Diagnosis

Like in many other metabolic disorders, clinical hypothesis-driven pattern recognition is traditionally based on information from history taking, physical examination and additional (laboratory, imaging) investigations. For several disorders of carbohydrate absorption, transmembrane transport and metabolism, the nutritional history is of utmost importance for clinical reasoning and the following questions should be addressed:

- Is there intolerance or avoidance of certain carbohydrates (lactose, fruit, or fruit juice)?
- Did symptoms occur with a change in diet?
- When do symptoms occur in relation to the patient's last meal?
- How does the patient tolerate nocturnal fasting?

The answers to these questions can lead to a new direction of thinking in which the following signs and symptoms can point to fasting intolerance:

- Tremor, perspiration (adrenergic response, effective or ineffective counterregulation)
- Drowsiness, lethargy, double vision, seizures (neuroglycopenia)
- Morning anorexia can be a sign of nocturnal counter-regulation with mobilisation of ketones that can even cause an abnormal, strong, penetrating smell in the bedroom.
- Muscle pain in the morning may indicate nocturnal counterregulatory proteolysis.

To approach the aetiology of fasting hypoglycaemia, the following information is helpful:

- The relationship between the time when the patient becomes symptomatic or hypoglycaemic and the last meal
- The presence of hepatomegaly
- The lactate concentration during hypoglycaemia
- The ketone concentrations during hypoglycaemia

Special laboratory tests (*see* Table below) to come to a diagnosis should be performed in laboratories with specific expertise. These procedures may include both in vivo clini-

cal (loading or provocation) tests, in vitro functional studies in tissues expressing the affected protein (a transporter or an enzyme), prenatal diagnosis, and molecular genetic analysis of the relevant gene (usually in DNA samples from peripheral blood, but DNA can also be obtained from other sources, such as fibroblasts).

Since in vivo and in vitro functional studies are laborious and may be invasive, nowadays a primary molecular genetic approach may be warranted. In that case, a working hypothesis has to be formulated on the basis of clinical and non-invasive paraclinical investigations. This is an option, particularly in disorders in which the affected gene is small or when few prevalent mutations are responsible for the cases of a population (*see* Table 'Special conditions for enzymatic and/or molecular genetic diagnosis in disorders of carbohydrate metabolism').

Alternatively, genetic testing by (panel) DNA has become preferable to (invasive, laborious) enzymology and has replaced invasive in vivo testing in many situations. However, these traditional approaches may still be warranted when no definite diagnosis can be made non-invasively, or to confirm the pathogenicity of genetic variants of unknown significance found by panel, whole exome, or whole genome sequencing.

Reference Values and Pathological Values

The reference values for metabolites whose concentrations are altered in disorders of carbohydrate metabolism are shown in Table below. Due to variable assay conditions, results of additional transport or enzymatic tests have to be interpreted in comparison to laboratory-specific reference values and can be presented as a percentage of the average of normal controls. For example, diagnostic values of monosaccharide uptake by enterocytes in SGLT1 deficiency (an autosomal recessive condition) usually fall below 10% of normal; diagnostic values of glucose uptake by erythrocytes in GLUT1 deficiency (an autosomal dominant condition) have been reported to be 46 ± 8% of controls.

Reference and pathological values for metabolites related to carbohydrate metabolism

Metabolite		Age group	Reference values		Pathological values	
Glucose (P)	Fasting	1 d	2.2–3.3 mmol/L	40–60 mg/dL		
		>1 d	2.8–5.0 mmol/L	50–90 mg/dL		
		Child	3.3–5.5 mmol/L	60–100 mg/dL		
		Adult	3.9–5.8 mmol/L	70–105 mg/dL		
	1 h after ingestion	Adult	6.6–9.4 mmol/L	120–170 mg/dL		
Glucose (CSF)	Fasting	Child	1.7–3.7 mmol/L	32–68 mg/dL	<3.3 mmol/L	<60 mg/dL
					or <P10 for age for GLUT1-D[a]	
Glucose (CSF/P ratio)		Child	65–85%xyx			<40–60%[a]
Glucose (U)			<0.8 mmol/L	<15 mg/dL	>0.8 mmol/L	>15 mg/dL
			0.13–0.32 g/1.73 m^2/d		>0.32 g/1.73 m^2/d	
Reducing substances (stool)			*Negative*			*Positive*
Galactose (P)	Fasting		0–0.03 mmol/L	0–0.5 mg/dL		
	After milk ingestion	Newborn	<1.1 mmol/L	<20 mg/dL	>1.1 mmol/L	>20 mg/dL
		Child	<0.5 mmol/L	<9 mg/dL	>0.5 mmol/L	>9 mg/dL
		Adult	<0.24 mmol/L	<4.3 mg/dL	>0.24 mmol/L	>4.3 mg/dL
Galactose-1-phosphate (RBC)			<0.17 µmol/g Hb		>1.70 µmol/g Hb	
Galactose (U)			<377 mmol/mol crea		>631 mmol/mol crea	
Galactitol (U)			2–5 mmol/mol crea		>30 mmol/mol crea	
Fructose (B)			<0.16 mmol/L		>0.16 mmol/L	
Fructose (U)			10–14 mmol/mol crea		>20 Mmol/mol crea	
Sorbitol (U)			2–26 mmol/mol crea			
Lactic acid (P)	Fasting	Child	0.6–1.8 mmol/L		>3.0 mmol/L	
Lactic acid (CSF)		Child	1.1–2.6 mmol/L		>3.0 mmol/L	
Lactic acid (U)		Child	<200 mmol/mol crea		>300 mmol/mol crea	
Biotinidase (P)			7.0–10.6 mU/mL		>10.6 mU/mL	
Glycogen (L)			<5.0 g/100 g wet tissue		>5.0 g/100 g wet tissue	
Glycogen (M)			<1.0 g/100 g wet tissue		>1.0 g/100 g wet tissue	

n.d. Not detectable

[a]Lumbar punction should be performed after 4 h of fasting. For age-dependent cut-off values for CSF glucose and CSF to plasma glucose ratio *see* Leen et al. (2013)

Functional In Vivo Tests

Functional in vivo (provocation and/or loading) tests can be helpful in certain conditions (Table below) and should only be performed by clinicians with expertise.

Functional tests glucose monitoring (CGM)
Indication: Assessment of fasting intolerance, recurrent episodes of hypoglycaemia of unknown origin, determination of metabolic profile during hypoglycaemia, monitoring of the dietary management. Can be performed in hospital or at home. Stable clinical condition. Instruct on documentation of the use of CGM and alarming function. For patients with ketotic fasting intolerance or ketogenic diets, parallel documentation of ketones by a specific device may be helpful. *Caution:* Correlation between subcutaneous glucose and blood/plasma glucose concentrations may be poor. Thresholds for CGM-alarms and capillary blood glucose/ketone values should be discussed on an individual basis. *Interpretation:* Requires integration of symptoms and signs, documented diet history (including times), CGM (including the slope of the curves), and capillary blood glucose and ketone concentrations.
Fasting test
Indication: Assessment of fasting intolerance, recurrent episodes of hypoglycaemia of unknown origin, determination of metabolic profile during hypoglycaemia. Stable clinical condition. Plan maximal fasting time according to anamnestic tolerance. During test measure glucose (P), blood gases, lactate (P), ketones (P, U) every hour starting with the first meal that is missed. Terminate test in case of hypoglycaemia (<45 mg/dL, <2.5 mM) or if clinical symptoms occur *after* diagnostic blood samples were drawn for glucose (P), blood gases, lactate (P), amino acids (alanine) (P), acylcarnitines (dried blood spots), organic acids (U), ketone bodies (P,U), (FFA (P), 3-hydroxybutyrate (P)), insulin (P), cortisol (P), growth hormone (P), others. *Caution:* Hypoglycaemia from dangerous causes has to be excluded prior to a fasting test. For example, accumulation of metabolites from disorders of fatty acid metabolism may lead to life-threatening complications which means that fatty acid oxidation defects have to be excluded by determination of acylcarnitines prior to such a test. In general, fasting tests should only be performed in specialised centres experienced with potential differential diagnoses. 10% i.v. glucose solution should be immediately available as needed in symptomatic patients (*see* Table "Emergency treatment"). *Interpretation:* Glucose (P) <45 mg/dL (2.5 mM) is suggestive of an abnormal response particularly when combined with typical changes of other metabolites such as ketones or lactate (*see* Sign and Symptoms Tables).
Oral glucose loading test
Indication: 1. To test for impaired intestinal uptake in SGLT1-D. 2. To test for glucose intolerance (decreased hepatic uptake in FBS and GSD-0a, decreased β-cell insulin secretion in FBS). Fasting state: 4–12 h (depending on age). Glucose dose: 2 g/kg as 10% solution or as an equivalent amount of oligosaccharides (maximum dose 50 g) given by mouth within 5–7 min. *Criteria:* ad 1. Clinical signs, abdominal pain, diarrhea, reducing substances in stool, H_2 breath test and glucose (P) determination at baseline and every 30 min for 3 h; ad 2. Glucose (P) and lactic acid (P) determinations at baseline and every 30 min for 3 h. *Caution:* Hypovolaemia may develop in SGLT1-D. *Interpretation:* Pathologic increase of H_2 (breath test) and diminished increase of glucose (P) in SGLT1-D. Glucose (P) low or normal and lactate (P) high or normal at baseline, exaggerated increase of glucose (P) and decrease of lactate (P) after glucose load in FBS. Exaggerated increase of glucose (P) and increased lactate (P) after glucose in GSD-0a.
Oral galactose loading test
Indication: 1. To test for impaired intestinal uptake in SGLT1-D. 2. To test for galactose intolerance (decreased hepatic uptake) in FBS. Fasting state: 4–12 h (depending on age). Galactose dose: 1 g/kg as 20% solution given by mouth within 5–7 min. *Criteria:* ad 1. Clinical signs, abdominal pain, diarrhea, reducing substances in stool, H_2 breath test and glucose (P) determination at baseline and every 30 min for 3 h; ad 2. Glucose (P), galactose (P) and lactic acid (P) determinations at baseline and every 30 min for 3 h. *Caution:* Hypovolaemia may develop in SGLT1-D. Not indicated in galactosaemia patients who may be detected in screening programs or by typical metabolites and enzymatic studies on a galactose-containing diet. *Interpretation:* Pathologic increase of H_2 (breath test) and diminished increase of galactose (P) in SGLT1-D. Glucose low or normal and lactate high or normal at baseline, exaggerated increase of galactose after galactose load in FBS.
Oral fructose loading test
Indication: While dangerous and obsolete in the diagnosis of HFI, the *oral* fructose loading test may serve as a reference test in the diagnosis of SGLT1-D. Fasting state: 4–12 h (depending on age). Fructose dose: 1 g/kg as 20% solution given by mouth within 5–7 min. *Criteria:* Clinical signs, abdominal pain, diarrhea, reducing substances in stool, H_2 breath test and glucose (P) determination at baseline and every 30 min for 2 h. *Interpretation:* No increase of H_2 (breath test) and normal increase of glucose (P) in SGLT1-D.

Functional tests (continued)

Intravenous fructose loading test
Indication: Diagnosis of HFI and FBP-D (FK-D) in questionable cases. (Before this test, think of less dangerous ways of diagnosis. Should only be performed in experienced centres.) Preparation: 2 weeks before the test a diet without sucrose and fructose is prescribed. Fasting state: overnight or 6 h. Fructose dose: 0.25 g/kg as 10% solution given over 1–3 min. Blood samples: baseline, 10, 20, 30, 40, 50, 60 and 90 min. Determinations: glucose, (fructose), lactic acid, phosphate and uric acid (P). *Caution:* Watch for hypoglycaemia between 20 and 50 min. 10% i.v. glucose solution should be immediately available as needed in symptomatic patients (*see* Table "Emergency treatment"). Nausea and abdominal pain are frequent in affected individuals. *Interpretation:* A decrease of glucose and phosphate and an increase of uric acid are typical for HFI. A decrease of glucose and an increase of lactate are characteristic for FBP-D. In FK-D a blunted increase of glucose and a rise in fructose can be detected. Oral fructose loading test is not advocated in the case of suspicion of HFI since oral administration of fructose may cause severe gastrointestinal symptoms and long-lasting hypoglycaemia. *Indications:* Patients with a suspicion of glycerate kinase deficiency (*see* Chap. 71). Fasting state: overnight or 6 h. Fructose dose: 1.0 g/kg as 10% solution given over 5–10 min. Following the load, approximately 4% of the test dose is excreted as d-glycerate in a 24-h urine. A loading test with 200–300 mg/kg of the amino acid l-serine may be equally effective.

Functional tests (continued)

Intravenous glucagon test
Indication: Differentiation of hypoglycaemia. Today less important after development of enzymatic and molecular genetic studies. Helpful in questionable cases. Application of glucagon 0.03 mg/kg (slowly iv) during spontaneous or induced hypoglycaemia. Baseline glucose (P) <60 mg/dL (<3.5 mM), glucose (P) and lactate (P) at 15, 25, 35, 45, 60 min *Caution:* Nausea, vomiting, if given too fast; may be caused by additional formation of ketones. *Interpretation:* Normally, glucose (P) rises by >25 mg/dL (>1.4 mM). Insufficient response indicates depleted glycogen stores, inability to convert glycogen to glucose, or, at the end of a fasting test, impaired gluconeogenesis. Lactate (P) may rise in disorders of gluconeogenesis. X
Non-ischaemic forearm test (*see also* Hogrel et al. 2015)
Indication: Diagnosis of muscular GSDs, *e.g.,* types V and VII. An indwelling catheter is placed in the exercising arm. Grip contraction at 70% of maximal voluntary contraction for 30 s. Blood samples: baseline, 1, 2, 3, 4, 6 and 10 min after the end of the exercise Determinations: ammonia (P) and lactate (P). *Cautions:* In case of muscle cramp, stop exercise immediately. *Interpretation:* No increase of lactate (P) occurs in muscle GSDs (except GSD-XI, LDH deficiency), in contrast ammonia (P) increases.

Specimen Collection

For specimen collection see Table below.

Specimen collection for laboratory tests in disorders of carbohydrate metabolism

Test	Material	Preconditions	Handling	Pitfalls
Metabolites				
Glucose	P	Fasted/*non*-fasted	NaF tubes	Bacterial contamination[a]
Glucose	CSF	Fasted (!)[b]		Bacterial contamination[a], pleocytosis
Glucose	U			Bacterial contamination[a]
Reducing substances	U			Bacterial contamination[a] , medications
Reducing substances	Stool			Bacterial contamination[a]
Galactose	P	Fasted/*non*-fasted	Perchloric acid extract	
Galactose	U			Bacterial contamination[a]
Gal-1-P	RBC		Washed	
Galactitol	U			Bacterial contamination[a]
Sorbitol	U			Bacterial contamination[a]
Lactic acid	P	Fasted/*non*-fasted	Perchloric acid extract or NaF tubes	Hypoxia[a]
Lactic acid	CSF	Fasted (!)	Perchloric acid extract or NaF tubes	[a]
Glycogen	Liver		Freeze immediately, store at −70 °C[c]	
Glycogen	Muscle		Freeze immediately, store at −70 °C[c]	
Enzymes				
Lactase	Intestine		Freeze immediately, store at −70 °C[c]	
Sucrase	Intestine		Freeze immediately, store at −70 °C[c]	

Test	Material	Preconditions	Handling	Pitfalls
Isomaltase	Intestine		Freeze immediately, store at −70 °C[c]	
Trehalase	Intestine		Freeze immediately, store at −70 °C[c]	
Galactokinase	RBC		Washed, frozen[c]	
GALT	RBC		Washed, ship at room temperature[c]	
UDPGal-4-epimerase	RBC		Washed, frozen[c]	
Frc-1-P aldolase (AldoB)	Liver, Intestine		Freeze immediately, store at −70 °C[c]	
Frc-1,6-P biphosphatase	Liver		Freeze immediately, store at −70 °C[c]	
Liver GSD enzymes	Liver		Freeze immediately, store at −70 °C[c]	
Muscle GSD enzymes	Muscle		Freeze immediately, store at −70 °C[c]	
Transporter assays				
GLUT1	RBC		Assay in unfrozen EDTA sample[c]	
SGLT1	Intestinal biopsy		Assay in unfrozen tissue[c]	
Glucose-6-P-translocase	Liver		Assay in unfrozen tissue[c]	

[a]Always store samples at −20 °C if immediate processing is not possible
[b]Always use fasted samples and draw a plasma sample for determination of CSF/P ratio just *before (!)* the lumbar puncture
[c]Since assay conditions may vary with time and with different reference laboratories, you are encouraged to contact these laboratories before obtaining specimens

DNA Testing

Table 'Special conditions for enzymatic and/or molecular genetic diagnosis in disorders of carbohydrate metabolism' refers to the question how to arrive at a definite diagnosis with minimal invasiveness and calculated costs.

Metabolites (in easily accessible samples!) can be helpful in some cases but it is not necessary, for example, to quantitate glycogen content in liver or muscle tissue in all cases with a suspicion of GSD. Likewise, it is possible to arrive at a definite diagnosis by transporter studies or measurement of enzymatic activity in biopsy samples; however, affected proteins are not always expressed in tissues that are easily available, which can make conventional diagnosis very invasive. Today, molecular genetic studies from DNA samples from peripheral blood are possible for all disorders. Targeted genetic diagnosis is warranted in cases with good clinical classification; it will depend on the size of the respective gene and the existence of common genetic variants in the population under study. DNA panel studies have become available recently for cases without high suspicion of a single gene defect, and cases with unspecific clinical signs and symptoms will be diagnosed by whole exome, genome, or transcriptome studies with increasing frequency.

Special conditions for enzymatic and/or molecular genetic diagnosis in disorders of carbohydrate metabolism (Detailed information should be retrieved from databases)

No.	Disorder	Basis for enzyme/transporter assay (from peripheral blood)		Basic data for molecular genetic characterisation

Prenatal Diagnosis

In principle, prenatal diagnosis is possible for all disorders by molecular genetic techniques with DNA samples from chorionic villi or amniotic fluid cells. For some disorders, prenatal enzymatic studies in amniotic fluid cells have been reported.

Treatment Summary

Treatment depends on the underlying disorder and, for some disorders (*highlighted in bold in* Table 'Principles and measures of long-term treatment'), guidelines are published. In many of these disorders with symptomatic hypoglycaemia as part of the acute presentation, a rapid normalisation of blood glucose is important (*see* Table 'Initial treatment'). Long-term treatment aims and measures are summarised in Table 'Principles and measures of long-term treatment'; specific treatment in certain groups of disorders are given below. Many patients require personalised dietary measures prescribed by specialised dietitians, familiar with age-specific requirements, from the newborn period until late adulthood.

Emergency Treatment

In some disorders, episodes of metabolic emergencies can be triggered by catabolism, evoked by combinations of fever, decreased enteral intake and increased enteral losses by vomiting and/or diarrhea. To ensure safe shared care for patients with fasting intolerance in a subset of the disorders of carbohydrate absorption, transmembrane transport and metabolism, a written emergency protocol is warranted and should be personalised based on the age/body weight and specific disorder. If possible, the responsible metabolic centre should be contacted in advance in the case of a surgical procedure, to provide perioperative recommendations.

Initial treatment of acute, symptomatic hypoglycaemia in patients with a disorder affecting endogenous glucose production[a]

Age		Immediate bolus (within 5–10 min)		Followed by continuous glucose infusion[b]
		mg Glc/kg b.w.	mL (Glc 10%)/kg b.w.	mg glucose/kg b.w.per min
0–1	Years	500	5	7–9
1–6	Years	400	4	6–8
6–12	Years	350	3.5	5–7
Adolescents		300	3	4–6
Adults		250	2.5	2–4

[a]In patients with a confirmed metabolic disorder causing hypoglycaemia, treatment is challenged by (a) the risk of rebound hypoglycaemia due to hyperinsulinism, (b) the necessity of continuation of iv glucose, and/or (c) the careful reintroduction of enteral feeds. If possible, oral treatment is preferable to manage both symptomatic and asymptomatic hypoglycaemia, under clinical supervision. Based on symptoms and signs, the exogenous glucose intake should be titrated based on blood glucose values and secondary metabolic parameters, such as lactate concentrations and blood gas analyses in GSD-I patients.
[b]Consider to adapt rate of glucose in case of fever

If galactose-1-phosphate uridyltransferase deficiency is suspected, for instance after positive newborn screening tests, a galactose-restricted diet should be started immediately, without waiting for confirmation of the diagnosis. Likewise, severe liver problems (*e.g.* a coagulation disorder) and a suitable dietary history justify to stop fructose intake with the diet. Severe postnatal osmotic diarrhoea and hypovolaemia should be treated by intravenous rehydration and omitting enteral carbohydrates prior to a definite diagnosis.

Standard Treatment

Principles and measures of long-term treatment of disorders of carbohydrate metabolism[a]

No.	Disorder	Principle	Measures
39.1	CL-D	Avoid *non*-absorbable lactose	Lac-free diet for life
39.2	CSI-D	Avoid *non*-absorbable disaccharides, starch	Sac-restricted diet, sucrase replacement with feeds
39.3	TREH-D	Avoid *non*-absorbable disaccharide	Treh-restricted diet
39.4	SGLT1-D (GGM)	Avoid *non*-absorbable monosaccharides	Glc- and Gal-restricted diet for life
39.5	SGLT2-D		*No specific Tx necessary*
39.6	MAP17-D		*No specific Tx necessary*
39.7	**GLUT1-D**	Improve energy supply to the brain: Use ketone bodies (transported by MCT1 at the BBB) as an alternative substrate	Avoid fasting, avoid valproic acid; low CH, high-fat (modified Atkins) diet, ketogenic diet
39.8	IDDNPF	*as for* 39.7 (?)	*as for* 39.7 (?)
39.9	GLUT2-D (FBS)	Compensate for impaired hepatic Glc uptake and release Compensate for impaired hepatic Gal uptake Compensate for generalised impairment of proximal renal tubular cells secondary to Glc and glycogen overload	Continuous enteral supply of slowly released CH to stabilise blood Glc and suppress gluconeogenesis Gal restriction Symptomatic Tx of renal Fanconi syndrome
39.10	GALM-D	Prevent accumulation of toxic galactitol in eye lens	Gal-restricted diet for life
39.11	GALK-D	Prevent accumulation of toxic galactitol in eye lens	Gal-restricted diet for life
39.12	**GALT-D**	Prevent accumulation of toxic Gal-1-P	Gal-restricted diet for life
39.13	GALE-D	Prevent accumulation of toxic Gal-1-P	Gal-restricted diet for life
39.14	FK-D		*No specific Tx necessary*
39.15	ALDOB-D (HFI)	Prevent accumulation of toxic Frc-1-P	Strict Frc-restriction for life, avoid iv Frc/sorbitol
39.16	HK1-D		
39.17	HK1 (NEDVIBA)		
39.18	HK1 (HMSNR)		
39.19	HK1 (RP79)		
39.20	**GCK-D** (MODY2)	Normalise blood glucose	Diet, antidiabetic drugs, insulin
39.21	GCK-HI (HHF3)	Normalise blood glucose	Diet, diazoxide
39.22	G6PI-D		
39.23	GSD-VII	Compensate for diminished access to glycogen (M)	Symptoms can worsen if carbohydrates are taken before exercise
39.24	ALDOA-D	Compensate for diminished access to glycogen (M)	
39.25	TPI-D		
39.26	PGK-D	Compensate for diminished access to glycogen (M)	
39.27	GSD-X	Compensate for diminished access to glycogen (M)	
39.28	GSD-XIII	Compensate for diminished access to glycogen (M)	
39.29	**PK-D**		
39.30	LDHA-D (GSD-XI)	Compensate for diminished access to glycogen (M)	
39.31	LDHB-D		*No specific Tx necessary*
39.32	D-LDH-D	Avoid accumulation of uric acid	Allopurinol
39.33	GSD-XV (PGBM2)	Compensate for diminished glycogen stores (M)	
39.34	GSD-0b	Compensate for diminished glycogen stores (M)	
39.35	GSD-0a	Provide exogenous CH that can compensate for diminished glycogen stores (L)	Avoid fasting, frequent CH-rich feeds, continuous enteral supply of slowly released CH
39.36	GSD-IV	Treat cirrhosis induced by abnormal glycogen (L)	Symptomatic Tx (… liver Tpx)
39.37	GSD-IXd	Compensate for diminished access to glycogen (M)	
39.38	**GSD-IXa**	Provide exogenous CH that can be metabolised despite impairment of glycogenolysis (L)	Avoid fasting, frequent CH-rich feeds, continuous enteral supply of slowly released CH
39.39	**GSD-IXb**	*See* 39.38	*See* 39.38
39.40	**GSD-IXc**	*See* 39.38, treat cirrhosis	*See* 39.38, symptomatic Tx of cirrhosis (… liver Tpx)
39.41	AMPK-A		*No specific Tx available,* symptomatic Tx (… heart Tpx)
39.42	**GSD-V**	Compensate for diminished access to glycogen (M)	Diet rich in complex carbohydrates, exercise program

Standard Treatment (continued)

No.	Disorder	Principle	Measures
39.43	**GSD-VI**	Provide exogenous CH that can be metabolised despite impairment of glycogenolysis (L)	Avoid fasting, frequent CH-rich feeds, continuous enteral supply of slowly released CH
39.44	**GSD-III**	Provide exogenous CH that can be metabolised despite impairment of glycogenolysis (L) Treat cirrhosis	Avoid fasting, frequent CH-rich feeds, continuous enteral supply of slowly released CH Symptomatic Tx (… liver Tpx)
39.45	**GSD-Ia**	Provide exogenous CH that can be metabolised despite impairment of glycogenolysis and gluconeogenesis (L) Avoid accumulation of uric acid Correct primary defect Treat adenoma complications (anaemia, tumour) Treat renal complications	Avoid fasting, frequent CH-rich feeds, continuous enteral supply of slowly released CH, Gal- and Frc-restriction Allopurinol L-Tpx (?) aFor disorders presented in bold an international treatment guideline exists (*see* Kossoff et al. 2018; Welling et al. 2017; Rubio-Cabezas et al. 2014; Bianchi et al. 2019; Kishnani et al. 2019; Quinlivan et al. 2014; Rake et al. 2002; Kishnani et al. 2010; Kishnani et al. 2014; Visser et al. 2002; Kishnani et al. 2006; van der Ploeg et al. 2017)

Intestinal Carbohydrate Malabsorption

Neonatal hypertonic dehydration frequently requires intravenous fluid therapy for which glucose-containing solutions with electrolytes can be used. Long-term enteral nutrition has to avoid the offending sugars: both glucose and galactose as monomers, as well as disaccharides and polymers of these sugars in GGM, and lactose in CL-D. Specialised commercial infant formulas containing fat and protein but free of a carbohydrate component can be used in GGM and fructose should be added according to the dietary allowances for carbohydrates to meet caloric needs. Small amounts of glucose and galactose are usually tolerated later in life. Patients with CL-D tolerate mono- and oligosaccharides. High fluid intake is recommended to prevent renal stone formation, which has repeatedly been reported in both conditions.

Follow-up: Clinical monitoring (nutrient intake, growth, nutritional status, general health), biochemical and paraclinical monitoring (haemoglobin, total protein, general parameters of liver and kidney function, plasma osmolarity and electrolytes, urinary glucose, renal ultrasound) should be planned depending on age, severity of initial decompensation and compliance.

Renal Glucosuria

Allow free access to fluid. Caloric intake should compensate for renal losses in the severe cases. No specific treatment is necessary.

Follow-up: Only the severe recessive types need systematic follow-up.

Glucose Transporter-1 Deficiency

For most patients, an effective treatment is available by means of a modified Atkins diet or a ketogenic diet, both providing ketones as an alternative fuel for the brain. Ketones enter the brain via the facilitative MCT1 transporter. The diet should be introduced in a clinical setting and requires an experienced pediatrician and a dietitian. The classic ketogenic diet, with a

3:1 ratio (fat vs *non*-fat intake in grams) using long-chain triglycerides is used for seizure control in infantile cases and preschool children. A modified Atkins diet, which is less restrictive, may be sufficient in milder cases with an isolated movement disorder. It can be considered in school-age children, adolescents and adults when the classic ketogenic diet is not tolerated. Fluids and calories are not restricted. Supplements (multivitamins, calcium and often carnitine) are required. Certain anticonvulsive drugs are relatively contraindicated: chloralhydrate, valproate and topiramate interfere with the diet, while others (phenobarbital, methylxanthines (caffeine), ethanol) have been shown to affect GLUT1 function.

Experimental treatment: In individual patients, acetazolamide has shown good responses in movement disorders caused by GLUT1-D. However, when acetazolamide is given in combination with a ketogenic diet, there is an increased risk of nephrolithiasis and it may potentiate metabolic acidosis. *Alpha*-lipoic acid, an antioxidant, has been shown to increase glucose transport in cultured muscle cells but *in vivo* data is not available. Oral triheptanoin, an artificial triglyceride composed of three seven-carbon fatty acids and potentially providing additional fuel for brain energy metabolism, is currently on clinical trial.

Pitfalls/dangers of a ketogenic diet

1. Incorrect calculations: *Note* that the ratio of the ketogenic diet is defined in grams, not in calories or percentages! A 3:1 ratio means that, for 3 g of ingested fat, only 1 g of protein and carbohydrates is allowed. Thus, on a 3:1 ketogenic diet, 87% of kilocalories per day are supplied by fat. Percentages of protein and carbohydrates vary due to age-dependent protein requirements.
2. Non-compliance: *Assess* ketones in blood and urine. If ketones are inappropriately low, intensify dietary instructions and be aware that many medications have a high carbohydrate content!
3. Contraindications: β-oxidation defects, disorders of gluconeogenesis, ketolysis defects, porphyria, long QTc syndrome, relative contraindication concomitant use of propofol or pentobarbital coma
4.During intercurrent illness there is a risk of ketoacidosis and/or hypoglycaemia, provide an emergency protocol for these situations. Include a perioperative plan regarding intravenous fluids and monitoring of glucose/ketones in case surgery is necessary.

Nutritional requirements on a ketogenic diet

Age		Fat requirements (g/kg bw per day)	Protein requirements[a] (g/kg bw per day)	Carbohydrates (g/kg bw per day)	Energy demand[b] (g/kg bw per day)
0–4	months	9.0	2.2	0.8	93
4–12	months	9.0	1.6	1.4	91
1–3	years	8.7	1.2	1.7	90
4–6	years	7.8	1.1	1.5	80
7–9	years	7.0	1.0	1.3	72
10–12	years	5.8	1.0	0.9	60
13–15	years	5.0	1.0	0.7	52
Adults		5.0	1.0	0.7	52

Monitoring of ketosis on a ketogenic diet

Sample	Ketone body	Test	Target value
Urine	Acetoacetate	Test strips	80 (++)–160 (+++) mg/dL
Blood	Hydroxybutyrate	Test strips (hand devices)	>2 mmol/L
Serum/plasma	Total ketone bodies	Enzymatic	3–5 mmol/L

Fanconi-Bickel syndrome

Patients with FBS show signs of a hepatic GSD with impaired glycogenolysis and gluconeogenesis. Therefore, treatment should be similar to GSD-1 (*see below*) with frequent feeds and the use of slowly absorbed carbohydrates. Continuous nocturnal enteral nutrition may rescue growth failure (Pennisi et al. 2020). Blood glucose concentrations should be in a range, so that gluconeogenesis is suppressed in order to avoid glycogen accumulation. This can be accomplished by a constant supply of slow release carbohydrates (frequent feeds, corn starch, nasogastric oligosaccharide drip feeding). In contrast to GSD-1, there is no evidence that a fructose-/sucrose-restricted diet is beneficial to FBS patients. Likewise, there are patients with FBS that have ingested high amounts of galactose/lactose without developing cataracts. Therefore, galactose restriction is not generally recommended, but galactose and galactose-1-phosphate levels should be monitored.

Due to the propensity to hypoglycaemia of FBS patients, the use of insulin for impaired glucose tolerance has to be considered with extreme caution and only after dietary measures have failed.

There is no specific treatment for the Fanconi-type nephropathy. Symptomatic treatment is recommended to compensate for losses of water, sodium, potassium, calcium, phosphate, vitamin D and bicarbonate. Maintenance therapy should be monitored by urinary calcium excretion. Carnitine supplementation should only be performed at low plasma levels or when signs and symptoms of a secondary mitochondrial disorder are observed.

Disorders of Galactose Metabolism

If a disorder of galactose metabolism is suspected in a newborn, dietary treatment consisting of a lactose-/galactose-free feeding regimen should be initiated without delay, even before the diagnosis has been confirmed enzymatically or by DNA analysis. In classical galactosaemia, supportive care depends on the severity of liver, renal and central nervous system disease and comprises intravenous fluids, plasma and vitamin K. Initiate treatment with broad-spectrum antibiotics without delay if suspicion of sepsis arises, since, in the event of acute metabolic derangement, patients are at risk of infections due to the compromised response of the immune system.

Long-term treatment requires a galactose-restricted diet for life in all four conditions. There is increasing evidence that small amounts of galactose are acceptable in GALK-D and GALT-D as long as it is in the range of endogenous galactose production. In the severe forms of GALE-D, some dietary galactose (1–2 g/d) and also N-acetyl-galactosamine intake is even necessary for the biosynthesis of complex carbohydrates and galactolipids. Excess, however, should be avoided, as this leads to accumulation of galactose-1-phosphate. Sufficient calcium intake and if necessary supplementation of vitamin D should be guaranteed to protect patients from osteoporosis.

Ovarian dysfunction with hypergonadotropic hypogonadism is observed in almost all female patients with GALT-D. Start ethinyl estradiol therapy from age 12–13 years, when gonadotropin levels are high and estradiol levels are low (first 6 months 2 µg daily; 6–12 months 2–5 µg daily; 12–24 months 5 µg daily; 24–36 months 10 µg daily; after 3 years, followed by an oral contraceptive preparation containing ethinyl estradiol and a progestagen daily for 21 days, 7 days abstinence) (Berry et al. 2016, Welling et al. 2017).

Follow-up in patients with disorders of galactose and fructose metabolism

Disorder	Investigations	Frequency
GALM-D	Ophthalmological investigation Paraclinical Calcium metabolism, 25-OH-vitamin D Galactose (P,U) Galactitol (P,U)	<18 years: annually >18 years: biannually
GALK-D	Ophthalmological investigation Paraclinical Calcium metabolism, 25-OH-vitamin D Galactose (P,U) Galactitol (P,U)	<18 years: annually >18 years: biannually
GALT-D	Clinical[a,b] Ophthalmological investigations Paraclinical Liver/kidney parameters Calcium metabolism, 25-OH-vitamin D Gal-1-P (RBC) Galactitol (P,U) CDT[d] LH, FSH, estradiol (in females, starting around 12 years) Pelvic ultrasound (in females)[e] X-ray (left hand for bone age)[f] Bone mineral density assessment[g]	<1 year: 3 monthly 1–4 years: 4 monthly 4–8 years: 6 monthly[c] >18 years: annually[c]

Disorder	Investigations	Frequency

[d]CDT, carbohydrate-deficient transferrin (abnormal glycosylation of transferrin)
[e]Not routinely recommended
[f]Depending on growth
[g]Start at age 8–10 years, repeat at puberty with follow-ups every 5 years
[h]In milder forms of GALE-D, follow-up can be less extensive

Disorders of Fructose Metabolism

If HFI or FBP-D is suspected, dietary treatment consisting of a sucrose-, fructose-, and sorbitol-free feeding regimen should be initiated without delay, even before the diagnosis has been confirmed enzymatically or by DNA analysis (Steinmann and Santer 2016). Supportive care depends on the severity of liver and renal disease and comprises intravenous fluids, plasma and vitamin K.

In the long term, fructose tolerance in HFI is highly variable. At least in infancy, fructose should be maximally restricted and intake should not be determined by subjective tolerance.

For the maintenance of normal blood glucose concentrations, patients with FBP-D depend on glycogen breakdown and on exogenous glucose from intestinal absorption. Especially in young children, the relative amount of hepatic glycogen is limited. Only after a short period of fasting, patients may develop hypoglycaemia accompanied by accumulation of lactate. The most important aim of the dietary treatment is therefore maintenance of normoglycaemia by avoidance of fasting. In FBP-D, fructose intake should therefore be limited during periods of acute illness because accumulating fructose-1-phosphate inhibits liver phosphorylase. Certain amounts of fructose, particularly when taken with other carbohydrates, are generally tolerated in *non*-catabolic periods.

In patients on a fructose-restricted diet, vitamin C and folic acid should be supplemented.

Glycogen Storage Diseases—Mainly Affecting Liver

Patients with defects in hepatic glycogenolysis (FBS, GSD-I, GSD-III, GSD-VI, GSD-IXa-c) but also with diminished hepatic glycogen formation (GSD-0a) may develop hypoglycaemia after only a short period of fasting. This holds especially true for younger patients and patients with GSD-I. A guideline for acute treatment of hypoglycaemia is given in Table ‘Initial treatment of acute, symptomatic hypoglycaemia in patients with a disorder affecting endogenous glucose production’, but amounts should be interpreted with caution because of the risk of overtreatment and iatrogenic hypoglycaemias. Hypoglycaemia may be accompanied by metabolic acidosis caused by accumulation of lactate (fasted in GSD-I, postprandial in so-called ‘ketotic’ GSDs) or ketones (GSD-III, GSD-VI, GSD-IXa-c, GSD-0, FBS). While lactic acidaemia will improve upon glucose administration in GSD I patients, in patients with a disorder affecting endogenous glucose production application of an excess of glucose in GSD-0a patients may lead to hyperglycaemia and/or lactacidaemia.

The aim of long-term treatment in hepatic GSDs is the stabilisation of blood glucose with concentrations at which gluconeogenesis and secondary metabolic perturbations are suppressed as much as possible, in order to prevent long-term complications and maximise quality of life. No consensus exists about the extent of avoiding lactate production in GSD-I from galactose, fructose and sucrose. Moderate hyperlactacidaemia may prevent cerebral symptoms if blood glucose concentration is low, as lactate may serve as an alternative fuel for the brain. On the other hand, some evidence exists that avoiding lactate production from endogenous sources or from galactose and fructose intake may favor long-term outcome.

Since glycogenolysis is impaired in hepatic GSDs (with the additional involvement of gluconeogenesis in GSD-I), these patients depend on exogenous glucose from intestinal absorption for the maintenance of a normal blood glucose concentration. After a short period of fasting, especially younger patients and patients with GSD-I may develop hypoglycaemia. There is evidence that both the *G6PC* genotype and alternative pathways of glycogenolysis define the GSD-Ia phenotype severity. The most important aim of dietary treatment is avoidance of fasting. Intensive dietary treatment induces catch-up growth, reduces liver size and ameliorates secondary biochemical abnormalities. In GSD-I, life-long dietary treatment is necessary. In GSD-III, dietary treatment is often less demanding and in general, in types VI and IX therapy is markedly easier with only about 50% of patients being prone to hypoglycaemia. In the latter types, dietary treatment is generally limited to younger children. In GSD-IV, dietary treatment may improve fasting intolerance related symptoms and signs, improve growth, normalize serum aminotransferases, and delay or prevent liver transplantation in a subset of patients (Derks et al. 2020).

Intensive dietary treatment with carbohydrates slowly absorbed from the intestine and dietary protein enrichment may also ameliorate secondary myogenic symptoms in the group of hepatic GSDs by counteracting increased gluconeogenesis and avoiding a drain from muscle protein.

Dietary treatment is based on frequent feedings during daytime depending on GSD type and individual fasting tolerance. For type I patients, the entire estimated endogenous glucose production has to be replaced by enteral feedings. The numbers given in the right column of Table 'Initial treatment of acute, symptomatic hypoglycaemia in patients with a disorder affecting endogenous glucose production' can serve as an orientation for a dietary prescription and have to be adapted individually and throughout life based on the age-specific requirements. Fasting tolerance during daytime can be prolonged by using uncooked cornstarch from which glucose is only slowly released to the blood stream. During the night and at a younger age (especially in GSD-I and III), continuous gastric drip-feeding may be necessary for 8–12 h. Uncooked cornstarch should not be started in children less than 6 months and may be carefully introduced after the age of 6-12 months, when pancreatic amylase activity maturates. Alternatively, but only at a later age, uncooked cornstarch may be given during the night at 4- to 6-h intervals, in late adolescence or adulthood at 6- to 8-h intervals, depending on parameters of metabolic control (Chen 2001).

In general, it is not necessary to replace breast milk in infants, except for those with GSD-I who may benefit from glucose-enriched lactose-/sucrose-free feedings or an oligosaccharide-based formula. In GSD-I for continuous gastric drip-feeding, a glucose/glucose polymer solution should be used; formulas enriched with maltodextrin are not recommended due to their high energy content.

Dietary manipulations in hepatic glycogen storage diseases

Disorder	
GSD-0a	Frequent feeds, prevention of fasting[a] Protein enriched diet (20%)
GSD-Ia GSD-Ib	Frequent feeds, prevention of fasting[a] High carbohydrate intake (55–70% of energy) Moderate fat restriction (20–30%) Predominantly polyunsaturated fatty acids Moderate protein restriction (10-15%) Sodium restriction Galactose/fructose restriction
GSD-III	Frequent feeds, prevention of fasting[a] Carbohydrate enriched diet (50–55% of energy) Moderate fat restriction (20–30%) Predominantly polyunsaturated fatty acids Protein enriched diet (20%)[b]
All	Frequent feeds, prevention of fasting[a]

[a]Depending on GSD type, individual fasting tolerance and age consider frequent snacks or corn starch during daytime and continuous gastric drip feeding and use of corn starch during the night (*see* text)
[b]In type IIIa with muscle involvement

In adolescent patients with GSD-I, in analogy to proteinuric insulin-dependent diabetic mellitus, reduction of protein intake should be considered. Furthermore, a reduction in sodium intake may enhance the beneficial effects of angiotensin-converting enzyme inhibitors.

Renoprotective treatment with an ACE inhibitor should be started in GSD-I patients as soon as microalbuminuria persists and before hypertension develops. Angiotensin II antagonists may elicit comparable results; however, clinical experience in GSD-I is more limited.

In order to prevent urate nephropathy in patients with hepatic glycogenosis, allopurinol (10 mg/kg/d in 3 doses, max 900 mg/d) should be started if serum uric acid concentration exceeds the upper normal level for age despite optimal dietary treatment. As uric acid is regarded to be a potent radical scavenger (with a possible protective role against premature atherosclerosis), the targeted uric acid concentration is in the high normal range.

Supplementation of vitamins should commence when WHO recommendations are not met. Furthermore, supplementation of calcium and vitamin D is important when intake of milk and milk-derived products is limited (GSD-I). Special attention is also needed regarding vitamin B_1 intake as increased metabolism of carbohydrates needs sufficient vitamin B_1.

If GSD-I patients show persistence of a deficit of bases (base excess <−5 mmol/L) or a low blood bicarbonate concentration (<20 mmol/L) despite intensive dietary treatment, it is recommended to correct lactacidaemia with (sodium) bicarbonate or (potassium) citrate. In addition to correcting acidosis, this will result in alkalinisation of the urine, which reduces the risk for urolithiasis and nephrocalcinosis. Citrate (initial dosage 1–2 mEq/kg/d in 3–4 doses) is preferred since it also corrects hypocitraturia, another risk factor for urolithiasis. Hypocitraturia is more often seen with increasing age of the patients.

A percutaneous endoscopic gastrostomy (PEG) tube should be placed only under the protection of granulocyte colony-stimulating factor (G-CSF; Neupogen) if a patient has neutropenia.

In GSD-Ib, prophylactic oral antibiotic treatment may be beneficial in patients with neutropenia but the effect has not been systematically studied. Cotrimoxazol has been recommended in symptomatic patients or those with an absolute neutrophil count below 500/nL.

For more than 25 years, GSD-Ib patients have been treated with G-CSF. The use of G-CSF should be restricted to the following indications: (1) persistent neutrophil count $<0.2 \times 10^9$/L; (2) a life-threatening infection requiring intravenous antibiotics; (3) complaints of inflammatory bowel disease, including oral or perianal infections, or severe diarrhoea. The clinical benefits (bacterial infections, enterocolitis) should be carefully balanced against the drawbacks (invasiveness, increased spleen size, risk of myelodysplasia or acute myeloid leukaemia) and the indication of haematopoietic stem cell transplantation, in severe cases.

A recent study enrolled 103 patients with a median G-CSF dose of 3.0 µg/kg/day. GSD-Ib patients seem to respond to low doses of G-CSF: a starting dose of 1.0 µg/kg sc daily or every other day is therefore recommended. Determine neutrophil count frequently and adjust the dose in steps of 2.5–5 µg/kg/d (maximum 25 µg/kg) based on symptoms and signs and target ANC of $0.5–1.0 \times 10^9$/L. However, symp-

toms and signs do not seem to correlate strongly with ANC. In many cases, G-CSF decreases bacterial infections and ameliorates enterocolitis, but in some cases, conservative treatment (for instance, with 5-aminosalicylic acid, Mesalazin) might be of additional benefit.

Empagliflozin may develop into a promising treatment for neutropenia and neutrophil-dysfunction-related symptoms and signs in GSD-Ib patients (Santer et al. 2010, Wortmann et al. 2020).

Fibrates are indicated if triglyceride concentration in patients with hepatic GSDs remain above 10.0 mmol/l despite maximal dietary efforts. Fish oil treatment of hyperlipidaemia has a limited and temporary effect; use of medium-chain triglycerides has been advocated but remains controversial. Statins may be indicated in adult GSD-I patients with massive hypercholesterolaemia.

Treatment with growth hormones in patients with hepatic GSDs and growth retardation is not advocated, since the effect on final height is negligible.

Liver transplantation is considered with increasing frequency in patients with hepatic GSDs. It can be an option in GSD-Ia to correct the basic defect in liver. Also, patients with hepcidin-producing adenoma and severe anaemia and proven or suspected hepatocellular carcinoma within an adenoma (mainly GSD-I) may benefit. Finally, patients with cirrhosis, observed in disorders associated with an abnormal glycogen structure (GSD-III, GSD-IV) but also in GSD-IXc, will require this procedure.

A rather unique development regarding the definition of research priorities has been the international priority-setting partnership for liver GSDs. From these activities, there is now a list of 11 top research priorities (Table 'Research priorities for liver glycogen storage disease'), among which are novel treatment modalities (*see* Table 'Novel treatments in disorders of carbohydrate absorption, transmembrane transport and metabolism').

Research priorities for liver glycogen storage disease (from Peeks et al. 2020)

Rank	Priority
1	What are the best options (*e.g.* gene therapy or enzyme replacement therapy) for achieving sufficient amount of working enzyme in patients with liver GSDs?
2	Can consensus guidelines (for management) be achieved for patients with liver GSD?
3	How should optimal metabolic control both clinically and biochemically (like lactate, ketones and/or lipids) be achieved in liver GSD?
4	How should sickness and emergency situations be managed for patients with liver GSD?
5	What is the best way to start dietary treatment, finding the optimal doses, and to administer the diet for patients with liver GSD?
6	How can existing cornstarch preparations be modified or alternative treatments be implemented that are easier to administer and/or keep blood sugar levels more stable for patients with liver GSD?
7	What is the role for new methods for monitoring metabolic control (like non-invasive continuous glucose and lactate measurements, new biomarkers) for patients with liver GSD?
8	How to manage diet regimen in relation to 'before, during and after' physical exercise (sport, playing) for patients with liver GSD?
9	What are the long-term complications (liver, renal, gut) of a diet rich in uncooked cornstarch and/or high protein and should the diet be adjusted to prevent complications in liver GSD?
10	What are the risks and benefits of different options for overnight treatment for patients with liver GSD and how can we maximise safety?
11	How to prevent and/or treat muscle problems in patients with liver GSD?

Follow-Up and Monitoring

Follow-up in patients with hepatic glycogen storage diseases

Disorder	Investigations	Frequency/ Remarks
FBS	*See* GSD-I *plus* Ophthalmologic examination (cataract?)	
	Glucose (P) (postprandial target conc <10.0 mM) Gal, Gal-1-P Carnitine	Depending on age, symptoms and medication
GSD-I	Clinical[a,b,c,•]	0–3 years: 2 monthly 3–20 years: 3 monthly >18 years: 6 monthly
	Paraclinical Haematological parameters• Electrolytes Blood gases, lactate Lactate (U) (target conc <0.6 mmol/L or <0.06 mmol/mmol crea) Liver parameters• Kidney function (creatinine, GFR) Uric acid (P)• Calcium, phosphate, AP, PTH, vitamin D Cholesterol, triglycerides, amylase, lipase Home blood glucose profile[d,•] (preprandial target conc >3.5–4.0 mM) Microalbumin (U), protein (U) α-fetoprotein• Ultrasound (liver•, pancreas, ovaries) Bone density EEGc	Depending on age, symptoms and medication
GSD Ib	*See* GSD-I *plus*	
	CRP, ESR Fecal α_1-antitrypsin, calprotectin Total blood count with differential Bone marrow	Depending on age, symptoms and medication
GSD IIIa	*See* GSD-I *plus*	

Disorder	Investigations	Frequency/ Remarks
	Creatine kinase (P), pre-albumin BNP EKG, echocardiography Muscle function Lung function	Depending on age, symptoms and medication (in general less often than in GSD I)
GSD VI, GSD IXa-c	*See* GSD-I	Depending on age, symptoms, and medication (in general markedly less often than in GSD I) and restricted to investigations marked by •.

Urinary tetrasaccharide is an important biomarker for follow-up of GSD-II patients, but not specific, and it can be increased in patients with hepatic GSDs, especially GSD-III. The role in single-patient follow up after (novel) treatment needs to be considered

[a]Nutrient intake, growth, sexual maturation, nutritional status, somatic findings (liver size)

[b]Neurological, psychological, cognitive functions, developmental investigations on demand

[c]Particular in cases with frequent hypoglycaemia

[d]Consider subcutaneous continuous monitoring

Glycogen Storage Diseases—Mainly Affecting (Skeletal and Cardiac) Muscle

Patients with GSD-0b, GSD-XV, GSD-XIV, GSD-III, GSD-V, GSD-IXb and d, GSD VII, ALDOA-D, PGK-D, GSD-X, GSD-XIII and LDHA-D may have primary muscle weakness; in GSD-V and GSD-VII and the rare types GSD-XIV, ALDOA-D, PGK-D, GSD-X, GSD-XIII, LDHA-D, severe rhabdomyolysis, which sometimes results in acute renal failure, may additionally occur after (short-term) intensive exertion (Tarnopolsky 2018). These patients benefit from regular physical exercise at a submaximal level.

A carbohydrate-enriched diet (55-65% of energy) and sucrose, ribose or glucose ingestion before exercise may improve aerobic exertion tolerance in patients with GSD-V. However, it may also lead to overweight and to increased insulin secretion, potentially inhibiting the use of fatty acids. The benefits of using uncooked cornstarch in these patients to guarantee a constant glucose source from blood to muscle as oxidative substrate for glycolysis needs further investigation. Supplementation with branched-chain amino acids, vitamin B_6 (50–100 mg/kg/d) and creatine (10–20 g/d) has been recommended; however, there is a lack of evidence for these supplements.

Patients with GSD-VII depend on fatty acid oxidation in muscle as the main energy substrate. Therefore, in these patients, a surplus of dietary carbohydrates should be avoided, since it would enhance the metabolic muscle problems by decreasing the availability of fatty acids for oxidation. The diet should be rich in fat (30–40%) and proteins (15–20% of energy).

GSD-IIa

A special role among GSDs with muscular (and cardiomuscular) symptoms is taken by GSD-IIa, a lysosomal disorder. Symptomatic treatment with regular physical exercise and physiotherapy, and a protein-enriched diet (20% of energy) still are important to maintain a range of motions and assist in ambulation in all affected age groups. Furthermore, individualised care of cardiomyopathy is important as standard drugs may be contraindicated and risk for tachyarrhythmia and sudden death is high. Respiratory support may include CPAP and/or tracheostomy. Surgery for contractures may be needed.

Enzyme replacement therapy (ERT) with alglucosidase-α (Myozyme® or Lumizyme®, at a dosage of 20 mg/kg every other week but also higher (Khan et al. 2020)) has been available for a few years now and should be started as soon as the diagnosis is established. In some countries, newborn screening for GSD-IIa exists and ERT can be started within the first days of life. A majority of infants in whom ERT was initiated before the age of six months and before the need for ventilatory assistance demonstrated improved survival, ventilator-independent survival, acquisition of motor skills, and reduced cardiac mass compared to untreated controls.

In patients with late-onset disease, ERT may stabilise ventilatory function and motor ability, measured by a six-minute walk and pulmonary function testing. ERT can be accompanied by treatable infusion reactions as well as anaphylaxis. Prevention of secondary complications includes aggressive management of infections; keeping immunisations up to date; annual influenza vaccination of the patient and household members; respiratory syncytial virus (RSV) prophylaxis (palivizumab) in the first two years of life; and use of anesthaesia only when absolutely necessary.

Follow-up in patients with muscle glycogen storage diseases

Disorder	Investigations	Frequency/ Remarks
GSD-IIa GSD-V GSD-VII	Clinical[a,b] Paraclinical Creatine kinase (P) Urinary glucose tetrasaccharide[c] Uric acid (P) Kidney function Myoglobin (U) BNP Antibodies (in ERT)[c] EKG, echocardiography Muscle function Lung function Sleep evaluation, oximetry, capnometry Hearing evaluation[c] Haematology parameters (haemolysis)[d]	depending on underlying disorder, age, symptoms and medication

[d]In GSD-VII

Novel Treatments

Reimbursement of (novel) treatments is a general matter of concern for rare diseases and exemplified in patients with disorders of carbohydrate absorption, transmembrane transport and metabolism. For several disorders, novel treatment options are available, either off-label or registered in controlled clinical trials. Examples include dietary interventions, drugs (repurposing), enzyme replacement therapies and gene therapy. In the process of novel treatment development, many companies act as either sponsor or collaborator.

Novel treatments in disorders of carbohydrate absorption, transmembrane transport and metabolism

Number	Disorder	Intervention/Treatment	Sponsor	Phase	ClinicalTrials.gov Identifier or EudraCT number
39.7	GLUT1-D	Other: Red Blood Cell Transfusion	University of Texas Southwestern Medical Center, USA	1	NCT04137692

Disorders of the Pentose Phosphate Pathway and Polyol Metabolism

40

Mirjam M. C. Wamelink and Monique Williams

Contents

Summary

Five inborn errors in the pentose phosphate pathway (PPP) have been described of which *Glucose-6-phosphate dehydrogenase (G6PD) deficiency* is a defect in the first, irreversible step of the pathway. As a consequence, nicotinamide adenine dinucleotide phosphate (NADPH) production is decreased, making erythrocytes vulnerable to oxidative stress. Drug- and fava bean-induced haemolytic anaemia is the main presenting symptom of this defect. G6PD deficiency is an X-linked disorder. This haematological disorder is not further discussed.

Three other defects with associated clinical pictures are:

Deficiency of ribose-5-phosphate isomerase has to date been described in three cases, who presented with psychomotor developmental delay, visual impairment, spasticity and leukoencephalopathy.

Transaldolase deficiency presents with hepato- and splenomegaly, cardiac abnormalities, liver function problems, anaemia, thrombocytopenia and abnormal skin (e.g. cutis laxa) in most patients.

Transketolase deficiency was identified by whole exome sequencing (WES) in five patients of three

families with common clinical findings: short stature, developmental delay and congenital heart defects.

Four other inborn errors with polyol abnormalities without a clear suspected clinical phenotype are:

Sedoheptulokinase deficiency results in urinary accumulation of sedoheptulose and erythritol and is the result of mutations in the *SHPK* gene. A 57-kb-deletion, the most common cause of nephropathic cystinosis, also results in SHPK deficiency. Two unrelated patients with isolated SHPK deficiency have been described with completely different clinical pictures suggesting the clinical phenotype may not be related to sedoheptulokinase deficiency.

l-*xylulose reductase deficiency,* a defect of the glucuronic oxidation pathway with the biochemical feature of pentosuria, is a benign condition.

l-*arabinosuria* has been documented in only one patient. The defect has not been fully elucidated in humans.

Sorbitol dehydrogenase is an enzyme that participates in fructose and mannose metabolism. Deficiency is associated with cataract, although no direct relation has been confirmed of this enzyme deficiency and (congenital) cataract.

Introduction

The pentose phosphate pathway (PPP), also known as the hexose monophosphate shunt, provides an alternative pathway for glucose oxidation. It is present in the cytosol of all cells and has two major functions: production of NADPH, and synthesis of ribose-5-phosphate. The pathway can be divided into two branches. The oxidative branch consists of three irreversible reactions, which result in NADPH and pentose phosphate production. The non-oxidative branch of the pathway reconverts pentose phosphates into glucose-6-phosphate (glucose-6P), and two of the intermediates, fructose-6P and glyceraldehyde-3P, are also glycolytic intermediates. The reactions in the non-oxidative branch are reversible. The flow of glucose-6P through the PPP or glycolysis is dependent upon the cellular requirement for NADPH, ribose-5P and ATP. The PPP is linked to the glucuronic oxidation pathway through xylulose-5P (Fig. 40.1).

Ribose-5-phosphate isomerase (RPI) deficiency was first described in a patient with a slowly progressive leukoencephalopathy with accumulation of the pentitols ribitol and arabitol in brain and body fluids (van der Knaap et al. 1999; Huck et al. 2004). Since then, two additional patients with RPI deficiency have been described. The first patient with RPI deficiency presented with impaired psychomotor development and epilepsy followed by neurological regression with cerebellar ataxia and peripheral neuropathy. At diagnosis, he suffered from serious intellectual disability, but somatic examination was normal. The second patient was similar to the first patient but lacked peripheral neuropathy (Naik et al. 2017). The 6-year-old patient described by Brooks et al. (2018) presented similarly as the first patient, showed dysmorphic features (resembling Allan-Hernon-Dudley syndrome), but has not developed epilepsy or regression yet. MRI showed extensive abnormalities of the cerebral white matter. Magnetic resonance spectroscopy (MRS) revealed abnormal resonances, corresponding to arabitol and ribitol. The diagnosis of RPI deficiency can be made by the analysis of sugars and polyols in urine, plasma or CSF. Urinary ribitol and arabitol, as well as xylulose, are elevated. High concentrations of the pentitols are also observed in CSF (see Table 40.1).

Transaldolase (TALDO) deficiency was first described in 2001 (Verhoeven et al. 2001) in a single patient presenting with cirrhosis, with to date more than 35 additional patients diagnosed from 22 different families (Williams et al. 2019, personal communication). A great phenotypic variability has been reported in TALDO patients. Most patients displayed the first symptoms of the disease in the neonatal or antenatal period when intra-uterine growth retardation, oligohydramnios and hydrops foetalis with dysmorphic features, and congenital heart defects have been described (Valayannopoulos et al. 2006). Neonates reveal hepatosplenomegaly, bleeding, abnormal liver function tests, cholestatic jaundice and elevated liver enzymes. Hepatic fibrosis or cirrhosis is the pathological liver hallmark in older patients. An asymptomatic sibling was diagnosed at 9 years of age, only then hepatomegaly was noted (LeDuc et al. 2014). Liver pathology includes hepatocellular damage and degeneration of hepatocytes or hyperplastic and enlarged hepatocytes with fibrosis and cirrhosis. In one patient, development of liver carcinoma occurred. Another frequent finding (in 76% of cases) is anaemia. Renal manifestations and endocrine disorders are seen in about 30% of patients. Mild transient hypotonia was described in several patients but mental and motor development were normal in the majority. Brain MRI and MRS did not reveal abnormalities in patients with TALDO deficiency. Death in TALDO deficiency occurs due to liver failure and consequences of liver complications later in life. TALDO deficiency results in the accumulation of seven-carbon sugars from sedoheptulose-7P and polyols derived from the pathway intermediates (see Table 40.2) (Wamelink et al. 2008). Citric acid cycle intermediates have been detected, indicating a possible disturbed mitochondrial metabolism in TALDO deficiency (Engelke et al. 2010).

Transketolase (TKT) deficiency was identified as disease causing when performing whole exome sequencing (WES) in five patients of three families with common clinical findings: short stature, developmental delay and congenital heart defects. Additional features can be found in Table 40.3. Elevated excretion of erythritol, arabitol, ribitol, and pent(ul)ose-5P, as well as

elevated plasma levels of erythritol, arabitol and ribitol, are found in affected patients. TKT activity in lymphoblasts, fibroblasts or erythrocytes from all five individuals showed complete absence or low residual enzyme activity (Boyle et al. 2016).

Sedoheptulokinase (SHPK) deficiency: The two patients described with SHPK deficiency excreted increased amounts of erythritol and sedoheptulose (Wamelink et al. 2015). The finding of erythritol is likely the result of phosphorylation of sedoheptulose by fructokinase to sedoheptulose-1P and cleavage of the latter by aldolase B to the formation of erythrose, and further reduction to erythritol (Kardon et al. 2008). Their clinical phenotype however was diverse, so a causal relationship seems doubtful. The phenotype ranged from neonatal cholestasis, hypoglycaemia, anaemia and cerebral abnormalities with facial dysmorphisms to congenital arthrogryposis with facial dysmorphisms (see Table 40.4).

l-*xylulose reductase deficiency* is associated with pentosuria, first shown in 1892 by Salkowski and Jastrowitz and was suggested an inborn error of metabolism in 1908. The defective enzyme in humans was found by Wang and Van Eys (1970). In 1981, in a group of 1117 patients with a suspected inherited disease, 20 patients (2%) with pentosuria were found (Vaca et al. 1981). Not only L-xylulose was found in urine but also increased levels in plasma were found. Touster and Harwell (1958) reported finding only L-arabitol in pentosuric urine compared to both D/L-arabitol in normal urine. The pentose sugar was identified as L-xylulose and mutations in *DCXR* leading to enzyme deficiency were found in 2011 in the persons with pentosuria that had been studied by Margaret Lasker (xyloketosuria) in 1936. It is an autosomal recessive phenomenon and a benign condition (Pierce et al. 2011) (see Table 40.5).

l-*arabinosuria*, detected in one patient with delayed motor development and facial dysmorphism (Onkenhout et al. 2002), possibly due to L-arabitol dehydrogenase, leads to strongly elevated excretion of L-arabitol and arabinose after ingestion of fruit. Additionally, high levels of arabinose and L-arabitol were also found in plasma and CSF (see Table 40.6). L-arabitol dehydrogenase has been detected in yeast and fungi. The enzyme has been purified from fungus and the gene cloned. This has not yet been established in human (Onkenhout et al. 2002). It is unclear whether this biochemical finding is disease related. However, it was speculated that accumulation of L-arabitol over time could be toxic to the brain.

Sorbitol dehydrogenase (SORD) deficiency was found in predominantly male patients of two families with congenital cataract (Vaca et al. 1981; Shin et al. 1984). SORD deficiency is also thought to play a role in diabetic complications (cataract) where at high glucose levels it is believed that the polyol pathway is very active, and that enzyme activity is high in kidney and lens (Carr and Markham 1995). Sorbitol dehydrogenase converts D-sorbitol to D-fructose in the fructose and mannose metabolism and xylitol to D-xylulose in the glucuronic oxidation pathway resulting in elevated sorbitol and xylitol in urine and plasma (see Table 40.7).

Nomenclature

No.	Disorder	Alternative name	Abreviation	Gene symbol	Chromosomal location	Mode of Inheritance	Affected protein	OMIM
40.1	Ribose-5-phosphate isomerase deficiency	RPI deficiency	RPI	*RPIA*	2p11.2	AR	Ribose-5-phosphate isomerase	608611

Diagnostic Flowcharts

(See Fig. 40.2)

Loading Test

In the case of L-arabinosuria, when the diet contains fruit, large amounts of L-arabinose and L-arabitol are detected. Without the ingestion of fruit arabinose and arabitol normalise. For the other defects loading tests are not applicable.

Specimen Collection

Investigation	Specimen	Storage
Sugars and polyols[a]	U, P, CSF	Frozen
C7-carbohydrates	U, BSP	Frozen
Transaldolase activity	FIB, LYB, ERY Liver	Room temperature Frozen
Ribose-5-phosphate isomerase activity	FIB, LYB	Room temperature
Transketolase activity	FIB, LYB	Room temperature
Sedoheptulokinase activity	FIB	Room temperature
Sorbitol dehydrogenase activity	SER, RBC	Room temperature

[a]Urine can be spotted on filter paper and sent at room temperature for analysis of polyols (sugars are not stable in spotted urine and therefore unreliable for diagnosis)

Prenatal Diagnosis

Disorder		Material	Testing	Trimester
40.1	RPI deficiency	CV, AMN	DNA	I, II
40.2	Transaldolase deficiency	CV, AMN Cell free amniotic fluid	DNA Metabolite	I, II (II), III (performed only ones at 28 weeks gestation)

40.7	Sorbitol dehydrogenase deficiency	Any DNA source (WBC, FB, CV, AMN)	15q21.1

Treatment Summary

For all disorders in polyol metabolism described in this chapter there is no specific treatment. For some clinical significance is still unclear, for example, SHPK deficiency, L-arabinosuria and SORD deficiency. L-xylulose reductase deficiency is a benign disorder and needs no treatment.

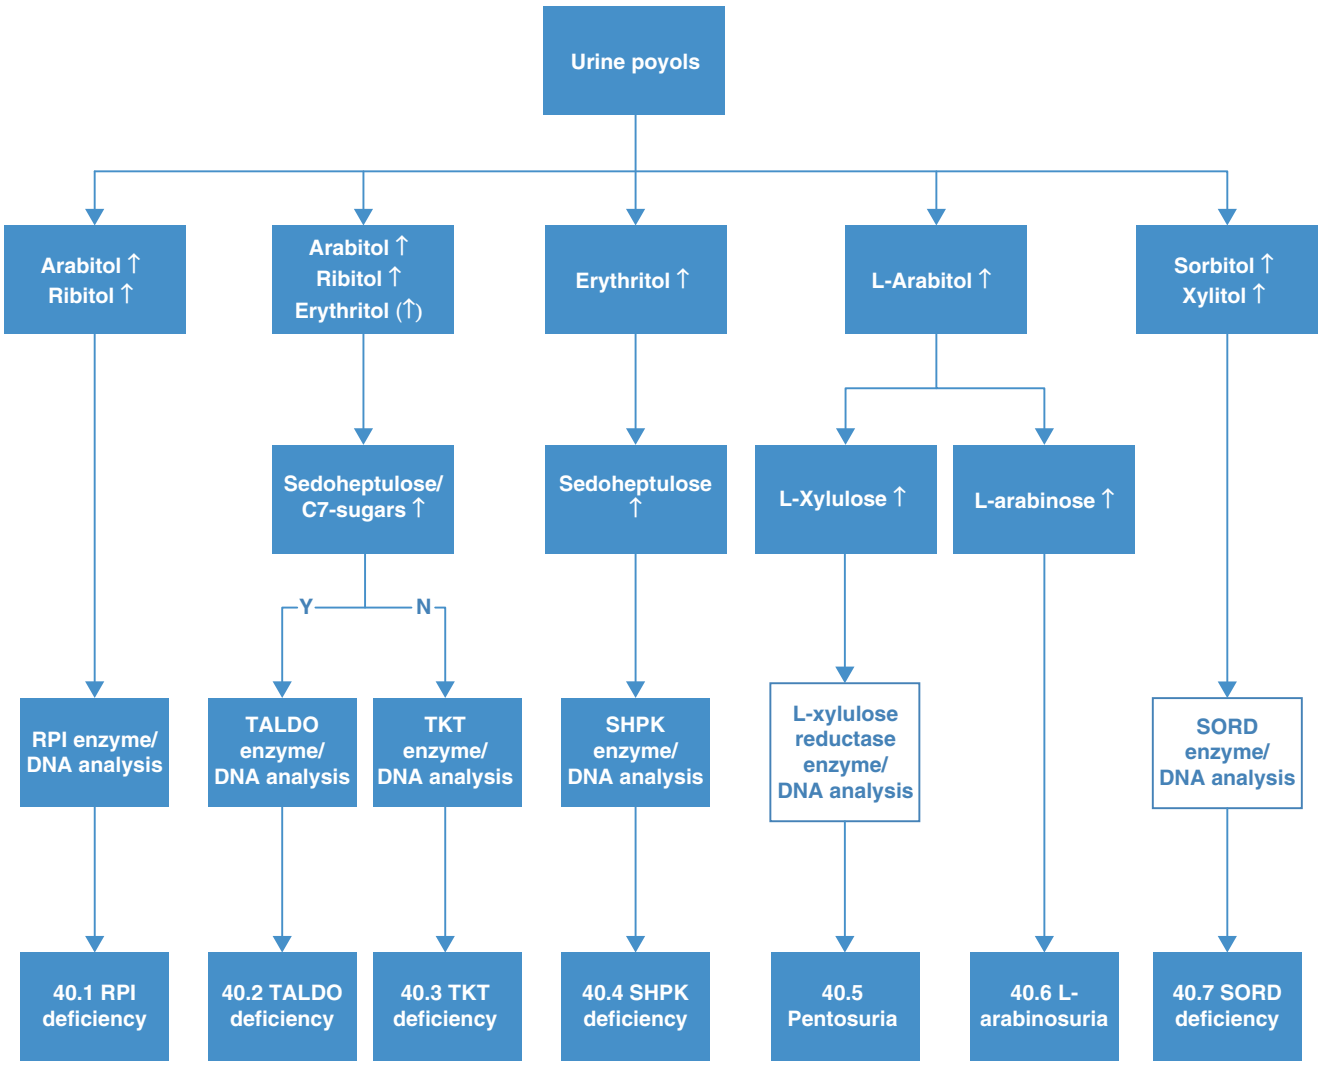

Fig. 40.2 Diagnostic flowchart in case of abnormally elevated urinary polyols

In RPI, and TKT deficiency supportive therapy for their symptoms are indicated.

For TALDO deficiency treatment is symptomatic and focused on liver disease, which is the main cause of morbidity and mortality of this condition. Medication with a possible liver toxic effect should be used with care and (possibly) adjusted in dosage. Liver transplantation, according to literature, has been performed in three affected patients before the age of 1 year (Williams et al. 2019). Two of the patients were stable at 7 and 3 years, the other died in the course of the liver transplantation. Correction of anaemia and low clotting factors may require transfusions of packed red cells and fresh frozen plasma, respectively. Surgical correction of heart septal defects and medical treatment of tubulopathy, arterial hypertension and endocrine disorders may be required.

The only patient described with L-arabinosuria has been treated with a fruit restricted diet; this resulted in a decrease in excretion of the metabolites concerned.

Emergency Treatment

There is currently no known emergency treatment for any of the disorders of polyol metabolism described in this chapter.

In TALDO deficiency, especially when liver dysfunction has been observed, care with respect to medications metabolised by the liver should be given. Dosing of medications might need to be reconsidered and acetaminophen even at normal dosage could be toxic. With the suggested positive effect of N-acetylcysteine on the pre-

vention of liver failure and carcinogenesis of the liver in the mouse, treatment with N-acetylcysteine can be considered in case of fulminant liver failure (replenishment of glutathione).

Experimental Treatment

In the TALDO knockout mouse model lifelong administration of the potent antioxidant N-acetylcysteine (NAC) prevented acetaminophen-induced liver failure, and blocked hepatocarcinogenesis in Taldo1−/− mice. (Hanczko et al. 2009). Rodan and Berry (2017) concluded that supplementation of NAC probably helped a TALDO-deficient patient, since NAC normalized AFP levels and could have resulted in decreased hepatocyte injury. The data from the long-term follow-up of Polish patients show that AFP levels however normalized with age (Limpinski et al. 2018)

In animal studies it has been shown that benfotiamine, a lipid-soluble thiamine derivative, can activate TKT and prevent retinopathy and vascular damage due to accumulation of glycolytic metabolites in diabetic rats. It is possible that benfotiamine could be used therapeutically in individuals with TKT deficiency with some residual activity, and this should of course be investigated (Hammes 2003).

For all other disorders in polyol metabolism no experimental treatment has been suggested.

Follow-Up and Monitoring

For TALDO deficiency the advice is to follow haematological parameters to evaluate anaemia (blood count, including reticulocyte, LDH, haptoglobin and erythropoietin), liver function (clotting factors, transaminases, bilirubin, conjugated bilirubin, gamma-glutamyl transpeptidase (GGT), alkaline phosphatase) and AFP for evaluation of liver carcinogenesis every 3–6 months, and kidney function (glomerular and tubular). Decreased tubular function also warrants evaluation of bone mineral content (dual-energy X-ray absorptiometry (DXA) scans). Regular visceral imaging studies (US, computed tomography, magnetic resonance imaging) should be performed according to local protocols for patients with chronic liver disease at risk for cirrhosis. Follow-up of height, weight and puberty, including Tanner staging, is important. Gonadal function should be assessed based on clinical symptoms such as cryptorchidism, microphallus, delayed puberty or infertility. We advise a low-threshold for assessment of thyroid function (Williams et al. 2019). Referral to a clinical geneticist and cardiologist when the diagnosis has been made is further suggested.

For RPI or TKT deficiency, follow-up programmes/guidelines for neurological and/or developmental impairment are most likely applicable. No specific advice for these diseases can be given, yet this is also determined by disease progression.

Summary

Hyperinsulinemic hypoglycaemia (HI) includes all conditions in which inappropriate high plasma insulin levels are observed during hypoglycaemia, regardless of whether the cause is related to a perinatal stress, to a genetic disorder (specific to the ß-cell or syndromic), drug-induced or else. In this chapter, we will consider genetic causes of HI, and discuss transient and syndromic aetiologies. Recently, exceptional causes of non-ketotic hypoglycaemia related to disorders of the insulin receptor pathway were added to the spectrum of HI. Congenital hyperinsulinism (CHI) is per se limited to all genetic defects of the pancreatic ß-cell leading to HI. CHI can present throughout life but is most common in infancy. CHI is responsible for recurrent severe hypoglycaemia in neonates, in whom delayed diagnosis or improper medical management is responsible for brain damage in about 1/3 of them. Most CHI patients are responsive to a first line oral treatment with diazoxide. When unresponsive, the treatment also includes somatostatin analogues and/or dietetic treatment. Further exploration of the histopathological form of CHI is a crucial point. Indeed, two main histopathological forms of CHI exist: a diffuse form, where all the ß-cells throughout the pancreas are involved, and a focal form, where hypersecreting ß-cells are restricted to a small region of the pancreas. The severity of CHI improves with time, allowing a progressive weaning of all therapies. Focal forms can also be immediately and definitively cured after a partial pancreatectomy, whereas alternative strategies for diffuse forms of CHI aim at avoiding a near-total pancreatectomy since surgery does not guarantee the achievement of normoglycaemia and leads to insulin-dependent diabetes in most cases. Developments of several new medical treatments are in process to ease the conservative medical treatment in order to limit the need of a near-total pancreatectomy.

Introduction

In adults and children, hyperinsulinemic hypoglycaemia (HI) is revealed by autonomic (pallor, sweating, tachycardia, tremor, paresthesias) and neuroglucopenic symptoms (drowsiness, faint, seizures, hallucinations, coma). In some patients, symptoms may be mistaken for epilepsy (unless glycaemia is sampled during/after seizures) or, in some others, hypoglycaemia can be asymptomatic. The hypoglycaemic events may happen after a meal or at fast, several times a day or occasionally. Some family history of hypoglycaemia or MODY diabetes can be found. Rarely, CHI can be induced by a strenuous physical exercise (MCT1, *SLC16A1* gene mutation). When the age at onset of HI is beyond 4 years, screening for insulinoma is recommended (Arnoux et al. 2014).

In newborns, HI is the most prevalent cause of hypoglycaemia. Hypoglycaemia may be screened by a routine capillary glycaemia which is recommended in all neonates *except* those born full-term, with normal birth weight and without pathological context (perinatal stress, sepsis, dysmorphisms, family history of hypoglycaemic disorder). Actually, half patients are still diagnosed following an episode of seizure or coma. In affected newborns, hypoglycaemia is almost permanent and a high rate of continuous glucose infusion (GIR) or feedings (>10 mg/kg/min; physiological requirements in newborns 4–8 mg/kg/min) is required to normalize glycaemia. Associated features may be a transient hypertrophic cardiomyopathy and a transient inadequate cortisol response to hypoglycaemia (Hussain et al. 2003). Because of late diagnosis or insufficient medical management, the neurological outcome is unsatisfactory in almost half of the patients. Thus, it is recommended to check glycemia in all newborns with risk factors of hypoglycaemia, because an early diagnosis and a prompt treatment of hypoglycemia are essential to avoid hypoglycemia-induced brain damage (Ludwig et al. 2018; Yorifuji et al. 2017).

