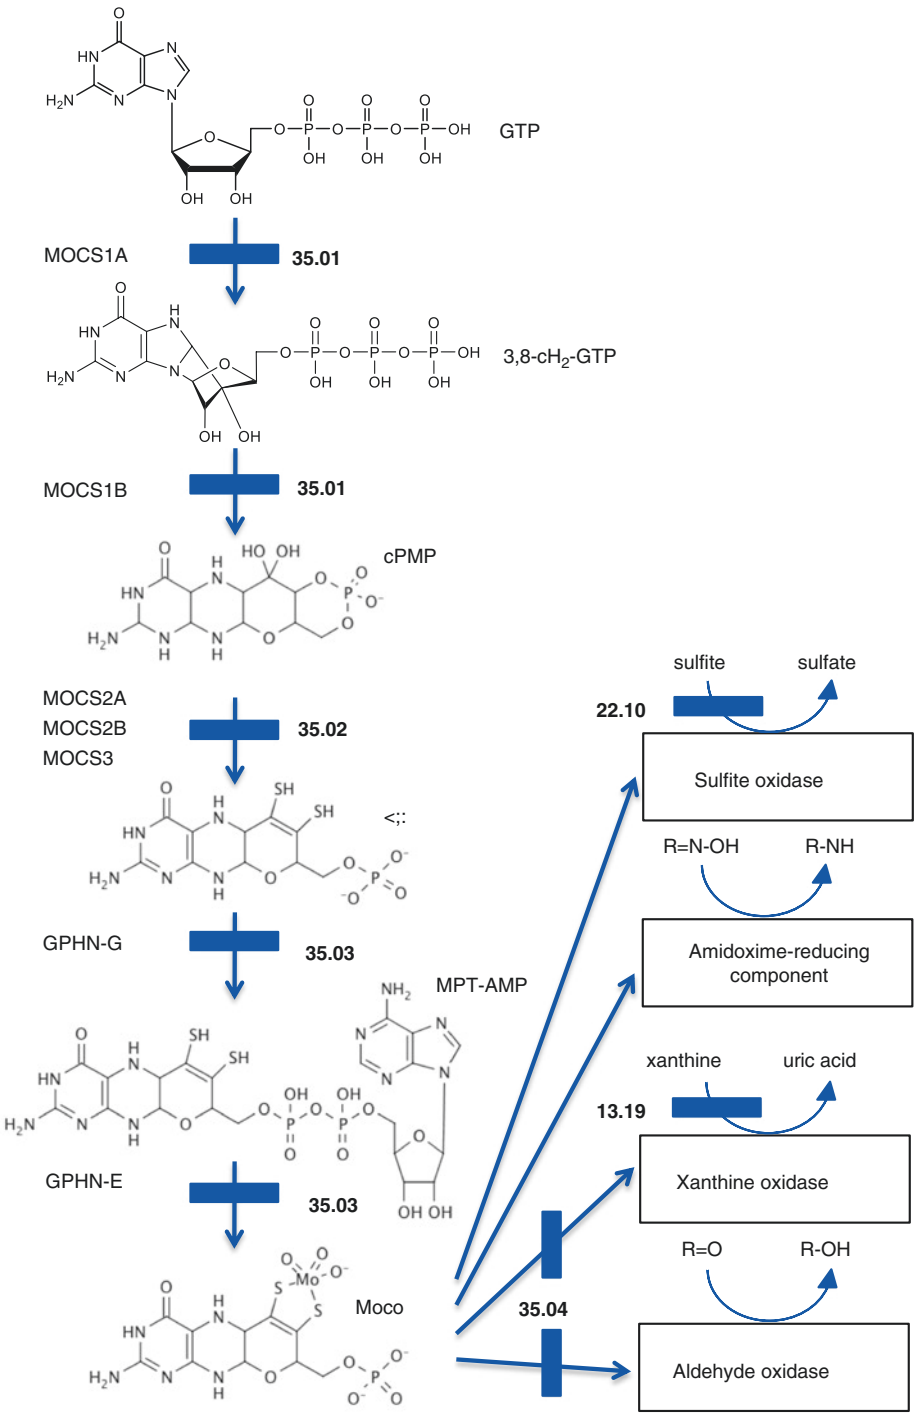

Fig. 35.1 *Moco biosynthesis, Mo enzymes, and deficiencies.* Intermediates of Moco synthesis are 3′ 8-cyclo 7,8-dihydro-GTP, cyclic pyranopterin monophosphate (cPMP), metal binding pterin (MPT), and adenylated MPT (MPT-AMP). Moco undergoes an additional sulfuration prior to its incorporation into xanthine oxidase and aldehyde oxidase. A deficiency in the latter step leads to xanthinuria type II (35.04). Proteins and domains (GPHN) involved in Moco synthesis are shown. Deficiencies in *MOCS1*, *MOCS2/3*, and *GPHN* cause MoCD type A (35.01), type B (35.02), and type C (35.03), respectively. Isolated deficiencies in SOX and XO cause ISOD 22.10 and XOD 13.19

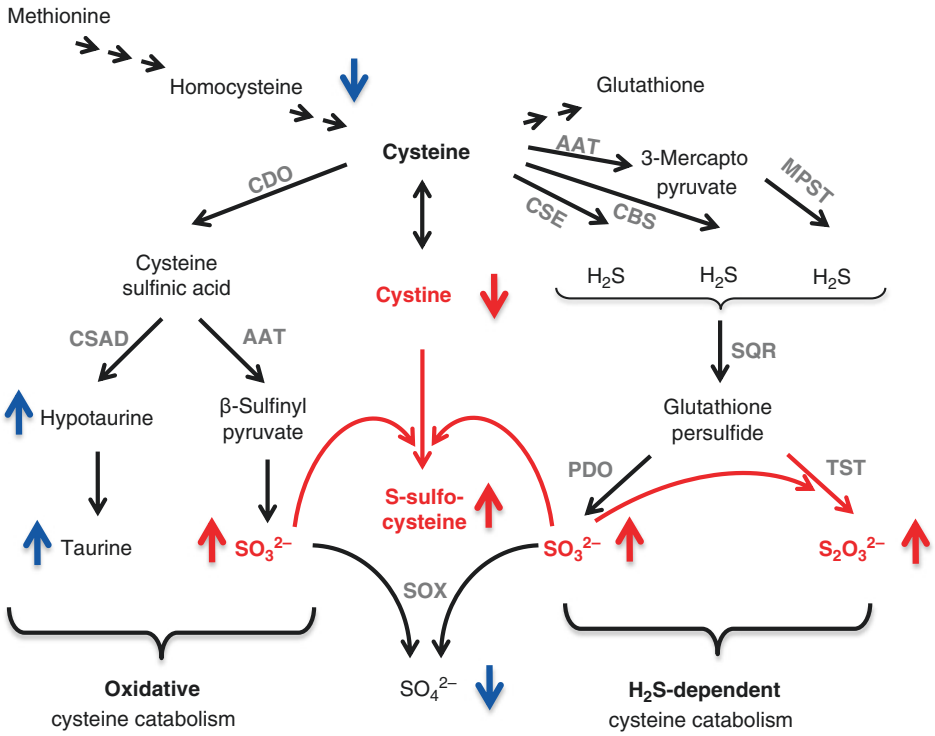

Fig. 35.2 *Cysteine catabolism and S-containing metabolites that are altered in MoCD and SOX deficiency.* Oxidative and H_2S-dependent cysteine catabolism are summarized with the involved enzymes and metabolites. Changes in metabolite concentrations in MoCD and ISOD are highlighted in blue/red with corresponding arrows indicating an increase or decrease in concentration in comparison to controls. Strongly increased sulfur fluxes/metabolite changes in response to MoCD/ISOD are indicated by red arrows. Enzyme abbreviations are *CBS* Cystathionine β-synthase, *CSE* Cystathionine γ-lyase, *CDO* Cysteine dioxygenase, *CSD* Cysteine sulfinate decarboxylase, *AAT* Aspartate aminotransferase, *SO* sulfite oxidase, *MPST* 3-Mercaptopyruvate sulfurtransferase, *SQR* Quinone oxidoreductase, *PSD* Persulfide dioxygenase, *TST* Thiosulfate sulfur transferase

Diagnostic Flowchart

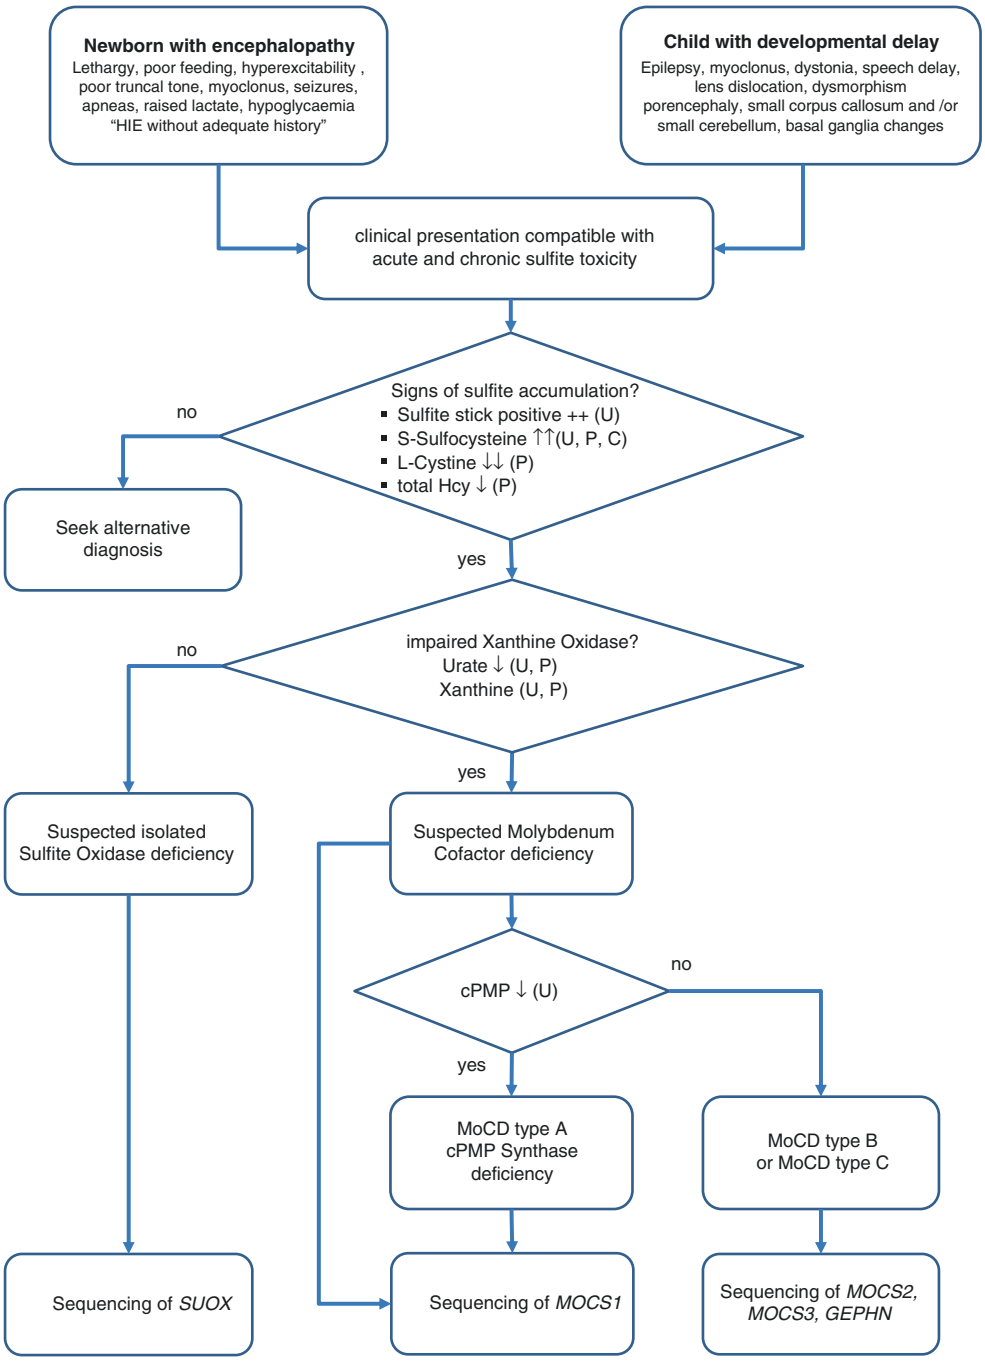

Fig. 35.3 Flowchart to establish the differential diagnosis of ISOD or MoCD subtypes. Sample matrices, urine (U), plasma (P), cerebrospinal fluid (C)

Specimen Collection

Specimen collection as early as possible, in those cases in which a treatment attempt with cPMP is undertaken; specimen to be collected prior to the first dose of cPMP.

Specimen collection

Test	Sample requirement
Sulfite dipstick	Fresh urine, bedside dipstick test
S-Sulfocysteine in urine	Urine, frozen 1 mL
S-Sulfocysteine in plasma	Plasma, 0.5 mL
Uric acid in urine	Urine
Uric acid in plasma	Plasma, 0.5 mL
Xanthine in urine	Urine
Xanthine in plasma	Plasma, 0.5 mL

Prenatal Diagnosis

When pathogenic variants have been identified in the index case, prenatal diagnosis is possible by mutation analysis of DNA extracted from chorionic villi or amniocytes.

Prenatal diagnosis sample requirement

Disorder	Material	Timing/ trimester
All MoCD types	Chorionic villus cells	I
	Cultured amniocytes	II
	Amniotic fluid (might be positive for SSC, unclear diagnostic accuracy)	III

DNA Testing

In MoCD patients pathogenic variants have been found in *MOCS1*, *MOCS2, MOCS3*, and *GEPH*. Given the higher prevalence of *MOCS1* mutations, analysis of this gene is suggested before testing for the *MOCS2* gene. Only if no variant has been found in either *MOCS1 or MOCS2*, sequence analysis of *GEPH* or *MOCS3* is suggested. Primers and protocols for Sanger sequencing have been published previously (Reiss et al. 1998; Reiss et al. 1999; Reiss et al. 2001).

Treatment

Early manifesting neonates often require medical intensive care to survive the initial acute encephalopathic period. Symptomatic treatment afterward focuses on improving quality of life and medication to manage cerebral palsy, myoclonus, dystonia, and treatment-resistant seizures. Most children are immobile and require tube feeding owing to orobulbar dysfunction. Diets restricted in L-methionine and L-cystine have been tried to reduce the accumulation of sulfite. A reduction of about one third of the usual daily intake can be achieved in infants without compromising growth, and while such diets lead to a modest biochemical improvement, the clinical effects in severely affected children have been disappointing. A low-sulfur diet and pyridoxine supplementation have been found to improve seizure control in some patients with attenuated MoCD although those would also be expected to respond to conventional anticonvulsive treatment (Boles et al. 1993; Del Rizzo et al. 2013; Touati et al. 2000).

After the proof of concept of treating MoCD type A with cyclic pyranopterin monophosphate (cPMP) was established in a mouse model (Schwarz et al. 2004), daily intravenous replacement therapy has been used since 2008 to treat amenable patients (Veldman et al. 2010) for as long as 12 years. Results of treatment of the first cohort of 11 patients for up to 5 years within a prospective cohort study suggests that cPMP substitution is generally safe and biochemically effective, leading to rapid and sustained normalization of biomarkers without adverse drug reactions or tachyphylaxis (Schwahn et al. 2015). The clinical outcome of treated patients critically depends on the timing of treatment in relation to the cascade of neurotoxic events triggered by sulfite accumulation after birth and in particular on whether it is started before excitotoxic neuronal cell death occurs (Kumar et al. 2017, Plate et al. 2019). Timely cPMP treatment of neonates with severe MoCD type A can prevent severe neurocognitive sequelae. However, the requirement for daily IV administration causes a significant burden of care and requires permanent venous access. While the treatment with cPMP must be started urgently, the decision whether to continue the treatment long-term needs to be well reflected, with the best interest of the child and family in mind.

In practical terms, cPMP has recently been granted a license for medical use and is available from the manufacturer Origin BioSciences Inc. A single daily dose of cPMP is administered as slow intravenous injection or short infusion. Doses from 0.24 to 1.2 mg per kg body weight per day have been successfully used.

Treatment with cPMP should include close monitoring of biomarkers to establish a biochemical response, which can also help to differentiate MoCD subtypes if genetic test results are not immediately available. A fall in urinary sulfite and SSC concentrations is seen within the first 24 h after administration, and a rise in plasma urate and L-cystine concentrations can be expected within a few days.

Emergency Treatment

Anticonvulsant treatment, airway protection, and neuromonitoring according to standard algorithms of pediatric emergency medicine and intensive care.

Given the risk-benefit ratio, it appears appropriate to commence cPMP replacement therapy in suspected cases prior to diagnostic confirmation and consider discontinuation after more information has become available.

Standard Treatment

Supportive treatment and anticonvulsive therapy according to local standards.

cPMP replacement is likely to become established as standard of care for pre-symptomatic infants with MoCD type A.

Experimental Treatment

Hemofiltration has been proposed as emergency treatment option to protect the neonatal brain against sulfite toxicity. During hemofiltration, careful monitoring of anticonvulsant plasma levels is required. Premature delivery of affected fetuses has been suggested to minimize exposure of the fetal brain to rising sulfite levels during late pregnancy. There is currently no evidence to support the efficacy of either proposition.