In neonates, HI can be related to three clinical pictures:

1. **Transient neonatal HI** can occur in newborns from diabetic mothers, large or small for gestational age or as a consequence of perinatal stress (foetal distress, birth asphyxia, maternal eclampsia, meconium aspiration syndrome, hypothermia, foetal erythroblastosis). Although hypoglycaemia can be severe, it usually resolves within a few weeks (max 3 months). However, it may require a transient treatment (glucose enriched feeds and/or diazoxide).
2. **Syndromic HI** is a condition in which HI is included in a developmental syndrome. Hypoglycaemia can be the revealing sign during the neonatal period (Beckwith-Wiedemann, Perlman, Simpson-Golabi, Kabuki, Sotos, Costello, Turner syndrome, Congenital Disorder of Glycosylation type I, etc.) or be discovered later during the follow-up (e.g. Ondine syndrome). In various series, about 10% of neonates with HI presented an underlying syndrome. Subsequently, an oriented clinical examination and imaging procedures (abdominal US, heart US, spine X-ray) are systematically recommended in newborns diagnosed with HI. Syndromic HI is usually responsive to diazoxide and shows HI resolution within months or a few years. HI was also occasionally described in patients with Moebius, Cowden, Nager, Usher type C,

Poland, CHARGE syndrome, trisomy 13 and tyrosinemia type I (Galcheva et al. 2019).

3. **"Isolated" congenital HI** occurs when HI is inherited and is mostly considered as an isolated symptom. However, despite isolated CHI is described as non-syndromic, patients may present with additional features (Arnoux et al. 2014):

   Mutations in known genes account for 50% of diazoxide-responsive cases: *ABCC8*, *KCNJ11*, *GCK, HK1, GLUD1*, *HADH*, *HNF4A*, *HNF1A*, *SLC16A1*, *UCP2*, *INSR*. Hypoglycaemia can start at any age. The familial history may disclose members with hypoglycaemia and/or maturity-onset diabetes of youth (*ABCC8, KCNJ11, GCK, HNF1A, HNF4A* genes), or with mild hyperammonemia, mental retardation and/or epilepsy (*GLUD1* gene). In neonates, the revealing symptom is seizures in half patients. The age at presentation is earlier in *HNF4A* mutation (1 day), variable in K_{ATP} genes mutation (1 day to 1 year, mean: 27.4 days), and delayed in *GLUD1* and *HADH* mutation (157 and 125 days) (Snider et al. 2013). Hypoglycaemia can occur in the fasting and the post-prandial states.

   CHI severity is classified as diazoxide responsive, in whom the genetic cause is identified in 47% of patients vs. diazoxide unresponsive patients, in whom almost 90% of patients display mutations in *ABCC8*, *KCNJ11* or *GCK* genes (Lord et al. 2013).

   CHI is a rare condition, involving 1/20,000–50,000 newborns in the Caucasian population (up to 1/2500 in countries with substantial inbreeding) and usually present from the neonatal period. In the ***diffuse form***, the disease involves the whole pancreas with presence of enlarged nuclei in the Langerhans islets β-cells throughout the pancreas, whereas in the ***focal form*** an adenomatous hyperplasia of the islets is limited to a small portion of the pancreas, and only the combination of genetics and pancreatic ^{18}F-DOPA PET/TC scan can distinguish between the two forms, which even share almost the same prevalence. Mutations in *ABCC8* and *KCNJ11* genes, which respectively encode for the SUR1 and Kir6.2 subunits of the K_{ATP} channel, have been associated with diffuse and focal forms. Particularly, diffuse forms of CHI are inherited as either autosomal recessive or dominant trait, whereas the focal form results from the combination of a paternally inherited germinal mutation, a somatic loss of heterozygosity of the maternal allele in a restricted group of β-cells, and a paternal disomy of the 11p15 chromosomal region in these cells (De Lonlay et al. 1997). Besides these two classical histopathological forms, ***atypical forms*** exist with negative genetics in blood leukocytes, and a particular one called LINE (localized islets cells nuclear enlargement), displays, in some cases, a somatic dominant mutation in the *ABCC8* or *GCK* genes, found after a genetic study on the abnormal pancreatic tissue. These forms lead to a "diffuse type histology" but restricted to a variable portion of the pancreas as segmental mosaic forms or extensive focal forms (Sempoux et al. 2011; Capito et al. 2011).

   Mutations in all the other known genes cause diffuse forms. Some forms exhibit peculiar characteristics: protein-sensitivity (K_{ATP} genes, *GLUD1*, *HADH*), leucine-sensitivity (*GLUD1*), hyperammonemia (*GLUD1*), increased urinary excretion of α-ketoglutarate (*GLUD1*), increased risk of neurological symptoms, atypical absence, myoclonia, ADHD, pyramidal syndrome, dystonia (*GLUD*1), increased hydroxybutirylcarnitine and urinary 3-hydroxyglutaric acid (*HADH*), family history of MODY (*HNF4A, HNF1A*), hepatomegaly and renal Fanconi syndrome (*HNF4A*), liver adenomatosis (*HNF1A*), exercise-sensitivity (*SLC16A1*, *HADH*), hypersensitivity to glucose-induced hypoglycaemia (*UCP2*).

Metabolic Pathways

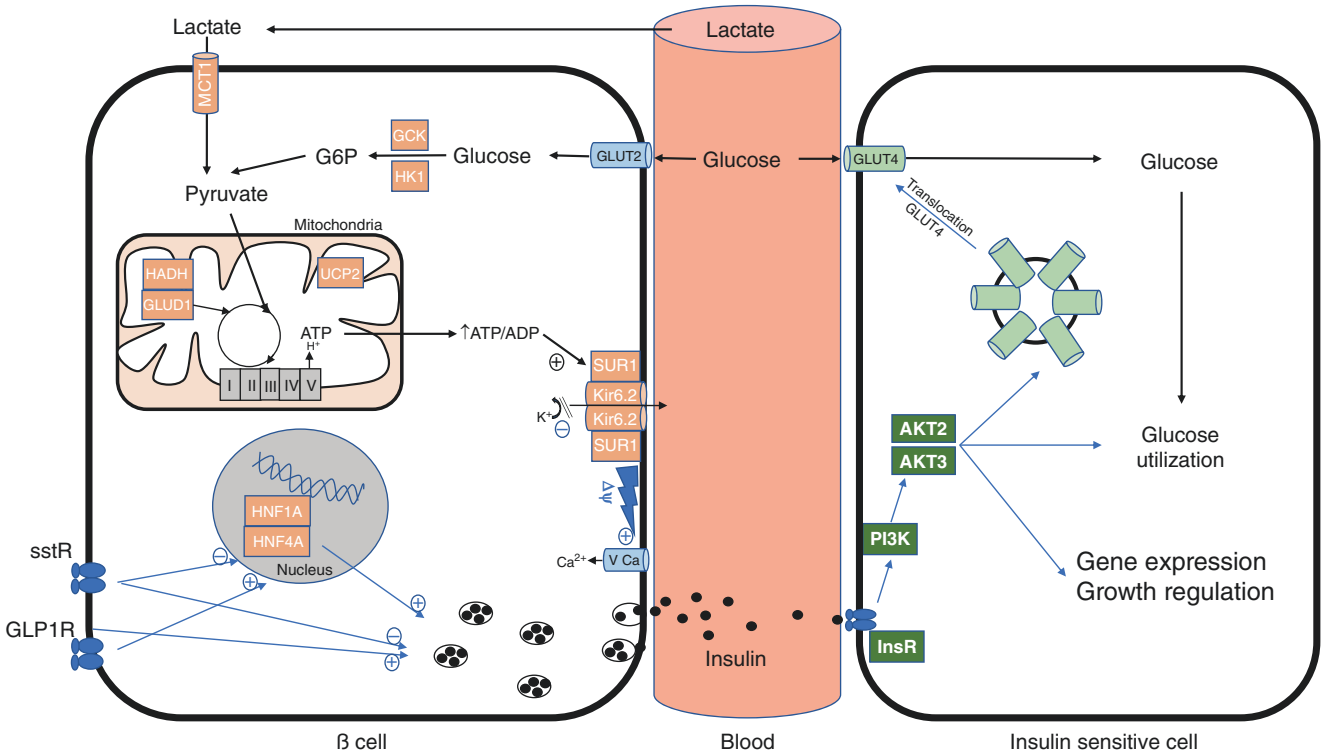

Fig. 41.1 Insulin secretion and action
Schematic representation of a ß-cell and of an insulin-sensitive cell (i.e. striated muscle). For simplicity not all the substrates and products of each reaction are shown. Black arrows: metabolic pathways. Blue arrows: signalling pathways. Red boxes: proteins involved in the GSIS, and responsible for isolated CHI: SUR1 and Kir6.2 (subunits of the K_{ATP} channel encoded respectively by *ABCC8* and *KCNJ11*); GCK; HK1, MCT1 (encoded by *SLC16A1*); HADH; GDH (encoded by *GLUD1*); HNF1A and HNF4A; UCP2. Glucose enters into the ß-cells through GLUT2 channels, is phosphorylated to glucose-6-phophate (G6P) then undergoes glycolysis to produce pyruvate. This latter will be oxidized in the Krebs cycle leading to the production of ATP. At the cell membrane, the ATP-dependent potassium channel (K_{ATP} channel) closes when the ATP/ADP ratio increases, stopping a potassium efflux, which leads to membrane depolarization and activation of the voltage-dependent calcium channels. The influx of calcium into the ß-cells will stimulate the exocytosis of insulin containing secretory granules and the transcription of new insulin. Therefore, all the mechanisms which lead to an increased ATP production will cause hyperinsulinism ("metabolic HI"): glucokinase or glutamate dehydrogenase hyperactivity, UCP2 or HAHD deficiency, improper MCT1 expression. Mutations of the K_{ATP} channel causing a permanent/predominant closed state of the channel are the most frequent cause of HI ("K_{ATP} HI"). Finally, some transcription factors, also involved in monogenic diabetes, can inversely lead to CHI during childhood: HNF1A, HNF4A ("Transcription factor CHI")

Green boxes: proteins involved in hypoketotic hypoinsulinemic hypoglycaemia related to a genetic defect of the insulin receptor pathway: PI3KCA, AKT2 and AKT3. When insulin binds the insulin receptor of an insulin-sensitive cell, it will activate the mTOR pathway, with consequences such as: externalization of GLUT4 glucose transporter; raise of the cell glucose uptake; activation of metabolic pathways involved in glucose utilization or storage; activation of the cellular growth

Signs and Symptoms

Table 41.1 ATP-sensitive potassium channel regulatory subunit deficiency (ABCC8-HI)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

[a]During hypoglycaemia
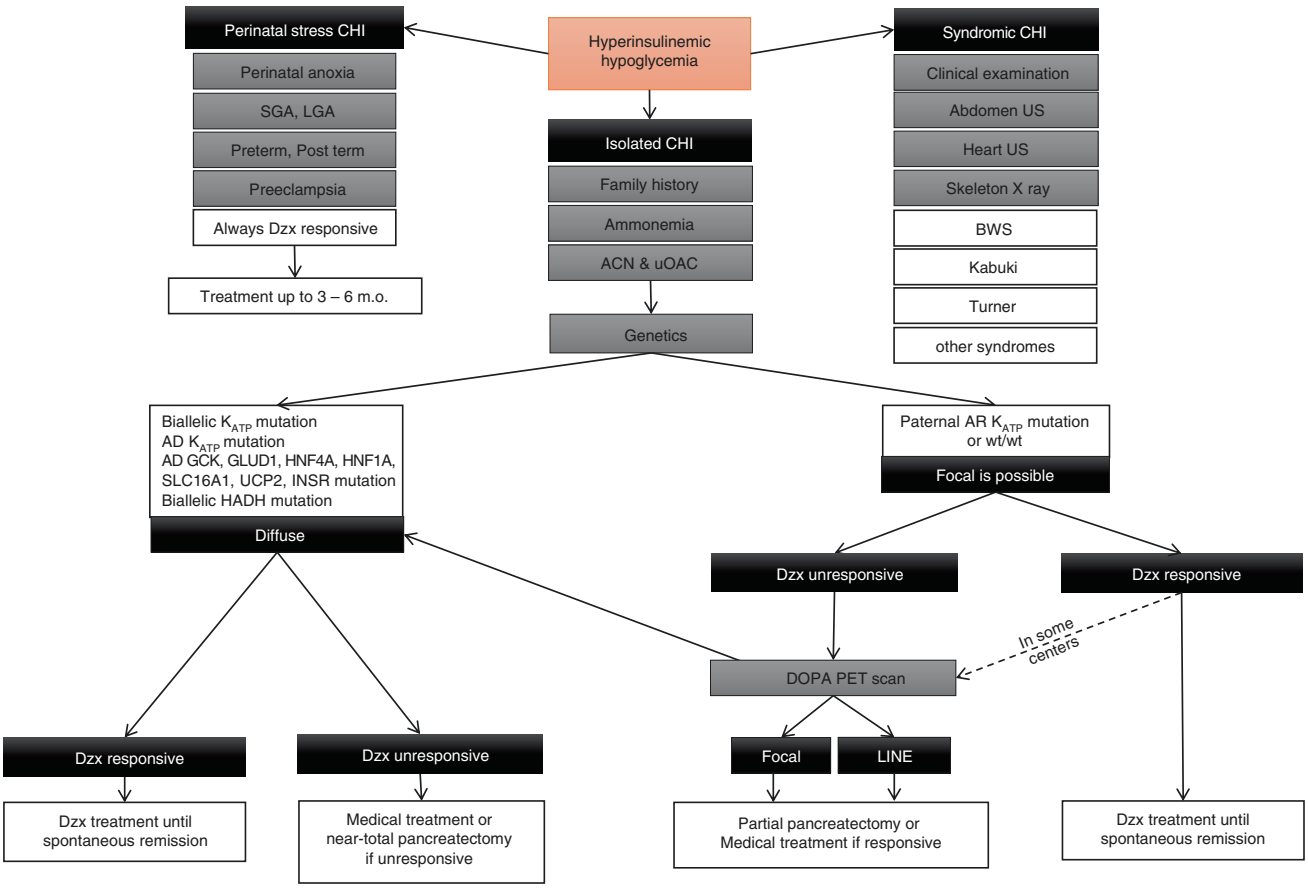
[b]C4-OH appears also during prolonged fasting with ketosis. In hyperinsulinemic hypoglycaemia, this marker is associated with a low/absent ketosis
[c]μmol/mmol creatinine

Diagnostic Flowchart



Dzx Diazoxide, *SGA* Small for gestational age, *LGA* Large for gestational age, K_{ATP} ATP-dependent potassium channel, *AD* Autosomal dominant, *ACN* Acylcarnitine (plasma or dried blood spot), *uOAC* Urine organic acid chromatography, *LINE* Localized islets nuclear enlargement, *US* Ultrasound, *BWS* Beckwith-Wiedemann syndrome.

Loading Test

– Glucagon loading test. This test can be performed for diagnostic purpose at the time of hypoglycaemia. An increase in blood glucose greater than 1.7 mmol/L (30 mg/dL) within 30–40 min after IM or IV administration of glucagon 1 mg proves the paradoxical hepatic glycogen content despite hypoglycaemia.
– Oral protein tolerance test. This test can be performed to investigate protein sensitivity. Patients are administered with protein powder 1 g/kg. Plasma glucose and insulin are measured every 30 min for 3 h. The test is positive if glycaemia <3.8 mmol/L (70 mg/dL) in response to the protein load.

Prenatal Diagnosis

Disorder			Test recommended
Disease Name	Disease Abbreviation	Gene symbols	
ATP-sensitive potassium channel regulatory subunit deficiency	KATP-HI	*ABCC8*	Diffuse form: Mutation analysis on DNA from CVS or AFC Focal form: Not applicable
ATP-sensitive potassium channel pore-forming subunit deficiency	KATP-HI	*KCNJ11*	Diffuse form: Mutation analysis on DNA from CVS or AFC Focal form: Not applicable
Glucokinase superactivity	GCK-HI	*GCK*	Mutation analysis on DNA from CVS or AFC
Short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	SCHAD-HI	*HADH*	Mutation analysis on DNA from CVS or AFC
Insulin receptor dysregulation		*INSR*	Mutation analysis on DNA from CVS or AFC
Glutamate dehydrogenase superactivity	HIHA syndrome	*GLUD1*	Mutation analysis on DNA from CVS or AFC
Exercise induced hyperinsulinemic hypoglycaemia	EI-HI	*SLC16A1*	Mutation analysis on DNA from CVS or AFC[a]
Hepatocyte nuclear factor-4α deficiency	MODY1	*HNF4A*	Mutation analysis on DNA from CVS or AFC[a]
Hepatocyte nuclear factor-1α deficiency	MODY3	*HNF1A*	Mutation analysis on DNA from CVS or AFC[a]
Uncoupling protein 2 deficiency	UCP2-HI	*UCP2*	Mutation analysis on DNA from CVS or AFC[a]
Beckwith-Wiedemann syndrome	BWS	Genetic or epigenetic changes of imprinted region 11p15.5	Prenatal testing may be requested occasionally in cases of familial chromosomal rearrangements affecting chromosomes 11p15 or in case of familial CDKN1C point mutation
Kabuki syndrome	KS	*KMT2D / KDM6A*	Mutation analysis on DNA from CVS or AFC
Turner syndrome	TS	Partial or complete X chromosome monosomy	Karyotype from CVS or AFC
Adenosine kinase deficiency	ADK deficiency	*ADK*	Mutation analysis on DNA from CVS or AFC
PMM2-CDG	CDG1a	*PMM2*	Mutation analysis on DNA from CVS or AFC
MPI-CDG	CDG1b	*MPI*	Mutation analysis on DNA from CVS or AFC
ALG3-CDG	CDG1d	*ALG3*	Mutation analysis on DNA from CVS or AFC
ALG6-CDG	CDG1c	*ALG6*	Mutation analysis on DNA from CVS or AFC
PGM1-CDG; glycogen storage disease type 14	CDG1t	*PGM1*	Mutation analysis on DNA from CVS or AFC
Sotos syndrome		*NSD1 / 5q35 deletion*	Mutation analysis on DNA from CVS or AFC
Thimothy syndrome	TS	*CACNA1C*	Mutation analysis on DNA from CVS or AFC
PASNA syndrome	PASNA	*CACNA1D*	Mutation analysis on DNA from CVS or AFC
MSSGM1 syndrome	MSSGM1	*TRMT10A*	Mutation analysis on DNA from CVS or AFC
Costello syndrome	FCS syndrome	*HRAS*	Mutation analysis on DNA from CVS or AFC
Perlmann syndrome	PRLMNS	DIS3L2	Mutation analysis on DNA from CVS or AFC
Simpson-Golabi-Behmel syndrome	SGBS	GPC3	Mutation analysis on DNA from CVS or AFC
FOXA2 / HNF3β	FOXA2	*FOXA2*	Mutation analysis on DNA from CVS or AFC
Ondine syndrome	CCHS	PHOX2B	Mutation analysis on DNA from CVS or AFC
Rubinstein-Taybi syndrome	RSTS1/2	CREBBP/EP300	Mutation analysis on DNA from CVS or AFC
AKT2 superactivity		*AKT2*	Mutation analysis on DNA from CVS or AFC
AKT3 superactivity	MPPH2	*AKT3*	Mutation analysis on DNA from CVS or AFC
CLOVE syndrome, MCAP syndrome	CLOVE syndrome, MCAP syndrome	*PIK3CA*	Not applicable (somatic mosaicism for postzygotic activating mutations in the PIK3CA gene)

Recommended analyses and sample requirements for prenatal diagnosis
CVS chorionic villous sampling, *AFC* amniotic fluid cells
[a]Is not a severe disorder. Prenatal diagnosis might not be appropriate in most cases

DNA Testing

Disorder			
Disease name	Disease abbreviation	Gene symbols	Sample and test recommended
Perinatal stress HI	/	/	Not applicable
ATP-sensitive potassium channel regulatory subunit deficiency	KATP-HI	*ABCC8*	Diffuse form: Mutation analysis on DNA from blood leukocytes
			Focal form: Mutation analysis on DNA from blood leukocytes
			LINE: Mutation analysis on DNA from the pancreatic lesion
ATP-sensitive potassium channel pore-forming subunit deficiency	KATP-HI	*KCNJ11*	Diffuse form: Mutation analysis on DNA from blood leukocytes
			Focal form: Mutation analysis on DNA from blood leukocytes
Glucokinase superactivity	GCK-HI	*GCK*	Diffuse form: Mutation analysis on DNA from blood leukocytes
			LINE: Mutation analysis on DNA from the pancreatic lesion
Short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	SCHAD-HI	*HADH*	Mutation analysis on DNA from blood leukocytes
Insulin receptor dysregulation		*INSR*	Mutation analysis on DNA from blood leukocytes
Glutamate dehydrogenase superactivity	HIHA syndrome	*GLUD1*	Mutation analysis on DNA from blood leukocytes
Exercise induced hyperinsulinemic hypoglycaemia	EI-HI	*SLC16A1*	Mutation analysis on DNA from blood leukocytes
Hepatocyte nuclear factor-4α deficiency	MODY1	*HNF4A*	Mutation analysis on DNA from blood leukocytes
Hepatocyte nuclear factor-1α deficiency	MODY3	*HNF1A*	Mutation analysis on DNA from blood leukocytes
Uncoupling protein 2 deficiency	UCP2-HI	*UCP2*	Mutation analysis on DNA from blood leukocytes
Beckwith-Wiedemann syndrome	BWS	Genetic or epigenetic changes of imprinted region 11p15.5, pathogenic variant in CDKN1C gene	Karyotype, methylation analysis at 11p15.5 locus, CDKN1C testing
Kabuki syndrome	KS	*KMT2D / KDM6A*	Mutation analysis on DNA from blood leukocytes
Turner syndrome	TS	Partial or complete X chromosome monosomy	Karyotype, CGH-array from blood leukocytes.
Adenosine kinase deficiency	ADK deficiency	*ADK*	Mutation analysis on DNA from blood leukocytes
PMM2-CDG	CDG1a	*PMM2*	Mutation analysis on DNA from blood leukocytes
MPI-CDG	CDG1b	*MPI*	Mutation analysis on DNA from blood leukocytes
ALG3-CDG	CDG1d	*ALG3*	Mutation analysis on DNA from blood leukocytes
ALG6-CDG	CDG1c	*ALG6*	Mutation analysis on DNA from blood leukocytes
PGM1-CDG; glycogen storage disease type 14	CDG1t	*PGM1*	Mutation analysis on DNA from blood leukocytes
Sotos syndrome		*NSD1 / 5q35 deletion*	Mutation analysis on DNA from blood leucocytes / array CGH
Timothy syndrome	TS	*CACNA1C*	Mutation analysis on DNA from blood leukocytes
PASNA syndrome	PASNA	*CACNA1D*	Mutation analysis on DNA from blood leukocytes

Disorder			
Disease name	Disease abbreviation	Gene symbols	Sample and test recommended
MSSGM1 syndrome	MSSGM1	*TRMT10A*	Mutation analysis on DNA from blood leukocytes
Costello syndrome	CSTLO	*HRAS*	Mutation analysis on DNA from blood leukocytes
Perlmann syndrome	PRLMNS	DIS3L2	Mutation analysis on DNA from blood leukocytes
Simpson-Golabi-Behmel syndrome	SGBS	GPC3	Mutation analysis on DNA from blood leukocytes
FOXA2 / HNF3β	FOXA2	*FOXA2*	Mutation analysis on DNA from blood leukocytes
Ondine syndrome	CCHS	PHOX2B	Mutation analysis on DNA from blood leukocytes
Rubinstein-Taybi syndrome	RSTS1/2	CREBBP/EP300	Mutation analysis on DNA from blood leukocytes / array CGH
AKT2 superactivity		*AKT2*	Mutation analysis on DNA from blood leukocytes
Megalencephaly-polymicrogyria-polydactyly-hydrocephalus syndrome	MPPH2	AKT3	Mutation analysis on DNA from blood leukocytes
CLOVE syndrome, MCAP syndrome	CLOVE syndrome, MCAP syndrome	*PIK3CA*	Mutation analysis on DNA from affected tissus

Treatment

In neonates, treatment should be intensively performed to prevent irreversible brain damage. In case of severe hypoglycaemia, patients should be urgently treated with 2 mL/kg 10% dextrose IV (200 mg/kg), followed by continuous 10% dextrose until glycemia >3.9 mmol/L (>70 mg/dL). Central lines are frequently required. After stabilization, patients should be transitioned to an enteral nutrition scheme by mouth or nasogastric tube. Glucagon IM, IV can also be used as emergency treatment, then can be maintained continuously IV or SQ when GIR is higher than 12 mg/kg/min or in case of diazoxide-unresponsiveness (Hawkes et al. 2019).

Unresponsive patients to diazoxide after 5 days of trial at maximum dosage should be screened for a focal form by performing a prompt genetic testing and a pancreatic ^{18}F DOPA PET scan (Blomberg et al. 2013). When a focal form is localized, it can be removed by a selective partial pancreatectomy, which is usually curative (Laje et al. 2012). However, in case of diffuse form, a near-total pancreatectomy is performed only if all conservative medical treatments fail, because of the high risk of insulin-dependent diabetes within 15 years after the surgery (Beltrand et al. 2012). Conservative medical treatment include: glucose-enriched feedings or enteral feeding, somatostatin analogues, nifedipine (Le Quan Sang et al. 2012; Modan-Moses et al. 2011; McMahon et al. 2017; Thornton et al. 2019) and/or experimental therapies: sirolimus (Maria et al. 2019), exendin (Ng et al. 2018), anti-insulin receptor antibodies (Patel et al. 2018), pasireotide (Schwetz et al. 2016). A case of GCK-HI with epilepsy and mild intellectual disability was successfully treated with a ketogenic diet, providing cerebral energy fuel alternative to glucose (Maiorana et al. 2015).

The long-term glycaemic control progressively improves, leading to wean sequentially the treatment. Rarely, some patients may evolve toward a diabetes.

A careful cognitive follow-up is also mandatory since one-third to half patients suffer from cognitive impairment and will need supportive therapies and rehabilitation (Ludwig et al. 2018).

Emergency Treatment

	Route	Neonate	Children/adults	Pitfalls	Important information
Dextrose	PO or IV	10% dextrose 2 mL/kg	30% dextrose 10 mL/20 kg (max 30 mL)		To be repeated every 5 min until glycemia reaches normal values
10% dextrose[a]	Continuous IV infusion	As needed to normalize glycemia.	As needed to normalize glycemia.	In severe neonates, the precocious insertion of a central IV line is recommended.	Normal GIR needs of neonates is <8 mg/kg/min. Needs over this threshold is pathognomonic for an insulin related hypoglycaemia. In HI neonates, the average GIR needed is 16 mg/kg/min.
Enteral feeding[a]	Continuous enteral feeding	Carbohydrate enriched feedings¥.	As needed to normalize glycemia.	Risk of enterocolitis if hyperosmolar feedings in neonates.	MCT supplements are useless, because HI inhibits gluconeogenesis.
Glucagon	IV	0.3 mg/kg (max 2 mg)	1 mg	Vomiting.	Emergency treatment of severe hypoglycaemia in HI. Give time to set a IV line.
Glucagon	Continuous IV, SQ	2.5–10 µg/kg/h	1–2 mg/24 h	Necrolytic migratory erythema. IV line and pump occlusion.	Not a long term treatment due to frequent catheter obstruction.

GIR Glucose infusion rate, *MCT* Medium chain triglycerides
[a]In neonates, glucose intake required to avoid hypoglycaemia may exceed the gut tolerance. Therefore, hyperosmolar feeding mixtures and fluids overloads should be avoided

Standard Treatment

	Route	Dose	Pitfalls	Important informations
Diazoxide	Orally	5–15 mg/kg/d	• Risk of PHT until 4 months old • Heart ultrasound mandatory before treatment and within 1 month after initiation • Risk of PHT stronger in premature, persistent ductus arteriosus, heart malformation • Risk of sodium and fluid retention,edema, PHT, thrombocytopenia, neutropenia	• At least 5 days of diazoxide treatment at maximum dosage are needed to evaluate its efficiency • Start with lower doses in premature babies • Hypertrichosis is a usual side effect
Octreotide	SQ q 6–8 h or continuous IV infusion or continuous SQ infusion with an insulin pump	5–30 µg/kg/d	• Risk of NEC in neonates contraindication in case of enteropathy, severe infection, hemodynamic distress • Risk of drug induced hepatitis • Risk of cholelithiasis	• Start with 5-10 µg/kg/d, then titrate up every 2–3 days by +5-10 µg/kg/d because of tachyphylaxis and to assess tolerance • Abdominal US to screen for gallblader stones • Injection site rotation is recommended to avoid nodule formation
Octreotide LAR	IM	Idem (cumulative dose) or 10–30 mg q4–6 weeks	• If somatostatin analogue were proven efficient with SQ octreotide	• Idem
Lanreotide	Deep SQ	Idem (cumulative dose) or 30–120 mg q4–6 weeks	• Idem	• Idem

	Route	Dose	Pitfalls	Important informations
Feeding	Oral, enteral	• Carbohydrate enriched diet additioned with maltodextridine or uncoocked cornstarch • Ketogenic diet can be discussed in unresponsive GCK-HI	• In neonates, risk of enterocolitis if hyperosmolar feedings. • Ketogenogenic diet: Risk of symptomatic hypoglycaemia in the phase of induction	• Risk of overweight in hypercaloric diet. Prefer carbohydrate enriched food without fat (maltodextridine, row corn starch from 12 month old) • Ketogenic diet: Risk of metabolic acidosis, hyperuricemia, dyslipidemia. • Ketogenic diet: Need of supplementation with multivitaminic, vitamin D and eventually calcium

Co-med diuretics at initiation of Dzx. Outside neonatal period, do not systematically readapt dose to the weight. Most patients are Dzx-responsive

PHT Pulmonary hypertension, *NEC* Necrotizing enterocolitis

Note: Patients with an insulin receptor pathway disorder (e.g. AKT2 hyperactivity) have an increased uptake of glucose in their insulin-sensitive tissues. Thus medications aiming at decreasing the pancreatic insulin secretion will not be effective

Experimental Treatments

Patients with a diffuse disease unresponsive to the standard treatment, thus requiring an enteral feeding, can be discussed for near-total pancreatectomy. Alternatively, if available, the patient can join a research program. Several experimental treatments are actually under investigation:

– Repositioning of drugs marketed in other indications: mTOR inhibitor (sirolimus, everolimus), somatostatin analogues.
– New therapies specific to hyperinsulinemic hypoglycaemia: GLP1 receptor inhibitor (Exendin (9–39), allosteric inhibitor of the insulin receptor (XMetD), soluble formulation of glucagon analogues (Dasiglucagon).

Part V

Mitochondrial Disorders of Energy Metabolism

Disorders of the Pyruvate Metabolism and the Krebs Cycle

42

Eva Morava, Linda de Meirleir, and Rosalba Carrozzo

Contents

Summary

This chapter focuses on pyruvate metabolism disorders, two classic Krebs cycle disorders (2-oxoglutaric aciduria and fumarase deficiency) and two other disorders of the Krebs cycle, severely affecting mitochondrial function and mitochondrial maintenance (succinyl-CoA synthetase—SCS—deficiencies, caused by mutations in *SUCLA2* and *SUCLG1* genes). Pyruvate carboxylase and pyruvate dehydrogenase deficiency are the most common disorders in pyruvate metabolism and almost always affect the central nervous system. The severity and the clinical phenotypes vary, with a range from severe neonatal lactic acidosis and early death to milder presentations. Pyruvate carboxylase (PC) deficiency constitutes a defect both in the Krebs cycle and in gluconeogenesis and

https://doi.org/10.1007/978-3-030-67727-5_42

generally presents with severe neurologic dysfunction and lactic acidosis more frequently than with fasting hypoglycemia. Pyruvate dehydrogenase deficiency (PDH) is most common due to deficiency in the X-linked PDH E1 alpha, but defects in other subunits of the PDH complex have been described. Secondary PDH deficiency and profound neurodegeneration was described in LONP1 deficiency. Neonatal lactic acidosis and Leigh's encephalopathy occur more frequently in boys; girls can present with severe seizures and microcephaly. Fumarase deficiency and 2-oxoglutaric aciduria are rare disorders with global developmental delay and severe neurologic problems in infants. Patients with oxoglutaric aciduria have a variable severity of neurological involvement and metabolic acidosis and develop severe microcephaly and intellectual disability. Some patients with oxoglutaric aciduria present with DOORS syndrome (deafness, onychodystrophy, osteodystrophy, mental retardation, seizures). New disorders, like LIPT1 deficiency are known in the lipoic pathway leading to combined oxoglutaric aciduria and PDHc deficiency. Patients with fumarase deficiency present with either a fulminant course associated with fatal outcome within the first 2 years of life or a subacute encephalopathy with profound speech delay without metabolic crises. Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) syndrome secondary to heterozygous germline fumarate hydratase (FH) mutations is an autosomal dominant condition and presents in young adults with cutaneous and uterine leiomyomas, and a distinctive aggressive renal carcinoma.

SUCLA2 and SUCLG1 defects have the clinical presentation of mitochondrial depletion syndromes with profound hypotonia, progressive dystonia, and muscular atrophy, in addition to severe sensorineural hearing impairment, which has been specifically associated with SUCLA2 defect. SUCLG1 defect has been also associated with congenital malformations (El-Hattab and Scaglia 2009).

In disorders of the pyruvate metabolism the diagnosis is suspected with lactic acidemia and hypoglycemia, in PDH deficiency, when lactate and pyruvate are elevated, with a normal pyruvate to lactate ratio. Further confirmation is done biochemically on fibroblasts, lymphocytes, muscle, and the different genes can be investigated.

The most important clues for the diagnosis in all the Krebs cycle disorders rely on urine organic analysis. 2-Oxoglutaric aciduria leads to chronic metabolic acidosis and variable urinary excretion of 2-oxoglutarate, while fumarase deficiency occurs with an increased excretion of fumarate associated with succinate and lactate excretion with eventual 2-oxoglutaric aciduria. A normal excretion of fumaric acid and a relative high fumarase residual activity do not rule out fumarase deficiency. In questionable cases, mutation analysis is needed to confirm the diagnosis. In SCS defects, mild methylmalonic aciduria with abnormal urine carnitine-ester profile is associated with only subtle abnormalities of the Krebs cycle intermediates. Due to the recognizable pattern of dystonia/±deafness syndrome and mild methylmalonic aciduria in SCS defects, direct genetic testing is a possible approach in the diagnosis of SUCLA2 and SUCLG1 defects. Carrier screening in fumarase deficiency is important due to the possible increased risk for certain malignancies.

Introduction

Pyruvate carboxylase is a biotin-containing nuclear-encoded mitochondrial enzyme, responsible for the carboxylation of pyruvate to oxaloacetate. The reaction covers for the replenishment of pools of intermediates of the citric acid cycle, a process called anaplerosis. Pyruvate carboxylase is also involved in several metabolic pathways that depend on the availability of oxaloacetate such as gluconeogenesis, glycogen synthesis, lipogenesis, glycerogenesis, and synthesis of amino acids and neurotransmitters.

Pyruvate carboxylase deficiency is associated with metabolic acidosis, failure to thrive, and developmental delay. Three phenotypes are associated with pyruvate carboxylase deficiency. In type A infantile North American phenotype, patients are severely ill between 2 and 5 months of age with progressive hypotonia. Episodes of acute vomiting, dehydration, tachypnea, facial pallor, cold cyanotic extremities, and metabolic acidosis, characteristically precipitated by metabolic or infectious stress, occur. Clinical examination includes pyramidal tract signs, ataxia, and nystagmus. All patients are severely mentally retarded and most of them have convulsions. In type B (French phenotype), patients become acutely ill 3–48 h after birth with hypothermia, hypotonia, lethargy, and vomiting. There is a rapid deterioration with rigidity, hypokinesia, and tremor (resembling infantile Parkinson) and abnormal ocular movements. Most die in the neonatal period. Some survive but remain unresponsive and severely hypotonic, often with death due to respiratory infection before the age of 5 months. Type C is a more benign phenotype, only reported in a few patients. The clinical course consists of acute episodes of lactic acidosis and ketoacidosis, usually responding rapidly to hydration and bicarbonate therapy. Despite the important enzymatic deficiency on testing in fibroblasts, the patients have a nearly normal cognitive and neuromotor development (Barnerias et al. 2010; De Meirleir 2013).

Pyruvate dehydrogenase (PDHC) is composed of three components: E1; E2, dihydrolipoamide acyl-transferase; and E3, dihydrolipoamide dehydrogenase. E1 utilizes thiamine

pyrophosphate and is composed of two different subunits, E1α and E1β. The E1 reaction results in decarboxylation of the specific α-ketoacid.

For the PDHC, the E1 component is the rate-limiting step and is regulated by phosphorylation/dephosphorylation catalyzed by two enzymes, E1 kinase (inactivation) and E1 phosphatase (activation). E2 is a transacetylase that utilizes lipoic acid. E3 is a flavoprotein common to all three 2-ketoacid dehydrogenases. Another important structural component of the PDHC is E3BP, E3 binding protein, formerly protein X. This component has its role in attaching E3 subunits to the core of E2.

PDHE1α deficiency is most commonly present with features of delayed development, hypotonia, seizures, and ataxia. In males, there are three presentations: neonatal lactic acidosis, Leigh's encephalopathy, and intermittent ataxia. In the first presentation, neonatal lactic acidosis is often associated with brain dysgenesis, such as agenesis of the corpus callosum. In Leigh's encephalopathy, the initial presentation is usually within the first 5 years of life and includes respiratory disturbances or episodic weakness and ataxia with absence of tendon reflexes. Respiratory disturbances may lead to apnea, dependence on assisted ventilation, or sudden unexpected death. Intermittent dystonic posturing of the lower limbs occurs frequently. A moderate to severe developmental delay becomes evident within the next years. A very small subset of male patients is initially much less severely affected, with intermittent episodic ataxia after carbohydrate-rich meals, progressing slowly over years into a mild Leigh's encephalopathy. A number of patients have developed an acute peripheral neuropathy during infancy or an acute episodic ataxia. In females with PDHE1α deficiency, there is a more uniform clinical presentation, although with variable severity. This includes dysmorphic features, microcephaly, moderate to severe mental retardation, and spastic di- or quadriplegia, resembling nonprogressive encephalopathy. Dysmorphism comprises a narrow head with frontal bossing, wide nasal bridge, upturned nose, long philtrum, and flared nostrils. Seizures are encountered in almost all female patients. These appear within the first 6 months of life and are diagnosed as infantile spasms (flexor and extensor) or severe myoclonic seizures. Brain MRI frequently reveals severe cortical/subcortical atrophy, dilated ventricles, and partial to complete corpus callosum agenesis. Severe neonatal lactic acidosis can be present.

Few cases have been reported with PDH E1beta deficiency with early-onset lactic acidosis and severe developmental delay. A moderate clinical course with slowly progressive neurological features reflecting basal ganglia and brain stem involvement associated with typical findings of Leigh syndrome has also been reported.

A few cases of PDH E2 (dihydrolipoamide transacetylase) deficiency have been reported recently with developmental delay and lactic acidosis.

PDH E3 is an enzyme, common to all the 2-ketoacid dehydrogenases; E3 deficiency results in multiple 2-ketoacid dehydrogenase deficiency and should be thought of as a combined PDHC and TCA cycle defect. E3 deficiency presents with severe and progressive hypotonia and failure to thrive, starting in the first months of life. Metabolic decompensations are triggered by infections. Progressively hypotonia, psychomotor retardation, microcephaly, and spasticity occur. Some patients develop a typical picture of Leigh's encephalopathy. A Reye-like picture with liver involvement and myopathy with myoglobinuria without intellectual disability is seen in the Ashkenazi Jewish population. Increased blood lactate and pyruvate, elevated plasma alanine, glutamate, glutamine, and branched-chain amino acids (leucine, isoleucine, and valine) and increased urinary lactic, pyruvic, 2-ketoglutaric, and branched-chain 2-hydroxy and 2-keto acids are characteristic.

The main clinical manifestations of E3BP (formerly protein X) deficiency are hypotonia, delayed psychomotor development, and prolonged survival. Often more slowly progressive, it also comprises early-onset neonatal lactic acidosis associated with subependymal cysts and thin corpus callosum.

E1-phosphatase deficiency has been identified in two brothers with hypotonia, feeding difficulties, and delayed psychomotor development. A lethal infantile phenotype has also been described (Lissens et al. 2000; Grafakou et al. 2003; Brown et al. 2006; Willemsen et al. 2006; De Meirleir 2013).

PDH deficiency was also described due to LonP1 deficiency in association with neurologic regression during infancy, profound hypotonia and muscle weakness, severe intellectual disability and normal plasma lactate:pyruvate ratios. PDH dysfunction was caused by increased levels of the phosphorylated E1α subunit of PDH, which inhibits enzyme activity (Nimmo et al. 2019).

The Krebs cycle disorders 2-oxoglutaric aciduria and fumarase deficiency are clinically similar disorders of hypotonia, spasticity, developmental delay, and extrapyramidal symptoms of variable severity. These very rare disorders present with episodes of acute metabolic acidosis and eventually hypoketotic hypoglycemia in stress situations. Krebs cycle disorders have recurrent episodes of severe decompensations, related mostly to acute, intercurrent infections. Lactic acidosis can be significant in acute episodes, and the disorder might imitate a mitochondrial disorder both based on the clinical and metabolic presentation. Most cases are lethal in the first 10 years of life.

The 2-KGD complex is composed of three separate enzymes: E1, E2, and E3. It has been postulated that in most patients, the E2 component could be responsible for the "classic metabolic" presentation of the defect (Bonnefont et al. 1992; Guffon et al. 1993). In occasional cases the disease appears only after infancy, with progressive extrapyramidal and psychiatric symptoms (Kohlschutter et al. 1982).

There are two distinct phenotypes in 2-oxoglutaric aciduria, an encephalopathic form related to E2 subunit deficiency and a clinically recognizable form of deafness, onycho-osteodystrophy, short terminal phalanges, intellectual disability and seizures, also labeled as DOORS syndrome, due to a defect of the E1 subunit of the enzyme complex (Surendran et al. 2002). DOORS syndrome is genetically heterogenous, also caused by *TBC1D24*, *SMARCB1*, and *PIGB* defects. The diagnosis in 2-oxoglutaric acidemia might remain uncertain in some cases, due to relatively high residual activity of the 2-oxoglutarate dehydrogenase in homogenates of cultured skin fibroblasts, which can be found in some patients with a proven E2 subunit deficiency.

Lipoate serves as a cofactor for both α-oxoglutarate dehydrogenase and pyruvate dehydrogenase [PDHc]). Mutations in the mitochondrial lipoate synthesis involving lipoyltransferase 1 (LIPT1) have been associated with nonketotic hyperglycinemia-like early-onset convulsions and encephalopathy combined with a defect in *LIPT1*-related mitochondrial energy metabolism, reduced leucine catabolic flux, and decreased protein lipoylation (Habarou et al. 2017).

Fumarase is a dual-targeted enzyme, detected in both the mitochondrial and cytosolic/nuclear compartments of all the eukaryotic organisms. Fumarase deficiency has been described in less than 50 cases with severe infantile encephalopathy (De Meirleir et al. 2006; Zinn et al. 1986; Zeman et al. 2000). The disorder is lethal in one-third of the patients in early childhood and leads to severe intellectual disability. Fumarase deficiency has been reported with intrauterine complications such as brain malformations and intrauterine growth retardation. Some of the children are dysmorphic (Maradin et al. 2006). Severe visual disturbance, Dandy–Walker malformation, and polymicrogyria have been observed in a few cases. The oldest reported patient survived to the second decade of life (Allegri et al. 2010).

The human fumarate hydratase (*FH*) gene consists of 10 exons encoding 510 amino acids. The first exon (exon 0) encodes a mitochondrial localization signal peptide of 43 amino acids. The 3-bp AAA duplication (c.1431_1433dupAAA) coding for an additional lysine amino acid is detected in approximately one-third of cases and is the most frequent abnormal allele in patients. All affected individuals with this allele are compound heterozygous with a different mutation on the other allele. Other mutations in the *FH* gene are private, although, interestingly, most mutations are clustered at the C-terminus (Picaud et al. 2011).

Most heterozygous relatives of patients with fumarase defect are normal. However, the finding of cutaneous leiomyomata without uterine fibroids in the mother of an affected child, a report of a mother with uterine myomas, and the death of the mother of an affected child from renal cell carcinoma led to the definition of a new hereditary condition with increased risk for tumor genesis (hereditary leiomyomatosis and renal cell carcinoma (HLRCC) syndrome) in carriers for fumarate hydratase deficiency (Bhola et al. 2018).

Mutations on *SUCLA2* and *SUCLG1* genes are associated to unique disorders due to the involvement of both the citric acid cycle, due to abnormal succinate metabolism, and the mitochondrial DNA (mtDNA) maintenance, manifesting with low mtDNA content in most patients. So far more than 50 patients have been reported with SUCLA2 and less than 25 with SUCLG1 defect.

Succinyl-CoA synthetase (SCS), which catalyzes the reversible conversion of succinyl-CoA and ADP or GDP to succinate and ATP or GTP, is part of the Krebs cycle. Deficient SCS activity has been associated with mutations in two out of the three subunits making up the enzyme: *SUCLA2* and *SUCLG1*, respectively. These genes encode the β-subunit of the ADP-forming SCS and the α-subunit of SCS. In multicellular eukaryotes, two different isoforms exist, consisting of the common α-subunit and a different β-subunit, one specific for ATP (A-SCS) and the other specific for GTP (G-SCS) (Johnson et al. 1998). Therefore, the β-subunits determine the substrate specificity of the two forms of the enzyme. Both enzymes are located in the mitochondrial matrix, where A-SCS, and probably also G-SCS, participates in the citric acid cycle. Several studies have indicated that SCS forms a complex with nucleoside diphosphate kinase (NDPK), which is important for the salvage of deoxyribo-

nucleotides for mtDNA synthesis and for its integrity (Kadrmas et al. 1991; Kavanaugh-Black et al. 1994; Kowluru et al. 2002).

Mutations in *SUCLA2*, the gene encoding the β-subunit of ADP-forming SCS (Elpeleg et al. 2005), have been reported in several ethnicities and are associated with a distinct clinical phenotype consisting of a Leigh-like syndrome, dystonia, deafness, and feeding difficulties. Other, less frequent, features include distinctive facial features, contractures, kyphoscoliosis, gastroesophageal reflux, ptosis, choreoathetosis, ophthalmoplegia, and epilepsy (infantile spasms or generalized convulsions) (El-Hattab and Scaglia 2017). Normal cognition has been also observed. There is a mild lactic acidosis, and a variable degree of deficiency of the respiratory chain enzyme complexes (complex I and IV) in muscle, a mild-to-moderate mtDNA depletion, and mild elevation of methylmalonic acid in body fluids (Carrozzo et al. 2007; Ostergaard et al. 2007a, b; Morava et al. 2009; Carrozzo et al. 2016). A founder effect has been found underlying the common mutation in the Faroese and Scandinavian population.

Patients with mutations in *SUCLG1*, the gene coding for the α-subunit of SCS, might present with either a severe, fatal form of mitochondrial encephalomyopathy (Ostergaard et al. 2007a, b) with severe lactic acidosis, hepathopathy, seizures, microcephaly, and multiple congenital anomalies including renal and cardiac defects (El-Hattab and Scaglia 2017), or a somewhat milder clinical syndrome highly reminiscent of that seen in children with mutations in *SUCLA2* (Ostergaard et al. 2009; Rouzier et al. 2010; Landsverk et al. 2014). Some affected individuals present with hypertrophic cardiomyopathy, myoclonus, sleep disturbance, rhabdomyolysis, contractures, hypothermia, and/or hypoglycemia. *SUCLG1* mutations that lead to complete absence of SUCLG1 protein are responsible for a very severe disorder with antenatal manifestations (malformations), and profound CNS involvement, whereas a SUCLA2-like phenotype is found in patients with residual SUCLG1 protein. Furthermore, it has been shown that in the absence of SUCLG1 protein, no SUCLA2 protein is found in fibroblasts by western blot analysis. This result is consistent with a degradation of SUCLA2 when its heterodimer partner, SUCLG1, is absent.

The outcome for the two disorders is quite different. The median onset of symptoms has been 2 months for patients with *SUCLA2* mutations and at birth for SUCLG1-deficient patients. Median survival has been 20 years for patients with SUCLA2 deficiency and 20 months for patients with SUCLG1 deficiency (Carrozzo et al. 2016).

Reference Values

Metabolite	Normal range	Sample
Fumaric acid (FA)	0–20 μmol/mmol creat	Urine
Succinic acid (SA)	0–50 μmol/mmol creat	Urine
2-Oxoglutaric acid (2OGA)	0–50 μmol/mmol creat	Urine
Methylmalonic acid (MMA)	0–5.0 μmol/mmol creat	Urine
Lactic acid (LA)	0.5–2.1 mmol/L	Blood
Lactic acid (LA)	0.4–1.4 mmol/L	CSF
Glucose	3.4–6.4 mmol/L	Blood

Pathological Values

	Differential diagnosis in PDHc deficiency
PC type A	Normal lactate/pyruvate ratio. Lactate 2–10 mmol/L; increased alanine and proline; normal citrulline and lysine. Hypoglycemia; ketosis
PC type B	Increased lactate/pyruvate ratio; increased acetoacetate to 3-OH-butyrate ratio; elevated concentrations of citrulline (100–400 μM, normal <40), lysine, and ammonia (100–600 μM, normal <60); low concentration of glutamine; lactate >10 mmol/L; pyruvate in type B 0.14–0.90 mmol/L; normal range 0.04–0.13, resulting in increased lactate/pyruvate ratio >20, hypoglycemia and ketosis
PC type C	Episodic metabolic acidosis with normal citrulline plasma concentrations and elevated lysine and proline plasma concentration. Lactate 2–5 mmol/L, lactate/pyruvate ratio normal, ketosis during metabolic stress
PDHC CSF	Elevated lactate and pyruvate. Marked reduced glutamine. Elevated glutamic acid and proline
PDHC urine	Organic acid profile shows, besides large amounts of lactate, pyruvate, and 3-OH-butyrate, an increase of 2-oxoglutarate

Disorder	Definition	Sample
20.1 2-Oxoglutaric aciduria	2OGA 5–1700 μmol/mmol creat	Urine
	LA 2.5–8.0 mmol/L	Blood
20.2 Fumarase deficiency	FA 20–3828 μmol/mmol creat	Urine
	SA 50–800 μmol/mmol creat	Urine
	2OGA 5–800 μmol/mmol creat	Urine
	LA 2.1–3.0 mmol/L	Blood
20.3 SUCLA2 deficiency	MMA 16–80 μmol/mmol creat	Urine
20.3 SUCLG1 deficiency	MMA 24–2400 μmol/mmol creat	Urine

Diagnostic Flowchart (see Fig. 42.2)

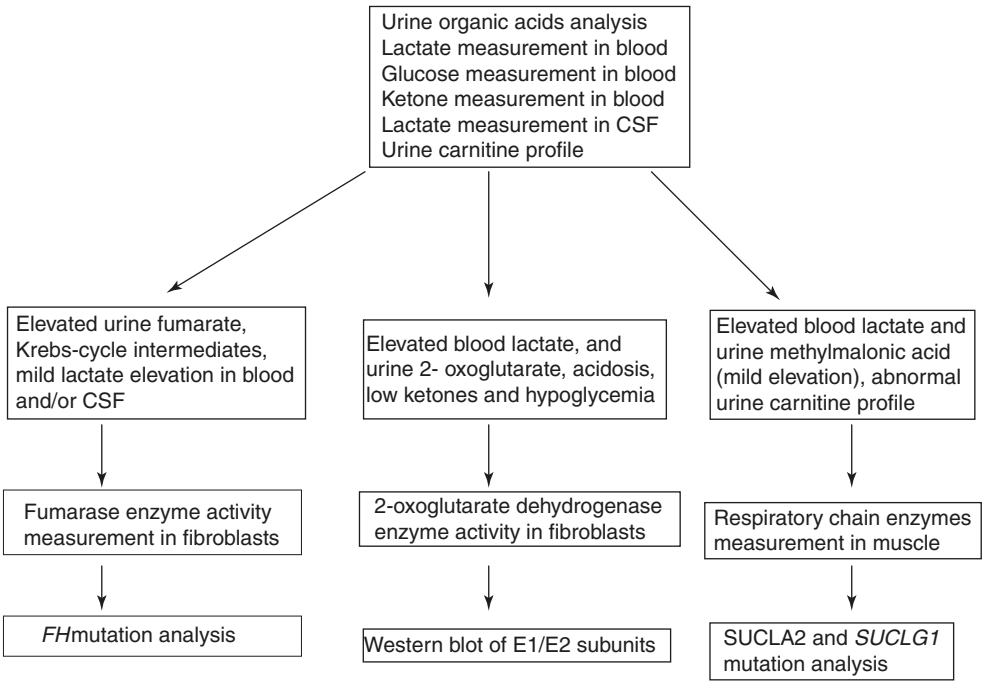

Fig. 42.2 Diagnostic flowchart. *Note*: direct sequencing can be performed without functional studies based on the clinical/metabolic phenotype

Specimen Collection and Pitfalls

The diagnosis of PC and PDHc deficiency is based on the collection of metabolic data during acute presentation including blood lactate, pyruvate, ketones and glucose, organic acids and amino acids in urine, and.

CSF measurements for lactate and pyruvate (see also Tables 42.5 and 42.6). While the diagnosis is highly challenging for PC deficiency, because of the variable clinical and metabolic phenotype, PDHc deficiency is mostly recognizable based on the normal lactate/pyruvate ratio and cerebral lactic academia. The confirmation of the diagnosis is typically possible in cultured fibroblasts or liver. PC enzyme assay in fibroblast shows a PC enzyme activity <5% of controls in type B and 5–23% in type A and <10% in type C; similar in lymphocytes. Assays can also be performed in postmortem liver, in which the activity of PC is tenfold higher than in fibroblasts but must be interpreted with caution because of rapid postmortem degradation of the enzyme. DNA testing is less invasive.

Total PDH activity, subunits, and DCA activation can be measured using spectrophotometric methods on cultured fibroblasts, lymphocytes, and muscle. Western blot for E3BP DNA testing is possible; most frequently PDH E1alpha on X chromosome (Willemsen et al. 2006).

Lipoic acid (LA) is an essential cofactor required for the activity of both pyruvate dehydrogenase (PDH), and 2-oxoglutarate dehydrogenase. LA is synthesized in a complex multistep process. Disease-causing mutations in genes encoding for proteins involved in LA metabolism have been reported in *NFU1*, *BOLA3*, *IBA57*, *LIAS*, *GLRX5*, *LIPT1*, *ISCA2*, and *LIPT2* (Tort et al. 2016).

The diagnosis of 2-oxoglutaric aciduria and fumarase deficiency is established by combining the clinical features, the metabolic findings, and the biochemical enzyme activity and should be validated by molecular genetic testing.

Metabolic Findings in Urine

The massive excretion of 2-oxoglutaric acid and fumaric acid in urine is, respectively, diagnostic in almost all patients. The excretion of 2-oxoglutaric or fumaric acid in the two different disorders is, respectively, 15- to 1000-fold elevated when compared to the normal control range.

DOORS syndrome is a severe form of 2-oxoglutaric aciduria. In case of mild increase of 2-oxoglutaric acid one should consider genetic heterogeneity in DOORS. *TBC1D24 and SMARCB1* mutations might lead to the same phenotype with normal 2-oxoglutarate excretion (Campeau et al. 2014). *PIGB* mutations cause a GPI biosynthesis defect with axonal neuropathy, DOORS syndrome, and 2-oxoglutaric aciduria (Murakami et al. 2019).

2-Oxoglutaric acid might be elevated in fumarase deficiency, but less pronounced. Unfortunately, fumarate is not at all times present in excessive amounts in the urine in children with fumarase deficiency, and the concentration is not always corresponding with the measured residual fumarase activity (Ottolenghi et al. 2011). High residual activity has been found in some of the patients with 2-oxoglutaric aciduria as well. The presence of Krebs cycle intermediates in fumarase deficiency is probably due to secondary enzymatic inhibition of succinate dehydrogenase (SDH). Other metabolites have been detected as well in the urine, without a consistent pattern.

2-Oxoglutaric acid excretion is also elevated in mitochondrial ribosomal protein MRPS2 deficiency. This shows an overlapping phenotype with motor developmental delay hearing loss, hypoglycemia, and OXPHOS complex deficiencies (Gardeitchik et al. 2018).

Mild methylmalonic aciduria, Leigh-like encephalomyopathy, dystonia, and deafness characterize the group of patients with *SUCLA2* gene mutations, in whom the key diagnostic features are represented by mild methylmalonic acid excretion combined with an abnormal profile of carnitine esters (specifically succinyl carnitine). Most of the patients present with early onset hypotonia, severe developmental delay or early neurological deterioration, slowly progressive dystonic/athetoid movements, and sensorineural deafness. In the course of the first year of life, no abnormalities or mild cerebral atrophy with enlarged subarachnoid spaces and widening of the ventricular system is observed. Later on basal ganglia involvement becomes obvious. At first putamen and caudate seem to be specifically affected, but after infancy also the other parts of the basal ganglia show abnormalities on the MRI. Unlike classical methylmalonic acid (MMA) (Trinh et al. 2001), the globus pallidus can be spared or seems to be the least affected. In the end stage of the disease, as observed postmortem in one case, only a very small residual volume of the nucleus caudatus remained intact. The increase of methylmalonic acid in body fluids is considerably less pronounced in these patients compared to classical MMA patients (Deodato et al. 2006). Abnormal activity of respiratory chain enzymes and mtDNA depletion, together with methylmalonic aciduria, are the biochemical hallmarks of this disorder.

In addition, in a subgroup of patients, all presenting with mild methylmalonic aciduria, Leigh-like encephalomyopathy, and dystonia, clinical features closely resembling those seen in patients with *SUCLA2* mutations (Carrozzo et al. 2007; Morava et al. 2009), but without sensorineural deafness in the vast majority of the cases, mutations in *SUCLG1* were discovered.

Metabolic Findings in Plasma and Cerebral Spinal Fluid

Increased plasma concentrations of 2-oxogutarate and significant elevation of lactate with increased L/P ratio and hypoketosis have been detected in 2-oxoglutaric aciduria. Increased plasma concentrations of fumarate, lactate, and pyruvic acid have been detected in fumarase deficiency. These metabolites are also abnormally elevated in the cerebrospinal fluid (CSF), especially lactic acid. In one patient with fumarase deficiency, additionally, two succinylpurine derivatives were found in CSF. These two metabolites, 5-aminoimidazole-*N*-succinyl-carboxamide ribotide (SAICAR) and adenylosuccinate, have a potential neurotoxic effect.

Mutations in *SUCLA2* and *SUCLG1* are associated with mild methylmalonic acidemia with normal homocysteine and the increased C4-dicarboxylic-carnitine level in plasma and even more in urine. As expected in a TCA cycle defect, variable lactic acidemia and consistent lactate increase in CSF are accompanying characteristics in patients with these defects. TCA cycle intermediates were found increased to a variable extent in the urine of the patients. The increase of methylmalonic acid in body fluids that is considerably less pronounced in patients with SCS defect than in classical MMA (Deodato et al. 2006) may be explained by the impaired conversion of succinyl-CoA to succinate, resulting in metabolite accumulation proximal to the enzymatic block.

Enzyme Measurements

The activity of 2-oxoglutarate dehydrogenase in homogenates of cultured skin fibroblasts can be as high as 25% of control values in patients. Additional Western blot analysis of the E1 and E2 subunits might be needed to confirm the diagnosis.

The residual enzyme activity of fumarate hydratase deficiency shows no clear correlation with either the metabolic derangement or the clinical severity. The enzyme activity can be measured in fibroblasts, lymphoblasts, and white blood cells. Different tissues show different residual activities, and although most patients show an activity below 10%, the FH activity can range from undetectable to 35% compared to the activity measured in healthy controls. Enzyme measurements therefore might be insufficient to confirm the diagnosis, since the FH activity in healthy heterozygous parents ranges from 22% to 74% of controls.

Fumarase deficiency can lead to mitochondrial dysfunction, including variable degree of complex I and II deficiency (Tyrakis et al. 2017).

The SCS-A activity in muscle mitochondria from a *SUCLA2*-mutated patient has been demonstrated to be reduced compared to controls (Carrozzo et al. 2007), as well as the *SUCLA2* and *SUCLG1* gene products measured through Western blotting in muscle homogenate and in fibroblasts mitochondria, respectively (Carrozzo et al. 2007; Ostergaard et al. 2007a, b). Analysis of respiratory chain enzyme activities in muscle generally shows a combined deficiency of complexes I and IV, but normal histological and biochemical findings in muscle did not preclude a diagnosis of succinate-CoA ligase deficiency (Carrozzo et al. 2016).

Prenatal Diagnosis

Prenatal diagnosis is the most frequently based on mutation analysis in familial cases of PDHC and PC deficiency. Measurement of PC or PDH activity in cultured amniotic fluid cells, or direct measurement in chorionic villi biopsy specimens are alternatives to DNA analysis, when the familial mutations are not known.

Molecular genetic testing is possible in fumarase deficiency and can be started with targeted mutation analysis of *FH* for the common 3-bp AAA duplication (c.1431_1433dupAAA), as the first genetic screening test. Due to compound heterozygosity of the mutation, further analysis of the whole *FH* gene is required to fully confirm the genetic defect. Prenatal diagnosis and preimplantation genetic diagnosis for at-risk pregnancies require prior identification of the disease-causing mutations in the family, although prenatal diagnosis of fumarase deficiency has even been successfully performed by enzyme activity measurements (Coughlin et al. 1998; Manning et al. 2000). In SUCLA2 and SUCLG1 defects, prenatal diagnosis is also possible in chorionic samples by sequence analysis in at-risk pregnancies.

Disorder	Prenatal diagnosis
PDH, PC, and fumarase deficiency	Mutation analysis in chorionic sample
	FH enzyme measurement in amniocytes
SUCLA2and SUCLG1 defects	Mutation analysis in chorionic sample

Treatment and Prognosis

Patients with PC and PDHc deficiency should be treated for their acute hypoglycemic and acidotic episodes. One should monitor lactate levels regularly, since high glucose intake increases lactic acidosis.

Neither biotin, thiamine, dichloroacetate, nor a high-fat or high-carbohydrate diet has been shown to provide clinical benefit.

The general prognosis for individuals with PDHC deficiency is poor, and treatment is not very effective. Best strategy for treating PDHC deficiency is the use of a ketogenic diet (Scholl-Bürgi et al. 2015). Thiamine has been given in variable doses (500–2000 mg/day), with lowering of blood lactate and clinical improvement in some patients. DL-lipoic acid has been tried, but its efficacy remains controversial in PDHE3.

So far there is no curative treatment, and there are no known distinctive clinical symptoms and biochemical or genetic findings that can be used for prognosis assessment and prediction of the course of 2-oxoglutaric aciduria and fumarase deficiency. In 2-oxoglutaric aciduria, bicarbonate supplementation might be needed due to the chronic metabolic acidosis, and dietary intervention should be applied in patients with recurrent hypoketotic hypoglycemia. The outcome of both disorders appears to depend on the progression of the central nervous system symptoms and how effectively these symptoms are treatable. The prognosis ranges from death within the first year of life to survival to puberty or adulthood. The oldest patient with fumarase deficiency described was 25 years old at time of the case report.

In patients with SCS defects, most patients have a slowly progressive neurodegenerative course with possible survival to adulthood. Most of the SUCLG1-deficient patients have a neonatal, or early pediatric fatal outcome.

Fumarate is a positive regulator of genome stability (its absence supports genome instability and tumorigenesis) and its accumulation drives angiogenesis and proliferation (thereby supporting tumor establishment). If the fumarate hydratase-causing mutations are known in the family, it is appropriate to consider offering molecular genetic testing to relatives who might be at risk of developing multiple cutaneous and uterine leiomyomas (MCUL) or papillary renal cell carcinoma with leiomyomatosis (HLRCC) (Tomlinson et al. 2000).

Disorder	Specific treatment
PDHc deficiency	Ketogenic diet
2-Oxoglutaric aciduria	Bicarbonate supplementation
	Frequent feedings
	Avoidance of high CH intake
Fumarase deficiency	None
SUCLA2 and SUCLG1 defects	Protein restriction was not proved to be effective

Alternative Therapies

An orthotopic hepatic transplantation reversed ketoacidosis and renal tubular abnormalities, and decreased lactic acidemia in a patient with a severe PDHc phenotype. A patient with the French phenotype was started on early.

treatment with triheptanoin in order to restore anaplerosis. Although there was a clinical improvement without evidence of neurodegeneration, the patient died during an episode of acute decompensation at 8 months of age.

Phenylbutyrate has been shown beneficial effect in increasing enzyme activity (Ferriero et al. 2014).

Disorder	Alternative therapies
2-Oxoglutaric aciduria	Not successful
Fumarase deficiency	Not successful
SUCLA2 and SUCLG1 defects	Anaplerosis

specific expression, or even related to specific metabolic states. Although these carriers are involved in the import and export of a large variety of chemically distinct cellular metabolic substrates, they are expected to act via a similar structural transport mechanism, which preserves the mitochondrial membrane potential during transport. Up to now, 15 mitochondrial carriers have been linked to various rare inherited metabolic diseases. This chapter provides an overview of the wide variety of clinical phenotypes associated with mitochondrial carrier deficiencies, including carnitine/acylcarnitine deficiency, HHH syndrome, epileptic encephalomyopathy, transient infantile hypertriglyceridemia, citrullinemia, sideroblastic anemia, Amish microcephaly, Gorlin–Chaudhry–Moss syndrome, Fontaine syndrome and neonatal myoclonic epilepsy. Both clinical and molecular phenotypes largely depend on the metabolites being transported, leading to a decreased function of one but often multiple metabolic pathways located in the mitochondrial matrix or the cytosol. This, however, most often causes a characteristic pattern of metabolite changes, which can be used for diagnostic purposes. A vast number of carrier deficiencies result in a decreased mitochondrial ATP production and oxidative phosphorylation (OXPHOS) function, whereas other deficiencies are characterized by deficient amino acid, galactose, or fatty acid metabolism. Although therapeutic strategies are lacking for most carrier deficiencies, some dietary alterations like a ketogenic diet or supplementation (i.e., riboflavin, citrate) have shown promising effects.

Introduction

Most mitochondrial metabolic pathways are heavily interconnected and dependent on cytosolic metabolic routes. To allow such a cooperative action, a large variety of metabolites need to be exchanged between both compartments. Although polar substrates can easily pass the mitochondrial outer membrane, which is permeable to molecules up to 5000 Da, they need an active transport step to cross the largely impermeable mitochondrial inner membrane. This transport is mediated by transport proteins embedded in the mitochondrial inner membrane. Most of these transporters belong to the mitochondrial carrier family, consisting of 53 members that enable import and efflux of a wide variety of metabolites (Ruprecht and Kunji 2020). Other type of transport proteins that are embedded in the mitochondrial inner membrane include six ATP-binding cassette (ABC) transporters (Schaedler et al. 2015), various ion channels, the mitochondrial pyruvate carrier (Bender and Martinou 2016), and five sideroflexins (Paul et al. 2019; Sofou et al. 2019).

The mitochondrial carrier family comprises proteins that are encoded by genes of the solute carrier (SLC) family 25, which are distributed equally over most chromosomes (Palmieri and Monné 2016). Expression patterns vary largely between different carriers ranging from ubiquitous expression in all organs up to organ-specific expression, or even related to specific metabolic states, like association of the glycolytic rate with ADP/ATP carrier isoform 2 expression (Palmieri and Monné 2016). These expression patterns are most likely due to the specialized function of the carrier proteins and their different isoforms.

Although mitochondrial carriers are involved in the import and export of a large variety of chemically distinct cellular metabolic substrates via different operating modes (e.g., uniporter, symporter, antiporter), they are expected to act via a similar structural transport mechanism, which has recently been clarified for the ADP/ATP carrier (Ruprecht and Kunji 2019). This is also evident from a highly conserved sequence similarity of the functional motives, which are essential for carrier function (Robinson et al. 2008). All carriers consist of three homologous sequence repeats of approximately 100 amino acids. Each repeat consists of an odd numbered helix (H1, H3, or H5), which penetrates the membrane, a matrix helix (h12, h34, h56), which is positioned parallel to the membrane, and an even numbered helix (H2, H4, H6), which also penetrates the membrane. Characteristic amino acid sequences in the cytoplasmic and matrix regions contribute to the formation of salt-bridge networks that form the cytoplasmic and mitochondrial brace, respectively. Upon binding of the carrier substrate, these salt-bridge networks and braces are formed and bring the carrier either in the matrix-open (m-state) or cytosolic-open (c-state) state. In both conditions, the central substrate binding cavity is protected by a ~15 Å wide gate, which is structurally unique for mitochondrial carrier proteins and is expected to prevent proton leak (Ruprecht et al. 2019). In contrast to the conserved regions required for the transport mechanism, the carriers contain a highly variable central region that determine substrate specificity (Robinson et al. 2008).

Since the first observation mentioning that mitochondrial carriers might cause mitochondrial disease, 15 mitochondrial carrier proteins have been linked to various rare inherited metabolic diseases (Trijbels et al. 1998; Palmieri and Monné 2016). The clinical phenotypes are very heterogenous and largely depend on the metabolic pathway in which the metabolic substrates are involved. Deficiencies of mitochondrial ADP/ATP and phosphate carries are, for example, associated with a decreased mitochondrial ATP production, as they facilitate the mitochondrial import of two main substrates for the oxidative phosphorylation (OXPHOS) (i.e., ADP and phosphate). Deficiencies of other carriers are associated with a disturbed fatty acid biosynthesis and oxidation, deficient urea cycle metabolism, decreased amino acid synthesis, or disturbed heme synthesis. Clinically, this results in a whole gamut of different symptoms and diseases associated with carrier deficiencies, including carnitine/acylcarnitine deficiency, HHH syndrome, epileptic encephalomyopathy, transient infantile hypertriglyceridemia, citrullinemia, sideroblastic anemia, Amish microcephaly, Gorlin–Chaudhry–Moss syndrome, Fontaine syndrome and neonatal myoclonic epilepsy.

Metabolic Pathways

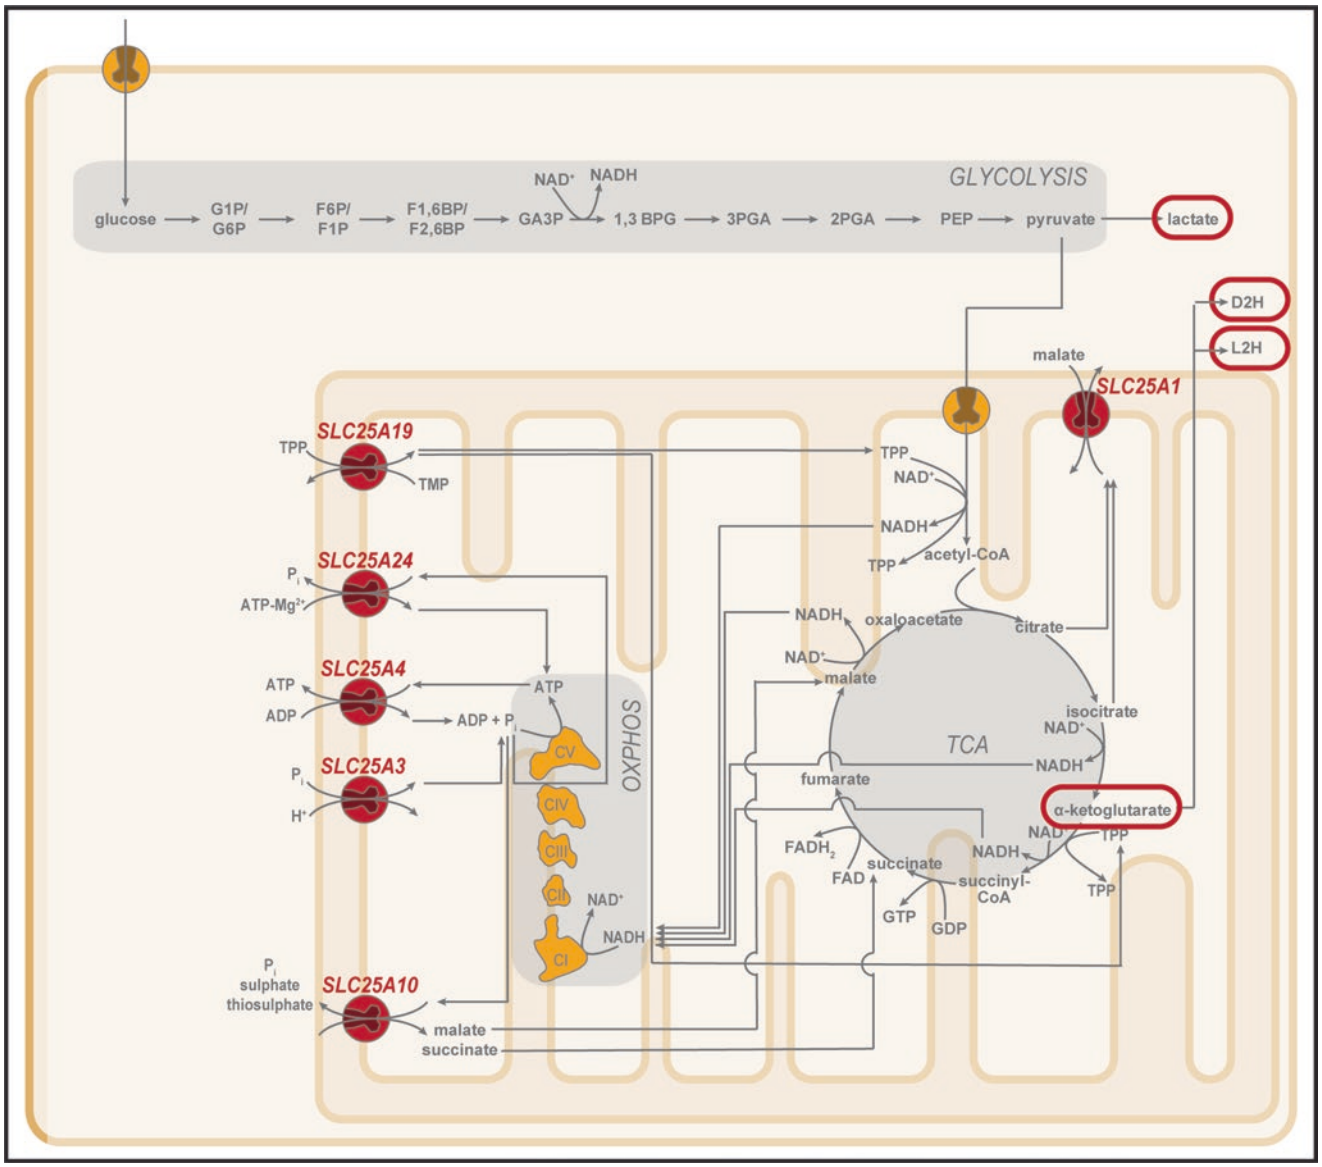

Fig. 43.1 Mitochondrial carrier deficiencies associated with a decreased TCA or OXPHOS capacity. Classically, mitochondrial ADP/ATP carrier (*SLC25A4*) and phosphate carrier (*SLC25A3*) deficiencies have been directly linked to an impaired OXPHOS capacity (Palmieri and Monné 2016), which is obvious as they facilitate the mitochondrial import of both substrates for ATP generation by the fifth OXPHOS complex (i.e., F_oF_1-ATP-synthase). The concurrent inhibition of the entire OXPHOS capacity results in a decreased mitochondrial respiration, which leads to the conversion of pyruvate to lactate. In addition to the ADP/ATP carrier, ADP and ATP can also be transported bidirectionally by the ATP-Mg^{2+}/phosphate carrier (*SLC25A24*). In contrast to the ADP/ATP carriers, this transport is not equimolar, which allows this carrier to regulate the size of the mitochondrial and cytosolic nucleotide pools (Palmieri and Monné 2016). Decreased OXPHOS capacity also occurs secondary to inhibition of the TCA cycle, which can result from deficiencies of the citrate carrier (*SLC25A1*), dicarboxylate carrier (*SLC25A10*), and thiamine pyrophosphate carrier (*SLC25A19*). Although most consequences of citrate carrier deficiencies are due to low cytosolic citrate availability to processes like cholesterol, fatty acid, and coenzyme Q synthesis, it also hampers the mitochondrial import of malate. On the other hand, increased matrix citrate concentrations lead to increased concentrations of downstream TCA metabolites, most prominently observed with α-ketoglutarate, which leads to increased levels of two enantiomers of 2-hydroxyglutarate (D2H, L2H) (Nota et al. 2013). Malate supply for the TCA cycle can, however, also be facilitated by the dicarboxylate carrier. This carrier also imports succinate into the mitochondrial matrix, and deficiencies are consequently associated with TCA cycle defects. Finally, the thiamine pyrophosphate carrier facilitates mitochondrial thiamine pyrophosphate import, which is an important cofactor for pyruvate dehydrogenase, but also for α-ketoglutarate dehydrogenase that converts α-ketoglutarate to succinyl-CoA. The latter gives rise to increased α-ketoglutarate levels. Abbreviations: *1,3 BPG* 1,3-biphosphoglycerate, *CI-V* mitochondrial OXPHOS complex I–V, *D2H* D-2-hydroxyglutaric acid, *F1P* fructose-1-phosphate, *F1,6BP* fructose-1,6-biphosphate, *F2,6BP* fructose-2,6-biphosphate, *F6P* fructose-6-phosphate, *G1P* glucose-1-phosphate, *G6P* glucose-6-phosphate, *GA3P* glyceraldehyde 3-phosphate, *3PGA* 3-phosphoglycerate, *L2H* L-2-hydroglutaric acid, *PEP* phosphoenol-pyruvate, *2PGA* 2-phosphoglycerate, *TCA* tricarboxylic acid cycle, *TMP* thiamine monophosphate, *TPP* thiamine pyrophosphate

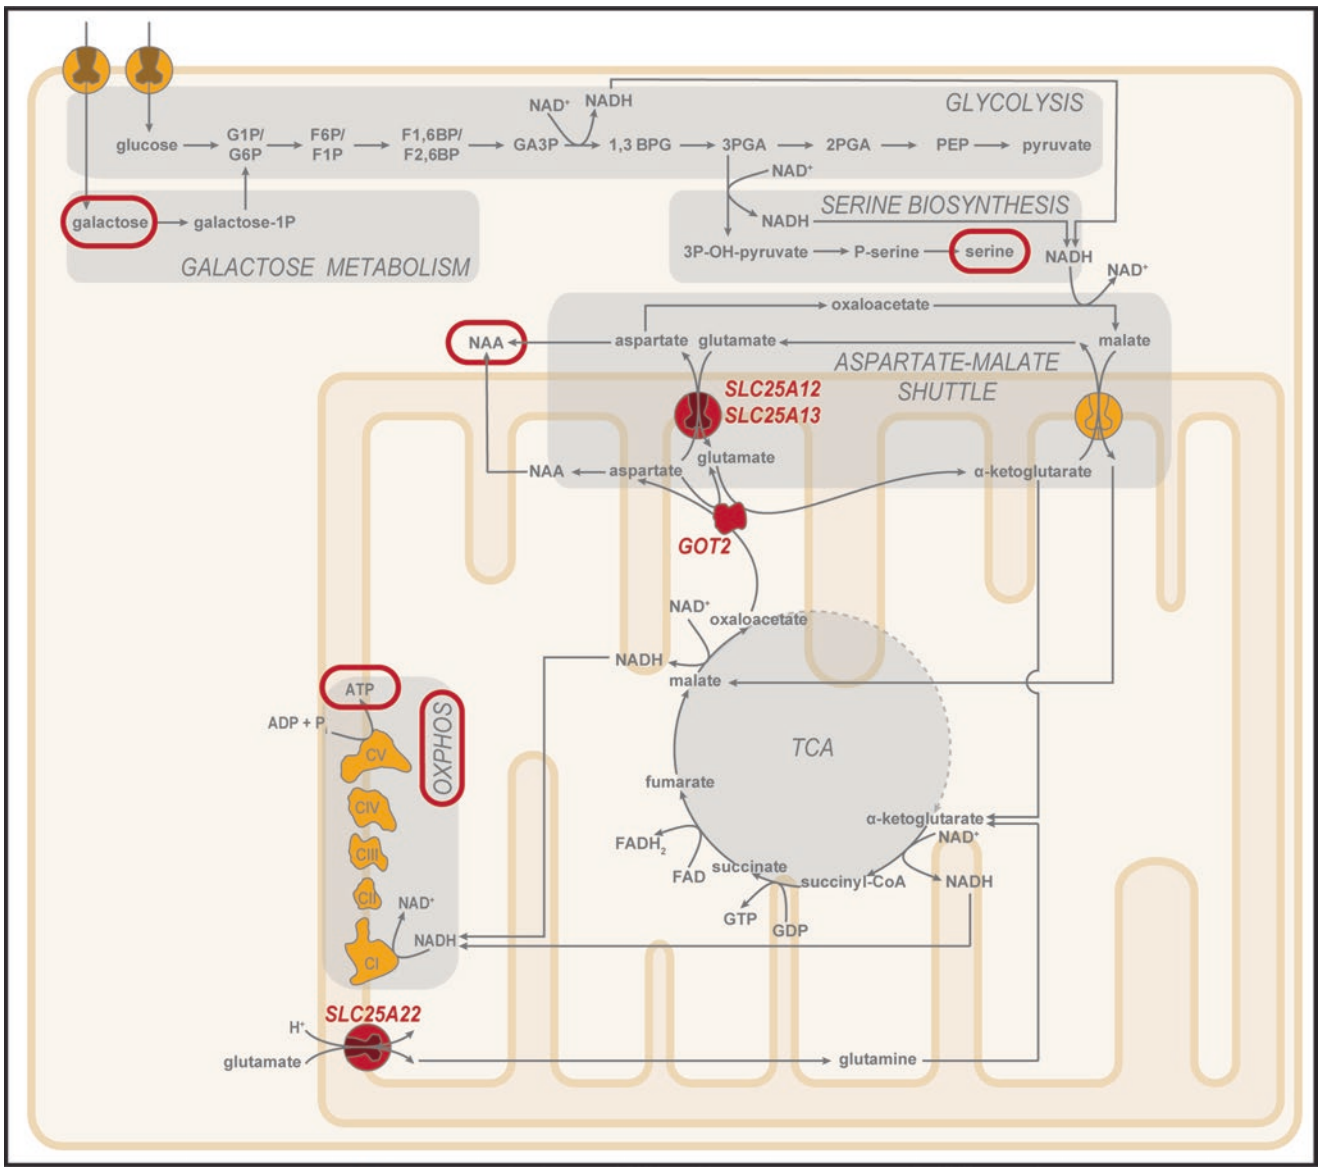

Fig. 43.2 Mitochondrial carrier deficiencies associated with aspartate–malate shuttle disturbance. The malate–aspartate shuttle is one of the mitochondrial shuttles that transfer reducing equivalents from cytosolic NADH to mitochondrial matrix NADH. Consequently, inhibition of this shuttle by deficiencies of the aspartate–glutamate carrier (*SLC25A12/A13*) leads to high cytosolic NADH levels. This will subsequently inhibit glycolysis, which also results in a decreased galactose utilization. In neurons, which mainly express *SLC25A12*, reduced activity of this carrier leads to decreased *N*-acetyl aspartate (NAA) levels, as cytosolic aspartate is the main precursor for this metabolite. In liver mitochondria, which predominantly express *SLC25A13*, deficiency of this carrier is mainly characterized by increased galactose levels as described above, and a disturbed urea cycle and amino acid metabolism as described in Fig. 43.3. The glycolytic inhibition will also lead to a decreased pyruvate production, simultaneously less glutamate will enter the mitochondrial matrix. Therefore, α-ketoglutarate production from glutamate will limit the potential of this compensatory mechanism to correct for the reduced pyruvate availability, consequently *SLC25A12* deficiencies result in a decreased mitochondrial OXPHOS capacity and ATP-production. Matrix glutamate levels are also regulated by the mitochondrial glutamate carrier (*SLC25A22*), for which a net efflux of glutamate (i.e., matrix to cytosol transport) was postulated based on deficiencies of this carrier (Reid et al. 2017). The resulting high glutamate concentrations also drive amino acid metabolism toward proline synthesis, as described in Fig. 43.3. Next to the aspartate–glutamate carrier deficiencies, inhibition of the malate–aspartate shuttle can result from *GOT2* deficiency, which is closely involved in this shuttle by the interconversion of aspartate to glutamate and glutamate to α-ketoglutarate. In analogy with SLC25A12/13 deficiencies this results in increased cytosolic NADH levels, which inhibits serine biosynthesis. Abbreviations: *1,3 BPG* 1,3-biphosphoglycerate, *CI-V* mitochondrial OXPHOS complex I–V, *F1P* fructose-1-phosphate, *F1,6BP* fructose-1,6-biphosphate, *F2,6BP* fructose-2,6-biphosphate, *F6P* fructose-6-phosphate, *G1P* glucose-1-phosphate, *G6P* glucose-6-phosphate, *galactose-1P* galactose-1-phosphate, *GA3P* glyceraldehyde 3-phosphate, *3PGA* 3-phosphoglycerate, *NAA N*-acetyl aspartate, *PEP* phosphoenolpyruvate, *2PGA* 2-phosphoglycerate, *3P-OH-pyruvate* 3-phosphohydroxypyruvate, *P-serine* phosphoserine, *TCA* tricarboxylic acid cycle

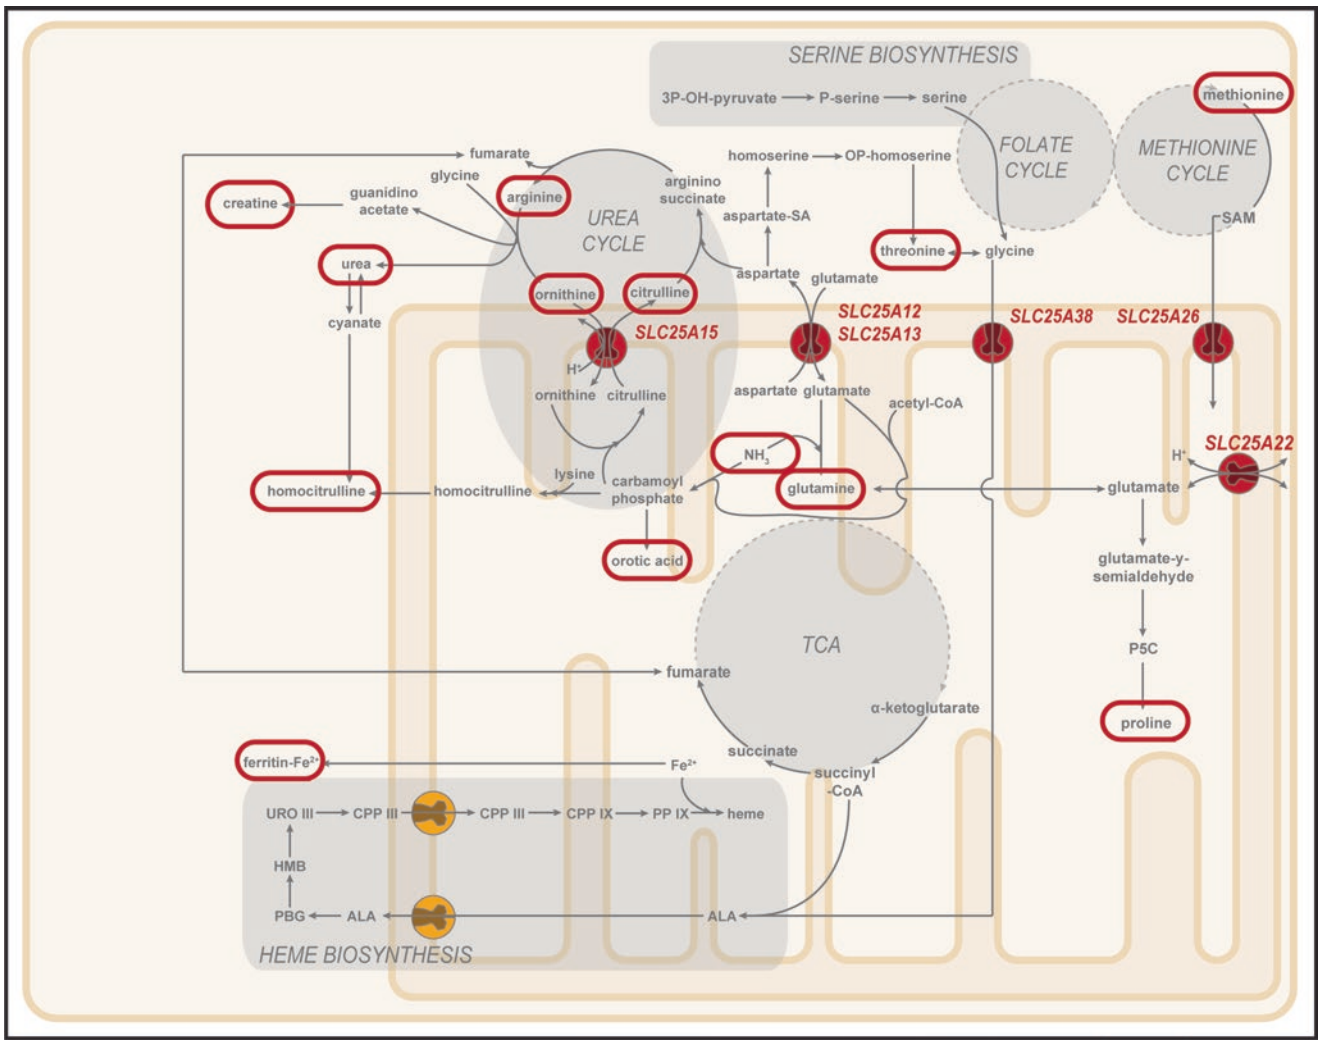

Fig. 43.3 Mitochondrial carrier deficiencies associated with disturbed amino acid metabolism. Various mitochondrial carrier deficiencies result in a disturbed amino acid metabolism, which is also reflected in amino acids plasma levels. For the majority of amino acid alterations this is due to interference with the urea cycle, which is partially located in the mitochondrial matrix and partially in the cytosol. Most obvious are ornithine carrier (*SLC25A15*) deficiencies, as this carrier exchanges ornithine for citrulline, and is therefore central in the coupling of the cytosolic and matrix steps of the urea cycle. Consequently, this results in increased cytosolic ornithine and (homo)citrulline levels, which is also reflected in high plasma levels of both amino acids. In contrast to these levels in the cytosol, mitochondrial levels are low. The urea cycle can also be disturbed by aspartate–glutamate carrier (*SLC25A12/13*) deficiencies, which is due to a shortage of cytosolic aspartate. These low aspartate concentrations also inhibit synthesis of threonine. In addition to disturbed amino acid patterns, this also leads to increased orotic acid levels and decreased synthesis of urea, which is directly generated by the urea cycle, and decreased levels of creatine formed from guanidinoacetate (i.e., a urea cycle product). Finally, urea cycle defects are characterized by increased ammonia and glutamine levels, the latter also being characteristic for hepatic aspartate-glutamate carrier (i.e., *SLC25A13*) deficiencies. Glutamine is interconverted with mitochondrial glutamate, which is mainly transported out of the matrix by the mitochondrial glutamate carrier (*SLC25A22*), as described in Fig. 43.2. Although deficiencies of this carrier result in high glutamate levels, glutamine levels are not increased. The high glutamate levels are, however, expected to promote proline synthesis (Reid et al. 2017), as apparent from the hyperprolinemia observed in glutamate carrier-deficient patients. Other amino acid disturbances associated with mitochondrial carrier deficiencies include increased cytosolic methionine levels, as its downstream product *S*-adenosylmethionine is not imported into the mitochondrial matrix by the *S*-adenosylmethionine carrier (*SLC25A26*). Finally, as a result of glycine carrier (*SLC25A38*) deficiencies matrix glycine concentrations are decreased, leading to an inhibited heme synthesis, as glycine is one of its primary metabolic building blocks. The decreased heme biosynthesis gives rise to a lower incorporation of iron, which then binds to ferritin in the cytosol. Consequently, increased ferritin concentrations are observed with glycine carrier deficiencies (Kannengiesser et al. 2011). Abbreviations: *ALA* Delta aminolevulinic acid, *aspartate-SA* Aspartate semialdehyde, *CPPIII* Coproporphyrinogen III, *CPP IX* Protoporphyrinogen IX, *PP IX* Protoporphyrin IX, *HMB* Hydroxymethylbilane, *OP-homoserine* *O*-phospho-homoserine, *3P-OH-pyruvate* 3-Phosphohydroxypyruvate, *P5C* Pyrroline-5-carboxylate, *PBG* Porphobilinogen, *P-serine* Phospho-serine, *SAM* *S*-adenosylmethionine, *TCA* Tricarboxylic acid cycle, *URO III* Uroporphyrinogen III

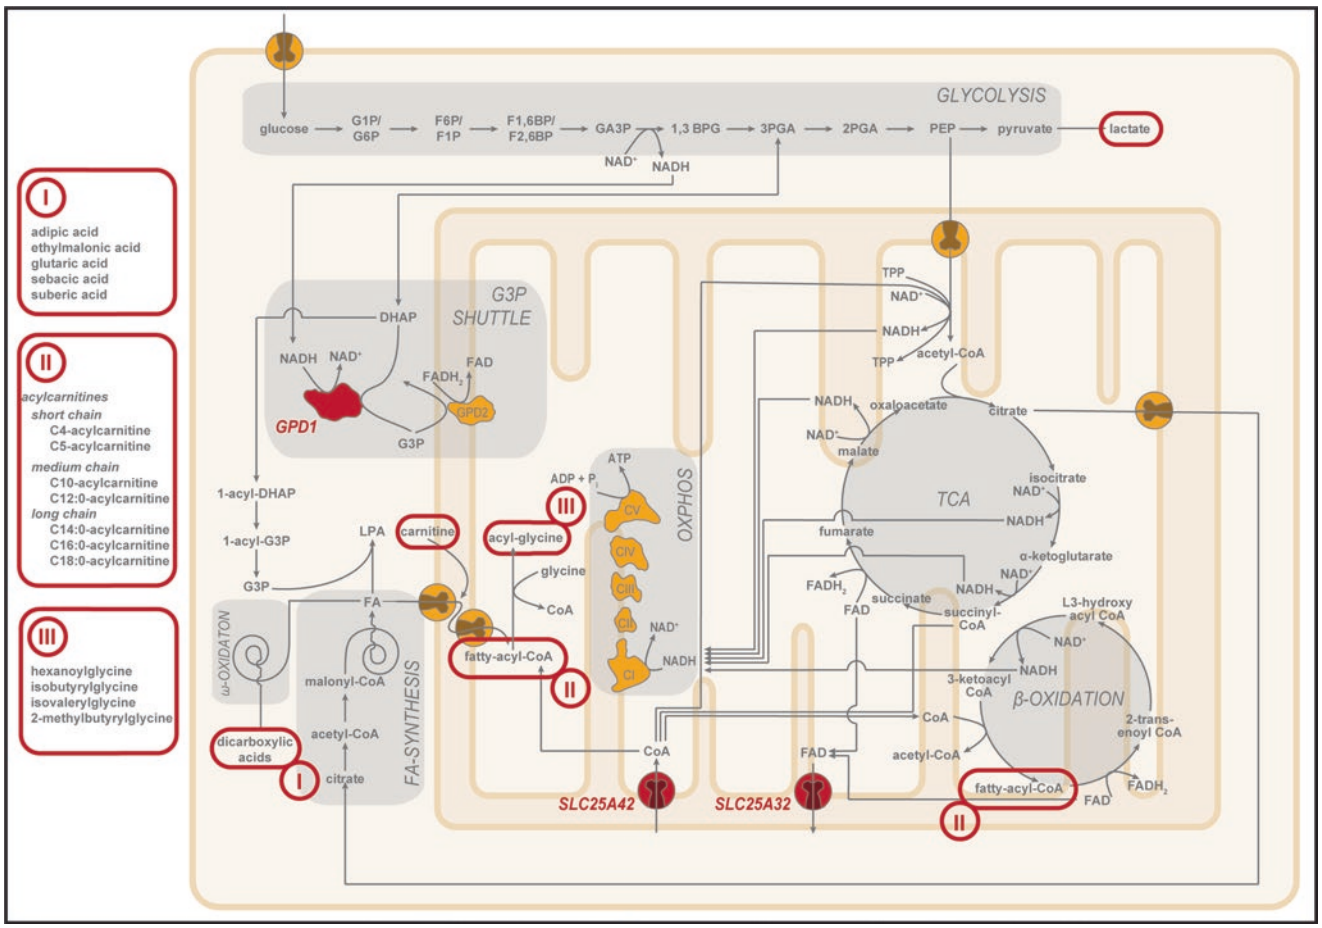

Fig. 43.4 Mitochondrial carrier deficiencies associated with decreased fatty acid metabolism. Increased acyl-glycine levels (see box III on the left), which are also observed in various fatty acid and branched chain amino acid oxidation disorders, are associated with mitochondrial folate carrier (*SLC25A32*) and coenzyme A (*SLC25A42*) carrier deficiencies. For folate carrier deficiencies, this phenotype results from a decreased fatty acid β-oxidation due to decreased mitochondrial flavin adenine dinucleotide (FAD) levels, which drive the first enzymatic conversion of this pathway and FAD is imported into the matrix by *SLC25A32* (Schiff et al. 2016). More severe deficiencies, also result in a decreased activity of the second OXPHOS complex (i.e., complex II), which similarly uses FAD as cofactor (Hellebrekers et al. 2017). This subsequently leads to a decreased ATP production capacity. The decreased fatty acid oxidation in these deficiencies also leads to increased cytosolic fatty acid levels that give rise to an increased peroxisomal fatty acid ω-oxidation, which results in increased dicarboxylic acid concentrations (see box I on the left). Increased acyl-glycine levels are also characteristic for coenzyme A carrier deficiencies, as coenzyme A (CoA) is vital for mitochondrial uptake of medium and long-chain fatty acids (see box II on the left). Moreover, this leads to increased carnitine levels that are used for mitochondrial fatty acid import. As CoA is essential for many other mitochondrial metabolic pathways, these deficiencies are also characterized by increased lactate levels, as the conversion of pyruvate to acetyl-CoA is inhibited. Moreover, decreased acetyl-CoA levels lead to a decreased urea cycle function, as acetyl-CoA together with glutamate leads to the production of carbamoyl phosphate (see Fig. 43.3). Such a decreased urea cycle function explains the increased ammonia levels in coenzyme A carrier deficiencies. Cytosolic glycerol-3-phosphate dehydrogenase deficiencies are characterized by an enhanced triglyceride synthesis, which can most likely be explained by an increased concentration of dihydroxyacetone phosphate (DHAP), which can alternatively be converted into glycerol-3-phosphate (G3P) by dihydroxyacetone phosphate acyltransferase (Hebestreit et al. 1996). The produced glycerol-3-phosphate can together with fatty acids be used for the production of triglycerides. This link with fatty acid metabolism is emphasized by increased dicarboxylic acid levels, indicative of an increased peroxisomal fatty acid ω-oxidation, as described above. Abbreviations: *1,3 BPG* 1,3-Biphosphoglycerate, *CI-V* Mitochondrial OXPHOS complex I–V, *DHAP* Dihydroxyacetone phosphate, *F1P* Fructose-1-phosphate, *F1,6BP* Fructose-1,6-biphosphate, *F2,6BP* Fructose-2,6-biphosphate, *F6P* Fructose-6-phosphate, *FA* Fatty acid, *G1P* Glucose-1-phosphate, *G3P* Glycerol-3-phosphate, *G6P* Glucose-6-phosphate, *GA3P* Glyceraldehyde 3-phosphate, *GPD1* Glycerol-3-phosphate dehydrogenase 1, *GPD2* Glycerol-3-phosphate dehydrogenase 2, *LPA* Lysophosphatidic acid, *3PGA* 3-Phosphoglycerate, *PEP* phosphoenolpyruvate, *2PGA* 2-Phosphoglycerate, *TCA* Tricarboxylic acid cycle, *TPP* Thiamine pyrophosphate

Diagnostic Flowchart

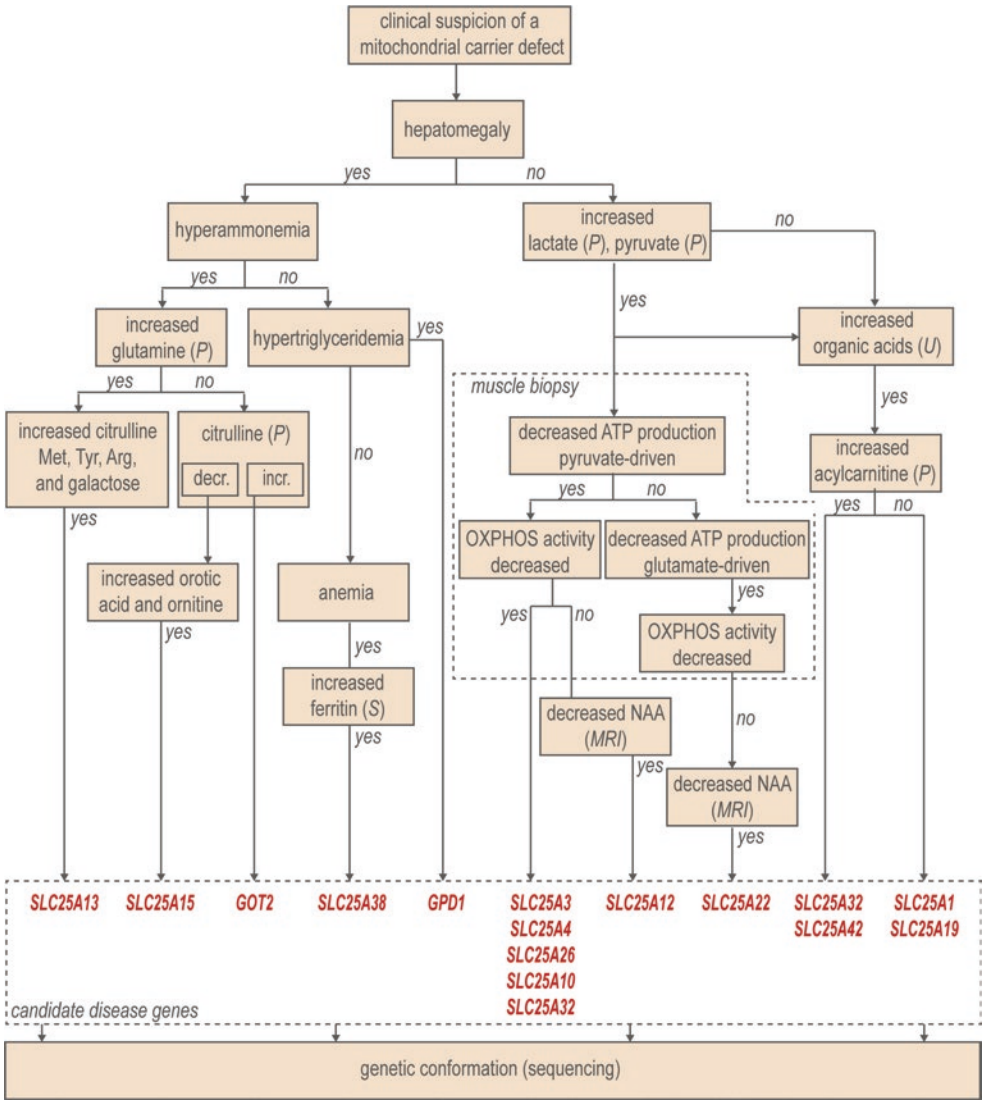

Fig. 43.5 Diagnostic flow chart of mitochondrial carrier deficiencies. If only one option (i.e., yes or no) is indicated, the other is associated with a disease not related to a mitochondrial carrier deficiency. Besides, nowadays hardly any single candidate gene approach is done, but instead direct whole exome sequencing (WES) or even whole genome sequencing (WGS). Abbreviations: *decr* Decreased, *incr* Increased, *MRI* Magnetic resonance imaging, *NAA N*-acetyl aspartate, *OXPHOS* Oxidative phosphorylation, *P* Plasma, *S* Serum, *U* Urine

Specimen Collection

The diagnostic workflow is initiated by a metabolic screening, as indicated in the above flow chart. Most often, whole exome sequencing or whole genome sequencing will subsequently be performed, which could identify a pathogenic gene defect. For others, a definite diagnosis can only be reached by biochemical examination of a tissue specimen, for example, when the genomic approaches identify a variant of uncertain significance. As a rule, the patient under investigation should not be on treatments that could mask possible enzyme deficiencies (e.g., vitamins, carnitine, certain drugs). For most biochemical determinations, one should ask the diagnostic center for information about specific requirements as to the practice of collecting and transporting material. Especially in the case of enzyme analysis in tissues or cells, it is important to consult the diagnostic laboratory in advance about the conditions for removal, preparation, storage, and transport of the specimens. If fresh tissue (e.g., a muscle biopsy) is to be studied, samples have to be collected in a special, ice-cold buffer and immediately transported to the laboratory and should preferentially be examined biochemically within 2 h after collection. In this fresh material, in which mitochondrial integrity has not been compromised, mitochondrial flux measurements, such as oxygen consumption, substrate oxidation, and ATP production can be performed. The physician should inform the laboratory about the clinical findings to ensure an adequate analysis and data interpretation. It is important to discuss which type of tissue or cell is preferable in each individual case, thereby causing the patient as little inconvenience as possible. Tissue-specific expression of mitochondrial deficiencies renders fibroblasts and lymphocytes less appropriate for general purposes than skeletal muscle, although fibroblast analysis does have an added diagnostic value when combined with a muscle sample examination. In the case of unexpected death, blood and urine specimens need to be collected as soon as possible after the patient has passed away. They should be snap frozen (not fixed) immediately after collection using liquid nitrogen and stored for possible additional studies. For enzymatic purposes, tissues must be removed within 1–2 h after death and should be frozen immediately in liquid nitrogen. Skin biopsies can be performed as late as 48 h after death and must be collected at room temperature in cell culture medium, after which the sample can be transported at room temperature to the cell culture laboratory. Because few reference values are generally available for neonates, it is recommended to perform a muscle biopsy beyond the first month of life, unless a life-threatening situation exists. To assess the effect of genetic deficiencies on functional transport, radiolabeled assays in liposomes are still considered as the 'golden standard' assay. These methods are, however, only performed in specialized diagnostic or research laboratories. This approach most often includes the overexpression of the human codon-optimized transporter in *E. coli* or *L. lactis*, followed by purification of the transporter and reconstitution of the transporter in liposomes (Thompson et al. 2016; Punzi et al. 2018). These assays are though not available in most diagnostic laboratories.

Test	Material	Collection and transport	Handling and storage	Pitfalls
Acylglycines Hexanoylglycine Isobutyrylglycine Isovalerylglycine 2-Methylbutyrylglycine	*U*	–	−20 °C	–
Acylcarnitines C4 acylcarnitine C5 acylcarnitine C10-acylcarnitine C12:0-acylcarnitine C14:0-acylcarnitine C16:0-acylcarnitine C18:0-acylcarnitine	*P, DBS*	Heparinized or EDTA blood (or serum) supernatant from clinical centrifugation (within 20 min), fresh or promptly frozen and shipped frozen (packed with dry ice) or lyophilized and shipped at room temperature with original volume specified.	*P*: 20 °C *DBS*: Ambient temp.	During anabolism eventually normal values, different profile with MCT diet, long-chain acylcarnitine accumulation also in healthy individuals during catabolism
Amino acids Arginine Citrulline Glutamine Methionine Ornithine Proline Serine Threonine Tyrosine	*P, CSF*	Heparinized blood sample.	−20 °C	*General*: Draw blood 3 – 4 h after a meal; harvest plasma promptly; avoid hemolysis. *Glutamine*: Freeze quickly since glutamine is unstable. *Methionine*: Liver disease, any cause. Immediate separation from plasma essential. *Citrulline*: Watermelon contains citrulline and can increase its level. *Proline*: Obtain fasting. *Tyrosine*: Liver disease, any cause; false negatives in diet - treated patients.

Test	Material	Collection and transport	Handling and storage	Pitfalls
Ammonia	*B, P*	Analyze within 30 min of blood drawing. Transport blood refrigerated. Arterial blood preferable, use tourniquets minimally, do not request muscular contractions.	No storage allowed	
ALAT	*P*	Blood sample should be processed (centrifuged) within 2 h. Avoid hemolysis.	−20 °C (up to 72 h)	
ASAT	*P*	Blood sample should be processed (centrifuged) within 2 h. Avoid hemolysis.	−20 °C (up to 72 h)	
ATP production	*M, FB*		No storage allowed	Maintain at 0 °C during analysis.
Carnitine, free	*P, DBS*		*P*: 20 °C *DBS*: Ambient temp.	
Cholesterol	*S*	Blood sample should be processed (centrifuged) within 2 h. transport at 4 °C.	Process and store up to 72 h at 4 °C	
Creatine	*P*			
Creatine kinase	*P*		−20 °C	
2-Hydroxyglutaric acid (D- and L-enantiomers)	*CSF, P, U*		−20 °C	For specific quantification of L2HG enantiomeric separation, hyphenated to mass spectrometry is required.
Organic acids Adipic acid Alpha-ketoglutarate Ethylmalonic acid Glutaric acid Orotic acid Sebacic acid Suberic acid	*U*	Fresh or frozen without preservatives and shipped frozen (packed in dry-ice) or lyophilized and shipped at room temperature with original volume specified or shipped as fresh sample with 1–2 drops of chloroform for preservation	−20 °C	If urine is refrigerated or frozen, it can precipitate out; heat urine at 37 °C until precipitate is dissolved.
Factor VII	*P*	Transport at ambient temperature.	Ambient temperature	Avoid hemolysis.

Prenatal Diagnosis

Prenatal diagnosis for mitochondrial carrier defects is indicated if mutations of mitochondrial carriers have been identified in family members. For such at-risk pregnancies, prenatal genetic testing is performed in chorionic villi, amniotic fluid cells, or cultured amniocytes.

DNA Testing

If a there is a clinical suspicion of a mitochondrial carrier deficiency, genetic variants of mitochondrial carriers can be determined using conventional sequencing techniques (e.g., whole exome sequencing, Sanger sequencing, whole genome sequencing). This can be accomplished in all DNA containing samples, but preferably in a non-invasive sample like peripheral blood mononuclear cells (PBMCs) or buccal swabs. When variants of uncertain significance are found, their pathogenic role should be investigated using functional (transport) assays described above.

Treatment

Depending on the specific clinical phenotype associated with mitochondrial carrier deficiencies, emergency treatments mainly focus on seizure control or the control of hyperammonemia and/or lactic acidosis. Although drug treatments are lacking for the 7 out of 16 carrier deficiencies, strategies for symptom alleviation have shown therapeutic potential for other carrier deficiencies. Confirmation of the therapeutic value in a more controlled setting is, however, warranted. These therapies comprise a switch to a diet with low carbohydrates and high fat and protein intake (i.e., ketogenic diet), which has mainly proven to be beneficial for carrier deficiencies that result in a defective aspartate malate shuttle (i.e., aspartate–glutamate carriers and mitochondrial aspartate aminotransferase). In contrast, protein-restricted diets are beneficial for ornithine carrier-deficient patients. Alternatively, carrier substrates or their precursors can be supplemented to compensate for the carrier defect. This has shown to be a promising option for defects in the citrate carrier (i.e., using citrate), thiamine pyrophosphate carrier (i.e., using thiamine), and flavin adenine dinucleotide carrier (i.e., using riboflavin). A similar approach is also applied in several experimental treatments that use folate and glycine or pantethine for glycine or coenzyme A carrier deficiencies, respectively. Interestingly, carrier deficiencies for which no treatment is available yet, all directly provide substrates or cofactors that are essential for proper OXPHOS function. Currently, therapeutic options for these patients are though limited to supportive care.

Emergency Treatment

No.	Disease name	Disease management and treatment
43.1	Adenine nucleotide translocator deficiency	Most patients reported to date demonstrate severely elevated plasma lactate levels. Buffering of these lactate levels by bicarbonate is of immediate significance to correct the lactic acidosis (Thompson et al. 2016). Moreover, most patients require mechanical ventilation.
43.2	Adenine nucleotide translocator deficiency	Most patients reported to date demonstrate severely elevated plasma lactate levels. Buffering of these lactate levels by bicarbonate is of immediate significance to correct the lactic acidosis (Thompson et al. 2016). Moreover, most patients require mechanical ventilation.
43.3	Mitochondrial phosphate carrier deficiency	Although the disease severity and associated progression differ largely between patients, most patients reported (i.e., five out of six) demonstrate severely elevated plasma lactate levels (Bhoj et al. 2014). Buffering of these lactate levels by bicarbonate was unsuccessful in one case and is not reported in all other cases. All patients demonstrate a characteristic cardiomyopathy. In one patient heart failure was treated with anticongestive therapy (e.g., digoxin and diuretics). Although clinically stabilized, cardiac hypertrophy was progressive in this patient who died at the age of 4 months (Mayr et al. 2007). Moreover, most patients require mechanical ventilation.
43.4	Aspartate-glutamate carrier 1 deficiency	Seizure episodes are experienced by all reported aspartate-glutamate carrier 1-deficient patients and should be treated with antiepileptic drugs or a combination thereof, like oxcarbazepine, levetiracetam, topiramate and phenobarbital (Kavanaugh et al. 2019). Moreover, most patients require mechanical ventilation.
43.5	Cytosolic glycerol-3-phosphate dehydrogenase deficiency	No specific emergency treatments have been reported for cytosolic glycerol-3-phosphate dehydrogenase-deficient patients.
43.6	Combined oxidative phosphorylation deficiency-28	Most patients reported to date demonstrate severely elevated plasma lactate levels. Buffering of these lactate levels by bicarbonate is of immediate significance to correct the lactic acidosis (Kishita et al. 2015). Moreover, most patients require mechanical ventilation.

(continued)

No.	Disease name	Disease management and treatment
43.7	Mitochondrial citrate carrier deficiency	Patients with citrate carrier deficiencies experience epileptic seizures, which often increase in frequency and severity over the disease course (Mühlhausen et al. 2014; Pop et al. 2018). These epileptic seizures should be treated with antiepileptic drugs, such as levetiracetam (Mühlhausen et al. 2014).
43.8	Mitochondrial ATP-Mg^{2+}/phosphate transporter deficiency	No specific emergency treatments have been reported for ATP-Mg^{2+}/phosphate carrier-deficient patients (Writzl et al. 2017).
43.9	Mitochondrial aspartate aminotransferase deficiency	In analogy with other aspartate-malate shuttle deficiencies (i.e., aspartate-glutamate carrier deficiency) seizure episodes are frequently reported in mitochondrial aspartate aminotransferase deficient patients (van Karnebeek et al. 2019). These seizures should be treated with antiepileptic drugs or a combination thereof (van Karnebeek et al. 2019), like carbamazepine, oxcarbazepine, lamotrigine, levetiracetam, topiramate, phenobarbital, and sodium valproate. GOT2-deficient patients, however, did not respond to antiepileptic drugs in all cases.
43.10	Mitochondrial dicarboxylate transporter deficiency	Seizure episodes are experienced by dicarboxylate carrier-deficient patients, and should be treated with antiepileptic drugs or a combination thereof, like clonazepam, levetiracetam, pyridoxine, and sodium valproate. It has, however, to be noted that seizures experienced by these patients are not always responsive to antiepileptic drugs.
43.11	Mitochondrial ornithine transporter deficiency	Rapid control of hyperammonemic episodes is of primary importance (Häberle et al. 2019). Therefore, protein intake should immediately be discontinued, accompanied by intravenous infusion of glucose. If needed, infusion of supplemental arginine can be added. Moreover, ammonia removal drugs like sodium benzoate and sodium phenylacetate can be used to control hyperammonemic episodes. However, if hyperammonemia persists and/or the neurologic status deteriorates hemodialysis/filtration is indicated.
43.12	Citrin deficiency	No specific emergency treatments have been reported for citrin-deficient patients. However, acute treatment of hyperammonemia may be required, using ammonia removal drugs like sodium benzoate and sodium phenylacetate. To prevent hyperammonemia on the long-term dietary adaptations should be made as described in Sect. 43.13.
43.13	Mitochondrial glutamate carrier 1 deficiency	Seizure episodes are experienced by all reported glutamate carrier-deficient patients, and should be treated with antiepileptic drugs or a combination thereof, like clonazepam, levetiracetam, pyridoxine, and sodium valproate (Reid et al. 2017).
43.14	Mitochondrial glycine transporter deficiency	Sideroblastic anemia in these patients should be treated by chronic blood transfusion with oral iron chelation therapy (Fernández-Murray et al. 2016).
43.15	Bilateral striatal necrosis (SLC25A19)	No specific emergency treatments have been reported for mitochondrial thiamine pyrophosphate carrier-deficient patients.
43.16	Mitochondrial flavin adenine dinucleotide transporter deficiency	No specific emergency treatments have been reported for mitochondrial flavin adenine dinucleotide carrier-deficient patients.
43.17	Mitochondrial coenzyme A transporter deficiency	Most patients reported to date demonstrate profoundly elevated plasma lactate levels (Almannai et al. 2018; Iuso et al. 2018a). Buffering of these lactate levels by bicarbonate is of immediate significance to correct the lactic acidosis. Moreover, hyperammonemia is observed in many coenzyme A carrier deficient patients (Almannai et al. 2018; Iuso et al. 2018a). To control hyperammonemia protein intake should be limited. Moreover, ammonia removal drugs like sodium benzoate and sodium phenylacetate can be used to control hyperammonemia.

Standard Treatment

No.	Disease name	Disease management and treatment
43.1	Adenine nucleotide translocator deficiency	Up to now, no treatments are available for childhood muscle and cardiomyopathy associated with adenine nucleotide translocator deficiencies. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).
43.2	Adenine nucleotide translocator deficiency	Up to now, no treatments are available for autosomal dominant progressive external ophthalmoplegia (adPEO) associated with adenine nucleotide translocator deficiencies in adults. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).

No.	Disease name	Disease management and treatment
43.3	Mitochondrial phosphate carrier deficiency	Although disease severity and progression differ significantly, patients with a less progressive and severe phenotype could benefit from symptomatic treatment as described in one of the patients reported. This treatment strategy consisted of carvedilol, sodium bicarbonate and vitamin D (Bhoj et al. 2014), but was only described for this one patient.
43.4	Aspartate-glutamate carrier 1 deficiency	Up to now, one patient with aspartate-glutamate carrier deficiency has benefited substantially from the introduction of a ketogenic diet. Initiation of the diet in this 6-year-old girl, significantly improved psychomotor development and demyelination was reversed (Dahlin et al. 2015). The diet was based on a modified Johns Hopkins diet, with an initial ketogenic ratio of 1:1 (fat to protein and carbohydrates). This was increased to 3:1 (10 days), 3.5:1 (8 months) and 4:1 (13.5 months). The therapeutic potential of a ketogenic diet has, up to now, not been investigated in four other cases reported (Kavanaugh et al. 2019). Consequently, the therapeutic value of ketogenic diet for aspartate-glutamate carrier deficient patients should be further evaluated.
43.5	Cytosolic glycerol-3-phosphate dehydrogenase deficiency	So far, 16 patients have been described with a mutation in cytosolic glycerol-3-phosphate dehydrogenase (Li et al. 2018). Most of these affected individuals present with liver fibrosis in early infancy, but because they have a good prognosis liver transplantation is not recommended. High plasma triglyceride levels can, however, require lipoprotein apheresis, but this is only recommended for patients with severe hyperlipidemia.
43.6	Combined oxidative phosphorylation deficiency-28	Up to now, no treatments are available for *S*-adenosylmethionine (SAM) carrier-deficient patients. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).
43.7	Mitochondrial citrate carrier deficiency	Several patients with citrate carrier deficiencies, characterized by a combined D2−/L2-hydroxyglutaric aciduria, experienced beneficial effects of off-label citrate use. The first case included a 5-month-old girl, who received increasing citrate doses up to 1500 mg/kg/day (Mühlhausen et al. 2014). This led to decreased concentrations of the toxic metabolites D2- and L2-hydroxyglutaric acid, and increased urinary TCA metabolites. Clinically, seizure frequency and severity were decreased upon citrate treatment. Similar effects were observed in two patients, who upon citrate treatment (800 mg/kg/day or 1500 mg/kg/day) had less cerebral attacks and showed developmental gains, increased muscle tone and the absence of clinical seizures and apneic events (Pop et al. 2018). However, therapy in these cases (3 months and 9 months old) as well as the first case was initiated well into the disease course (Pop et al. 2018). Consequently, the effect of earlier therapy initiation should be investigated, and especially whether it can so attenuate the other clinical phenotypes associated with citrate carrier deficiencies (e.g., developmental delay, microcephaly, structural brain malformations). Besides the need for systemic prospective studies to investigate these effects, it has to be noted that all patients treated showed a mild clinical phenotype. Therefore, it also needs to be explored whether patients with a severe phenotype, and poorer prognosis, can benefit from citrate therapy. Promising results have been observed in one patient with a severe neonatal phenotype. Treatment with a low citrate dose (3 mg/kg/day) at 33 months of age resulted in an improvement of apneic events and increased the spontaneous respiratory drive (Smith et al. 2015). Although blood lactate levels were decreased, urinary hydroxyglutaric acids remained increased.
43.8	Mitochondrial ATP-Mg^{2+}/phosphate transporter deficiency	Up to now, no treatments are available for ATP-Mg^{2+}/phosphate carrier-deficient patients. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).
43.9	Mitochondrial aspartate aminotransferase deficiency	Recently, two mitochondrial aspartate aminotransferase (GOT2)-deficient patients (i.e., a 17 months old boy and a 5-year-old boy) have demonstrated benefit from serine (300 mg/kg/day) and pyridoxine (20 mg/kg/day) supplementation, which was apparent from full seizure control and increased cognitive functions (van Karnebeek et al. 2019). Interestingly, single serine supplementation also showed beneficial effects, but addition of pyridoxine (vitamin B6), an essential precursor for *de novo* serine biosynthesis (Ramos et al. 2017), significantly enhanced these effects. The decreased serine biosynthesis in GOT2-deficient patients is most likely due to high cytosolic NADH levels arising from a decreased aspartate-malate shuttle function (Fig. 43.3). The reduction of these levels by pyruvate supplementation restored serine biosynthesis in GOT-2 deficient cells. Consequently, the authors suggest a diet low in carbohydrates, high in fat and supplemented with ketone bodies, the latter to circumvent lactate-induced acidification (van Karnebeek et al. 2019).
43.10	Mitochondrial dicarboxylate transporter deficiency	Up to now, no treatments are available for mitochondrial dicarboxylate carrier-deficient patients. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).
43.11	Mitochondrial ornithine transporter deficiency	After emergency measures described above (Sect. 43.12), an age-appropriate protein-restricted diet should be maintained and supplemented with citrulline and sodium phenylbutyrate to maintain plasma concentrations of ammonia, glutamine, arginine, and essential amino acids within normal range (Häberle et al. 2019).

(continued)

No.	Disease name	Disease management and treatment
43.12	Citrin deficiency	Glutamate aspartate carrier (SLC25A13) deficiencies are associated with neonatal intrahepatic cholestasis (NICCD) and adult-onset type II citrullinemia (CTLN2). For both clinical manifestations therapies are aimed at the preventions of cholestasis and the need for liver transplantation (Okano et al. 2019). For NICCD, positive effects were found by treatment with medium chain triglycerides (MCT) milk and lactose (galactose)-free milk (Hayasaka et al. 2011; Okano et al. 2019). These formulations need to be supplemented with vitamins, which are not absorbed due to cholestasis (i.e., vitamin K2 and lipid-soluble vitamins) and ursodeoxycholic acid to treat cholestasis (Okano et al. 2019). Around the age of one, many NICCD patients experience a spontaneous remission. Dietary therapy is the key in the adaptation/compensation stage that follows after the remission. Such dietary adaptations include a protein- and fat-rich diet with a protein: fat: carbohydrate ratio being 15–25%: 40–50%: 30–40%, along with the appropriate energy intake. The use of MCT oil and sodium pyruvate is also effective (Okano et al. 2019). These therapies, which aim to decrease cytosolic NADH levels and provide mitochondrial energy sources, have also shown to be promising as a treatment for CTLN2 (Hayasaka et al. 2014). However, continuous intravenous hyperalimentation with high glucose concentration or administration of Glyceol® is contraindicated (Okano et al. 2019). Commonly, NICCD patients develop CTLN2 at an older age, however, with the above dietary therapy and appropriate medical support no NICCD patients have shown to develop CTLN2 up to now (Okano et al. 2019).
43.13	Mitochondrial glutamate carrier 1 deficiency	Up to now, no treatments are available for mitochondrial glutamate carrier-deficient patients. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).
43.14	Mitochondrial glycine transporter deficiency	Up to now, no treatments are available for mitochondrial glycine carrier-deficient patients. Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15). More specifically, the sideroblastic anemia in these patients should be treated by chronic blood transfusion with oral iron chelation therapy (Fernández-Murray et al. 2016).
43.15	Bilateral striatal necrosis (SLC25A19)	Mitochondrial thiamine pyrophosphate carrier deficiencies are associated with Amish lethal microcephaly. This is characterized by severe congenital microcephaly, death before the age of one and severe 2-oxoglutaric aciduria. Patients with this phenotype all have a homozygous p.G177A mutation in the *SLC25A19* gene, and unfortunately do not respond to thiamine or biotin supplementation (Gowda et al. 2019). As a consequence, supportive care should be provided to these patients, as described below (Sect. 43.15). More recently, patients with other mitochondrial thiamine pyrophosphate carrier mutations have responded positively to thiamine supplementation. Three out of five patients with homozygous *SLC25A19* mutations (i.e., p.G125S and p.S194P) described by Ortigoza-Escobar et al, showed substantial improvement in peripheral neuropathy and gait after thiamin treatment (400–600 mg/day) (Ortigoza-Escobar et al. 2017). The absence of an effect in the other two patients may be explained by the age after onset at which therapy was initiated, which was significantly higher in these two (i.e., 9 and 12 years), compared to the other patients (i.e., 3 years). Interestingly, beneficial effects were reported after acute high dose (1500 mg/kg/day) thiamine in one of these patients to treat a severe episode of flaccid paralysis that occurred with fever. Two other patients with a p.E304K and p.L290G mutation experienced no recurring encephalopathy episodes over a 2-year follow-up (400–600 mg/day). The beneficial effects of thiamin supplementation thus seem to depend on the mutation and resulting severity of the clinical phenotype. This was also suggested by a recent report that described another mutation (p.Q192H), which did not respond on thiamin treatment (400 mg/day) (Bottega et al. 2019).
43.16	Mitochondrial flavin adenine dinucleotide transporter deficiency	Mitochondrial flavin adenine dinucleotide (FAD) carrier deficiencies are predominantly associated with exercise intolerance. Riboflavin, a FAD precursor, treatment has, however, been shown to dramatically improve these symptoms, as described for a 14-year-old girl administered 10 mg/kg/day (Schiff et al. 2016), and 51-year-old man administered 30 mg/day (Hellebrekers et al. 2017).
43.17	Mitochondrial coenzyme A transporter deficiency	Vitamins and cofactors, like thiamine, biotin, riboflavin, and carnitine, were tried in several subjects with no evidence of response or correlation to disease severity (Almannai et al. 2018). Consequently, supportive care should be provided to these patients, as described below (Sect. 43.15).

Experimental Treatment

For several mitochondrial carrier deficiencies, for which currently no therapy exists, experimental treatments have demonstrated positive effects. Conformation of their therapeutic potential in a more controlled setting is though warranted. This includes the supplementation of glycine and folate for glycine carrier deficiencies. Although beneficial effects of this combination were observed in yeast and zebrafish *SLC25A38*-deficient models (Fernández-Murray et al. 2016), no impact could be observed on transfusion requirements or hematological parameters in three *SLC25A38* patients (LeBlanc et al. 2016). It is though, unknown what may have caused this different response between zebrafish and humans, which could be related to a species difference in pathophysiology and/or pharmacokinetics. Currently, several efforts are attempting to elucidate these differences, which include the generation of a *SLC25A38*-deficient mouse model (LeBlanc et al. 2016). In addition to glycine carrier deficiencies, experimental studies have demonstrated therapeutic potential of pantethine for coenzyme A carrier deficiencies (Iuso et al. 2018a).

Pantethine replenishes the cellular CoA levels, and its supplementation increased the viability of Drosophila disease models also characterized by decreased CoA levels (i.e., *PKAN* (Iuso et al. 2018a); and *PPCS* (Iuso et al. 2018b)).

Follow-Up and Monitoring

For treatable carrier deficiencies described above, a careful clinical evaluation of the disease phenotype is essential. Moreover, supportive care is vital for most carrier-deficient patients, in particular if no treatment is available yet. Due to the multiple cellular metabolic pathways affected by carrier deficiencies (Figs. 43.1, 43.2, 43.3, 43.4), patients mostly present with a combination of various symptoms (see Sect. 43.4). Consequently, it is important to focus on symptom relief or adjustment of living environment (e.g., wheelchairs, splints, adjusted furniture). For patients with a cytosolic glycerol-3-phosphate dehydrogenase deficiency, specific follow-up measures should be considered, including evaluation of growth and development, liver function, total cholesterol, triglycerides, abdominal ultrasound, and FibroScan (Li et al. 2018). In addition, it is necessary in the long-term follow up to pay attention to coronary artery disease and pancreatitis, which is associated with hypertriglyceridemia (Li et al. 2018).

Contents

Summary

Mitochondrial disorders belong to the most frequently encountered inborn errors of metabolism. Most affected mitochondrial disease patients harbour a defect in the oxidative phosphorylation system (OXPHOS) of which the incidence is estimated to be over one in 5000 live births. The OXPHOS performs the final step in the aerobic production of adenosine triphosphate (ATP) in mitochondria. Defects in OXPHOS can be caused by mutations in either the mitochondrial DNA (mtDNA) or nuclear DNA (nDNA). Most patients with mitochondrial disorders present with a multisystem disorder. The organs requiring the most energy, such as the brain, retina, heart, kidney and skeletal muscle, are most commonly and severely affected. Onset of disease can be at any age and the symptoms are almost always progressive. A definitive diagnosis solely based on clinical signs and symptoms is very unlikely. Whole exome/

genome sequencing (WES/WGS) has greatly improved disease diagnosis and often simplified it, although in some cases has also resulted in new diagnostic challenges. Nonetheless, clinical diagnostic criteria, combined with brain imaging, metabolic, biochemical and other functional tests are still needed. Since specific treatment options are still limited, the management of mitochondrial disorders is largely supportive. For diagnosis and treatment, patients should be referred to a specialized centre.

Introduction

Physiology of the Oxidative Phosphorylation

The condensation of energy in the form of ATP by mitochondria is a stepwise process, of which the oxidative phosphorylation (OXPHOS) constitutes the final step. The metabolic pathways preceding the oxidative phosphorylation are fatty acid oxidation, glycolysis, pyruvate dehydrogenase and Krebs cycle. During the aerobic conversion of substrates, such as glucose and fatty acids, into ATP, the formation of the reduction equivalents NADH and $FADH_2$ takes place in the tricarboxylic acid cycle and the beta-oxidation. These reduction equivalents are oxidized by the respiratory chain complexes I and II, respectively. The electrons that are released during this conversion flow through the electron transport chain via coenzyme Q10 and cytochrome c and finally to molecular oxygen, which results in the formation of water. These subsequent conversions are catalyzed by the respiratory chain enzymes complex I, II, III and IV. The oxidation–reduction reactions are accompanied by the pumping of protons from the mitochondrial matrix to the cellular environment by complex I, III and IV. This results in a proton gradient (and membrane potential) over the inner mitochondrial membrane. This proton gradient is used by complex V (ATP synthase) to convert ADP and P_i into ATP. This results in an increase in the ATP/ADP ratio within the mitochondrial matrix, which is balanced by the export of ATP by the adenine nucleotide transporter (ANT), which in turn is accompanied by the import of equimolar amounts ADP.

Mitochondrial Function

The proteins that make up the OXPHOS, as well as the proteins and RNA molecules necessary for proper production, assembly, and functioning of the OXPHOS, are encoded by hundreds of genes distributed over the nuclear DNA (nDNA) and mitochondrial DNA (mtDNA). The mtDNA encodes 37 genes, 22 code for tRNAs, 2 for rRNAs and 13 code for subunits of the OXPHOS complexes I, III, IV and V. Mitochondria are not self-supporting entities, but require imported nDNA-encoded proteins and other imported molecules in order to function properly. In addition to the OXHPOS genes, the mtDNA also encodes the RNA molecules required for the translation of these mtDNA-encoded OXPHOS genes. The mtDNA encoded ribosomal RNAs, together with nuclear encoded ribosomal proteins, form mitoribosomes. The mtDNA encoded tRNAs are charged with amino acids by their corresponding (nDNA-encoded) aminoacyl tRNA synthases. The mitoribosomes and charged tRNAs, with the help of nuclear encoded translation initiation and elongation factors, synthesize the 13 polypeptides of the OXPHOS system encoded by the mtDNA. Replication of mtDNA, under the control of nuclear DNA-encoded products, involves the unwinding of the double-stranded mtDNA and the polymerization of new mtDNA strands. Factors involved include polymerase gamma (POLG), the helicase Twinkle (C10orf2 or TWNK), single stranded binding protein 1 (SSBP1) and several other proteins.

Mitochondrial Dysfunction

Mitochondrial dysfunction can be a result of a primary defect in the OXPHOS system or a defect in the regulation, organisation or maintenance of mitochondria, caused by a mutation in the nDNA or mtDNA. Secondary causes of mitochondrial dysfunction include aging, cellular stress and inactivity. Also other inherited metabolic diseases (e.g. creatine biosynthesis defects and organic acidurias) can cause secondary mitochondrial dysfunction. As this chapter is about isolated mitochondrial complex deficiencies, we will focus on primary mitochondrial dysfunction. The incidence of primary mitochondrial dysfunction, based on an OXPHOS defects is over 1:5000 of all live births. Mutations in the mtDNA genes encoding structural components of the OXPHOS enzymes theoretically cause isolated deficiencies of the complexes that contain these mtDNA-encoded subunits, complex I, III, IV and V. A mutation in one of the mtDNA-encoded tRNAs or rRNAs causes a combined deficiency of the complexes that contain mtDNA-encoded subunits. Mutations in nuclear genes encoding proteins involved in the OXPHOS system may cause single or multi-complex deficiencies.

Clinical Signs and Symptoms

Mitochondrial dysfunction causes a wide variety of symptoms, in many different organ systems. The disease course is often progressive, although the rate of deterioration is highly variable between different patients. The onset of symptoms can be at any age. The organs requiring the most energy, such

as the brain, retina, heart, kidney and skeletal muscle, are most commonly and severely affected. A mitochondrial disease should therefore be suspected in patients with progressive multisystem involvement, although mitochondrial disorders may present with *'Any symptom of any organ at any age'*. In general, symptoms present in mitochondrial disorders can also be seen in a variety of other diseases. Mitochondrial disorders should be first and foremost considered in the differential diagnosis of patients with signs and symptoms including combinations of encephalopathy and hepatopathy, myoclonic epilepsy, developmental regression, stroke-like episodes, ophthalmoplegia, optic nerve atrophy, retinal degeneration, early onset hearing loss and ataxia.

Approach to Diagnosis

Because of the clinical and genetic heterogeneity of mitochondrial diseases, there is no single diagnostic test. Instead, a range of multimodality testing needs to be performed in order to achieve a precise diagnosis. Currently, exome- or genome sequencing is often used in order to establish a molecular diagnosis. However, in many cases the biochemical examination of tissue specimens could be required, either to obtain biochemical information to guide the analysis of exome/genome data or to validate the possible pathogenicity of genetic variants of unknown clinical significance. When collecting tissue samples for functional/biochemical diagnostic tests, as a rule, the patient under investigation should not be on vitamin therapy, in order to avoid masking of possible enzyme deficiencies.

Metabolic Investigations

Although lactic acidosis is generally thought of as a cardinal feature of mitochondrial disease, plasma lactate might also be normal or only mildly elevated in patients with mitochondrial dysfunction. Post-exercise lactates are more consistently elevated, and the presence of raised alanine levels in the plasma amino acid profile is suggestive of intermittent lactic acidosis. Creatine kinase is often normal or only mildly elevated in patients with mitochondrial myopathies.

Imaging

Magnetic resonance imaging (MRI) brain is normal in many patients with mitochondrial disease, particularly in those patients with a predominantly neuromuscular clinical presentation. However, MRI can be very helpful in the differential diagnosis of patients with mitochondrial encephalomyopathies. Patients with MELAS syndrome may have parietooccipital lesions (not confined to vascular territories) during acute episodes, which subsequently resolve. Patients with Leigh syndrome present bilateral symmetrical lesions involving basal ganglia structures and brainstem nuclei. These lesions appear hyperintense on T2-weighted or Fluid-attenuated inversion recovery (FLAIR) sequences.

Neurophysiology

Electromyography reveals myopathy in approximately 50% of patients with mitochondrial disorders. Peripheral neuropathy is increasingly recognized in adults with mitochondrial diseases; a recent study showed evidence of axonal sensorimotor polyneuropathy in 36% of patients.

Muscle Histology

Muscle histology is frequently abnormal in patients presenting with mitochondrial disease. The morphological hallmarks of mitochondrial disease are ragged-red fibers (RRF), best observed in the modified Gomori trichrome stain and cytochrome *c* oxidase (COX) negative fibres. RRF often show increased mitochondrial numbers, with marked subsarcolemmal accumulation of mitochondria. COX-negative fibres are most easily demonstrated using the combined COX-SDH stain, in which they appear blue. The presence of small numbers of RRF and COX-negative fibres is normal in elderly individuals; for example, up to one RRF is normal in adults up to 40 years of age, while up to five RRF may be normal above 60 years of age. Electron microscopy may reveal increased mitochondrial numbers or size, abnormal morphology of cristae, such as whorling or electron-dense crystalline inclusions.

Muscle Biochemistry

For most biochemical determinations in tissue biopsy material one should ask the diagnostic centre for information about specific requirements as to the practice of collecting and transporting material. Especially in the case of enzyme analysis in tissues or cells, one must consult the diagnostic laboratory in advance about the conditions for removal, preparation, storage (usually at −70 °C) and transport of the specimens. If freshly collected tissue needs to be studied, samples have to be collected in a special, ice-cold but not frozen buffer and immediately transported to the laboratory. The biochemical tests of mitochondrial flux measurements, such as oxygen consumption, substrate oxidation and ATP production should be performed within 2 h of collection. Frozen tissue samples are suitable for the analysis of individual mitochondrial enzymes, and histochemical tests, and can be stored for many years.

The physician should inform the laboratory about the clinical findings to ensure an adequate analysis and to aid data interpretation. It is important to discuss which type of tissue or cell is preferable in each case, thereby causing the patient as little inconvenience as possible. Tissue-specific expression of mitochondrial deficiencies renders fibroblasts and lymphocytes less universally appropriate than skeletal muscle, although fibroblast analysis does have an added diagnostic value when combined with a muscle sample

examination and it is surprising how often mitochondrial abnormalities are evident in cells cultured in the laboratory.

In the case of unexpected death, tissue, blood and urine specimens should be collected as soon as possible after death. They should be snap frozen (not fixed) immediately after collection using liquid nitrogen, and stored for possible additional studies. For enzymatic purposes tissues must be removed within 1–2 h after death and should be frozen immediately in liquid nitrogen. Skin biopsies can be performed as late as 48 h after death, and must be collected at room temperature in cell culture medium, after which the biopsy can be transported at room temperature to the cell culture laboratory.

Because few reference values are generally available for neonates, it is recommended to perform a muscle biopsy beyond the first month of life, unless a life-threatening situation exists.

Genetic Testing

For most patients initial genetic testing should be directed towards the mitochondrial genome. Patients with suspected MIDD or MELAS should be screened for the common m.3243A>G mtDNA mutation in the *MT-TL1* gene, and those with suspected MERRF for the m.8344 mutation in *MT-TK*. Patients with LHON have one of three common mtDNA mutations in complex I subunits, while those with NARP usually have a mutation in the ATP6 subunit of complex V (most commonly m.8993T>G/C). These mutations are usually present in DNA extracted from blood or urinary epithelial cells, so a muscle biopsy is often not needed to secure a diagnosis for these syndromes. Large-scale mtDNA rearrangements are typically absent in the blood after the age of 20 years, and so a muscle sample is needed for genetic diagnosis of patients with progressive external ophthalmoplegia (PEO). Patients with Kearns–Sayre syndrome (KSS) typically present at an earlier age than those with isolated PEO, and in these patients screening for mtDNA deletions can be performed in blood or urinary epithelial cells. If this testing is negative, a muscle biopsy is indicated for further genetic (mtDNA) investigations. Sequence analysis of muscle DNA is needed to diagnose other mtDNA point mutations.

Some nuclear-encoded mitochondrial syndromes are associated with specific gene defects. If one of these syndromes is clinically suspected, then a sequence analysis of the relevant gene may be the appropriate first-line test, for example *SURF1* in classical Leigh syndrome with hypertrichosis, bypassing the need for muscle biopsy. Although in these cases, exome sequencing will most probably also result in the identification of the SURF1 defect, this approach does have a small chance of unsolicited genetic findings, and therefore specific gene sequencing is preferred over exome sequencing in the case of a strong clinical suspicion for such a specific gene defect. Patients with multiple mtDNA deletions in muscle may have mutations in one of 11 genes, which may be screened simultaneously using a next-generation sequencing gene panel approach. If a genetic diagnosis has not been achieved after screening the mtDNA for large-scale rearrangements and point mutations (using long-range PCR and sequence analysis respectively) whole exome sequence analysis is the most efficient method for identifying the causative nuclear gene defect. However, functional testing will still be needed in several situations, for example to verify the pathogenicity of genetic variants identified by sequencing.

Scoring Systems

Several scoring systems have been proposed to help in the diagnosis of mitochondrial disease. However, these tend to be complicated and cumbersome to use and may just indicate the relative likelihood of a mitochondrial disorder being present, rather than definitively establishing a diagnosis. Such scoring systems are likely to play a minor role in the future as genetic diagnosis becomes more widespread with the use of increasingly sophisticated diagnostic tools such as whole exome and whole genome sequencing. Besides a diagnostic tool, scoring systems are useful tools for evaluation of the disease course.

Metabolic Pathway

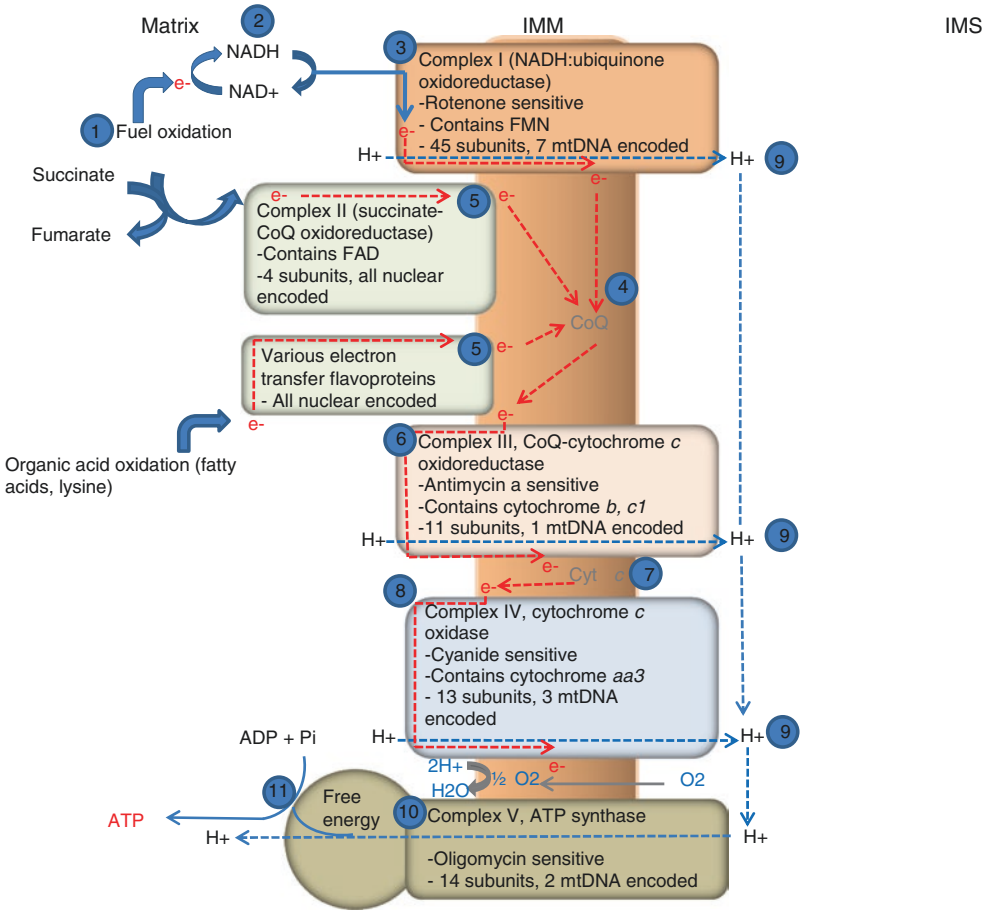

Fig. 44.1 Oxidative phosphorylation (OXPHOS) system in mammalian mitochondria. Electrons (e^-) from carbon oxidations (step 1 and red dotted lines) are transferred via NADH (step 2) into OXPHOS complex I (step 3), which is embedded in the inner mitochondrial membrane (IMM), then transported to coenzyme Q (CoQ) (step 4). Some electrons from organic-acid oxidations are transferred via other flavin-containing enzyme complexes (step 5) directly to CoQ. CoQ delivers electrons via complex III (step 6) and cytochrome c (Cyt *c*) to the final electron acceptor complex IV (step 8). Here, oxygen is reduced to water. The electrons lose free energy at each transfer step, and in complexes I, III and IV. The energy is harnessed and coupled to the movement of H^+ (step 9 and blue dashed lines) from the mitochondrial matrix to the intermembrane space (IMS). The proton-gradient thus generated is used for the production of ATP by complex V (steps 10 and 11). Except for complex II, all complexes contain some proteins encoded by the mitochondrial genome and others encoded by the nuclear genome. The number of subunits for each complex is indicated (FMN, flavin mononucleotide; mt, mitochondrial)

Signs and Symptoms

Table 44.1 Mitochondrial complex I subunit deficiency (NDUFV1)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	**Cardiomyopathy, hypertrophic**	+	+	+	+	
CNS	**Ataxia**	+	+	+	+	
	Basal ganglia abnormalities (MRI)	+	+	+	+	
	Brain stem lesions (MRI)					
	Encephalopathy	+	+	+	+	
	Leigh syndrome	+	+	+		
	Microcephaly	+	+	+	+	
	Regression, psychomotor	+	+	+	+	
Eye	**Ophthalmoplegia**		+	+	+	
Metabolic	Lactic acidosis	+	+	+	+	
Other	Failure to thrive	+	+	+	+	
Laboratory findings	Decreased complexI activity	↓	↓	↓	↓	
	Lactate (serum)	↑	↑	↑	↑

Diagnostic Flowchart

A proposed flowchart for the diagnosis of mitochondrial diseases is presented in Fig. 44.2. See also Chap. 45.

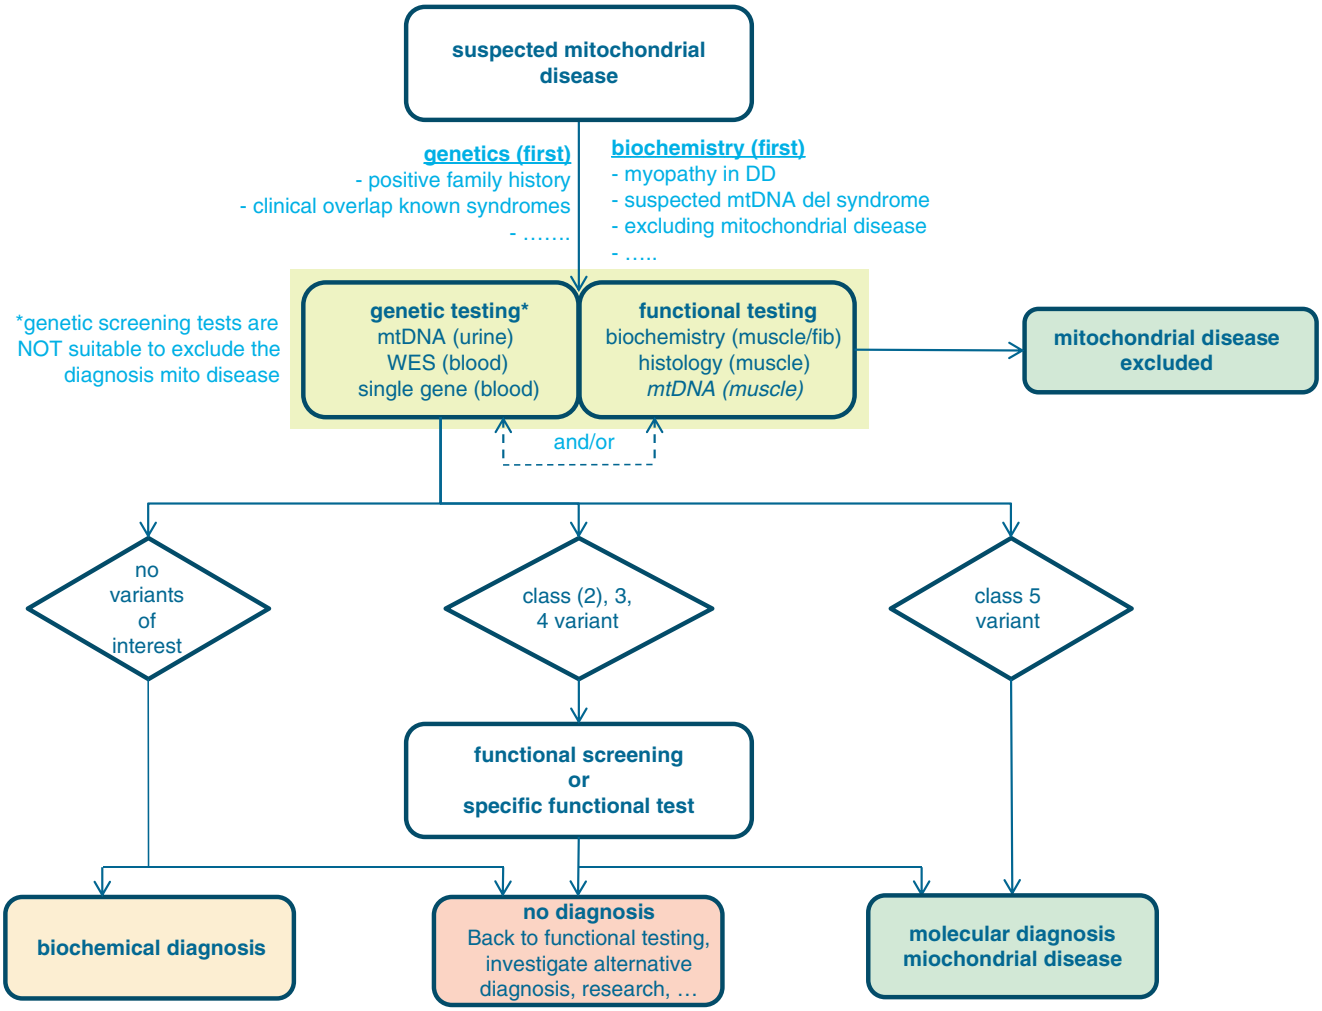

Fig. 44.2 Flowchart for the diagnosis of mitochondrial diseases

Specimen Collection

See Chap. 45.

Prenatal Diagnosis

See Chap. 45.

Treatment

Sodium valproate should never be used in patients with *POLG*-related mitochondrial disease. Certain drugs (e.g. propofol, midazolam, barbiturates) may have negative effects with the prolonged use, thus should be avoided. Overall the usual standards of good clinical practice prevail when prescribing any drug irrespective of the drug's mitochondrial toxicity potential or profile.

For more information on treatment of mitochondrial disorders, see Chap. 45.

Experimental Treatment

Many novel approaches to treating mitochondrial disorders are currently under investigation, in cell models and in preclinical trials. These include pharmacological stimulators of mitochondrial biogenesis (such as bezafibrate, resveratrol and 5-aminoimidazole-4-carboxamide ribonucleoside), novel antioxidants, modifiers of mitochondrial dynamics, nucleoside replacement and gene therapy. Current trials are registered in clinicaltrials.gov.