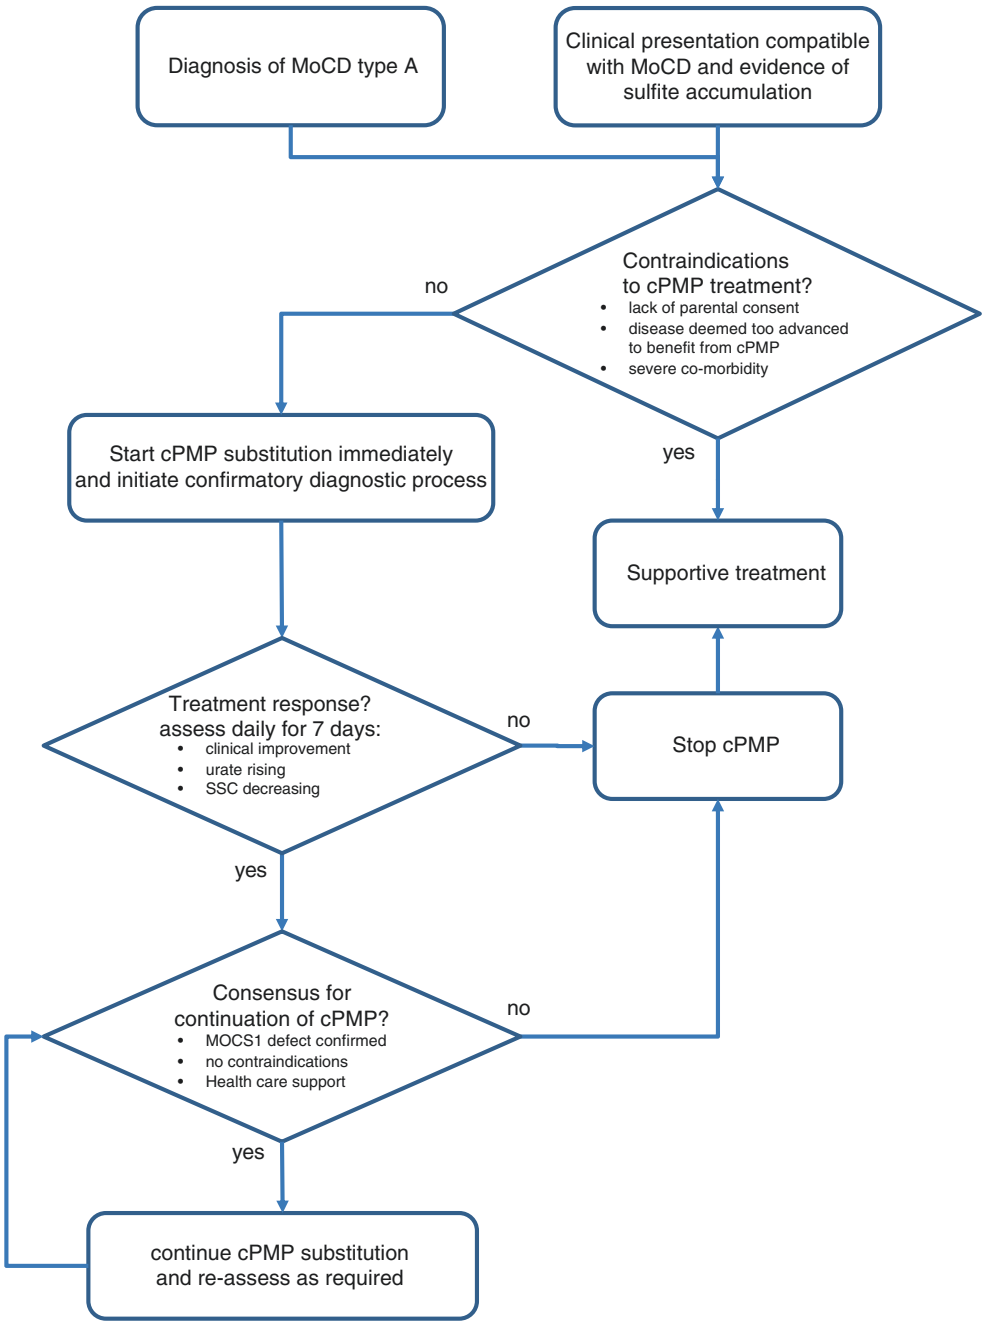

Fig. 35.4 Suggested decision-making process for the use of cPMP

Follow-Up and Monitoring

Plasma urate as well as urinary SSC and xanthine are suitable markers of biochemical efficacy, and the latter are stable compounds. This allows urine samples to be collected every few weeks at home and be sent to centralized laboratories for analysis. The ongoing evaluation of biochemical and clinical efficacy will establish justification for continuation of this novel treatment. Clinical monitoring includes regular assessments of nutritional status, motor and bulbar function, as well as cognitive developmental progress, to establish support needs.

Disorders of Copper, Zinc, and Selenium Metabolism

36

Diego Martinelli

Contents

Summary

Copper, zinc, and selenium are essential trace elements serving as cofactors of many important metalloenzymes. Copper and zinc uptake requires specific carriers in the intestine. Selenium absorption occurs in the duodenum via an active transport sodium pump. Copper excretion takes place only in the liver. Copper metabolism is regulated by two closely related ATPases that differ in tissue expression: ATP7A, present in most non-hepatic tissues; and ATP7B, predominantly expressed in liver.

Wilson's disease, associated to ATP7B defect, shows neuropsychiatric, ocular, and hepatic symptoms, caused by tissue copper overload due to impaired export into the bile.

Menkes disease, a devastating neurocutaneous disorder, and its milder variant occipital horn syndrome (OHS), due to ATP7A defect, cause systemic copper deficiency, impairing copper-dependent enzymes such as lysyl oxidase, tyrosinase, superoxide dismutase, dopamine beta-monooxygenase, and cytocrome oxidase.

Recently, five additional copper metabolism disorders have been described: (1) ATP7A-related distal hereditary

neuropathy, due to specific mutations affecting ATP7A trafficking; (2) Huppke-Brendel syndrome, caused by mutations in an acetyl-CoA transporter involved in copper proteins acetylation; (3) CCS deficiency, caused by defect of copper chaperone to SOD; (4) MEDNIK; and (5) MEDNIK-like syndrome, associated with defects in subunits of adaptor protein complex 1, which regulates copper pump trafficking. Aceruloplasminemia, due to mutations in *CP*, encoding the copper-containing enzyme ceruloplasmin, is discussed in the chapter on iron metabolism.

Zinc is involved in all major metabolic pathways, so its deficiency is highly detrimental. Conversely, high serum zinc is rarely toxic, probably because it binds to albumin and α_2-macroglobulin. Acrodermatitis enteropathica, the main inborn error of zinc metabolism, causes a cutaneous disorder associated with diarrhea, infections, and growth retardation. Rarer zinc metabolism disorders are Spondylocheirodysplastic Ehlers-Danlos syndrome, Birk-Landau-Perez syndrome, and Hyperzincemia with Hypercalprotectinemia.

Selenium is involved in antioxidant defenses, immune response, and thyroid function. Two genetic disorders have been associated so far with selenium metabolism.

Introduction

Wilson disease is an autosomal recessive disorder of copper metabolism due to mutations in *ATP7B*, encoding the copper transporting ATP-ase ATP7B (de Bie et al. 2007; Ala et al. 2007) (see Fig. 36.1). In Wilson disease, tissue copper overload, mainly in brain and liver, causes neurological, ocular (Kayser-Fleisher ring), and psychiatric symptoms, along with hepatic cirrhosis and liver failure due to impaired copper export into the bile (Ala et al. 2007). Younger patients generally present with hepatic symptoms, and even with fulminant liver failure, while at an adult age, a neurological presentation is more prevalent. However, even older patients (5th–6th decade of life) can manifest hepatic symptoms at onset (Ferenci et al. 2007), while in the pediatric age group, a neurological presentation is not unusual. The most common neurological syndrome is a movement disorder, particularly dysarthria and dysgraphia, tremor, dystonic rigidity, and drooling. In some patients, psychiatric symptoms (from impulsivity and irritability to psychosis) are predominant. Brain MRI usually shows striatal hyperintensity at T2-weighted images (Table 36.1).

As ATP7B is required for copper incorporation into ceruloplasmin, a defect in this copper pump causes the excretion of shorter half-life ceruloplasmin into the circulation without copper (apo-ceruloplasmin), explaining the characteristic low serum ceruloplasmin levels observed in Wilson disease. As 95% of serum copper is bound to ceruloplasmin, a low level of this protein also causes low serum copper. In Wilson disease, however, serum copper could be in the normal range, due to high release of copper from liver in severely affected patients. Most of this copper is unbound (so-called free serum copper), is toxic to erythrocytes, and can induce hemolysis. However, also subjects heterozygous for an *ATP7B* mutation, as well as patients with aceruloplasminemia, can show low serum ceruloplasmin, making this parameter alone insufficient for the diagnosis. Patients with neurological Wilson disease almost invariably present with Kayser-Fleischer rings, a greenish-brown deposit of copper molecules at the limbus of the cornea (Descemet membrane), which is absent in up to 50% of patients presenting with hepatic symptoms. This ocular sign is not specific, as it can be present also in other cholestatic liver diseases. Most characteristically, 24-h urinary copper excretion is elevated in Wilson disease, but also this parameter can be falsely elevated, for example, in other severe liver diseases. At the same time, 24-h urinary copper excretion can be normal in Wilson disease patients with a low copper load, such as in younger asymptomatic siblings of a known patient (Nicastro et al. 2010). Liver copper is usually elevated in Wilson disease, but it can also be abnormal in patients with cholestatic liver diseases. Therefore, none of the available laboratory tests is perfect or specific for Wilson disease, so the diagnosis is generally made through the combination of several parameters. A numerical value is given to the absence or presence of clinical signs (Kayser-Fleischer rings, neurologic symptoms) and laboratory features (copper in serum, urine, liver; serum ceruloplasmin; genetic testing), scoring from 0 (absent) to 2 (present), and the so-called Leipzig score is calculated (Ferenci et al. 2003). If the score is ≥4, the diagnosis of Wilson disease is very likely (see also the diagnostic flowchart in Fig. 36.2). Wilson disease has been associated with more than 500 possible pathogenic variants in *ATP7B*, mostly rare mutations. Recent improvements in next-generation sequencing techniques have made the genetic diagnosis easier, so it is now reasonable to perform molecular analysis of *ATP7B* gene in any patient who has a provisional diagnosis of Wilson disease, both for confirmation purposes and to facilitate the subsequent screening of family members.

Menkes disease is an X-linked recessive disorder due to mutations in *ATP7A*, encoding ATP7A, a copper-transporting ATPase, present in all tissues except the liver. As a consequence, cellular uptake of copper is normal, but it cannot be exported (Kaler 1998). Copper efflux from enterocytes is severely reduced, and insufficient copper reaches the circula-

tion, affecting the metallation of copper-dependent enzymes. Relevant cuproenzymes in the brain include dopamine-β-hydroxylase (DBH), crucial in catecholamine biosynthesis, and peptidyl glycine mono-oxygenase, required for the processing of neuropeptide precursors. Defect of these enzymes, and others like cytochrome c oxidase, which is essential for mitochondrial respiration, are probably responsible for the progressive neurological deterioration in Menkes disease, which generally starts at the age of 2–3 months. Other enzymes influenced by copper deficiency are sulfhydryl oxidase, involved in keratin crosslinking, causing sparse, fragile, greyish, and discolored hair ("pili torti"), and lysyl oxidase, essential for collagen crosslinking. Skin and joint laxity, as well as vascular tortuosity and bladder diverticula, are therefore characteristic features of this disease. Typical biochemical abnormalities in Menkes disease are low serum levels of copper and ceruloplasmin. However, at birth, serum copper and ceruloplasmin may be just below the usual range, making the diagnosis less straightforward. Abnormal levels of cathecholamines and their metabolites are instead quite specific for Menkes disease, especially the ratio between dopamine and norepinephrine as well as the ratio of dihydroxyphenylacetic acid to dihydroxyphenylglycol in plasma (Kaler et al. 2008) (Table 36.2). In cultured fibroblasts, it is possible to demonstrate an increase of copper content and retention rate, whereas egression rate is usually reduced, but these analyses are not available in most laboratories (Kim et al. 2003). Molecular testing of *ATP7A* gene allows the final diagnosis.

Occipital horn syndrome is a mild allelic variant of Menkes disease, caused by *ATP7A* mutations retaining a certain degree of protein function (Moeller et al. 2000). The clinical presentation is that of a connective tissue disorder, with skin and joint laxity, bone demineralization, and exostoses, predominantly at the occipital insertion of the paraspinal muscles, hence the origin of its name (Tsukahara et al. 1994). In addition, these patients have urinary tract diverticula and vascular tortuosity. Survival into adult life is usual (Tsukahara et al. 1994). A variable degree of intellectual disability may be present. Additionally, some patients have signs of autonomic dysfunction that point to DBH deficiency (Kaler et al. 2008). Serum copper and ceruloplasmin levels are in the low-normal range, whereas copper retention and egress rate in cultured fibroblasts are similar to those in Menkes disease (Table 36.3). A mutation analysis of *ATP7A* gene clarifies the diagnosis.

X-linked distal hereditary neuropathy is the third allelic variant associated with ATP7A defect and is caused by three unique missense mutations (p.A991D, p.T994I and p.P1386S) impairing the intracellular trafficking of this protein. The clinical phenotype is that of a late distal motor neuropathy with normal or slight low serum copper and ceruloplasmin levels and normal neurochemical ratios (Gualandi et al. 2019; Kennerson et al. 2010) (Table 36.4).

CCS deficiency has been reported in a patient with *SLC33A1* defect and a homozygous mutation (c.487C->T; p.Arg163Trp) in the *CCS* gene, encoding the intracellular chaperone involved in copper delivery to Cu/Zn superoxide dismutase (SOD1) (Huppke et al. 2012b). This patient, along with the clinical and biochemical features of Huppke-Brendel syndrome, presented additional symptoms not reported in that disease, namely severe muscular hypotonia, hypoglycemia, pericardial effusion, epilepsy, and persistent bilateral thalamic lesions at brain MRI. Although functional studies confirmed a pathogenic role of the *CCS* mutation and reduced SOD1 activity, it is not clear if this particular phenotype was a consequence of CCS defect with concomitant reduced metallation of SOD1.

MEDNIK (acronym for Mental retardation, Enteropathy, Deafness, Neuropathy, Ichthyosis, and Keratoderma) syndrome is a rare neurocutaneous disorder, originally described in consanguineous families from the Kamouraska region of Quebec (Martinelli et al. 2013). Aside from those clinical features, patients also presented a mild increase in plasma very long-chain fatty acid levels (VLCFA). Other relevant features reported by Martinelli and colleagues included bilateral T2-weighted hyperintensities of the basal ganglia and hepatopathy with elevated transaminases and cholestasis, reduced serum ceruloplasmin and copper although with increased non-ceruloplasmin bound copper, increased urine copper excretion, and increased liver copper concentration (Table 36.5). Liver biopsies showed intrahepatic cholestasis in one patient, and fibrosis and/or cirrhosis in the other two (Martinelli et al. 2013). The complete phenotype of the disease should therefore better be described as MEDNIK syndrome plus hepatopathy and copper abnormalities (MEDNIK-HC or Martinelli syndrome). MEDNIK syndrome has been associated with truncating mutations (c.364dupG and c.301-2A>G), in the *AP1S1* gene, which encodes for the σ1A subunit of adaptor protein complex 1 (AP-1). Adaptor protein complexes regulate clathrin-coated vesicle assembly, protein cargo sorting, and vesicular trafficking between organelles in eukaryotic cells (Martinelli et al. 2013). In basal conditions, the copper ATPases are localized at the level of the trans-Golgi network, where they transport copper to cuproenzymes synthesized within the secretory compartments. When the intracellular copper level rises, they translocate to the plasma membrane to traffic copper to the plasma membrane (ATP7A) or relocate it to cytoplasmic vesicles associated with bile ducts canalicular membrane (ATP7B). The trafficking of both copper pumps is clathrin-dependent and is mediated by the adaptor protein complex, thus explaining the clinical and biochemical findings of the disease, which combines some aspects of both

Menkes disease and Wilson disease, as well as other symptoms.

Interestingly, two novel missense *AP1S1* mutations, c.269T>C (p.Leu90Pro) and c.346G>A (p.Glu116Lys), have been recently associated with a non-syndromic form of congenital diarrhea in three patients who died within the first 3 months of life due to intractable diarrhea, without showing other symptoms of MEDNIK syndrome, such as sensorineural deafness and ichthyosis (Klee et al. 2020). It is not known, however, if these missense mutations may represent hypomorphs allowing for residual AP-1 complex function in the inner ear or skin, or if the patients have died before manifesting the characteristic features of MEDNIK disease.

MEDNIK-like syndrome is a recently described disease associated with two homozygous null variants in *AP1B1*, encoding the large β subunit of the AP-1 complex (Alsaif et al. 2019). Affected individuals showed the same neurocutaneous phenotype as MEDNIK patients, and abnormal copper metabolism highlighted by low plasma copper and ceruloplasmin, but lacked evidence of copper overload in the liver. Plasma VLCFA were also increased.

Acetyl-CoA transporter deficiency (Huppke-Brendel syndrome) is a rare disorder caused by mutations in the *SLC33A1* gene, encoding for a transporter (AT-1) that translocates acetyl-CoA into the ER lumen (Huppke et al. 2012a). Disease phenotypes include developmental delay, congenital cataracts, nystagmus, hearing loss, white matter hypomyelination, cerebral and cerebellar atrophy, early death, and low serum copper and ceruloplasmin levels, with normal urine copper. The pathogenesis has not been completely elucidated so far, but an abnormal acetylation of ceruloplasmin could lead to decreased secretion, with secondarily reduced serum copper (Table 36.6).

Acrodermatitis enteropathica is an autosomal recessive disorder of zinc transport caused by mutations in the *SLC39A4* gene encoding ZIP4, a zinc transporter expressed at the apical membrane of the enterocytes (Wang et al. 2002), affecting zinc absorption from the gut. Clinical symptoms develop after breastfeeding is stopped, whereas babies fed with infant formula develop the disorder as early as the first 2–4 weeks of life. Patients usually show severe erythematous dermatitis, initially localized at the acral and peri-orificial sites (Neldner and Hambidge 1975). Later on, these lesions become more pustular and hyperkeratotic. Mucosal lesions include gingivitis, stomatitis, and glossitis. Total alopecia is frequent, as well as nail deformities and ophthalmologic problems (blepharitis, conjunctivitis, photophobia, and impaired dark adaption). In addition, some patients present with watery diarrhea and failure to thrive. Behavioral disturbances such as irritability, apathy, and depression are common (Table 36.7). Patients are prone to frequent infections, as zinc deficiency affects cellular and humoral immunity. If untreated, the disease worsens and can even be fatal.

When the diagnosis is suspected on a clinical basis, serum zinc levels should be measured, as they are often severely reduced. Up to 15% of patients, however, show normal values because of zinc release from catabolized tissues (Van Wouwe 1989). Measurement of zinc in other tissues, such as hair or blood cells, does not improve diagnostic accuracy. In addition, several conditions, such as chronic diarrhea or infections, can be associated with secondary reduced serum zinc levels. Low urinary zinc excretion or low alkaline phosphatase (a zinc-dependent enzyme) activity can support the diagnosis. The recent improvement in genetic testing owing to NGS methodologies has made other approaches, such as intestinal zinc transport studies with radiolabeled zinc, archaic.

While waiting for the molecular results, zinc therapy should be started, and a positive response should be obtained within a week. The relapse of skin abnormalities after zinc withdrawal is conclusive.