Summary

Mitochondria are cellular organelles essential for ATP production and for a variety of metabolic pathways. They contain many copies of a small circular genome, which codes for 13 essential components of oxidative phosphorylation system, oxidative phosphorylation system (OXPHOS) and the RNAs needed for their synthesis. This mitochondrial DNA (mtDNA) requires a unique and specialized gene expression system for its replication, transcription and translation involving 200–300 nuclear-encoded gene-products. Therefore, mitochondrial function depends on the integration of few critical mtDNA-encoded factors together with many nuclear factors. Owing to its limited coding capacity, disorders of mitochondrial gene expression typically affect one or more enzymes of the OXPHOS system, but because of the central role of energy metabolism, the wider metabolic functions of mitochondria and tissue specific metabolic wiring, these diseases present with, and progress to a plethora of clinical manifestations.

Mitochondrial disorders form one of the largest groups of metabolic disorders with a birth prevalence of at least one in 5000. Within this group, disorders of mtDNA replication, transcription and translation form the largest category in which the OXPHOS system is affected, and these can stem from mutations in either nuclear or mitochondrial DNA. The most severe cases are fatal and usually present at, or shortly after, birth and involve multiple organ systems, although tissue-specificity is often observed and in these cases the most affected organs are the brain, skeletal muscle, heart and liver.

Whole exome/genome sequencing (WES/WGS) has in the past decade greatly improved disease diagnosis. But, given the complexity of the mitochondrial genetics and biochemistry, data from clinical phenotype, family history, imaging and laboratory findings need to be integrated to guide the diagnosis, including the best strategy for downstream gene analysis (WES vs. a more restricted mtDNA sequence or gene panel based analysis) and its interpretation. Because with very few exceptions there are no cures or effective treatments, patient care chiefly involves symptom management and the provision of genetic counselling. For diagnosis and care, patients should wherever possible be referred to a specialized centre.

Introduction

The Mitochondrial Genome and OXPHOS

Human mitochondrial DNA (mtDNA) is a small circular molecule of 16,569 nucleotide pairs (Andrews et al., 1999). It encodes 13 critical components of the oxidative phosphorylation system (OXPHOS) that converts the energy stored in food into a usable form of cellular energy, ATP (see Chap. 44). Hence, defects that directly affect mtDNA or its maintenance or expression impair the OXPHOS system, thus restricting cellular energy production. The two strands of mtDNA are transcribed almost in their entirety and processed to yield 11 messenger, 22 transfer and two ribosomal RNAs (Ojala et al., 1981). The ribosomal RNAs and tRNA(Val) are assembled into mitoribosomes with some 80 nuclear-encoded proteins (Amunts et al., 2015). This apparatus translates the 11 mRNAs into 13 proteins with the aid of the mitochondrial transfer RNAs that are charged with amino acids by tRNA synthetases and a range of ancillary proteins. Thus, the protein parts of the mitochondrial protein synthesis machinery are nuclear encoded, whereas the RNA elements derive from mtDNA. Consequently, mitochondrial translation disorders can be of dual genetic origin.

In contrast to nuclear genes, each consisting of one maternal and one paternal allele, mtDNA is maternally inherited and present with hundreds to thousands of copies in the cell. Thus, family history can guide to a nuclear or mitochondrial origin of the disease. As for the primary mtDNA mutations, they usually affect some but not all the mtDNA molecules, a situation known as heteroplasmy (Holt et al., 1988). Most of the mutations are recessive, and thus the phenotype manifests only when the percentage of the mutant molecules is above a certain threshold, which carries both for the mutation and tissue affected. Moreover, the levels of heteroplasmy (or mutant/wt ratio's) can be highly variable even within the same family, in part because a genetic bottleneck during germline development resets the ratio, and further segregation can occur throughout life. Although variation in heteroplasmy undoubtedly accounts for some of the considerable variation in disease penetrance, severity and progression, there are equally diverse clinical outcomes in diseases resulting from defects in nuclear-encoded factors required for mtDNA maintenance and expression, despite them following simple Mendelian rules.

Replication of Mitochondrial DNA

There is considerable debate about the mechanisms of mtDNA replication (Pohjoismaki et al., 2018), yet overall agreement about the role of many of the proteins required for this process. These include a number of important disease genes, such as the mitochondrial DNA polymerase (POLG) and helicase (Twinkle) that were discovered almost 20 years ago (Van Goethem et al., 2001; Spelbrink et al., 2001). The mutant proteins often cause replication to stall or slow replication, which can result in multiple deleted molecules that accumulate over time or loss of mtDNA in the most severe cases. New defects of mtDNA replication continue to come to light with an RNA processing enzyme (RNASEH1) (Bugiardini et al., 2017) and a DNA topology-modifying

enzyme (TOP3A) (Martin et al., 2018) being two of the most recent. Clinically, defects in mtDNA replication proteins produce features characteristic of mitochondrial disorders and overlap with those resulting from primary mtDNA mutations. Whilst the mitochondria share a number of DNA repair proteins with the nucleus, to date none of these have been unequivocally linked to mitochondrial disease.

Nucleotide Metabolism

Deoxynucleotide triphosphates (dNTPs) are the building blocks of DNA. All four (A, G, C and T) are required to be in a sufficient amount and appropriately balanced, as either a surplus or a deficiency of nucleotide precursors is detrimental to mtDNA integrity, and thus can cause disease. Both anabolic and catabolic enzymes participate in the maintenance of the mitochondrial dNTP pools, and these are localized in mitochondria as well as in the cytosol. The first enzyme deficiency of this class found to cause mitochondrial disease was the catabolic and cytosolic enzyme thymidine phosphorylase (TP) (Nishino et al., 1999). Loss-of function of TP greatly increases plasma levels of thymidine and deoxyuridine resulting in high dTTP levels, depression of mitochondrial dCTP levels and mtDNA deletions and depletion. Other diseases were later associated with impaired nucleotide homeostasis, including defects in the mitochondrial salvage pathways enzymes, deoxyguanosine kinase and thymidine kinase and a component of the cytosolic ribonucleotide reductase, p53r2, which supports the de novo synthesis of deoxynucleotides in non-dividing cells. Complicating matters, deoxynucleotide homeostatic disorders are not restricted to anabolic and catabolic enzymes. The mitochondrial inner membrane protein MPV17 is thought to function as some sort of channel, and MPV17 deficiency disturbs mitochondrial dNTP levels, especially guanosine (Dalla Rosa et al., 2016). Similarly, mitochondrial nucleotide transporters are another potential cause of mtDNA disorders, although the only one identified to date is the ATP/ADP carrier, ANT1. Clinically and biochemically, the end points are similar in that MPV17 deficiency closely resembles defects in the guanine salvage pathway enzyme, DGUOK. Importantly, defects in the genes that impact dNTP levels can cause either mtDNA depletion or multiple deletions, with the former associated with severe tissue-specific infantile forms, whereas the latter results in milder and adult-onset phenotypes.

Transcription and RNA Processing

Mitochondrial transcription involves a core machinery of four factors, the RNA polymerase, POLRMT, two transcription factors, TFAM and TFB2M and an elongation factor, TEFM. Both strands of mtDNA are transcribed almost in their entirety to yield two polycistronic transcripts in which the rRNAs and most of the protein-coding RNAs are flanked by tRNAs. This gene organization enables two enzymes that cut either side of the tRNA genes, RNase P and RNase Z, to process the polycistronic RNAs to individual tRNAs, mRNAs and rRNAs. Several conserved rRNA nucleotides are further modified by a number of enzymes (mostly RNA methyltranferases), prior or concurrent with assembly of the mitoribosome and mt-tRNA(Val), in a complex process of marrying scores of proteins with RNAs containing intricate and extensive secondary structure requiring a number of assembly factors (approximately 15 are currently known) (D'Souza & Minczuk, 2018). tRNAs are also heavily modified at conserved positions by various enzymes, and undergo CCA addition at their 3'-end by the CCA-adding tRNA-nucleotidyltransferase (TRNT1). The nine monocistronic and two bicistronic mRNAs, both rRNAs and mt-tRNAs can be oligo- or polyadenylated (for further details see Fig. 45.1). Polyadenylation is mediated principally by polyA polymerase and this enzyme is one of the few factors in this category to have been identified as a ´disease gene´.

Translation

In striking contrast to transcription and RNA processing, defects in genes contributing to mitochondrial protein synthesis form the largest class of mitochondrial diseases. All of the 22 tRNA genes in the mtDNA have been linked to disease. The tRNALeu(UUR) gene alone has 12 assigned pathological variants, one of which (m.3243G) is the most frequent type of mtDNA disorder. The m.3243G point mutation produces a wide range of signs and symptoms, including two quite distinct clinical syndromes (de Laat et al., 2012; van den Ouweland et al., 1994; Goto et al., 1990). Collectively, mutations in the aminoacyl-tRNA synthetase genes (whose protein products add the appropriate amino acid to the tRNAs) are another substantial cause of mitochondrial disease, that often manifest as fatal infantile forms (Gonzalez-Serrano et al., 2019). Pathological variants in mitochondrial translation activators, recycling and elongation factors have also been identified and characterized in some detail. Mutations in the structural components of the mitoribosome are relatively rare, with only about 10% of its constituent proteins having so far been linked to disease. Likewise, defects in the mitochondrial ribosomal RNAs are an extremely rare cause of disease. An important exception is the m.1555G variant that in most cases is benign, but carriers are susceptible to antibiotic induced hearing loss, because of the strong homology between mitochondrial and bacterial ribosomes.

Clinical Signs and Symptoms

Disorders of replication, transcription and translation of mtDNA can be of dual genetic origin, being caused either by maternally inherited mtDNA mutations or nuclear gene

mutations that follow Mendelian rules. They all ultimately affect the production or quality of the 13 proteins encoded by mtDNA and that are essential for OXPHOS. Disease symptoms for all the disorders described in this chapter and Chap. 44 (oxidative phosphorylation disorders) therefore have many common denominators and often overlap. Nonetheless, and as a general rule for mitochondrial OXPHOS disorders, the clinical presentations are highly variable, ranging from very severe neonatal disease that is progressive and rapidly results in a fatal multisystem failure, to the onset of relatively mild muscle disease (e.g. ptosis and CPEO) in late adulthood. The wide spectrum of symptoms and severity in subjects with mtDNA mutants is partly explained by heteroplasmy (differences in the proportion of mutant and normal mtDNA) varying across tissues and with time. However, similar clinical variation and disease progression is also seen in secondary mtDNA disorders caused by defects in nuclear genes, such as Twinkle, p53R2 and Mpv17, because they too compromise mtDNA integrity. Whatever the causal mutations, disease penetrance, development and prognosis also can be influenced by environmental factors and additional gene modifiers, including common mtDNA variants that define different haplogroups.

Nuclear gene mutations, even when they occur in what could be considered the same pathway, show a diverse spectrum of disease manifestation. For example, defective mitochondrial aminoacyl-tRNA synthetases often result in encephalopathy, but in some cases specifically affect the kidney or the heart (Goto et al., 1990). In addition, different mutations in the same gene can cause distinct syndromes. In part these are explained by different modes of inheritance, mutation position and severity, etc., but the variable tissue involvement is not always straightforward to explain. For example, autosomal dominant mutations in the mtDNA helicase Twinkle typically cause a relatively mild late-onset muscular phenotype with progressive external ophthalmoplegia, ptosis and the accumulation of multiple mtDNA deletions in muscle as distinguishing features. Recessive mutations can cause a severe early-onset disease with liver mtDNA depletion, or a less severe mtDNA depletion syndrome largely restricted to the brain. Lastly, different recessive Twinkle mutations have been described in Perrault syndrome with neurological involvement. This may reflect Twinkle (and many other proteins) having multiple functions (e.g. (Hensen et al., 2019)), which highlights the need to carry out further detailed functional studies.

Thus, disorders of mtDNA maintenance and expression, like other mitochondrial diseases can result in a highly variable spectrum of symptoms and organ/tissue involvement. The organs requiring the most energy, such as the brain, heart, skeletal muscle, senses and endocrine systems are most commonly and severely affected, and show a progressive decline in function. Mitochondrial disease should therefore be suspected in patients with progressive multisystem involvement. Signs and symptoms where mitochondrial disorders should be first and foremost considered during differential diagnosis include combinations of encephalopathy and hepatopathy, myoclonic epilepsy, developmental regression, stroke-like episodes, ophthalmoplegia and ptosis, optic nerve atrophy, retinal degeneration, early onset hearing loss and ataxia.

In many patients, diagnosis cannot be made on clinical signs and symptoms alone. A more structured approach is needed, including blood and/or cerebrospinal fluid (CSF) lactate, pyruvate and alanine concentrations, neuroimaging, cardiac evaluation and muscle biopsy for histological and histochemical evidence of mitochondrial disease, biochemistry and molecular genetic testing. Family history is often important, especially when a pedigree is sufficiently extensive to indicate maternal inheritance, as this is the identifier of a primary mtDNA mutation. In any case, the investigation of most suspected mitochondrial disorders begins with screening the mtDNA as it is so small; however, increasingly whole genome/exome sequencing is being performed in parallel as costs continue to fall. In this case it is important to take into account that maternal relatives can again present with highly variable phenotypes due to variable heteroplasmy and disease indicators can skip a generation.

Genotypic Confirmation of Mitochondrial Disorders

Some of the disorders presented in this chapter have characteristic clinical and biochemical phenotypes that should inform genotyping (see diagnostic flow diagram, Fig. 45.2). For example, the tRNA(Lys) 8344A>G mtDNA mutation is almost invariably associated with myoclonic epilepsy with ragged red fibers (MERRF). Likewise, patients presenting with mitochondrial neurogastrointestinal encephalopathy (MNGIE) most often have a mutation in the thymidine phosphorylase gene (TYMP). Nevertheless, as set out in the nomenclature table and discussed earlier in the introduction, different gene mutations in nuclear or mitochondrial DNA can produce similar symptoms. Since the costs of whole mitochondrial genome and whole exome/genome sequencing (WES/WGS) have fallen dramatically in recent years it is frequently cost effective to take this approach, rather than targeted gene sequencing, especially if the symptoms are compatible with many forms of mitochondrial disease. The small size of the mitochondrial genome means determining its sequence and integrity is an almost universal starting point for suspected mitochondrial diseases, particularly if the family history is compatible with maternal inheritance. Some specialist centres have developed PCR/sequencing arrays that screen the mitochondrial genome and around 100 nuclear genes linked to mitochondrial disorders, which provides an intermediate between sequencing one or a few targeted genes and WES/WGS and should have a lower false negative rate than the latter.

Nomenclature

Fig. 45.1 Pathways and proteins involved in mitochondrial DNA replication, transcription and translation. Mitochondrial DNA (mtDNA) is a small double-stranded circular molecule that has a relatively simple machinery for its replication (***1***). Both strands serve as template for the transcription machinery (***2***) that initiates at the H-strand promoter (HSP) or the L-strand promoter (LSP), to give two large primary polycistronic transcripts here called 'HSP derived polycistronic' and 'LSP derived polycistronic' transcript. MtDNA replication requires deoxyribonucleotides provided by interconnected de novo and salvage pathways (***3***). Primary transcripts are interspersed with tRNA transcripts represented here by the standard tRNA cloverleaf structure. Endonucleolytic cleavage of the tRNAs at both ends by RNaseP and RNaseZ yields the two pre ribosomal RNAs (rRNA, 12S and 16S), pre tRNAs and pre mRNAs (***4***). These are all further processed (***5***) and in particular both rRNAs and all tRNAs are further modified at specific nucleoside positions, whilst all RNA types are also oligo/poly adenylated. Ribosomal RNAs together with mt tRNA(Val) (not indicated) are assembled into mature ribosomes (***6***) that include 82 nuclear encoded mitoribosomal proteins. This process involves approximately 15 so far identified additional 'assembly' factors, some of which have been associated with mitochondrial disease. The tRNAs after extensive modification are matured by 3′CCA addition (not indicated) and are now ready to be aminoacylated by 19 aminoacyl-tRNA synthethases (***7***), all of which have been associated with mitochondrial disease. There is no dedicated enzyme to charge the glutamine (Q)-tRNA but instead it is charged with glutamate that is converted to glutamine by the trimeric Glu-tRNA (Gln) amidotransferase complex consisting of GATA (QRSL1), GATB and GATC subunits. All these various pathways come together so that the 11 mitochondrial mRNAs that direct the synthesis of 13 essential subunits of four of the five oxidative phosphorylation complexes can be translated by the dedicated mitochondrial ribosomes and charged tRNAs (as indicated, (***8***)). A considerable number of additional nuclear encoded factors are involved in this process, for example to recycle tRNAs, and to assist in the initiation, elongation and termination of protein synthesis. Mitochondria also have a machinery to degrade dysfunctional RNA as well as long non-coding RNAs that are mostly derived from LSP initiated transcription. In total almost 200 nuclear-encoded mitochondrial proteins are here indicated to be involved in the process of mtDNA maintenance and expression, of which some 80 (here indicated in red) have so far been associated with mitochondrial disease. In addition, all mitochondrial tRNA genes have been associated with disease (indicated here with a red dot on the tRNAs of the two polycistronic transcripts), whilst one rRNA mutation [m. 1555A>G in 12S (MT-RNR1); also indicated with a red dot on mtDNA] is known principally for its association with aminoglycoside-induced hearing loss

Hematological	Coagulopathy	++	++	n	n	
Laboratory findings	Multiple oxidative phosphorylation enzymes	↓	↓	↓	↓	↓

Table 45.38 Mitochondrial RNA-processing endoribonuclease deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Musculoskeletal	Cartilage hypoplasia	+++	+++	+++	+++	+++
	Chondrodysplasia	+++	+++	+++	+++	+++
Hematological	Lymphopenia	+	+	+	±	±

Notes: Although some reports link this RNA to mtDNA replication, one study found a maximum of one molecule MRP per cell to reside in mitochondria, with the vast majority localizing to the nucleoli (PMID: 1377982). Therefore, it is not certain this is a mitochondrial disease, and the clinical features are not a good match for established mtDNA disorders.

Table 45.39 2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Diagnostic Flowchart

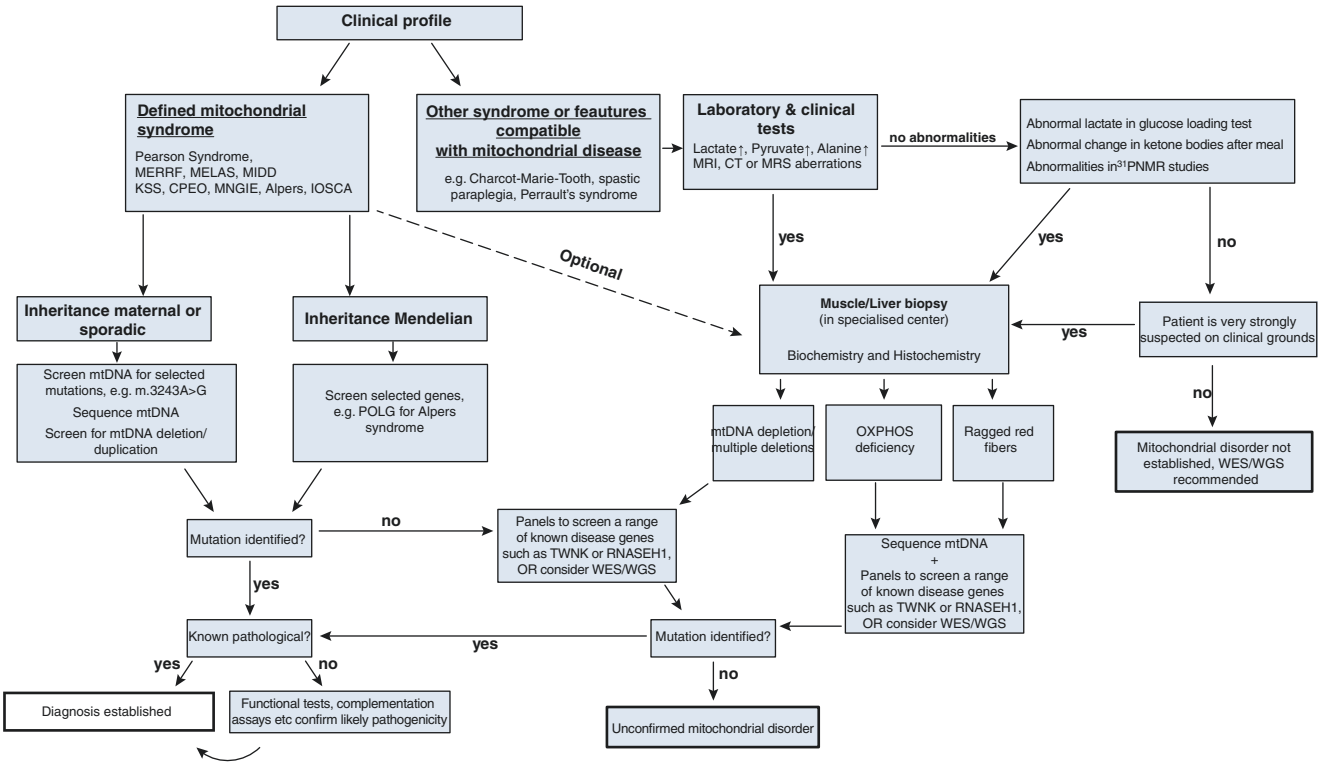

Fig. 45.2 Common practice diagnostic flowchart for mitochondrial oxidative phosphorylation defects caused by defects in replication, transcription or translation of mtDNA

Specimen Collection

The remainder of this Chapter reflects similar information to that found in Chap. 44, since both Chaps. 44 and 45 deal with mitochondrial diseases directly or indirectly affecting the oxidative phosphorylation system.

In order to reach a definite diagnosis, biochemical examination of tissue specimens is usually required, with the exception of a small number of well-defined mitochondrial syndromes that can be tested genetically. As a rule, the patient under investigation should not be on vitamin therapy, in order to avoid masking of possible enzyme deficiencies.

For most biochemical determinations one should ask the diagnostic centre for information about specific requirements as to the practice of collecting and transporting material. Especially in the case of enzyme analysis in tissues or cells, one must consult the diagnostic laboratory in advance about the conditions for removal, preparation, storage (usually at −70 °C) and transport of the specimens. If fresh tissue is to be studied, samples have to be collected in a special, ice-cold but not frozen buffer and immediately transported to the laboratory. The biochemical tests of mitochondrial flux measurements, such as oxygen consumption, substrate oxidation and ATP production should be performed within 2 h of collection. Frozen tissue samples are suitable for the analysis of individual mitochondrial enzymes and histochemical tests.

The physician should inform the laboratory about the clinical findings to ensure an adequate analysis and to aid data interpretation. It is important to discuss which type of tissue or cell is preferable in each case, thereby causing the patient as little inconvenience as possible. Tissue-specific expression of mitochondrial deficiencies renders fibroblasts and lymphocytes less universally appropriate than skeletal muscle, although fibroblast analysis does have an added diagnostic value when combined with a muscle sample examination, and it is surprising how often mitochondrial abnormalities are evident in cells cultured in the laboratory [e.g (Bugiardini et al. 2019)].

In the case of unexpected death, tissue, blood and urine specimens should be collected as soon as possible after death. They should be snap frozen (not fixed) immediately after collection using liquid nitrogen, and stored for possible additional studies. For enzymatic purposes tissues must be removed within 1–2 h after death and should be frozen immediately in liquid nitrogen. Skin biopsies can be performed as late as 48 h after death, and must be collected at room temperature in cell culture medium, after which the biopsy can be transported at room temperature to the cell culture laboratory.

Because few reference values are generally available for neonates, it is recommended to perform a muscle biopsy beyond the first month of life, unless a life-threatening situation exists.

MtDNA analysis can, in principle, be performed in all types of tissues or cells available. However, heteroplasmy varies from tissue to tissue, and partial deletions of mtDNA are not usually detectable in blood. Therefore, it is recommended to perform mtDNA studies in biopsies from affected tissue (usually skeletal muscle). However, some mutations can also be tested non-invasively, such as LHON mutations in blood and the MELAS/MIDD m.3243A>G mutation in urine.

Test	Material	Storage	Pitfalls
Lactate	B, CSF, U	−20 °C	Prevent glycolysis
Pyruvate	B, CSF	−20 °C	Prevent glycolysis and LDH activity
Amino acids	S, P, U, CSF	−20 °C	–
Blood gases	B	No storage allowed	–
Creatine kinase	S	−20 °C	–
Acetoacetate	B	−20 °C	Feeding state is important
3-Hydroxybutyrate	B	−20 °C	Feeding state is important
Carnitine	S, M, L, FB	−20 °C	–
Organic acids	U	−20 °C	–

Screening	Material	Storage	Pitfalls
Amino acids	U	−70 °C	Anti epileptic drugs, antibiotic artefacts
Pyruvate dehydrogenase	M, FB, L, CV	−70 °C	
2-Oxoglutarate dehydrogenase	M, FB, L	−70 °C	
Fumarase	M, FB, L	−70 °C	
Respiratory chain enzymes	M, FB, L, CV	−70 °C	
ATPase	M, FB	−70 °C	
ATP/ ADP-translocator	M, FB, L	−70 °C	
Substrate oxidations	M, FB, FL	No storage allowed	Maintain at 0 °C
ATP production	M, FB	No storage allowed	Maintain at 0 °C
Oxygen consumption	M, FB, BrF	No storage allowed	Maintain at 0 °C
Coupling state	M, FB	No storage allowed	Maintain at 0 °C

Prenatal Diagnosis

At present prenatal diagnosis, at the enzyme level, in mitochondrial disorders can be performed in families in which the proband is suffering (or has suffered) from a complex I, complex II, succinate:cytochrome *c* oxidoreductase, complex IV or pyruvate dehydrogenase deficiency (or combinations of these enzymes), at least in our centre. A prerequisite for prenatal diagnosis at the enzyme level is that mtDNA mutations must have been excluded in the proband. In case an mtDNA mutation has been identified, preimplantation genetic diagnosis (PGD) is possible.

PGD is an IVF-based treatment that may be suitable for some women who are at risk of transmitting a mitochondrial DNA mutation to their children (Poulton et al. 2010). PGD for mtDNA disease is based on the principle that the level of mutated mitochondrial DNA can vary widely between eggs produced by a women who carries a mixture of mutated and normal mitochondrial DNA. PGD is only suitable for women who are expected to produce some eggs with low levels of mutated mitochondrial DNA.

Prenatal diagnosis at the enzyme level is preferably performed in native chorionic villi because they can be obtained earlier in pregnancy as compared with amniocytes. Moreover, it is not necessary to cultivate chorionic villi in contrast with amniocytes, thus reducing the time of the diagnostic procedure considerably. In case the investigation of chorionic villi yields no conclusive result, amniocytes can also be investigated, although in practice this is hardly ever necessary. In case causative mutations in the nuclear DNA have been identified, prenatal diagnosis is possible using conventional prenatal genetic testing for all nuclear genetic defect. Because of the expanding possibilities of molecular genetic testing of suspected mitochondrial patients, nuclear DNA-based prenatal diagnosis is expected to increase in the future. However, for those families in which it has not (yet) been possible to identify the causative genetic defect, the measurement of enzyme activities in chorionic villi provides an alternative possibility for prenatal diagnostic testing.

Treatment

In contrast to the progress in understanding biochemical and molecular aspects of mitochondrial disease, treatment is still limited. Many potentially therapeutic agents have been used to treat mitochondrial disorders, but few of these disorders have any proven effective therapy. The management of mitochondrial disease is largely supportive, therefore clinicians must have a thorough knowledge of the potential complications of mitochondrial disorders to prevent unnecessary morbidity and mortality.

Supportive Therapy

- *Central nervous system*: Seizures should be treated adequately, and in many cases respond well to conventional anticonvulsants. Valproic acid should be used with great caution, and has strong contraindication in, for example, Alpers-Huttenlocher syndrome.
- *Heart*: Timely placement of a pacemaker can be lifesaving in patients with cardiac conduction blocks. Cardiomyopathy can be treated with heart-failure therapy. Heart transplantation is controversial, but when cardiac involvement is the predominant problem, transplantation is justified.
- *Gastrointestinal:* Patients often have complaints of vomiting, diarrhea, constipation or abdominal pain related to dysmotility, which can be treated with prokinetics and/or laxatives. Because of these problems the diet can be inadequate, and for this reason patients should be referred to a dietician for evaluation. Exocrine pancreatic dysfunction requires replacement therapy with pancreatic enzymes.
- *Kidney:* Patients with proteinuria may be treated with ACE inhibitors. Renal tubular acidosis and Fanconi syndrome require therapy to readjust electrolyte balance. Patients with renal failure may also require dialysis or a renal transplant. Patients with a known mitochondrial disorder due to an mtDNA mutation should not be transplanted with a kidney from a maternal family member.
- *Endocrine:* Diabetes can be treated with oral medication, but as the disease progresses usually insulin is required. Hypothyroidism can be treated with thyroid hormone.
- *Eye:* Ptosis can be ameliorated by surgery, although the results of blepharoplasty are often transient. Congenital cataracts are also treated surgically.
- *Hearing*: Hearing aids are often necessary. When hearing problems are progressive, cochlear implants may be useful.
- *Muscular:* Aerobic exercise is useful in mitochondrial disease, improving work capacity, oxygen delivery to muscle (i.e. cardiac output), oxygen extraction and utilization by muscle and muscle energy metabolism. Sustained aerobic exercise is associated with mitochondrial proliferation (reflected by increased activity of citrate synthase) and improvement of respiratory chain activity (reflected by increased activity of COX) (Jeppesen et al. 2006). The specific questions that arise in those disorders associated with heteroplasmic mtDNA mutations are whether exercise preferentially promotes proliferation of normal mitochondria and, if not, whether proliferation of both normal mitochondria and abnormal mitochondria is beneficial. The former could increase ATP production, whereas the latter could increase production of reactive oxygen species. These questions have not yet been totally resolved but are being addressed in ongoing clinical trials.

Vitamins and Cofactors

Over the last 15 years several open-label and randomized control clinical trials for potential treatments of mitochondrial diseases have been reported or are in progress. These include trials of administering dichloroacetate (an activator of PDHc), arginine or citrulline (precursors of nitric oxide), coenzyme Q_{10} (CoQ_{10}; part of the electron transport chain and an antioxidant), idebenone (a synthetic analogue of CoQ_{10}), EPI-743 (a novel oral potent 2-electron redox cycling agent), creatine (a precursor of phosphocreatine) and combined administration (of creatine, α-lipoate, and CoQ_{10}). These trials have included patients with various mitochondrial disorders, a selected subcategory of mitochondrial disorders, or specific mitochondrial disorders (LHON, MELAS, Leigh). Trial designs varied from open-label/uncontrolled to open-label/controlled or double-blind/placebo-controlled/crossover. Primary outcomes ranged from single, clinically relevant scores to multiple measures. Eight of these trials have been well-controlled, completed trials (Glover et al. 2010). Of these only one (treatment with creatine) showed a significant change in primary outcomes, but this was not reproduced in two subsequent trials with creatine with different patients. One trial (idebenone treatment of LHON) did not show significant improvement in the primary outcome, but there was significant improvement in a subgroup of patients (Klopstock et al. 2013).

Despite the paucity of benefits found so far, well-controlled clinical trials are essential in the continuing search for more effective treatment of mitochondrial disease (Pfeffer et al. 2013), and current trials based on information gained from these prior experiences are in progress. Because of difficulties in recruiting sufficient mitochondrial disease patients and the relatively large expense of conducting such trials, advantageous strategies include crossover designs (where possible), multicentre collaboration and the selection of very few, clinically relevant, primary outcomes.

Emergency Treatment

Medication	Indication	Dose (route)
Sodium bicarbonate	Severe lactic acidosis (lactate >7 mmol/L)	(0.33 mmol/kg) × base deficit
L-arginine	Acute stroke like episode	150–500 mg/kg/day (IV)

Summary

This chapter describes gene mutations and disorders linked to mitochondrial homeostasis, dynamics, protein import, and quality control. Although clinically highly variable, we here functionally categorized these mutations as impacting on mitochondrial biogenesis, mitochondrial morphology/motility ("mitochondrial dynamics"), and mitochondrial degradation ("mitophagy"). These three processes are described in more detail in the Introduction. In addition, several other mutations that affect mitochondrial function are presented. The gene mutations discussed in this chapter are all nuclear DNA

(nDNA) mutations. Most patients with mitochondrial disorders present with a multi-system disorder. The organs requiring the most energy, such as the brain, retina, heart, kidney, and skeletal muscle, are most commonly and severely affected. Onset of disease can be at any age and the symptoms are almost always progressive. A definitive diagnosis solely based on clinical signs and symptoms is very unlikely. Whole exome/genome sequencing (WES/WGS) has greatly improved disease diagnosis and often simplified it, although in some cases has also resulted in new diagnostic challenges. Nonetheless, clinical diagnostic criteria, combined with brain imaging, metabolic, biochemical, and other functional tests are still needed. Since specific treatment options are still limited, the management of the described mitochondrial disorders is largely supportive. For diagnosis and treatment, patients should be referred to a specialized center.

Introduction

Mitochondria consist of a double membrane system, the mitochondrial outer membrane (MOM) and mitochondrial inner membrane (MIM), which envelops the mitochondrial matrix compartment. The MIM is highly folded to accommodate the many proteins and protein complexes required for mitochondrial ATP production and other functions (Bulthuis et al. 2019). Mitochondrial functioning requires about ~1500 proteins. Since the mitochondrial DNA (mtDNA) encodes only for 13 proteins the majority of mitochondrial proteins is encoded by the nuclear DNA (nDNA; Koopman et al. 2012). These nDNA-encoded proteins are synthesized in the cytosol and are imported into mitochondria by a dedicated machinery consisting of translocases of the mitochondrial outer membrane (TOM) and translocases of the mitochondrial inner membrane (TIM). This TOM/TIM system not only imports nDNA-encoded proteins, but also carries out posttranslational modifications and mediates the sorting of imported proteins to the correct mitochondrial subcompartment: MOM, MIM, matrix, or intermembrane space (IMS). In this sense (Fig. 46.1a), proper functioning of the TIM/TOM system is crucial for mitochondrial biogenesis and sustained mitochondrial functioning (Jackson et al. 2018). Inside cells, single mitochondria are motile and continuously fuse and divide. Although still incompletely understood, these "mitochondrial dynamics" are required for cell and organismal survival in allowing (Kluge et al. 2013): (1) individual mitochondria to reach distant parts of the cell (e.g., for their local functioning in neurons), (2) mixing of mitochondrial content (e.g., to exchange mtDNA or damaged biomolecules), (3) distribution of mitochondria between daughter cells during cell division, and (4) degradation of dysfunctional mitochondria (see below). Three main proteins are currently described to be involved in mitochondrial fusion: Mitofusin 1 (Mfn1), Mitofusin 2 (Mfn2), and Optic Atrophy Protein 1 (OPA1). With respect to mitochondrial fission, 6 main proteins were implicated: Dynamin-related protein 1 (Drp1/DNM1L), Dynamin 2 (Dyn2), Fission protein 1 (Fis1), Mitochondrial Elongation Factor 1 (MIEF1), Mitochondrial Elongation Factor 2 (MIEF2), and Mitochondrial fission factor (Mff). The function of mitochondrial fission/fusion proteins is interfaced with cellular regulatory pathways and redox signaling, primarily by posttranslational modifications like phosphorylation (Willems et al. 2015). As a consequence of mitochondrial dynamics, mitochondrial morphology can be highly heterogeneous within/between cells and ranges from "filamentous" (elongated) to fragmented phenotypes (Fig. 46.1b). Experimental evidence suggests that mitochondrial function and morphology are mutually dependent, giving rise to the concept of mitochondrial "morphofunction" (Bulthuis et al. 2019).

Following biogenesis, it is believed that individual mitochondria can accumulate damage during their life cycle. This, for instance, could be due to the presence of mitochondrial protein-encoding gene mutations, increased reactive oxygen species (ROS) levels, or external influences like environmental toxins or off-target drug effects (Koopman et al. 2012). As a homeostatic system, cells are equipped with a mitochondrial quality control mechanism that removes dysfunctional organelles by autophagy (Fig. 46.1c). The current evidence suggests that dysfunctional mitochondria are unable to maintain their trans-MIM inside-negative electrical potential ($\Delta\psi$), and that this inability can trigger mitochondria-specific autophagy ("mitophagy"). Depending on the extent of $\Delta\psi$ depolarization, mitochondrial dysfunction is associated with MOM rupture, reduced O_2 consumption, and blocked ATP synthesis. In the mitophagy mechanism, $\Delta\psi$ depolarization activates MOM accumulation of PTEN-induced kinase 1 (PINK1). Next, PINK recruits and activates the protein Parkin to ultimately stimulate mitochondrial recognition by the autophagy machinery (Gustaffson and Dorn 2nd 2019). In addition to this "Parkin-dependent pathway," there are also various other mechanisms to recognize and remove dysfunction mitochondria, including receptor- and lipid-mediated pathways (Yang et al. 2019).

Nomenclature

	Disorder	Alternative name(s)	Abbreviation	Gene symbol	Chromosomal localization	Inheritance	Affected protein	OMIM

All info in this table was taken from the Inborn Errors of Metabolism Knowledgebase (IEMbase; www.iembase.org) except the parts highlighted in blue, which were compiled using information from the HUGO Gene Nomenclature Committee (HGCN; www.genenames.org) and/or from Online Mendelian Inheritance in Man (OMIM; www.omim.org)

Metabolic Pathways

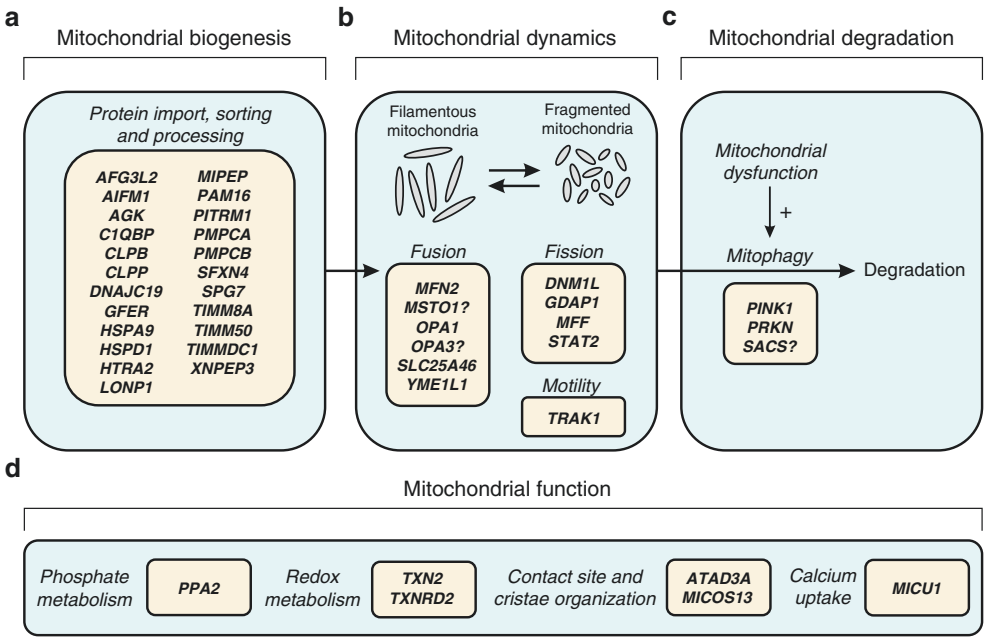

Fig. 46.1 Mechanisms involved in disorders of mitochondrial homeostasis, dynamics, protein import, and quality control. (**a**) Biogenesis of mitochondria and their sustained functioning require import of nuclear DNA-encoded proteins, sorting of these proteins to the correct mitochondrial compartment (i.e., mitochondrial outer membrane, mitochondrial intermembrane space, mitochondrial inner membrane, and mitochondrial matrix) and posttranslational processing of these proteins. (**b**) Within cells, individual mitochondria are motile and undergo continuous fusion/fission events. Proper mitochondrial dynamics is required for mitochondrial function and is mediated by a set of dedicated mitochondrial fusion, fission, and motility proteins. (**c**) When dysfunctional, mitochondria can be removed from the cell by a mitochondria-specific autophagy process ("mitophagy"). (**d**) Aberrant mitochondrial function at the level of phosphate and redox metabolism, organization of mitochondrial contact sites, mitochondrial inner membrane folds ("cristae"), and mitochondrial calcium uptake. Within this figure, gene names linked to disease causing mutations are highlighted in bold italic. Since no exhaustive functional data was available, RTN4IP1, TMEM162A, USP9X, and VCP were not included in this figure

Signs and Symptoms

Table 46.1 Peroxisomal and mitochondrial fission defect

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Abnormal gyral pattern (MRI)	+				
	Areflexia	+				
	Cerebral atorphy (MRI)		+	+		
	Delayed myelination (MRI)	+	+	+		
	Delayed psychomotor development		+	+		
	Failure to thrive	+	+	+		
	Hypotonia	+	+	+		
	Microcephaly	+	+	+		
	Neurologic decline		+	+		
	Pyramidal signs			+		
	Seizures		+	+		

Table 46.1 (continued)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Eye	Oculomtor apraxia		+			
	Optic atrophy	+	+	+	+	+
	Poor visual fixation	+				
Musculoskeletal	Muscle weakness	+				
Other	Death		+			
Laboratory findings	Lactate (P)	↑	↑	↑		
	Very-long-chain fatty acids (P)	↑

Diagnostic Flowchart

See flowchart in Chap. 44.

Specimen Collection

See Chap. 44.

Prenatal Diagnosis

Prenatal DNA testing can be offered for the nDNA mutations after confirmation of parental carriage of the mutations.

DNA Testing

If a nuclear-encoded mitochondrial syndrome is clinically suspected, then a sequence analysis of the relevant gene may be the appropriate first-line test. Although in these cases, exome sequencing will most probably also result in the identification of the defect, this approach does have a small chance of unsolicited genetic findings, and therefore specific gene sequencing is preferred over exome sequencing in the case of a strong clinical suspicion for such a specific gene defect.

Treatment

See Chap. 44.

Primary Coenzyme Q_{10} Deficiencies

47

Leonardo Salviati and Rafael Artuch

Contents

Summary

Coenzyme Q_{10}(CoQ_{10}) is a small lipophilic molecule which plays a number of crucial roles in cellular homeostasis. It is an electron carrier in the mitochondrial respiratory chain (MRC), and it is involved in other biochemical pathways such as mitochondrial fatty acid oxidation, sulfide detoxification, and pyrimidine biosynthesis. Moreover, it is modulator of the permeability transition pore, and an essential antioxidant. CoQ10 biosynthesis is still incompletely understood and involves the products of at least 12 different genes (collectively known as *COQ* genes). Mutations in these genes cause primary CoQ_{10} deficiencies, a clinically and genetically heterogeneous group of conditions. To date mutations in nine genes (*PDSS1, PDSS2, COQ2, COQ4, COQ6, COQ7, COQ8A, COQ8B*, and *COQ9*) have been related to CoQ_{10} deficiency in humans, while the association of two other genes (*ADCK2* and *COQ5*) must be confirmed.

The age of onset can span from birth to the 6–7th decade of life. Manifestations range from catastrophic multiorgan failure, to isolated cerebellar ataxia or steroid resistant nephrotic syndrome (SRNS). SRNS is a peculiar manifestation of CoQ_{10} deficiency, since it is rarely seen in other mitochondrial disorders. Interestingly only some genetic defects cause SNRS (*PDSS1, PDSS2, COQ2, COQ6*, and *COQ8B*), while mutations in other genes (*COQ4*, *COQ7*, *COQ8A*, and *COQ9*) have never been observed in association with SRNS, but instead cause

encephalomyopathy or multisystem disorders without glomerular involvement.

CoQ_{10} deficiency is one of the few treatable mitochondrial disorders. In fact, many patients (especially those with milder forms, and who are treated soon after the onset of symptoms) respond well to high-dose oral CoQ_{10} supplementation. Therefore, it is essential to recognize promptly this condition to institute an appropriate treatment.

Traditionally, the diagnosis relied on biochemical analysis of CoQ_{10} in muscle or cultured fibroblasts, while molecular studies were performed in a second time. Nowadays, NGS has revolutionized the diagnostic approach, and the molecular diagnosis generally precedes the biochemical one.

Introduction

Coenzyme Q_{10} (CoQ_{10}) is a small lipophilic molecule, comprised of a quinone group and an isoprenoid tail, which plays different crucial roles in cellular homeostasis. It is an electron carrier in the mitochondrial respiratory chain (MRC), where it shuttles electrons from respiratory complexes I and II to complex III; it is a cofactor of several other mitochondrial dehydrogenases (among which sulfide:quinone oxidoreductase which is essential for detoxification of H_2S), a modulator of the permeability transition pore, and an essential antioxidant (Turunen et al. 2004).

CoQ_{10} biosynthesis is still incompletely understood in eukaryotic cells where it involves the products of at least 12 genes (collectively known as *COQ* genes). The precursor of the quinone group, 4-hydoxybenzoate (4HB), is derived from tyrosine through a poorly characterized set of reactions (Payet et al. 2016). The tail shares its initial biosynthetic steps with cholesterol through the cytosolic mevalonate pathway. Farnesyl-pyrophosphate is then condensed to form decaprenyl-pyrophosphate within mitochondria, by PDSS1 and PDSS2. Decaprenyl-pyrophosphate is then joined to 4HB by COQ2. The final biosynthetic steps are thought to be rate limiting and are carried out by a set of enzymes comprised of COQ3, COQ5, COQ6, and COQ7 located in the mitochondrial matrix associated to the inner membrane (Acosta et al. 2016). The proteins responsible for the decarboxylation and hydroxylation of position C1 of the ring, the first ring modifications to occur in mammals (Acosta Lopez et al. 2019), have not been identified yet. The process requires four other proteins, COQ9, which is required for the synthesis of COQ7, COQ8A, and COQ8B, which have a regulatory function, although their precise role is unclear, and COQ4, which is thought to be essential for holding together the other COQ proteins in a complex (Marbois et al. 2009).

CoQ_{10} deficiency can be defined as the presence of reduced levels of CoQ_{10} in tissues or cells of a patient (Acosta et al. 2016). The term primary CoQ_{10} deficiency comprises a clinically and genetically heterogeneous group of disorders caused by mutations in *COQ* genes. Primary deficiencies must be distinguished from secondary forms, in which reduction of CoQ_{10} is associated with mutations in genes unrelated to CoQ_{10} biosynthesis (or to non-genetic factors) (Sacconi et al. 2010; Cordero et al. 2009). In this chapter, we will focus exclusively on primary forms. To date mutations in nine genes (*PDSS1, PDSS2, COQ2, COQ4, COQ6, COQ7, COQ8A, COQ8B*, and *COQ9*) have been related to primary CoQ_{10} deficiency (Salviati et al. 2017), while the association with *COQ5* and *ADCK2* mutations must be confirmed.

Primary CoQ_{10} deficiencies are associated with dramatically different *clinical presentations*, ranging from fatal neonatal multisystem disorders, to juvenile or adult-onset diseases with involvement of isolated organs. The genotype–phenotype correlations are only partially known. Most clinical symptoms are common to other respiratory chain disorders. However, a peculiar manifestation of CoQ_{10} deficiency is renal glomerular involvement, manifesting as steroid resistant nephrotic syndrome (SRNS), which is rarely seen in other mitochondrial disorders (Emma et al. 2016).

The most severe forms are characterized by a catastrophic multiorgan failure, which leads to death at birth, or in the first days of life. Other forms may have a more subtle onset, and present in the first weeks of life with encephalomyopathic symptoms and features of Leigh syndrome on MRI. These forms are virtually indistinguishable from other severe MRC defects. Neonatal onset cases usually do not display glomerular involvement, although renal tubulopathy has been reported in patients with *COQ9* defects (Duncan et al. 2009) and renal morphological abnormalities, that did not affect function, were reported in *COQ7* patients (Kwong et al. 2019). SRNS may appear later in the course of the disease in long surviving early onset patients, or it can be the first manifestation in patients affected by intermediate forms, with disease onset occurring from the end of the first year of life through adolescence. In some cases, SRNS may be the only manifestation of CoQ_{10} deficiency, while other patients develop features of neurological involvement. Curiously, SRNS has been observed in patients with mutations in *PDSS1*, *PDSS2*, *COQ2*, *COQ6*, and *COQ8B*, while it has never been reported in those with *COQ4*, *COQ7*, *COQ8A*, and *COQ9* mutations, which display only neuromuscular involvement (*COQ8A*) or neuromuscular involvement and multisystem dysfunction (*COQ4, COQ7,* and *COQ9*) (Acosta et al. 2016; Kwong et al. 2019). The reasons for these phenotypic differences are still unknown.

The *pathogenesis* of CoQ_{10} deficiency involves deficient ATP production, increased ROS, impairment of pyrimidine metabolism (Lopez-Martin et al. 2007; Quinzii et al. 2010), and possibly impaired H_2S clearance (Kleiner et al. 2018). At very low CoQ_{10} concentrations, the defect in energy production prevails, while ROS are not increased, and the clinical manifestations are those of classical MRC defects. With milder CoQ_{10} deficiency, ATP production is less impaired, and classical "mitochondrial" symptoms are less evident, whereas ROS production gradually increases causing the glomerular damage (Quinzii et al. 2008; Quinzii et al. 2013). For some genes, for example *COQ2*, the genotype–phenotype correlation is clear and depends on the presence of residual enzymatic activity (Desbats et al. 2016), while for others, such *COQ8B*, there is no clear genotype–phenotype correlation (Vazquez Fonseca et al. 2018).

Traditionally, the *diagnosis* was based on direct biochemical measurements of CoQ_{10} in muscle biopsies or cultured fibroblasts, and then molecular genetics followed. NGS has revolutionized the diagnostic protocols, and it is simpler and cheaper to run the genetic analysis first, and then to confirm the findings with biochemical analyses on patients' tissues (Yubero et al. 2018). Measurements of plasma CoQ_{10} levels are not indicated for diagnosis because they reflect dietary intake rather than tissue concentration of CoQ_{10}. Furthermore, in our experience, patients with later-onset forms (who present in late childhood, adolescence or even later) may display little or no reduction of CoQ_{10} in fibroblasts and even in skeletal muscle, despite harboring clearly pathogenic mutations.

The suspicion of primary CoQ_{10} deficiency should arise in cases of early onset mitochondrial disorders, SRNS (even isolated), and unexplained ataxia (Trevisson et al. 2011). NGS panels for these conditions routinely include *COQ* genes, but whole exome sequencing is becoming the first line investigation in these patients.

Primary CoQ_{10} deficiency is one of the few treatable mitochondrial disorders. Many patients respond well to oral CoQ_{10} supplementation. *Treatment* can stop the progression of the encephalopathy and reverse the nephropathy. It must however be instituted before severe tissue damage has occurred, otherwise it is largely ineffective. Severe neonatal cases often do not respond (or respond only partially) to treatment (Alcazar-Fabra et al. 2018). Doses employed range from 10 to 30 or even 50 mg/kg per day of ubiquinone (the oxidized form of CoQ_{10}). Ubiquinol (the reduced form) appears to be more effective than ubiquinone in animal models (Garcia-Corzo et al. 2014), but there is much less clinical experience. Moreover, long-term data about the efficacy of CoQ_{10} supplementation in patients are however scarce.

Recently a novel approach, bypass therapy, has been proposed. It involves the use of specific analogues of the quinone ring which can bypass individual genetic defects (Pierrel 2017). Results are promising in cellular and animal models, but there is currently no experience in patients.

Metabolic Pathway

The precursors of CoQ_{10}, 4-hydroxybenzoate (4-HB) and farnesyl-pyrophosphate, are derived from tyrosine through a still poorly characterized set of reactions, and from acetyl-CoA, through the mevalonate pathway. Farnesyl-pyrophosphate is joined by a heterotetrameric enzyme comprised of PDSS1 and PDSS2 to form decaprenyl-pyrophosphate which is then joined to 4-HB by COQ2. The next two steps (the decarboxylation and hydroxylation of the C1 carbon) are catalyzed by still unknown enzymes, while the hydroxylation of the C5 carbon of the ring is carried out by COQ6. COQ3 then transfers a methyl group to this hydroxyl, and COQ5 transfers another methyl group directly on the C2 carbon. Last, COQ7 hydroxylates the C6 carbon and COQ3 adds the final methyl group. COQ9 is essential for the stabilization of COQ7. The precise role of COQ4, COQ8A, COQ8B, and ADCK2 is still under investigation. Gene products in red have been definitely associated to human CoQ_{10} deficiency (Fig. 47.1a and b).

Besides being an electron carrier within the respiratory chain, where it shuttles electron from complex I (CI) and II (CII) to complex III (CIII), CoQ is a cofactor of electron transfer flavoprotein dehydrogenase (ETFDH) (involved in mitochondrial fatty acid oxidation), sulfide:quinone oxidoreductase (SQOR) (involved in sulfide detoxification), and dihydroorotate dehydrogenase (DHODH) involved in pyrimidine nucleotides biosynthesis. Moreover, it is a cofactor of uncoupling proteins (UCP), a modulator of the permeability transition pore (PTP) thus controlling apoptosis, and one of the most important cellular antioxidants (Fig. 47.1c).

It should be noted that relatively few patients have been described (for some genes less than 10), therefore clinical data are probably incomplete. Moreover, clinical presentations differ dramatically depending on the age of onset (see for example the case of COQ2) (Desbats et al. 2016). There are no pathognomonic manifestations, although the association of SRNS with other neurological manifestation should immediately raise the suspicion of CoQ_{10} deficiency.

Reference Values

There are currently no universally accepted reference values for CoQ_{10} in muscle or fibroblasts, although most authors reported muscle CoQ10 values in a range between 110 and 580 nmol CoQ_{10}/g protein and in fibroblasts between 39 and 112 nmol/g protein. It is important to refer the data to a set of in-house age matched controls and it is also useful to normalize data by citrate synthase activity (Yubero et al. 2014).

Diagnostic Flowchart

The traditional approach privileged biochemical determinations, and genetic analyses, which were more complex and expensive, were performed only in a second stage. Nowadays, NGS allows analysis of very large numbers of genes for a fraction of the cost and of the time required by traditional Sanger sequencing. Targeted NGS gene panels are commonly used for SRNS, ataxias, and mitochondrial disorders. Whole Exome Sequencing (WES) is theoretically the best option, but costs are higher and coverage is inferior to targeted panels. Moreover CNV analysis is more efficient with targeted panels. Clinical exome panels include 5–7000 genes associated with Mendelian diseases. They may be a good compromise although they may lack some critical genes (see also Chap. 9).

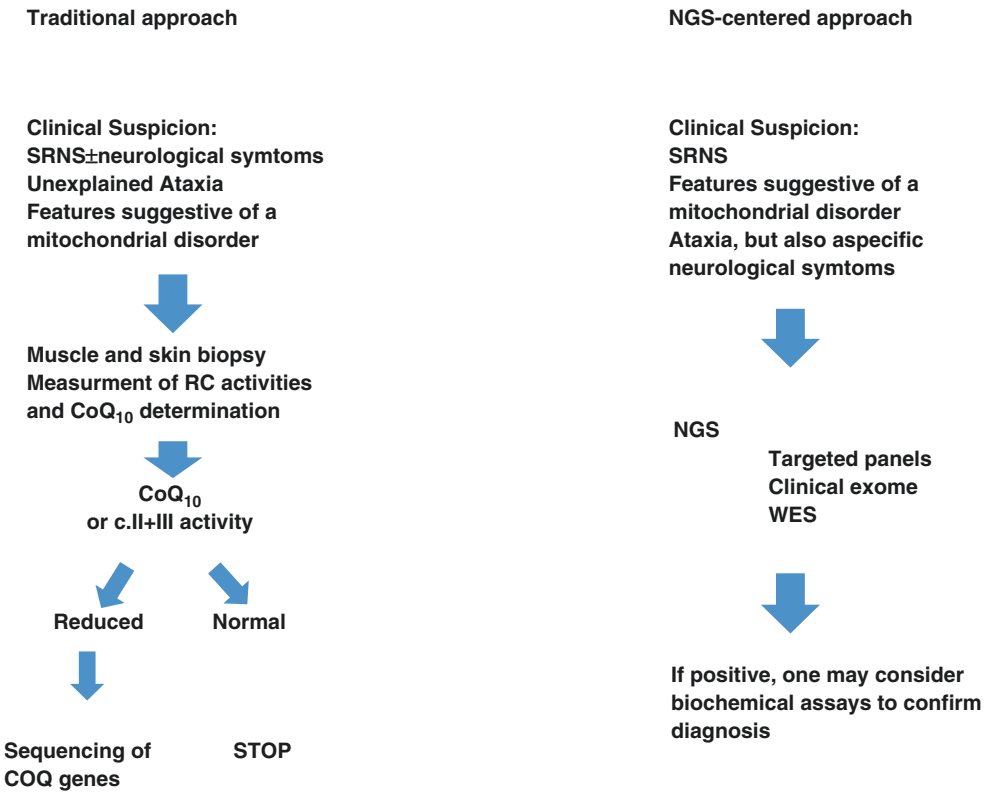

Fig. 47.2 Traditional versus NGS-centered approaches for the diagnosis of primary CoQ_{10} deficiency

Specimen Collection

Plasma CoQ_{10} content determination is meaningless and should not be performed. Serum lactic acid should be measured with the precautions discussed for other mitochondrial disorders to avoid false positive results.

If possible CoQ_{10} should be measured in muscle samples (which can be safely frozen at −80 °C or, better, in liquid nitrogen, and can be shipped in dry ice) and in cultured skin fibroblast.

Prenatal Diagnosis

Prenatal diagnosis can be performed by molecular testing on standard chorionic villi or amniotic fluid cells, for all these forms, provided that the molecular defect in the index case has been unambiguously identified.

Biochemical tests, such as CoQ_{10} determination in amniocytes, are not usually employed.

DNA Testing

DNA testing is available for all forms of CoQ_{10} deficiency. Specific strategies have been described above.

In particular cases, RNA analysis from cultured fibroblasts can be performed.

Treatment

The mainstay of treatment is oral supplementation with high dose CoQ_{10}. Most reports refer to ubiquinone, the oxidized form of CoQ_{10}. Dosages range from 5 to 50 mg/kg/day divided in three or more doses. Several formulations are available, but in general soluble forms, soft gel caps, or oily formulations should be preferred (Desbats et al. 2015). Tablets should not be administered because of poor absorption (Bhagavan and Chopra 2007). Ubiquinol, the reduced form of CoQ_{10} is also available, but there is limited experience in patients. Idebenone is not effective and should not be employed in these patients. Patients with SRNS may also benefit of treatment with ACE inhibitors. Bypass therapy using analogues of the precursor of the quinone ring has been tested in cells and model organisms, but to date there are no data in patients.

Renal transplantation is an option for patients with end-stage renal disease.

Summary

Mitochondrial fatty acid oxidation disorders (FAODs) impair the ability of the body to utilize fats for energy production during times of physiologic stress such as fasting or illness, and thus can be asymptomatic and difficult to diagnose when a patient is well. Reducing equivalents from fatty acid oxidation (FAO) enzyme reactions directly enter the electron transfer chain (ETC) to support generation of adenosine triphosphate (ATP) through oxidative phosphorylation (oxphos), or by entry of its end product acetyl-coenzyme A (acetyl-CoA) into the tricarboxylic acid cycle (TCA or Krebs cycle). Acetyl-CoA from FAO can also be used to synthesize ketones, a fuel source that is used by some peripheral tissues and especially the brain during catabolic situations. Due to the ability to prevent life-threatening symptoms through early diagnosis, FAODs have been included in newborn screening (NBS) panels worldwide through tandem mass spectrometry-based screening. Acylcarnitine profiles are specific for the respective enzyme defects; however, the diagnosis should be confirmed by enzyme assay and/or molecular analysis as they may also offer insight into clinical severity. Metabolic profiles can be normal in the anabolic state and, consequently, newborn screening may miss the diagnosis when performed outside the catabolic state on days 2 and 3 of life. Mitochondrial fatty acid oxidation disorders are comprised of four groups: (1) disorders of the entry of long-chain fatty acids into mitochondria (often referred to as carnitine cycle defects), (2) intramitochondrial ß-oxidation defects of long-chain fatty acids, (3) β-oxidation defects of short- and medium-chain fatty acids affecting enzymes of the mitochondrial matrix, and (4) disorders of impaired electron transfer to the respiratory chain from mitochondrial β-oxidation. All told, more than 20 different genetic enzyme defects of FAO have now been identified, some with disease-specific characteristics that distinguish them from others in the group. The main pathophysiologic mechanism of all FAODs is an energy deficiency due to impaired fatty acid oxidation and ketone body formation. Toxic effects of accumulating acylcarnitine and acyl-CoA species may also play a role. FAODs present with heterogeneous phenotypes. Before addition of FAODs to newborn screening (NBS) panels in many countries, the commonest clinical presentations were hypoketotic hypoglycemia and sudden death, usually precipitated by an infection or fasting in the neonatal period or early childhood. With newborn screening, apparent disease incidence has significantly increased, while the proportion of milder phenotypes has grown. Newborn screening greatly reduces the morbidity and mortality, though it does not eliminate early neonatal death in severe phenotypes in some of the defects. Three major phenotypes are now recognized. Non-ketotic hypoglycemia predominates in the first few years of life, but is uncommon after age 4–6 years. Cardiomyopathy and arrhythmias are seen at any time, may be of acute onset, and can also be reversible. Exercise- or illness-induced rhabdomyolysis is a common presentation in adolescents or young adults, but muscle pain and elevated creatine kinase (CK) can occur in infancy. With some disorders, patients can remain asymptomatic throughout life if they have mild defects and are not exposed to the metabolic stress. Affected asymptomatic mothers have been identified due to pathological newborn screening in their child. Correlation of genotype and/or residual enzyme activity with disease phenotype has been reported for some defects but is imperfect, suggesting an additional role for disease modifiers and environment. Treatment must be tailored to the severity of the phenotype and the specific disorder, with a focus on avoidance of fasting, mitigation of stress, and fluid and caloric support through episodes of rhabdomyolysis. New therapies are in development and may change significantly the long-term prognosis for patients.

Introduction

Fat is an important source of energy and the body's principal fuel store. It is the main fuel for skeletal muscle during sustained exercise, and provides reducing equivalents to make ATP through oxidative phosphorylation during periods of fasting and physiologic stress. In postnatal life, fatty acids are used in preference to glucose by the heart regardless of caloric intake.

Mitochondrial fatty acid oxidation involves four processes: (1) entry of fatty acids into mitochondria (the carnitine cycle), (2) mitochondrial ß-oxidation of long-chain fatty acids via a spiral pathway utilizing membrane-bound enzymes, (3) mitochondrial β-oxidation of chain-shortened fatty acids using matrix enzymes, and (4) electron transfer to the respiratory chain.

The clinical presentation of these disorders is heterogeneous. FAODs have three characteristic clinical presentations:

1. *Acute hypoketotic hypoglycemia and encephalopathy, accompanied by hepatomegaly and liver dysfunction* precipitated by fasting or an infection, often described as the hepatic presentation or "Reye-like symptoms." Presentation generally occurs in the first weeks and months of life, and the appearance and severity can be mitigated by early identification through newborn screening by mass spectrometry. Sudden death due to a first acute episode is reduced, but not eliminated by newborn screening. Intermittent recurrence of symptoms during intercurrent illness

is common in the first few years of life, but less common after age 4–6 years.
2. *Cardiomyopathy* (usually hypertrophic, but also dilated in later stages), *arrhythmias*, or *conduction defects*. The cardiac phenotype often occurs in the first weeks and months of life, but patients are at lifelong risk for acute or chronic symptoms. Cardiomyopathy is reversible without sequelae if treated early.
3. *Myopathy*, presenting either with weakness, pain, or with acute rhabdomyolysis, precipitated by exercise or infection. The myopathic phenotype mainly occurs after the first few years of life, in later childhood and adolescence.

Since implementation of newborn screening for FAODs, milder phenotypes (including asymptomatic) associated with specific genotypes have been recognized. It is not yet clear how many of the NBS-diagnosed patients will remain asymptomatic throughout life.

Fasting hypoglycemia is due to increased peripheral glucose consumption, decreased production of glucose due to an intracellular ATP deficit, and a concomitant decreased production of glucose utilization sparing ketones (Brunengraber and Roe 2006; Herrema et al. 2008). While small amounts of ketone bodies can be synthesized, particularly in medium- or short-chain FAODs or if there is high residual enzyme activity, the plasma concentrations are lower than expected for the degree of hypoglycemia, and thus the classification as hypoketotic. Hyperammonemia occurs in some severe defects and lactic acidemia is seen particularly in long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), mitochondrial trifunctional protein (MTP), and multiple acyl-CoA dehydrogenase (MAD) deficiencies. Rhabdomyolysis leads to elevated creatine kinase (CK), which can exceed 100.000 U/L (normal <~150 depending on the lab). Hepatomegaly and steatosis resulting from endogenous lipolysis are reflected by increased liver transaminases (aspartate aminotransferase [AST], alanine aminotransferase [ALT]), but note that AST and ALT also are present in muscle and especially AST is elevated in rhabdomyolysis independent of hepatocellular dysfunction. The toxic effects of accumulating long-chain acylcarnitines and acyl-CoA esters are likely responsible for cardiac arrhythmias in these disorders and are especially severe in disorders of the mitochondrial trifunctional protein (MTP and LCHAD deficiencies) and carnitine acylcarnitine translocase (CACT) deficiency (Bonnet et al. 1999; Tonin et al. 2010; Tonin et al. 2014). The development of retinopathy and peripheral neuropathy in LCHAD and MTP deficiencies is associated with the accumulation of long-chain 3-hydroxyacylcarnitines, though the definite pathophysiology of these problems is unknown.

The disease-specific acylcarnitine profile determined by tandem mass spectrometry is useful as a diagnostic test and for newborn screening, but must be performed on days 2 and 3 of life for the latter as delayed blood sampling in the anabolic state may yield false negative results. The acylcarnitine profile may also normalize when a patient is well or if there is a secondary carnitine deficiency. Organic acid analysis in urine can be diagnostic with accumulation of characteristic dicarboxylic acids during a metabolic crisis; however, since they are often normal in milder phenotypes or when a patient is well, acylcarnitine analysis is typically the primary diagnostic tool. Abnormal metabolite profiles, as well as normal profiles in the context of a suggestive clinical history, should be followed by confirmatory studies such as enzyme or molecular analysis.

Carnitine Transporter Deficiency

The organic cation carnitine transporter 2 (OCTN2) encoded by the *SLC22A5* gene is responsible for carnitine uptake across the plasma membrane, particularly in heart, muscle, and kidney. Defects of the transporter lead to primary systemic carnitine deficiency with increased renal loss of carnitine and extremely low plasma carnitine concentrations (Longo et al. 2006). Parallel measurement of carnitine in blood and urine is the first diagnostic step. On newborn screening, low carnitine concentrations may also be found in newborns of vegetarian or vegan mothers or mothers with an undiagnosed OCTN2 deficiency. Asymptomatic adults with very low plasma carnitine concentrations have been identified. Therefore, carnitine measurement in the maternal plasma and urine should be part of the diagnostic workup of a low carnitine on NBS. A common founder mutation is present in the population of the Faroe Islands. The intake of certain antibiotics such as aminoglycosides, which are eliminated as carnitine esters via the urine, may lead to an additional decrease of carnitine in affected patients and can induce life-threatening clinical symptoms in otherwise asymptomatic patients (Holme et al. 1992; Makino et al. 2007; Rasmussen et al. 2013; Nasu et al. 2014; Nakazaki et al. 2018).

Carnitine Palmitoyltransferase I (CPTI) Deficiency

Three different genetic isoforms of CPTI have been found in liver and kidney (CPTIA), muscle and heart (CPTIB), and brain (CPTIC). CPTIA deficiency has been identified in humans presenting in infancy with hypoketotic hypoglycemia and hepatopathy, induced by fasting or illness (Longo et al. 2006). Affected patients have an extremely high level

of free carnitine in their blood spot with a concomitant decrease in the long-chain acylcarnitines. Free carnitine in blood spots is generally higher than measured in plasma. A mild variant is found in First Nation peoples of North America. CPTIC deficiency presents as an autosomal dominant spastic paraplegia with heterozygous mutations in the *CPTIC* gene. It has no reported metabolic phenotype and will not be discussed further in this chapter (Carrasco et al. 2013; Rinaldi et al. 2015).

Carnitine-Acylcarnitine Translocase (CACT) Deficiency

Most patients have presented in the neonatal period and died in infancy; however, milder variants have been reported (Longo et al. 2006). This phenotype is characterized by severe ventricular arrhythmias that are most likely triggered by accumulating toxic fatty acid metabolites during catabolism. The acylcarnitine profile is indistinguishable from that found in carnitine palmitoyltransferase II deficiency.

Carnitine Palmitoyltransferase II (CPTII) Deficiency

The most common form of CPTII deficiency presents with recurrent episodes of rhabdomyolysis and myoglobinuria precipitated by prolonged exercise, mainly in adolescents or young adults (Longo et al. 2006). The plasma CK often normalizes between episodes but it may also remain moderately elevated, associated with chronic muscle weakness and pain. Severe neonatal onset CPTII deficiency is lethal and is associated with congenital malformations, principally renal cysts and neuronal migration defects (North et al. 1995). The adult myopathic form of CPTII deficiency, due to a common mutation that preserves partial enzyme activity, is biochemically difficult to diagnose since acylcarnitine profiles may be normal, even during metabolic derangement. This phenotype is common in the Ashkenazi Jewish population.

Very Long-Chain Acyl-CoA Dehydrogenase (VLCAD) Deficiency

VLCAD deficiency is the second most common fatty acid oxidation disorder in Europe and the USA, with a prevalence between 1:50,000 and 1:100,000 since implementation of newborn screening, much higher than originally calculated from the incidence of clinically manifesting patients. It is characterized by episodes of hypoketotic hypoglycemia with or without hyperammonemia in the first few years of life, with recurrent rhabdomyolysis (usually without hypoglycemia) in older children and young adults. Cardiomyopathy may be acute or chronic and can appear at any age. It can also be completely reversible if diagnosed early not leaving any sequelae. Neonatal screening by tandem mass spectrometry of dried blood spots for acylcarnitine profile has identified milder phenotypes with different genotypes and higher residual activities (Spiekerkoetter et al. 2010; Pena et al. 2016). Some of these patients remained asymptomatic from diagnosis to follow-up of over 10 years. Blood acylcarnitine and urine organic acid profiles can make the diagnosis but may normalize when patient is well. Thus, functional enzyme and molecular testing are critical to make or confirm the diagnosis in a suspected patient.

Mitochondrial Trifunctional Protein (MTP), LKAT, and LCHAD Deficiencies

Isolated long-chain 3-ketoacyl-CoA thiolase (LKAT) deficiency is rare and has only been reported in two patients. Patients with isolated LCHAD deficiency or general MTP deficiency irrespective of the localization of the mutation in the HADHA or HADHB genes present with heterogeneous phenotypes similar to other long-chain FAODs (Spiekerkoetter et al. 2004). Importantly, this is the only FAOD associated with retinopathy and peripheral neuropathy (Tyni et al. 1998). First-line diagnosis is by blood acylcarnitines. However, the acylcarnitine profile may be normal, even during an episode of rhabdomyolysis, especially in patients with primarily neuromyopathic symptoms, therefore enzymatic or molecular testing especially for LCHAD deficiency due to the prevalent 1528G>C mutation is essential in case of clinical suspicion. This common mutation alters the catalytic residue in the LCHAD domain of the MTP alpha subunit. Pregnant women who are heterozygous for LCHAD or MTP deficiencies have an increased risk of HELLP syndrome—Hemolysis, Elevated Liver enzymes and Low Platelets—and acute fatty liver of pregnancy (AFLP) during pregnancies when they are carrying an affected fetus (Wilcken et al. 1993).

Acyl-CoA Dehydrogenase 9 (ACAD9) Deficiency

ACAD9 is homologous to VLCAD and has dehydrogenase activity toward various long-chain acyl-CoA esters in vitro. Its primary physiological role is in the assembly of the mitochondrial respiratory chain complex I, and it presents pre-

dominantly as a respiratory chain deficiency with cardiomyopathy (Repp et al. 2018) and therefore is treated in Table 44.36.

Medium-Chain Acyl-CoA Dehydrogenase (MCAD) Deficiency

MCAD deficiency (MCADD) has an incidence of approximately 1:10,000 in Europe, Australia, and the USA. Affected patients present clinically primarily if exposed to an appropriate environmental stress such as prolonged fasting or an intercurrent illness. The most common presentations before the era of newborn screening were sudden death or Reye-like symptoms, but many affected individuals identified through family screening were asymptomatic (Pourfarzam et al. 2001; Wilcken et al. 2007). MCADD is readily identifiable by newborn screening and once diagnosed, sudden death is rare as preventive measures can be taken. The risk for hypoglycemia decreases in late childhood and adulthood, but is never zero. Blood octanoylcarnitine (C8) is a highly specific marker, but may be only moderately elevated in mild phenotypes. The excretion of hexanoyl- and phenylpropionylglycine is elevated in urine; however, in milder phenotypes they may not be detectable. Residual enzyme activity correlates with the genotype and the expected clinical phenotype. A common mutation accounts for 75% of the mutations in patients with MCADD. A less common but recurrent c199T>C variant leads to sufficient residual activity to probably be protective from disease in combination with an inactivating mutation on the other allele.

Short-Chain Acyl-CoA Dehydrogenase (SCAD) Deficiency

There are two polymorphisms in the SCAD gene (c.625G>A and c.511C>T). In northern Europe, 6% of the general population has one of these variants on both alleles. A common inactivating gene variant is present in Ashkenazi Jews. The biochemical diagnosis relies on the finding of increased blood butyrylcarnitine (C4) and/or urine ethylmalonic and methylsuccinic acids. A variety of clinical symptoms has been reported in patients with SCAD mutations, but patients identified through newborn screening have remained well. Thus, SCADD appears to be a biochemical phenotype rather than a clinically relevant disorder (Gallant et al. 2012). Nevertheless, it has been suggested that it may confer susceptibility to neuromuscular disease in combination with other impairments in mitochondrial function (Nochi et al. 2017).

Short-Chain 3-Hydroxyacyl-CoA Dehydrogenase (SCHAD) Deficiency

SCHAD deficiency is associated with hypoglycemia but due to a different mechanism than the other FAODs. SCHAD has a second role independent of FAO, binding and inhibiting glutamate dehydrogenase (GDH). SCHAD mutations that prevent GDH binding lead to increased GDH activity and insulin secretion and subsequent hypoglycemia, particularly in response to leucine (Li et al. 2010). Increased plasma L-3-hydroxyl-C4-carnitine as well as urine 3-hydroxyglutaric acid are the accepted diagnostic markers.

Nomenclature

No	Disease Name	Alternative Disease Name	Abbreviation	Gene Symbol	Chromosomal Localization	Mode of Inheritance	Affected protein	OMIM#

Metabolic Pathway

Fatty acids are released from tissue stores or from dietary fat, are transported to cells on carrier proteins, and enter cells in response to hormonal signals including dropping insulin. In the cytoplasm, they are activated to coenzyme A (CoA) esters by acyl-CoA synthases. Long-chain acyl-CoAs must be esterified with carnitine in order to cross the inner mitochondrial membrane, while medium- and short-chain acyl-CoAs appear to enter the mitochondria independent of carnitine. Endogenous synthesis in the liver generally supplies about half of cellular needs and thus the remainder is derived from diet, largely meat. Endogenous production in vegans is enhanced, but in many cases still have clinically insignificant low levels in blood. Carnitine itself is actively transported into cells by the high-affinity organic cation carnitine transporter 2 (OCTN2) carnitine (Fig. 48.1). A low-affinity transporter provides some capacity to transport carnitine into cells in the face of OCTN2 deficiency. At the outer mitochondrial membrane, carnitine palmitoyltransferase I (CPTI) catalyzes the formation of acylcarnitine esters. The carnitine esters are shuttled across the inner membrane by the carnitine acylcarnitine translocase (CACT), and carnitine palmitoyltransferase II (CPTII), which is attached to the inner mitochondrial membrane, catalyzes the release of CoA esters. Within the mitochondria, ß-oxidation is catalyzed by enzymes of different chain length specificities, and each turn of the β-oxidation spiral involves four enzymatic steps, shortening the acyl-CoA by two carbons. The enzymes for the β-oxidation of long-chain substrates (C18-C12 fatty acids) are also membrane-associated, including very long-chain acyl-CoA dehydrogenase (VLCAD) and the mitochondrial trifunctional protein complex (mTFP or MTP) composed of three enzymatic activities on two different subunits. Long-chain enoyl-CoA hydratase (LCEH) and the long-chain 3-hydroxyacyl-CoA dehydrogenase

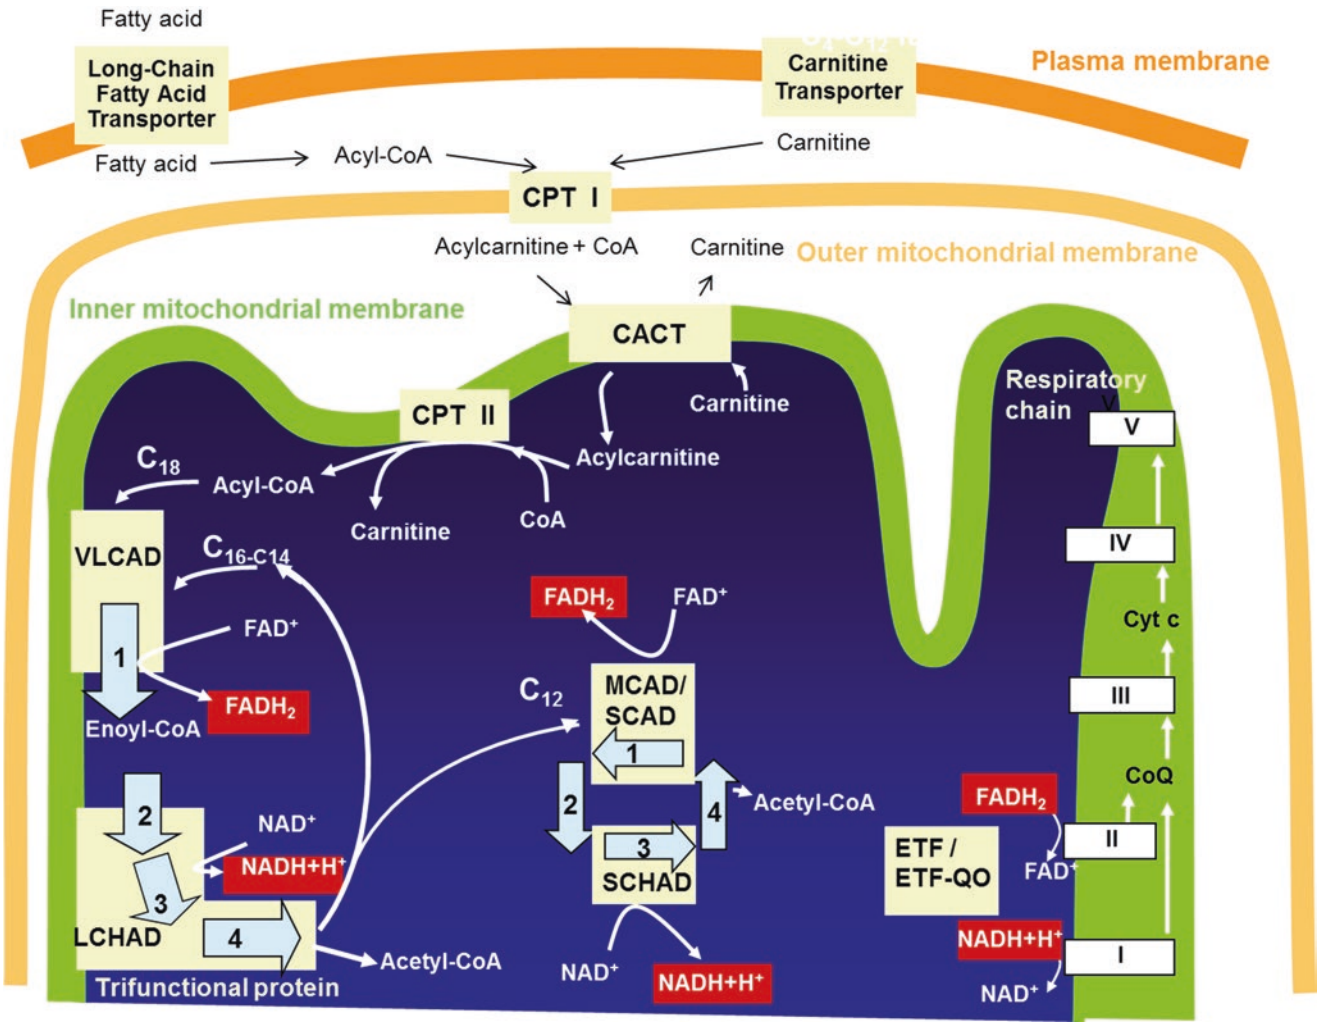

Fig. 48.1 Transport of fatty acids into the mitochondrion, mitochondrial β-oxidation, and electron transfer. Modified according to Bonnefont et al. (2010)

(LCHAD) both are contained in the α-subunit, while the long-chain 3-ketoacyl-CoA thiolase (LKAT) is localized to the β-subunit. Medium- and short-chain-specific enzymes, including medium-chain acyl-CoA dehydrogenase (MCAD), short-chain acyl-CoA dehydrogenase (SCAD), enoyl-CoA hydratase or crotonase, and short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD), are located in the mitochondrial matrix. The acyl-CoA dehydrogenase reaction produces two electrons, which are transferred sequentially to the electron transfer flavoprotein (ETF), ETF-ubiquinone oxidoreductase (ETF:QO), and ultimately to ubiquinone of the mitochondrial electron transfer chain. Flavin adenine dinucleotide (FAD), which is derived from riboflavin, acts as a cofactor in these reactions (see Chap. 32). Acetyl-CoA produced by ß-oxidation can either enter the Krebs cycle or be utilized to synthesize ketone bodies in the liver (Fig. 48.1). The LCHAD reaction utilizes nicotinamide adenine dinucleotide (NAD) as an electron acceptor, which serves as a substrate for complex I of the electron transfer chain. The long-chain fatty acid oxidation enzymes VLCAD and LCHAD, along with electron transfer flavoprotein dehydrogenase (ETFDH), have been shown to interact with respiratory chain supercomplexes in a multiprotein enzyme complex that optimizes catalytic efficiency (Wang et al. 2010; Wang et al. 2019). The LCHAD (alpha) subunit of MTP interacts with the matrix arm of respiratory chain complex I and VLCAD, while ETFDH interacts with the coenzyme Q binding subunit of complex III (Fig. 48.2).

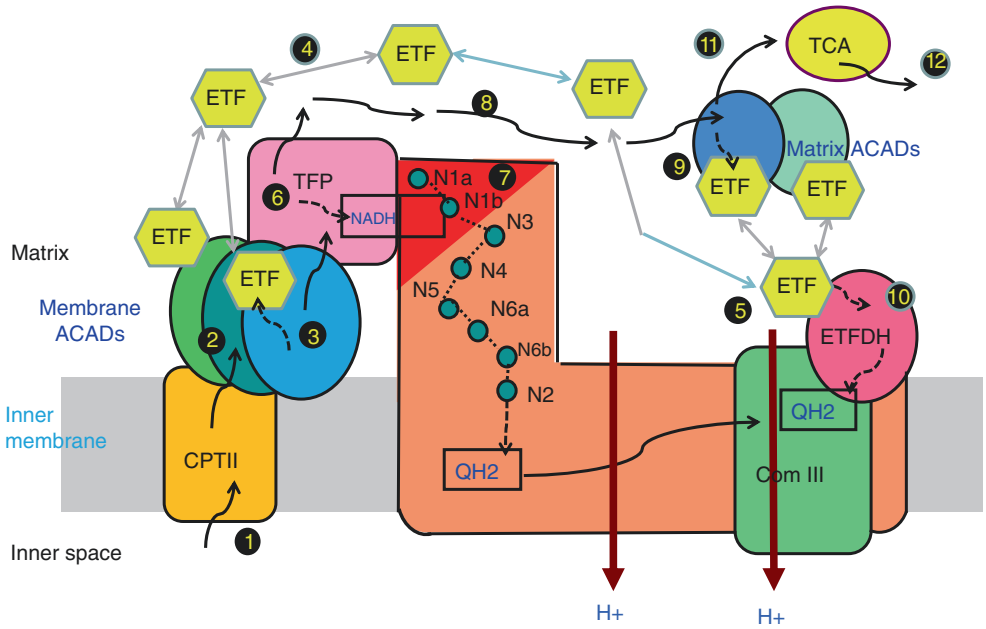

Fig. 48.2 The model depicts the path of oxidation of long-chain fatty acids (Wang et al. 2019). Steps 1–3: Long-chain acyl-CoA substrates are transferred into VLCAD through CPTII, channeling its product to the MTP (Steps 6–7). Steps 4–5: Reduced ETF is released from VLCAD into the mitochondrial matrix, where it is free to find its redox partner, ETFDH, and shuttle its reducing equivalents (QH_2) to ETC complex III. Step 8: In complex I, NADH is oxidized with channeling of electrons to complex III. Medium- and short-chain acyl-CoA substrates produced by TFP are transferred to MCAD and SCAD in the matrix, or in amore weakly associating peripheral domain of the multifunctional FAO-ETC complex (Steps 9–10). ETFDH oxidizes reduced ETF by reducing CoQ to QH_2 Finally, acetyl-CoA enters the TCA cycle or is utilized for ketone body production (Steps 12–13)

Reference Values

Measured values of carnitine and acylcarnitines differ in dried blood spots and plasma (de Sain-van der Velden et al. 2013). They also change with age, especially in newborns over the first days of life. Catabolism increases acylcarnitine concentrations in patients and healthy individuals. Reference values are given in Chap. 5. Organic acid analysis in urine reveals a disease-specific profile distinct from healthy individuals; however, organic acids can also be normal in patients during anabolism and in milder phenotypes. Fasting significantly increases the excretion of disease-specific organic acids in patients.

Pathological Values

An extremely wide variation in blood acylcarnitine values is observed in patients, related both to the specific diagnosis and timing of the most recent meal, and may normalize when the patient is well and not fasting (Smith and Matern 2010). Collecting diagnostic samples immediately prior to a meal or during acute illness maximizes the likelihood of making a diagnosis. In general, patients with milder disease have less dramatic changes in metabolite profiles than those with more severe neonatal/infantile presentations. Normal ketosis increases acylcarnitine levels even in healthy individuals and should not be confused with disease patterns.

Acylcarnitine levels in newborn blood spot samples generally decrease in the first days of life and may normalize, even in patients with FAODs, and therefore late screening can lead to missed diagnoses (Lindner et al. 2010). Importantly, healthy newborns and children may present with abnormal acylcarnitine profiles suggestive of a FAOD during severe catabolism. Pathological reference values taken from a large worldwide cohort have been reported (McHugh et al. 2011). Consideration of the acylcarnitine pattern and calculation of metabolite ratios rather than relying on single metabolite values improve testing accuracy (Marquardt et al. 2012).

Diagnostic Tools and Flowchart

Laboratory investigation of a suspected FAOD should begin with measurement of the acylcarnitine profile and includes consideration of individual metabolite values as well as the ratios of various acylcarnitines (Fig. 48.3). The acylcarnitine profiles in severe CPTII and CACT are indistinguishable, as are those in LCHAD and MTP deficiencies. In CPTI deficiency, carnitine concentration in dried blood spots is higher than in plasma, and diagnosis may be missed with measurement in plasma.

Clinical circumstances have a major effect on the acylcarnitine profile. Abnormalities are usually more marked during catabolism but, if the plasma-free carnitine concentration is very low, abnormal acylcarnitines may be hard to detect. Abnormalities decrease with intravenous glucose or dietary treatment, and metabolites from medium-chain fat oxidation increase with the use of medium-chain triglycerides (MCTs). An interpretation is especially difficult for terminal or post-mortem samples as they often show multiple raised acylcarnitine species, resembling MAD deficiency (MADD). In cases of very low free carnitine, diagnostic changes may be induced by overnight fasting or carnitine loading, respectively. However, these challenges can be dangerous and should only be considered in the inpatient setting, and the fasting period should be adjusted to the age of the patient. It is probably better to move to functional testing molecular analysis before considering challenge testing.

While acylcarnitine analysis is often consistent with a specific diagnosis, enzyme and/or mutation analyses are required for confirmation. The in vitro assays described below may be useful to reach a diagnosis when metabolite testing is normal in spite of a strong clinical suspicion.

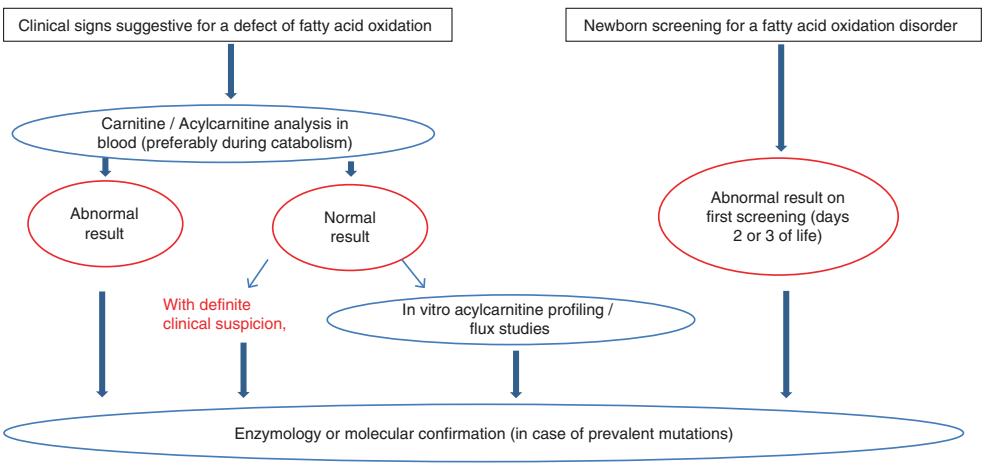

Fig. 48.3 Diagnostic flow chart

Enzyme Testing

Enzyme assays are generally performed in cultured fibroblasts or lymphocytes (Wanders et al. 2010) but are available in limited geographic areas. Enzymology in lymphocytes allows a rapid confirmation of diagnosis. Moreover, for VLCAD and MCAD deficiencies, residual activity may allow some predictions with respect to the expected severity of the defect (Hoffmann et al. 2012).

Fibroblast or Lymphocyte Acylcarnitine Profiling

Fibroblast or lymphocyte acylcarnitine profiling may identify an enzymatic defect if a diagnosis is not clear from blood testing. Here, acylcarnitines are analyzed by tandem mass spectrometry after incubating fibroblasts or lymphocytes with fatty acids' stable isotope-labeled substrates (^{2}H or ^{13}C) (Ventura et al. 1999; Sim et al. 2002). This technique can identify most FAODs except carnitine transporter and CPTI deficiencies. CACT and severe CPTII deficiencies cannot be distinguished and respiratory chain defects sometimes mimic FAODs (Sim et al. 2002).

Fatty Acid Oxidation Flux

Fatty acid oxidation flux is measured by incubating cells with radio-labeled fatty acids and collecting the oxidation products (Olpin et al. 1997). This technique identifies a global defect in FAO, is useful in assessing the severity of a disorder, but is not as specific as acylcarnitines in arriving at a diagnosis.

Urinary Organic Acids and Acylglycines

Urine organic acid analysis is normal in many FAODs when patients are well. Dicarboxylic acids are formed by ß-oxidation in peroxisomes and ω-oxidation in microsomes when plasma-free fatty acid concentrations are increased, but normally they are accompanied by ketonuria. During fasting or illness, however, medium-chain (and sometimes long-chain) dicarboxylic acids are elevated with little or no increase in ketone bodies. Dicarboxylic aciduria without ketonuria can also be seen in some respiratory chain defects. The analysis of acylcarnitines in the urine may identify carnitine esters of dicarboxylic acids that are of additional diagnostic significance. Defects of LCHAD and MTP deficiencies can accumulate unusual 3-hydroxydicarboxylic acids in urine. MCADD is characterized by an abnormal excretion of several acylglycines including hexanoylglycine, suberylglycine, and phenylpropionylglycine. These same acylglycines, in addition to short branched-chain acylcarnitines, are characteristic of MADD and, in general, are accompanied by a variety of dicarboxylic acids including as ethylmalonic acid, glutaric acid, and D-2-hydroxyglutaric acid. Unfortunately, normal organic acids do not exclude an FAO disorder since they can be normal in milder phenotypes and in anabolic situations.

Specimen Collection

Test	Material	Handling	Transport	Pitfalls
Acylcarnitines	Plasma; dried blood spot (DB)	Room temperature (DB); Frozen (plasma)	Normal mail	During anabolism eventually normal values; different profile with MCT diet; long-chain acylcarnitine accumulation also in healthy individuals during catabolism
Carnitine	Plasma; dried blood spot (DB)	Room temperature (DB); Frozen (plasma)	Normal mail	Blood and tissue concentrations do not correlate; in CPTI deficiency, carnitine is lower in plasma than in DB; it may be missed on analysis in plasma
Dicarboxylic acids	Spot urine	Frozen for longer storage	Normal mail	MCT diet and glucose infusion change the profile
Free fatty acids	Plasma	Frozen	Frozen	Determine before the next food intake
Enzyme assays in lymphocytes	Ethylenediamine tetraacetic acid (EDTA) plasma (2 mL)	Room temperature	Has to reach the laboratory within 48 hours after withdrawal; room temperature	Poor quality of the lymphocytes (due to transport conditions, low temperature, etc.) may result in lower residual enzyme activities
Enzyme assays in fibroblasts	Skin biopsy	Room temperature, in sterile 0.9% sodium chloride, fibroblast culture	In culture medium	Fibroblast culture must grow 4–8 weeks until enzyme assays can be performed
Molecular analysis	EDTA blood; dried blood spot	Room temperature	Normal mail	Delineation of only one mutation does not rule out deficiency of the enzyme

Prenatal Diagnosis

Prenatal diagnosis is available for all fatty acid oxidation disorders. Mutation analysis is the preferred technique if the molecular defect is known in the index case. Acylcarnitine and acylglycine assays of amniotic fluid have been reported for many FAODs, but are not routinely clinically available. These latter assays do not exclude the disease if metabolites are normal on prenatal diagnosis. All enzymes of fatty acid oxidation are expressed in chorionic villus biopsies and amniocytes and can be used for prenatal diagnosis. Chorionic villus biopsy can be performed at 11 gestational weeks, and amniotic fluid test at 14 + 0 weeks.

Deficiency of	Prenatal diagnosis suggested	Remarks
OCTN2	**–**	Very favorable clinical outcome
CPTI	**–**	Very favorable outcome
CACT	**+**	Majority of patients die in the neonatal period due to severe cardiac arrhythmias
CPTII	**+**	Suggested for severe neonatal phenotypes with congenital anomalies
	–	Myopathic phenotypes
VLCAD	**–**	Very favorable clinical outcome; many asymptomatic "patients"; skeletal myopathy needs to be discussed with the parents
MTP	**+** **(+)**	Suggested for severe phenotypes; neonatal phenotypes generally lethal; irreversible neuropathy/retinopathy needs to be discussed with the parents in milder phenotypes
LCHAD	**±**	Irreversible retinopathy/neuropathy needs to be discussed with the parents
LKAT	**+**	Only two patients so far; both died in the neonatal period
ACAD 9	**+**	Global mitochondrial dysfunction
MCAD	**–**	Very favorable clinical outcome since screening
SCAD	**–**	Only predisposition for disease
SCHAD	**±**	Phenotypes of different severity and response to treatment

DNA Analysis

All mitochondrial FAODs are inherited in an autosomal recessive pattern. There is molecular heterogeneity in all of the disorders but prevalent mutations have been identified in most. The relationship between genotype and phenotype varies among the different FAODs. In CPTII and VLCAD deficiencies, nonsense mutations on both alleles are generally associated with severe early onset disease, whereas adult onset rhabdomyolysis is associated with conservative missense mutations. A common mutation in VLCAD is found in nearly half of patients identified through newborn screening and is associated with a mild phenotype (c.848T>C). A common mutation accounts for 75% of the mutations in patients with MCADD and leads to complete deficiency, while a recurrent c.199T>C variant is associated with significant residual activity and appears to be benign. A common mutation in the *HADHA* gene alters the catalytic residue in the LCHAD domain and is the predominant cause of isolated LCHAD deficiency.

Enzyme name	Gene name	Prevalent mutations (Caucasian population)		Remarks
		Mutation	Amino acid change	
OCTN2	*SLC22A5*	No prevalent mutation		
CPTI	*CPT1*	c.1436C>T (Inuit population)	p.P479L	70% of babies homozygous for c.1436C>T in the Inuit population (Canada and Greenland)
CACT	*SLC25A20*	No prevalent mutation		
CPTII	*CPT2*	c.338C>T	p.S113L	Allele frequency (60%)
VLCAD	*ACADVL*	c.848T>C	p.V243A	Suggestive of mild VLCADD
MTP	*HADHA/HADHB*	No prevalent mutations		Many deletions and splice site mutations in the HADHA gene; Most compound heterozygotes for c.1528G>C and a second HADHA mutation have MTP deficiency
LCHAD	*HADHA/HADHB*	c.1528G>C	p.E474Q	Heterogeneous presentations despite one mutation
LKAT	*HADHA/HADHB*	No prevalent mutation		Only two patients known
ACAD9	*ACAD9*	No prevalent mutation		
MCAD	*ACADM*	c.985A>G c.199G>C	p.K329E p.Y67H	Classical MCADD; before screening: 80% homozygosity Asymptomatic/(mild) variant; allele frequency: 6% of mutant alleles in screened population; not found in a clinically diagnosed patient before screening
SCAD	*ACADS*	c.625G>A c.511C>T	p.G209S p.R171W	Polymorphisms with predisposition for disease; 625G > A: Allele frequency, 22%; c.511C > T: Allele frequency, 3%
SCHAD	***HADH***	No prevalent mutation		

Treatment

Prolonged fasting should be avoided in all FAODs in order to prevent acute metabolic decompensation. Frequent, regular feeds are recommended, especially during the first year of life, but subsequently overnight fasting (8 h) will be tolerated in most disorders. Prolonged overnight fasting should be postponed until later childhood/adolescence, especially in MTP and LCHAD deficiencies, in order to reduce the risk of retinopathy and neuropathy as a consequence of accumulating toxic metabolites.

Dietary fat restriction is not indicated in MCAD deficiency. In mild long-chain FAODs, the dietary fat intake does not have to be reduced if MCT oil is not prescribed; however, the fat intake should not exceed the dietary recommendation for healthy individuals. If MCT is used in severe long-chain FAODs, some restriction of long-chain fat will be necessary to maintain appropriate nutrient balance. Supplementation with 2–4 gm/kg of body weight per day of MCT oil may be used in young patients (<2 years of age) with a severe phenotype, and may be provided by an MCT-containing formula (Spiekerkoetter et al. 2009). Such high amounts are usually not tolerated in older children or adults, and 1–2 gm/kg/day is more usual. A bolus of MCT before exercise reduces accumulation of long-chain acylcarnitine species and may reduce the risk of rhabdomyolysis in patients with long-chain FAODs (Gillingham et al. 2006). Studies in VLCAD-deficient mice highlight the need to give MCT in accordance to the energy needs, since MCT are otherwise elongated and stored as saturated long-chain fatty acids (Tucci et al. 2015).

Carnitine treatment is undisputedly effective in patients with carnitine transporter deficiency. With a dose of 100–300 mg/kg/day, plasma concentrations may reach the lower normal range but muscle carnitine concentrations remain less than 5% of normal (Stanley et al. 1991). The value of carnitine supplementation in other FAODs is controversial. Plasma-free carnitine concentration is often low, particularly after an acute illness, but tissue concentrations have seldom been measured. In many patients, carnitine concentration in blood reach normal values when well, likely due to induced endogenous carnitine biosynthesis. Carnitine treatment has been hypothesized to be harmful in long-chain FAODs, as it increases the concentrations of potentially arrhythmogenic long-chain acylcarnitines (Primassin et al. 2008). However, this remains unproven and must be balanced against a potential benefit of providing some additional FAO capacity if the free carnitine is exceedingly low.

Bezafibrates (PPARα and PPARδ agonists) may be promising in the treatment of patients with myopathic CPTII or VLCAD deficiencies, though a randomized controlled clinical trial failed to show a clinical effect (Bonnefont et al. 2010). Triheptanoin (C7 odd-chain fatty acid) has been tested

anecdotally and in clinical trials as a substitute for MCT (Vockley et al. 2019). It has been presumed that patients with long-chain FAODs have reduced levels of TCA cycle intermediates that is more effectively addressed by supplying both acetyl-CoA and propionyl-CoA from triheptanoin as compared to acetyl-CoA alone from MCT (Vockley et al. 2019). In a double-blind study of the two compounds in patients with long-chain FAODs, patients showed improvement in cardiac function on triheptanoin compared to MCT. A phase-2 open-label trial of triheptanoin in long-chain FAOD patients showed an overall decrease in major clinical events defined as hypoglycemia, development and worsening of cardiomyopathy, and frequency and severity of rhabdomyolysis. A report on compassionate use of triheptanoin with acute onset or exacerbation of cardiomyopathy in long-chain FAOD patients while on MCT, showed rescue of critically ill patients in many cases (Vockley et al. 2016). The drug is being considered for approval in the USA, but has not been extensively tested in Europe. So far it is still considered an experimental treatment and has not been included in general treatment recommendations for FAO defects.

Emergency Treatment

Deficiency of	Emergency treatment	Pharmacological emergency treatment
OCTN2	Glucose i.v.; oral glucose monomer (to avoid hypoglycemia) Reach anabolism	L-carnitine i.v. (100–300 mg/kg per day)
CPTI **CACT** **CPTII** **VLCAD** **MTP** **LCHAD** **LKAT** **ACAD9**	Glucose i.v.; oral glucose monomer (to avoid hypoglycemia) Reach anabolism: <3 years: 10–12 mg/kg/min 3–10 years: 8–10 mg/kg/min >10 years: 5–8 mg/kg min Oral MCT; i.v. MCT generally not available (only special preparations) When severe decompensation, reach anabolism with use of insulin ACAD 9: Monitor lactate	L-carnitine typically not needed unless free carnitine is very low (<10 mM) D,L-3-hydroxybutyrate with severe cardiomyopathy Pharmacological treatment of arrhythmias
MCAD	Glucose i.v.; oral glucose monomer (to avoid hypoglycemia) Reach anabolism No MCT	
SCAD	Glucose i.v. in case of hypoglycemia	
SCHAD	Glucose i.v.	Glucagon, somatostatin (treatment of hyperinsulinism)

Standard Treatment

Deficiency of	Dietary treatment	Pharmacological treatment
OCTN2	Normal diet; regular meals; avoid catabolism	L-carnitine p.o. (100–300 mg/kg per day)
CPTI	Normal diet; rarely MCT supplementation in severe phenotypes	L-carnitine supplement only if blood level is very low (<10 mM)
CACT	MCT modified diet; strictly avoid catabolism (cave arrhythmias!)	
CPTII	Severe phenotypes: Carbohydrate-enriched diet (65–75% of total calories); fat restriction (25% of total calories: 10–15% MCT, 4% essential fatty acids, up to 10% long-chain triglyceride [LCT]) Regular meals After first year of life: Glucose polymer at night *Myopathic phenotypes*: Fat-reduced or normal diet MCT prior to exercise Regular meals; normal overnight fasting tolerance Asymptomatic patients: No dietary interventions	
VLCAD		
MTP	Strict long-chain fat reduction MCT supplementation (see CPT2, VLCAD) Docosahexaenoic acid (200–400 mg/kg per day) supplementation to prevent retinopathy is controversial	
LCHAD		
LKAT		
ACAD9	No recommendations available	
MCAD	No dietary intervention; regular meals	
SCAD	No dietary intervention; regular meals	
SCHAD	No dietary intervention; regular meals	Glucagon, somatostatin (treatment of hyperinsulinism)

Experimental Treatment

Treatment	Mechanism of treatment	Current status	Disorders
Bezafibrate	PPARα and PPARδ agonists; stimulate residual activity in milder phenotypes	Successful in isolated patients; clinical trials going on	Myopathic CPTII and VLCAD deficiencies
Triheptanoin	Odd-chain C7 fatty acid; anaplerotic action by provision of propionyl-CoA	Successful clinical trials in the USA	Long-chain FAODs

Disorders of Glycerol Metabolism

49

Katrina M. Dipple

Contents

Summary

Disorders of glycerol metabolism include glycerol kinase deficiency (GKD: both complex, cGKD, and isolated, iGKD), glycerate kinase deficiency (also known as D-glyceric aciduria), aquaporin 7 deficiency (AQP7, also known as hyperglyceroluria with mild platelet secretion defect), and cytosolic glycerol-3-phosphate dehydrogenase deficiency. GKD is involved in glycerol metabolism while glycerate kinase deficiency is involved in serine and fructose metabolism. Aquaporin 7 is associated with glycerol transport and presents with hyperglyceroluria like GKD. Cytosolic glycerol 3-phosphate dehydrogenase deficiency is a transient infantile hypertriglyceridemia. Disorders of glycerol metabolism vary in severity from asymptomatic to characteristic signs and symptoms. The hallmark of GKD and AQP7 is glyceroluria.

Introduction

Glycerol kinase deficiency (GKD) has three distinct clinical phenotypes: the complex form and two subtypes of the isolated form—symptomatic (juvenile) and benign (adult) (McCabe 2001a). GKD is due to deletion or mutations within the glycerol kinase (GK) gene on Xp21.2.

The clinical features of a patient with a complex glycerol kinase deficiency will depend on the loci that are involved in this contiguous gene syndrome (McCabe 2001a; McCabe 2001b). Deletion of the adrenal hypoplasia congenita (AHC) locus (*DAX1* gene) results in the cytomegalic form of adrenal hypoplasia (McCabe 2001b). Affected patients exhibit the signs and symptoms of glucocorticoid and mineralocorticoid deficiency, including bronzing of the skin and gums, and inability to respond appropriately to stresses such as intercurrent illnesses, leading to hypoglycemia, hyponatremia, and hyperkalemia. Death may occur during these Addisonian crises. Deletion of *DAX1* also is associated with hypogonadotropic hypogonadism (Zanaria et al. 1994; Muscatelli et al. 1994; Guo et al. 1995; Habiby et al. 1996). Patients with loss of the glycerol kinase (*GK*) gene have episodes of vomiting, acidemia, and stupor that seem to be unrelated to adrenal insufficiency and are similar to those observed in patients with the juvenile form of GKD (see below) (McCabe 2001a). Involvement of the Duchenne muscular dystrophy (DMD) gene may be associated with severe, progressive muscle weakness as in classical Duchenne muscular dystrophy, but also has been associated with milder muscle disease (Guggenheim et al. 1980; McCabe et al. 1989). All patients with involvement of the AHC, GK, and DMD or GK and DMD loci, and many but not all with deletion of the AHC and GK genes, have been mentally retarded (McCabe 2001a). For those with deletions extending telomeric from *DAX1* the mental retardation may be due to loss of a novel interleukin-1 receptor family member, *IL1RAPL1* (Carrié et al. 1999; Jin et al. 2000). Characteristic facies are seen among patients with deletions of all three loci. They have a triangular face with a broad nasal bridge and a bulbous nasal tip, described as an hourglass appearance to the midface (Goubau et al. 2013). The rest of this chapter will focus on isolated GKD (iGKD; Table 49.1).

There are two forms of iGKD: symptomatic (juvenile) and benign (adult) (McCabe 2001a). The symptomatic form of isolated glycerol kinase deficiency presents in early childhood. Affected boys have had hypothermia and lethargy beginning in the first week of life. More commonly, there is episodic vomiting between 2 and 6 years of age variably associated with acidosis and central nervous system depression, which may include lethargy, somnolence, stupor, unconsciousness, and hypoglycemia, interpreted by some as a Reye-like illness (McCabe 2001a).

The benign form of isolated glycerol kinase deficiency is not associated with the episodic metabolic and central nervous system (CNS) deteriorations seen with the other forms. Males with this biochemical phenotype are identified incidentally with pseudo-hypertriglyceridemia when routine laboratory studies incorrectly identify the elevated free glycerol concentration in their blood as triglycerides (McCabe 2001a). These individuals have increased levels of glycerol in blood and urine and may be at an increased risk for insulin resistance and type 2 diabetes mellitus (Basel-Vanagaire et al. 2012). Diagnosis is made by glycerolemia, glycerolluria, and mutations in the *GK* gene.

Glycerate kinase deficiency (GLYCTK-D; Table 49.2) also known as D-glyceric aciduria (DGA) is caused by deficiency of D-glycerate kinase (*GLYCTK*) gene and the glycerate kinase enzyme. It is a rare autosomal recessive inborn error of metabolism of serine and fructose metabolism (Sass et al. 2010). It is characterized by increased D-glyceric acid in the blood and urine. Patients can present with a variety of symptoms ranging from asymptomatic to hypotonia, failure to thrive, encephalopathy, seizures, intellectual disability, microcephaly, metabolic acidosis, to early death. Some consider it a benign disorder. It is distinguished from L-glyceric aciduria, which is primary hyperoxaluria type 2 due to deficiency of glyoxylate reductase/hydroxypyruvate reductase and will not be discussed here (Sass et al. 2020) (see Chap. 67). Diagnosis is made by elevated D-glyceric acid levels in plasma, urine, or cerebrospinal fluid and reduced glycerate kinase activity in the liver.

The aquaglyceroporin family are pore-forming transmembrane proteins that transport glycerol and water (Goubau et al. 2013). Aquaporin 7 (AQP7) is expressed in adipose tissue as well as in the kidney, pancreas, liver, and muscle. AQP7 deficiency (Table 49.3) is an autosomal recessive disorder due to mutations in the aquaporin 7 gene (*AQP7*). Patients with AQP7 deficiency also present with hyperglyceroluria; however, they do not have the hyperglycerolemia seen in GKD. Many patients are asymptomatic, but some patients can have delayed development, autism, epilepsy, hypotonia, and a mild platelet secretion defect. Aquaporin 7 knock out mice are at risk of adult onset diabetes; however, this has not been seen in humans with AQP7 deficiency (Goubau et al. 2013).

Cytosolic glycerol-3-phosphate dehydrogenase is encoded by the *GPD1* gene on 12q13.12 (Basel-Vanagaire et al. 2012). Its deficiency, cytosolic glycerol-3-phosphate dehydrogenase deficiency (HTGT; Table 49.4), is inherited in an autosomal recessive manner and is also known as transient infantile hypertriglyceridemia. Patients may present with elevated triglycerides, cholesterol, and transaminases. In addition, there might be liver steatosis, liver fibrosis, and splenomegaly. The hypertriglyceridemia is transient and normalizes with age (See Tables 49.1, 49.2, 49.3, and 49.4).

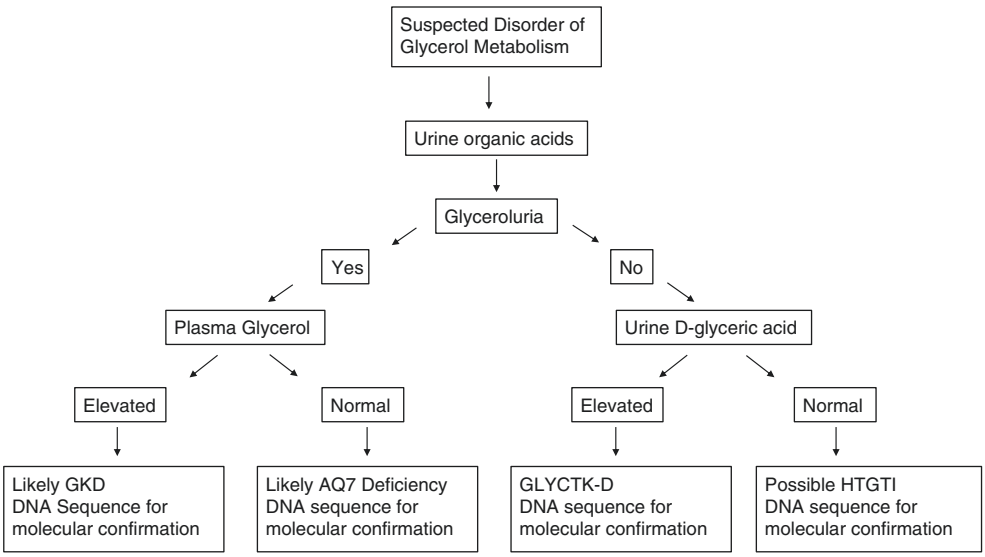
Diagnostic Flowchart



Specimen Collection

Test	Preconditions	Material	Handling	Pitfalls
Glycerol (U) urine organic acids	None	Random or 24 h	Keep cool or frozen	Contamination by emollients or glycerin suppository
Glycerol (S, P)	None	Serum/plasma	Keep cool or frozen	Some rubber stoppers in vacuum tubes use glycerol as lubricant

Prenatal Diagnosis

No.	Disorder	Tests recommended
49.1	Glycerol kinase deficiency	Mutation analysis on DNA from CVS or AF Glycerol level on amniotic fluid
49.2	Glycerate kinase deficiency	Mutation analysis on DNA from CVS or AF
49.3	Aquaporin 7 deficiency	Mutation analysis on DNA from CVS or AF
49.4	Cytosolic glycerol-3-phosphate deficiency	Mutation analysis on DNA from CVS or AF

Abbreviations: *AF* amniotic fluid, *CVS* chorionic villus, *DNA* deoxyribonucleic acid

DNA Testing

DNA testing by next-generation sequencing is available for all the disorders in this chapter. DNA can be obtained from peripheral blood leukocytes or buccal swab.

Treatment

Initial treatment is indicated if the patient is acutely ill, with vomiting and/or CNS depression. Initial treatment for GKD (isolated of complex with metabolic decompensation) includes starting an intravenous (IV) solution containing glucose, evaluating blood pH and serum electrolytes, drawing blood for adrenocorticotropic hormone (ACTH), and, if concerned about adrenal insufficiency (cGKD), considering initiating glucocorticoid and mineralocorticoid treatment. Long-term treatment includes avoiding of fasting in GKD and supportive treatment for the related neuropsychiatric issues with the other disorders.

Emergency treatment

No.	Disorder	Emergency treatment
49.1	Glycerol kinase deficiency	IV fluids with glucose
49.2	Glycerate kinase deficiency	IV hydration if metabolic acidosis
49.3	Aquaporin 7 deficiency	None
49.4	Cytosolic glycerol-3-phosphate deficiency	Supportive care

Standard care

No.	Disorder	Emergency treatment
49.1	Glycerol kinase deficiency	Avoidance of fasting Supportive care
49.2	Glycerate kinase deficiency	Decreased serine and fructose Supportive care
49.3	Aquaporin 7 deficiency	Supportive care
49.4	Cytosolic glycerol-3-phosphate deficiency	Supportive care

Disorders of Ketone Body Metabolism and Transport

50

Jörn Oliver Sass and Sarah C. Grünert

Contents

Summary

Ketone body utilisation is of special importance in times of fasting/starvation or increased energy demand. However, both formation and utilisation of ketone bodies (ketogenesis, ketone body transport and ketolysis) can be impeded by inborn errors of metabolism. In case of genetic deficiency of mitochondrial 3-hydroxy-3-methylglutaryl-coenzyme A synthase (mHMGS) or of 3-hydroxy-3-methylglutaryl-coenzyme A lyase (HMGL), the formation of ketone bodies is impaired. If the monocarboxylate transporter 1 (MCT1, encoded by *SLC16A1*) or one of the enzymes of ketolysis is affected, namely, succinyl-CoA:3-oxoacid CoA transferase (SCOT) or methylacetoacetyl-CoA thiolase (MAT, 'β-ketothiolase'), ketones accumulate and a life-threatening ketoacidosis may result. Since treatment options allow to minimise the risk for metabolic decompensations, awareness of those diseases is important, as is information on how to treat and to prevent clinical manifestations. MCT1 superactivity is clearly different from the other disorders of ketone body metabolism addressed here. While MCT1 is not normally expressed in pancreatic β-cells, gain-of-function mutations in the promoter region of *SLC16A1* enable its expression in those cells, thus causing exercise-induced hyperinsulinism that can result in hypoglycaemia.

Introduction

Ketone bodies acetoacetate and D-3-hydroxy-*n*-butyric acid are mainly formed in the liver. They are derived from fatty acids and ketogenic amino acids (Sass 2012; Sass et al. 2018). In contrast to free fatty acids, acetoacetate and D-3-hydroxy-*n*-butyric acid can be utilised by the brain. After prolonged fasting, they can account for a large proportion of the brain's energy supply.

During ketone body synthesis (ketogenesis), mitochondrial 3-hydroxy-3-methylglutaryl-coenzyme A synthase (mHMGS [EC 4.1.3.5]) catalyses the formation of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) from acetyl-CoA and acetoacetyl-CoA (Fig. 50.1). This is the rate-limiting step of ketogenesis. HMG-CoA, which can also result from leucine degradation, is converted by 3-hydroxy-3-methylglutaryl-coenzyme A lyase (HMGL [EC 4.1.3.4]) to acetyl-CoA and acetoacetate.

The interconversion of acetoacetate with D-3-hydroxy-*n*-butyric acid is catalysed by D-3-hydroxy-*n*-butyrate dehydrogenase (EC 1.1.1.30) and essentially reflects the oxidation status of the mitochondrial matrix (Mitchell et al. 1995). So far, genetic deficiency of D-3-hydroxy-*n*-butyrate dehydrogenase has not been identified. Acetone, which may give ketotic patients a typical odour, is formed by nonenzymatic decarboxylation of acetoacetate (Fig. 50.1).

For zebrafish, Hugo et al. reported a transporter of D-3-hydroxy-*n*-butyric acid that is required for hepatocyte secretion of ketone bodies during fasting and to avoid hepatic steatosis (Hugo et al. 2012). However, deficiency in humans of the orthologous human gene *SLC16A6*, encoding MCT7, is not known so far.

Ketone body utilisation (ketolysis) occurs in extrahepatic tissues. Ketone bodies may enter such tissues via monocarboxylate transporter 1 (MCT1, encoded by *SLC16A1*). The first and rate-limiting step of ketolysis requires succinyl-CoA:3-oxoacid CoA transferase (SCOT [EC 2.8.3.5]), which activates acetoacetate to acetoacetyl-CoA (Fig. 50.1). The enzyme methylacetoacetyl-CoA thiolase (MAT [EC 2.3.1.9]) then catalyses the formation of two acetyl-CoA molecules per molecule of acetoacetyl-CoA. Genetic deficiency of mHMGS typically presents as hypoketotic hypoglycaemia, while the lack of HMGL activity not only affects ketone body formation but also results in the accumulation of leucine metabolites (Fig. 50.3). SCOT deficiency is characterised by ketotic episodes or even permanent ketosis, but presents no specific metabolite abnormalities. Since MAT is not only involved in ketone body metabolism but also in the catabolism of the amino acid isoleucine, it may yield a characteristic, isoleucine-derived metabolite pattern in addition to hyperketosis.

Cytosolic acetoacetyl-CoA thiolase (EC 2.3.1.9) also catalyses the thiolytic cleavage of acetoacetyl-CoA. It has been considered the first enzyme of cholesterol synthesis (Fig. 50.2). In two girls, deficiency of cytosolic acetoacetyl-CoA thiolase has been assumed (De Groot et al. 1977; Bennett et al. 1984). One of the patients with developmental delay showed a pronounced metabolic reaction on a ketogenic diet, the other had persistent ketonuria as the only abnormal laboratory finding. However, at that time optimised enzyme assays were not available and the metabolic disorder had never been confirmed on the gene level. Therefore, this supposed metabolic disease will not be addressed further here. However, it may be appropriate to consider detailed studies of cholesterol and ketone body metabolism in future patients with severe neurologic symptoms and persistent ketonuria not explained otherwise. While MCT1 is normally silenced in pancreatic β-cells, certain mutations in the promoter of *SLC16A1* induce expression of MCT1 in this tissue, permitting pyruvate uptake and resulting in pyruvate-stimulated insulin secretion with consecutive hypoglycaemia during anaerobic exercise or following a pyruvate load (Otonkoski et al. 2003, 2007). The majority of the individuals reported with this exercise-induced hyperinsulinism (EIHI) so far is of Finnish origin.

Metabolic Pathways

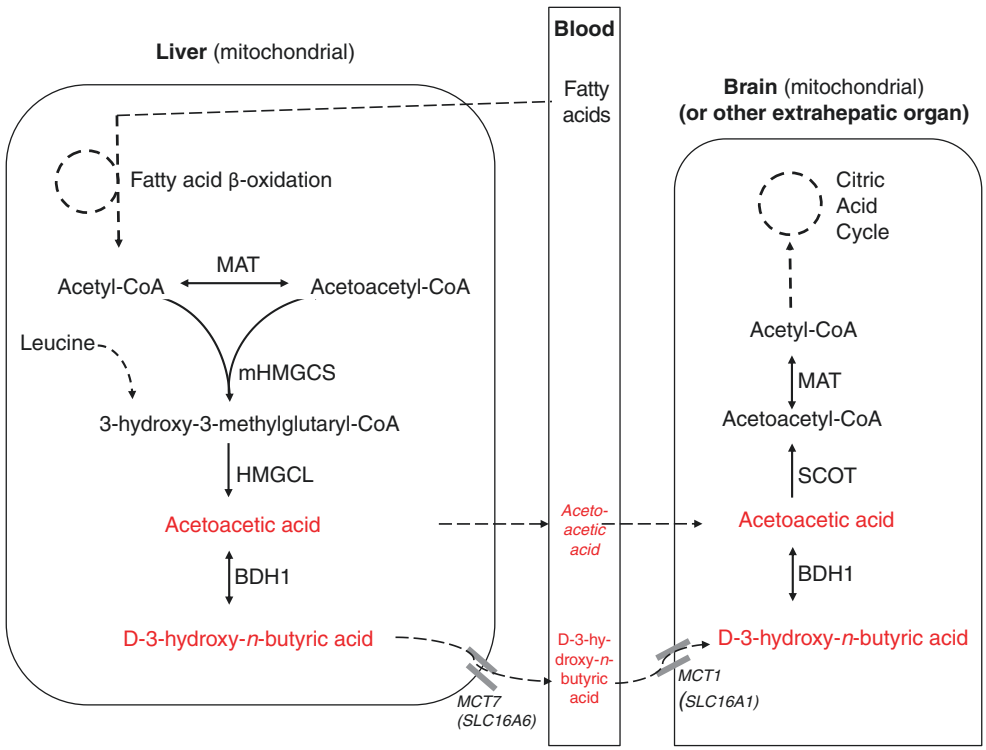

Fig. 50.1 Ketone body metabolism and transport. Schematic view of the enzymes and transporters of ketone body metabolism that are clearly linked to inborn errors. It is not exhaustive. In particular, additional monocarboxylate transporters (MCT) may be involved in ketone body transfer, and information is very limited regarding the transport of acetoacetic acid. Also, other sites than liver may provide small contributions to ketogenesis, for example, astrocytes and newborn gut. Mitochondrial acetoacetyl-CoA thiolase (MAT) and D-3-hydroxy-*n*-butyrate dehydrogenase (BDH1) participate in both ketogenesis and ketolysis. In liver mitochondria, during ketogenesis, MAT and other thiolases equilibrate the pools of acetoacetyl-CoA and acetyl-CoA. In contrast, in extrahepatic tissues, during ketolysis, MAT is the major mitochondrial thiolase that performs this reaction, and the most critical physiological role of MAT is in ketone body utilisation. Note that up to now the purported role of MCT7 (encoded by *SLC16A6*) has been confirmed in the zebrafish only. Figure and legend taken and slightly modified from the article by Sass et al. (2018), which is distributed under the terms of the Creative Commons Attribution 4.0 License (http://www.creativecommons.org/licenses/by/4.0/) that permits any use, reproduction and distribution of the work without further permission, provided that the original work is attributed as specified on the SAGE and Open Access pages (https://us.sagepub.com/en-us/nam/open-access-at-sage)

Signs and Symptoms

Deficiency of mHMGS (Table 50.1) typically presents with episodes of (mostly) hypoketotic hypoglycaemia, hepatomegaly and acute encephalopathy, much resembling disorders of fatty acid oxidation. During a metabolic crisis, urine organic acids can reveal dicarboxylic aciduria, often—but not always—without ketonuria. Elevated free fatty acids may be found in serum, while levels of lactic acid and ammonia are typically unremarkable. Since leucine enters the pathway at the subsequent step only (Fig. 50.1), mHMGS deficiency affects conversion of fatty acids to ketone bodies, but not amino acid catabolism. Although raised plasma acetylcarnitine (acylcarnitine C2) has been suggested as a marker if associated with hypoketotic hypoglycaemia, hepatomegaly and dicarboxylic aciduria, there are no established specific metabolite markers for this inborn error of metabolism. Crotonylglycine has been suggested as a candidate in this regard based on special investigations in urine of a single patient (Kouremenos et al. 2010). Thompson et al. (1997) reported several novel organic acids in urine of patients with mHMGS deficiency during periods of metabolic decompensation. In particular the pattern of 4-hydroxy-6-methyl-2-pyrone together with high concentrations of adipic acid in urine could be helpful for obtaining a diagnosis of mHMGS deficiency. However, Conboy et al. (2018) have questioned the diagnostic specificity of those biomarkers. All these metabolites warrant confirmation in a higher number of affected individuals and further validation.

Deficiency of HMGL (Table 50.2) presents with episodes of hypoketotic hypoglycaemia and metabolic acidosis,

usually early in life, although diagnosis may sometimes be delayed until adulthood (Grünert et al. 2017a). Cerebral infarction and pancreatitis are among the reported complications (Muroi et al. 2000).

HMGL deficiency affects not only the synthesis of ketone bodies from fatty acids but also the catabolism of the amino acid leucine. Therefore, both the pattern of urinary organic acids and blood acylcarnitines usually show characteristic abnormalities. Reports on eight pregnancies in five women with HMGCL deficiency suggest that an increased risk of miscarriage is associated with this disease. Pregnancy is a ketogenic state and may make women with this inborn error of metabolism particularly prone to metabolic compensations (Sass et al. 2018).

In nondiabetic patients, repeated or severe ketoacidotic episodes as well as persistent ketonuria without fasting are suggestive of an inborn error of ketone body transport or utilisation. In 2014, MCT1 deficiency (Table 50.3) due to mutations in *SLC16A1* was identified as a cause of ketoacidosis (van Hasselt et al. 2014). Notably, van Hasselt et al. reported clinical symptoms not only in patients who were homozygous or compound-heterozygous for *SLC16A1* mutations but also in some heterozygous individuals with only a single affected allele. This was confirmed by Balasubramaniam et al. who reported symptomatic half-brothers with the same mother but different fathers (Balasubramaniam et al. 2016). Those observations suggest that under some circumstances, heterozygous MCT1 deficiency can lead to ketoacidosis.

Accumulation of ketone bodies due to insufficient ketolysis because of SCOT deficiency also may result in life-threatening ketoacidosis (Table 50.4). As in MCT1 deficiency, there are no specific metabolite changes pointing to SCOT deficiency. Although permanent/postprandial ketosis/ketonuria may lead to the suspicion of SCOT deficiency, it is not a sensitive marker (Fukao et al. 2011b).

It has been reported that not only homozygous individuals but also heterozygous carriers of *OXCT1* mutations can develop severe ketoacidosis in episodes of ketogenic stress (Sasai et al. 2017).

Differential diagnoses in patients with severe ketonuria include diabetes mellitus type I, endocrine disorders, glycogen storage disease type 0, ketotic types of hepatic glycogen storage diseases and idiopathic ketotic hypoglycaemia. Elevated ketone body levels as a physiological consequence of enhanced ketogenesis (e.g., following heavy physical exercise) will normally not result in a ketoacidotic decompensation, while type I diabetes mellitus may present in such a way, albeit usually associated with polyuria, polydipsia, weight loss and hyperglycaemia. While SCOT deficiency is typically not associated with major abnormalities in

blood glucose, ketotic hypoglycaemia may have endocrine causes such as adrenocortical insufficiency, growth hormone deficiency and panhypopituitarism (Mitchell et al. 1995). In contrast to patients with SCOT deficiency, individuals with glycogen storage disease type 0, who also present without hepatomegaly and who suffer from hypoglycaemic-hyperketotic episodes, may show postprandial increase in lactate and alanine (Weinstein et al. 2006). Hyperketotic hypoglycaemia can also be caused by the ketotic forms of glycogen storage diseases affecting the liver (mainly type III, VI and IX). While most patients with these metabolic disorders present with hepatomegaly, some patients may have a normal liver size. Another differential diagnosis of ketoacidosis during the first 8 or 9 years of life is idiopathic ketotic hypoglycaemia. It usually represents an extreme constellation of a high ratio of brain to muscle mass, which can usually be adequately managed by glucose administration, because ketonuria usually precedes hypoglycaemia by hours. Idiopathic ketotic hypoglycaemia essentially represents a diagnosis made by exclusion.

In contrast to SCOT deficiency, MAT deficiency (less precisely called 'β-ketothiolase deficiency') represents not only a disorder of ketolysis but also a defect of isoleucine catabolism (Fig. 50.3; Table 50.5). Consequently, it is more easily identified based on the pattern of urinary organic acids comprising 3-hydroxy-2-methylbutyric acid and usually, but not always, tiglylglycine (Fukao et al. 2011a). If rather labile 2-methylacetoacetate is not detected, this may reflect inadequate preanalytical conditions. However, it may also suggest that a defect of the enzyme catalysing the preceding step in isoleucine catabolism, HSD10 disease (17-β-hydroxysteroid dehydrogenase X [17-β-HSD10], OMIM 300256), needs to be included into the differential diagnosis (Ofman et al. 2003). Although the acylcarnitines C5:1 and C5-OH are sometimes used for newborn screening for MAT deficiency, this is not reliable, as their blood levels can be unremarkable in metabolically stable patients. Although fatal outcomes are documented in some patients with MAT deficiency, a recent study on this inborn error of metabolism suggests that MAT deficiency may be a rather benign metabolic disorder, with a substantial proportion of largely asymptomatic individuals (Grünert et al. 2017b).

Superactivity of MCT1 (Table 50.7) due to gain-of-function mutations in the *SLC16A1* promoter is a cause of exercise-induced hyperinsulinism and underlies familial hyperinsulinemic hypoglycaemia 7 (HHF7).

It can result in seizures and in loss of consciousness due to hypoglycaemia (Meissner et al. 2001; Otonkoski et al. 2003, 2007).

Reference Values

In view of the many variables affecting ketone body concentrations physiologically, it is difficult to provide general reference values. The concentrations of ketone bodies fluctuate widely. For details on 3-hydroxy-*n*-butyrate and free fatty acids under fasting conditions, see Bonnefont et al. (1990) and Morris et al. (1996).

Using organic acid analysis according to Lehnert (1994) (applying methylation as the derivatisation procedure), the following reference values have been obtained based on 42 metabolically stable control individuals (mean ± standard deviation): 3-hydroxy-2-methylbutyric acid, 10.7 ± 7.6 mmol/mol creatinine; tiglylglycine, 24.6 ± 14.6 mmol/mol creatinine (Fukao et al. 2011a).

Notably, it is known from quality assessment programs that quantitative organic acid data vary largely between laboratories, and laboratories are encouraged to establish their own reference ranges. However, organic acid analysis is mostly performed on a qualitative/semiquantitative basis based on recognition of diagnostic signal patterns.

Pathological Values

During metabolic decompensations, levels of diagnostic metabolites may be elevated 100-fold and more. In mHMGCS deficiency, the organic acids of a metabolically decompensated patient may resemble the dicarboxylic aciduria

observed in individuals in ketotic states but without concomitant ketonuria. However, in metabolically stable conditions, defects in ketogenesis or ketolysis may result in unremarkable metabolite profiles, and thus escape detection, which is more easily accomplished in samples obtained during a metabolic decompensation.

Diagnostic Flowchart

mHMGCS deficiency and HMGCL deficiency are easily distinguished from each other in urinary organic acid profiles and plasma amino acids. MCT1 superactivity is one of many complex differential diagnoses of hypoglycaemia that is beyond the scope of this chapter. However, a flow chart is presented for the disorders of ketone body transport and catabolism (Fig. 50.4).

If characteristic isoleucine metabolites are present, MAT deficiency is the first tentative diagnosis in a ketoacidotic patient. As 2-methylacetoacetic acid is prone to degradation, its absence does not exclude MAT deficiency. If characteristic isoleucine metabolites such as 3-hydroxy-2-methylbutyric acid are not detected, it is useful to start with sequence analysis of *SLC16A1*, which encodes MCT1. If the results are negative, it may be helpful to add a functional test for SCOT deficiency in cells from the same blood sample. Investigations for MAT deficiency would usually follow as last test, if suggestive isoleucine metabolites have not been observed.

Loading Tests

A leucine load that was performed in one of the first patients with suspected mHMGCS deficiency (Morris et al. 1998), but it is not used anymore today because of the opportunities of genetic testing. Similarly, the intravenous pyruvate test applied in the initial characterisation of several patients with MCT1 superactivity has been replaced by deoxyribonucleic acid (DNA) studies. While an isoleucine loading test was

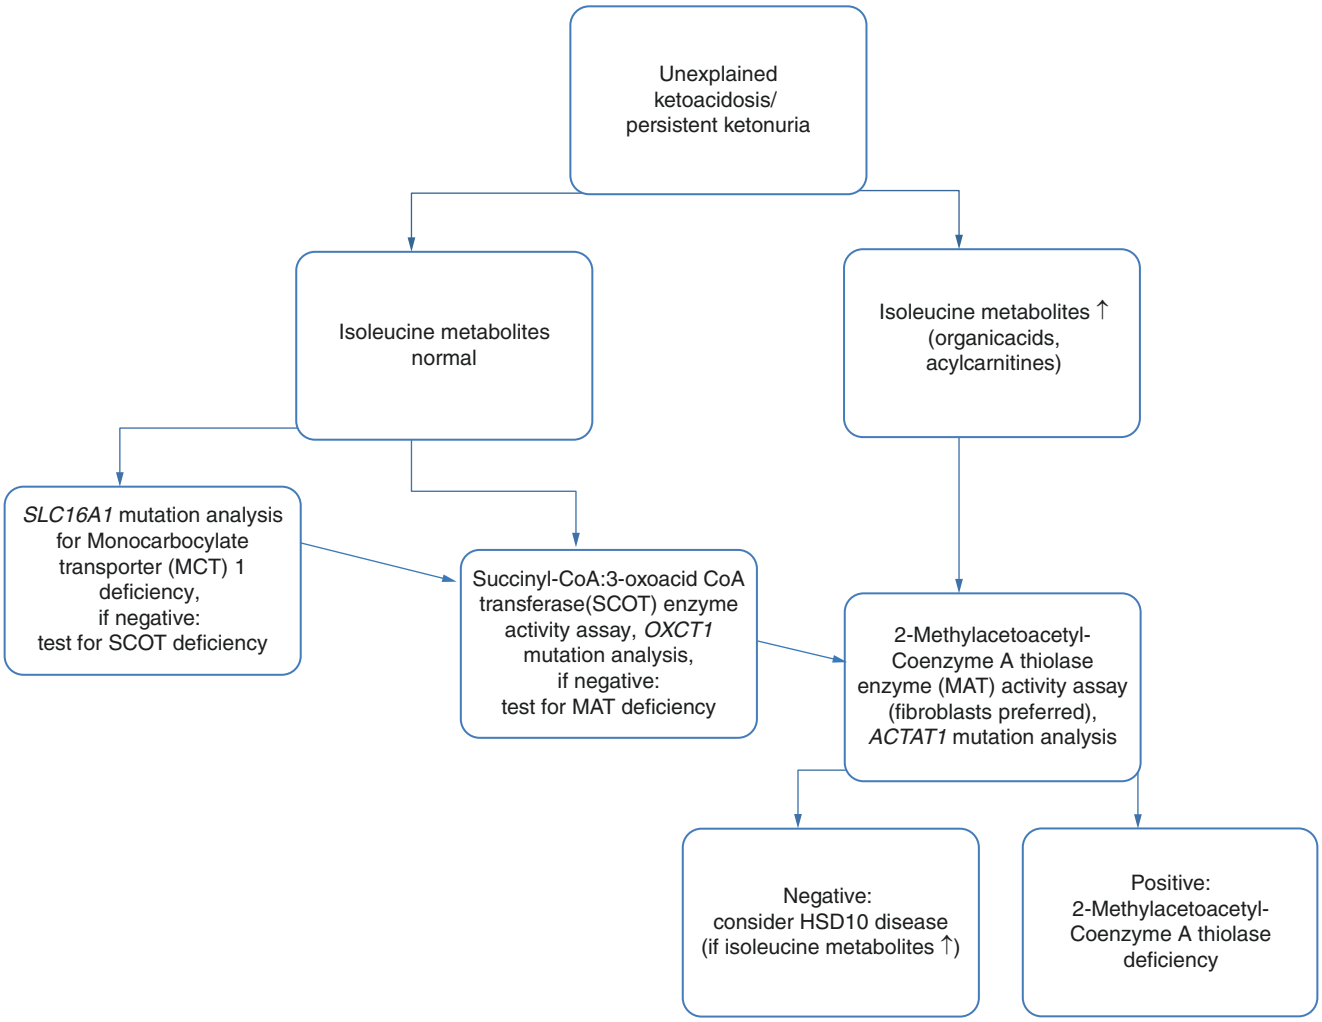

Fig. 50.4 Diagnostic flowchart for differentiation between inborn errors of ketone body transport and catabolism

important in the discovery of MAT deficiency by Daum et al. in (1971), and was of diagnostic use in subsequent years, it has now been replaced by enzyme activity assays and mutation analysis.

Specimen Collection

Confirmation of suspected deficiencies of SCOT, MAT and HMGL is usually approached by enzyme activity tests or mutation analyses. In contrast, mutation analysis is the method of choice in suspected deficiencies of mHMGCS or MCT1 (as well as in tentative MCT1 superactivity). If a defect of ketone body transport or catabolism is suspected but no abnormal isoleucine metabolite pattern is found, sequencing of *SLC16A1* (just five exons) can be performed while immortalised lymphocytes from the same blood sample are growing for a SCOT enzyme activity test to be added if the *SLC16A1* testing does not yield a diagnosis.

No.	Disorder	Metabolites	Enzyme assay	Mutation analysis

[a]Methylacetoacetate, which helps to distinguish MAT deficiency from HSD10 disease, is prone to degradation, thus recommending the shipment of urine in frozen state

[b]Cultured skin fibroblasts preferred, lymphocytes not recommended

Prenatal Diagnosis

Once the diagnosis is known, disorders of ketone body metabolism are amenable to preventive measures including dietary treatment. However, if prenatal testing is requested, it is technically feasible.

No.	Disorder	Metabolite	Enzyme assay	Mutation analysis	Source

50.7	Monocarboxylate transporter 1 superactivity			X	A, CV[b]

Abbreviations: *A* Amniocytes, *AFC* Amniotic fluid cells, *CV* Chorionic villi

[a]Not known whether actually done, but can in principle be performed by DNA analysis

[b]For DNA analysis only

Treatment

The mainstay of therapy in deficiencies of HMG-CoA synthase/lyase, MCT1, SCOT and MAT is a rather preventative measure: ketogenesis has to be obviated to the extent possible.

Therefore, prolonged fasting has to be avoided and increased energy requirements have to be met. During acute decompensations, hypoglycaemia, if present, needs to be corrected immediately followed by constant high-rate intravenous glucose infusion with adequate electrolytes. Carbohydrates have not only antilipolytic effects but may also be useful due to antiproteolytic effects in HMGL, MCT1, SCOT and MAT deficiencies. In the acute phase with ketoacidosis and dehydration, fluid therapy is mandatory. The treatment of metabolic acidosis by bicarbonate is controversial but alkalinisation may be beneficial in severe ketoacidosis (pH < 7.1). Invasive methods such as dialysis have been shown to be effective but are rarely necessary, although haemodiafiltration may play a crucial role in HMG-CoA synthase deficiency. After diagnosis, treatment with frequent carbohydrate-rich meals during mild infections and intercurrent illnesses is advisable to prevent metabolic decompensation. Deficiency of L-carnitine should be compensated, if present. After childhood, metabolic decompensations have hardly been reported in patients with defects in ketone body utilisation or transport.

Management of acute events

Nr.	Disorder	Management
50.1	3-Hydroxy-3-methylglutaryl-CoA synthase deficiency	Immediate correction of hypoglycaemia, if present, followed by constant high-rate glucose infusion
		Consider haemodiafiltration and administration of L-carnitine
50.2	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	Immediate correction of hypoglycaemia, if present, followed by constant high-rate glucose infusion
		Consider administration of L-carnitine
50.3	Monocarboxylate transporter 1 deficiency	Immediate correction of hypoglycaemia, if present, followed by constant high-rate glucose infusion
		Consider alkalinisation if acidosis is very pronounced (pH < 7.10)
50.4	Succinyl-CoA:3-oxoacid CoA transferase deficiency	Immediate correction of hypoglycaemia, if present, followed by constant high-rate glucose infusion
		Consider alkalinisation if acidosis is very pronounced (pH < 7.10)
50.5	Methylacetoacetyl-CoA thiolase deficiency	Immediate correction of hypoglycaemia, if present, followed by constant high-rate glucose infusion
		Consider alkalinisation if acidosis is very pronounced (pH < 7.10) and administration of L-carnitine
50.7	Monocarboxylate transporter 1 superactivity	Ensure adequate carbohydrate supply (consider glucose infusion)

In periods of well-being, the avoidance of fasting is considered of crucial importance in all disorders of ketogenesis and ketolysis. This can usually be achieved with a normal meal frequency. In young children, a bedtime snack or the administration of uncooked corn starch at bedtime or midnight might be necessary. A special diet is usually not required; however, extremes of dietary fat intake should be avoided. A ketogenic diet is clearly contraindicated. Protein restriction may be useful in HMGCL and MAT deficiencies and possibly in SCOT deficiencies while a high protein intake may—at least in theory—be beneficial in mHMGS deficiency by compensating for the metabolic block and providing a source of ketone bodies. Most paediatric patients

with HMGCL or MAT deficiency are stable on a protein intake of about 1.5 g/kg/day. However, protein intake needs to be individualised (Mitchell et al. 1995) and the expected benefit of protein restriction is based on limited evidence only. In patients with low levels of carnitine, L-carnitine supplementation should be considered and may help to eliminate accumulating tiglyl-CoA. But treatment and outcome studies are still sparse in most of these rare diseases so far.

Treatment when metabolically stable (maintenance therapy)

Nr.	Disorder	Management
50.1	3-Hydroxy-3-methylglutaryl-CoA synthase deficiency	Avoid fasting and extreme fat intake Regular feeding in daytime Consider additional bedtime snack in young children and supplementation with L-carnitine
50.2	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	Avoid fasting and extreme fat intake Regular feeding in daytime Consider additional bedtime snack in young children and mild protein restriction (individualised, about 1.5 g/kg body weight/day) and compensate deficiency of free carnitine, if present
50.3	Monocarboxylate transporter 1 deficiency	Avoid fasting and extreme fat intake Regular feeding in daytime Consider additional bedtime snack in young children
50.4	Succinyl-CoA:3-oxoacid CoA transferase deficiency	Avoid fasting and extreme fat intake Regular feeding in daytime Consider additional bedtime snack in young children
50.5	Methylacetoacetyl-CoA thiolase deficiency	Avoid fasting and extreme fat intake Regular feeding in daytime Consider additional bedtime snack in young children and mild protein restriction (individualised, about 1.5 g/kg body weight/day) and compensate deficiency of free L-Carnitine, if present
50.7	Monocarboxylate transporter 1 superactivity	Avoid extensive physical exercise

Contents

Summary

The advent of exome sequencing has greatly increased the discovery of new disease genes, especially in groups of patients with complex pathology including spastic paraplegias, congenital ichthyosis, and lipodystrophies. Many of these disease-causing genes turned out to be involved in complex lipid metabolism and are dispersed throughout the different branches of the lipid biosynthetic tree. Lipids not only are structural components needed for cell compartmentalization but also are involved in dynamic processes including inter- and intracellular transport and signal transduction. The synthesis, remodeling, and degradation of lipids are tightly coordinated in mammalian cells and involve and affect almost all organelles of the cell. Using simple building blocks including glycerol, amino acids, and radyl units (fatty acids/alcohols), a plethora of lipid species can be produced. The chapter is divided into five parts dealing with disorders in (1) phospholipid and neutral lipid metabolism, (2) fatty acid synthesis and elongation, (3) triglyceride/lipid droplet metabolism, (4) sphingolipid metabolism, and (5) a miscellaneous category. Given the very diverse gene functions and clinical phenotypes, we have chosen a different chapter structure. For each disorder, in addition to the phenotype tables, we have separately listed their function, a brief clinical synopsis, and if known/available specific treatment options, other than supportive care.

Introduction

Lipids are best known as structural components of biological membranes to form permeability barriers of cells and organelles. In addition, they can function as an energy source, are used to modify proteins, participate in membrane fusion/fission, and can be bioactive messengers that directly or indirectly regulate gene expression. There are many types of lipids, each with different chemical properties that in turn dictate the fluidity and permeability of membranes. By varying the composition of lipids, a huge diversity in membranes can be generated that allows the formation of organelles, cells, and tissues (Harayama and Riezman 2018). Because the chemical properties are crucial to the function of lipids, small changes in lipid structure or composition (a missing double bond or a different fatty acid composition) can have large implications for cells, affecting tissues and therefore the entire human metabolism. The genomics revolution has resulted in the identification of causative genes for many disorders/syndromes, including an increasing number of lipid metabolism genes. Together with considerable advances in lipid analysis, catalyzed by new technological possibilities in mass spectrometry, a new field of inborn errors of lipid metabolism has emerged. Before discussing the clinical, genetic, and functional aspects of these many disorders, it is crucial to first briefly address the metabolism of complex lipids with emphasis on their synthesis.

The synthesis, remodeling, and degradation of lipids are tightly coordinated in mammalian cells, and key organelles involved in this process are the endoplasmic reticulum (ER), mitochondria, lipid droplets (LD), lysosomes, and the Golgi apparatus. At these locations, lipids are assembled from simple building blocks including glycerol, phosphate, fatty acids, fatty alcohols, serine, choline, ethanolamine, and inositol to form a plethora of complex lipids belonging to different major classes. The main categories of lipids discussed in this chapter are fatty acids, glycerophospholipids (from here on called phospholipids), neutral lipids (i.e., sterols and glycerolipids), and sphingolipids. Figure 51.1 shows the molecular structures of the most relevant lipids for this chapter, the three major classes: phospholipids, glycerolipids, and sphingolipids.

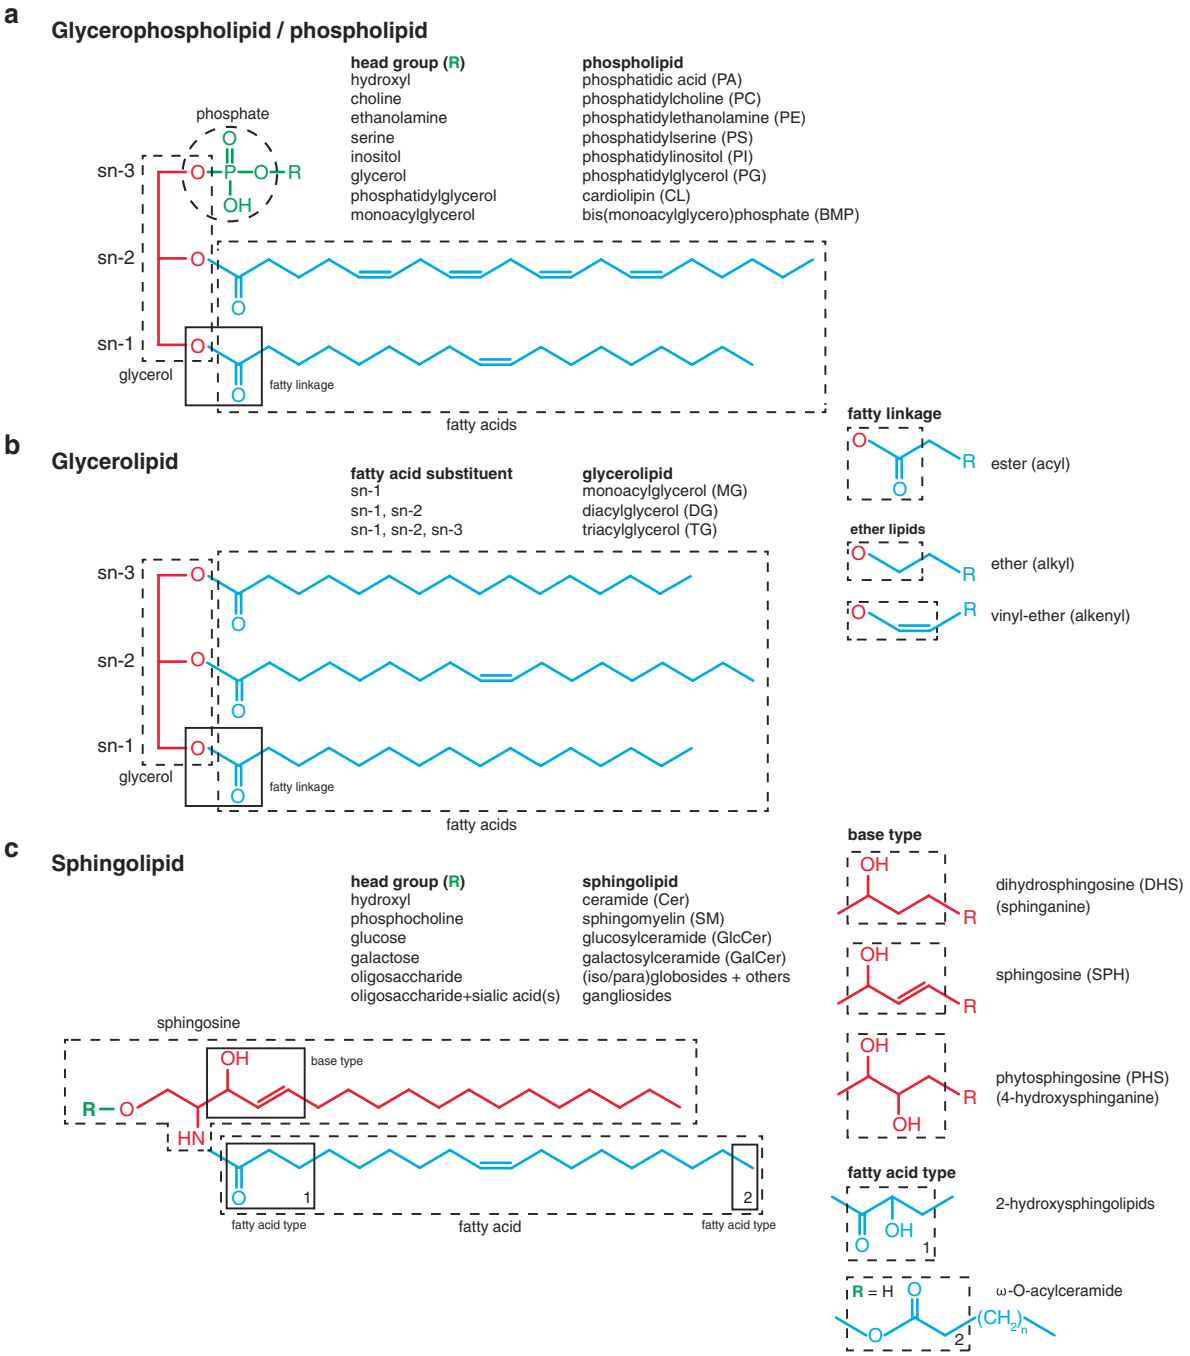

Fig. 51.1 Molecular structures of different lipid classes. (**a**) Glycerophospholipids or phospholipids contain a glycerol backbone (*red*) attached to one or two fatty acid/fatty alcohol (*blue*) substituents at the *sn*-1 and *sn*-2 position and characteristic phosphate-linked headgroup (*green*) at the *sn*-3 position. Most common headgroups are listed with the name and abbreviation of the corresponding phospholipid. In ether phospholipids, the fatty linkage at the *sn*-1 position is either an ether or a vinyl-ether, and the latter substitution defines the subclass that is known as plasmalogens. (**b**) Glycerolipids contain a glycerol backbone (*red*) attached to one up to three fatty acid/fatty alcohol (*blue*) substituents. In analogy to ether phospholipids, ether variants of glycerolipids also exist with an ether fatty linkage on the *sn*-1 position. (**c**) Sphingolipids consist of a sphingoid base (*red*) coupled to a headgroup (*green*) and an N-linked fatty acid (*blue*). Hydroxylation and (un)saturation define the sphingoid base type. 2-Hydroxylation of the fatty acid (1) or ω-acylation (2) determines the fatty acid type. The headgroup (*green*) defines the type of sphingolipid, common headgroups, and sphingolipids and abbreviations are listed

Nomenclature

No.	Disease name	Alternative disease names	Disease abbreviation	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	Disease OMIM#

Metabolic Pathways

Phospholipid and Neutral Lipid Synthesis

Figure 51.2 shows the general metabolic pathways of phospholipid synthesis, fatty acid synthesis, and elongation and triacylglycerol (TG) usage in the lipid droplet. For clarity, only disease genes have been indicated. Briefly, there are two main synthetic pathways with some overlap. The majority of membrane phospholipids are synthesized in the ER and are made from glycerol-3-phosphate that, after two acylations, forms phosphatidic acid (PA). Attachment of a headgroup to this phosphate designates to which major phospholipid class the lipid belongs. Major phospholipid classes include (in order of cellular abundance) phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylserine (PS), and phosphatidylglycerol (PG). PG can be further metabolized to cardiolipin (CL) in the mitochondrion, and PG, likely via mitochondria-associated membranes, is the precursor for the late endosomal lipid bis(monoacylglycero)phosphate (BMP). Cytidine triphosphate (CTP) is used to create high-energy molecules of either the headgroup (cytidine diphosphate (CDP)-choline (➔PC) and CDP-ethanolamine (➔PE)) or the acylated glycerol backbone (CDP-diacylglycerol (CDG-DG)) which then condenses with diacylglycerol (DG) or the headgroup (inositol (➔PI), glycerol (➔PG) or phosphatidylglycerol (➔CL)), respectively, to yield the specific lipid. DG is an intermediate metabolite that either is incorporated in phospholipids or that, mainly for energy storage in lipid droplets, is acylated to form TG (Vance 2015). Stepwise hydrolysis of TG at the lipid droplet surface yields three free fatty acids and a glycerol molecule which can be used for energy generation or other metabolism (Fig. 51.2a). Lipid droplet synthesis and degradation plays an important role in cellular lipid homeostasis, storing cholesterol esters and TG that serve as a source of energy substrates or precursors for signaling lipids or membrane (phospho)lipid synthesis (Sztalryd and Brasaemle 2017).