Additional biochemical abnormalities that can be observed are increased blood ammonia (due to the defect of ornithine transcarbamylase deficiency), hypobetalipoproteinemia, and an altered fatty acid pattern. Biochemical evidence of depressed humoral and cell-mediated immunity may coexist.

Transient Neonatal Zinc Deficiency

Transient neonatal zinc deficiency is due to maternal heterozygous mutations in *SLC30A2*, which encodes ZnT2, a zinc transporter in mammary epithelial cells. This disorder causes low maternal milk zinc concentrations. Therefore, during breastfeeding, infants show signs of zinc deficiency, resembling acrodermatitis enteropathica, but they resolve after weaning (Chowanadisai et al. 2006) (Table 36.8).

Spondylocheirodysplastic Ehlers-Danlos Syndrome (SCD-EDS)

The zinc transporter protein ZIP13, encoded by *SLC39A13*, plays a crucial role in bone, tooth, and connective tissue development. Biallelic mutations in this gene cause the spondylocheirodysplastic form of Ehlers-Danlos syndrome (SCD-EDS). Affected patients exhibit both the common features of EDS, like articular hypermobility and skin hyperelasticity, and distinct physical signs such as short stature, tapering fingers, wrinkled palms, and downslanted palpebral fissures with a lack of periorbital tissue.

Skeletal radiographs show platyspondyly, osteopenia, irregular endplates of the vertebral bodies, metaphyseal widening, and epiphyseal flattening (Giunta et al. 2008). A useful biomarker of the disease is a fivefold increase of urinary deoxypyridinoline-to-pyridinoline ratio compared to normal (Table 36.9). Serum zinc levels are normal, but the intracellular distribution of zinc is abnormal, affecting proper nuclear translocation of transcription factor SMADs, which respond to BMP and TGF-β, and are critical for connective

tissue development. Electron microscopy studies on skin biopsies documented normal elastic fibers and collagen fibrils (Giunta et al. 2008).

Birk-Landau-Perez Syndrome is an autosomal recessive disorder caused by mutations in *SLC30A9*, encoding ZnT9 (Ferreira and Gahl 2017). The ZnT9 defect causes a cerebrorenal syndrome with early-onset intellectual disability and tubulointerstitial nephropathy. After a normal psychomotor development, patients show progressive neurodegeneration, starting at 1–2 years of life. Brain MRI is normal (Table 36.10). ZnT9 is located in the endoplasmic reticulum, and its deficiency affects zinc homeostasis, leading to decreased cytosolic zinc concentrations (Ferreira and Gahl 2017).

Asymptomatic Familial Hyperzincemia occurs as a consequence of a variant form of albumin (the major transport protein in blood for zinc) with higher affinity to this metal. Therefore, serum zinc excess is caused by increased binding to albumin (Table 36.11). The condition has no clinical effects, and it is also called Familial Dysalbuminemic Hyperzincemia.

Hyperzincemia and Hypercalprotectinemia is an autoinflammatory disorder characterized by pustular and ulcerative inflammatory cutaneous lesions, recurrent arthritis, hepatosplenomegaly, pancytopenia, and growth failure caused by a mutation in the proline-serine-threonine phosphatase-interacting protein 1 (*PSTPIP1*) gene, leading to dysregulation of the metabolism of calprotectin (Holzinger et al. 2015). This protein has zinc-binding capacity, as well as antimicrobial and proinflammatory activity. Laboratory tests show extremely high serum levels of zinc and mostly calprotectin (500–12,000 times the normal levels) (Table 36.12).

SBP2 Deficiency is due to biallelic mutations in *SECISBP2*, encoding SBP2. In all reported patients, the deficiency of deiodinases causes abnormal thyroid metabolism, with elevated T4 and rT3, high/normal TSH, and low T3 levels.

Additional clinical symptoms, variably present, include psychomotor or speech delay, sensorineural hearing loss, oligospermia, and progressive congenital myopathy (Ferreira and Gahl 2017). Serum selenium concentration is low, indicating a global selenoprotein synthesis deficiency (Table 36.13). Organic or inorganic selenium supplementation is not able to revert thyroid function abnormalities (Ferreira and Gahl 2017).

Progressive Cerebellocerebral Atrophy is caused by biallelic mutations in the *SEPSECS* (Sep (O-phosphoserine) tRNA:Sec (selenocysteine tRNA synthetase) gene, responsible for a severe neurodegenerative disease with intellectual disability, postnatal microcephaly and spasticity, progressive atrophy of the cerebrum and cerebellum, and variable myoclonic or generalized tonic-clonic seizures (Agamy et al. 2010). Serum selenium is normal, and thyroid function has not been investigated in detail (Table 36.14).

Metabolic Pathways

Metabolic Pathway for Copper (see Fig. 36.1)

Metabolic Pathway for Zinc

Zinc is involved in a variety of biological processes, as a structural, catalytic, and intracellular and intercellular signaling component. Zinc is a cofactor for several enzymes, including ornithine transcarbamylase, alkaline phosphatase, carbonic anhydrase, superoxide dismutase, DNA and RNA polymerases, lactate dehydrogenase, and alcohol dehydrogenase. Two groups of proteins involved in zinc transport are involved in cellular zinc homeostasis: the Zip family that mediates zinc transport from outside the cell into the cytoplasm and the ZnT family that mediates export of zinc, either into the extracellular space or into intracellular organelles. The exact role of each of these zinc transport proteins in the various cell types has not been completely elucidated. In humans, there are nine known ZnT transporters and 15 Zip transporters. The ZIP4 defect has been associated with a zinc absorption defect in the enterocytes, leading to Acrodermatitis Enteropathica. ZIP13 is relevant for bone and connective tissue development, and its loss of function is causative for the spondylocheirodysplastic form of Ehlers-Danlos syndrome. For the zinc export proteins identified in humans, the ZnT2 defect has been associated with low breast milk concentration, whereas the ZnT9 defect causes a cerebro-renal disease, Birk-Landau-Perez syndrome.

Metabolic Pathway for Selenium

Selenium salts are toxic in large amounts, but trace amounts are crucial for cellular function in humans. Selenium is mainly found in foods in its organic form—selenomethionine in plant sources, selenocysteine in animal sources—while the inorganic forms of selenium—selenate and selenite—are mainly found in dietary supplements.

More than 80% of the ingested selenium is absorbed through the small intestines.

Most biological effects of Se are mediated by selenoproteins, proteins containing the 21st proteinogenic amino acid, selenocysteine (Sec), a cysteine analogue with a selenium-containing selenol group in place of the sulfur-containing thiol group. There are 25 human selenoproteins, including five forms of glutathione peroxidase, three forms of thioredoxin reductase, and three deiodinases, those three participating in thyroid hormone metabolism

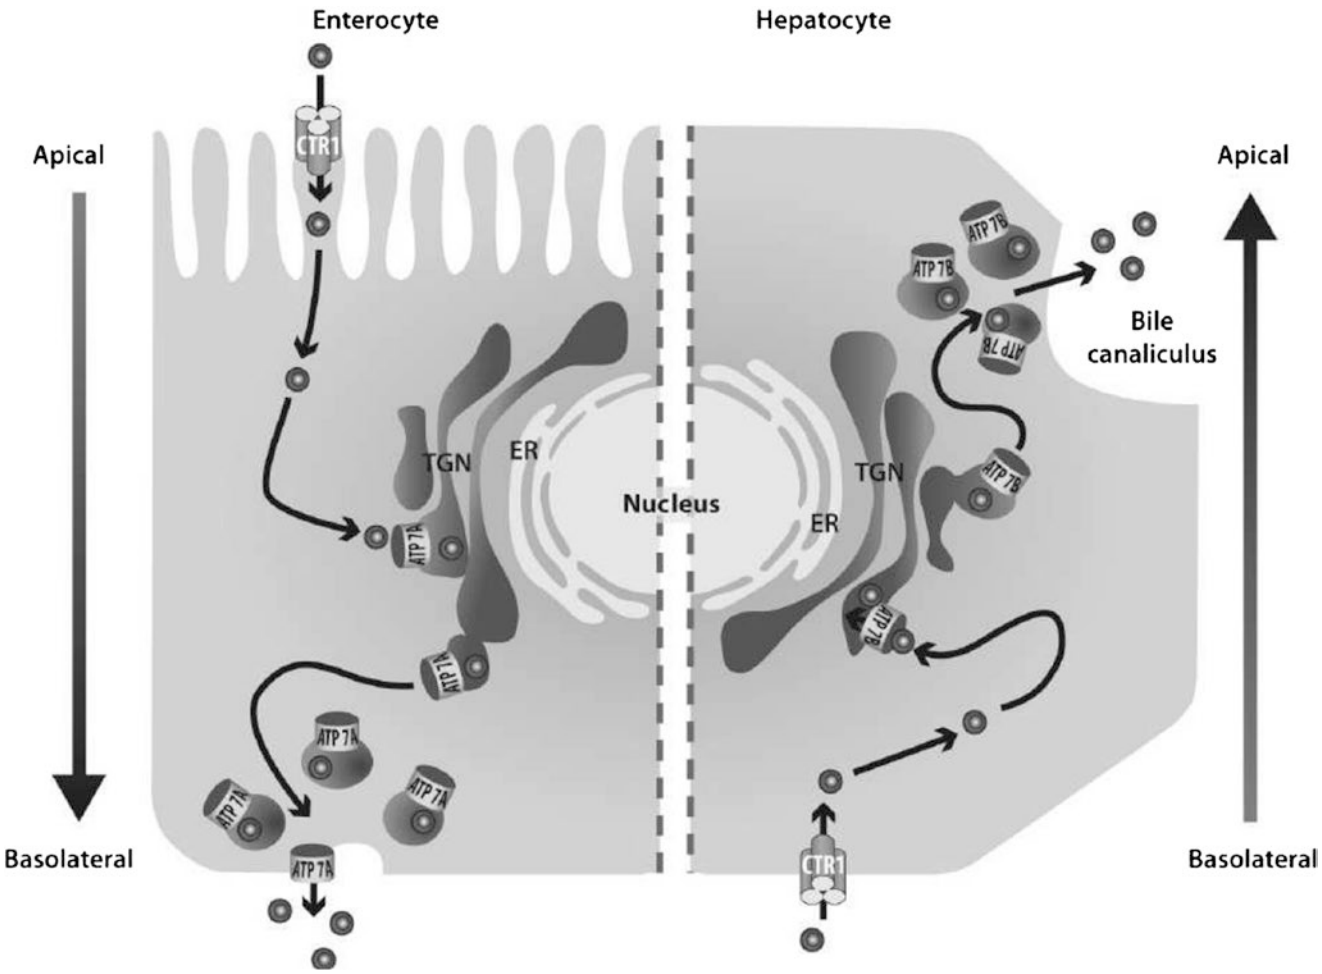

Fig. 36.1 Schematic representation of the key elements of copper homeostasis (adapted from Agamy et al. (2010)). Left panel: Copper is required for numerous processes, including mitochondrial respiration, antioxidant defense, neurotransmitter synthesis, connective tissue formation, and skin pigmentation. Dietary copper from the intestine is taken up by the enterocytes through CTR1 and transported intracellularly to ATP7A, localized in the trans-Golgi network (TGN). This protein will export copper to the portal circulation. When ATP7A is defective, as in Menkes disease, no copper can leave the enterocyte, resulting in a systemic shortage of copper. Right panel: copper from the portal circulation is taken up through CTR1, transported to ATP7B in the trans-Golgi network (TGN). This protein will export copper to the bile canaliculus. When this pathway is defective, as in Wilson disease, the hepatocytes will gradually accumulate copper, which above a threshold level will induce cellular damage

(Ferreira and Gahl 2017). There is no specific codon for Sec; instead, the UGA codon, usually a stop codon, is made to encode selenocysteine by the presence of a selenocysteine insertion sequence (SECIS), a stem–loop structure present in the 3′-untranslated region of mRNA. Selenocysteine synthesis occurs on a specialized tRNA, called tRNA[Ser]Sec, but there are no tRNA synthetases specific for Sec, so serine is charged onto tRNA[Ser]Sec by Seryl-tRNA synthetase first. Ser-tRNA[Ser]Sec is then converted into Sec-tRNA[Ser]Sec by selenocysteine synthase (SEPSECS). A specific elongation factor, EF-Sec, directs Sec-tRNA[Ser]Sec to the ribosome, which translates UGA as selenocysteine (Sec) instead of termination. SECIS-binding protein 2 (SECISBP2) is crucial for the interaction with the SECIS element (Agamy et al. 2010).

Signs and Symptoms

[a]One patient

Diagnostic Flowchart

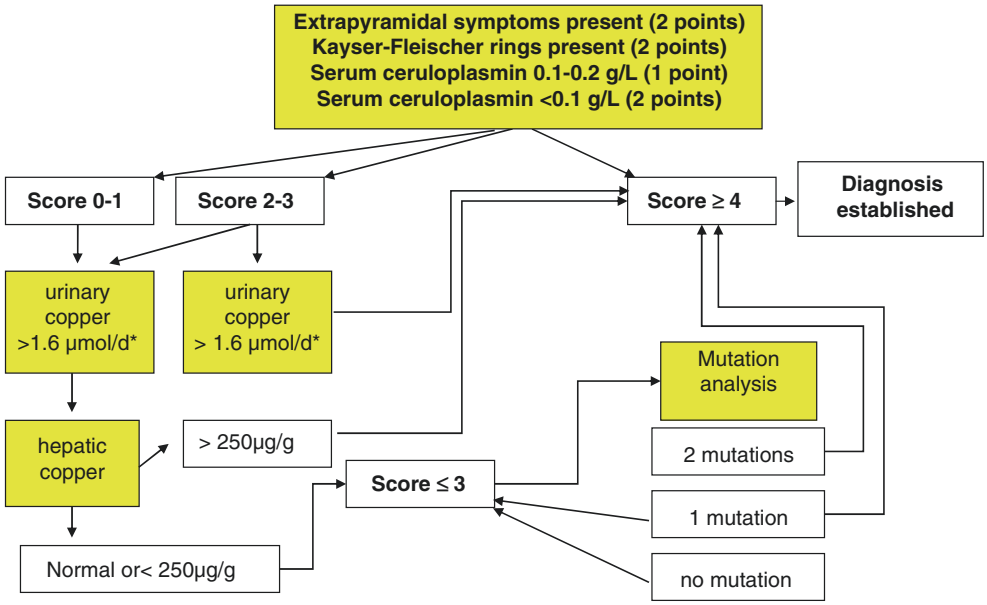

Fig. 36.2 Diagnostic flowchart for Wilson disease (Modified from Ferenci et al. (2003) and European Association for the study of the Liver (2012). *In asymptomatic children the cut-off can be lowered to 0.6 μmol/day (Ala et al. 2007)

Menkes Disease

Diagnosis should be suspected in any child with symptoms suggestive of Menkes disease or a positive family history. A quick confirmation is essential, as an early diagnosis is a prerequisite for effective treatment. This can be obtained by determining the ratio of plasma dopamine to norepinephrine (N: 0.04 ± 0.03; Menkes: 0.83 ± 0.71), as well as the ratio of plasma dihydroxyphenylacetic acid to dihydroxyphenylglycol (N: 1.5 ± 0.4; Menkes: 13.0 ± 6.6) (Kaler et al. 2008). Serum copper and ceruloplasmin are generally low, but this may not be discriminatory as levels tend to be low in infancy. An analysis of *ATP7A* for mutations confirms a biochemical diagnosis.

Occipital Horn Syndrome

In a patient with symptoms suggestive of occipital horn syndrome, serum copper and serum ceruloplasmin are generally low, but can be normal too. Therefore, a genetic analysis of *ATP7A* is mandatory for establishing a diagnosis.

Acetyl-CoA Transporter Deficiency

The presence of the characteristic constellation of clinical signs, as well as low serum copper and ceruloplasmin, should prompt to sequence the *SLC33A1* gene.

CCS Deficiency

As this disorder was described only in one patient, who also carried pathogenic mutations in *SLC33A1*, there is not at the moment a definite flowchart to direct the diagnosis.

MEDNIK and MEDNIK-Like Syndrome

These two disorders should be suspected in presence of the characteristic clinical phenotype associated with low serum copper and ceruloplasmin, and a slight increase in VLCFA. Some symptoms (such as peripheral neuropathy) may not be present in the first phases of the disease. A genetic analysis of *AP1S1* and *AP1B1* gene is required to differentiate between the two disorders.

Acrodermatitis Enteropathica

Patients who develop the characteristic erythematous dermatitis at the acral and periorificial areas when breastfeeding is stopped should be investigated for *acrodermatitis enteropathica.*

Serum zinc levels are usually low, but 15% of the patients have levels in the normal range (Van Wouwe 1989). The diagnosis is confirmed by disease-causing mutations in *SLC39A4*. All suspected patients should receive zinc therapy waiting for genetic results. A response should be obtained within a week.

SCD-EDS and Birk-Landau-Perez Syndrome may be suspected only on the basis of the phenotype, due to the absence of overt serum zinc abnormalities, except for a mild increase in the urinary deoxypyridinoline-to-pyridinoline ratio in SCD-EDS.

Familial Asymptomatic Hyperzincemia may be suspected in subjects with persistent evidence of increases in serum zinc, without clinical signs of disease. Conversely, an autoinflammatory disorder with ulcerative cutaneous lesions and systemic involvement may suggest to measure calpro-

tectin. In the presence of a dramatic increase in this protein, serum zinc should be measured, to aid in the diagnosis of *hyperzincemia and hypercalprotectinemia.*

In **SBP2 deficiency**, abnormal thyroid function and low selenium are diagnostic handles whereas in **progressive cerebello-cerebral atrophy** there are no reliable biomarkers.

Specimen Collection

Tubes for routine blood collection in fasting subjects should be copper, zinc, selenium, and other trace metals free. Copper measurement on dry liver tissue should be performed by collecting the fresh samples in metal-free specimen vials and immediately freezing them in liquid nitrogen. The sample should be store at −80 °C until analysis.

For copper measurement in urine over 24 hr, it is crucial to use copper-free urine collection containers to exclude false positives due to contamination of the collection vessels.

For 24-hr urine collection, it is recommended to keep the urine aliquots refrigerated (at 4 °C), and after completion to send the samples to the laboratory in a well-isolated package. Urine can be stored in the refrigerator at 4 °C for a maximum of 1 week until analysis, or stored frozen at −20 °C (1 week–2 months).

Prenatal Diagnosis

Prenatal diagnosis in each condition discussed is possible by gene sequencing when the defect in the family is known.

DNA Testing

For each of the disorders discussed, the gene is known. Molecular analyses could be performed on DNA extracted from blood collected in EDTA tubes. Available options include sequencing of all coding exons and intron–exon boundaries of the gene of interest by Sanger, or as part of a targeted gene panel for Mendelian syndromes, or by exome or whole-genome sequencing. Exon or whole-gene deletions/duplications may be identified by diverse methods including quantitative PCR, long-range PCR, multiplex ligation-dependent probe amplification, and chromosomal microarray that include that gene/chromosome segment.

Treatment Summary

Wilson disease treatment is based on reducing the amount of copper in the body. Several copper chelators are available, that is, penicillamine and trientine, as well as zinc. Penicillamine is the drug of choice in patients with hepatic problems, while in patients with neurologic problems, zinc should be considered (European association for the study of the liver 2012). Zinc treatment is also advisable in patients still without clinical symptoms, for example, those identified through family screening. Many patients, both those with mainly neurological symptoms and those with hepatic disease, especially in the phase of end-stage cirrhosis or liver failure, do not respond to the therapy. For those patients, liver transplantation is an option.

Earlier, *Menkes disease* patients died mostly before the age of 3, but with current supportive care, a longer survival is possible. Treatment with subcutaneous injections of copper histidine or copper chloride before age 10 days is able to normalize the developmental outcome in some patients and improves the neurologic outcome in others (Kaler et al. 2008). However, it is evident that some infants show poor or no significant response at all, also after starting copper histidine treatment very early in life, depending on the residual functional activity of ATP7A protein (Kaler et al. 2008).

In *Occipital horn syndrome*, there is no evidence so far that copper replacement therapy can be clinically beneficial, although it seems reasonable to expect better neurodevelopmental and neurocognitive outcomes in these individuals if they are treated with copper during their first 3 years of age.

Acetyl-CoA transporter deficiency. Four patients were treated with copper replacement therapy without reasonable evidence of improvement (Huppke et al. 2012a).

MEDNIK syndrome might respond to zinc acetate therapy. In the only patient tested with this treatment, oral zinc acetate therapy at a dose of 50 mg/day was associated with a relevant improvement of both clinical and laboratory abnormalities.

Acrodermatitis Enteropathica. Zinc supplementation results in the disappearance of skin lesions within a week and normalization of plasma and urinary excretion of zinc, as well as serum alkaline phosphatase values. The usual therapeutic dose ranges between 30 and 50 mg Zn/day (10–30 μmol elemental zinc/kg/day, 0.5–2 mg/kg elemental zinc/day) and most patients are kept at the same total dose per day during their entire childhood. Zinc is usually provided as zinc salts (gluconate, acetate, and, more often, sulfate), administered in three divided doses daily if gastric problems occur. As zinc competes with copper for absorption at the intestinal level, plasma copper should be monitored to avoid hypocupremia.

Long-term prognosis is excellent and the good response to zinc therapy suggests that other, low-affinity transporters, may be involved in importing this cation at higher luminal concentrations (Neldner and Hambidge 1975; Van Wouwe 1989).

Standard Treatment

	Therapy	Application	Dose	Duration
36.1 Wilson disease	Chelating agents (D-penicillamine, trientine)	Orally	Children: 25 mg/kg/day Adults: 1–2 g in 4 doses	Lifelong
	Zinc salts (zinc acetate)	Orally	1–5 years: 2 × 25 mg/day 6–16 years: 3 × 25 mg/day >16 years: 3 × 50 mg/day	Lifelong
36.2 Menkes disease	Cu-histidinate	SC	250 μg twice daily 250 μg daily after 1 year	Lifelong
36.3 Acrodermatitis enteropathica	Zinc sulphate Zinc acetate	Orally	50–90 mg Zn^{2+}/day	Lifelong
36.4 MEDNIK syndrome	Zinc acetate	Orally	50 mg/day	Lifelong?

Follow-Up

Wilson disease: Each follow-up visit should include a clinical evaluation, both neurological and hepatological, and laboratory tests of copper metabolism (mainly 24-h urinary copper excretion) and liver function (synthesis, bilirubin, transaminases). These parameters should all improve. On stable, long-term chelator therapy, urinary copper excretion should be 3–8 μmol/24 h, while a urinary copper excretion in excess of 1.6 μmol/24 h after 2 days cessation of chelators may indicate insufficient decoppering or non-adherence to therapy [European association for the study of the Liver]. Similarly, on stable, long-term zinc treatment, urinary copper excretion should be below 1.6 μmol/24 h.

Menkes disease patients on copper histidine treatment must be regularly monitored with special emphasis on neurodevelopmental outcome and renal side effects. Serum copper and ceruloplasmin values should normalize under therapy and need to be checked to avoid supranormal levels (Kaler et al. 2008). Serum copper levels, however, are poor predictors of long-term neurodevelopmental outcome.

Acrodermatitis enteropathica patients will be monitored clinically to follow the effect of zinc supplementation on symptomatology. Therapy will rapidly improve dermatological signs. Biochemical parameters (serum zinc level, serum alkaline phosphatase, and urinary zinc excretion) will also normalize.

For MEDNIK syndrome, it is not possible at the moment to give recommendations. As for all the other disorders reported in this chapter, for which a therapy is not available, long-term management is mainly directed at preventing disease complications.

Disorders of Iron Metabolism

Contents

Summary

Iron (Fe) is an essential element for almost every living organism. In humans and other mammals, iron homeostasis evolved to prevent iron excess, which leads to reactive and toxic oxygen species causing cell damage. This situation is attained by mechanisms for efficient regulation and internal iron recycling; however, this sophisticated control limiting iron absorption may easily promote the development of iron deficiency. Other than secondary iron overload conditions (i.e., transfusional iron overload or iron-loading anemias) and secondary iron deficiency, there are several genetically determined iron disorders. The first type of inherited iron-related disorder is "Hereditary Hemochromatosis (HH)," caused by mutations in genes maintaining Fe homeostasis. Different types of HH have been discovered; however, regardless of the mutated gene, the final outcome is an inappropriate hepcidin expression. The most common type of HH (type I) is caused by a mutation in *HFE*, with adult onset, and it accounts for >80% of all hemochromatosis patients, mostly Caucasian. The prevalent p.Cys282Tyr substitution leads to the inability of HFE to sense increased levels of Fe and interact with TfR1, which causes decreased hepcidin expression. Type II or juvenile HH, due to hemojuvelin (HJV) or hepcidin mutations, is a more severe disorder that affects younger individuals and causes a fast and heavy Fe overload in the liver and parenchyma. Type III HH is rare; it is similar to type 1, but is caused by mutations in the *TFR2* gene. Type IV HH differs from the other ones for having an autosomal dominant transmission and for not directly affecting hepcidin expression. It is caused by mutations in the *SLC40A1* gene, which encodes the Fe exporter ferroportin (Fpn), namely the hepcidin target. HH in general is not associated with anemia, whereas the conditions with iron overload associated with anemia suggest congenital atransferrinemia, hereditary aceruloplasminemia, and divalent cation transporter 1 (DMT1)-related iron overload. Finally, there are genetic defects that cause iron deficiency such as mutations occurring in *TMPRSS6* (matriptase 2) responsible for an iron-refractory iron deficiency anemia (IRIDA).

Introduction

Iron (Fe) is an essential element that is involved in a variety of vital functions, including oxygen transport, DNA synthesis, metabolic energy, and cellular respiration. However, excess iron can lead to the generation of reactive oxygen species (ROS), which cause oxidative stress, lipid peroxidation, and DNA damage, compromising cell viability and promoting cell death (Coffey and Ganz 2017). Under physiologic conditions these deleterious effects are prevented by sophisticated regulatory mechanisms, which maintain systemic and cellular Fe homeostasis (Anderson and Frazer 2017). Iron homeostasis is the result of balanced cooperation between functional compartments (erythroid and proliferating cells), uptake and recycling systems (enterocytes and splenic macrophages), storage elements (hepatocytes), and mobilization processes. The intracellular iron homeostasis is maintained by a posttranscriptional mechanism based on iron responsive elements (IREs) and iron regulatory proteins (IRPs) that bind to the IREs (Muckenthaler et al. 2008). In humans, there is no regulated excretion of iron, thus the iron balance is primarily controlled at the level of intestinal absorption, which takes place in the proximal portion of the duodenum. Fe^{2+} iron enters enterocytes through DMT1 localized to the apical membrane and to subapical endosomes. DMT1 remains the primary transmembrane iron transporter and its expression is highly induced in iron deficiency. Once inside the intestinal epithelial cells, a portion of iron remains in the cell for use or storage and it is sloughed into the gut lumen when enterocytes become senescent; the rest is exported across the basolateral membrane of the enterocytes through the iron exporter ferroportin. Iron entry into the bloodstream is critical for systemic iron homeostasis and is negatively regulated by hepcidin, the iron regulatory hormone (Papanikolaou and Pantopoulos 2017; Ganz 2013). Hepcidin, a peptide hormone produced in the liver, is responsible for modulating iron availability to meet iron needs. Hepcidin operates by binding to ferroportin in tissue macrophages, duodenal enterocytes, and other target cells, triggering its tyrosine phosphorylation, internalization, and ubiquitin-mediated degradation in lysosomes. By removing ferroportin from the plasma membrane, hepcidin shuts off cellular iron export. The final consequence is the decrease in serum iron. Iron and inflammation are the major hepcidin inducers. Following iron intake or an increase in body iron stores, hepcidin is mainly upregulated through the activation of the Bone Morphogenetic Proteins, BMP/SMAD signaling, to prevent further dietary iron absorption. Under inflammatory conditions, hepcidin induction serves to promote hypoferremia and iron sequestration in macrophages (Nemeth et al. 2004; Ganz and Nemeth 2015). On the other hand, hepcidin expression is suppressed in iron deficiency, hypoxia, and erythropoietic expansion (stress erythropoiesis). Hepcidin inhibitors are the liver protease matriptase 2, encoded by the transmembrane serine protease 6 (*TMPRSS6*) gene and the erythroid-released hormone erythroferrone (*ERFE*). In iron deficiency, matriptase 2 inhibits hepcidin by cleaving the BMP coreceptor hemojuvelin (HJV) on the hepatocyte membrane (Silvestri et al. 2008). *ERFE* is an EPO target gene activated by Janus Kinase 2-Signal transducer and activator of transcription. It is widely expressed, and it is increased by EPO only in the erythropoietic (bone marrow and spleen) tissues. There are many observations that strengthen the role of *ERFE* in stress erythropoiesis, although *TMPRSS6* has a dominant effect over *ERFE (*Arezes et al. 2018*)*.

The human iron disorders are invariably disorders of iron balance or iron distribution, either in terms of iron overload or iron deficiency. Hence, understanding iron homeostasis is critical for understanding these disorders, as well as understanding genetic iron disorders (Table 1). The first type of inherited iron-related disorder is hemochromatosis (HH). This term must be reserved for iron overload of genetic origin related to hepcidin deficiency. According to the most recent classification updated in 2018 (Brissot et al. 2018, 2019), hemochromatosis encompasses the following entities:

1. hemochromatosis type 1, related to mutations of the *HFE* gene (the *C282Y* mutation in the homozygous state is prevalent), which is by far the most common form, affecting mainly Caucasian populations (Allen et al. 2008)
2. hemochromatosis type 2 (the so-called juvenile hemochromatosis) corresponding to mutations in the hemojuvelin (*HJV*) gene (type 2A hemochromatosis) or to mutations in the hepcidin gene (*HAMP*) (type 2B hemochromatosis) (Kong et al. 2019)
3. hemochromatosis type 3 due to mutations in the transferrin receptor 2 (*TFR2*) gene (Kawabata 2019)
4. hemochromatosis type 4 due to mutations in the ferroportin gene (*SLC40A1*) in rare cases where these mutations lead to a refractory state to hepcidin ("gain-of-function"). There are different mutations in the ferroportin gene that affect the subcellular localization or transporter function of ferroportin ("loss-of-function"); this condition is characterized by macrophage iron loading and preferentially should be called "ferroportin disease." Both are autosomal dominant disorders (Pietrangelo 2017)

Thus, based on the current understanding, the molecular pathogenesis of "hemochromatosis" can be divided into three classes: first, mutations in the hepcidin gene itself (*HAMP*) that cause hemochromatosis by preventing the production of functional hepcidin protein; second, mutations in the genes encoding HFE (*HFE*), TFR2 (*TFR2*), and hemojuvelin (*HFE2*) inactivating signaling pathways that normally upregulate hepcidin expression; and finally, mutations in the gene encoding ferroportin (*SLC40A1*) that can cause

hemochromatosis by rendering the transporter insensitive to hepcidin regulation. These different types of hemochromatosis are characterized by common signs including increased plasma iron, increased transferrin saturation, and parenchymal iron accumulation primarily into hepatocytes. The clinical expression may differ in severity among the different forms (Andrews 2008). Anemia is not a manifestation of hemochromatosis; however, there are interesting genetic conditions presenting with microcytic iron deficiency anemia associated with tissue iron overload; it is the case of atransferrinemia (Beaumont-Epinette et al. 2015), DMT1 deficiency (Iolascon et al. 2008), and aceruloplasminemia (Piperno and Alessio 2018). Congenital atransferrinemia is a rare, early onset autosomal recessive disorder caused by transferrin deficiency (<20 mg/dL) due to mutations in the transferrin-encoding *TF* gene on chromosome 3q22.1. The disease is also referred to as hypotransferrinemia, as the complete absence of functional transferrin is lethal. Patients exhibit very low to undetectable levels of plasma transferrin. This leads to impaired erythropoiesis, microcytic hypochromic anemia, growth retardation, and iron overload in parenchymal cells of the liver, heart, and pancreas (Beaumont-Epinette et al. 2015). Mutations in the genes encoding DMT1 (*SLC11A2*) are associated with autosomal recessive hypochromic, microcytic anemia (given the role of DMT1 in the uptake of iron at the apex of duodenal cells), but also have hepatic iron overload. Aceruloplasminemia is a rare autosomal recessive disorder caused by loss of ceruloplasmin function caused by mutations in the *CP* gene on chromosome 3q23-q24 (Kono 2013). The phenotype is quite heterogeneous but is always characterized by iron-restricted erythropoiesis leading to microcytic anemia, diabetes, and in some cases late in life to progressive retinal and neurological degeneration. An impaired iron absorption due to mutations in *TMPRSS6*, leading to an inability to cleave the BMP coreceptor HJV and inhibiting hepcidin, is observed in a recessive condition named IRIDA (congenital, iron-refractory, iron deficiency anemia). IRIDA patients are refractory to oral iron supplementation (Camaschella 2019).

Hyperferritinemia-cataract syndrome is a dominant condition due to IRE-IRP deregulation in which mutations in the IRE of L-ferritin mRNA make L-ferritin refractory to IRP binding; as a result, the protein synthesis becomes iron-independent. Ferritin is high but total body iron is normal. L-ferritin may accumulate in the lens, leading to early onset of cataract (Tsantoula et al. 2014). A dominant rare disease named neuroferritinopathy may be due to nucleotide insertions in the C-terminus of L-ferritin leading to neurodegeneration because of increased oxidation and cell death (Kuwata et al. 2019).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM No.
37.1	Hereditary Hemochromasis type 1		HH	*HFE*	6p21.3	Homeostatic iron regulator	613609

[a]Neonatal hemochromatosis: very rare
[b]Hemochromatosis type 2 and 2B
[c]Hemochromatosis type 1, 3 and 4

Despite the high prevalence of C282Y homozygosity, only a minority of individuals will accumulate enough iron to cause organ damage. Given the autosomal recessive inheritance of C282Y, the frequency of C282Y homozygosity is similar in men and women, but the prevalence of clinical manifestations is much higher in men.

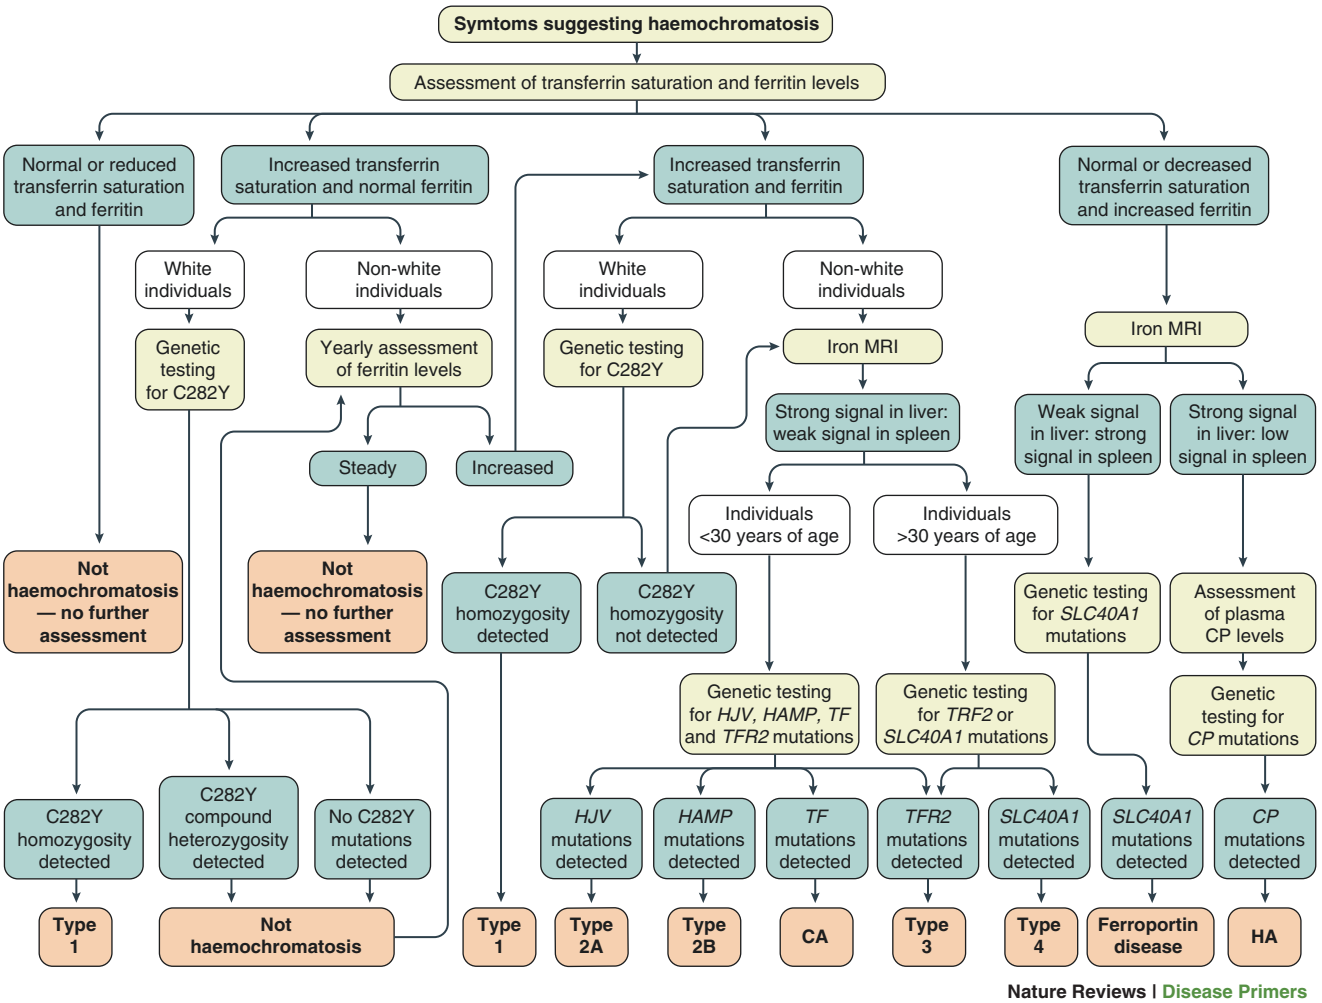
Diagnostic Flowchart



Brissot, P. et al. (2018) Haemochromatosis (Brissot et al. 2018) *Nat. Rev. Dis. Primers*. doi: https://doi.org/10.1038/nrdp.2018.16