Another important class of lipids is the so-called ether lipids that are characterized by a fatty alcohol on the *sn*-1 position that creates an ether bond with the glycerol backbone (Fig. 51.2b). The precursor is not glycerol-3-phosphate but dihydroxyacetone phosphate, which in a number of steps is converted to 1-alkylglycerol in the peroxisome. The remainder of the synthetic pathway is located at the ER. After acylation of the *sn*-2 position to form 1-alkyl-2-acylglycerol (DG[O]), CDP-choline or CDP-ethanolamine can be used to form the ether phospholipids PC[O] and PE[O]. Desaturation of the ether-linked fatty alcohol on the *sn*-1 position yields a vinyl-ether which is characteristic of plasmalogen species, a subclass of ether phospholipids that are especially important for the brain. Alternatively, DG[O] can be acylated to form 1-alkyl-2,3-diacylglycerol (TG[O]), the ether analog of TG, a relatively uncharacterized ether lipid (Dean and Lodhi 2018; Braverman and Moser 2012).

Fatty Acid Synthesis and Elongation

Figure 51.2 also shows three relevant auxiliary pathways: the mitochondrial fatty acid synthesis (mFAS), long-chain fatty acid synthesis (FAS) in the cytosol, and very long-chain fatty acid elongation in the ER. mFAS produces mainly octanoate that is subsequently used for synthesis of lipoic acid. Lipoic acid is needed in five mitochondrial reactions including 2-oxoacid dehydrogenases (the pyruvate dehydrogenase, 2-ketoglutarate dehydrogenase, and branched-chain dehydrogenase complexes) and the glycine cleavage system (Kastaniotis et al. 2017). Cytosolic FAS synthesizes mainly palmitate (C16:0) destined for storage in TG, incorporation in other lipids, or further elongation in the ER. Further elongation of saturated or polyunsaturated fatty acids in the ER produces different types of very long-chain fatty acids that can be used for complex lipid synthesis and/or can be used to tune the fatty acid composition of other complex lipids (Kihara 2012). Very and ultra-long-chain fatty acids, for example, are used to synthesize ω-O-acylceramides that are needed for the barrier function of the skin (Kihara 2016a). The three pathways are shown and explained in more detail in Fig. 51.3, including disease genes. mFAS uses acyl carrier protein (ACP) to carry the nascent fatty acid, whereas the cytosolic FAS system and the ER elongation system use coenzyme A. The process of fatty acid synthesis/elongation starts by the generation of malonyl-CoA by carboxylation of acetyl-CoA which condenses with an acyl-CoA or an acyl-unit attached to acyl carrier protein (ACP) to form a 3-ketoacyl-CoA/ACP. Subsequent reduction, dehydrogenation, and another reduction yield an acyl-CoA/ACP with two additional carbon atoms (see Fig. 51.3).

Sphingolipid Synthesis and Metabolism

Sphingolipids are membrane lipids that not only are structural components but also can participate in membrane microdomain formation, serve as ligands of lectins, and modulate the activity of membrane receptors. They are particularly abundant in the brain and crucial for the development and correct function of the nervous system. Sphingolipid metabolism is shown in Fig. 51.4 and starts by the synthesis of ceramide. The production of ceramide is the backbone of sphingolipid synthesis that branches out into subclasses of complex sphingolipids including phosphocholine-containing sphingomyelins (SM), (oligo)saccharide-containing glycosphingolipids, and

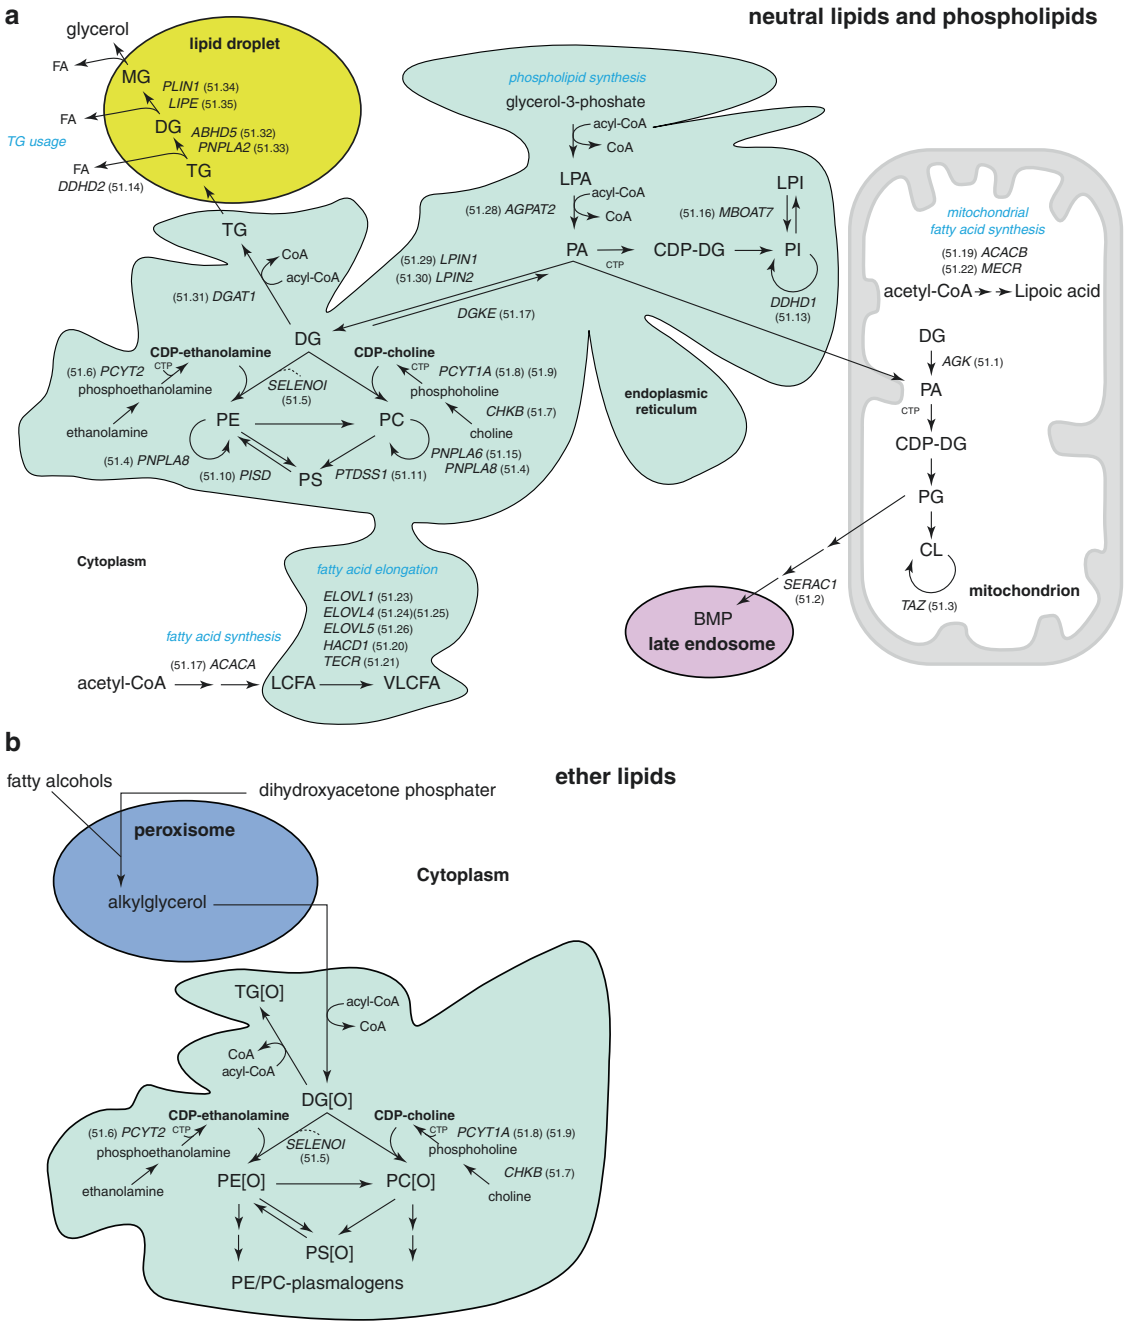

Fig. 51.2 Phospholipid synthesis, fatty acid synthesis/elongation, and lipid droplet metabolism including disease genes. (**a**) Neutral lipid, fatty acid, and phospholipid synthetic pathways. Glycerol-3-phosphate is acylated on the *sn*-1 position to form lysophosphatidic acid (LPA) followed by a second acylation step on the *sn*-2 position to form phosphatidic acid (PA). At the expense of cytidine triphosphate (CTP), PA can be converted into the high-energy molecule CDP-diacylglycerol (CDP-DG) which can condense with inositol in the endoplasmic reticulum (ER) to form phosphatidylinositol (PI) or in mitochondria with phoshatidylglycerol (PG) to form cardiolipin (CL). PG also is the precursor of the late endosomal lipid bis(monoacylglycero)phosphate (BMP). In the ER, PA can be dephosphorylated to form diacylglycerol (DG) that can condense with activated headgroups CDP-ethanolamine and CDP-choline to form phosphatidylethanolamine (PE) and phosphatidylcholine (PC), respectively. CDP-ethanolamine and CDP-choline are made via phosphorylation and subsequent activation with CTP from ethanolamine and choline, respectively, part of the so-called Kennedy pathway. Phosphatidylserine (PS) can be made by base = headgroup exchange from PE or PC. DG can also be acylated to form triacylglycerol (TG) which can be stored in lipid droplets. Usage of TG is executed by sequential hydrolysis of the fatty acid esters, finally resulting in the formation of glycerol and three fatty acids. Fatty acids can be synthesized from acetyl-CoA in the cytosol to form long-chain fatty acids (LCFA) that can be further elongated in the ER to very long-chain fatty acids. Another fatty acid synthesis system is present in mitochondria, but this is involved in the synthesis of lipoic acid, a special sulfur-containing fatty acid required for three mitochondrial dehydrogenase complexes. (**b**) Ether lipid metabolism. Dihydroxyacetone phosphate and a fatty alcohol is converted to alkylglycerol in the peroxisome after which alkylglycerol is acylated in the ER to form 1-alkyl-2-acylglycerol (DG[O]). Like non-ether lipids, DG[O] can be converted to ether-analogs of PE and PC by condensation with CDP-ethanolamine and CDP-choline, forming plasmanyl-PE and plasmanyl-PC. Creation of a vinyl-ether by desaturation in the ER yields plasmenyl-PE/PC which are collectively called plasmalogens. Like DG, DG[O] can also be acylated which yields 1-alkyl-2,3-diacylglycerol (TG[O]). Remodeling activities are indicated by a circular arrow

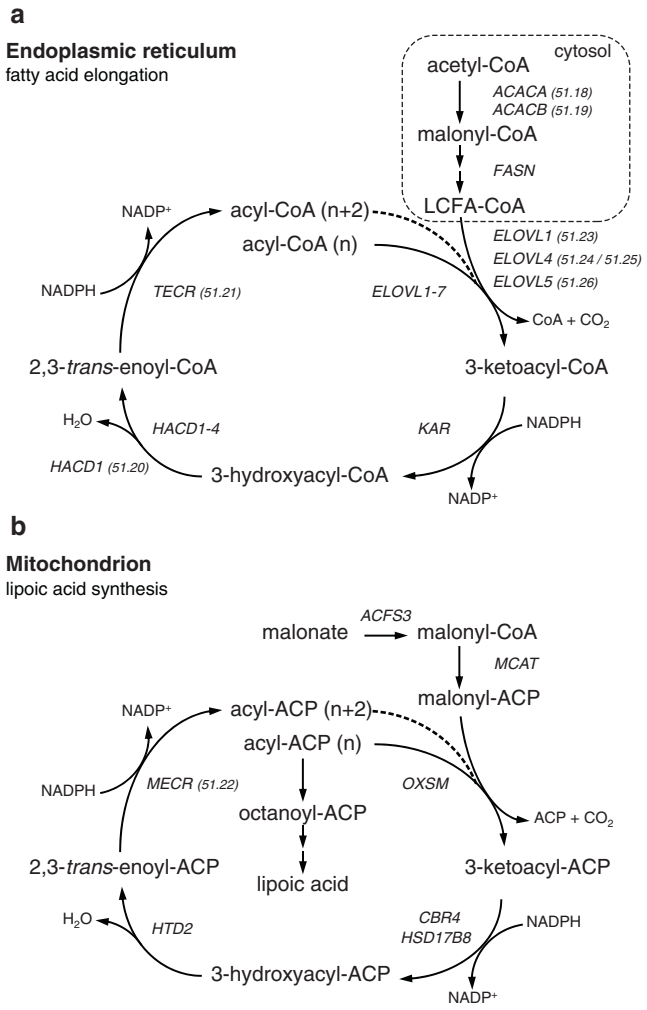

Fig. 51.3 Fatty acid synthesis and elongation, including disease genes. (**a**) Fatty acids are synthesized in the cytosol from malonyl-CoA by the fatty acid synthase complex (*FASN*) to form a long-chain acyl-CoA (LCFA-CoA). This LCFA-CoA can then be elongated in the ER to yield a variety of very long-chain fatty acids. The first step, the condensation of malonyl-CoA with the LCFA-CoA, is catalyzed by a family of very long-chain 3-oxoacyl-CoA synthases (ELOVLs) with different tissue expression patterns and with variable substrate specificities depending on the fatty acid length and degree of unsaturation. 3-Ketoacyl-CoA-reductase (*KAR*) reduces the keto-group to a hydroxyl-group. The resulting 3-hydroxyacyl-CoA is dehydrated by a family of 3-hydroxyacyl-CoA dehydratases (*HACD1–4*) with different tissue expression patterns to form 2,3-trans-enoyl-CoA. Finally, this double bond is reduced to by trans-2,3-enoyl-CoA reductase (*TECR*) resulting in an acyl-CoA that is two carbon atoms longer. (**b**) The mitochondrial fatty acid synthesis system, also known as mFAS, uses acyl carrier protein (ACP) instead of CoA to carry the growing acyl-unit. After carboxylation of acetyl-CoA to form malonyl-CoA, malonate is transferred by mitochondrial malonyl CoA-acyl carrier protein transacylase to ACP. Malonyl-ACP condenses with acyl-ACP to form 3-ketoacyl-ACP which is catalyzed by 3-oxoacyl-acyl-carrier-protein synthase, encoded by *OXSM*. Carbonyl reductase 4 (*CBR4*) and ketoacyl-ACP reductase (*HSD17B8*) are involved in the NADPH-dependent reduction to form 3-hydroxyacyl-ACP, which is subsequently dehydrated by 3-hydroxyacyl-thioester dehydratase type 2 (*HTD2*) to a 2,3-trans-enoyl-ACP. Mitochondrial trans-2-enoyl-CoA reductase (*MECR*) reduces the double bond to create an acyl-ACP that is two carbon atoms longer. The end product of mitochondrial fatty acid synthesis is octanoyl-ACP. The octanoyl-moiety is then converted into lipoic acid in a number of steps (Mayr et al. 2014)

ω-acylated ceramides. The condensation of L-serine and palmitoyl-CoA leads to the formation of the sphingoid base which is then N-acylated by ceramide synthases resulting in the formation of ceramide. Variation and modification of the molecular structure of either the sphingoid base or the N-acyl group yields many different ceramide species which are precursors of different complex sphingolipids (Figs. 51.1 and 51.4) where the addition of many different headgroups creates an additional multiplication of the amount of subspecies that can be formed. This chapter does not deal with the catabolism of complex sphingolipids (for this metabolism and associated disorders, including sphingolipidoses, see Chap. 60) but does cover ceramide degradation as this not only is the sole exit from the sphingolipid network but also is the way to produce bioactive molecules as sphingosine and sphingosine-1-phosphate (S1P). Ceramide is degraded by first removing the N-acylated fatty acid, followed by phosphorylation to form S1P which is then lysed to phosphoethanolamine and a long-chain aldehyde (Fig. 51.4a). This route controls the levels of ceramide, sphingosine, and S1P which are intra- and intercellular messengers that are involved in cell differentiation, autophagy, and apoptosis (Hannun and Obeid 2018; Jennemann and Gröne 2013).

A particularly important branch of the sphingolipid tree for this chapter is the production of ω-O-acylceramides, shown in Fig. 51.4b, as these ceramide species are required for epithelial permeability and skin barrier function. ω-O-acylceramides are enriched in very long-chain fatty acids, and disturbance of either fatty acid elongation or (ω-O-acyl) ceramide synthesis frequently gives rise to skin phenotypes (Kihara 2016a).

Lastly, ceramide is the precursor for complex sphingolipid synthesis (Fig. 51.4c) which proceeds by the sequential glycosylation of ceramide to form glycosphingolipids or the addition of a phosphocholine headgroup to form sphingomyelins (SM). Glycosphingolipids can contain oligosaccharides with the acidic sugar N-acetylneuraminic acid (gangliosides) or become sulfated (sulfatides) by the action of different biosynthetic enzymes. Deficiency of the corresponding genes gives rise to phenotypes that almost all (severely) affect the central nervous system (Li and Schnaar 2018). As the glycosyltransferases that function in glycosphingolipid metabolism also are involved in protein glycosylation, some of the disorders are also classified as CDG syndromes.

Remodeling

In addition to the biosynthetic pathways, fatty acid composition of lipids is fine-tuned through a process called remodeling so that the lipid is suited for and supports the function of the cell or organelle. This process is performed by removing a fatty acid side chain from a target lipid by (phospho)lipases, forming a lysolipid, followed by reacylation of the lysolipid by either acyl-CoA-dependent acylases

or by transacylation by so-called transacylases. Transacylases use one of the fatty acids of a donor lipid to reacylate the target lysolipid yielding an acylated lipid (from the target) and a new lysolipid (from the donor). Many of the described disorders are caused by a defect in remodeling of particular lipid species. An overly represented class of genes/proteins in this chapter is the calcium-independent phospholipases of the patatin-like phospholipase domain-containing lipase A (PNPLA) family that has a total of nine members. PNPLAs are active at both *sn*-1 and *sn*-2 positions of phospholipids, depending on its substrate and also can have transacylase activity (Hermansson et al. 2016). Deficiency of the structurally similar PNPLAs 1, 2, 6, 8, and 9 leads to very different disorders as a result of their diverse functions in lipid metabolism (Sects. 51.2.4.8, 51.2.3.6, 51.2.1.15, 51.2.1.4, and 51.2.1.12, respectively).

Clinical Spectrum of Disorders of Complex Lipid Metabolism in Brief

The clinical spectrum of these disorders is wide and will be presented in more detail in the following sections. Most frequently, the central nervous system is affected which can present with related signs and symptoms (e.g., intellectual disability, developmental delays, (complex) hereditary spastic paraplegia, movement disorder, optic atrophy, hearing loss, etc.). Like other inborn errors of metabolism affecting complex systems such as mitochondrial disorders and congenital disorders of glycosylation, every organ (system) can be affected, which adds to the diversity of symptoms. These include lipodystrophy, insulin resistance, bone abnormalities, recurrent rhabdomyolysis, ichthyosis, anemia, protein-losing enteropathy, and pigmentary retinopathies.

Chapter Structure

For this chapter, we have divided the metabolism and disorders into five parts: (1) phospholipid and neutral lipid metabolism (Fig. 51.2), (2) fatty acid synthesis and elongation (Figs. 51.2 and 51.3), (3) triglyceride/lipid droplet metabolism (Fig. 51.2), (4) sphingolipid metabolism (Fig. 51.4), and (5) a miscellaneous category. The identification of these disorders mostly has been done by molecular analysis using next-generation sequencing. Given the very wide spectrum of gene functions, if known at all, and the fact that specific diagnostic biomarkers and/or treatments are frequently not available/known, we have chosen a different structure for

Fig. 51.4 Sphingolipid metabolism, including disease genes. (**a**) Synthesis and degradation of ceramide in the ER. L-Serine condenses with an acyl-CoA (mainly palmitoyl-CoA) to form 3-ketodihydrosphingosine (3-ketosphinganine) by the combined action of serine palmitoyltransferases (SPT) 1, 2, and 3. Alanine or glycine can also be used (instead of serine), yielding 1-deoxysphinganine (from alanine) and 1-deoxymethylsphinganine (from glycine). After reduction of the keto-function to a hydroxyl group by 3-ketodihydrosphingosine reductase, dihydrosphingosine (sphinganine) is produced. Ceramide synthases (*CERS* 1–6) catalyze the condensation of sphinganine with a fatty acyl-CoA on the primary amino group yielding dihydroceramide. Fatty acid 2-hydroxylase (encoded by *FA2H*) can hydroxylate fatty acids at the 2-position, which, after activation to its corresponding 2-OH-acyl-CoA, can be used by ceramide synthases to form 2-OH-ceramides and downstream complex sphingolipids. Dihydroceramide desaturase (encoded by *DEGS1*) creates a trans-double bond at the 4-position that converts the base type from sphinganine to sphingosine and thus yields ceramide. Alternatively, hydroxylation of dihydroceramides by dihydroceramide hydroxylase can lead to the formation of phytoceramides. These different ceramide species can be used to synthesize complex sphingolipids as shown in the remainder of the figure. For the degradation of ceramides, ceramidases (including that encoded by *ACER3*) are responsible for the hydrolysis of the amide bond of ceramide, thereby creating sphingosine and a fatty acid. Sphingosine can be phosphorylated by sphingosine kinases to sphingosine-1-phosphate. Sphingosine-1-phosphate can be cleaved by sphingosine-1-phosphate lyase (encoded by *SGPL1*) yielding a fatty aldehyde (in case of the C18-base shown here; hexadecenal) and phosphoethanolamine. (**b**) ω-O-Acylceramide synthesis. This pathway is especially relevant as ω-O-acylceramides are required for skin permeability barrier formation. Long-chain fatty acids (LCFA) are elongated via very long-chain fatty acids (VLCFA) to ultra-long-chain fatty acids (ULCFA) by *ELOVL1* and *ELOVL4*. The cytochrome P450 enzyme encoded by *CYP4F22* catalyzes the ω-hydroxylation of ULCFA creating ω-OH-ULCFA. After activation to its corresponding CoA-ester, ceramide synthases use ω-OH-ULCFA-CoA to synthesize ω-OH-ceramides. Acylceramide transacylase (encoded by *PNPLA1*) uses a linoleoyl-containing TG to transfer the linoleic acid from TG to the ω-OH group of ω-OH-ceramide yielding ω-O-acylceramide. In the Golgi, UDP-glucose ceramide glucosyltransferase (encoded by *UGCG*) converts ω-O-acylceramide into ω-O-acyl-glucosylceramide, and this molecule is excreted in the extracellular space where glucosylceramidase cleaves off the glucose and thereby regenerates the ω-O-acylceramide to contribute to the lipid lamellae formation of the skin. (**c**) Complex sphingolipid synthesis. Complex sphingolipids are synthesized by the stepwise addition of monosaccharides to ceramide, with the exception of sphingomyelin (SM) where a phosphocholine headgroup is added. Different glycosyltransferases use nucleotide-activated sugars to yield a plethora of glycosphingolipids which takes place mainly in the Golgi. First, glucosylceramide (GlcCer) is produced by UDP-glucose ceramide glucosyltransferase (encoded by *UGCG*) followed by addition of galactose yielding lactosylceramide (LacCer) which is at the main branching point of glycosphingolipids. The action of different glycosyltransferase on LacCer initiates different glycosphingolipid series including ganglio-, globo-, lacto-, and neolactoseries. The presence of N-acetylneuraminic acid = sialic acid makes a glycosphingolipid a "ganglioside"

this chapter. For each disorder, in addition to the signs and symptoms tables, we have separately listed their function, a brief clinical synopsis, and if known/available specific treatment options, other than supportive care.

Signs, and Symptoms

Phospholipid and Neutral Lipid Metabolism

Acylglycerol Kinase Deficiency AGK, Sengers Syndrome, AGK → See 72.04

Function: The mitochondrially located AGK catalyzes the phosphorylation formation of diacylglycerol (DG) and, with lesser affinity, monoacylglycerol (MG) forming phosphatidic acid (PA) and lysophosphatidic acid (LPA), respectively (Fig. 51.2a). In addition to being a lipid kinase at the hinge of neutral lipid and phospholipid metabolism, AGK is believed to be part of the TIM22 import complex that supports the import of a subset of multi-spanning membrane proteins. AGK deficiency causes reduced levels of adenine nucleotide translocator (ANT, SLC25A4) in the heart and muscle, which can lead to multiple respiratory chain complex deficiency. The import function is independent of the lipid kinase activity of AGK, which is required for maintaining mitochondrial cristae integrity (Vukotic et al. 2017; Kang et al. 2017).

Clinical: AGK deficiency is characterized by congenital cataracts, hypertrophic cardiomyopathy, skeletal myopathy, and exercise intolerance. The metabolic feature is lactic acidosis (Table 51.1).

SERAC1 Deficiency, 3-Methylglutaconic Aciduria with Deafness, Encephalopathy, and Leigh-Like Syndrome (MEGD(H)EL), SERAC1 → See 72.03

Function: SERAC1 is localized at the interface of mitochondria and endoplasmic reticulum where it is believed to be involved in phosphatidylglycerol (PG) remodeling (Fig. 51.2a); however, its exact function has not been determined. Additional abnormalities were seen in downstream products of PG, cardiolipin (CL), and bis(monoacylglycero) phosphate (BMP) as well as possible abnormalities of cholesterol trafficking.

Clinical: The main features of *SERAC1* deficiency are 3-methylglutaconic aciduria, dystonia-deafness, hepatopathy, encephalopathy, and Leigh-like syndrome, basing the acronym MEGDHEL syndrome. Lactic acidosis and/or respiratory chain complex deficiency in different tissues can be seen (Table 51.2).

Tafazzin Deficiency, Barth Syndrome, TAZ → See 72.02

Function: The *TAZ* gene encodes a mitochondrial transacylase that is involved in the remodeling of CL. TAZ deficiency causes accumulation of monolysocardiolipins (three instead of four fatty acid side chains) and deficiency of linoleic acid-enriched CL species (Fig. 51.2a).

Clinical: Main features of TAZ deficiency are cardiomyopathy, muscle weakness, short stature (when young), and neutropenia. Biochemically, CL metabolism is disturbed which causes monolysocardiolipin accumulation and CL deficiency in addition to impaired oxidative phosphorylation and 3-methylglutaconic aciduria (Table 51.3). A specific blood spot/lymphocyte/fibroblast test based on this biochemical

PNPLA8 Deficiency, Mitochondrial Myopathy with Lactic Acidosis, PNPLA8

Function: *PNPLA8* encodes the calcium-independent phospholipase A2γ (iPLA2γ) (Fig. 51.2a) which is a member of the patatin-like phospholipase domain-containing lipase (PNPL) family and is active at both *sn*-1 and *sn*-2 positions of phospholipids, depending on its substrate. Different isoforms are localized to mitochondria, peroxisomes, and possibly also to the ER, where iPLA2γ is believed to be involved (based on mouse models) in the remodeling of phospholipids, in particular plasmalogens containing essential fatty acids as arachidonic acid (AA, C20:4ω6), docosahexaenoic acid (DHA, C22:6ω3), and linoleic acid (LA, C18:2ω6). The activity of iPLA2γ toward arachidonic acid containing PC species is activated by the presence of CL. iPLA2γ also has been shown to deacylate oxidized CL and is suggested to have a role in managing mitochondrial oxidative stress (Liu et al. 2017).

Clinical: Only three patients reported from two pedigrees. Patients show progressive muscle weakness, severe global developmental delay, as well as loss of very early milestones, epilepsy, and cardiomyopathy (Saunders et al. 2015; Shukla et al. 2018). Lactic acidosis has been reported. In mice models, CL content was also affected as well as mitochondrial morphology and function (Table 51.4) (Hara et al. 2019).

Ethanolaminephosphotransferase 1 Deficiency, SELENOI

Function: *SELENOI* encodes ethanolaminephosphotransferase 1 and is also known as selenoprotein 1 (Fig. 51.2). It catalyzes the final step in Kennedy pathway that makes ethanolamine glycerophospholipids PE and PE[O] from CDP-ethanolamine and DG or DG[O] (Table 51.5).

Clinical: Only five patients from two pedigrees. Severe developmental delay, intellectual disability, demyelinating peripheral neuropathy, pigmentary retinopathy, sensorineural hearing loss, and epilepsy. Lipidomics showed that especially ether lipid metabolism is affected with increases of alkyl-species of PC[O] and decreases of PE[O] plasmalogens in patient fibroblasts (Horibata et al. 2018; Ahmed et al. 2017).

Phosphoethanolamine Cytidylyltransferase 2 Deficiency, PCYT2

Function: *PCYT2* encodes CTP/phosphoethanolamine cytidylyltransferase (ET) which is the rate-limiting enzyme for PE synthesis via the CDP-ethanolamine pathway (Vaz et al. 2019). ET catalyzes the conversion of CTP and phosphoethanolamine into CDP-ethanolamine. CDP-ethanolamine is then used for the synthesis of PE and PE[O] via condensation with DG or DG[O] (Fig. 51.2).

Clinical: One report of four individuals from three families with biallelic *PCYT2* variants with a complex HSP. Patients suffered from global developmental delay with regression, spastic para- or tetraparesis, epilepsy, and progressive cerebral and cerebellar atrophy (Table 51.6) (Vaz et al. 2019).

Choline Kinase β Deficiency, Congenital Muscular Dystrophy, Megaconial Type, CHKB

Function: *CHKB* encodes choline kinase β which catalyzes the phosphorylation of choline to phosphocholine that is used to synthesize PC and PC[O] (Fig. 51.2).

Clinical: Congenital muscular dystrophy, cardiomyopathy, developmental delay, intellectual disability, and in the muscle biopsy; peculiar enlarged mitochondria (megaconial) that are prevalent toward the periphery of the fibers but are sparse in the center of the muscle biopsy. Choline

kinase activity in muscle tissue was undetectable and decreased PC levels were found (Table 51.7) (Mitsuhashi et al. 2011).

Phosphocholine Cytidylyltransferase 1α Deficiency, Retinoskeletal Phenotype, PCYT1A

Function: *PCYT1A* encodes the α-form of choline-phosphate cytidylyltransferase that catalyzes the conversion of phosphocholine into CDP-choline (Fig. 51.2). This is the rate-limiting step of PC and PC[O] synthesis (Table 51.8).

Clinical: Only two reports, 12 patients from 8 pedigrees. Short stature, spondylometaphyseal dysplasia, progressive lower limb bowing, and cone-rod dystrophy (Hoover-Fong et al. 2014; Yamamoto et al. 2014).

Phosphocholine Cytidylyltransferase 1α Deficiency, Lipodystrophy Phenotype, PCYT1A

Function: See Sect. Retinoskeletal Phenotype

Clinical: Only two patients from two pedigrees. Lipodystrophy, severe insulin resistance, low HDL cholesterol levels, and insulin resistance (Table 51.9) (Payne et al. 2014).

Phosphatidylserine Decarboxylase Deficiency, PISD

Function: *PISD* encodes phosphatidylserine decarboxylase (PSD) that converts PS to PE in the inner mitochondrial membrane. After production of the PSD enzyme, an autocatalytic processing event generates two subunits (α and β) which is required to form a functional PSD enzyme. In cellular models, severe depletion or complete loss of PSD

results in decreased mitochondrial oxidative phosphorylation and fragmentation of the mitochondrial network. The complete loss of PSD is embryonically lethal in mice; heterozygote animals show no disease phenotype (Zhao et al. 2019; Girisha et al. 2019).

Clinical: Four patients from three families have been reported for this disorder. Two siblings were reported with congenital cataracts in early infancy, progressive sensorineural hearing loss, global developmental delay (mild), short stature with skeletal dysplasia, facial dysmorphism (midface hypoplasia and a depressed nasal ridge), and white matter changes with progressive volume loss and hypomyelination of the corpus callosum (Zhao et al. 2019). Two additional younger individuals were reported with spondyloepimetaphyseal dysplasia with severe platyspondyly (Girisha et al. 2019).

Biochemically, patient-derived fibroblasts showed fragmented mitochondrial morphology and mitochondrial dysfunction which was linked to the (mitochondrial) lack of the fusogenic lipid PE (the product of PSD reaction). Addition of either ethanolamine (Girisha et al. 2019) or lyso-PE (Zhao et al. 2019) appeared to restore the morphological and functional mitochondrial defects. PSD activity was decreased to 50% of control in PSD fibroblasts, and it was shown that the reported point mutation variants of both reports affect the autocatalytic cleavage of PSD needed for functional activity (Table 51.10) (Zhao et al. 2019).

Phosphatidylserine Synthase 1 Superactivity, Lenz-Majewski Syndrome, PTDSS1

Function: *PTDSS1* encodes phosphatidylserine synthase 1 (PSS1) which is one of the two enzymes that synthesizes PS. PSS1 synthesizes PS through the exchange of serine with the choline moiety of PC (Fig. 51.2a).

Clinical: Sclerosing bone dysplasia, developmental delay, intellectual disability, and distinct craniofacial, dental, skin- (cutis laxa), and distal-limb anomalies. All patients harbor de novo heterozygous pathogenic variants that render PSS1 insensitive to feedback inhibition by PS levels leading to enhanced PS synthesis. Recent studies have shown that the pathogenic variants found in Lenz-Majewski syndrome patients also disturb the metabolism of phosphorylated PI species at the Golgi and the plasma membrane (Table 51.11) (Sohn et al. 2016).

Phospholipase A2 Group 6 Deficiency, Infantile Neuroaxonal Dystrophy; Seitelberger Disease; Neurodegeneration with Brain Iron Accumulation Type 2B, PLA2G6

Function: *PLA2G6* encodes iPLA2-VI or iPLA$_2$β, a calcium-independent phospholipase from the patatin-like lipase family (also known as *PNPLA9*). It demonstrates no substrate specificity and manifests lipase activity on the *sn*-1 and *sn*-2 position but also lysophospholipase and transacylase activities. Function is unclear. It is likely involved in phospholipid remodeling and has been implicated in nitric oxide-induced or vasopressin-induced arachidonic acid release and in leukotriene and prostaglandin production. Under basal conditions, iPLA$_2$β is predominantly localized in the cytosol, and stimulatory conditions translocate iPLA$_2$β to the Golgi, ER, mitochondria, and nucleus. A role in cardiolipin remodeling was suggested (Table 51.12) (Ramanadham et al. 2015).

Clinical: *PLA2G6*-associated neurodegeneration (PLAN). The clinical phenotypes and genotypes of PLAN are closely intertwined and vary widely. Depending on the age of onset and progressive clinical features, there are PLAN subtypes: infantile neuroaxonal dystrophy (INAD), idiopathic neurodegeneration with brain iron accumulation (NBIA), atypical neuroaxonal dystrophy (ANAD), and parkinsonian syndrome which contains adult-onset dystonia-parkinsonism (DP) and autosomal recessive early-onset parkinsonism (AREP) (Guo et al. 2018).

Phosphatidic Acid-Preferring Phospholipase 1 Deficiency, Autosomal Recessive Spastic Paraplegia Type 28 (SPG28), DDHD1

Function: *DDHD1* encodes phosphatidic acid-preferring phospholipase A1. DDHD is the amino acid code sequence, AspAspHisAsp, found in DDHD domain proteins and is involved in the phospholipase activity but also in binding to phosphorylated forms of PI (phosphoinositides) which is believed to be important for specific membrane association to target membranes. *DDHD1* is ubiquitously expressed in human tissues such as the brain and testis, but the physiological role of this enzyme is not clear but is likely involved in remodeling of phospholipids. DDHD1 is mainly localized in cytosol with a partial localization in microsomes and mitochondria. In mouse, DDHD1 was shown to hydrolyze PI/PS to LPI/LPS with *sn*-1 selectivity and to account for a substantial fraction of the PI/PS lipase activity in brain tissue. DDHD1 deletion led to decreased

levels of polyunsaturated fatty acids arachidonic acid (AA, C20:4ω6) and docosahexaenoic acid (DHA, C22:6ω3) in lysolipids, particularly lyso-PI (Inloes et al. 2018a) (Fig. 51.2a).

Clinical: Autosomal recessive spastic paraplegia type 28 (SPG28): complex HSP with retinal dystrophy and neurodegeneration with brain iron accumulation (NBIA) (Table 51.13).

Phosphatidic Acid-Preferring Phospholipase 2 Deficiency, Autosomal Recessive Spastic Paraplegia Type 54 (SPG54), DDHD2

Function: *DDHD2* encodes phosphatidic acid-preferring phospholipase 2, also known as KIAA0725p, which is ubiquitously expressed and localized to or proximal to ER and Golgi. Functionally (from mouse/rat work), DDHD2 was shown to hydrolyze both DG and TG and is believed to be the principal TG hydrolase of the lipid droplet in the central nervous system (Inloes et al. 2014).

Clinical: Autosomal recessive spastic paraplegia type 54 (SPG54), pure or complex with developmental delay, intellectual disability, and abnormal eye movements. An abnormal lipid peak was detected in many patients by brain MR spectroscopy. Genetic deletion in mice leads to ectopic lipid droplet accumulation in neurons throughout the brain, and TG accumulation was established (Inloes et al. 2014; Inloes et al. 2018b) suggesting that disturbed neutral lipid metabolism in CNS is relevant for the pathology in *DDHD2* deficiency (Table 51.14).

PNPLA6 Deficiency, Autosomal Recessive Spastic Paraplegia Type 39; Oliver-McFarlane Syndrome; Boucher-Neuhauser Syndrome; Laurence-Moon Syndrome, PNPLA6

Function: *PNPLA6*, also PLPL6 or NTE (neuropathy target esterase), encodes patatin-like phospholipase domain-containing 6 (PNPLA6) also known as $iPLA_2\delta$ (Fig. 51.2a). It localizes to ER and Golgi and is expressed primarily in neurons. It liberates fatty acid from phospholipids, monoacylglycerols, and lysophospholipids, with a preference for the latter (van Tienhoven et al. 2002). More recent experiments have shown that PNPLA6 catalyzes the sequential double deacylation of PC to yield glycerophosphocholine and two free fatty acids (Quistad et al. 2003; Zaccheo et al. 2004).

Clinical: Main symptoms include ataxia, motor neuron disease, hypogonadism, and chorioretinal dystrophy. Homozygous or compound heterozygous *PNPLA6* variants have been identified in:

- Boucher-Neuhauser syndrome: cerebellar ataxia, chorioretinal dystrophy, and hypogonadotropic hypogonadism (Synofzik et al. 2014).
- Gordon Holmes syndrome: cerebellar ataxia, hypogonadotropic hypogonadism, and pyramidal signs (Synofzik et al. 2014).
- Oliver-McFarlane syndrome: trichomegaly, chorioretinal dystrophy, and congenital or childhood hypopituitarism (Hufnagel et al. 2015).
- Laurence-Moon syndrome: cerebellar ataxia, chorioretinal dystrophy, peripheral neuropathy, spastic paraplegia, and congenital or childhood hypopituitarism (Hufnagel et al. 2015).

Overall, disease onset is usually in the first two decades of life with anterior hypopituitarism, visual impairment, gait alterations, or delayed puberty. Gait alterations may precede visual impairment or anterior hypopituitarism. Conversely, gait disturbance may follow visual impairment or hypopituitarism decades later. Gait disturbances are related to cerebel-

Table 51.15 PNPLA6 deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Ataxia, cerebellar			±	±	+

	Hypogonadotropic hypogonadism		±	+	+	+
	Hypothyroidism		±	±	±	±
Eye	Chorioretinal degeneration		±	±	±	+

lar ataxia more than spasticity or peripheral neuropathy. Rarely, cerebellar ataxia is isolated (Wiethoff et al. 2017). Motor neuron involvement mostly occurs in adults. Congenital hypothyroidism and growth hormone deficiency can cause cognitive dysfunction and short stature. Hypogonadotropic hypogonadism usually becomes manifest during the second decade of life. Hormone deficiencies are responsive to hormone replacement therapy. Cognitive dysfunction may be related to hypothyroidism in some patients (Table 51.15).

Membrane-Bound O-Acyltransferase Domain-Containing 7 Deficiency, MBOAT7

Function: *MBOAT7* encodes membrane-bound O-acyltransferase domain-containing 7 also known as lysophosphatidylinositol (lyso-PI) acyltransferase 1 (LPIAT1) (Fig. 51.2a). LPIAT1 is an ER remodeling enzyme that uses arachidonoyl-CoA to transfer arachidonic acid to lyso-PI yielding an arachidonic acid-containing PI (Johansen et al. 2016). LPIAT1-deficient mice are small and atactic, display atrophy of the cerebral cortex and hippocampus, and have a shorter life span (Lee et al. 2012). There is accumulation of lyso-PI in the brain as well as shortage of arachidonic acid-containing species of PI and selected phosphoinositides in addition to accumulation of other (non-arachidonic acid-containing) PI molecular species (Anderson et al. 2013).

Clinical: *MBOAT7* pathogenic variants have been reported in patients with severe intellectual disability, epilepsy (focal and general seizures), and autistic features (Johansen et al. 2016; Jacher et al. 2019). Additional features may include microcephaly, truncal hypotonia (Johansen et al. 2016), ataxic gait, strabismus, and cerebellar cortical dysgenesis on brain MRI (Table 51.16) (Jacher et al. 2019).

Diacylglycerol Kinase ε Deficiency, Nephrotic Syndrome Type 7; Atypical Hemolytic Uremic Syndrome Type 7, DGKE

Function: *DGKE* encodes diacylglycerol kinase ε (DGKε) that catalyzes the ATP-dependent phosphorylation of DG to form PA. DGKε is associated with ER and plasma membranes. DGKε has been suggested to catalyze one of the steps of the phosphatidylinositol (PI) cycle, the major pathway to regenerate PI and its phosphorylated forms, the phosphoinositides. By its preference for DG species with a fatty acid composition found in PI and phosphoinositide species, DGKε enriches the PA pool with molecular species that are subsequently used for PI and phosphoinositide synthesis (Bozelli and Epand 2019).

Clinical: *DGKE* pathogenic variants have been associated with membranoproliferative-like glomerular microangiopathy (MGPN) (Ozaltin et al. 2013) and atypical hemolytic-uremic syndrome (HUS) (Lemaire et al. 2013). It now appears that pathogenic *DGKE* variants cause a heterogeneous glomerular disorder with histopathologic and clinical features ranging from HUS to MPGN. The disease progresses to a chronic nephropathy kidney transplantation which is then indicated with no disease recurrence so far (Table 51.17) (Azukaitis et al. 2017).

Fatty Acid Synthesis and Elongation

Acetyl-CoA carboxylase 1 deficiency, ACACA

Function: *ACACA* encodes cytosolic acetyl-CoA carboxylase 1 (ACC1, also known as ACCα) and catalyzes the first committed step of the fatty acid synthesis process which is the biotin-dependent addition of a carboxyl moiety from carbonate to acetyl-CoA producing the malonyl-CoA extender for fatty acyl group elongation (Figs. 51.2a and 51.3a). Its expression is high in the liver, adipose, and other lipogenic tissues (Tong 2013).

Clinical: Only one patient was reported in 1981 with a clinical picture clouded by perinatal asphyxia; there was no genetic testing performed. Biochemically, acetyl-CoA carboxylase was measured in the liver of the patient and found to be 2% of control. In fibroblasts of the patient, acetyl-CoA

	Myopathy	+				
Laboratory findings	2-Ethyl-3-hydroxy-hexanoic acid (urine)	↑				
	2-Ethyl-3-keto-hexanoic acid (urine)	↑				
	2-Ethyl-hexanedioic acid (urine)	↑				

carboxylase activity was 10% of control. Urine organic acid analysis showed presence of 2-ethyl-3-keto-hexanoic acid, 2-ethyl-3-hydroxy-hexanoic acid, and 2-ethyl-hexanedioic acid. The authors explain this as condensation of two butyryl-CoA molecules forming 2-ethyl-3-keto-hexanoyl-CoA (that is converted into the three metabolites mentioned above) and refer to a similar mechanism that has been observed in propionic acidemia where two molecules of propionyl-CoA give rise to 2-methyl-3-keto-valeric acid. The accumulation of butyryl-CoA was suggested to occur because butyryl-CoA is believed to (also) act as a primer for fatty acid synthase which is not used in the absence of malonyl-CoA (Blom et al. 1981). Given the single report and lack of genetic confirmation, this is a candidate gene which needs to be confirmed (Table 51.18).

Acetyl-CoA Carboxylase 2 Deficiency, ACACB

Function: *ACACB* encodes mitochondrial acetyl-CoA carboxylase 2 (ACC2, also known as ACCβ) and like ACC1 catalyzes the biotin-dependent carboxylation of acetyl-CoA to generate malonyl-CoA. ACC2 is located in the outer mitochondrial membrane and is primarily expressed in heart and muscle tissues, as well as the liver (Tong 2013) and is thought to play a role in the production of malonyl-CoA that is used to control the fatty oxidation flux by regulating the activity of carnitine palmitoyltransferase 1 in these tissues.

Clinical: Only one patient reported with speech delay and, from 19 months on, recurrent fever-induced and biotin-responsive episodes of lethargy and lactic acidosis with metabolites suggestive of multiple carboxylase deficiency.

Given the single report, this is a candidate gene which needs to be confirmed (Table 51.19) (Tarailo-Graovac et al. 2016).

3-Hydroxyacyl-CoA Dehydratase 1 Deficiency, HACD1

Function: *HACD1* encodes 3-hydroxyacyl-CoA dehydratase 1 (HACD1) that performs the third of the four reactions of the long-chain fatty acid elongation cycle (Figs. 51.2a and 51.3a). It catalyzes the dehydrogenation of 3-hydroxyacyl-CoA to form 2,3-trans-enoyl-CoA. HACD1 is localized at the ER and forms a complex with the other enzymes of VLCFA synthesis (ELOVL1–7, KAR, and TCER).

Clinical: Seven patients from a highly inbred family have been reported with rare, potentially protein disturbing biallelic *HACD1* variants. They showed severe generalized muscular hypotonia with absent deep tendon reflexes that gradually improved, together with a relatively normal cognition (Table 51.20) (Muhammad et al. 2013).

Trans-2-Enoyl-CoA Reductase Deficiency, Autosomal Recessive Mental Retardation Type 14, TECR

Function: *TECR* encodes trans-2,3-enoyl-CoA reductase (TECR) which performs the last step of the four reactions of the long-chain fatty acid elongation cycle (Figs. 51.2a and 51.3a). It is localized at the ER and catalyzes the NADPH-dependent reduction of the trans-2,3-enoyl-CoA to an acyl-CoA.

Clinical: Autosomal recessive mental retardation type 14: only five patients were found in one inbred family. Patient displayed nonsyndromic intellectual disability. Functional studies in immortalized B-cells showed that the pathogenic variants lead to decreased trans-2,3-enoyl-CoA reductase activity and decreased level of C24-sphingomyelin and C24-ceramide (Abe et al. 2013; Çalışkan et al. 2011), likely due to shortage of VLCFA due to the elongation defect (Table 51.21).

Table 51.19 Mitochondrial acetyl-CoA carboxylase 2 deficiency

Enoyl-CoA Reductase Deficiency, Mitochondrial Trans-2-Enoyl-CoA Reductase Protein-Associated Neurodegeneration (MEPAN), MECR

Function: *MECR* encodes the mitochondrial trans-2-enoyl-CoA reductase (MECR) and performs the last step of the four reactions of the mitochondrial fatty acid synthesis (mFAS) cycle which is the NADPH-dependent reduction of a trans-2,3-enoyl-ACP to acyl-ACP (Figure 51.3b).

Clinical: Only one paper that describes seven individuals from five unrelated families. Patients suffer from developmental delay, intellectual disability, childhood-onset dystonia, optic atrophy, and basal ganglia signal abnormalities on MRI. Fibroblast cell lines from affected individuals displayed reduced levels of both MECR and lipoylated proteins as well as defective mitochondrial respiration (Table 51.22) (Heimer et al. 2016).

VLCFA Elongase 1 Deficiency, Ichthyotic Keratoderma, Spasticity, Hypomyelination, ELOVL1

Function: *ELOVL1* encodes elongation of very long-chain fatty acid protein 1 (ELOVL1) which is localized at the ER and catalyzes the condensation of malonyl-CoA with the growing long-chain fatty acyl-CoA (Figs. 51.2a and 51.3a). ELOVL1 is ubiquitously expressed and prefers saturated and monounsaturated C20–C26 VLCFAs. These VLCFAs are required for the synthesis of ω-O-acylceramides for skin barrier function but also are used for synthesis of complex lipids during myelination of the brain.

Clinical: Only two patients (5 and 12 years old) have been reported so far, but surprisingly, they share the same de novo pathogenic variants. They present with an early-onset spastic paraplegia with brain hypomyelination, associated with sensorineural deafness, optic atrophy, ichthyosis, and *acanthosis nigricans*. The pathogenic variants abrogated ELOVL1 enzymatic activity and reduced the levels of ≥C24 ceramides and sphingomyelins in patient cells. Reduced plasma C24:0/C22:0 may be a supportive diagnostic marker (Table 51.23) (Mueller et al. 2019; Kutkowska-Kaźmierczak et al. 2018).

VLCFA Elongase 4 Deficiency, Neurologic Phenotype, Pseudo-Sjögren-Larsson Syndrome (Recessive); Spinocerebellar Ataxia Type 34 (Dominant), ELOVL4

Function: *ELOVL4* encodes elongation of very long-chain fatty acid protein 4 (ELOVL4) which is localized in the ER and catalyzes the condensation of malonyl-CoA with the growing long-chain fatty acyl-CoA (Figs. 51.2a and 51.3a). ELOVL4 is expressed in the retina, brain, testes, and skin

Dermatological	Hyperpigmentation ('acanthosis nigricans')			+	+	
	Ichthyosis			+	+	
Ear	Deafness, sensorineural			+	+	
Eye	Nystagmus			+	±	
	Optic atrophy			+	+	
Laboratory findings	C24:0/C22:0 and C26:0/C22:0 (fibroblasts)			↓–n	↓–n	
	C24:0/C22:0 (plasma)			↓–n	↓–n	

and acts on saturated and monounsaturated ≥C26 and elongates up to C38. In addition, ELOVL4 also elongates very long-chain polyunsaturated fatty acids (Cadieux-Dion et al. 2014; Deák et al. 2019).

Clinical: Heterozygous inheritance of a different set of autosomal dominant *ELOVL4* pathogenic variants that leads to a full-length protein with single amino acid substitutions causes spinocerebellar ataxia 34 (SCA34). The neurological phenotype is characterized by an adult-onset cerebellar ataxia, but gait ataxia has been reported in adolescence, possibly associated with pyramidal signs and rarely spasticity. Brain MRI shows cerebellar and pons atrophy, called "hot cross bun sign." Often, patients also present with erythrokeratodermia, which may disappear in adulthood. Rarely, patients exhibit a pigmentary retinopathy. Autosomal recessive inheritance of a different set of *ELOVL4* pathogenic variants may cause a severe and early-onset infantile disease characterized by seizures, spasticity, profound psychomotor retardation, ichthyosis, and premature death (Deák et al. 2019). However, biallelic *ELOVL4* pathogenic variants have also been reported with an isolated ichthyosis with dry, erythematous, and hyperkeratotic skin (Table 51.24) (Mir et al. 2014).

VLCFA Elongase 4 Deficiency, Retinal Phenotype, Stargardt Disease Type 3, ELOVL4

Function: See Neurologic Phenotype

Clinical: Stargardt disease type 3: heterozygous inheritance of one set of autosomal dominant *ELOVL4* pathogenic variants leads to truncation of the ELOVL4 protein and causes Stargardt-like macular dystrophy (STGD3), a juvenile- or adult-onset retinal degeneration of variable severity (Table 51.25) (Deák et al. 2019).

VLCFA Elongase 5 Deficiency, Spinocerebellar Ataxia Type 38, ELOVL5

Function: *ELOVL5* encodes elongation of very long-chain fatty acid protein 5 (ELOVL5) which is localized at the ER and catalyzes the condensation of malonyl-CoA with the growing long-chain fatty acyl-CoA (Figs. 51.2a and 51.3a). *ELOVL5* is ubiquitously expressed with highest levels in the testis and adrenal gland. ELOVL5 mediates elongation of long-chain polyunsaturated fatty acids (essential fatty acid as linoleic acid (C18:2ω6) and linolenic acid (C18:2ω3)) as well as long-chain straight-chain fatty acids between 18 and 22 carbons in length (Jakobsson et al. 2006).

Clinical: Autosomal dominant *ELOVL5* pathogenic variants cause spinocerebellar ataxia type 38. Patients, mostly described in Italy so far, present with a late-onset gait ataxia, nystagmus, and cerebellar atrophy, usually between 30 and 50 years old. The disease is slowly progressive and patients often also present with *pes cavus* and hyposmia and less frequently with hearing loss and peripheral neuropathy (Di Gregorio et al. 2014; Borroni et al. 2016). Low levels of arachidonic acid (AA) and docosahexaenoic acid (DHA) have been measured in patients' plasma.

Treatment: Given the decreased plasma levels of AA and DHA, a phase 2 randomized controlled trial was conducted

Table 51.24 Very long-chain fatty acid elongase 4 deficiency, neurologic phenotype

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

	Spastic paraplegia		±	±		
Eye	Ichthyosis		++	++	+	+

Table 51.25 Very long-chain fatty acid elongase 4 deficiency, retinal phenotype

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Musculoskeletal	Macular dystrophy			±	±	+

using 600 mg of DHA in ten SCA38 patients. After 16 weeks of treatment, the authors observed a mild but significant improvement of cerebellar functions, which was maintained over 40 weeks (Manes et al. 2017) and 104 weeks (Manes et al. 2019) of treatment (open label). Cerebellar glucose metabolism, assessed by PET-FDG, also improved at 40 and 104 weeks of treatment compared to baseline (Table 51.26).

LCFA-CoA Ligase 4 Deficiency, X-Linked Mental Retardation 63, FACL4

Function: *FACL4* encodes fatty acyl-CoA synthetase 4 (FACL4). It catalyzes the activation of mainly arachidonic acid (C20:4ω6) and eicosapentaenoic acid (C20:5ω3) to their corresponding CoA-ester. FACL4 is expressed in the placenta, brain, testis, ovary, spleen, and adrenal cortex, with low expression in the liver, colon, and small intestine (Cao et al. 1998).

Clinical: X-linked mental retardation 63: *FACL4* is deleted—together with the *COL4A5* gene—in X-linked Alport syndrome, elliptocytosis, and mental retardation, a continuous gene deletion syndrome (Piccini et al. 1998). Biallelic point pathogenic variants in *FACL4* were identified as the possible cause for nonspecific X-linked mental retardation in five patients from two families. Males presented with nonsyndromic severe to moderate mental retardation. Heterozygous females showed completely skewed X-inactivation but displayed variable cognition, from mild mental retardation to normal intelligence. Lymphoblast enzyme activity analysis showed low synthetase activity with arachidonic acid as substrate (Meloni et al. 2002). A third family with four affected males carrying a novel *FACL4* mutation was reported in 2003 (Longo et al. 2003) but no more since, only continuous gene deletions encompassing the *FACL4* gene. The *FACL4* gene therefore should be considered a candidate gene (Table 51.27).

Triglyceride/Lipid Droplet Metabolism

Lysophosphatidic Acid Acyltransferase Deficiency, Congenital Generalized Lipodystrophy Type 1, Berardinelli-Seip Syndrome, AGPAT2

Function: *AGPAT2* encodes 1-acylglycerol-3-phosphate O-acyltransferase 2 (AGPAT2) which is an acyltransferase involved in the synthesis of TG at the ER (Fig. 51.2a). It catalyzes the acylation of lysophosphatidic acid (LPA) to PA. AGPAT2 is highly expressed in adipose tissues where it is needed for TG synthesis and its storage in adipocytes.

Clinical: Congenital generalized lipodystrophy type 1: patients suffer from generalized lipodystrophy, extreme insulin resistance, hypertriglyceridemia, acromegaloid features, hepatic steatosis, and early onset of diabetes (Agarwal et al. 2002; Craveiro Sarmento et al. 2019). One patient was reported with learning disabilities and a non-diabetic polyneuropathy (Oswiecimska et al. 2019). Interestingly,

	Enzymatic activity (leukocytes)					↓

AGPAT2 heterozygous pathogenic variant may cause partial lipodystrophy (Broekema et al. 2018).

Treatment: Long-term leptin-replacement therapy was shown to be effective and safe in two patients (Table 51.28) (Ebihara et al. 2007).

Lipin 1 Deficiency, LPIN1

Function: *LPIN1* encodes lipin-1, a phosphatidic acid phosphatase which is a key enzyme in triglyceride and membrane phospholipid biosynthesis (Fig. 51.2a) that catalyzes the removal of the phosphate from PA to form DG. There are three lipins (1, 2, and 3) with different expression tissue patterns (Csaki et al. 2013a). Lipins regulate the levels of both PA and DG and thereby function at the branch point of lipid synthesis channeling it in the direction of neutral lipids, zwitterionic phospholipids (PC and PE), or anionic phospholipids (PG, PS, CL). Lipins may reside in the cytosol and associate with other organellar membranes in a transient manner via a PA-stimulated manner that also depends on the fatty acid composition of the membrane. Lipin-1 is highly expressed in white adipose tissue and skeletal muscle tissue but also, at lower levels, in most other tissues (Csaki et al. 2013a; Zhang and Reue 2017). Lipin 1-can associate with ER and lipid droplets and can translocate to the nucleus in a nutrient-dependent manner, where it has been shown to act as transcriptional co-activator that interacts with PGC1α/PPARα and PPARγ to regulate the expression of genes involved in energy metabolism (Michot et al. 2012). It is this function that is believed to be affected in lipin-1 deficiency leading to inappropriate activation of cell-specific signaling pathways (Lee & Ridgway, 1865).

Clinical: Early-onset, recurrent, and acute rhabdomyolysis (Table 51.29).

Lipin 2 Deficiency, Majeed Syndrome, LPIN2

Function: *LPIN2* encodes lipin-2, a phosphatidic acid phosphatase, and catalyzes the removal of the phosphate from PA to form DG but also, like lipin-1, can act as a transcriptional coregulator (Fig. 51.2a). Lipin-2 is ubiquitously expressed; highest levels are found in the white adipose tissue, liver, intestine, and brain. Although believed to be similar/overlapping with lipin-1, lipin-2 function is unclear. Subcellular localization of lipin-2 is primarily cytosolic (Csaki et al. 2013b).

Clinical: Majeed syndrome: early-onset chronic recurrent multifocal osteomyelitis and congenital dyserythropoietic anemia of varying severity.

Treatment: TNF-α inhibition was not effective. IL-1 inhibition, however, with either a recombinant IL-1 receptor antagonist (anakinra) or an anti-IL-1β antibody (canakinumab) resulted in clinical and laboratory improvement of bone and systemic inflammation in a sibling pair (Table 51.30) (Herlin et al. 2013).

Diacylglycerol Acyltransferase Deficiency, Congenital Diarrhea Type 7, DGAT1

Function: *DGAT1* encodes diacylglycerol acyltransferase 1 (DGAT1) that acylates DG using acyl-CoA to form TG. DGAT1 is an ER enzyme that diverts DG toward TG and to the lipid droplet, away from phospholipid synthesis (Fig. 51.2a). This is especially relevant for fat absorption in the intestine where absorbed fatty acids are re-esterified into TG and stored in lipid droplets or packaged into chylomicrons before transport into the lymphatic system.

Clinical: Congenital diarrhea type 7: early-onset vomiting and/or diarrhea and protein-losing enteropathy with hypoalbuminemia leading to failure to thrive, anemia, and susceptibility to infection.

Treatment: Low-free diet with supplementation of essential fatty acids and fat-soluble vitamins is the first line of therapy; often patients depend on total parenteral nutrition (Table 51.31) (van Rijn et al. 2018).

CGI-58 Deficiency, Chanarin-Dorfman Syndrome; Neutral Lipid Storage Disease with Ichthyosis, ABHD5

Function: *ABHD5* encodes α−/β-hydrolase domain-containing 5 (ABHD5) and is also known as CGI-58 (comparative gene identification 58) (Fig. 51.2a). Localized at the lipid droplet, ABHD5 binds to and is a co-activator of ATGL which in turn catalyzes the first step of TG hydrolysis. Independently of ATGL, ABHD5 also is involved in the hydrolysis of TG needed for synthesis of ω-O-acylceramides in the skin (Brown and Mark Brown 2017).

Clinical: Neutral lipid storage disease with ichthyosis: ichthyosis and, more variably, liver steatosis with hepatomegaly, short stature, developmental delay, and intellectual disability. Intracellular lipid accumulation is also seen in muscle tissue (mainly TG), and this causes "Jordan's anomaly" of vacuolated polymorphonuclear leukocytes that can be observed in a simple blood smear showing the characteristic lipid droplets in granulocytes. These droplets are also seen in leukocytes of heterozygous carriers (Lefèvre et al. 2001). Skin pathology likely results from the lack of skin ω-O-acylceramides (Table 51.32).

Adipose Triglyceride Lipase Deficiency, Neutral Lipid Storage Disease with Myopathy, PNPLA2

Function: *PNPLA2* encodes the ubiquitously expressed patatin-like phospholipase domain-containing lipase 2, also known as adipose triglyceride lipase (ATGL) that performs the initial step of TG hydrolysis, converting TG into DG and a fatty acid, at the lipid droplet surface (Fig. 51.2a). ATGL is activated by CGI-58.

Clinical: Neutral lipid storage disease with myopathy (calfs, shoulder, and limb girdle), cardiomyopathy elevated creatine kinase levels, and liver steatosis as well as diabetes mellitus. Individuals show Jordan's anomaly, which is diagnostically helpful (see Sect. 51.2.2.3). Heterozygotes can be symptomatic (lipid myopathy, cardiomyopathy, hepatomegaly, insulin resistance, or diabetes) and have lipid accumulation in muscle, leukocytes (also Jordan's anomaly), and basal keratinocytes (Wu et al. 2015).

Treatment: Bezafibrate (400 mg/day), a PPARα agonist, was tried and *not* successful in contrast to the promising results in mice models of ATGL deficiency (Table 51.33) (van de Weijer et al. 2013).

Perilipin 1 Deficiency, Familial Partial Lipodystrophy Type 4, PLIN1

Function: *PLIN1* encodes perilipin 1 (PLIN1) which is a protein that coats lipid droplets, and it is required for optimal lipid incorporation and release from the lipid droplet primarily through the regulation of lipases, including adipose triglyceride lipase (ATGL, 51.33) and hormone-sensitive lipase (HSL, 51.35) which catalyze the hydrolysis of tri- and diacylglycerol, respectively (Fig. 51.2a).

Clinical: Familial partial lipodystrophy type 4; autosomal dominant. Patients have partial lipodystrophy, cushingoid appearance, severe dyslipidemia, and insulin-resistant diabetes. Subcutaneous fat from the patients shows smaller adipocytes, suggesting impaired TG storage in lipid droplets. The inability to store TG in adipocytes likely results in the observed ectopic deposition of lipids in tissues such as the

Table 51.33 Adipose triglyceride lipase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

skeletal muscle and liver, leading to insulin resistance and hypertriglyceridemia (Gandotra et al. 2011). Interestingly, individuals with a heterozygous *PLIN1* null allele were reported that do not display a partial lipodystrophy phenotype, suggesting that the initially reported heterozygous variants cause a specific disease mechanism leading to the reported partial lipodystrophy phenotype. The authors caution the interpretation of *PLIN1* null allele in diagnostic gene testing for lipodystrophy, insulin resistance, and diabetes (Table 51.34) (Laver et al. 2018).

Hormone-Sensitive Lipase Deficiency, Familial Partial Lipodystrophy Type 6, LIPE

Function: *LIPE* encodes hormone-sensitive lipase (HSL) and is the predominant mediator of the hydrolysis of DG, cholesterol esters, and retinyl esters in human white adipose tissue (Fig. 51.2a). HSL is ubiquitously expressed and involved in lipolysis in adipocytes, steroidogenesis, and spermatogenesis (Albert et al. 2014).

Clinical: Familial partial lipodystrophy type 6; heterozygous patients also show symptoms, but symptoms are more prominent in homozygous individuals. Clinically characterized by partial lipodystrophy (reduced lower limb subcutaneous fat), dyslipidemia, hepatic steatosis, and systemic insulin resistance (Table 51.35) (Albert et al. 2014; Zolotov et al. 2017).

Sphingolipid Metabolism

Serine Palmitoyltransferase Subunit 1 Deficiency, Hereditary Sensory and Autonomic Neuropathy Type 1A, SPTLC1

Function: The de novo biosynthetic pathway is initiated in the ER by the action of serine palmitoyltransferase (SPT) which catalyzes the condensation of L-serine and an acyl-CoA and generates 3-ketodihydrosphingosine (or 3-ketosphinganine). Depending on the tissue/cell requirements, the acyl-CoA is palmitoyl-CoA (C16:0-CoA) or myristoyl- (C14:0), stearyl- (C18:0) or lignoceryl- (C24:0)-CoA. *SPTLC1* encodes serine palmitoyltransferase subunit 1, one of the three SPTLC genes (*SPTLC1–3*) that together with two separately encoded small

subunits, SPTssa and SPTssb, forms different heterotrimeric complexes that have acyl-length specificity and thereby modulate the length of the sphingoid base (Fig. 51.4a). Hereditary sensory and autonomic neuropathy type 1A is caused by (missense) pathogenic variants that induce a shift in the substrate specificity of SPTs, which leads to the formation of the atypical deoxysphingoid bases 1-deoxysphinganine and 1-deoxymethylsphinganine. These deoxysphingoid bases lack the 1-hydroxylgroup required for the coupling of headgroups which abrogates the creation of complex sphingolipids and cannot be degraded. Deoxysphingoid bases, especially deoxysphinganines, are neurotoxic and are elevated in plasma of these patients and can be used as a blood biomarker (Penno et al. 2010).

Clinical: Hereditary sensory and autonomic neuropathy type 1A: autosomal and dominantly inherited-axonal neuropathy. Onset is usually in the second or third decade of life, and initial symptoms are sensory loss and pain in the feet and hands followed by distal muscle wasting and weakness caused by motor neuron degeneration. Loss of pain sensation leads to chronic skin ulcers and distal amputations (Dawkins et al. 2001). However, the age of onset can be quite variable (from infancy to late adulthood), disease penetrance is incomplete, and sensory loss may occur without pain (Houlden et al. 2006). In some families, males presented with more severe and earlier onset, with significant motor involvement and demyelinating motor conduction velocities (Houlden et al. 2006). *SPTLC1* variants have also been associated with macular telangiectasia type 2 (Gantner et al. 2019). Most SPTLC1-deficient patients present with both sensory and autonomic neuropathy and macular telangiectasia.

Treatment: L-serine has been tested as treatment for SPTLC1 deficiency (400 mg/kg/d L-serine, https://clinicaltrials.gov/ct2/show/NCT01733407) resulting in lower levels of deoxysphingolipids. L-serine treatment in mice and rat has shown positive effects on peripheral nerve function and should be considered a potential treatment in humans (Garofalo et al. 2011). A randomized controlled trial of 16 patients showed a significant improvement on the Charcot-Marie-Tooth neuropathy score of patients treated by 400 mg/kg/d L-serine compared to placebo, with evidence of continued improvement in the second year of treatment (Table 51.36) (Fridman et al. 2019).

Serine Palmitoyltransferase Subunit 2 Deficiency, Hereditary Sensory and Autonomic Neuropathy Type 1C, SPTLC2

Function: *SPTLC2* encodes serine palmitoyltransferase subunit 2 (SPTLC2, Fig. 51.4a).

Clinical: *SPTLC2* pathogenic variants are a rarer cause of hereditary sensory and autonomic neuropathy (Rotthier et al. 2010). Age of onset and severity is very variable, from infancy to late adulthood (Suriyanarayanan et al. 2016; Murphy et al. 2013). Patients have elevated plasma levels of deoxysphinganine.

Treatment: A small study in one SPTLC2-deficient patient showed that L-serine treatment was well supported and also lowered deoxysphinganine levels in plasma, but there was no change in the Charcot-Marie-Tooth neuropathy score (Auranen et al. 2017). Further studies are warranted in SPTLC2-deficient patients considering the benefit of L-serine supplementation in SPTLC1-deficient patients (Table 51.37).

Ceramide Synthase 1 Deficiency, Progressive Myoclonic Epilepsy Type 8, CERS1

Function: *CERS1* encodes ceramide synthase 1 (CERS1), a transmembrane ER protein that catalyzes the condensation of sphinganine with a fatty acyl-CoA, in case of CERS1 preferably C18-CoA, on the primary amino group yielding dihydroceramides (Fig. 51.4). *CERS1* is highly expressed in the brain, especially in neurons (Kihara 2016b). Mouse models of the disease showed impaired exploration of novel objects, impaired locomotion and motor coordination, neuronal apoptosis in the cerebellum, and dramatic changes in levels of cerebellar sphingolipids (Ginkel et al. 2012).

Clinical: Only five patients reported, four from the same family (Ferlazzo et al. 2009; Vanni et al. 2014; Godeiro Junior et al. 2018). Patients presented with action myoclonus with onset in childhood or adolescence, generalized tonic-clonic seizures, and progressive cognitive deterioration up to dementia. Cerebellar ataxia was also present in one patient (Table 51.38) (Godeiro Junior et al. 2018).

Ceramide Synthase 3 Deficiency, Autosomal Recessive Congenital Ichthyosis Type 9, CERS3

Function: *CERS3* encodes ceramide synthase 3 (CERS3), a transmembrane ER protein that catalyzes the condensation of sphinganine with a fatty acyl-CoA to form dihydroceramides (Fig. 51.4). CERS3 has broad substrate specificity, exhibiting activity toward ≥C18-CoAs (Kihara 2016b). CERS3 is also responsible for creating ceramides containing ultra-long-chain fatty acids that are found in the epidermis (saturated and monounsaturated) and testis (polyunsaturated), which corresponds with the expression pattern of *CERS3*.

Clinical: Pathogenic variants in *CERS3* cause autosomal recessive congenital ichthyosis (ARCI). Patients are characterized by collodion membranes at birth, generalized scaling of the skin, and mild erythroderma. Ceramides containing ≥C24 fatty acids, including ω-O-acylceramides, are reduced in the epidermis of *Cers3* knockout mice and in *CERS3* patients (Table 51.39) (Eckl et al. 2013).

Dihydroceramide Desaturase Deficiency, DEGS1

Function: *DEGS1* encodes Δ4-dihydroceramide desaturase that converts dihydroceramide to ceramide by creation of a Δ4,5 *trans* double bond into the sphinganine backbone (Karsai et al. 2019) (Fig. 51.4a).

Clinical: Nineteen patients from 13 unrelated families were identified with *DEGS1* pathogenic variants (Pant et al. 2019). Most of them presented with very poor psychomotor development, dystonia and severe spasticity, failure to thrive, and frequent seizures. A less severe phenotype was observed in some patients with capacity to sit or walk and to use verbal communication (Pant et al. 2019; Dolgin et al. 2019). Brain MRI was remarkable and showed hypomyelination, sometimes associated with atrophy of the thalami and hypointense T2/FLAIR of the pallidi (Pant et al. 2019). In fibroblasts, dihydroceramide accumulated, and the dihydroceramide/ceramide ratios in patients' plasma, fibroblasts, and muscle were elevated (Karsai et al. 2019; Pant et al. 2019). Lipidomic analyses confirmed elevated levels of dihydroceramides, dihydrosphingosine, dihydro-S1P, and dihydrosphingomyelins in whole blood with concomitant reduced levels of ceramide (mild, still present), sphingosine, S1P, and monohexosylceramides (Table 51.40) (Karsai et al. 2019; Dolgin et al. 2019).

Alkaline Ceramidase 3 Deficiency, Early Childhood-Onset Progressive Leukodystrophy, ACER3

Function: *ACER3* encodes alkaline ceramidase 3 (ACER3), localized to both the ER and Golgi, and catalyzes the hydrolysis of natural phytoceramide, dihydroceramide, and ceramides carrying an unsaturated fatty acid (C18:1, C20:1, and C20:4) (Fig. 51.4a). Its tissue expression is widespread, but is highly expressed in the placenta (Hu et al. 2010).

Clinical: Only one paper reporting two patients (siblings) from Ashkenazi Jewish origin suffering from developmental regression at 6–13 months, truncal hypotonia, appendicular spasticity, dystonia, optic disc pallor, and peripheral neuropathy. The disorder is progressive; both patients (at 11 and 13 years of age) are neurologically severely impaired. Enzyme activity was measured in patients' fibroblasts and lymphoblasts using either C18:1-ceramide or NBD-C_{12}-phytoceramide as substrate and was (severely) reduced. Plasma analysis showed increased levels of ACER3 substrates as well as upstream complex sphingolipids (Table 51.41) (Edvardson et al. 2016).

CYP4F22 Omega Hydroxylase Deficiency, Autosomal Recessive Congenital Ichthyosis Type 5, CYP4F22

Function: *CYP4F22* (cytochrome P450, family 4, subfamily F, polypeptide 22, previously *FLJ39501*) encodes an ER localized ω-hydroxylase that catalyzes the NADPH and O_2-dependent ω-hydroxylation of ultra-long-chain fatty acids longer than C26 and is most active toward species with ≥C28 carbon atoms (Ohno et al. 2015) (Fig. 51.4b). These ω-hydroxylated ultra-long-chain fatty acids are used especially in the skin where they are needed for the synthesis of ω-O-acylceramides, which are important for skin permeability barrier formation.

Clinical: Autosomal recessive congenital ichthyosis type 5: nonsyndromic autosomal recessive congenital ichthyosis (ARCI), generally mild to moderate ARCI phenotype (Hotz et al. 2018). In rare cases, the skin is minimally involved, the so-called self-healing collodion babies (Noguera-Morel et al. 2016). Pathogenic variants lead to considerably reduced ω-hydroxylase activity, decreased levels of ω-O-acylceramides, and concomitantly increased non-acylated ceramides (Table 51.42) (Ohno et al. 2015).