In genetic conditions characterized by iron overload, transferrin saturation and ferritin levels are the key parameters to be assessed. However, increased ferritin levels (>300 mcg/L for men and >200 mcg/L for women) need rigorous interpretation before they are assigned to iron overload. Several conditions can be associated with increased ferritin levels independent of substantial iron overload such as metabolic syndrome (which is the most frequent cause), alcoholism, inflammation, and marked cytolysis. Despite these limitations, increased ferritin levels are critical for the diagnosis of hemochromatosis. Any acquired iron overload situation must be excluded (i.e., blood transfusions, dyserythropoiesis, or parenteral iron supplementation) by clinical history; family history could be helpful in some cases. Ethnicity is important considering the fact that *HFE*-associated hemochromatosis is observed almost exclusively in Caucasians and more frequently in men because the phenotypic expression of hemochromatosis is usually less pronounced in women. Age of onset is also important as *HFE*-associated (type 1) and *TFR2*-associated (type 3) hemochromatosis are generally observed in individuals >30 years of age, whereas clinical expression in younger individuals is typical of *HJV*-related (type 2A) or *HAMP*-related (type 2B) hemochromatosis. The non-*HFE* hemochromatosis diseases are very rare, in contrast to *HFE*-associated hemochromatosis.

Treatment

Phlebotomy (weekly) remains the key of treatment for hemochromatosis. The goal of phlebotomy is to reach iron depletion to prevent tissue damage. After achieving such iron balance, maintenance phlebotomy (1–4 yearly) is advisable lifelong. In the most severe cases with decompensated cirrhosis or heart failure (for example, individuals with severe juvenile hemochromatosis) that badly tolerate phlebotomy, adjunctive oral chelation can be used. Phlebotomies are also efficient for treatment of patients with loss-of-function ferroportin disease but should be carried out on a less intensive schedule given the risk of anemia (Kowdley et al. 2019).

Although randomized clinical trials are missing, a sufficient body of data has suggested that phlebotomy therapy can improve chronic fatigue and cardiac function, stabilize liver disease, reverse hepatic fibrosis, and reduce skin pigmentation in patients with hemochromatosis (Adams and Barton 2010). The effectiveness of phlebotomy is much better if it starts before the development of severe organ damage such as cirrhosis. An alternative to phlebotomy could be erythrocytapheresis; this procedure could be useful in patients suffering from hypoproteinemia or thrombocytopenia (Rombout-Sestrienkova et al. 2016). A phase I/II clinical trial with Deferasirox in non-cirrhotic HFE hemochromatosis patients has been conducted, showing a dose-dependent ferritin reduction.

IRIDA, differently than classical iron deficiency anemia where hepcidin levels are low or even undetectable, has normal or high hepcidin levels, and is resistant to oral iron and only partially responsive to intravenous iron, which still remains the advisable treatment.

Future Treatments

Although phlebotomy is inexpensive, safe, and effective in reversing many complications of iron overload, it is not well tolerated by a minority of patients. Moreover, phlebotomy is not feasible in iron-loading anemias because the patients become even more anemic. For these reasons, there is a consensus that novel therapeutic approaches are needed for all iron overload diseases. As hepcidin represents the iron homeostasis controller, the use of hepcidin agonists or antagonists could be beneficial, depending on the specific disorder (Katsarou and Pantopoulos 2018).

(a) **Hepcidin agonists** include compounds that mimic the activity of hepcidin and agents that increase the production of hepcidin by targeting hepcidin-regulatory molecules. The potential of these future drugs includes the improvement in erythropoiesis as shown in thalassemia mouse models and in phase I/II clinical trial.
(b) **Hepcidin antagonists** may be beneficial in IRIDA or in anemias associated with a variety of inflammatory disorders and malignancies, and in chronic renal disease with or without inflammatory etiology.

Contents

Summary

Manganese is an essential trace metal that is a constituent of metalloenzymes and is required as an enzyme activator. Blood manganese levels are under tight homeostatic control by the liver as both manganese overload and deficiency impair neuronal function and integrity.

To date, three inherited manganese transporter defects have been identified that lead to abnormal blood manganese levels: mutations in *SLC30A10* (hypermanganesaemia with dystonia 1, HMNDYT1) and *SLC39A14* (hypermanganesaemia with dystonia 2, HMNDYT2) cause manganese overload, while mutations in *SLC39A8* (Congenital Disorder of Glycosylation, Type IIn; CDG2N) cause manganese deficiency. SLC39A14 and SLC30A10 are required for hepatic uptake and adequate biliary excretion of manganese, respec-

tively. Both these transporter defects are characterised by childhood-onset, progressive Parkinsonism-dystonia due to the accumulation of manganese in the basal ganglia, particularly the globus pallidus, with pathognomonic MRI brain appearances of hyperintensity on T1-weighted images. Whole blood manganese levels are highly raised. In addition to the movement disorder, SLC30A10 loss-of-function causes liver disease, polycythaemia and depletion of iron stores. Intravenous chelation with disodium calcium edetate and iron supplementation effectively lowers the manganese load and can lead to significant improvement in neurological symptoms and halt the progress of liver disease.

SLC39A8 is required for manganese uptake into the organism. Loss-of-function leads to a manganese deficiency syndrome characterised by neurodevelopmental delay, seizures, dystonia and short stature. Biochemically, SLC39A8 deficiency causes hypomanganesaemia and a characteristic dysglycosylation pattern corresponding to a type II congenital disorder of glycosylation because manganese acts as a cofactor for the β-1,4-galactosyltransferase. In addition, manganese deficiency leads to respiratory chain abnormalities and Leigh-like mitochondrial disease. Manganese supplementation can improve clinical symptoms and normalise biochemical findings.

Manganese dyshomeostasis has also been observed in a juvenile type of Parkinson's disease associated with supranuclear gaze palsy, spasticity and dementia due to mutations in *ATP13A2* (PARK9), also known as Kufor-Rakeb Syndrome. ATP13A2 has been shown to transport manganese from the cytosol to the lysosome. In addition, the phenotype can vary from neuronal ceroid lipofuscinosis type 12 (CLN12) to complicated hereditary spastic paraplegia (HSP).

Introduction

Manganese is one of the six transition metals essential for human metabolism. It is required as a cofactor for numerous enzymatic reactions including glycosylation and phosphorylation, and is involved in amino acid, lipid and carbohydrate metabolism, immune function, bone and connective tissue growth and blood clotting. As a constituent of metalloenzymes such as the manganese superoxide dismutase, it acts as a scavenger of reactive oxygen species (Chen et al. 2015).

Manganese levels are under precise homeostatic control because both excess and deficiency of manganese are deleterious for neuronal function and integrity. Excess manganese accumulates in the basal ganglia and causes a clinical syndrome known as manganism—an extrapyramidal movement disorder characterised by dystonia, bradykinesia and rigidity, accompanied by psychiatric and cognitive defects (Chen et al. 2015). Manganese overload can occur in inherited manganese transporter defects (HMNDYT1 and HMNDYT2 caused by mutations in *SLC30A10* and *SLC39A14*, respectively) or as a result of environmental overexposure, excess manganese in parenteral nutrition or impaired hepatic excretion in patients with liver cirrhosis (Tuschl et al. 2012, 2016; Quadri et al. 2012). Manganese deficiency, on the other hand, leads to dysglycosylation and impaired mitochondrial function. Due to its ubiquitous presence in the diet, acquired manganese deficiency rarely occurs and, hence, deficiency of manganese is only observed in an inherited manganese transporter defect caused by *SLC39A8* mutations (congenital disorder of glycosylation type IIn) (Park et al. 2015a; Boycott et al. 2015; Riley et al. 2017).

Tight homeostatic control of intestinal absorption and biliary excretion of manganese maintains stable tissue concentrations of the metal. This requires a group of solute carrier (SLC) transporters localised at the cell membrane. SLC39A8 and SLC39A14 facilitate uptake of manganese into the cell, while SLC30A10 mediates manganese efflux (Leyva-Illades et al. 2014; Clayton 2017). SLC39A14 appears to be the main transporter allowing for the uptake of manganese into the liver, the primary regulator of manganese homeostasis. Manganese transport also occurs at iron transporters including DMT1, transferrin/transferrin receptor complex and ferroportin, as well as the dopamine (DAT) and citrate transporters (Peres et al. 2016). Because iron competes with manganese for transport, iron supplementation can reduce manganese levels in disorders associated with excess manganese (Clayton 2017). Within the cell, manganese is transported via a number of transporters including ATP13A1 at the endoplasmic reticulum, SPCA1 at the Golgi, ATP13A2 at the lysosome and Mfrn-1 and DMT1 at the mitochondria (Chen et al. 2015; Sorensen et al. 2018; Christenson et al. 2018).

Hypermanganesaemia with dystonia 1 (HMNDYT1) caused by biallelic mutations in *SLC30A10* was the first inherited manganese transporter defect described. Impaired biliary excretion leads to accumulation of manganese in the liver and brain, resulting in liver disease and generalised dystonia. Manganese deposition in the brain causes characteristic neurodegenerative features including severe neuronal loss in the globus pallidus and a vacuolated myelinopathy. MRI brain appearances are pathognomonic with hyperintensity on T1-weighted images of the globus pallidus and striatum, and the white matter of the cerebrum and cerebellum, midbrain, dorsal pons and medulla, while the ventral pons is typically spared (Fig. 38.1a, b). T2-weighted images show corresponding hypointensity of the globus pallidus and striatum (Fig. 38.1c). Activation of erythropoietin

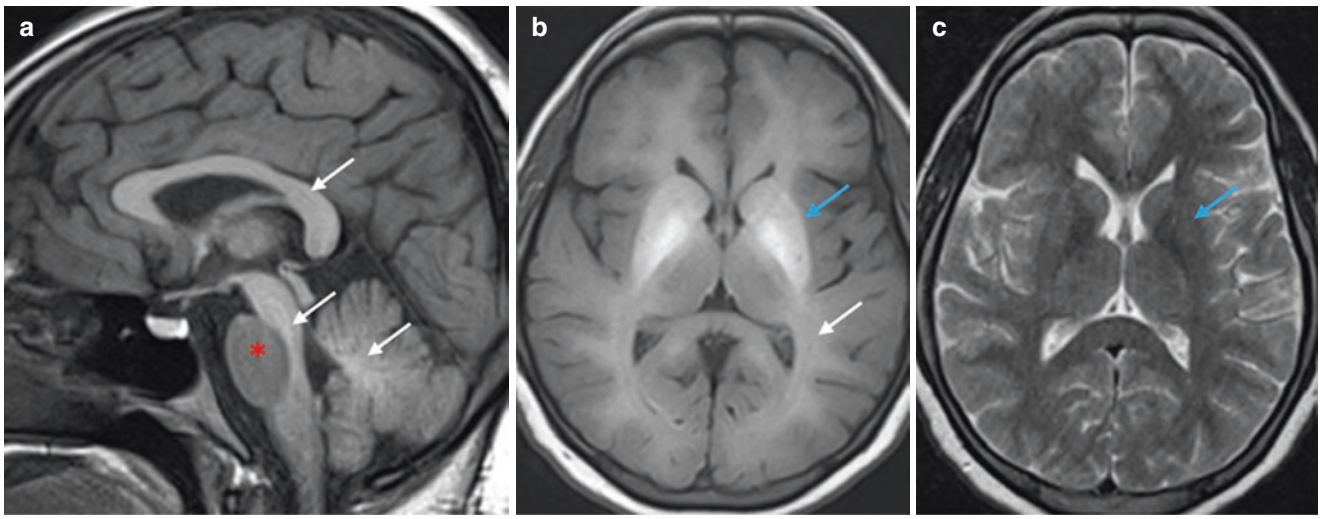

Fig. 38.1 Characteristic MRI brain appearances due to manganese overload in SLC30A10 (HMNDYT1) and SLC39A14 (HMNDYT2) transporter defects (Tuschl et al. 2016). (**a**, **b**) T1-weighted MR imaging shows hyperintensity of the globus pallidus and striatum (blue arrow), and the white matter in the cerebrum, cerebellum, midbrain, dorsal pons (white arrows) with a pathognomonic sparing of the ventral pons (red star). (**c**) T2-weighted MR imaging shows corresponding hypointensity of the globus pallidus and striatum (blue arrow)

gene expression due to excess manganese leads to polycythaemia, which often precedes clinical symptoms. Whole blood manganese levels are significantly raised and usually exceed 1000 nmol/L. Another characteristic is a depletion of iron stores with increased total iron-binding capacity and low ferritin values. Some patients develop hypothyroidism, which is consistent with findings in SLC30A10 knockout mice (Hutchens et al. 2017). Disease onset is usually within the first few years of life with progressive, generalised dystonia; however, cases of adult-onset atypical Parkinson's disease have been described. Some patients have also presented with primary hypotonia or spastic paraplegia (Gospe Jr. et al. 2000; Gulab et al. 2018; Zaki et al. 2018). Manganese chelation with intravenous disodium calcium edetate, in combination with iron supplementation to reduce the uptake of manganese, reduces manganese blood and tissue levels, improves neurological symptoms and halts liver disease progression (Tuschl et al. 2012, 1993; Quadri et al. 2012, 2015).

Biallelic mutations in *SLC39A14* cause hypermanganesaemia with dystonia 2 (HMNDYT2) due to impaired uptake of manganese into the liver for subsequent biliary excretion. Manganese accumulates in extrahepatic tissues, causing an isolated neurological phenotype of rapidly progressive Parkinsonism-dystonia with onset in infancy or childhood. Whole blood manganese levels are highly raised and MRI brain appearances are identical to that of HMNDYT1 (Fig. 38.1). Hypointensity of the globus pallidus and striatum on T2-weighted images is often pronounced and may be mistaken as the eye of the tiger sign observed in neurodegeneration with brain iron accumulation (NBIA) disorder. Chelation therapy with disodium calcium edetate has been used with some success; however, clinical response is poor in most patients, most likely due to advanced disease progression and significant degree of neurodegeneration (Tuschl et al. 2016, 1993; Zeglam et al. 2018).

Inherited manganese deficiency with low blood manganese levels is caused by biallelic mutations in *SLC39A8* and leads to a type II congenital disorder of glycosylation (Type IIn; CDG2N). Dysglycosylation occurs because manganese is a cofactor for the β-1,4-galactosyltransferase, essential for galactosylation of glycan chains. Affected individuals present as early as infancy with neurodevelopmental delay, hypotonia, seizures, dystonia, ataxia, vision and hearing impairment, dysmorphism and short stature/dwarfism (Park et al. 2015a; Boycott et al. 2015). This disorder may also manifest with Leigh-like mitochondrial disease including features such as raised CSF lactate, respiratory chain abnormalities, bilateral basal ganglia hyperintensities on T2-weighted imaging and cerebellar atrophy (Riley et al. 2017). Treatment has been attempted with oral manganese sulphate with remarkable clinical and biochemical improvement. Upon manganese supplementation, the glycosylation pattern and blood manganese levels normalised. Clinically, this was associated with cessation of seizures and improvement in hearing, vision and motor abilities (Park et al. 2017).

There is evidence that manganese dyshomeostasis also plays a role in individuals with mutations in *ATP13A2*. ATP13A2 facilitates manganese transport into the lysosome and thereby protects cells from manganese toxicity. Biallelic mutations in *ATP13A2* have been reported in three neurodegenerative disorders with parkinsonism as a shared clinical

feature: (1) Juvenile-onset Parkinson's disease (PARK9), also known as Kufor-Rakeb-Syndrome, which is accompanied by supranuclear gaze palsy, dementia and generalised brain atrophy (Racette et al. 2012). (2) Neuronal ceroid lipofuscinosis (CLN12) with typical accumulation of autofluorescent lipopigment, which presents with learning difficulties, parkinsonism, spinocerebellar ataxia, bulbar syndrome and pyramidal involvement (Bras et al. 2012). (3) Complex hereditary spastic paraplegia (SPG78), which is accompanied by ataxia and neuropathy, parkinsonism and cognitive decline (Estrada-Cuzcano et al. 2017). The parkinsonian features tend to respond well to treatment with levodopa; however, dyskinesias develop early. In addition, heterozygous mutations in *ATP13A2* pose a genetic risk factor for early-onset Parkinson's disease (Park et al. 2015b). Despite the fact that ATP13A2 is involved in manganese transport, blood manganese levels are normal in affected individuals. T2-weighted MR images show iron accumulation in the basal ganglia, and, hence, *ATP13A2* mutations are also classified as an NBIA disorder (Schneider et al. 2010) (Fig. 38.2).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal location	Mode of Inheritance	Affected protein	OMIM
38.1	Hypermanganesemia with Dystonia 1	SLC30A10 deficiency; Syndrome of Hepatic Cirrhosis, Dystonia, Polycythemia, and Hypermanganesemia	HMNDYT1	*SLC30A10*	1q41	AR	SLC30A10 (ZNT10)	613280

38.4	Parkinson disease 9	Kufor-Rakeb Syndrome; Neuronal ceroid lipofuscinosis 12; Complex hereditary spastic paraplegia 78	PARK9, NCL12, SPG78	*ATP13A2*	1p36	AR	ATP13A2	606693

Metabolic Pathways

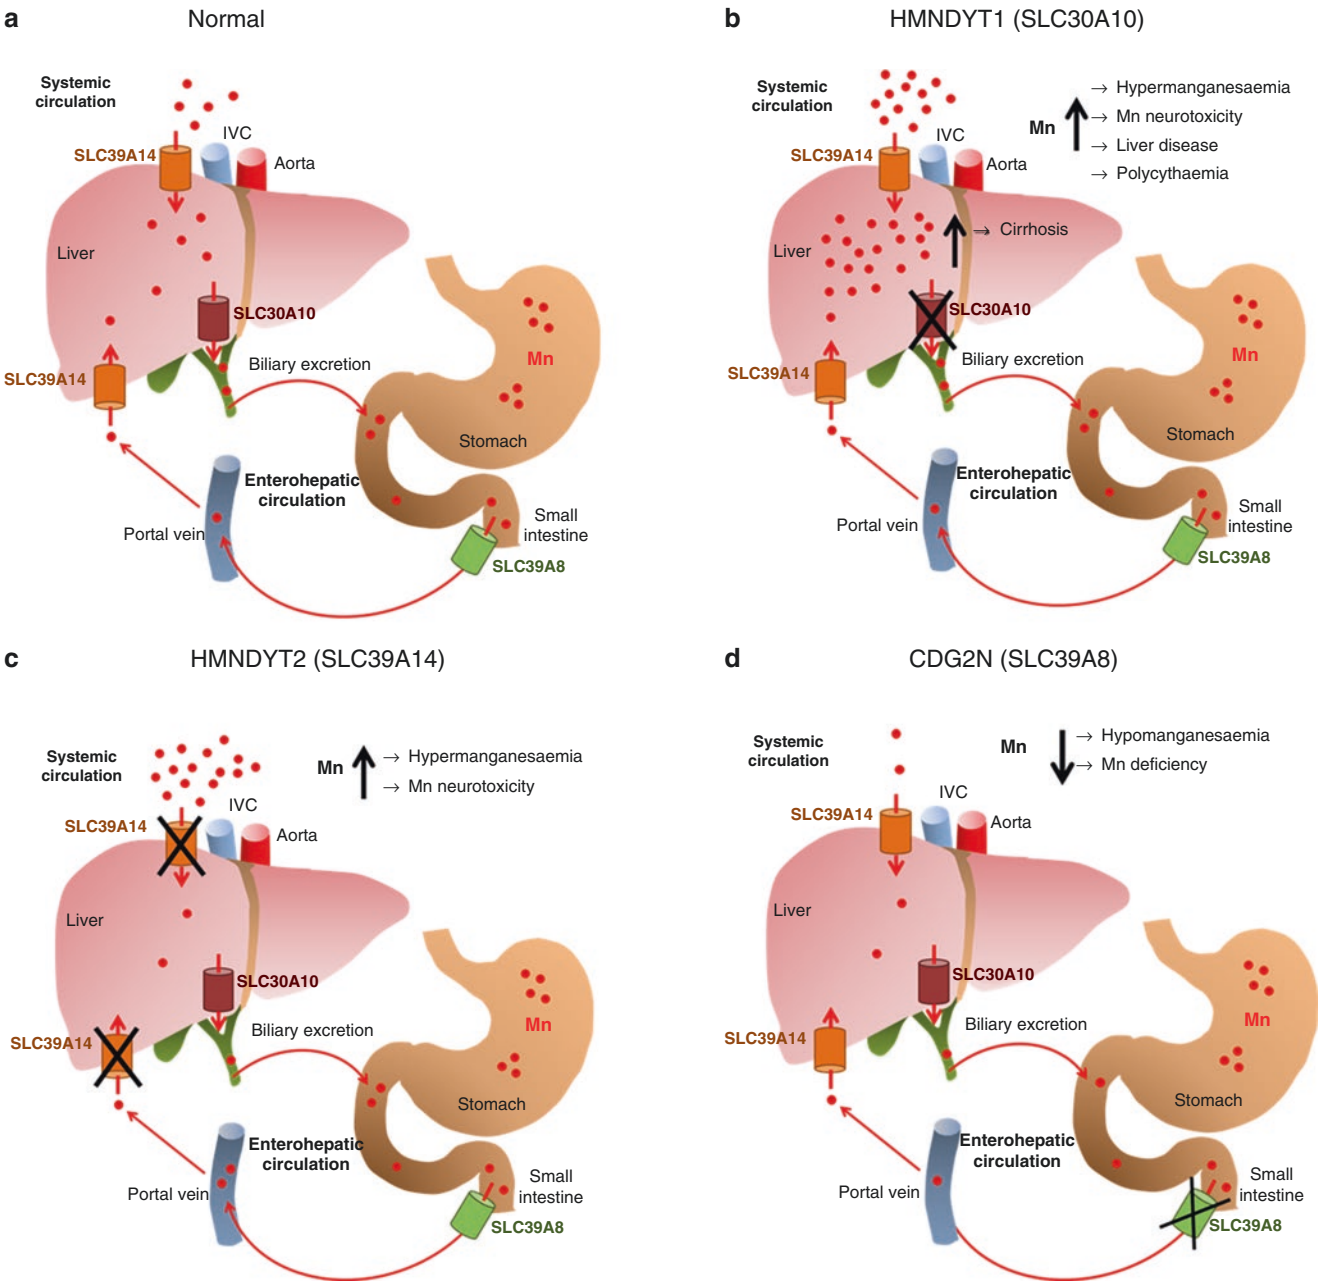

Fig. 38.2 Our current understanding of how manganese homeostasis (**a**) is maintained under physiological conditions and (**b**–**d**) is impaired in manganese transporter defects (Tuschl et al. 2016). (**a**) In healthy individuals, manganese from the diet is taken up in the small intestine via SLC39A8 and enters the liver via SLC39A14. The liver regulates blood manganese levels via biliary excretion through SLC30A10. (**b**) In SLC30A10 deficiency (HMNDYT1), biliary excretion of manganese is impaired leading to accumulation of manganese in the liver (causing liver cirrhosis and polycythaemia), the blood (hypermanganesaemia) and the brain where it causes neurotoxicity within the globus pallidus resulting in dystonia. (**c**) In SLC39A14 deficiency (HMNDYT2), manganese uptake into the liver is reduced and manganese accumulates in extrahepatic tissues. (**d**) In SLC39A8 deficiency (CDG2N), uptake of manganese is impaired resulting in systemic manganese deficiency

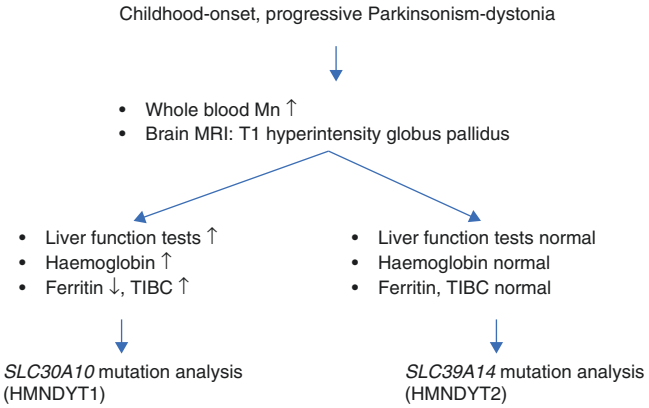
Diagnostic Flowchart

HMNDYT1 and HMNDYT2



In any individuals with childhood-onset, progressive Parkinsonism-dystonia, whole blood manganese levels should be determined as well as brain MR imaging obtained. If features of manganese accumulation are identified, the above diagnostic algorithm should be followed.

Specimen Collection

Test	Precondition	Material	Handling	Pitfalls
Mn (B)	–	Blood	Ambient	False elevation due to contamination. Secondary causes of hypermanganesaemia due to liver disease, environmental manganese exposure, parenteral nutrition.

Ideally, blood for metal determination should be collected in trace-metal-free EDTA blood containers. Alternatively, if such containers are unavailable, common EDTA blood containers can be used and an empty blood container analysed in parallel to rule out background contamination of the container.

Prenatal Diagnosis

Prenatal diagnosis can be performed by molecular analysis of all four disorders of manganese transport provided the mutation of each biological parent is known. DNA can be isolated from cells directly or by culture after amniocentesis, from chorionic villous samples, from maternal blood, or at the preimplantation stage.

DNA Testing

Genetic diagnosis can be made by standard molecular diagnostic procedures including gene sequencing of *SLC30A10*, *SLC39A14*, *SLC39A8* and *ATP13A2*, whole exome sequencing, and deletion/duplication analysis using genomic DNA of any source.

Treatment Summary

HMNDYT1 and HMNDYT2

The recommended treatment for disorders of manganese overload including HMNDYT1 and HMNDYT2 is the regular chelation of manganese with intravenous disodium calcium edetate in combination with iron supplementation to maintain iron parameters (TIBC, ferritin) within the high normal range. Individuals with HMNDYT1 deficiency seem to respond well with improvement of Parkinsonism-dystonia and liver disease, normalization of haemoglobin, reduction in blood manganese levels and manganese accumulation on brain MRI. However, individuals with HMNDYT2 have a less favourable response, probably due to advanced disease progression and different disease pathogenesis. Chelation treatment can lead to a deficiency of calcium, zinc, copper and selenium, which need frequent monitoring and supplementation as required (Tuschl et al. 2016, 1993).

CDG2N

High-dose manganese supplementation in individuals with CDG2N can improve neurological symptoms and normalise glycosylation and blood manganese levels. Therapy requires close monitoring of glycosylation assays and blood manganese to prevent manganese toxicity (Park et al. 2017). In addition, galactose and uridine supplementation can normalise glycosylation patterns (Park et al. 2015a; Riley et al. 2017).

PARK9

Initially, the parkinsonian features in individuals with *ATP13A2* mutations tend to respond well to the standard treatment of Parkinson's disease with levodopa. However, early development of dyskinesias and visual hallucinations complicates treatment (Schneider et al. 2010; Di Fonzo et al. 2007).

Standard Treatment

	Therapy	Application	Dose	Duration
HMNDYT1	Disodium calcium edetate	iv	20 mg/kg/dose (max 1 g) twice daily for 5–8 days every 4 weeks	Lifelong
	Ferrous sulphate/fumarate	po	To keep iron parameters within the normal range (TIBC low normal, ferritin high normal)	Lifelong
HMNDYT2	Disodium calcium edetate	iv	20 mg/kg/dose (max 1 g) twice daily for 5–8 days every 4 weeks	Lifelong
	Ferrous sulphate/fumarate	po	To keep iron parameters within the normal range (TIBC low normal, ferritin high normal)	Lifelong
CDG2N	Manganese sulphate	po	15–20 mg/kg to keep blood manganese within the normal range	Lifelong

Contents

Summary

Carbohydrates are an important source of energy in the human organism. Within the body, glucose is the most abundant monosaccharide that can be stored as glycogen, a branched polymer with a protein core (glycogenin), mainly in liver and muscle. Inborn errors of metabolism may affect the uptake, distribution and reabsorption of monosaccharides in different organs, a process that is meticulously regulated by a system of transporter proteins. Congenital disorders may impair the intestinal digestion of disaccharides and the conversion of monosaccharides (fructose, galactose) into glucose. They can further affect glycogen synthesis, glycogen breakdown (glycogenolysis), glucose metabolism to acetyl-CoA (glycolysis) and de novo synthesis of glucose (gluconeogenesis).

Glucose absorption and transport disorders present with a very variable clinical picture depending on which of the organ- and substrate-specific transporters is affected. Likewise, disorders of galactose and fructose metabolism affect different organs due to the accumulation of toxic intermediates. After the introduction of these monosaccharides with the diet, impaired liver function is frequently among the first signs.

Glycogen storage diseases can be divided into those mainly presenting with hepatic manifestations (hepatomegaly, fasting intolerance, hypoglycaemia) and those with muscular presentations (exertion intolerance, rhabdomyolysis). Some show a combination of these symptoms, cardiomyopathy may be an additional feature and further accompanying signs, *for example,* haemolytic anaemia, may be observed depending on tissue distribution of the affected protein.

Management of most carbohydrate disorders requires symptomatic measures, supportive care and a multidisciplinary approach. In some conditions, dietetic treatment is possible which may have its basis in an exclusion of certain di- or monosaccharides. Outcome, however, is highly variable and mainly depends on the underlying type of disorder. Causal treatment is not available for most diseases and for some patients, organ transplantation (liver, kidney, heart) is an option. Experimental treatments may include enzyme replacement therapy (available, *e.g.,* for lysosomal α-glucosidase deficiency, GSD-IIa) and gene therapy.

Introduction

The disorders in this chapter can be divided into disorders of carbohydrate absorption and transmembrane transport, galactose and fructose metabolism, glycolysis, glycogen synthesis, glycogenolysis and gluconeogenesis (Nomenclature Table). Most are inherited according to an autosomal recessive trait. The clinical presentations can be acute or chronic, mild or severe, in some even life threatening. The clinical features are highly variable and can be understood when considering age- and organ-specific pathophysiology. Other groups of metabolic disorders of carbohydrate metabolism are mentioned in Chaps. 40 (pentose phosphate pathway and polyol metabolism), 41 (insulin secretion and signalling) and 61 (oligosaccharidoses and sialic acid disorders).

Disorders of Carbohydrate Absorption and Transmembrane Transport

Dietary carbohydrates (disaccharides, oligo- and polysaccharides, starch) have to be digested to monosaccharides before entering the human organism. Congenital defects at this step include congenital lactase, sucrose-isomaltase and trehalase deficiencies.

The cellular uptake and release of glucose and other monosaccharides is a protein-mediated process. Such proteins are embedded into the cell membrane and can be regarded as hydrophilic pores within the hydrophobic lipid bilayer. Monosaccharide transporters are substrate- and stereospecific. Their action is saturable and, like for an enzymatic reaction, kinetic characteristics can be described by affinity constants. The number of transporter protein molecules determines maximal transport velocity (v_{max}).

Three classes of monosaccharide transporters have been associated with human diseases. The SGLT (*s*odium-dependent *gl*ucose *t*ransporter) family is characterised by the fact that glucose transport is coupled with sodium transport. Since the driving force for this type of transport is the electrochemical gradient for sodium (produced by the cellular Na^+/K^+-ATPase system), glucose can be (actively) transported against its own gradient. A second family, the GLUT (*glu*cose *t*ransporter) proteins, mediates so-called facilitative diffusion along an existing glucose gradient and, in the past, members of this family have been regarded to function as 'passive' transporters. However, GLUT proteins are hormonally and substrate regulated; thus, they play a pivotal role in the regulation of carbohydrate metabolism. As an example, one of the key functions of insulin is the translocation of GLUT4-bearing vesicles to the cell membrane of muscle cells and adipocytes, allowing glucose influx.

The genes of the growing number of members of both the SGLT and GLUT families have been identified during recent years. This was a key step in the study of the function of these proteins, of their tissue-specific expression and in the identification of genetic defects. Knowledge of the tissue-specific expression of monosaccharide transporter proteins helps define the clinical picture of the different disease entities. Many tissues carry more than one type of transporter and many members of the monosaccharide transporter families are expressed in more than one tissue. Therefore, congenital disorders of different isoforms of monosaccharide transporters may present with a complex clinical picture and may involve different organ systems. Well-characterised disease entities are congenital intestinal glucose-galactose malabsorption (GGM, *SGLT1* defect), the glucose transporter-1 deficiency syndrome (GLUT1-D) and the Fanconi-Bickel syndrome (FBS, *GLUT2* defect). In contrast, due to the high solubility of glucose, renal glucosuria due to SGLT2 deficiency (SGLT2-D) or due to the rare defect of an SGLT2-associated protein in the renal tubular cell membrane (MAP17), is rarely accompanied by specific clinical symptoms and, like some of the amino acid transporter defects, it can be classified as a '*non*-disease'. The diagnosis has, however, a clinical significance as it prevents repeated investigation for diabetes mellitus in these patients.

Only recently, an inborn error affecting a member of a third monosaccharide transporter family, the glucose/proton cotransporters (encoded by the *SLC45* gene family), has been described. In this condition, glucose supply to neuronal

cells is impaired with symptoms of developmental delay, psychiatric features, and epilepsy (Srour et al. 2017).

Disorders of Galactose and Fructose Metabolism

There are four known disorders of galactose metabolism affecting the enzymes of the Leloir pathway: galactose mutarotase deficiency (GALM-D), galactokinase deficiency (GALK-D), galactose-1-phosphate uridyltransferase deficiency (galactosaemia, GALT-D), and uridine diphosphate galactose-4-epimerase deficiency (GALE-D). Among these disorders, galactosaemia is the most common and can be the most severe. Several partial defects of transferase deficiency have been reported, of which the best known is the Duarte-2 variant (Berry et al. 2016).

Unlike most disorders in this chapter that highly depend on clinical ascertainment/clinical and biochemical pattern recognition, all four disorders of galactose metabolism can be identified by newborn screening programs. These programs are based on enzymatic investigations and detection of increased amounts of galactose and galactose-1-phosphate in dried blood spots. The clinical manifestations of classic galactosaemia occur after galactose is introduced with the diet and the accumulation of metabolic intermediates is responsible for organ damage. Galactitol causes cataract formation, while galactose-1-phosphate (together with phosphate depletion) is a key factor for hepatic, renal tubular and central nervous manifestations.

Four disorders affecting fructose metabolism are known: fructokinase deficiency (FK-D), fructose-1-phosphate aldolase deficiency (hereditary fructose intolerance, HFI), fructose-1,6-bisphosphatase deficiency (FBP-D) and glycerate kinase deficiency (GLYCTK-D). While FK-D is a *non*-disease, severe symptoms in HFI occur after the ingestion of fructose and are the consequence of accumulation of fructose-1-phosphate, with secondary effects mainly on liver cell metabolism, phosphate depletion and protein glycosylation. FBP-D is a disorder of gluconeogenesis; symptoms may occur in the fasted state and without fructose ingestion, although fructose may enhance these effects. For GLYCTK-D, which is related to fructose metabolism but also impairs several other metabolic pathways, *see* Chap. 71.