Acylceramide Transacylase Deficiency, Autosomal Recessive Congenital Ichthyosis Type 10, PNPLA1

Function: *PNPLA1*, also known as *ARCI10*, encodes patatin-like phospholipase domain-containing 1 (PNPLA1) which is a CoA-independent transacylase (Fig. 51.4b). Linoleate esterified in triglyceride is used as an acyl donor to acylate the ω-hydroxyl group of ω-hydroxyceramide. *PNPLA1* expression is highly restricted to the differentiated, stratified squamous epithelium of the skin but not evident in most other tissues. PNPLA1 is involved in the synthesis of ω-O-acylceramides, which are important for skin permeability barrier formation (Hirabayashi et al. 2018; Ohno et al. 2017).

Clinical: Autosomal recessive congenital ichthyosis type 10: Most patients with biallelic *PNPLA1* pathogenic variants are born as collodion babies and show a stable or improving course of the disease with age. Adult patients present with generalized fine lamellar ichthyosis with whitish or brownish scales and mild or moderate erythroderma. Differentiated keratinocytes prepared from a *PNPLA1*-mutated patient showed defective ω-O-acylceramide generation (Table 51.43) (Hirabayashi et al. 2018; Pichery et al. 2017).

UDP-Glucose Ceramide Glucosyltransferase Deficiency, Autosomal Recessive Congenital Ichthyosis, UGCG

Function: *UGCG* encodes UDP-glucose ceramide glucosyltransferase/glucosylceramide synthase (UGCG) that is localized in the ER (Fig. 51.4b). UGCG catalyzes the transfer of glucose to ceramide producing glucosylceramide (GlcCer) which is the precursor for the majority of complex sphingolipids. Production of GlcCer is also important for skin barrier formation as ceramides and acylceramides are transported into the extracellular space of the stratum corneum in glucosylated form and liberated by the action of β-glucosidase 1 (encoded by *GBA1*, defective in Gaucher disease).

Clinical: Autosomal recessive congenital ichthyosis: Only two patients from the same family presented with polyhydramnios during pregnancy, collodion membrane, joint contractures, hypernatremic dehydration, and death at 2 months of age. Another molecular event cannot be ruled out with

respect to the contractures in these patients. In mice, complete UGCG deletion is early embryonic lethal, but the keratinocyte-specific conditional knockout displays a severely impaired skin barrier defect as seen in the two reported patients (Table 51.44) (Monies et al. 2018; Amen et al. 2013).

Nonlysosomal Glucosylceramidase Deficiency, Autosomal Recessive Spastic Paraplegia Type 46, GBA2

Function: *GBA2* encodes the ubiquitously expressed (highest expression levels found in the liver, brain, and testis) β-glucosidase 2 or nonlysosomal glucosylceramidase 2 (GBA2), an integral membrane protein located at the ER/Golgi and close to the cell surface. The exact function of GBA2 is still under investigation.

Clinical: *GBA2* pathogenic variants have been associated predominantly with an early-onset spastic paraplegia, SPG46 (Martin et al. 2013), or cerebellar ataxia (Hammer et al. 2013). Overall, patients usually present with a spastic ataxia in childhood or adolescence, slowly progressive, often associated with intellectual disability and cataract (i.e., Marinesco-Sjögren-like syndrome, (Haugarvoll et al. 2017)). Glucosylceramide levels were elevated in erythrocytes and plasma, in the range of untreated Gaucher patients. Enzyme activity can be measured in leukocytes (not in fibroblasts) by subtraction (with and without GBA2 inhibitor AMP-deoxynojirimycin) to selectively measure GBA2 activity (Table 51.45) (Haugarvoll et al. 2017).

Fatty Acid 2-Hydroxylase Deficiency, Autosomal Recessive Spastic Paraplegia Type 35 (SPG35); Fatty Acid Hydroxylase-Associated Neurodegeneration (FAHN), FA2H

Function: *FA2H* encodes fatty acid 2-hydroxylase (FA2H) which hydroxylates fatty acids at the 2 (or α)-position (Fig. 51.4a). This can subsequently be activated to its corresponding 2-OH-acyl-CoA and used by ceramide synthases to form 2-OH-ceramides and downstream complex sphingolipids. FA2H is highly expressed in the brain where it is involved in the formation of 2-hydroxy galactosylceramides and 2-hydroxy sulfatides which are critical for normal myelination and myelin function (Alderson et al. 2004).

Clinical: Most patients with *FA2H* pathogenic variants present with a rather homogeneous and severe phenotype characterized by an early-onset spastic tetraparesis (SPG35), cerebellar ataxia with dysarthria, dysphagia, truncal hypotonia, and cognitive deficits, frequently accompanied by exotropia and dystonia/rigidity (Edvardson et al. 2008; Kruer et al. 2010; Rattay et al. 2019). Patients may also present with seizures and optic atrophy. Disease onset is usually around 4 years of age, with loss of ambulation within 7 years (Rattay et al. 2019). Rarely, adult-onset forms have been reported (Tonelli et al. 2012). Brain MRI is rather evocative with a combination of periventricular white matter T2 hyperintensities, T2 hypointensity of the globus pallidus as seen in neurodegeneration with brain iron accumulation (NBIA), pontocerebellar atrophy, and thin corpus callosum (Kruer et al. 2010). These four imaging findings have been grouped under the acronym "WHAT"—white

Table 51.46 Fatty acid 2-hydroxylase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Abnormalities in the globus pallidus (MRI)			±	+	+

Eye	Exotropia		±	±	±	±
	Optic atrophy			±	±	±

matter changes, hypointensity of the globus pallidus, pontocerebellar atrophy, and thin corpus callosum (Rattay et al. 2019). The enzyme activity cannot be measured in fibroblasts due to other fatty acid hydroxylation activities (Edvardson et al. 2008). Of note, uniparental disomy seems to be a rather frequent genetic mechanism for homozygous *FA2H* pathogenic variants in non-consanguineous families (Table 51.46) (Soehn et al. 2016).

Sphingosine-1-Phosphate Lyase Deficiency, SGPL1

Function: *SGPL1* encodes the ubiquitously expressed sphingosine-1-phosphate lyase (SGPL1) which cleaves sphingosine-1-phosphate (S1P) yielding a fatty aldehyde and phosphoethanolamine. SGPL1 is an essential enzyme in the sphingolipid catabolic pathway and regulator of S1P levels and other sphingoid bases (Fig. 51.4a). S1P is a bioactive lipid implicated in the regulation of cell survival, apoptosis, proliferation, and migration via both extracellular signaling of G-coupled protein receptors and intracellular signaling (Lovric et al. 2017). Mouse work shows that SGPL1 is also involved in (neuronal) autophagy as the released phosphoethanolamine can be used for synthesis of PE that anchors LC3 to the phagophore membranes.

Clinical: *SGPL1* pathogenic variants were identified simultaneously in patients presenting with an atypical form of axonal peripheral neuropathy—characterized by acute or subacute onset and episodes of recurrent mononeuropathy during adolescence (Atkinson et al. 2017)—and children presenting with nephrotic syndrome (NPHS14) and adrenal insufficiency (Lovric et al. 2017; Prasad et al. 2017). Nephrotic syndrome and adrenal insufficiency were variably associated with neurodevelopmental delay, microcephaly, brain malformations, ichthyosis, deafness, and adrenal calcifications (Bamborschke et al. 2018). The levels of SGPL1 substrates, S1P, and sphingosine (latter differentiates best in blood, three- to sixfold elevated) were markedly increased in the patients' blood and fibroblasts. Total serum ceramide levels and C24:0- and C16:0-lactosylceramides were also elevated (Table 51.47) (Lovric et al. 2017).

Ceramide Transfer Protein Superactivity, Autosomal Dominant Mental Retardation Type 34, COL4A3BP

Function: *COL4A3BP* encodes collagen type IV alpha-3-binding protein, also known as ceramide transfer protein (CERT) or StAR-related lipid transfer protein 11 (STARD11). In vitro assays show that this lipid transfer-catalyzing domain specifically extracts ceramide from phospholipid bilayers and is suggested to mediate intracellular trafficking of ceramide in a non-vesicular manner (Hanada et al. 2003).

Clinical: Only three patients in large-scale discovery of novel genetic causes of developmental disorders, The Deciphering Developmental Disorders Study: the three identical Ser132Leu pathogenic variants in CERT that remove a serine that when phosphorylated downregulates transporter activity from the ER to the Golgi. Authors suggest that this leads to superactivity of CERT and that this results in intracellular imbalances in ceramide and its downstream metabolic pathways (Deciphering Developmental Disorders Study 2015). As there is no functional proof, it should be considered a candidate gene awaiting confirmation (Table 51.48).

Table 51.47 Sphingosine-1-phosphate lyase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

GM3 Synthase Deficiency, Amish Infantile Epilepsy Syndrome; Salt and Pepper Developmental Regression Syndrome, ST3GAL5 Now Also Called ST3GAL5-CDG

Function: *ST3GAL5* encodes lactosylceramide α-2,3-sialyltransferase, or GM3 synthase, a Golgi enzyme which catalyzes the formation of GM3 ganglioside from lactosylceramide, the first step in the synthesis of complex ganglioside species of the a-, b-, and c-series (Fig. 51.4c).

Clinical: Autosomal recessive infantile-onset symptomatic epilepsy syndrome associated with microcephaly, choreoathetosis, blindness, and deafness and failure to thrive (Simpson et al. 2004; Bowser et al. 2019). Pathogenic variants in *ST3GAL5* also have been found in the salt & pepper syndrome, a very similar neurodevelopmental disorder associated with altered "salt & pepper" dermal pigmentation (= freckle-like hyperpigmented and depigmented macules). As *ST3GAL5* deficiency also affects both N-linked and O-linked glycosylation, this disorder is also known as *ST3GAL5*-CDG. Plasma glycosphingolipids of *ST3GAL5*-deficient patients completely lack GM3 and gangliosides derived from GM3 (GM2, GM1a, GD3, GD1a), and its precursor lactosylceramide and its alternative derivatives (LacCer, Gb3, Gb4) are elevated (Simpson et al. 2004). Secondary respiratory chain dysfunction in fibroblasts and the liver was reported (Fragaki et al. 2013) as well as high blood lactate levels (Table 51.49) (Lee et al. 2016).

GM2_GD2 Synthase Deficiency, Autosomal Recessive Spastic Paraplegia Type 26 (SPG26), B4GALNT1

Function: *B4GALNT1* encodes β-1,4-N-acetyl galactosaminyltransferase 1 (GalNAc-T), or GM2/GD2 synthase, a Golgi enzyme which catalyzes the reaction GM3➔GM2 and GD3➔GD2 in ganglioside synthesis of a-, b-, and c-series, but also lactosylceramide➔GA2 and Gb3➔Gb4 of 0-series and globo-series, respectively (Fig. 51.4c).

Clinical: *B4GALNT1* pathogenic variants were identified in patients with an early-onset but slowly progressive spastic paraparesis (SPG26) associated with mild intellectual disability and possibly *pes cavus*, cerebellar ataxia, peripheral neuropathy, dystonia, cataract, and hypogonadism in males (Boukhris et al. 2013). Analysis of patient fibroblasts revealed lack of GM2 production and increased levels of the precursor GM3 (Table 51.50) (Harlalka et al. 2013).

GD1a_GT1b Synthase Deficiency, ST3GAL3-CDG, ST3GAL3

Function: *ST3GAL3* encodes the Golgi enzyme β-galactoside-α2,3-sialyltransferase-III (ST3Gal-III) that transfers sialic acid (N-acetylneuraminic acid) in α2,3-linkage to galactose and is needed for the synthesis of GD1a and GT1b in ganglioside a-, b-, and c-series but also takes part in the formation of the sialyl-Lewis (sLe^a and sLe^x) epitopes on proteins (Edvardson et al. 2013) (Fig. 51.4c).

Table 51.49 GM3 synthase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Musculoskeletal	Pes cavus		±	±	±	±
Laboratory findings	GM2 gangliosides (fibroblasts)			↓↓	↓↓	↓↓
	GM3 gangliosides (fibroblasts)			↑	↑	↑

Clinical: *ST3GAL3* deficiency also affects protein glycosylation, therefore also called *ST3GAL3*-CDG. Few patients have been reported so far with *ST3GAL3* pathogenic variants: two families with nonsyndromic severe intellectual disabilities (Hu et al. 2011) and two families with severe intellectual disability and epileptic encephalopathy (Table 51.51) (Edvardson et al. 2013).

Gb3 Synthase Deficiency, NOR Polyagglutination Syndrome, A4GALT

Function: *A4GALT* encodes α-1,4-galactosyltransferase (A4GALT or Gb3 synthase) that uses UDP-galactose to add a galactose to lactosylceramide forming Gb3 (Fig. 51.4c) as well as reactions more downstream in the globo-series (not shown) that lead to the formation of the human P1PK blood group antigens P1, P(k), and P. The antigen P(k) in fact is Gb3, which is also known as cluster of differentiation 77 (CD77).

Clinical: Polyagglutination is the occurrence of red cell agglutination by virtually all human sera, but not by autologous serum or sera from newborns. NOR polyagglutination syndrome was designated "NOR" since the family where this phenomenon was first observed was from Norton, Virginia. The syndrome is transmitted in an autosomal dominant pattern of inheritance and results from a specific mutation in *A4GALT*, c.631C > G, and p. Q211E, which changes the substrate specificity of A4GALT, so it cannot only attach galactose to another galactose but also to N-acetylgalactosamine (GalNac). The latter reaction leads to synthesis of NOR antigens, which are glycosphingolipids with terminal Gal(α1–4)GalNAc sequence, which does not occur in mammals. The NOR-positive individuals do

Table 51.51 GD1a/GT1b synthase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Encephalopathy, epileptic		±	±	±	
	Severe intellectual deficiency	+	+	+	+	

Table 51.52 GB3 synthase deficiency

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Other	Polyagglutination syndrome (erythrocytes)	+	+	+	+	+

not show any morbid symptoms, but their erythrocytes are agglutinated by most human sera, creating a risk of complications during transfusion of NOR erythrocytes. NOR-positive individuals should therefore be disqualified as blood donors (Table 51.52) (Suchanowska et al. 2012; Kaczmarek et al. 2016) (also see https://omim.org/entry/111400).

Miscellaneous

Phospholipid-Transporting ATPase IB Deficiency, Cerebellar Ataxia, Mental Retardation, and Dysequilibrium Syndrome Type 4, ATP8A2

Function: *ATP8A2* encodes ATPase aminophospholipid transporter type 8A member 2 (ATP8A2) and belongs to the P4-ATPases subfamily of P-type ATPases, which are involved in the transport of aminophospholipids. ATP8A2 is involved in the transport of aminophospholipids (PE and PS) from the outer leaflet of the plasma membrane toward the inner leaflet (PS and to a lesser extent PE) in brain cells, retinal photoreceptors, and the testis. This is important to maintain membrane asymmetry in the plasma membrane (Cacciagli et al. 2010).

Clinical: Cerebellar ataxia, mental retardation, and dysequilibrium syndrome type 4 (CAMRQ4): autosomal recessive condition with intellectual disability, developmental delay, ophthalmoplegia, movement disorder, hearing loss, epilepsy, and short stature (Table 51.53) (Guissart et al. 2019).

CYP2U1 Deficiency, Autosomal Recessive Spastic Paraplegia Type 56, CYP2U1

Function: *CYP2U1* encodes cytochrome P450 family 2 subfamily U member 1 (CYP2U1), is localized to both ER and mitochondria, and catalyzes the ω- and (ω-1)-hydroxylation of arachidonic acid (C20:4ω6, AA) as well as hydroxylation of docosahexaenoic acid (C22:6ω3, DHA) and other long-chain fatty acids (saturated/monounsaturated C16-C22). This yields a series of oxygenated products including two bioactive metabolites 19- and 20-hydroxyeicosatetraenoic acid (so-called HETEs). *CYP2U1* is highly expressed in the thymus and cerebellum and has been suggested to modulate the arachidonic acid signaling pathway and play a role in other fatty acid signaling processes (Chuang et al. 2004).

Clinical: Autosomal recessive spastic paraplegia type 56. Patients with *CYP2U1* pathogenic variants usually present with an infantile-onset but slowly progressive complicated spastic paraplegia (Tesson et al. 2012). Possible associated symptoms are dystonia, psychomotor retardation or regression, intellectual disability, and/or subclinical sensory motor neuropathy (Tesson et al. 2012; Kariminejad et al. 2016; Iodice et al. 2017). Brain MRI may show delayed myelination, white matter abnormalities, and/or thin corpus callosum (Tesson et al. 2012). CT scan may reveal basal ganglia calcifications (23176821). Adult-onset spastic paraplegia has been reported, associated with a pigmentary maculopathy (Table 51.54) (Leonardi et al. 2016).

ABHD12 Deficiency, Polyneuropathy, Hearing Loss, Ataxia, Retinitis Pigmentosa, and Cataract (PHARC) Syndrome, ABHD12

Function: *ABHD12* encodes α−/β-hydrolase domain-containing protein 12 (ABHD12) which is an integral membrane plasma/ER membrane protein that was shown to hydrolyze the endocannabinoid 2-arachidonoylglycerol (2-AG) into arachidonic acid (C20:4ω6) and monoacylglycerol in vitro. More recently, ABHD12 was shown to be the major lipase acting on VLCFA-containing lysophosphatidylserine (LPS) (Blankman et al. 2013) in the brain and that it also hydrolyzes oxidized PS and LPS species. The oxidation of PS species due to elevated reactive oxygen species is

linked to their transmembrane migration to the exofacial membrane surface which is a pro-apoptotic signal (Kelkar et al. 2019). LPS itself has been recognized as a signaling molecule (Makide et al. 2014), and ABHD12 therefore has been suggested to be involved in the regulation of (L)PS and oxidized (L)PS levels, thereby regulating immunological and neurological processes (Kelkar et al. 2019; Kamat et al. 2015). In *Abhd12−/−* mouse, accumulation of LPS, mainly VLCFA-containing as well as oxidized PS species, has been observed. Lipopolysaccharide challenge of *Abhd12−/−* mice showed a fivefold accumulation of oxidized PS levels in the brain. Reactive oxygen species and oxidative stress may play a role in PHARC pathology where deficient ABHD12 cannot mitigate the excess oxidized PS produced (Blankman et al. 2013; Kelkar et al. 2019).

Clinical: *ABHD12* pathogenic variants have been associated with a pseudo-Refsum syndrome called PHARC: polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and cataract (Fiskerstrand et al. 2010). Disease onset can be in childhood or adolescence, especially hearing loss and gait abnormalities that are related to sensory (i.e., demyelinating neuropathy) and/or cerebellar dysfunction. Visual impairment may occur in adolescence or adulthood due to bilateral cataracts and/or pigmentary retinopathy. *ABHD12* pathogenic variants have also been reported in patients with Usher syndrome (deafness, retinopathy, and sometimes cataract), but neurological examination often revealed cerebellar ataxia or peripheral neuropathy (Eisenberger et al. 2012). Still, some adult patients may present with isolated pigmentary retinopathy (Table 51.55) (Nishiguchi et al. 2014).

Table 51.55 ABHD12 deficiency

Ear	Deafness, sensorineural				±	+
Eye	Cataract			±	±	+
	Pigmentary retinopathy			±	±	±

Diagnostic Flowchart

Given the heterogeneity of this group of disorders, no diagnostic flowcharts apply. Depending on the clinical symptoms—if available—specific biomarkers/tests can be measured, but the most common way of diagnosing these disorders is DNA diagnostics by whole-exome/whole-genome sequencing. At this time, lipidomics is not (yet) suited for clinical diagnostics as the measurement is not standardized, the optimal specimen type is variable, and no reference ranges have been established. Still, for disorders where a biomarker profile is known, this measurement can be used for the functional confirmation of the diagnosis. For uncharacterized disorders, however, it should be considered to perform lipidomics to search for new biomarkers that can be developed into targeted tests and/or panels for these types of disorders. To do this, it is crucial that specimens are collected from different cases (or if not available, at least sequential samples from the same patient) and suitable controls to allow comparative lipidomics in search of new biomarkers.

Specimen Collection

Test	Preconditions	Material	Handling
DNA analysis		Whole blood (EDTA)	RT or frozen (−20 °C)
Lipidomics (blood)	>4 h after last meal or after overnight fast	Whole blood (EDTA) Plasma (EDTA)	Frozen (−20 °C) Frozen (−20 °C)
Lipidomics (fibroblasts)		Fibroblasts: • Live cells • Cell pellets (from T-175)	RT Frozen (−80 °C)
Lipidomics (tissues)	No formalin, rapid transfer to N_2 and then freezer	Tissue	Frozen (−80 °C)

Prenatal Diagnosis

No specific biochemical tests exist at this time to perform prenatal testing. Like many disorders, if the index patient is known, DNA analysis can be used for prenatal testing if warranted.

DNA Testing

See Chapter structure.

Disorders of Eicosanoid Metabolism

Contents

Summary

Eicosanoids, including prostaglandins and leukotrienes, are lipid mediators that have been implicated in various pathological processes. They are biologically active metabolites mainly derived from arachidonic acid, a membrane polyunsaturated fatty acid. Prostaglandins (PGs) and thromboxane A_2 (TXA_2) are formed when arachidonic acid is released from the plasma membrane by phospholipases and metabolized by sequential actions of prostaglandin G/H synthase, cyclooxygenase, or thromboxane synthase (TBXAS1). Leukotrienes (LTs) are synthesized from arachidonic acid by 5-lipoxygnase. This chapter focuses on very rare disorders of eicosanoid metabolism caused by enzymatic defects in the synthesis of TXA_2 or of the primary cysteinyl leukotriene C_4 (LTC_4) as well as defects in the degradation of PGE_2.

Thromboxane synthase deficiency (Ghosal hematodiaphyseal dysplasia (GHDD) syndrome) is caused by mutations in the *TBXAS1* gene. This disorder is characterized by increased bone density (predominantly diaphyseal) and non-regenerative corticosteroid-sensitive anemia.

A defect in the degradation of PGE_2, primary hypertrophic osteoarthropathy (PHOAR), is – on the basis of the different pathogenetic genes – categorized into two subtypes. PHOAR type 1 is caused by mutations in the *HPGD* gene encoding for 15-hydroxyprostaglandin dehydroge-

nase whereas PHOAR type 2 is caused by mutations in the *SLCO2A1* gene which encodes for the prostaglandin transporter. Affected patients in both types are mainly characterized by digital clubbing, pachydermia, and periostosis.

In the biosynthesis of leukotrienes, a primary defect has been described in the form of LTC_4 synthase deficiency (LTC4SD) leading to decreased levels of cysteinyl leukotrienes in biological fluids. Affected patients seem to be severely affected with symptoms including muscular hypotonia, psychomotor retardation, microcephaly, and failure to thrive. A better understanding of the role of leukotrienes in the brain and their pathophysiological role is a prerequisite for the suggestion of therapeutical approaches. It is possible that this disorder is underdiagnosed since leukotrienes are usually not included in the metabolic workup.

Introduction

Certain polyunsaturated fatty acids, such as arachidonic acid, are metabolized by oxygenation into a large family of biologically active substances, the eicosanoids. They comprise several compounds including most prominently prostaglandins, thromboxanes, and leukotrienes. Eicosanoids exert their functions through different mechanisms, e.g., by receptor binding and intracellular signaling pathway modulation. Their effects are diverse with a short half-life. A tight regulation on the processes of formation and inactivation is fundamental to prevent exacerbation of their effects. Their actions are primarily linked to inflammatory processes and cellular homeostasis.

Thromboxane synthase deficiency (Ghosal hematodiaphyseal dysplasia (GHDD) syndrome) is an inherited disorder caused by homozygous mutation in the *TBXAS1* gene, which encodes thromboxane synthase (Geneviève et al. 2008). This enzyme catalyzes the conversion of PGH_2 to thromboxane A_2 (TXA_2). Deficiency of thromboxane synthase leads to abnormal bone remodeling and fibrosis of the bone marrow causing non-regenerative severe anemia. Patients, most have been from the Middle East and India, are characterized by sclerosis of long bones with widening of medullary cavities and cortical hyperostosis (Ghosal et al. 1988; Arora et al. 2015). The bone changes specifically affect both diaphysis and metaphysis. Moreover, anemia is a characteristic feature. In addition, defects in arachidonic acid-induced platelet aggregation in vitro have been reported in some patients, although they do not show a clinically significant bleeding diathesis.

Thromboxane synthase seems to be important for bone remodeling. TXA_2 modulates the expression of *TNFSF11* and *TNFRSF11B* that encode RANKL and osteoprotegerin in osteoblasts promoting osteosclerosis.

Though mutational analysis is confirmatory, the clinical and radiological picture helps to differentiate from other sclerosing bony disorders. This is important since corticosteroids may lead to considerable improvement, at least with respect to anemia (Mondal et al. 2015; John et al. 2015).

Hypertrophic osteoarthropathy (HO) is a syndrome mainly involving bones and the skin (Martinez-Lavin et al. 1993). It is characterized by a distinct triad: digital clubbing, pachydermia, and periostosis. HO is classified either as primary or secondary. Secondary HO is the most common form and associated with an underlying pulmonary, cardiac, hepatic, or intestinal disease, or it may occur with systemic inflammatory or neoplastic processes (Castori et al. 2005). Primary hypertrophic osteoarthropathy (PHOAR) represents about 3–5% of all cases of HO (Poormoghim et al. 2012). Two causative genes both encoding proteins participating in the degradation of PGE_2 were identified. Based on these different pathogenic genes, PHOAR is categorized into two subtypes. Homozygous mutations in the 15-hydroxyprostaglandin dehydrogenase (*HPGD*) gene causes PHOAR type 1 (Uppal et al. 2008). *HPGD* encodes 15-hydroxyprostaglandin dehydrogenase (15-PGDH), which is the main enzyme of prostaglandin degradation. In addition, mutations in the solute carrier organic anion transporter family, member 2A1 (*SLCO2A1*) gene, encoding the prostaglandin transporter (PGT), cause PHOAR type 2 (PGT deficiency) (Zhang et al. 2012). Mutations in the *SLCO2A1* gene are the major cause of PHOAR in the Japanese population, whereas mutations in the *HPGD* gene have not been identified in Japanese patients.

The age of symptom onset has a bimodal distribution, peaking during the first year of life in type 1, with a higher frequency of patent ductus arteriosus and cranial suture defects, and at puberty in PHOAR type 2 (Castori et al. 2005). It has a marked predominance in male, especially in PHOAR type 2. Diagnosis is based on the triad of digital clubbing, pachydermia, and periostosis of the tubular bones. Joint swelling, arthralgia or arthritis, and hyperhidrosis are other common symptoms. Peptic ulcers, chronic gastritis,

anemia, and myelofibrosis occur only in patients with PHOAR type 2. Isolated digital clubbing can also be caused by homozygous mutation in the *HPGD* gene.

Both causative genes of PHOAR encode proteins participating in the degradation of PGE_2. PGE_2 is degraded through two main steps: first, the PGT mediates the uptake of PGE_2 across the plasma membrane; then PGE_2 is degraded by 15-PGDH in the cell into PGEM. Elevated levels of PGE_2 are present in affected patients of both subtypes. In addition, urinary levels of PGEM are elevated in PHOAR type 2 (Hou et al. 2018). Therefore, prostaglandins are considered to be involved in the pathogenesis of PHOAR (Uppal et al. 2008; Zhang et al. 2012). Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in improving arthralgia or arthritis in majority of affected patients.

Leukotrienes are derived from arachidonic acid via the 5-lipoxygenase pathway. They include the cysteinyl leukotrienes (LTC_4, LTD_4, LTE_4) and LTB_4 (Lewis et al. 1990; Mayatepek and Hoffmann 1995). The role of leukotrienes in the CNS is poorly understood, but there is evidence that they are messengers or modulators of CNS activity.

A few disorders have been identified causing secondary disturbances in leukotriene elimination and degradation (Mayatepek et al. 1993; Mayatepek and Lehmann 1996; Willemsen et al. 2000). In the synthesis of leukotrienes, a primary defect has been detected in the enzymatic step in the form of leukotriene C_4 synthase deficiency (LTC4SD). So far, this defect has been identified in two independent patients (Mayatepek and Flock 1998; Mayatepek et al. 1999). The clinical picture was mainly characterized by severe muscular hypotonia, psychomotor retardation, failure to thrive, microcephaly, and death in infancy. There was a complete absence of the primary cysteinyl leukotriene, LTC_4, and its metabolites in the CSF (Mayatepek et al. 2000). Absence of LTC_4, especially in the brain, might at least in part be responsible for the neurological symptoms.

Because of the very limited number of patients identified so far and due to the lack of profound understanding of the role of leukotrienes in the brain and their pathophysiological significance in deficiency states, there exist no therapeutic approaches. It is possible that this disorder is underdiagnosed, suggesting that leukotriene analysis might be included in the metabolic workup in patients with severe neurological symptoms who have no apparently other cause.

Nomenclature

Metabolic Pathways

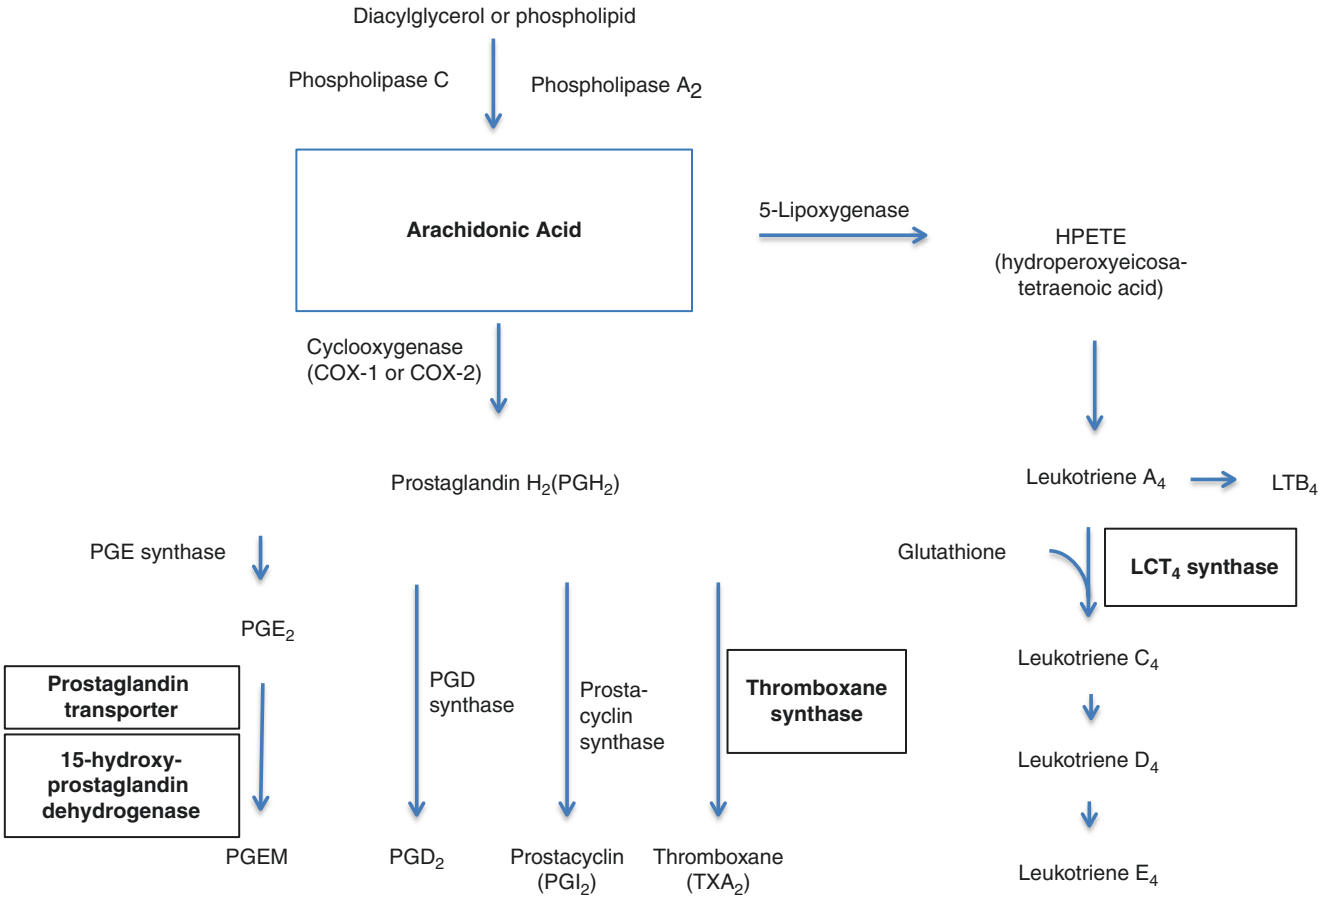

Fig. 52.1 The arachidonic acid cascade. For simplicity, not all reactions are shown in detail. Prostaglandins (PGs) are derived from enzymatic metabolism of arachidonic acid to PGG_2 and subsequently to PGH_2 followed by the production of bioactive prostaglandins (e.g., PGE_2, PGI_2, PGD_2) and thromboxane A_2 (TXA_2) by tissue-specific synthases. Cyclooxygenase (COX-1 or COX-2) is the rate-limiting enzyme responsible for the first two steps in the synthesis of prostaglandins. TXA_2 is formed from PGH_2 via the enzyme thromboxane synthase. PGE_2 is degraded through two main steps: first, the prostaglandin transporter (PGT) mediates the uptake of PGE_2 across the plasma membrane. Then PGE_2 is degraded by 15-hydroxyprostaglandin dehydrogenase (15-PGDH) in the cell into PGEM. Synthesis of the primary cysteinyl leukotriene (LT), LTC_4, results from conjugation of the unstable LTA_4 with glutathione and is mediated by LTC_4 synthase. Stepwise cleavage of glutamate and glycine from LTC_4 by γ-glutamyl transpeptidase membrane-bound dipeptidase yields LTD_4 and LTE_4, respectively

Diagnostic Flowchart

Diagnosis of thromboxane synthase deficiency as well as primary hypertrophic osteoarthropathy is primarily not made on the basis of specific metabolic analyses or profiles but instead based on typically clinical symptoms and especially in the first one on the basis of typical radiological findings. This is completely different in LTC_4 synthase deficiency (see Fig. 52.2).

Specimen Collection

For laboratory measurements of prostaglandins, a thorough drug history is mandatory since nonsteroidal anti-inflammatory drugs or acetylsalicylic acid can affect such analyses.

Leukotrienes are very susceptible to oxidative degradation. Collection of CSF, urine, or plasma (from heparinized blood after centrifugation) and storage should be done preferably in polypropylene tubes (if possible immediately kept in liquid nitrogen) and frozen immediately preferably at −70 °C. Long-term storage may result in lower contents. Bacterial contamination may cause artificial higher contents. Leukotrienes are easily artificially generated and released from leukocytes during blood sampling.

Prostaglandins and leukotrienes are analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS).

For mutational analysis, DNA is preferred.

Prenatal Diagnosis

Prenatal diagnosis has not been performed yet.

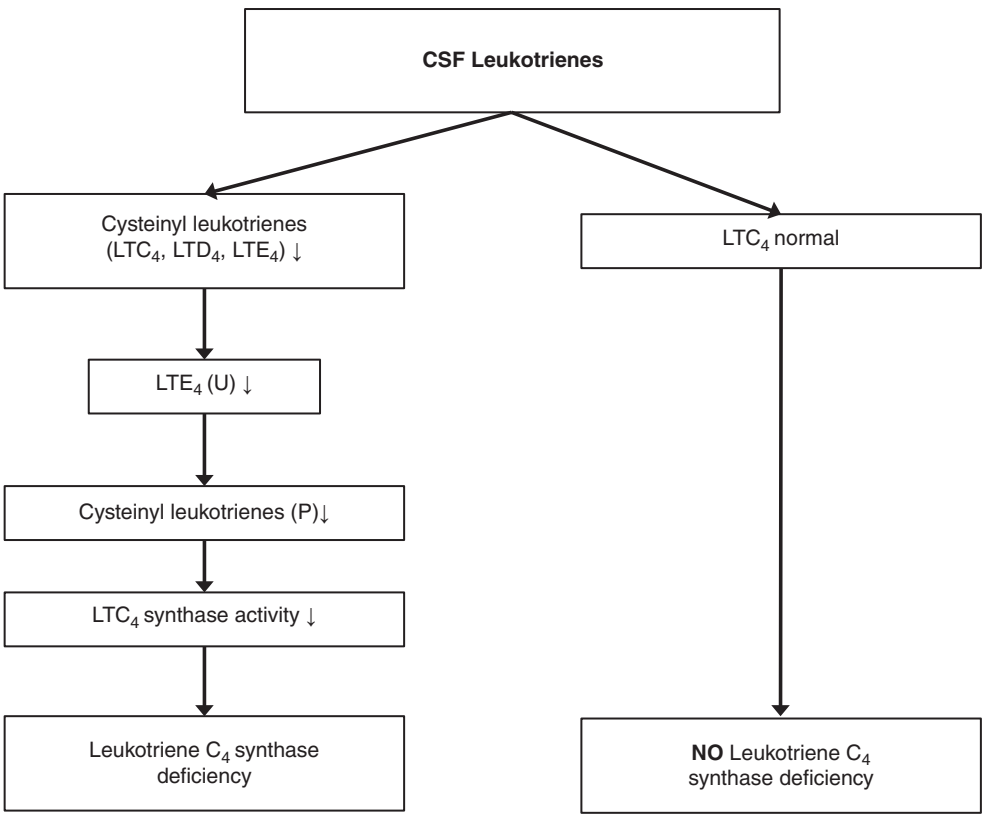

Fig. 52.2 Diagnostic flow chart for a defect in the primary cysteinyl leukotriene C_4 (*LT* leukotriene)

DNA Testing

Mutational analysis is feasible in GHDD as well as in PHOAR type 1 and type 2. It has not been performed yet in LTC4SD. DNA from peripheral blood leukocytes should be used for PCR and direct sequencing.

Treatment

Summary

In GHDD, steroid therapy is the mainstay of treatment especially for hypoplastic anemia negating the need for blood transfusions.

No drug effectively treats PHOAR of both subtypes. NSAID, colchicine, or corticosteroids may be used for symptomatic relief. Bisphosphonates or infliximab has been attempted in patients refractory to these drugs.

There exist no treatment options in LTC4SD.

Emergency Treatment

No emergency treatment available.

Standard Treatment

In GHDD, there exists no standard steroid regimen for this steroid-sensitive disorder. Most studies have reported good response to maintenance therapy with low-dose oral prednisolone throughout life.

NSAIDs with their analgesic and anti-inflammatory activities via inhibition of COX activity and prostaglandin synthesis are reasonable in patients with painful osteoarthropathy in both subtypes. Colchicine may be helpful for the pain due to subperiosteal new bone formation. Corticosteroids have been given for rheumatologic symptoms.

No standard treatment available in LTC4SD.

Experimental Treatment

There exist no experimental treatment options for the disorders discussed here.

Disorders of Lipoprotein Metabolism

53

Amanda J. Hooper, Robert A. Hegele, and John R. Burnett

Contents

Summary

Disorders of lipoprotein metabolism-dyslipoproteinemias-can be classified based on the primary biochemical disturbance, such as high or low plasma levels of low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, or triglyceride (TG), or some combination of these. Lipoproteins are physiological transporters of hydrophobic lipids and fat-soluble vitamins through plasma from their site of origin (intestine or liver) to their site of uptake and disposition. Abnormal levels of certain plasma lipids and lipoproteins increase the risk of

cardiovascular disease (CVD) end points, such as myocardial infarction and stroke, and other complications such as pancreatitis. Numerous genetic and environmental factors contribute to inter-individual variation in plasma concentrations of lipids and lipoproteins. Disorders with a monogenic basis typically present earlier in life, while those that present later in life also have genetic, mainly polygenic, determinants, but their expression further depends on interactions with nongenetic environmental or lifestyle factors. Early diagnosis is central to specific dietary, lifestyle, and pharmacological interventions to delay death, disability, and medical complications. For example, to prevent premature CVD in heterozygous familial hypercholesterolemia, it is important to screen subjects at risk, make the appropriate diagnosis (which may include DNA analysis), and initiate treatment, which includes diet, exercise, and lipid-lowering medications. Here we describe the current understanding of genetic determinants, clinical manifestations, and treatment of disorders of lipoprotein metabolism, focusing on defined monogenic disorders that are diagnosed throughout the lifespan.

Introduction

Disorders of lipoprotein metabolism are usually diagnosed biochemically from a plasma lipid profile. The most important lipids clinically are cholesterol, a key component of cell membranes and a precursor for steroid hormones, and TG, a key energy source comprised of three fatty acids each linked to a glycerol backbone. Due to their hydrophobic nature, lipids are transported in plasma in spheroidal particles called lipoproteins. These consist of a core of cholesterol esters and TG, surrounded by a phospholipid and free cholesterol surface, along with associated proteins called apolipoproteins. Lipoproteins can be distinguished from each other by size, density, composition, and function.

There are three major lipoprotein transport pathways: the exogenous, endogenous, and reverse cholesterol transport. In the exogenous pathway, dietary fats are packaged into large, TG-rich chylomicron particles and secreted from enterocytes via the lymphatic system into plasma. Chylomicrons are rapidly acted upon by lipoprotein lipase (LPL), which hydrolyzes TG to release free fatty acids and to form smaller remnant particles that are cleared by the liver. In the endogenous pathway, the liver produces TG-rich very-low-density lipoproteins (VLDL) that are similarly metabolized by lipase activity to form intermediate-density lipoproteins (IDL) and then low-density lipoproteins (LDL). While the majority of LDL is cleared via the LDL receptor pathway by the liver or peripheral tissues, LDL can become modified, e.g., oxidized, and taken up by foam cells, forming a fatty streak in artery walls that is the early stage of atherosclerosis. This process is a function of atherogenic lipoprotein concentrations over time, with the fatty streak and accompanying inflammation progressing to an atherosclerotic plaque, which may eventually rupture, resulting in CVD end points, such as myocardial infarction or stroke. High-density lipoprotein (HDL) functions to, in part, reverse the process of atherosclerosis, by transporting cholesterol from cells and tissues back to the liver for excretion or reuse.

Apolipoproteins provide lipoproteins with stability and also act as ligands for receptors or activators for enzymes. Apolipoprotein (apo) B forms an integral part of chylomicrons and VLDL and their remnants and, as there is only one molecule of apo B per particle, which stays with the lipoprotein for its circulating life, provides an estimate of atherogenic particle number. The other apolipoproteins are exchangeable between lipoproteins and include apo A-I, the main apolipoprotein of HDL; apo E, a ligand for receptor-mediated clearance particularly for IDL; and apo C-II and apo A-V, cofactors for LPL-mediated hydrolysis of TG.

Plasma lipid and lipoprotein concentrations generally follow a right-skewed Gaussian distribution in the general population. Median levels vary by age and sex, with older age and male sex associated with a less favorable lipid profile. Increased plasma TG concentrations are associated with an increased risk of acute pancreatitis, while plasma concentrations of LDL cholesterol and apo B are directly related to the incidence of coronary events and cardiovascular deaths. Clinical trials using lipid-lowering drugs have unequivocally shown that lowering LDL cholesterol results in significant reductions in both morbidity and mortality in patients with or without established coronary heart disease. While there is an inverse association between HDL cholesterol and CVD, genetic studies suggest that this relationship is not causal; in contrast, increased TG levels appear to have a causative association with CVD.

Important genetic determinants of lipoprotein levels, and therefore targets for novel therapies, have been identified through studies of monogenic lipid disorders. These disorders are generally found at the extremes of the population-specific lipoprotein distribution. While familial hypercholesterolemia (FH) affects ~1 in 250 individuals,

other monogenic disorders are classified as rare disorders, affecting less than 1 in 2000 individuals (Ng et al. 2019). Many of these disorders are autosomal recessive, due to homozygous mutations in causative genes. Some affected patients are compound heterozygotes, a category implied whenever the term "homozygous" is used throughout this chapter.

It is important to recognize that common dyslipidemias are often associated with other conditions and therefore are termed secondary. For example, untreated hypothyroidism, nephrotic syndrome, and cholestatic liver disease may cause a marked elevation of LDL cholesterol similar to levels seen in FH. Hypolipidemia may be caused by lipid-lowering therapy, cachexia, hyperthyroidism, or malnutrition/malabsorption. Hypertriglyceridemia is commonly associated with type 2 diabetes, obesity, and alcohol. However, secondary dyslipidemias may have a genetic component that is usually polygenic in nature; subjects who develop secondary dyslipidemia might have inherited one or more subtle metabolic defects that confer susceptibility. It is important to determine whether there is a strong secondary factor underlying the dyslipidemia, since this may guide the preferred means of intervention.

This chapter will focus primarily on genetic disorders that affect the concentrations of the major circulating lipoproteins, indicated biochemically on a lipid profile. Each disorder has specific clinical features, including physical manifestations across a range of tissues and organ systems, a distinctive biochemical profile, and often a discrete molecular genetic basis. The increased availability of DNA sequencing means that this technology is often the most direct and cost-effective path to a diagnosis for monogenic dyslipoproteinemias (Berberich and Hegele 2019; Hegele et al. 2015).

Metabolic Pathways

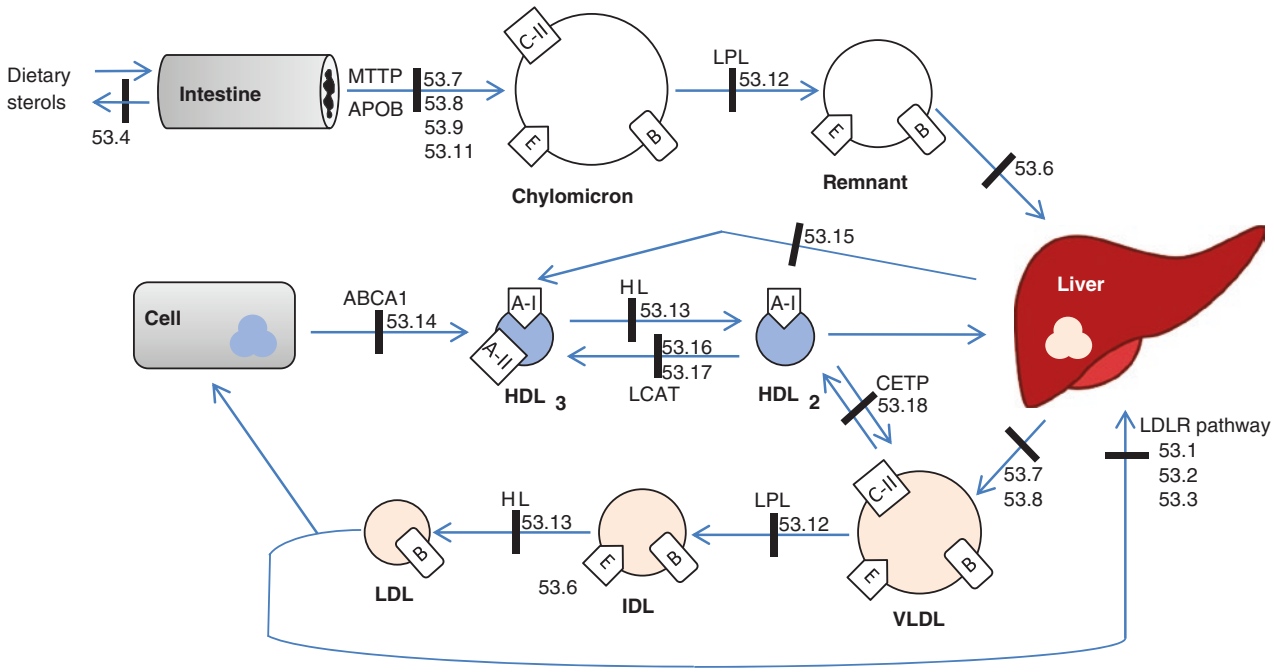

Fig. 53.1 In enterocytes, dietary fats are loaded onto apoB-48 with the assistance of the microsomal triglyceride transfer protein (MTTP), forming large, triglyceride (TG)-rich chylomicron particles, which enter the plasma via the lymphatic system. Chylomicron TG are hydrolyzed by lipoprotein lipase (LPL) to release free fatty acids and to form smaller remnant particles that are cleared by the liver. Similarly, the liver produces TG-rich very-low-density lipoproteins (VLDL) containing apoB-100 that are metabolized by lipase activity to form intermediate-density lipoproteins (IDL) and then low-density lipoproteins (LDL), which is cleared via the LDL receptor pathway. The ATP-binding cassette transporter A1 (ABCA1) and lecithin: cholesterol acyltransferase (LCAT) facilitate the formation of mature high-density lipoprotein (HDL), while cholesteryl ester transfer protein (CETP) transfers cholesterol from HDL to apoB-containing lipoproteins

Signs and Symptoms

Table 53.1 Familial hypercholesterolemia heterozygous (*LDLR*, *APOB*, *PCSK9*)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Carotid or femoral bruits					+
	Myocardial ischemia					++
Dermatological	**Xanthelasmas**					+
	Xanthomas, tendon					++
Eye	**Arcus cornealis**					+
Laboratory findings	Apo B (plasma)	↑↑	↑↑	↑↑	↑↑	↑↑
	HDL cholesterol (plasma)	↓-n	↓-n	↓-n	↓-n	↓-n
	LDL cholesterol (plasma)	↑↑	↑↑	↑↑	↑↑	↑↑
	LDLR, APOB or *PCSK9* mutation, heterozygous, on DNA sequencing	+	+	+	+	+
	TG (plasma)	n	n	n	n	n

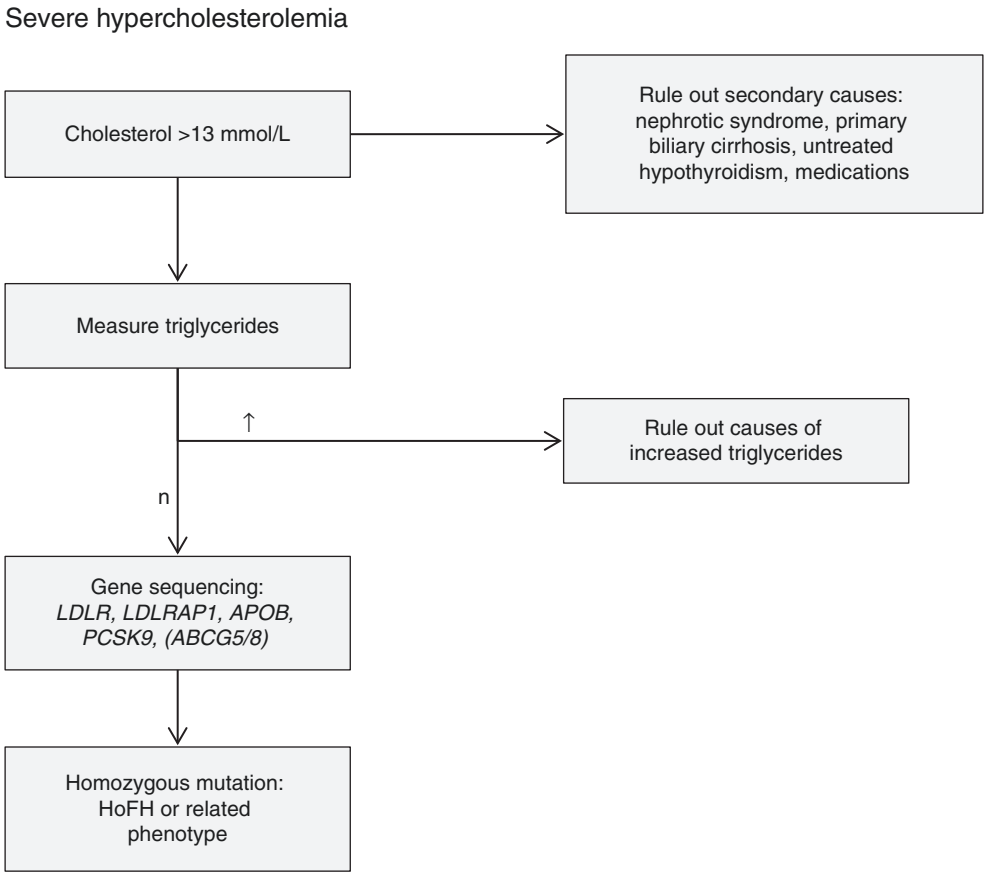
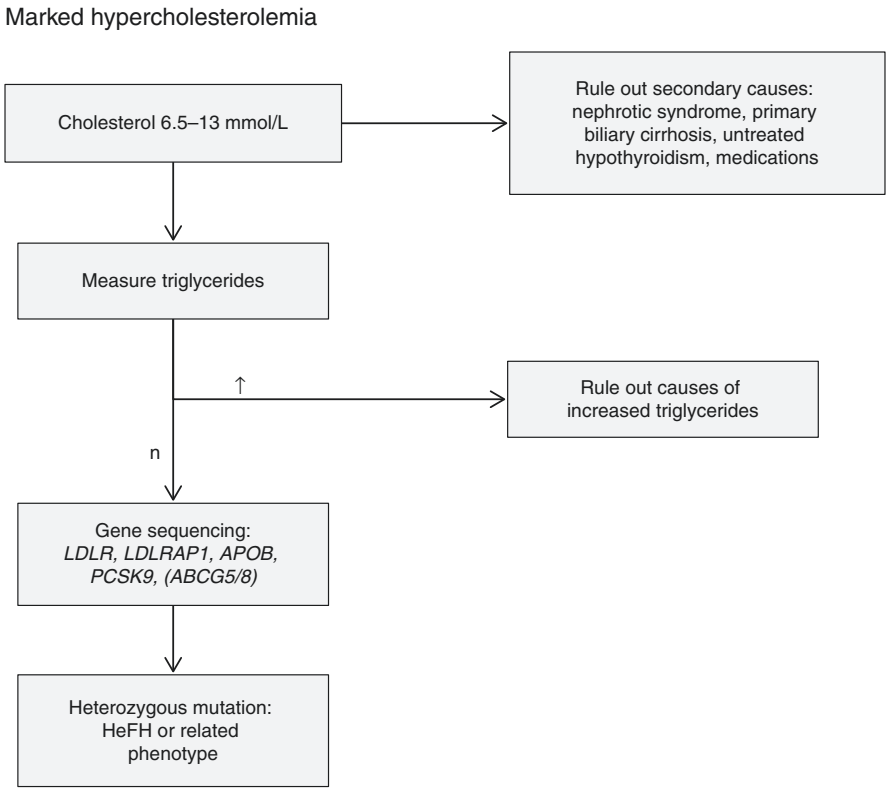
53.13	Hepatic lipase deficiency	>6.0	↓-n	>3.0	>2.0	>1.4	Homozygous *LIPC* gene mutation
53.14	Tangier disease	n	↓-n	Increased	<0.1	n	Homozygous *ABCA1* gene mutation
53.15	Apolipoprotein A1 deficiency	n	↓-n	n	<0.2	n	*APOA1* gene mutation
53.16 and 53.17	Lecithin: cholesterol acyltransferase deficiency	n	↓-n	n-↑	<0.2	n	Homozygous *LCAT* gene mutation
53.18	Cholesteryl ester transfer protein deficiency	n-↑	n	n	>2.5	n	*CETP* gene mutation

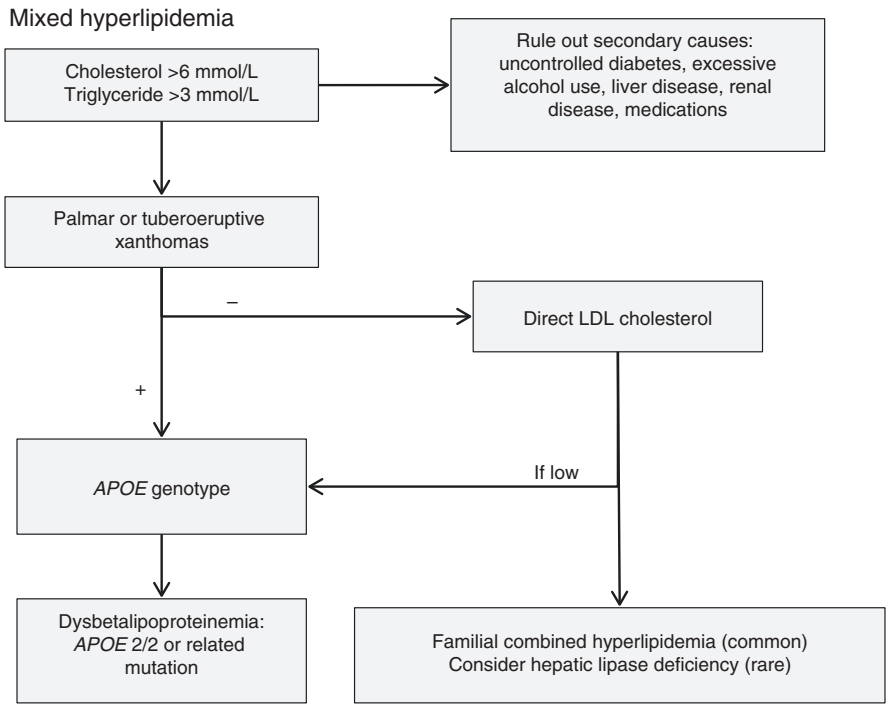
LDL-C low-density lipoprotein cholesterol, *HDL-C* high-density lipoprotein cholesterol, *Apo B* apolipoprotein B, *Lp(a)* lipoprotein(a)

Diagnostic Flow Charts



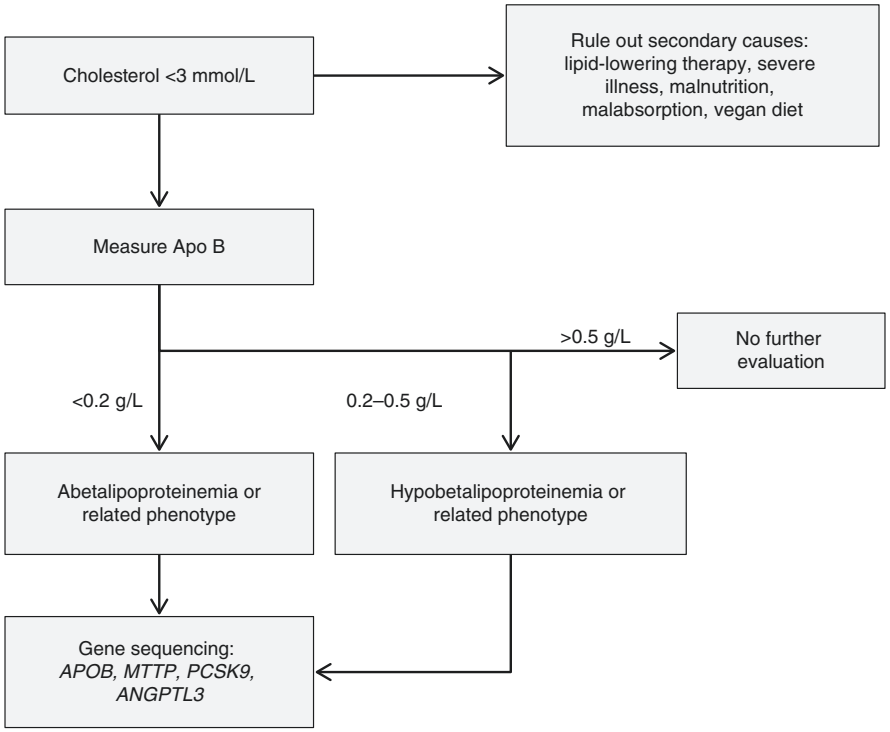


Marked hypercholesterolemia
Cholesterol 6.5–13 mmol/L
Rule out secondary causes: nephrotic syndrome, primary biliary cirrhosis, untreated hypothyroidism, medications
Measure triglycerides
↑
Rule out causes of increased triglycerides
n
Gene sequencing: LDLR, LDLRAP1, APOB, PCSK9, (ABCG5/8)
Heterozygous mutation: HeFH or related phenotype

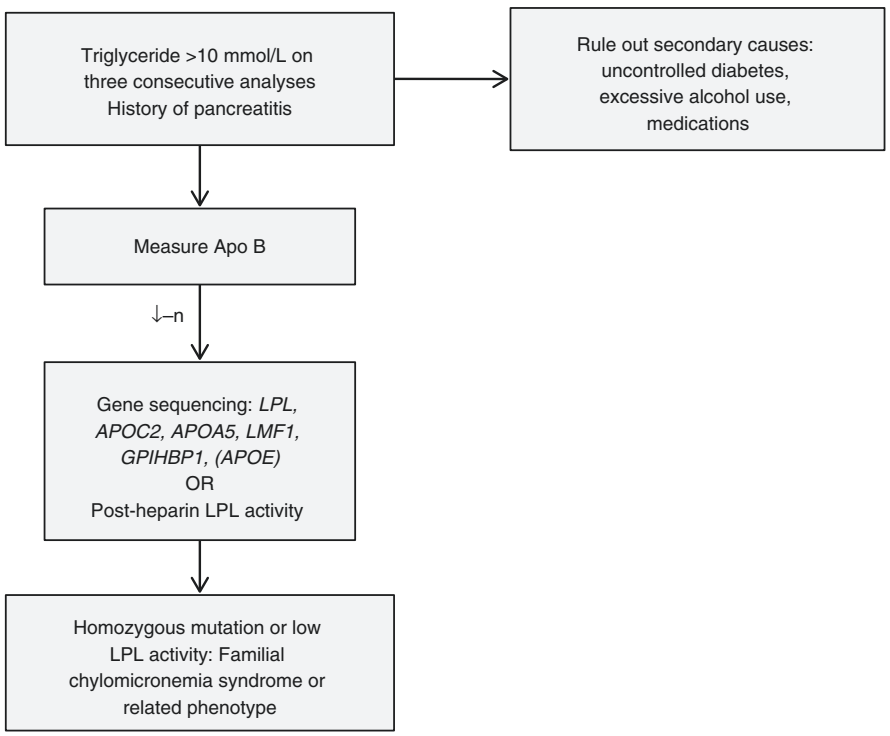


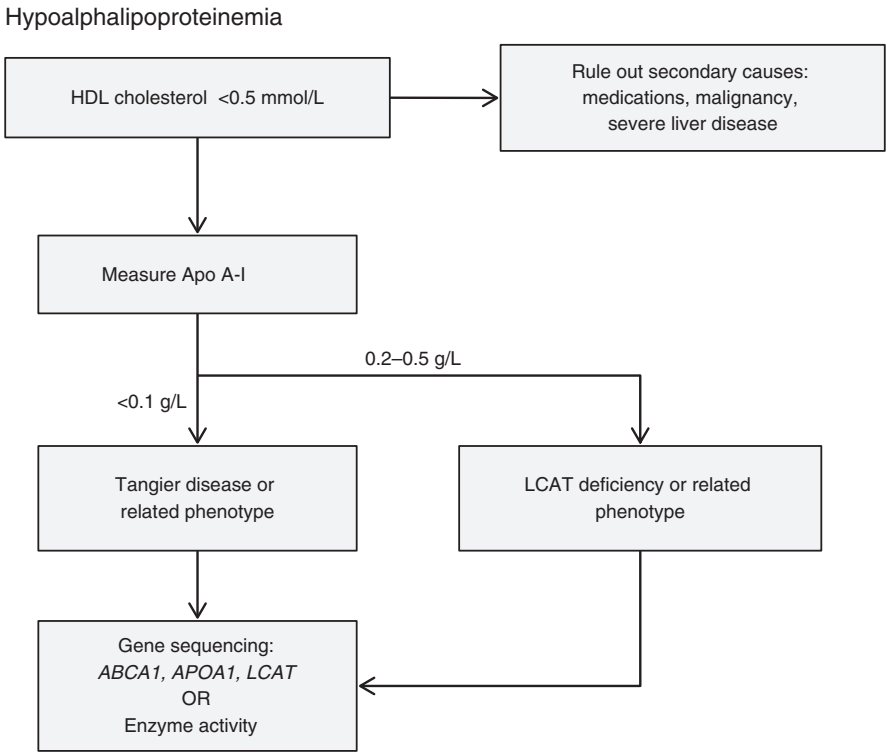
Mixed hyperlipidemia
Cholesterol >6 mmol/L
Triglyceride >3 mmol/L
Rule out secondary causes: uncontrolled diabetes, excessive alcohol use, liver disease, renal disease, medications
Palmar or tuberoeruptive xanthomas
–
Direct LDL cholesterol
+
APOE genotype
If low
Dysbetalipoproteinemia: APOE 2/2 or related mutation
Familial combined hyperlipidemia (common)
Consider hepatic lipase deficiency (rare)

Hypolipidemia



Severe hypertriglyceridemia





Specimen Collection

DNA for sequence analysis or genotyping: standard DNA collection procedures from blood, buccal swabs, or saliva.

Skin fibroblasts for LDL receptor activity assay: standard skin biopsy and storage; expertise in performing this test is becoming rare.

Post-heparin plasma for lipase activity: baseline fasting plasma sample, followed by intravenous injection of 50–100 units of normal molecular weight heparin per kg body weight; followed in 30 minutes by a second plasma sample to assay total and fractionated lipase activities; expertise in performing this test is becoming rare.

Other plasma biochemical activities: LCAT activity or cholesterol esterification rate can be measured from plasma, but several available assay kits are research-based and are not standardized for clinical use.

Prenatal Diagnosis

Prenatal diagnosis for the purpose of pregnancy termination is not usually indicated for monogenic dyslipoproteinemias.

When the index of suspicion for a homozygous illness is high, it is theoretically feasible to sequence genomic DNA sequence of chorionic villus samples for prenatal diagnosis of HoFH for two parents known to have HeFH: vast majority of mutations are found within the *LDLR* gene.

For other severe recessive disorders of lipoprotein metabolism, e.g., LPL deficiency or abetalipoproteinemia, since carrier parents are asymptomatic, diagnosis of the condition within the family follows from diagnosis of an initial offspring. Once the mutation(s) and their segregation within the family are identified, subsequent chorionic villus tissue can be tested with focused genomic DNA analysis.

DNA Testing

Clinical suspicion + biochemical disturbance	DNA sequencing of gene(s)
HeFH + LDL cholesterol >6.5 mmol/L	*LDLR*, *APOB, PCSK9,* and possibly *APOE* and *LDLRAP1*
HoFH + LDL cholesterol >10 mmol/L	*LDLR*, *LDLRAP1, APOB,* and possibly *PCSK9* and *ABCG5/G8*
Dysbetalipoproteinemia (approximately equimolar total cholesterol and triglyceride elevations)	*APOE* genotype (ε2/2); followed by *APOE* sequencing for rare variants
ABL + LDL cholesterol <0.5 mmol/L	*MTTP*, *APOB,* and possibly *PCSK9* and *ANGPTL3*
Hypertriglyceridemia + TG >10 mmol/L	*LPL*, *APOC2, APOA5, LMF1,* and *GPIHBP1*
Hypoalphalipoproteinemia + HDL cholesterol <0.5 mmol/L	*ABCA1*, *APOA1*, and *LCAT*
Hyperalphalipoproteinemia + HDL cholesterol >2.5 mmol/L	*CETP*, *LIPC*, *SCARB1*

Treatment

National agencies recommend LDL cholesterol as the primary target of therapy to reduce CVD risk (Anderson et al. 2016; Catapano et al. 2016; Grundy et al. 2019). LDL cholesterol goals are recommended for patients stratified into particular risk categories with more stringent goals for patients at high coronary heart disease (CHD) risk. In children, no strong evidence is available to show improvements in end points in regard to achieved LDL cholesterol. Intervention to reduce LDL cholesterol includes lifestyle management and if necessary, pharmacologic therapies. However, certain monogenic disorders are associated with dramatically increased CVD risk, placing these individuals into the highest risk strata (Brunham et al. 2018; Cuchel et al. 2014; Defesche et al. 2017; Raal et al. 2018; Wiegman et al. 2015). Individualized therapies are required for the individual conditions.

General dietary interventions depend on the pattern of dyslipidemia and whether the individual is overweight or obese. *Trans* and saturated fats should be replaced with monounsaturated and polyunsaturated fats and functional foods with beneficial effects on the lipid profile. In overweight or obese individuals, treatment aims to additionally achieve a better balance between energy intake and expenditure. In individuals with high triglycerides, simple sugars and "high glycemic index" foods should be replaced with complex carbohydrates, physical activity increased, and alcohol eliminated in some cases. The intake of animal products should be reduced and fish, seafood, and plant-based foods emphasized. Fish oil supplements may be useful for hypertriglyceridemia. In general, the severity of the dyslipidemia dictates the intensity of the intervention. For severe hyperchylomicronemia, fat intake should be restricted to 10–15% of total calories (Brahm and Hegele 2015; Stroes et al. 2017). For patients with sitosterolemia, elimination of plant sterols is required. A specialized dietician can be very helpful in these circumstances.

Regular exercise and avoiding sedentary behavior are important habits that may be established early. In addition to contributing to energy balance, exercise lowers blood pressure and improves insulin resistance; more directly, it increases the catabolism of TG-rich lipoproteins and increases tissue lipolysis leading to reduced TG and increased HDL cholesterol levels. Recommendations relating to the intensity of regular exercise depend on the health and fitness of the patient; individuals need to engage in the equivalent of 60 minutes of moderately intense physical activity daily. Avoiding cigarettes and other tobacco products is imperative.

Finally, drug therapy may be started together with lifestyle interventions in high-risk patients. The patient's level of risk guides the timing of treatment initiation and also the intensity of the treatment. Moderate- or low-risk patients may be started on medication after a trial period of lifestyle interventions. The main priority of drug therapy is to achieve the identified LDL cholesterol target level. Therefore, once drug therapy has been decided upon for a general patient with high CVD risk and dyslipidemia, an LDL-lowering drug is almost always the first step. Care should be given to choose drugs with documented reductions in cardiovascular disease in adults—no end point trials have been conducted in children.

Emergency Treatment

Medical emergency	Treatment
Chylomicronemia syndrome (caused by any form of severe hypertriglyceridemia), presenting with sepsis, abdominal pain, pancreatitis	Cessation of oral intake (NPO); intravenous saline to correct or prevent hypovolemia; correction of secondary causes, such as uncontrolled hyperglycemia or alcohol use; with hospitalization, NPO, and hydration, TG will fall with half-life of 2–3 days; there is typically no need for plasmapheresis or heparinization
Acute coronary syndromes	As per usual clinical guidelines for the management of acute coronary syndromes

Standard Treatment

Disorder number	Disorder name	Diet	Medications (adult regimens)	Other
53.1	Familial hypercholesterolemia (HeFH)	Saturated fat <7–10% of energy intake Cholesterol <200 mg/day	Statin as foundation: Simvastatin 10–80 mg/day; atorvastatin 10–80 mg/day; pravastatin 20–80 mg/day; lovastatin 20–40 mg/day; fluvastatin 20–80 mg/day; rosuvastatin 10–40 mg/day Additional agents for combination treatment: Ezetimibe 10 mg/day; cholestyramine 12 g/day or colesevelam 3.75 g/day or colestipol 15 g/day in divided doses; niacin preparations 2–4 g/day; PCSK9 monoclonal antibodies	In children and adolescents, use half-maximal statin dose; half-maximal doses for other medications also
53.2	Familial hypercholesterolemia homozygous (HoFH)	As above	As above, also lomitapide 5–60 mg/day; mipomersen (where available) or evolocumab (specifically indicated for HoFH with at least one non-null allele)	As above, plus serial plasma exchange, or plasmapheresis or lipoprotein apheresis
53.3	Autosomal recessive hypercholesterolemia	As above	As above	As above
53.4	Sitosterolemia	Cessation of plant sterols; reduction of dietary cholesterol	Ezetimibe, bile acid sequestrants, and statins have been shown to have varying effectiveness	Hooper et al. (2017a)
53.5	Elevated lipoprotein(a)	General prudent diet and lifestyle for CHD prevention	Consider statin therapy as in HeFH if indicated by global cardiovascular risk assessment	
53.6	Dysbetalipoproteinemia	Balanced diet and physical activity to maintain body weight in relation to growth. Restrict sugars to <10% of energy, saturated fat to <10% of energy	As for HeFH based on clinical assessment of cardiovascular disease risk	
53.7	Abetalipoproteinemia; homozygous familial hypobetalipoproteinemia	Low-fat diet (<30% total calories) with minimum long-chain FAs; medium-chain TG; essential FA supplements	High doses of oral preparations of vitamins A, D, E, and K	Monitor blood levels of fat-soluble vitamins and titrate therapy (Burnett et al. 2018; Lee and Hegele 2014)
53.8	Familial hypobetalipoproteinemia	No specific diet	No specific drug therapy	Monitor liver function
53.9	PCSK9 deficiency with low LDL	No specific diet	No specific drug therapy	Monitor blood levels of fat-soluble vitamins and treat if indicated
53.10	Familial combined hypolipidemia	No specific diet	No specific drug therapy	As above
53.11	Chylomicron retention disease	Low-fat diet (<30% total calories) with minimum long-chain FAs; medium-chain TG; essential FA supplements	High doses of oral preparations of vitamins A, D, E, and K	Monitor blood levels of fat-soluble vitamins and titrate therapy (Levy et al. 2019; Peretti et al. 2010)
53.12	Lipoprotein lipase deficiency; familial chylomicronemia syndrome	Fat <10%–20% of total energy. Medium-chain triglyceride supplements	Try fish oil capsules (EPA mainly) 2–4 g once daily; consider a fibrate (e.g. fenofibrate 145–200 mg/day)	Plasma exchange or plasmapheresis is almost never indicated or definitively helpful in this condition
53.13	Hepatic lipase deficiency	General prudent diet and lifestyle for CHD prevention	Consider statin therapy as in HeFH if indicated by global cardiovascular risk assessment	

Disorder number	Disorder name	Diet	Medications (adult regimens)	Other
53.14	Tangier disease	As above	As above	Hooper et al. (2017b), Rader and deGoma (2012)
53.15	Apolipoprotein A-I deficiency	As above	As above	
53.16 and 53.17	Familial lecithin: cholesterol acyltransferase deficiency	As above	As above	
53.18	Cholesteryl ester transfer protein deficiency	As above	As above	

Experimental Treatment

Disorder number	Disorder name	Experimental treatment
53.1	Familial hypercholesterolemia (HeFH)	Inclisiran (PCSK9 antisense RNA)
53.2	Familial hypercholesterolemia homozygous (HoFH)	As for HeFH; also evinacumab (ANGPTL3 monoclonal antibody); LDL receptor gene therapy
53.3	Autosomal recessive hypercholesterolemia	As for HeFH
53.4	Sitosterolemia	As for HeFH
53.5	Elevated lipoprotein(a)	*LPA* antisense RNA
53.6	Dysbetalipoproteinemia	
53.7	Abetalipoproteinemia; homozygous familial hypobetalipoproteinemia	
53.8	Familial hypobetalipoproteinemia	
53.9	PCSK9 deficiency with low LDL	
53.10	Familial combined hypolipidemia	
53.11	Chylomicron retention disease	
53.12	Lipoprotein lipase deficiency; familial chylomicronemia syndrome	Evinacumab (ANGPTL3 monoclonal antibody), volanesorsen (APOC3 antisense RNA)
53.13	Hepatic lipase deficiency	
53.14	Tangier disease	
53.15	Apolipoprotein A-I deficiency	Apo A-I peptide infusion
53.16 and 53.17	Familial lecithin: cholesterol acyltransferase deficiency	Recombinant human LCAT enzyme replacement therapy
53.18	Cholesteryl ester transfer protein deficiency	

Follow-Up and Monitoring

Disorder number	Disorder name	Clinical monitoring	Laboratory investigations
53.1	Familial hypercholesterolemia (HeFH)	Cardiovascular examination; coronary atherosclerosis imaging	Lipids, including apolipoproteins
53.2	Familial hypercholesterolemia homozygous (HoFH)	As above	As above
53.3	Autosomal recessive hypercholesterolemia	As above	As above
53.4	Sitosterolemia	As above	As above; plant sterols
53.5	Elevated lipoprotein(a)	As above	As for HeFH
53.6	Dysbetalipoproteinemia	As above	As for HeFH
53.7	Abetalipoproteinemia; homozygous familial hypobetalipoproteinemia	Neurological and ophthalmological examination; hepatic ultrasonography, bone mineral density, echocardiography	Lipids, liver function tests, vitamin A, D, E, INR
53.8	Familial hypobetalipoproteinemia	Hepatic ultrasonography	Lipids, liver function tests
53.9	PCSK9 deficiency with low LDL	None	–
53.10	Familial combined hypolipidemia	None	–

Disorder number	Disorder name	Clinical monitoring	Laboratory investigations
53.11	Chylomicron retention disease	Neurological and ophthalmological examination; hepatic ultrasonography, bone mineral density, echocardiography	Lipids, liver function tests, vitamin A, D, E, INR
53.12	Lipoprotein lipase deficiency; familial chylomicronemia syndrome		Lipids
53.13	Hepatic lipase deficiency	Cardiovascular examination; coronary atherosclerosis imaging	Lipids
53.14	Tangier disease	Cardiovascular, gastrointestinal, neurological, and ophthalmological examination; coronary atherosclerosis imaging	Lipids
53.15	Apolipoprotein A-I deficiency	Cardiovascular, gastrointestinal, neurological, and ophthalmological examination; coronary atherosclerosis imaging	Lipids
53.16 and 53.17	Familial lecithin: cholesterol acyltransferase deficiency	Renal and ophthalmological examination	Lipids, renal function
53.18	Cholesteryl ester transfer protein deficiency	None	–

Disorders of Cholesterol Biosynthesis

54

Lisa E. Kratz and Richard I. Kelley

Contents

Summary

Cholesterol has several essential functions in cell physiology. In addition to being a major component of cellular membranes, cholesterol serves as the precursor of bile acids and steroid hormones and plays an important role in embryonic morphogenesis. For many years, mevalonate kinase deficiency (MKD) was the only known genetic disorder of the cholesterol biosynthesis pathway (Hoffmann et al. Pediatrics 91:915–921, 1993). However, the discovery in 1993 of increased levels of 7-dehydrocholesterol (7DHC) and hypocholesterolemia in patients with Smith-Lemli-Opitz syndrome (SLOS) (Irons et al. Lancet 341:1414, 1993) heralded the emergence of a new group of metabolic disorders—inborn errors of cholesterol biosynthesis. The discovery of the biochemical bases of these rare genetic disorders has not only provided biochemical methods for their diagnosis but also allowed the delineation of the broad spectrum of their clinical and biochemical phenotypes.