Disorders of Glycolysis

Defects in the glycolysis pathway may present as muscle glycogen storage disorders, while others result in haemolysis as they affect erythrocyte metabolism (Bianchi et al. 2019, Tarnopolsky 2018). Some present with both muscle symptoms and haemolysis or give rise to mostly neurological symptoms (Fermo et al. 2019). Genetic variants in *HK1*, the gene coding for hexokinase 1, can present as four distinct clinical pictures: haemolytic anaemia due to loss of hexokinase enzymatic activity on one side, and hereditary motor and sensory neuropathy (Russe type, HMSNR), retinitis pigmentosa type 79 (RP79), and a recently described neurodevelopmental disorder with visual defects and brain anomalies (NEDVIBA) on the other (Jamwal et al. 2019, Okur et al. 2019).

Disorders of Glycogen Synthesis and Glycogenolysis

Glycogen storage disorders (GSDs) result from enzymatic blocks or impaired transporter function in the pathway of glycogen degradation (glycogenolysis) but defects of glycogen synthesis in liver and muscle have also been termed 'glycogenoses' (GSD-0, GSD-IV). Simply speaking, glycogen storage disorders with cytosolic glycogen accumulation may present as a disease of liver only (GSD-I, GSD-III, GSD-VI and GSD-IX), of liver and kidney (FBS, GSD-I), with liver involvement and (cardio)myopathy (GSD-III, GSD-IX) and myopathy without liver involvement (GSD-V, GSD-VII, rare muscular types (Tarnopolsky 2018)). Lysosomal storage of glycogen results in a multisystem disorder generally presenting with cardiac and/or muscular problems (GSD-II).

GSD-I, GSD-III, GSD-VI and GSD-IX are similar in physical appearance and are usually detected during infancy or childhood because of fasting intolerance, failure to thrive and marked hepatomegaly (and, generally, without splenomegaly or cholestasis) (Fig. 39.1). Hypoglycaemia is another leading sign in hepatic GSDs, which is most severe in GSD-I where both glycogenolysis and gluconeogenesis are affected.

Muscle is unable to produce glucose for systemic use, because glucose-6-phosphatase activity is absent. Classical muscle GSDs involve skeletal muscle and present with muscle weakness, exertion intolerance and/or myoglobinuria, but are usually not diagnosed before late childhood and adolescence. Rare muscle GSDs with defects in the glycolysis pathway of muscle may, however, present with a more complex clinical picture.

Disorders in which detection of polyglucosan bodies is a hallmark are related to GSDs. Examples are muscle glycogenin-1 deficiency, Laforin deficiency and Malin deficiency. Polyglucosan bodies can be found in many tissues but are typically found in muscle or brain. The presence of such insoluble aggregates of abnormally branched glycogen with increased phosphorylation and (in brain) ubiquitination is associated with impaired autophagy. Since such cases with unstable glycogen are rare, the clinical and biochemical phenotypes of the disorders are incompletely defined (Sullivan et al. 2017).

Finally, glycogenolysis is impaired in a congenital disorder of glycosylation, phosphoglucomutase-1 deficiency,

which is discussed in more detail elsewhere in this book (*see* Chaps. 58 and 66).

Disorders of Gluconeogenesis

Glucose can be formed from *non*-hexose precursors such as lactate, pyruvate, glycerol and amino acids, a metabolic pathway called gluconeogenesis. Three *non*-reversible reactions of glycolysis characterise the disorders of gluconeogenesis, which are featured by fasting intolerance with associated recurrent hypoglycaemia and lactic acidosis, with or without ketosis. The mitochondrial matrix enzyme pyruvate carboxylase converts pyruvate to oxaloacetate, a central metabolite involved in gluconeogenesis, the urea cycle, the citric acid cycle, the glyoxylate cycle, amino acid synthesis and fatty acid synthesis. Hence, central nervous system signs and symptoms are part of the clinical phenotype and hyperammonaemia and severe metabolic acidosis may occur. In phosphoenolpyruvate carboxykinase deficiency, an extremely rare condition which may result from deficiency of a mitochondrial or a cytosolic enzyme, the conversion of oxaloacetate into phosphoenolpyruvate is deficient. Fructose-1,6-bisphosphatase deficiency causes relatively mild fasting intolerance, severe lactic acidosis and moderate hepatomegaly during metabolic crises. The disorders involved in the conversion of glucose-6-phosphate into glucose affect both glycogenolysis and gluconeogenesis. Defects of the hepatic proteins result in severe fasting intolerance; in patients with glucose-6-phosphatase catalytic subunit-3 deficiency, the neutrophil enzyme, severe congenital neutropenia is found.

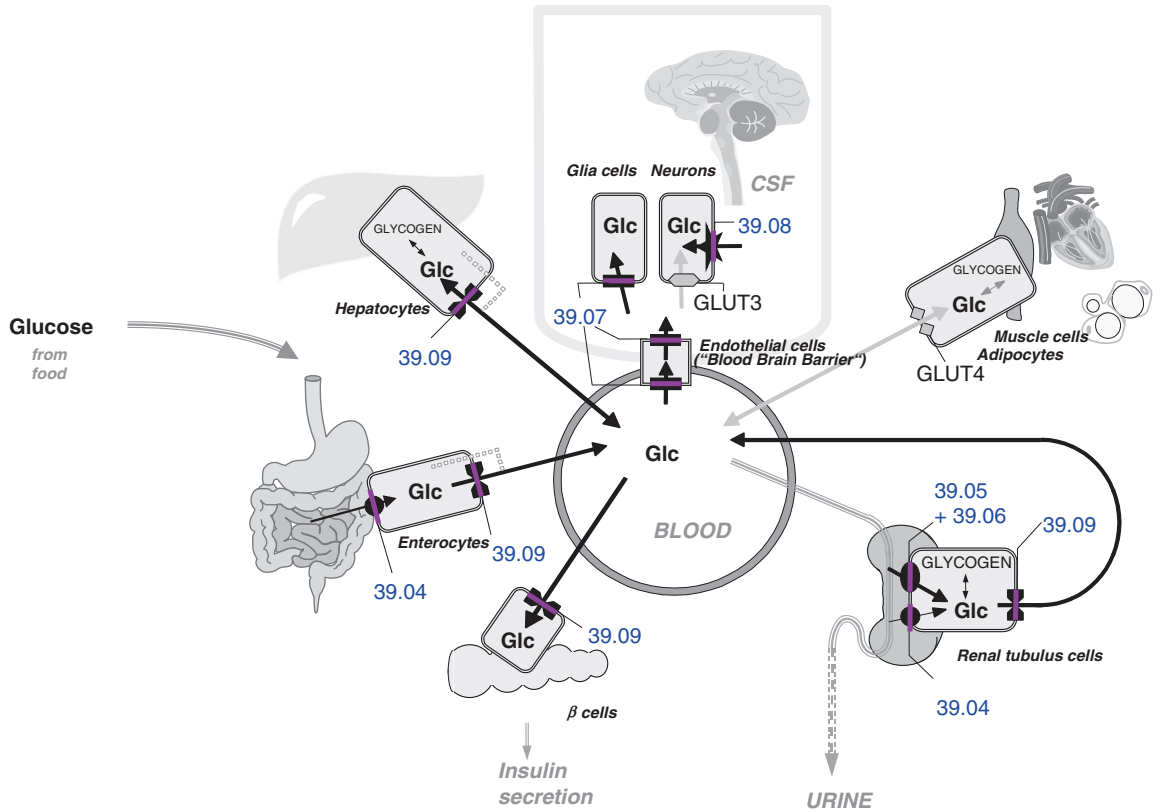
Metabolic Pathways

Metabolic pathways of carbohydrate metabolism discussed in this chapter are divided into (i) carbohydrate absorption and transmembrane transport in different organs, (ii) the intracellular pathways linking the metabolism of other monosaccharides to glucose metabolism, (iii) glycolysis, glycogen synthesis and glycogenolysis and (iv) gluconeogenesis.

Accordingly, disorders of organ-specific glucose transport are systematically depicted in Fig. 39.2, galactose and fructose metabolism are presented in Figs. 39.3 and 39.4, respectively. The major steps in disorders affecting glycogen synthesis and breakdown and defects of glycolysis and gluconeogenesis are presented in Fig. 39.5. The steps of glycogenolysis impaired in the different types of glycogen storage diseases are shown in detail in Fig. 39.6.



"active" transport:	"passive" transport:				H⁺-dependent transport:	vesicular transport:
SGLT1 *SLC5A1* 39.04	SGLT2 *SLC5A2* 39.05	GLUT1 *SLC2A1* 39.07	GLUT2 *SLC2A2* 39.09	GLUT3 *SLC2A3*	GLUT4 *SLC2A4*	PAST-A *SLC45A1* 39.08	

Fig. 39.2 Cellular uptake and release of glucose and transcellular transport mediated by specific transporter proteins. Transport across cell membranes is indicated by arrows. Transporter proteins are depicted by different symbols. Round symbols represent sodium-dependent '*active*' transporters (encoded by genes of the *SLC5* family), rectangular symbols stand for facilitative, so-called '*passive*' transporters (encoded by genes of the *SLC2* family), and the star-shaped symbol represents a member of the novel glucose/proton cotransporters (encoded by genes of the *SLC45* family). Known defects are shown by pink bars and the respective number. *GLUT3* Glucose transporter-3, *GLUT4* Glucose transporter-4, *CSF* Cerebrospinal fluid

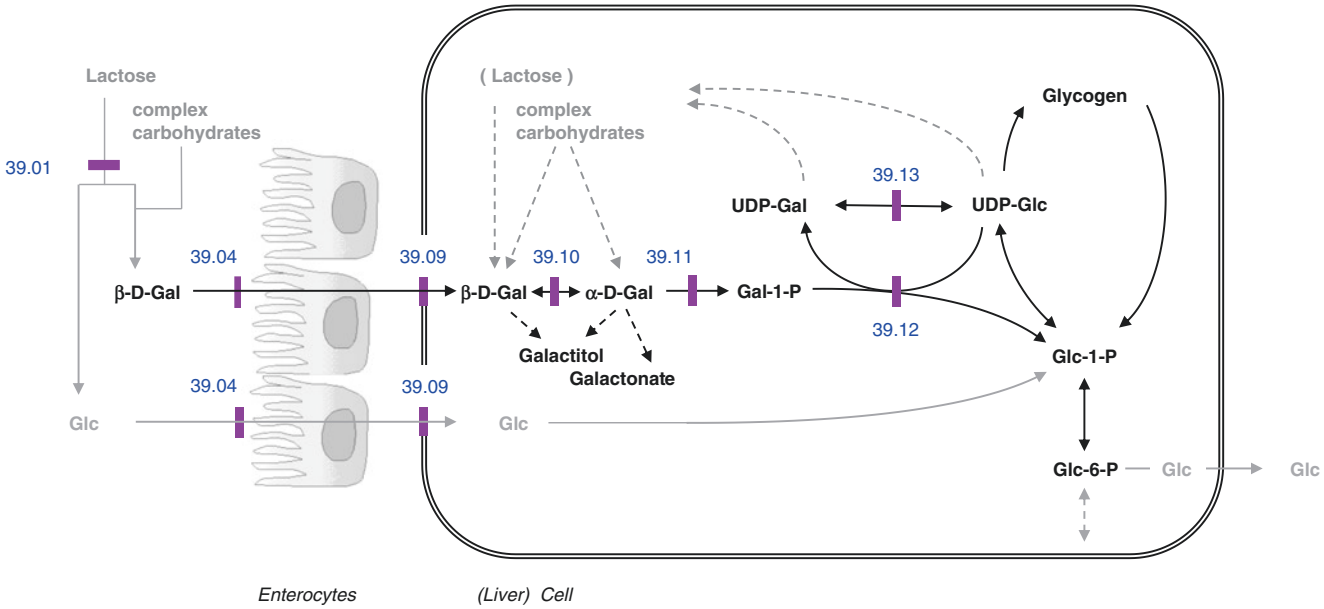


Fig. 39.3 Metabolic pathway of galactose metabolism

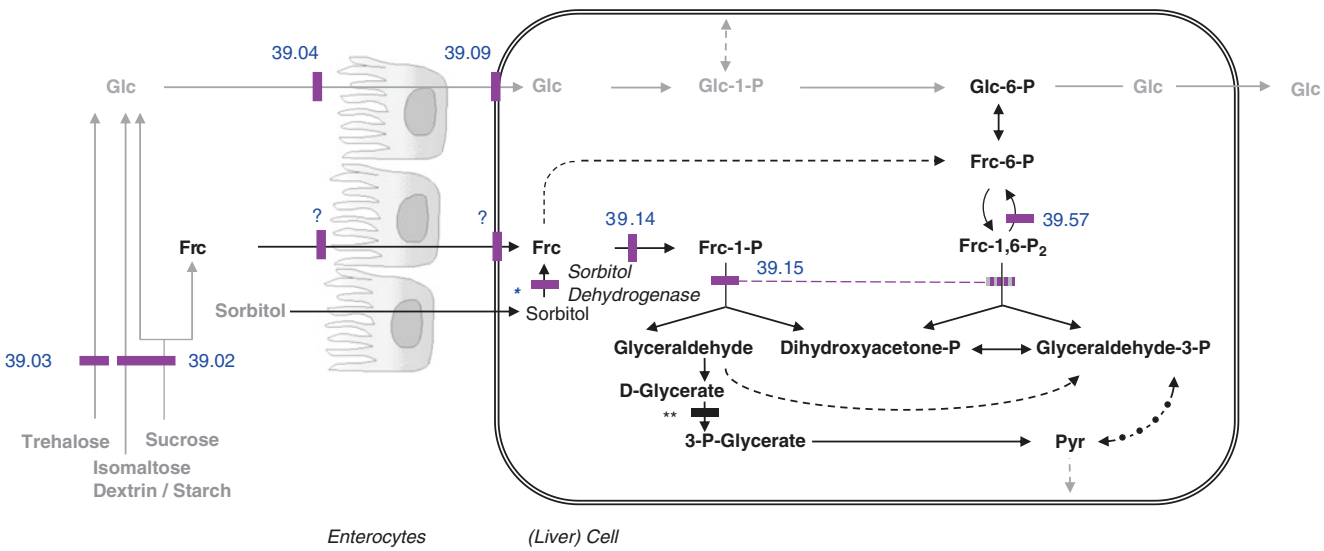

Fig. 39.4 Metabolic pathway of fructose metabolism (* *Note added in proof:* Biallelic variants in the gene of sorbitol dehydrogenase (*asterisk*) have only recently been reported as a cause of a common and potentially treatable hereditary neuropathy; *see* Cortese et al. 2020), ** for glycerate kinase deficiency (D-glyceric acidemia, GLYCTK-D) *see* Chap. 71

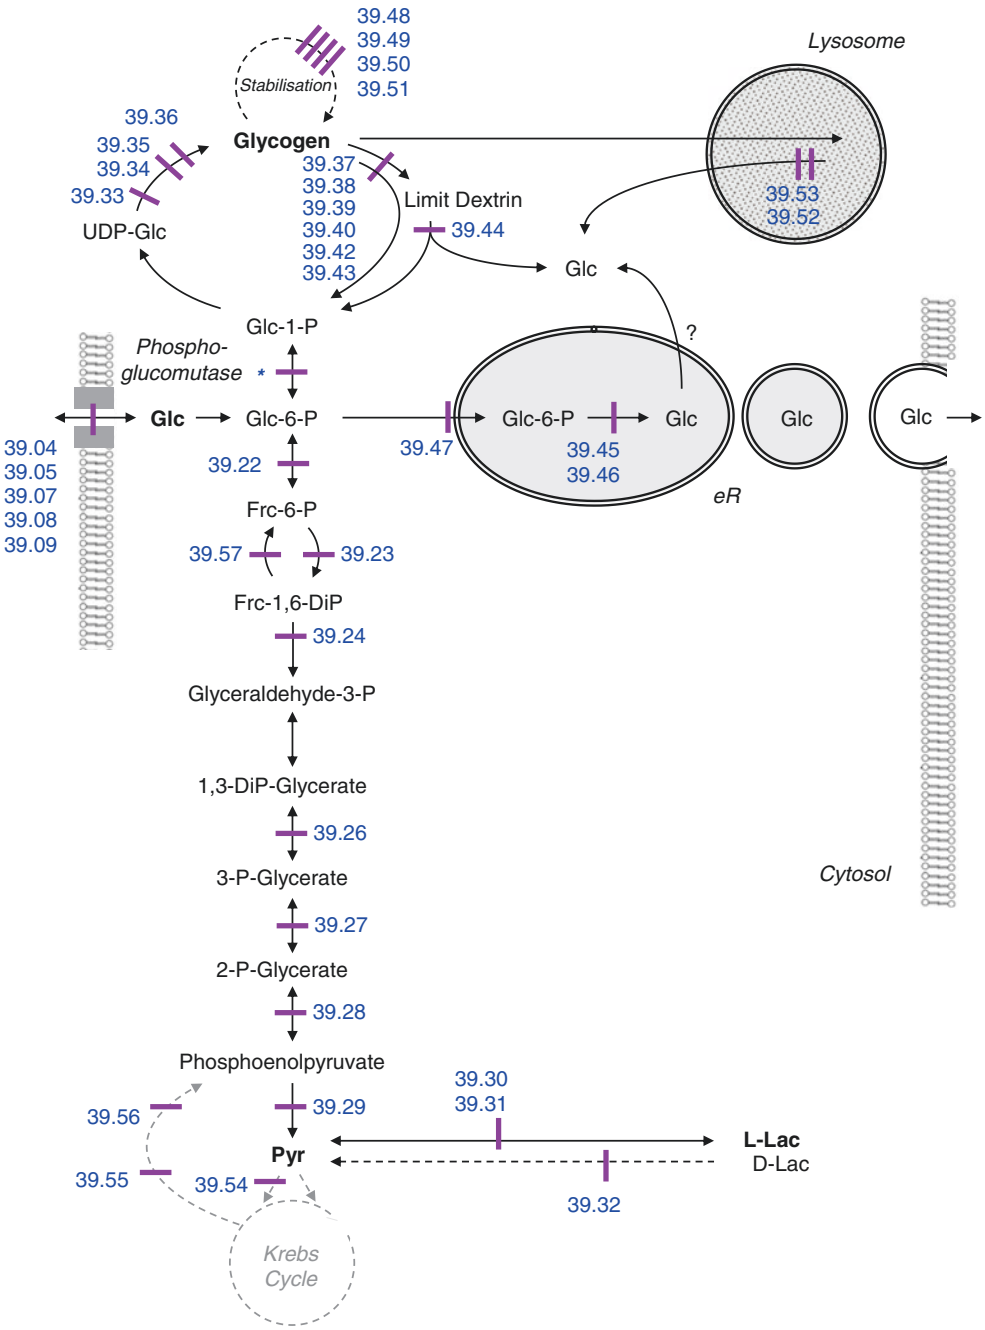

Fig. 39.5 Principal steps in glycogen synthesis and degradation. *Note* that the scheme is a summary of pathways in different tissues. Tissue-specific isoforms of enzymes (*e.g.*, in liver and muscle) may result in different disease entities with tissue-related signs and symptoms. *eR* endoplasmic reticulum, * *see* Chaps. 58 and 66

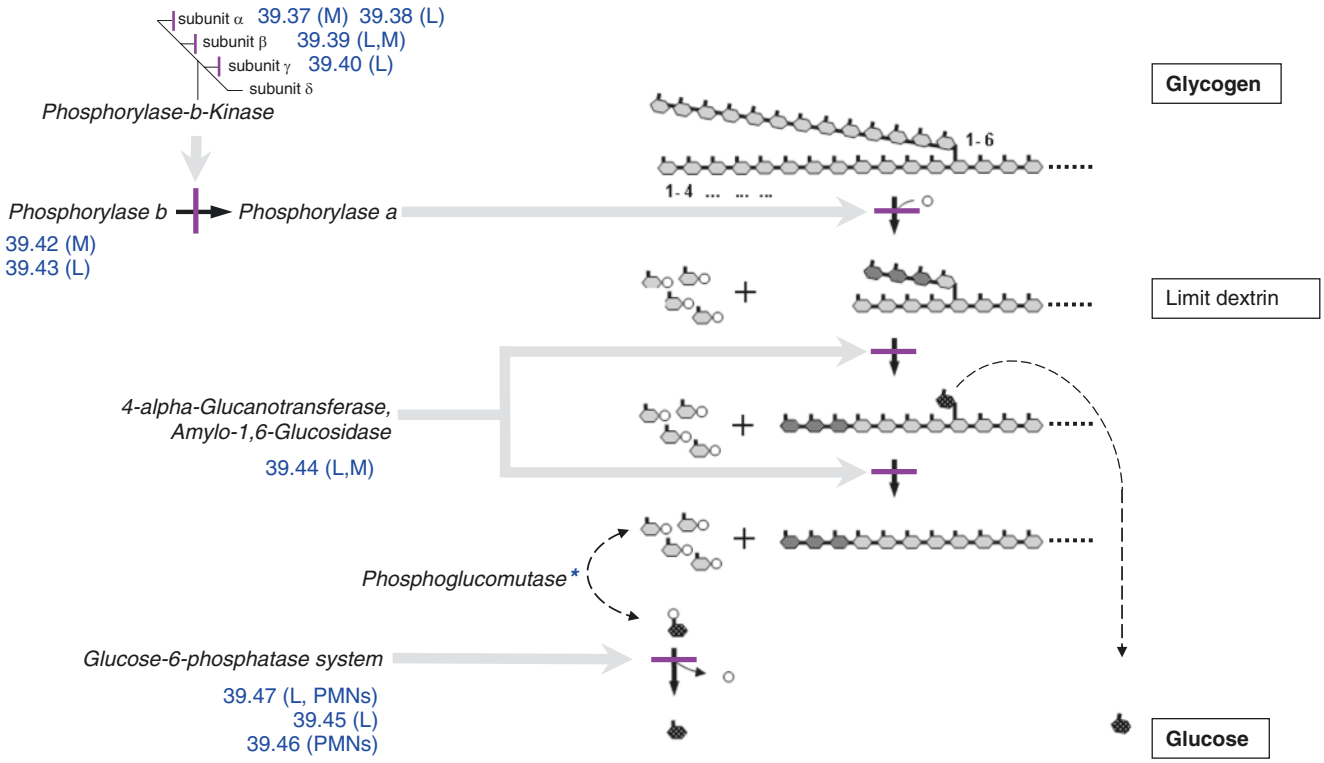

Fig. 39.6 Metabolic pathway of glycogen degradation. *Note* that the scheme is a summary of pathways in different tissues. Impairment of tissue-specific isoforms of enzymes (L, liver; M, muscle, PMNs, polymorph nuclear cells) results in different disease entities with tissue-related signs and symptoms. **see* Chaps. 58 and 66

Signs and Symptoms

Table 39.1 Congenital lactase deficiency (*see also* Wanes et al. 2019)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Digestive	**Diarrhea, profuse, osmotic**[a]	+++	+++	++	++	++
Other	**Dehydration**[a]	+++	+++	++	++	++
	Failure to thrive[a]	±	±	±	±	±
	Hypovolaemic shock[a]	±	±	±	±	±
Renal	Urolithiasis[a]	±	±	±	±	±
Laboratory findings	Isomaltase activity (intestinal mucosa)	n	n	n		
	Lactase activity in intestinal biopsy	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓

	Cranial nerve involvement			±	±	±
	Distal sensory loss with areflexia		±	+	++	+++
Musculoskeletal	Foot deformity (pes cavus), hand deformity (clawing), scoliosis			+	+	+
	Progressive weakness with onset in the distal lower limbs		±	+	++	+++
Laboratory findings	Hexokinase activity (red blood cells)		n	n	n	n
	No biochemical markers		+	+	+	+

Table 39.19 Retinitis pigmentosa type 79

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Eye	Changes electroretinogram			±[a]	+	+
	Macular atrophy			±[a]	+	+
	Nyctalopia			±[a]	+	+
	Optic disc pallor			±[a]	+	+
	Pigmentary deposits of the retina			±[a]	+	+
	Progressive (peripheral) vision loss			±[a]	+	+
	Retinal vascular attenuation			±[a]	+	+
Laboratory findings	Hexokinase activity (red blood cells)			n	n	n
	No biochemical markers			+	+	+

[a]A severe presentation in the first decade has been described in a patient with homozygosity for a *HK1* variant

Table 39.20 Glucokinase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Endocrine	Diabetes mellitus					+
Laboratory findings	Glucose (plasma)		↑	↑	↑	↑
	Glucose (urine)		↑	↑	↑	↑
	Insulin (serum)		↓	↓	↓	↓
	Ketones (urine)		n	n	n	n

Table 39.21 Glucokinase superactivity

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Epilepsy	±	±	±	±	±
	Intellectual disability		±	±	±	±
Endocrine	Diabetes mellitus, type 2			+	+	++
	Hyperinsulinism	++	++	++	++	++
Metabolic	Hypoglycaemia	++	++	++	++	±
	Hypoglycaemia, hypoketotic	++	++	++	++	±
Laboratory findings	Free fatty acids (serum)[a]	↓	↓	↓	↓	↓ - ↑
	Glucose (plasma)	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓	↓↓↓ - ↑↑↑
	Insulin (plasma)[a]	↑ - ↑↑↑	↑ - ↑↑↑	↑ - ↑↑↑	↑ - ↑↑↑	↑ - ↑↑↑
	Ketones (plasma, urine)[a]	↓	↓	↓	↓	↓ - ↑

[a]During hypoglycaemia

Table 39.22 Glucose-6-phosphate isomerase deficiency (*see also* Fermo et al. 2019)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Intelectual disability/ neurologic symptoms			±	±	±
Digestive	Pigment gallstones	±	±	±	±	±
	Splenomegaly	±	+	+	+	+
Haematological	**Chronic haemolytic anaemia improving with age**	±	+	+	+	+
	Haemolytic crisis	±	±	±	±	±
	Transfusion dependency	±	±	±	±	±
Musculoskeletal	Muscle weakness			±	±	±
Other	Hydrops fetalis	±				
	Stillbirth	±				
Laboratory findings	Glucosephosphate isomerase activity (red blood cells, leukocytes)	↓	↓	↓	↓	↓
	Haemoglobin (blood)	↓-n	↓ to ↓↓↓	↓ to ↓↓↓	↓ to ↓↓↓	↓ to ↓↓↓
	Mean corpuscular volume (MCV)	n-↑	↑	↑	↑	↑
	Osmotic fragility (red blood cells)	n	n	n	n	n
	Oxidative burst (leukocytes)	↓	↓	↓	↓	↓
	Reticulocytes	n-↑	↑	↑	↑	↑
	Unconjugated bilirubin	n-↑	↑	↑	↑	↑

Table 39.23 Glycogen storage disease type VII (Muscle phosphofructokinase deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Digestive	Gallstones			±	+	+
	Jaundice			+	+	+
Haematological	**Anaemia, haemolytic**			+	+	+
	Low RBC life span		+	+	+	+
Musculoskeletal	**Exertion intolerance**		++	+	+	+
	Muscle cramps		++	+	+	+
	Muscle pain		++	+	+	+
	Muscle weakness		++	+	+	+
	Second wind phenomenon		–	–	–	–
Laboratory findings	2,3-Diphosphoglycerate (red blood cells)		↓	↓	↓	↓
	Ammonia rise in forearm exercise test (blood)			n	n	n
	Bilirubin (plasma)		n	↑	↑	↑
	Creatine kinase (plasma)		↑	↑	↑	↑
	Glycogen (muscle)	↑	↑	↑	↑	↑
	Lactate rise in forearm exercise test (plasma)			↓	↓	↓
	Myoglobin (urine)		±	±	±	±
	Phosphofructokinase (blood cells)	↓	↓	↓	↓	↓
	Phosphofructokinase (fibroblasts)	↓	↓	↓	↓	↓
	Phosphofructokinase (muscle)	↓	↓	↓	↓	↓
	Reticulocytes (blood)		n	↑	↑	↑
	Uric acid (plasma)		↑	↑	↑	↑

Table 39.24 Glycogen storage disease type XII (Aldolase A deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	**Intellectual disability**		±	±	±	±
Haematological	**Anaemia, haemolytic**		+	+	+	+
Musculoskeletal	**Dysmorphic features**		±	±	±	±
	Muscle weakness		±	±	±	±
	Rhabdomyolysis		±	±	±	±
	Short stature		±	±	±	±
Laboratory findings	Aldolase A (red blood cells)		↓	↓	↓	↓
	Bilirubin (plasma)		↑	↑	↑	↑
	Creatine kinase (plasma)		n-↑	n-↑	n-↑	n-↑
	Glycogen (liver)		n-↑	n-↑	n-↑	n-↑
	Glycogen (muscle)		n-↑	n-↑	n-↑	n-↑
	Reticulocytes (blood)		↑	↑	↑	↑

Table 39.25 Triosephosphate isomerase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Cardiomyopathy		±	±	±	
CNS	Dystonia		±	±	±	
	Intellectual disability		±	±	±	
	Seizures		±	±	±	
	Stroke		±	±	±	
	Tremor		±	±	±	
Haematological	**Anaemia, haemolytic**		+	+	+	
Musculoskeletal	Progressive muscle weakness		±	±	±	
Other	**Recurrent infections**		+	+	+	
Laboratory findings	Dihydroxyacetone phosphate (red blood cells)		↑	↑	↑	
	Triosephosphate isomerase (red blood cells)	↓	↓	↓	↓	

Table 39.26 Muscle phosphoglycerate kinase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Retardation, motor		±	±	±	±
	Seizures		±	±	±	±
Eye	Retinal dystrophy		±	±	±	±
Haematological	**Anaemia, haemolytic**		±	±	±	±
	RBC life span		↓-n	↓-n	↓-n	↓-n
Musculoskeletal	**Exertion intolerance**		±	±	±	±
	Muscle cramps		±	±	±	±
	Muscle pain		±	±	±	±
	Muscle weakness		±	±	±	±
Laboratory findings	Bilirubin (plasma)		n-↑	n-↑	n-↑	n-↑
	Creatine kinase (plasma)		n-↑	n-↑	n-↑	n-↑
	Myoglobin (urine)		n-↑	n-↑	n-↑	n-↑
	Phosphoglycerate kinase (blood cells)		↓	↓	↓	↓
	Phosphoglycerate kinase (muscle)		↓	↓	↓	↓
	Reticulocytes (blood)		n-↑	n-↑	n-↑	n-↑

Table 39.27 Glycogen storage disease type X (Muscle phosphoglycerate mutase deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Musculoskeletal	**Exertion intolerance**				+	+
	Muscle cramps				+	+
	Muscle pain				+	+
	Muscle weakness				+	+
Laboratory findings	Creatine kinase (plasma)				↑	↑
	Glycogen (muscle)				n-↑	n-↑
	Myoglobin (urine)				↑	↑
	Phosphoglycerate mutase (muscle)				↓	↓

Table 39.28 Enolase β deficiency (GSD XIII)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Musculoskeletal	**Exertion intolerance**					+
	Muscle cramps					+
	Muscle pain					+
	Muscle weakness					+
Laboratory findings	Creatine kinase (plasma)					↑
	Enolase beta (muscle)					↓
	Glycogen (muscle)					↑

Table 39.29 Pyruvate kinase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Pulmonary hypertension	±	±	±	±	±
Digestive	Cholecystitis			±	±	±
	Cholelithiasis			±	±	±
	Liver cirrhosis					+
	Neonatal jaundice (severe)	±				
	Neonatal liver failure	±				
	Splenomegaly	±	±	±	±	±
Haematological	Anaemia, haemolytic	+ to +++	+ to +++	+ to +++	+ to +++	+ to +++
	Haemolytic crisis	±	±	±	±	±
	Post-splenectomy thrombosis			±	±	±
	Transfusion dependency	±	±	±	±	±

(continued)

Table 39.29 (continued)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Other	Hydrops fetalis	±				
	Intrauterine growth retardation	±				
Laboratory findings	Bilirubin, unconjugated (plasma)	↑	↑	↑	↑	↑
	Ferritin		↑ - ↑↑↑	↑ - ↑↑↑	↑ - ↑↑↑	↑ - ↑↑↑
	Haemoglobin (blood)	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓	↓ - ↓↓↓
	Mean corpuscular volume (MCV)	n - ↑	n - ↑	n - ↑	n - ↑	n - ↑
	Osmotic fragility	n - ↑	n - ↑	n - ↑	n - ↑	n - ↑
	Pyruvate kinase activity (spectrophotometric assay, red blood cell)[a]	+	+	+	+	+
	Reticulocytes (blood)	↑	↑	↑	↑	↑

[a]False normal values can be due to reticulocytosis or recent transfusion (Bianchi et al. 2019)

Table 39.30 Glycogen storage disease type XI (Lactate dehydrogenase A deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Dermatological	Skin rash[a]				±	±
Genitourinary	Uterine muscle stiffness, in pregnancy					+
Musculoskeletal	**Exertion intolerance**				+	+
	Muscle cramps				+	+
	Muscle pain				+	+
	Muscle weakness				+	+
Laboratory findings	Ammonia rise in forearm exercise test (blood)				n	n
	Creatine kinase (plasma)				↑	↑
	Glycogen (muscle)				n-↑	n-↑
	Lactate (plasma)				↑	↑
	Lactate dehydrogenase (muscle)				↓	↓
	Lactate dehydrogenase (red blood cells)				↓	↓
	Lactate rise in forearm exercise test (plasma)				↑	↑
	Myoglobin (urine)				↑	↑

[a]Psoriasis-like lesions

Table 39.31 Lactate dehydrogenase B deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Musculoskeletal	Myoglobinuria					±
Other	No clinical significance					+
Laboratory findings	Lactate dehydrogenase, LDH (plasma)					↓
	Myoglobine (urine)					↑

Table 39.32 D-Lactate dehydrogenase deficiency (*see also* Monroe et al. 2019)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Other	Gout		±	±	±	
	No clinical significance[a]	+	+	+	+	+
Metabolic	Acidosis	±	±	±	±	±
Laboratory findings	Anion gap (plasma)	±	±	±	±	±
	d-2-Hydroxyisocaproic acid (urine)	n-↑	n-↑	n-↑	n-↑	n-↑
	d-2-Hydroxyisovaleric acid (urine)	n-↑	n-↑	n-↑	n-↑	n-↑
	d-Lactate (plasma)	n-↑	n-↑	n-↑	n-↑	n-↑
	d-Lactate (urine)[c]	n-↑	n-↑	n-↑	n-↑	n-↑
	Lactate dehydrogenase, LDH (plasma)	n	n	n	n	n
	l-Lactate (plasma)[b]	n	n	n	n	n
	Uric Acid (P)		n-↑	n-↑	n-↑	
	Uric Acid (U)		n-↑	n-↑	n-↑	

[a]But may be relevant in bacterial overgrowth in short bowel patients
[b]Routine lactate (plasma) determinations are specific for l-lactate
[c]Routine lactate (urine) determinations (by GC-MS) detect both l- and d-lactate

Table 39.33 Glycogen storage disease type XV (Muscle glycogenin 1 deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	**Cardiomyopathy, hypertrophic**				+	+
	Ventricular arrhythmia				+	+
Musculoskeletal	**Exertion intolerance**		±	±	+	+
	Muscle weakness		±	±	+	+
Laboratory findings	Glycogen (muscle)	↓↓	↓↓	↓↓	↓↓	↓↓

Table 39.34 Glycogen storage disease type 0b (Muscle glycogen synthase deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Cardiac arrest, sudden			±	±	±
	Cardiomyopathy, hypertrophic			+	+	+
	Syncope			±	±	±
CNS	Seizures			±	±	±
Musculoskeletal	**Exertion intolerance**			+	+	+
	Muscle weakness			+	+	+
Laboratory findings	Glycogen (muscle)	↓↓↓	↓↓↓	↓↓↓	↓↓↓	↓↓↓
	Glycogen synthase (muscle)	↓	↓	↓	↓	↓

Table 39.35 Glycogen storage disease type 0a (Hepatic glycogen synthase deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Seizures	±	±	±		
Digestive	Hepatomegaly	n	n	n	n	n
Metabolic	**Hypoglycaemia (fasting)**	±	±	±		
Laboratory findings	Glucose, fasted (plasma)	↓	↓	↓	↓-n	↓-n
	Glucose, fed (plasma)	n-↑	n-↑	n-↑	n-↑	n-↑
	Glycogen (liver)	↓-n	↓-n	↓-n	↓-n	↓-n
	Glycogen synthase (liver)	↓	↓	↓	↓	↓
	Ketones, fasted (plasma)	↑	↑	↑	n-↑	n-↑
	Ketones, fasted (urine)	↑	↑	↑	n-↑	n-↑
	Lactate, fed (plasma)	↑	↑	↑	n-↑	n-↑

Table 39.36 Glycogen storage disease type IV (Glycogen branching enzyme deficiency)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Cardiomyopathy		±	±		
Digestive	**Hepatopathy**	±	+	+		
	Liver cirrhosis		+	+		
	Splenomegaly		+	+		
Metabolic	Fasting intolerance		+	+