Introduction

Mevalonate kinase deficiency. Mevalonic kinase deficiency (MKD) is a rare, autosomal recessive disorder with principal characteristics of (1) periodic autoinflammatory crises associated with arthralgia, edema, diarrhea, and morbilliform rash; (2) developmental delays, often profound; (3) hepatosplenomegaly secondary to extramedullary hematopoiesis; and (4) marked mevalonic aciduria (Hoffmann et al. 1993). More severely affected patients have dysmorphic facial features, failure to thrive, rhizomelic dwarfism, cataracts, and anemia. Biochemically more mildly affected patients included in the spectrum of MKD may have only minimal psychomotor retardation, hypotonia, myopathy, and cerebellar ataxia. A third group of patients with mild mevalonic kinase deficiency (approximately 5% residual enzyme activity) have recurrent, every 3- to 4-week crises associated with hyperimmunoglobulinemia D (hyper-IgD syndrome), minimally increased urine levels of mevalonic acid and none of the developmental or physical abnormalities associated with classical MKD (Houten et al. 1999). The diagnosis of all forms of MKD is based on finding increased urinary levels of mevalonic acid, deficient activity of mevalonate kinase activity in cultured cells, or disabling mutations in *MVK*.

Squalene synthase deficiency. The condensation of two molecules of farnesyl pyrophosphate to form the 30-carbon molecule, squalene, catalyzed by squalene synthase, FDFT1, is the first committed step in cholesterol synthesis. Squalene synthase deficiency is unique among disorders of cholesterol synthesis in being identifiable by a diagnostic urine organic acid pattern of branched-chain, principally unsaturated dicarboxylic acids produced by the combination of beta- and omega-oxidation of high cytoplasmic levels of farnesol (Coman et al. 2018). Three patients with FDFT1 deficiency, two sibs and an unrelated child, have been described. Clinical characteristics included IUGR, postnatal failure to thrive, neonatal-onset seizures, cerebral defects (agenesis of the corpus callosum, white matter hypoplasia, polymicrogyria), optic atrophy (2/3), SLOS-like facial and skeletal dysmorphisms, and profound developmental delays. All four mutations in the two families were exonic or large intronic deletions but with variable persistence of small amounts of FDFT1 activity. A fourth patient with a deletion/stop-gain mutation and a missense mutation (p. V273G) presented at age 2 days with seizures but had no identifiable physical anomalies (R. Kelley unpublished). Treatment with simvastatin rapidly eliminated the organic aciduria except for minimal residual mevalonic aciduria. At age 6 years, he is developmentally normal except for mild speech delay.

Lanosterol synthase deficiency. Lanosterol synthase (LSS) catalyzes the conversion of (S)-2,3-oxidosqualene to lanosterol, the first sterol in the cholesterol synthesis pathway. Several reports have associated variants in the gene encoding LSS with isolated congenital cataracts (Zhao et al. 2015), hypotrichosis simplex (Romano et al. 2018), or a combination of congenital cataracts and alopecia (Chen and Liu 2017). Identification of an additional 11 individuals from seven unrelated families by Besnard et al. (Besnard et al. 2019) extended the phenotype to include intellectual disability, developmental delays, and seizures. Although plasma sterol levels in these patients are normal, a mildly increased desmosterol level relative to the level of total sterols was observed in cultured lymphoblasts for 2/2 patients tested (L. Kratz unpublished).

Lanosterol 14α-demethylase deficiency. Sterol 14α-demethylase (lanosterol demethylase), encoded by the cytochrome P450 gene, *CYP51A1*, catalyzes an early, rate-limiting step in post-squalene cholesterol biosynthesis. This enzyme, in conjunction with P450 oxidoreductase (POR), removes the 14α-methyl group from lanosterol to form 4,4-dimethylcholesta-8(9),14,24-trien-3ß-ol. Three patients with biochemical evidence and molecular confirmation of lanosterol 14α-demethylase deficiency have been identified [(Gillespie et al. 2014), L. Kratz unpublished, Melissa Crenshaw personal communication]. All cases had congenital cataracts, as did a fourth patient identified by exome sequencing of patients with congenital cataracts (Aldahmesh et al. 2012). Additional features in one patient included microcephaly, short stature, reduced skin pigmentation, developmental delays, and behavioral abnormalities. The second patient had cryptogenic neonatal cirrhosis and spastic diplegia, while the third case had short stature but no other anomalies. Plasma sterol analysis in all three cases and cultured lymphoblasts from case 1 revealed an increased level of lanosterol and dihydrolanosterol. All cases had biallelic mutations in *CYP51A1*.

Sterol C14-reductase deficiency. Hydrops-ectopic calcification-moth-eaten skeletal dysplasia (HEM), or "Greenberg dysplasia," is an especially rare, autosomal recessive, prenatally lethal skeletal dysplasia characterized by fetal hydrops, extreme short-limbed dwarfism, disorganized chondro-osseous mesenchymal proliferation, and abnormal bone mineralization (Konstantinidou et al. 2008). Radiographic findings include marked limb shortening with a "moth-eaten" appearance of the long bones, platyspondyly, ectopic epiphyseal calcifications, and abnormal laryngeal and tracheal calcifications. Sterol analysis in cartilage, cultured fibroblasts, and chondrocytes from affected fetuses revealed small amounts of 14-unsaturated sterols, suggesting a deficiency of sterol C14 reductase. Molecular studies confirmed biallelic pathogenic mutations in the lamin B receptor gene, *LBR* (Waterham et al. 2003), which encodes a fusion protein carrying both sterol C14 reductase enzymatic activity and nuclear lamin B receptor function. Heterozygosity for mutations in *LBR* causes autosomal dominant Pelger-Huët anomaly (PHA) featuring benign, microscopically identifiable, abnormal (reduced) lobation of neutrophils (Hoffmann et al. 2002). A much rarer homozygous form of PHA causes nonlethal skel-

etal abnormalities of variable severity (Thompson et al. 2019) in addition to abnormally lobated neutrophils. The minimal biochemical abnormality in cells and tissues of a lethal disorder like Greenberg dysplasia presumably indicates the functional importance of a second microsomal enzyme with sterol 14-reductase activity, TM7SF2, for which an associated deficiency in humans remains unknown. However, studies by Clayton et al. (Clayton et al. 2010) indicate that severe skeletal dysplasia is a consequence of the LBR-associated impaired sterol 14α-reductase.

Sterol C4-methyl oxidase deficiency. Sterol C4-methyl oxidase, encoded by *SC4MOL*, is one of the three enzymes and one non-enzymatic protein comprising the heteromultimeric enzyme complex, sterol 4α-methyl-4-demethylase. The first patient shown to have SC4MOL deficiency was an adolescent female with congenital cataracts, mild developmental delays, microcephaly, short stature, persistent hypocholesterolemia, and a severe ichthyosiform erythroderma that developed after age 2 years (He et al. 2011). A sibling pair with similar skin manifestations has subsequently been identified (He et al. 2014). However, two additional, unrelated cases of SC4MOL deficiency had no skin involvement, the first presenting with congenital cataracts, microcephaly, hypotonia, and moderate developmental delays (He et al. 2014) and the second with congenital cataracts, growth delay, learning disabilities, behavioral disorders, and short stature (Frisso et al. 2017). While plasma sterol analysis in all reported cases showed increased levels of 4α-methyl and 4,4'α-dimethyl sterols, only the first case had a moderately decreased plasma cholesterol level. The combination of simvastatin treatment and cholesterol supplementation in the first patient was associated with resolution of the ichthyosiform erythroderma and improved growth and development (M. He and J. Vockley personal communication 2011).

X-linked dominant sterol-4α-carboxylate 3-dehydrogenase deficiency (CHILD syndrome). *C*ongenital *h*emidysplasia, *i*chthyosis, and *l*imb *d*efects (CHILD syndrome) is a rare, X-linked dominant disorder defined by unilateral ichthyosiform skin lesions and ipsilateral reduction deformities of the limbs (Happle et al. 1980). Concomitant anomalies on the affected side include punctate epiphyseal calcifications of vertebrae and long bones, abnormal calcification of the laryngeal and tracheal cartilages, and, less frequently, hypoplasia of internal organs, especially the kidney. This syndrome is most often caused by a deficiency of 3ß-hydroxysteroid dehydrogenase, an enzyme encoded by *NSDHL* (NAD(P)H steroid dehydrogenase-like), one of the four proteins constituting the sterol 4α-methyl-4-demethylase complex (König et al. 2000). Patients with NSDHL deficiency CHILD syndrome have abnormal levels of 4α-methylsterols in affected skin and cultured cells, but plasma sterol levels are often normal (Liu et al. 1999). A few patients with unilateral skin and skeletal lesions given an initial diagnosis of CHILD syndrome were later found to have a deficiency of sterol Δ^8-isomerase, the cause of X-linked dominant Conradi-Hünermann syndrome (CDPX2) (Grange et al. 2000). Conversely, one patient with an initial clinical diagnosis of CDPX2 at birth was later found to have a deficiency of NSDHL by biochemical and genetic analysis (R. Kelley unpublished).

X-linked recessive sterol-4α-carboxylate 3-dehydrogenase deficiency (CK syndrome). Although males hemizygous for NSDHL deficiency were assumed to die early in utero, hypomorphic missense mutations in *NSDHL* have recently been reported in three unrelated families with multiple males having an X-linked recessive intellectual disability syndrome (McLarren et al. 2010; Preiksaitiene et al. 2015), now designated "CK syndrome." Plasma sterol levels were normal in these patients.

X-linked dominant sterol Δ8,Δ7-isomerase deficiency (X-linked dominant Conradi-Hünermann syndrome; CDPX2). This is a rare disorder characterized in females by a variable combination of (1) bilateral but asymmetric shortening of long bones; (2) punctate calcifications of the epiphyses, trachea, and larynx; (3) segmental cataracts; and (4) patches of ichthyosiform erythroderma that mostly follow the lines of Blaschko (Silengo et al. 1980). The cause is a deficiency of 3ß-hydroxysteroid-Δ^8,Δ^7-isomerase (sterol-Δ^8,Δ^7-isomerase, emopamil-binding protein, "EBP"), which converts 8(9)-cholestenol into lathosterol (Braverman et al. 1999). The diagnosis of CDPX2 can be made by detection of increased plasma levels of 8(9)-cholestenol and 8-dehydrocholesterol or by mutation analysis. If a mutation in the gene encoding sterol-Δ^8,Δ^7-isomerase (*EBP*) is found, the mother should always be tested, because carrier mothers can have no clinical manifestations of the disorder or only mild short stature. Although rare, there are reports of males with a CDXP2 clinical phenotype and sterol profile who are mosaic for a pathogenic variant in *EBP (*Aughton et al. 2003*;* Pacault et al. 2018*)*. In one case, paternal transmission of the pathogenic variant resulted in an affected daughter and granddaughter (Pacault et al. 2018).

X-linked recessive sterol Δ8,Δ7-isomerase deficiency. Although *EBP* mutations that cause CDPX2 were once assumed to be uniformly lethal in hemizygous males early in gestation, sterol-Δ^8,Δ^7-isomerase deficiency has been identified in males based on a diagnostic CDPX2 sterol profile and hemizygosity for a damaging mutation in *EBP* (Milunsky et al. 2003; Barboza-Cerda et al. 2014). Males who are hemizygous for mutations in *EBP* have a malformation syndrome distinct from that of heterozygous CDPX2 females, including microcephaly, Dandy-Walker variant, and agenesis of the corpus callosum. Other findings in hemizygous males include seizures, hypotonia, developmental delays, 2/3-toe syndactyly, polydactyly, and heart defects, whereas both chondrodysplasia punctata and other skeletal abnormalities can be absent.

Sterol Δ5-desaturase deficiency (lathosterolosis). Lathosterolosis is caused by a deficiency of lathosterol 5-desaturase (SC5D), which converts lathosterol to 7-dehydrocholesterol (Brunetti-Pierri et al. 2002). Three patients surviving birth had phenotypic findings compatible with the diagnosis of SLOS, but, in contrast to SLOS, two also had progressive hepatosplenomegaly caused by intracellular accumulation of lipids and mucopolysaccharides (Ho et al. 2014). Recently, a lathosterolosis patient with a milder phenotype was ascertained at age 5 years because of bilateral cataracts, developmental delays, and subtle dysmorphic features (Anderson et al. 2019). For all cases, sterol analysis showed a marked increase in the level of lathosterol in plasma and/or cultured fibroblasts but, unlike most individuals with SLOS, a normal plasma cholesterol level. Disabling mutations in *SC5D* were identified in all families. The strong phenotypic resemblance of lathosterolosis to SLOS, a disorder routinely screened in the evaluation of children with dysmorphic features and often just developmental delays, suggests that lathosterolosis is one of the rarest known autosomal recessive enzymopathies, having an estimated incidence substantially less than 1 in a million births.

24-Dehydrocholesterol reductase deficiency (desmosterolosis). Desmosterolosis is a disorder of cholesterol synthesis caused by damaging mutations in *DHCR24*, the gene encoding 3ß-hydroxysteroid-Δ^{24}-reductase (desmosterol reductase) (Waterham et al. 2001) and characterized biochemically by increased plasma and tissue levels of desmosterol [FitzPatrick et al. 1998; Rohanizadegan and Sacharow 2018, L. Kratz unpublished]. All 12 known desmosterolosis patients from eight unrelated families have had structural brain abnormalities, most notably, agenesis of the corpus callosum (12/12) and severe psychomotor delays (10/10). Other variably present abnormalities include arthrogryposis (9/12), microcephaly (7/12), macrocephaly (4/12), cleft palate (5/12), neonatal seizures (5/10), nystagmus, and strabismus (6/10).

7-Dehydrocholesterol reductase deficiency (Smith-Lemli-Opitz syndrome). The most common disorder of cholesterol biosynthesis, with an estimated incidence of 1 in 80,000 births, is Smith-Lemli-Opitz syndrome (SLOS) (Kelley and Hennekam 2000). This well-known, autosomal recessive malformation syndrome is characterized by distinctive facial and oral anomalies, limb and genital malformations, and mild to profound developmental disabilities (Nowaczyk and Irons 2012). In biochemically more severely affected patients, malformations of the kidney, heart, and gastrointestinal tract are common. With the identification in 1993 of diagnostically increased plasma and tissue levels of 7-dehydrocholesterol (7DHC) and later identification of causative mutations in *DHCR7* encoding the last enzyme in the cholesterol biosynthetic pathway, the clinical spectrum for this disorder has broadened to include biochemically minimally affected patients with no discrete malformations and normal intelligence at one extreme and severely affected fetuses dying early in gestation at the other (Nowaczyk and Irons 2012). Although the detection of an increased plasma 7DHC level remains an accurate and efficient screening test for SLOS, rare patients will have normal plasma levels of cholesterol and 7DHC, in which case mutation analysis or sterol analysis in cultured cells must be undertaken. In many patients, treatment with supplemental dietary cholesterol and/or a statin (to upregulate residual DHCR7 activity) leads to clinical and biochemical improvement. A common, nongenetic cause of mildly increased levels of 7DHC is treatment with one of several, mostly psychotropic, medications, which directly inhibit DHCR7 (Hall et al. 2013).

Porokeratosis. Porokeratosis (PK) is a rare dermatologic condition characterized by excessive accumulation of keratin in skin cells, often associated with exposure to ultraviolet light or immunosuppression. Although PK is variable in presentation, with classifications based on number, size, morphology, and distribution of the skin lesions, all variants have cornoid lamellae and a vertical column of parakeratotic cells in the upper epidermis. Recently, certain forms of PK have been associated with heterozygosity for variants in genes responsible for isoprenoid biosynthesis, and autosomal dominant transmission has been demonstrated (Zhang et al. 2015). These genes include *MVK*, *PMVK*, *MVD*, and *FDPS*, encoding the enzymes mevalonate kinase, phosphomevalonate kinase, mevalonate pyrophosphate decarboxylase, and farnesyl diphosphate synthase, respectively. Although there is evidence for genotype-phenotype correlation, no one gene is responsible for all cases of a specific PK variant, suggesting the influence of genetic modifiers of the enzyme deficiencies. No biochemical marker for PK has yet been identified and, thus, evaluation is by molecular testing only.

Geranylgeranyl pyrophosphate synthase deficiency. Although a primary deficiency of geranylgeranyl pyrophosphate synthase has not been described, heterozygous variants in the gene encoding this enzyme (*GGPPS*) have been associated with bisphosphonate-related atypical femoral fractures (Roca-Ayats et al. 2018).

Note: The non-metabolic disorders, i.e., those associated with a porokeratosis phenotype and geranylgeranyl pyrophosphate synthase deficiency, will not be described further in this chapter, as they are rare and/or incompletely defined and have no associated clinical biochemical markers at this time.

Nomenclature

No.	Disorder[a]	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM no.
54.1	Mevalonate kinase deficiency	Mevalonic aciduria	MKD	*MVK*	12q24.1	Mevalonate kinase	610377
54.2	Hyper-IgD syndrome	Mevalonic aciduria	HIDS	*MVK*	12q24.1	Mevalonate kinase	260920
54.3	Squalene synthase deficiency	Farnesyldiphosphate farnesyltransferase 1 deficiency		*FDFT1*	8p23.1	Farnesyldiphosphate farnesyltransferase (squalene synthase)	618156
54.4	Lanosterol synthase deficiency			*LSS*	21q22.3	2,3-Oxidosqualene-lanosterol cyclase (lanosterol synthase)	618275/616509
54.5	Lanosterol 14α-demethylase deficiency	CYP51 deficiency		*CYP51A1*	7q21.2	Lanosterol 14α-demethylase	601637
54.6	Sterol C14-reductase deficiency	Hydrops-ectopic calcification-moth-eaten skeletal dysplasia, Greenberg skeletal dysplasia	HEM dysplasia	*DHCR14*	1q42.12	3β-hydroxysteroid Δ14-reductase	215140
54.7	Sterol C4-methyl oxidase deficiency	SC4MOL deficiency		*MSMO1*	4q32.3	Sterol C4-methyl oxidase	616834
54.8	X-linked dominant sterol 4α-carboxylate 3-dehydrogenase deficiency	Congenital hemidysplasia with ichthyosiform erythroderma and limb defects syndrome	CHILD syndrome	*NSDHL*	Xq28	3β-Hydroxysteroid dehydrogenase	308050
54.9	X-linked recessive sterol 4α-carboxylate 3-dehydrogenase deficiency	CK syndrome		*NSDHL*	Xq28	3β-Hydroxysteroid dehydrogenase	300831
54.10	X-linked dominant sterol Δ8,Δ7-isomerase deficiency	X-linked dominant chondrodysplasia punctata type 2; Conradi-Hünermann-Happle syndrome	CDPX2	*EBP*	Xp11.23	3β-Hydroxysteroid Δ8,Δ7-isomerase	302960
54.11	X-linked recessive sterol Δ8,Δ7-isomerase deficiency	Male EBP disorder with neurologic defects	MEND syndrome	*EBP*	Xp11.23	3β-Hydroxysteroid Δ8,Δ7-isomerase	300960
54.12	Sterol Δ5-desaturase deficiency	Lathosterolosis		*SC5D*	11q23.3	Sterol Δ5-desaturase	607330
54.13	24-Dehydrocholesterol reductase deficiency	Desmosterolosis	DHCR24 deficiency	*DHCR24*	1p32.3	3β-Hydroxysteroid 24 reductase	602398
54.14	7-Dehydrocholesterol reductase deficiency	Smith-Lemli-Opitz syndrome; RSH syndrome	SLOS	*DHCR7*	11q13.4	7-Dehydrocholesterol reductase	270400
54.15	Mevalonate kinase deficiency, Porokeratosis phenotype	Porokeratosis type 3		*MVK*	12q24.1	Mevalonate kinase	175900
54.16	Phosphomevalonate kinase deficiency	Porokeratosis type 1		*PMVK*	1q21.3	Phosphomevalonate kinase	175800
54.17	Mevalonate pyrophosphate decarboxylase deficiency	Porokeratosis type 7		*MVD*	16q24.2	Mevalonate pyrophosphate decarboxylase	614714
54.18	Farnesyl diphosphate synthase deficiency	Porokeratosis type 9		*FDPS*	1q22	Farnesyl diphosphate synthase	616631
54.19	Geranylgeranyl pyrophosphate synthase deficiency	Atypical femoral fractures with bisphosphonates		*GGPS1*	1q42.3	Geranylgeranyl pyrophosphate synthase	606982

[a]Non-metabolic disorders, including those associated with a porokeratosis phenotype (54.15–54.18) and geranylgeranyl pyrophosphate synthase deficiency (54.19), are not described in detail in this chapter

Metabolic Pathway

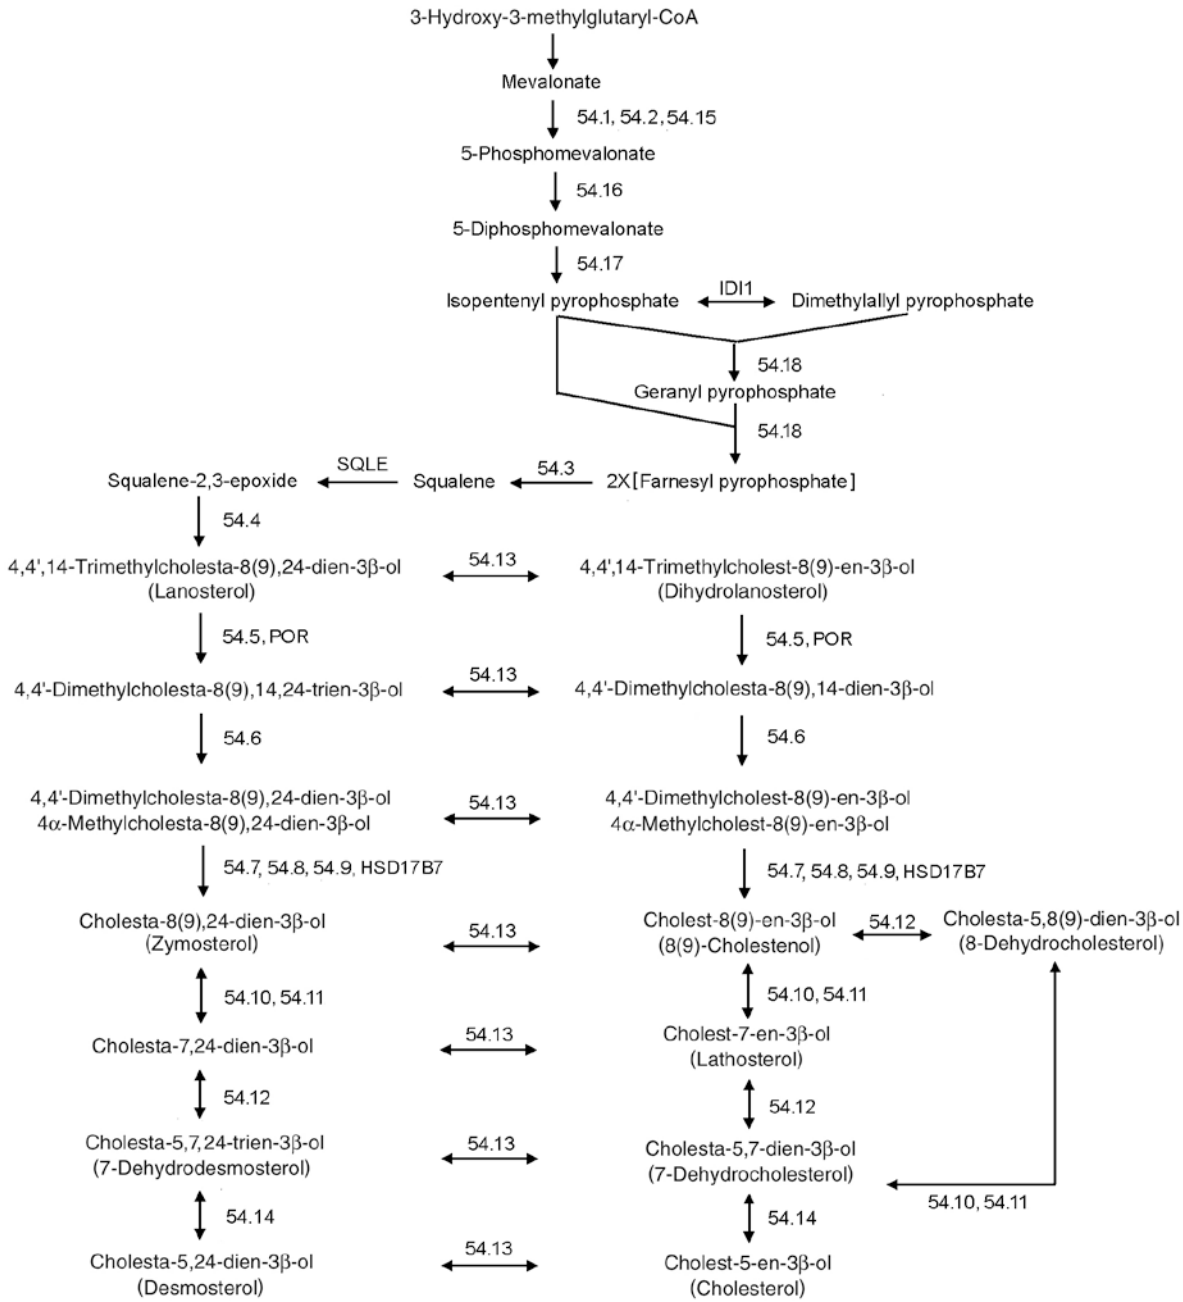

Fig. 54.1 The pathway of cholesterol biosynthesis. Cholesterol biosynthesis begins with the formation of mevalonate from 3-hydroxy-3-methylglutaryl-CoA by 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, the major regulatory enzyme of this pathway. From mevalonate are formed the isoprenoids geranyl pyrophosphate and farnesyl pyrophosphate, which are required for the synthesis of squalene, but which also are essential for isoprenylation of proteins and the synthesis of dolichols and coenzyme Q10. Lanosterol is the first sterol in the pathway and is further metabolized to cholesterol by a series of dehydrogenation, reduction, and demethylation steps. In most tissues, the principal route of cholesterol synthesis is through lathosterol and 7-dehydrocholesterol (Kandutsch-Russell pathway). However, an alternative route through desmosterol (Bloch pathway) appears to be important in neuronal cells, given the relative abundance of desmosterol in these tissues. 54.1, 54.2, 54.15 Mevalonate kinase; 54.16 Phosphomevalonate kinase; 54.17 Mevalonate pyrophosphate decarboxylase; *IDI1* Isopentenyl-diphosphate delta isomerase 1; 54.18 Farnesyl diphosphate synthase; 54.3 Farnesyldiphosphate farnesyltransferase 1 (squalene synthase); *SQLE* Squalene epoxidase; 54.4 Lanosterol synthase; 54.5 Lanosterol 14α-demethylase; *POR* Cytochrome P450 oxidoreductase; 54.6 3β-Hydroxysteroid Δ14-reductase (Sterol C14-reductase); 54.7 Sterol C4-methyl oxidase of the sterol 4α-methyl-4-demethylase complex; 54.8, 54.9 3ß-Hydroxysteroid dehydrogenase of the sterol 4α-methyl-4-demethylase complex; *HSD17B7* Hydroxysteroid 17ß-dehydrogenase 7 (3-keto-steroid reductase) of the sterol 4α-methyl-4-demethylase complex; 54.10, 54.11 3ß-Hydroxysteroid Δ^8,Δ^7-isomerase (sterol Δ^8,Δ^7-isomerase); 54.12 Sterol Δ^5-desaturase (lathosterol desaturase); 54.13 3ß-Hydroxysteroid Δ^{24}-reductase (desmosterol reductase); 54.14 3ß-Hydroxysteroid Δ^7-reductase (7-dehydrocholesterol reductase)

Signs and Symptoms

Table 54.1 Mevalonate kinase deficiency

System	Symptoms and Biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Ataxia		+	+		
	Cerebellar hypoplasia	+	+	++		
	Hypotonia	++	+	+		
	Retardation, psychomotor		++	++		
Digestive	**Hepatosplenomegaly**	++	++	++		
Eye	Cataract	±	±	±		
Hematological	Anemia	±	±	±		
	Leukocytosis	±	±	±		
	Thrombocytopenia	±	±	±		
Musculoskeletal	**Dysmorphic features**	+	+	+		
	Hypotonia, muscular-axial	++	++	++		
Respiratory	Respiratory failure	+	+	+		
Laboratory findings	Cholesterol (serum)	↓-n	↓-n	↓-n		
	C-reactive protein (serum)	n-↑	n-↑	n-↑		
	Creatine kinase (plasma)	n-↑	n-↑	n-↑		
	Immunoglobulin D	n-↑	n-↑	n-↑		
	Leukotriene E4 (plasma)	↑	↑	↑		
	Mevalonic acid (urine)	↑↑↑	↑↑↑	↑↑↑		
	Transaminase (plasma)	n-↑	n-↑	n-↑		
	Ubiquinone-50 (plasma)	↓-n	↓-n	↓-n		

Table 54.2 Hyper-IgD syndrome

System	Symptoms and Biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Digestive	Diarrhea		±	±	±	±
	Hepatosplenomegaly	±	±	±	±	±
	Malabsorption		±	±	±	±
Hematological	**Anemia**	±	+	+	+	±
	Leukocytosis	±	+	+	+	±
	Thrombocytopenia	±	+	+	+	±
Musculoskeletal	Hypotonia, muscular-axial	n	±	±	±	n
Laboratory findings	Cholesterol (serum)	n	n	n	n	n
	Erythrocyte sedimentation rate		n-↑	n-↑	n-↑	n-↑
	Immunoglobulin D		n-↑	n-↑	n-↑	n-↑
	Leukotriene E4 (plasma)	↑	↑	↑	↑	↑
	Mevalonic acid (urine)	↑	↑	↑	↑	↑
	Ubiquinone-50 (plasma)	↓-n	↓-n	↓-n	↓-n	↓-n

By standard GC/MS urine organic acid quantification, urine mevalonic acid often will be below the limit of detection if not collected during the first 3 days of a febrile episode. Measurement by stable isotope dilution, however, will always be abnormal

Specimen Collection

All specimens should be stored frozen at −20 °C.

Disorder	Test	Sample	Pitfalls
54.1 Mevalonate kinase deficiency Please insert a box between 54.21 and 54.3 that contains the following information: Test: Sample: Pitfalls: a	Organic acid analysis	Urine (random)	[a]
54.2 Hyper-IgD syndrome	Mevalonate	Urine (acute specimen preferred)	[a]
54.3 Squalene synthase deficiency	Organic acid analysis Farnesol	Urine (random) Plasma	[a]
54.6 Sterol C14-reductase deficiency (Greenberg dysplasia)	Sterol analysis	Tissue, fibroblasts	[b]
54.8 X-linked dominant sterol 4α-carboxylate 3-dehydrogenase deficiency (CHILD syndrome)	Sterol analysis	Skin flakes, lymphoblasts	[c,d]
54.9 X-linked recessive sterol 4α-carboxylate 3-dehydrogenase deficiency (CK syndrome)	Sterol analysis	Lymphoblasts	[b]
54.10 X-linked dominant sterol Δ8,Δ7 isomerase deficiency (CDPX2) 54.11 X-linked recessive sterol Δ8,Δ7 isomerase deficiency (MEND syndrome)	Sterol analysis	Plasma, tissue, lymphoblasts, fibroblasts	[d]
Autosomal recessive post-squalene inborn errors of cholesterol synthesis: 54.5 Lanosterol 14α-demethylase deficiency 54.7 Sterol C4-methyl oxidase (SC4MOL) deficiency 54.12 Sterol Δ5-desaturase deficiency (Lathosterolosis) 54.13 24-Dehydrocholesterol reductase deficiency (Desmosterolosis) 54.14 7-Dehydrocholesterol reductase deficiency (Smith-Lemli-Opitz syndrome; SLOS)	Sterol analysis	Plasma, tissue, lymphoblasts, fibroblasts	[e,f]

[a]Quantification of mevalonate by stable isotope GC-MS for diagnosis of hyper-IgD syndrome and squalene synthase deficiency is preferred and often essential, because standard organic acid analysis is inadequately sensitive

[b]CK syndrome and Greenberg skeletal dysplasia are best diagnosed by targeted mutation analysis

[c]Sterol abnormality not reliably detectable in plasma

[d]In females, there could be skewed X-inactivation in favor of the normal allele, causing normal sterol levels in plasma or tissues

[e]Plasma sterol levels can be mildly increased secondary to certain medications. Most notable are amiodarone and imatinib, which can increase plasma desmosterol levels, and aripiprazole (Abilify), trazodone, haloperidol, and other "sigma-1" ligand, which can increase plasma 7DHC and 8DHC levels

[f]7-Dehydrocholesterol and 8-dehydrocholesterol are subject to degradation (oxidation) over weeks in plasma at room temperature and more slowly (months) when frozen

Prenatal Diagnosis

Disorder	Material	Timing, trimester
54.1 Mevalonate kinase deficiency	CV, CCV, AF, AFC	I, II
54.10 X-linked dominant sterol-Δ8,Δ7-isomerase deficiency (CDPX2)	CV, AF	II[a]
54.11 X-linked recessive sterol-Δ8,Δ7-isomerase deficiency (MEND syndrome)	AF	II[b]
54.14 7-Dehydrocholesterol reductase deficiency (Smith-Lemli-Opitz syndrome; SLOS)	CV, AF Maternal urine (steroid analysis)	I, II II

Prenatal diagnosis is possible for all disorders by DNA sequencing

CV direct chorionic villi, *CCV* cultured chorionic villi, *AF* amniotic fluid, *AFC* amniocytes

[a]Experience by biochemical prenatal testing limited to four female fetuses with ultrasound anomalies consistent with CDPX2

[b]Experience by biochemical prenatal testing limited to one male fetus originally evaluated for SLOS

DNA Testing

Molecular testing can be performed for all disorders of cholesterol biosynthesis by direct sequencing and del/dup analysis of DNA isolated from blood or tissue. In addition, some genes may be included on gene panels designed for a specific phenotypic feature, e.g., *CYP51A1* is often included on cataract gene panels.

Treatment

There is no required emergent metabolic management for disorders of cholesterol biosynthesis, but serious or life-threatening physical anomalies requiring acute medical or surgical intervention are common. For SLOS, cholesterol supplementation has become standard of care, and studies of selected patients with SLOS have also shown amelioration of the metabolic abnormalities with simvastatin treatment (Jira et al. 2000). In addition, when there is an acute life-threatening condition, such as pneumonia or major surgery, and oral cholesterol replacement therapy is not possible, intravenous banked plasma ("fresh-frozen" plasma) can be a valuable parenteral source of cholesterol. Steroid therapy might be required for severely affected patients during periods of stress, usually those with a cholesterol level less than 0.5 mM, because of possible glucocorticoid and/or mineralocorticoid deficiency. Treatment schemes for non-SLOS sterol disorders are limited due, in part, to the rarity of these disorders. Cholesterol supplementation in conjunction with statin therapy has caused improved growth and development in one patient with SC4MOL deficiency, and simvastatin has proved effective in the treatment of squalene synthase deficiency (R. Kelley, unpublished).

For the treatment of periodic severe inflammatory crises, which, among disorders of sterol synthesis, are unique to MKD, especially the HIDS variant, treatment of severe, acute crises with glucocorticoids ("pulse steroids) works rapidly, but overly frequent use of steroids should, of course, be avoided. However, other, often effective, immunosuppressants designed to block cytokines or otherwise blunt the inflammatory response include leukotriene receptors antagonists (e.g., montelukast, zafirlukast), anti-TNF medication (e.g., etanercept), and IL-1 inhibitors (e.g., anakinra), among several others (van der Hilst et al. 2008). Because chronic treatment with these drugs is required, sustained use of these medications risks medically significant immunosuppression, with the exception of the usually mild immunosuppressive effect of montelukast and zafirlukast.

Disorders of Adrenals and Gonads

55

Anna Biason-Lauber

Contents

Summary

Defects in steroid biosynthesis in adrenals and gonads lead to complex and profound clinical consequences that can be grouped in three categories: (1) defects of saltwater homeostasis and sexual development (DSD), (2) defects of saltwater homeostasis, (3) defects of sexual development, and (4) end-organ steroid hormone resistance. Among the members of the first group, lipoid adrenal hyperplasia is characterized by lack of all steroid hormones, with consequent 46, XY DSD and salt loss in the first weeks of life. 17α-Hydroxylase deficiency leads also to 46, XY DSD associated with hypertension and hypokalemia. 3β-Hydroxysteroid dehydrogenase deficiency causes incomplete virilization in male fetuses, together with salt loss. 21-Hydroxylase deficiency, whose nonclassic form is one of the most common autosomal recessive diseases in humans, is responsible for female ambiguous genitalia at birth and salt loss. 11β-Hydroxylase deficiency differs from 21-hydroxylase deficiency for the absence of salt wasting and later presence of hypertension and hypokalemia. Defects of P450 oxidoreductase, a cofactor common to 21-hydroxylase, 17α-hydroxylase, and aromatase, lead to a complex combined defect of all three enzymes.

Enzymatic defects of the second group cause either salt wasting symptoms in the neonatal period, spontaneously resolving in adulthood, as in the case of corticosterone methyl oxidase II deficiency, or hypertension and hypokalemia as in the cases of glucocorticoid-suppressible hyperaldosteronism and apparent mineralocorticoid excess. The third group of defects includes enzymatic blocks of the last steps of sex hormone biosynthesis. 17,20-Lyase, 17β-hydroxysteroid dehydrogenase, 5α-reductase, and aldo-keto reductase deficiencies determine incomplete virilization of the male fetus. In 17,20-lyase deficiency, there is no spontaneous puberty in males and females; in the lat-

ter, two male puberty occurs. Aromatase deficiency is a cause of nonadrenal 46, XX DSD.

The end-organ resistance syndromes, which are still an exclusion diagnosis, represent a further challenge for future diagnostic and therapeutic applications. The treatment of these defects is based on exogenous administration of the deficient hormones and corrective surgery in intersexuality. Given the rarity of most of these diseases, prenatal diagnosis is possible only in a family at risk. In the case of 21-hydroxylase deficiency, however, advances in prenatal diagnosis allowed in utero treatment. Progress in molecular analysis of steroid biosynthesis and action defects will allow a better prenatal diagnosis and treatment of such diseases.

Introduction

The biosynthesis of steroid hormones is a fascinating process in which the neutral lipid cholesterol, a normal constituent of lipid bilayers, is transformed via a series of hydroxylation, oxidation, and reduction steps into a vast array of biologically active compounds: mineralocorticoids, glucocorticoids, and sex hormones. The majority of these transformations occur in the adrenal, testis, and ovary, although other tissues, such as the liver, kidney, placenta, brain, and skin, are also quite active.

Steroid hormone action is a complex process that is only recently beginning to be understood. Steroid hormones bind to specific intracellular receptors, which upon dimerization interact with the DNA in the nucleus. As a result, gene activity is modulated and a hormone-specific response occurs (Evans 1988). It is logical that abnormalities in any step of this cascade will interfere with the action of a particular hormone. Defects in the receptor or the post-receptor machinery will lead for the most part to abnormalities of action of one specific hormone. Abnormalities of steroid hormone production, however, can result in more profound and complex effects. A block in the pathway of steroid biosynthesis leads to the lack of hormones downstream and accumulation of the upstream compounds that can activate other members of the steroid receptor family. The consequences of such defects can be schematically categorized in three groups: (1) defects leading to abnormalities of sexual differentiation and saltwater balance, (2) defects leading to abnormalities of saltwater balance, and (3) defects leading to abnormalities of sexual differentiation. Abnormalities of end-organ action of steroid hormones, exemplified by the hormone insensitivity syndromes, can be grouped in a fourth category.

The first group of steroid biosynthesis defects include the so-called congenital adrenal hyperplasia (CAH), a collective name given to a group of disorders characterized by inherited inability of the adrenals to secrete cortisol. The consequent compensatory rise of ACTH production causes hyperplastic growth of the adrenal glands. Blocks of the initial steps of the steroidogenic pathway impair the production of all the three types of steroids, causing abnormalities in the saltwater homeostasis and in sexual differentiation. That is the case in *lipoid adrenal hyperplasia*, where no conversion of cholesterol to any steroid takes place. This rare cause of CAH is characterized by salt loss and male pseudohermaphroditism in XY individuals. In XX subjects, internal and external genitalia are female, and the syndrome cannot clinically be separated from congenital adrenal hypoplasia (Prader and Gurtner 1955). The molecular bases of such a defect have been recently clarified as mutations in the steroidogenic acute response protein (StAR) (Lin et al. 1995). *17α-Hydroxylase deficiency* leads to male pseudohermaphroditism, due to the lack of precursors for testosterone. In XX individuals, there is primary amenorrhea and absent development of estrogenic secondary sexual characteristics. Both sexes display hypertension and hypokalemic alkalosis due to accumulation of mineralocorticoid precursors, which do not need 17α-hydroxylation for their synthesis (Biglieri et al. 1966). Adrenal hyperplasia and glucocorticoid deficiency are less marked than in the other types of CAH, because of the ability of corticosterone of suppressing ACTH. Male patients affected by CAH due to *3β-hydroxysteroid dehydrogenase* deficiency display incomplete prenatal masculinization due to the impaired synthesis of bioactive androgens and salt loss due to lack of mineralocorticoid (Bongiovanni 1962). XX subjects have normal female external genitalia or mild virilization due to the action of the weak androgen DHEA. *21-Hydroxylase deficiency* accounts for most cases of CAH (80–90%, depending on the ethnic group). Clinical consequences of 21-hydroxylase deficiency arise from overproduction of androgens. Affected females with the *classical* 21-hydroxylase deficiency are born with ambiguous genitalia. Postnatally, untreated patients of both sexes manifest rapid somatic growth with accelerated skeletal maturation, early closure of the epiphyses, and short adult stature. Other symptoms include excessive pubic and body hair and decreased fertility. Seventy-five per cent of patients with classic 21-hydroxylase deficiency also have reduced synthesis of aldosterone with salt loss. Patients with *nonclassical* disease are born without symptoms of prenatal androgen exposure. Subsequently, they may remain asymptomatic or may develop signs of androgen excess. Deficiency of 21-hydroxylase is inherited as an autosomal recessive trait, closely linked to the HLA major histocompatibility complex on the short arm of chromosome 6. While classic 21-hydroxylase deficiency is found in about 1 in 14.000 births, nonclassical deficiency is far more frequent, occurring in up to 3% of persons amongst certain ethnic groups (New et al. 1989). Steroid *11β-hydroxylase deficiency*, which is responsible for 10–20% of cases of CAH, produces symptoms of androgen excess similar to those in 21-hydroxylase deficiency. The blocked enzymatic step also results in accumulation of 11-deoxycorticosterone which has

mineralocorticoid activity, leading in untreated patients to hypertension (New et al. 1989).

The second group of diseases includes rare defects in the final step in the biosynthesis of mineralocorticoid and glucocorticoid that lead to water-sodium disequilibrium. Adrenal *corticosterone methyl oxidase II deficiency* impairs the synthesis of aldosterone with consequent salt loss in the neonatal period. Some patients, however, become completely asymptomatic later in life. *Glucocorticoid-suppressible hyperaldosteronism* is an autosomal dominant disease characterized by mineralocorticoid hypertension due to an abnormal stimulatory action of ACTH on aldosterone synthesis. This is due to unequal crossing over between the *zona glomerulosa* 11β-hydroxylase (angiotensin II regulated) and the *zona fasciculata* 11β-hydroxylase (ACTH regulated) genes (White and Pascoe 1992). Defects in the inactivation of cortisol, such as *11* β-hy*droxysteroid dehydrogenase type II deficiency*, can lead to hypertension with hypokalemia in the absence of elevated levels of mineralocorticoids. The mechanism underlying such phenomenon is the prolonged half-life of cortisol that binds to the relatively unselective mineralocorticoid receptor in the kidney and acts like a mineralocorticoid, causing the so-called apparent mineralocorticoid excess syndrome (New 1994). The disorder in which cortisone is overproduced is called *cortisone reductase deficiency* (CRD). CRD (previously known as apparent cortisone reductase deficiency, AERD) is a disorder in which there is a failure to regenerate the active glucocorticoid cortisol (F) from cortisone (E) via the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD1), encoded by the *HSD11B1* gene. This disease is caused by an increased metabolic rate for cortisol at the expense of ACTH-mediated androgen excess, without any clinical symptoms of hypercortisolism (Biason-Lauber et al. 2000). The cortisol-regenerating reductase activity of 11β-HSD1 is critically dependent upon the provision of reduced nicotinamide adenine dinucleotide phosphate (NADPH) in the endoplasmic reticulum lumen and is provided by the enzyme hexose-6-phosphate dehydrogenase (H6PDH, encoded by the *H6PD* gene). CRD has been shown to demonstrate a triallelic digenic pattern of inheritance involving mutations in the *HSD11B1* and *H6PD* genes (Draper et al. 2003).

The third group is characterized by deficiencies of enzymes responsible for the final steps of sex hormone synthesis, such as *17,20-lyase, 17 β-hydroxysteroid dehydrogenase* (17β-HSD), *5α-reductase, and aromatase*. Deficient activity of 17,20-lyase, 17β-HSD, and 5α-reductase enzymes leads to male pseudohermaphroditism with varying genital ambiguity in XY individuals. In XX individual, the genitalia are generally normal. In 17,20-lyase (or 17,20-desmolase) deficiency, there is no male or female pubertal development. Cortisol is normal, and there is no hypertension. The deficient enzyme is the same as in 17α-hydroxylase deficiency, and it is unknown why the defect manifests itself as 17α-hydroxylase in some and as 17,20-lyase deficiency in other families. Possibly, estrogen replacement induces a conversion to 17α-hydroxylase deficiency (Zachmann et al. 1982). In 17β-HSD deficiency, there is some male pubertal development in XY individuals due to androstenedione and often gynecomastia due to estrone. In XX individuals, there is mild virilization and insufficient development of estrogenic sexual characteristics. In 5α-reductase deficiency, male puberty is present in XY subjects because testosterone is sufficient, and dihydrotestosterone (DHT) is not necessary for expression of male sexual secondary characteristics. In XX individuals, there are no symptoms. Interestingly, at the time of expected puberty, the patients affected by these deficiencies display some degree of virilization. Particularly high is the incidence of 5α-reductase deficiency in the Dominican Republic (Imperato-McGinley et al. 1986). Patients of both sexes affected by *aromatase deficiency* show a delayed somatic development and slower skeletal maturation, with consequent tall adult stature. Female patients affected by aromatase deficiency display various degrees of genital ambiguity, due to the lack of prenatal exposure to estrogens, and signs of hyperandrogenism, such as acne (Conte et al. 1994).

In the fourth class are grouped defects in the action of steroid hormones due to receptor defects. Androgens exert their effects in mediating the development of normal male phenotype via a single receptor protein, the androgen receptor (AR), which is encoded on the X chromosome. Abnormalities that alter the function of this receptor result in a range of abnormalities of male phenotypic development, called *complete and partial androgen insensitivity syndrome* (CAIS and PAIS, respectively). These phenotypes range from normal female (female habitus, normal female breast development, absent pubic and axillary hair, female external genitalia, no internal genital organs, and undescended testes) to those that are characterized by only minor degrees of undervirilization and/or infertility (McPhaul and Griffin 1999).

In patients, loss-of-function mutations in estrogen receptor alpha (or estrogen receptor 1, ESR1) cause *estrogen resistance 1* characterized by osteoporosis, delayed bone age and continuous growth in adulthood, high estrogen levels in both sexes, delayed puberty with no breast development, infantile uteri, primary amenorrhea, and multiple ovarian cysts in women (Smith et al. 1994; Bernard et al. 2017; Quaynor et al. 2013). In addition, the first male patient displayed insulin resistance and glucose intolerance. Genetic abnormalities in the estrogen receptor beta (ESR2, *estrogen resistance 2*) have been reported in genetically male patients (46, XY) with differences of sex development and gonadal dysgenesis, demonstrating an unexpected role for ESR2 in testis formation (Baetens et al. 2018). More recently, we described a female patient (46, XX) with lack of breast development, infantile uterus, primary amenorrhea, and severe osteoporosis but normal bone age and complete primary early-onset ovarian failure (Lang-Muritano et al.

2018). This case suggested that ESR2 is necessary for early human ovarian development and/or maintenance and that ESR1 is not sufficient to support gonadal function.

Although rare, the estrogen resistance was of crucial importance for the understanding of skeletal physiology, since it demonstrated that estrogen is important for bone maturation and mineralization in men as well as in women.

Progesterone prepares the endometrium for blastocyst implantation and allows maintenance of pregnancy. Complete end-organ resistance to progesterone would be incompatible with reproductive competence in females. Males would not be expected to be affected since progesterone has no known function in men. Failure of the uterus to respond to progesterone would lead to the development of a "constantly proliferative" endometrium incompatible with blastocyst implantation. *Partial resistance to progesterone*, on the other hand, would be expected to be associated with various degrees of incomplete maturation of the endometrium, expressed clinically as infertility or early abortions. The syndrome presents with the clinical and histologic picture of a luteal phase defect in which the life span of the corpus luteum and the plasma progesterone concentrations are normal or slightly elevated (Chrousos et al. 1986).

Glucocorticoid resistance is characterized by high levels of cortisol (without stigmata of Cushing syndrome), resistance of the hypothalamic-pituitary-adrenal axis to dexamethasone, and an affinity defect of the glucocorticoid receptor. Some of the affected patients presented with hypertension and hypokalemia due to pathological activation of the mineralocorticoid receptor by cortisol (Lipsett et al. 1986).

Pseudohypoaldosteronism (type I) is characterized by salt wasting in infancy that is responsive to supplementary sodium but not to mineralocorticoids. Marked aldosterone excess is present in all reported cases and the renin level is increased in most. Salt supplementation often can be discontinued after infancy without adverse effects, even though aldosterone excess is persistent. Sweat and salivary glands and colonic mucosa are unresponsive to mineralocorticoids as is the distal renal tubule. The basic defect in this disease resides in the mineralocorticoid receptor NR3C2 (Geller et al. 1998).

More recently, two new defects in steroid synthesis were identified. An intriguing case is that of *P450 oxidoreductase* (POR) *deficiency*. Cytochrome P450 oxidoreductase is a flavoprotein that donates electrons to all microsomal P450 enzymes, including the steroidogenic enzymes P450c17, P450c21, and CYP51A1 (Miller 1986). In 1985, a clinical report described a patient with genital ambiguity and an abnormal urinary steroid profile suggesting partial combined deficiencies of what was then thought to be three distinct steroidogenic enzymes: 17α-hydroxylase, 17,20-lyase, and 21-hydroxylase (Peterson et al. 1985). Affected girls are born with ambiguous genitalia, indicating intrauterine androgen excess. After birth, however, virilization does not progress, and amounts of circulating androgens are low or normal. Conversely, affected boys are sometimes born undermasculinized. The majority but not all of patients described to date with POR deficiency also had a pattern of skeletal malformations termed Antley-Bixler syndrome (ABS). This disorder is characterized by craniosynostosis (premature fusion of bones of the skull), radio-ulnar or radio-humeral synostosis, bowed femora, and other more variable skeletal disorders (Antley and Bixler 1975; Crisponi et al. 1997). Findings of biochemical investigations of urinary steroid excretion in affected patients have shown accumulation of steroid metabolites, indicating impaired C17 and C21 hydroxylation, suggesting concurrent partial deficiencies of the two steroidogenic enzymes, P450C17 and P450C21. As these steroidogenic enzyme activities were known to be catalyzed by type II cytochrome P450 enzymes, it was suggested that this patient had a disorder in the electron donor for these enzymes, P450 oxidoreductase (Miller 1986). This fascinating idea remained dormant until Fluck first reported four cases of POR deficiency (Fluck et al. 2004). Since that time, about 50 additional patients have been reported (for review, see (Fluck et al. 2008; Scott and Miller 2008).

The other defect concerns the so-called backdoor pathway of fetal androgen synthesis. Following development of the fetal bipotential gonad into a testis, male genital differentiation requires testicular androgens. Fetal Leydig cells produce testosterone that is converted to dihydrotestosterone in genital skin, resulting in labioscrotal fusion. An alternative "backdoor" pathway of dihydrotestosterone synthesis that bypasses testosterone has been described in marsupials, but its relevance to human biology has been uncertain. The classic and backdoor pathways share many enzymes, but a 3α-reductase, AKR1C2, is unique to the backdoor pathway (Fig. 55.1). Human *AKR1C2* mutations cause disordered sexual differentiation, establishing that both pathways are required for normal human male genital development. These observations show that fetal dihydrotestosterone acts both as hormonally and as a paracrine factor, substantially revising the classic paradigm for fetal male sexual development (Fluck et al. 2011).

Defects of the ACTH receptor (M2CR) or of its accessory proteins MRAPs cause *familial glucocorticoid deficiency*. Most of these mutations lead to the production of a MRAP protein that cannot interact with the ACTH receptor and so is unable to transport it out of the ER to the cell membrane. As a result, the ACTH receptor is not at the cell surface where it is needed to bind to ACTH. Without the binding of the ACTH receptor to its hormone, there is no signal to trigger the adrenal glands to produce glucocorticoids. This condition is characterized by potentially life-threatening low blood sugar (hypoglycemia), recurrent infections, and skin coloring darker than that of other family members (hyperpigmentation) (reviewed in Novoselova et al. 2018). These last two conditions will not be discussed in details.

Reference Values

Important note: Steroid hormone reference values vary enormously depending on the assay and the clinical chemistry laboratory. Therefore, the following values must be considered an example and not used for everyday clinical practice. In the case of the semiquantitative urinary steroid profile using gas chromatography-mass spectrometry (GC-MS), the interpretation of the results is even more complex and should be made by an expert in such assay. For these reasons, only the diagnostic ratios are mentioned in this chapter.

For more information, see also (Wudy and Homoki 2003).

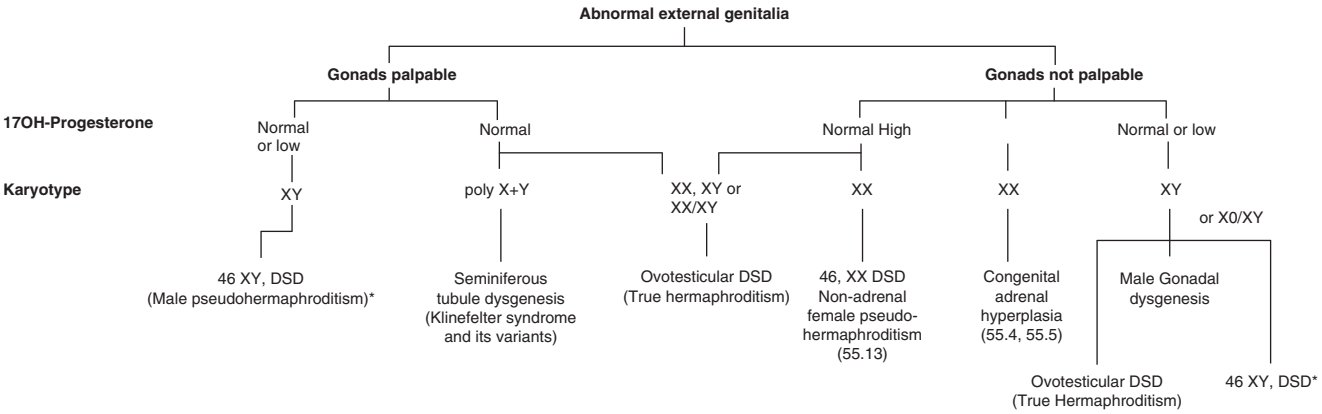
Diagnostic Flow Chart

Diagnosis of Disorders of Sex Development (DSD) and Intersexuality.

1. History: family history, pregnancy (hormones, virilization).
   Palpation of inguinal region and labioscrotal folds: rectal examination, karyotype.
   Initial studies: plasma 17OH-progesterone, DHEA, androstenedione, testosterone, DHT, and estradiol.
   Serum electrolytes.
   Sonogram of kidneys, ureters, and pelvic content.
2. Provisional diagnosis: "abnormal external genitalia" → proceed as in the following figure.



Specimen Collection

Test	Preconditions	Material	Handling	Pitfalls
Plasma or serum quantitative steroids, ACTH, and gonadotropins	None	Frozen plasma or serum	Keep frozen (−20°C) until analyzed	None, except laboratory error
Urine for gas chromatography-mass spectrometry analysis of urinary metabolites	None	Fresh or frozen 24-h urine (discard the morning urine of the first day but collect the morning urine of the second and final day)	Keep frozen (−20 °C) until analyzed	None, except laboratory error

Prenatal Diagnosis

Disorder	Material	Timing, trimester
All disorders (except 55.9 and 55.15–18 that are adult-onset diseases)	CV, AF	I, II

Treatment

The therapeutic management in disorders of steroid synthesis and action can be distinguished in two phases:

1. Management of life-threatening situations (adrenal crisis): emergency.
2. Management of lifelong consequences: no emergency.

Whereas the therapeutic intervention in phase 1 is straightforward, those for phase 2 are complex and different from case to case. It is therefore mandatory to create a multidisciplinary team of experts especially when the patient has a DSD, and not try to manage these complex cases alone.

Phase 1–Initial Treatment

Disorders 55.1, 55.2, 55.5, 55.7, 55.21 (salt-losing forms)

1. Parenteral isotonic saline.
2. Hydrocortisone (cortisol).

Note: salt-loss symptoms do not appear before 6–10 days after birth.

Disorders 55.3, 55.6, 55.8, 55.9 (hypertensive, hypokalemic forms).

1. Restoration of potassium concentrations.
2. Diuretic therapy to reduce blood pressure.

Phase 2: Disorders 55.1–6, 55.11–16, 55.22 (DSD)

1. Sex assignment.
2. Reconstructive genital surgery.

After the adrenal emergency has been managed, the type and timing of genital surgery and the correspondent sex assignment,

necessity, and timing of gonadectomy should be discussed case by case in a multidisciplinary team of experts in DSD.

Emergency Treatment

All the salt-losing forms (55.1, 55.2, 55.5, 55.7, 55.21) are prone to adrenal crisis in stress situations. Therefore:

Initial hydrocortisone i.v.	Infants and preschool children: 25 mg
	School-age children: 50 mg
	Adults: 100 mg

Successive i.v. hydrocortisone doses 3–4x the maintenance dose/day, divided in four doses (every 6 h).

Standard Treatment

Disorders 55.1, 55.2, 55.5, 55.7, 55.21.

Type of glucocorticoid	Suggested dose (mg/d)	Daily doses
Hydrocortisone (HC)	15–25	2–3
Prednisone	5–7.5	2
Prednisolone	4–6	2
Dexamethasone	0.25–0.5	1
Fludrocortisone (mineralocorticoid)	0.05–0.2	1

Patients affected by the salt-losing forms of steroid synthesis defects should be informed of the necessity of an emergency treatment (55.15).

Disorders: 55.3, 55.6, 55.8, 55.9 (hypertensive, hypokalemic).

DSD (55.3, 55.6, 55.8, 55.9): Induction of puberty according to sex assignment.

Disorders of Bile Acid Synthesis

56

Frédéric M. Vaz, David Cassiman,
and Sacha Ferdinandusse

Contents

Abstract

Bile acid synthesis defects often result in a deficiency of the primary bile acids—cholic acid and chenodeoxycholic acid—that are needed for absorption of fats and fat-soluble vitamins. Fat malabsorption leads to steatorrhea and growth retardation, and the fat-soluble vitamin deficiency can lead to coagulation defects and rickets. As bile acids are needed for bile flow, their deficiency can cause cholestasis, jaundice, and liver disease. In addition to the bile acid deficiency, accumulation of bile acid intermediates or their derivatives can cause other symptoms including progressive neurological disease. Bile acid synthesis defects can present from the neonatal period to adulthood. When a bile acid synthesis defect is suspected, bile acid analysis by tandem mass spectrometry in plasma and urine should be performed. As most bile acid synthesis defects have a characteristic bile acid profile, bile acid analysis can readily identify the underlying disorder, but for some disorders genetic analysis is required. Besides supplementation of the fat-soluble vitamins, bile acid replacement therapy can be beneficial in most of the bile acid synthesis disorders. This not only restores the bile acid pool but also strongly reduces the production of toxic bile acid intermediates by feedback inhibition of the bile acid synthesis pathway.

Introduction

Bile acids are well-known for their role in the absorption of fats and fat-soluble vitamins, but are also important for the maintenance of cholesterol homeostasis, excretion of toxic

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_56

substances, induction of bile flow and as signaling molecules that influence glucose homeostasis, lipid metabolism, and energy expenditure (Halilbasic et al. 2013; Russell 2009). The primary bile salts produced in man are the taurine and glycine conjugates of cholic acid (CA) and chenodeoxycholic acid (CDCA). They are synthesized in the liver from cholesterol via numerous modifications of the steroid nucleus and the aliphatic side chain. After synthesis, the (activated = coenzyme A (CoA) esters of the) bile acids (CA-CoA and CDCA-CoA) are converted into bile salts (glycine or taurine conjugates) via a process called amidation. The bile salts are excreted together with other bile components into the canaliculi, and the resulting bile is transported to and stored in the gallbladder. After a meal, the bile is secreted into the duodenum to facilitate fat and fat-soluble vitamin absorption. Gut bacteria modify and/or deconjugate part of the bile salts resulting in secondary bile acids (deoxycholic acid, lithocholic acid, ursodeoxycholic acid (UDCA), hyodeoxycholic acid, and hyocholic acid). Ninety-five percent of the bile acids/salts are recycled in the enterohepatic circulation. The fecal loss is compensated by hepatic bile acid synthesis, thereby maintaining bile acid homeostasis (Heubi et al. 2018).

Many enzymes located in different subcellular compartments including the cytosol, endoplasmic reticulum, mitochondria, and peroxisomes are involved in bile acid biosynthesis (see Figs. 56.1 and 56.2). Bile acid synthesis can roughly be divided into three processes: (1) modifications to the steroid nucleus, (2) modifications to the aliphatic side chain, and (3) amidation. Four main biosynthetic pathways have been delineated, of which the two most commonly described will be briefly discussed: the classic or neutral pathway and the alternative or acidic pathway. The majority of the enzymes are shared between these pathways with the exception of the enzymes involved in 7α-hydroxylation (cholesterol 7α-hydroxylase in the classic pathway and oxysterol-7α-hydroxylase in the acidic pathway) and 12α-hydroxylation, but the order of steps differs. In this respect, it is important to keep in mind that several intermediates are substrates for more than one biosynthetic enzyme. The neutral pathway is considered the most significant in adults, whereas the acidic pathway seems to play a more prominent role early in life. In the classic pathway, which starts with the hydroxylation of cholesterol to 7α-hydroxycholesterol by sterol 7α-hydroxylase (CYP7A1), modifications of the steroid ring structure precede the oxidative chain shortening of the side chain. In the acidic pathway, sterol 27-hydroxylase (CYP27A1) first generates a C27-carboxylic acid, followed by modifications of the steroid nucleus and shortening of the side chain (Fig. 56.1). The side-chain shortening occurs in the peroxisome via β-oxidation and converts C27-bile acid intermediates (cholestanoids) into C24-bile acids (cholanoids). Amidation of the newly synthesized bile acids also occurs in the peroxisome, but amidation of recycled bile acids occurs via cytosolic bile acid-CoA: amino acid *N*-acyltransferase (BAAT), which has a dual localization (Fig. 56.2) (Vaz and Ferdinandusse 2017).

A defect in bile acid biosynthesis results, in most disorders, in a deficiency of the primary bile acids. Because bile acids are crucial for the absorption of fats and fat-soluble vitamins, the characteristic clinical symptoms of a bile acid deficiency are fat malabsorption, leading to steatorrhea and growth retardation and deficiency of fat-soluble vitamins and their sequelae (e.g., coagulation defects and rickets). As bile acids drive bile flow, patients generally present with a failure of bile flow (cholestasis) and a conjugated hyperbilirubinemia (jaundice), but γ-glutamyl transpeptidase (γGT) is characteristically normal as opposed to other causes of cholestasis. Especially in the disorders where transformation of the steroid nucleus is affected (disorders 56.1–56.4), abnormal metabolites are produced which are not proper substrates for excretion into bile and generation of bile flow. Cholesterol 7α-hydroxylase deficiency (56.1) is a notable exception since it does not result in overt bile acid deficiency as the alternative pathway can still produce bile acids via oxysterol 7α-hydroxylase and patients present with statin-resistant hyperlipidemia and gallstones later in life (Pullinger et al. 2002). Oxysterol 7α-hydroxylase deficiency (56.4) not only has been identified in patients with severe neonatal liver disease but also in children or adults with a progressive spastic paraplegia (type SPG5A).

In addition to the bile acid deficiency in the different bile acid biosynthesis defects, there is accumulation of disease-specific bile acid intermediates that can contribute to the clinical presentation. In cerebrotendinous xanthomatosis (CTX), the classic presentation is neonatal cholestasis and intractable diarrhea that is attributed to bile acid deficiency. The progressive deposition of cholestanol and cholesterol, however, can lead to the formation of cataracts, intellectual disability, and developmental delay in the first decade and to tendon xanthomas, premature atherosclerosis, cognitive decline, and motor dysfunction in later life. Especially in disorders that affect the modification of the cholesterol side chain (disorders 56.5–56.8), clinical symptoms appear to be mainly caused by the accumulation of intermediates proximal to the metabolic block. The bile acid deficiency appears to be less important because in these defects, cholestanoids (C27-bile acids) are formed that, to some extent, can still drive bile flow. In peroxisomal disorders, also other metabolic pathways may be affected causing accumulation of different metabolites that may contribute to the clinical presentation. For example, in α-methylacyl-CoA racemase (AMACR) deficiency, not only C27-bile acid intermediates accumulate but also pristanic acid, which causes neurological disease, especially later in life. Still, AMACR deficiency in childhood can present with the bile acid deficiency phenotype characterized by neonatal cholestasis and mild to severe liver

disease in addition to fat-soluble vitamin malabsorption and is for that reason discussed in this chapter. Disorders of peroxisome biogenesis (Zellweger spectrum disorders) and defects of peroxisomal β-oxidation (such as D-bifunctional protein deficiency) also affect bile acid synthesis but are considered elsewhere since they clinically do not present as a bile acid deficiency [Ref Chapter Ron Wanders].

In the defects of bile acid amidation (disorders 56.9 and 56.10), 85–95% of the bile acids are unconjugated. They are substrate for active transport into bile and drive bile flow but do not function properly as detergent leading to fat malabsorption and a deficiency of fat-soluble vitamins. In BAAT deficiency, this results in steatorrhea, coagulopathy, rickets, and jaundice, i.e., a classic bile acid deficiency phenotype. The clinical presentation of bile acid-CoA ligase (BACS) deficiency is not entirely clear yet since the only symptomatic patient described also was homozygous for a mutation in the gene encoding the bile salt export pump (BSEP) (Chong et al. 2012).

Overall, most disorders of bile acid biosynthesis present with cholestatic liver disease early in life, but can also cause neurological symptoms (neuropathy, spastic paraplegia, cognitive decline, movement disorder) in juvenile or adult patients. When a bile acid synthesis disorder is considered, both plasma and urine bile acid analysis should be performed. Currently, electrospray ionization-mass spectrometry (ESI-MS) with prior liquid chromatography (LC) separation is the method of choice for analyzing a cholanoid profile (Vaz and Ferdinandusse 2017).

Nomenclature

Disease number	Disease name	Alternative disease name 1	Alternative disease name 2	Disease abbreviation	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	Disease OMIM#
56.1	Cholesterol 7α-hydroxylase deficiency			CYP7A1	*CYP7A1*	8q12.1	AR	Cholesterol 7α-hydroxylase	118455
56.2	3β-Hydroxy-Δ5-C27-steroid oxidoreductase deficiency	Congenital bile acid synthesis defect type 1		CBAS1	*HSD3B7*	16p11.2	AR	3β-Hydroxy-Δ5-C27-steroid dehydrogenase	607764
56.3	Δ4–3-Oxosteroid-5β-reductase deficiency	Congenital bile acid synthesis defect type 2		CBAS2	*AKR1D1*	7q33	AR	Δ4–3-Oxosteroid-5β-reductase	604741
56.4	Oxysterol 7α-hydroxylase deficiency	Congenital bile acid synthesis defect type 3	Spastic Paraplegia 5A	CBAS3	*CYP7B1*	8q12.3	AR	Oxysterol 7α-hydroxylase	603711
56.5	Sterol 27-hydroxylase deficiency	Cerebrotendinous xanthomatosis	Cerebral cholesterinosis	CTX	*CYP27A1*	2q35	AR	Sterol 27-hydroxylase	213700
56.6	PMP70/ACBD3 deficiency	Congenital bile acid synthesis defect type 5		CBAS5	*ABCD3*	1p21.3	AR	ATP-binding cassette protein, subfamily D, member 3	616278
56.7	α-Methylacyl-CoA racemase deficiency	Congenital bile acid synthesis defect type 4		CBAS4	*AMACR*	5q13.2	AR	α-Methylacyl-CoA racemase	604489
56.8	Peroxisomal acyl-CoA oxidase 2 deficiency	Congenital bile acid synthesis defect type 6		CBAS6	*ACOX2*	3p14.3	AR	Peroxisomal acyl-CoA oxidase 2	617308
56.9	Bile acid-CoA:amino acid N-acyltransferase deficiency	Familial hypercholanemia		FHCA	*BAAT*	9q31.1	AR	Bile acid-CoA:amino acid N-acyltransferase	602938
56.10	Bile acid-CoA ligase deficiency			SLC27A5	*SLC27A5*	19q13.43	AR	Bile acid-CoA ligase	603314

Metabolic Pathways

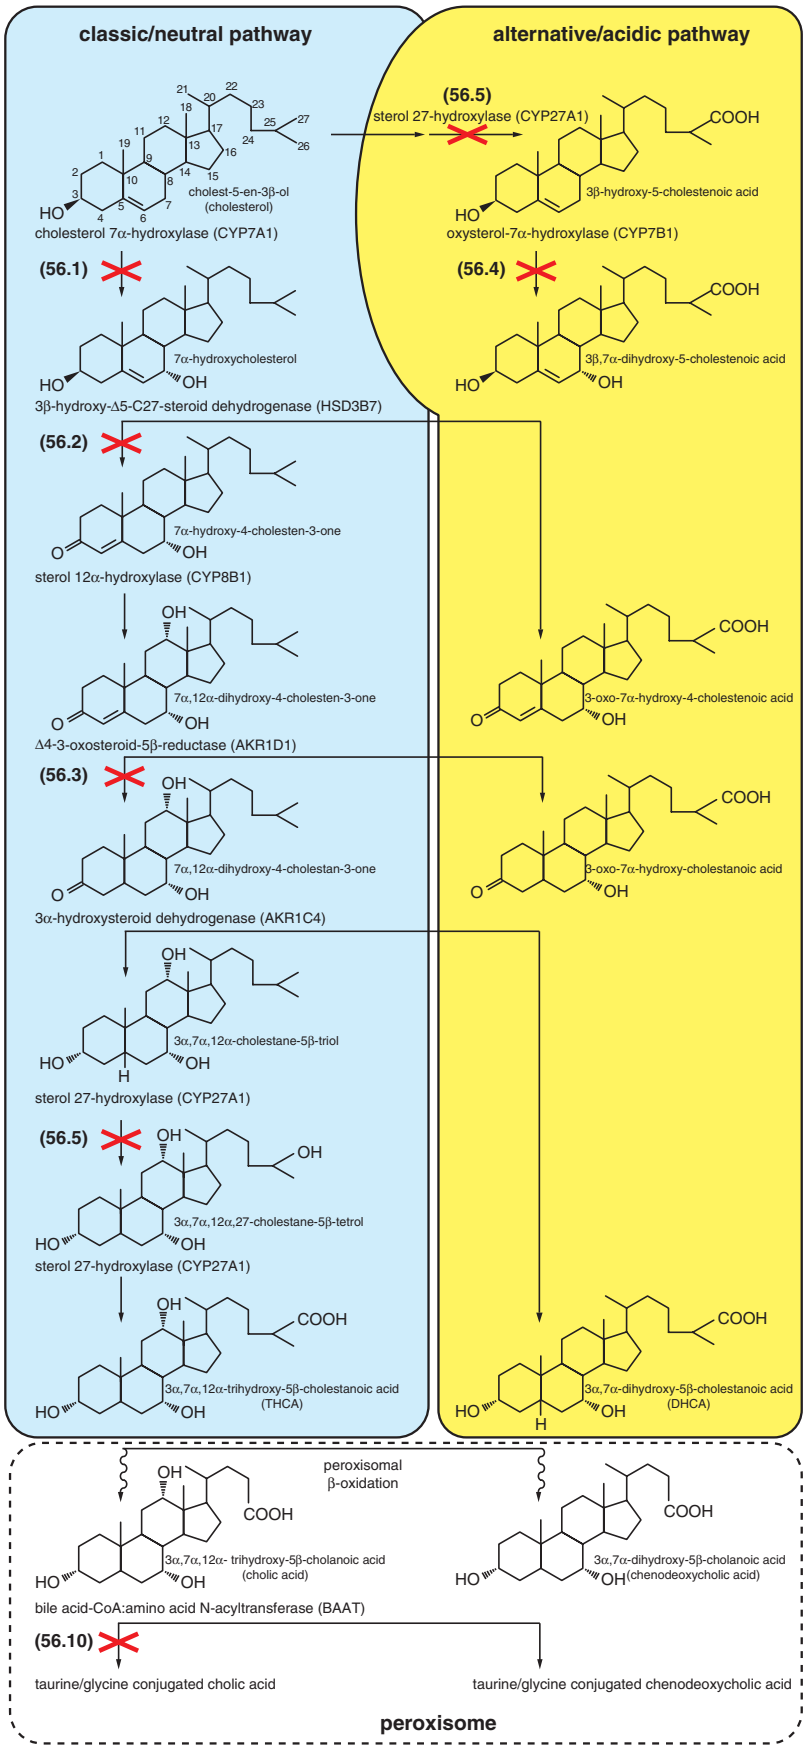

Fig. 56.1 Schematic representation of the intermediates, enzymes, and corresponding genes of the classic/neutral pathway and the acid/alternative pathway of bile acid synthesis. Known inborn errors discussed in this chapter are indicated by red crosses and the disease number between parentheses. In the neutral pathway, modification of the sterol ring structure precedes the conversion to an acid, whereas in the acidic pathway, an acid = carboxylic group first is formed followed by steroid nucleus modifications. Peroxisomal shortening of the aliphatic side chain of dihydroxy- and trihydroxycholestanoic acid (DHCA and THCA) produces the primary bile acids chenodeoxycholic and cholic acids, respectively. These bile acids can be amidated to form taurine or glycine conjugates, i.e., the bile salts

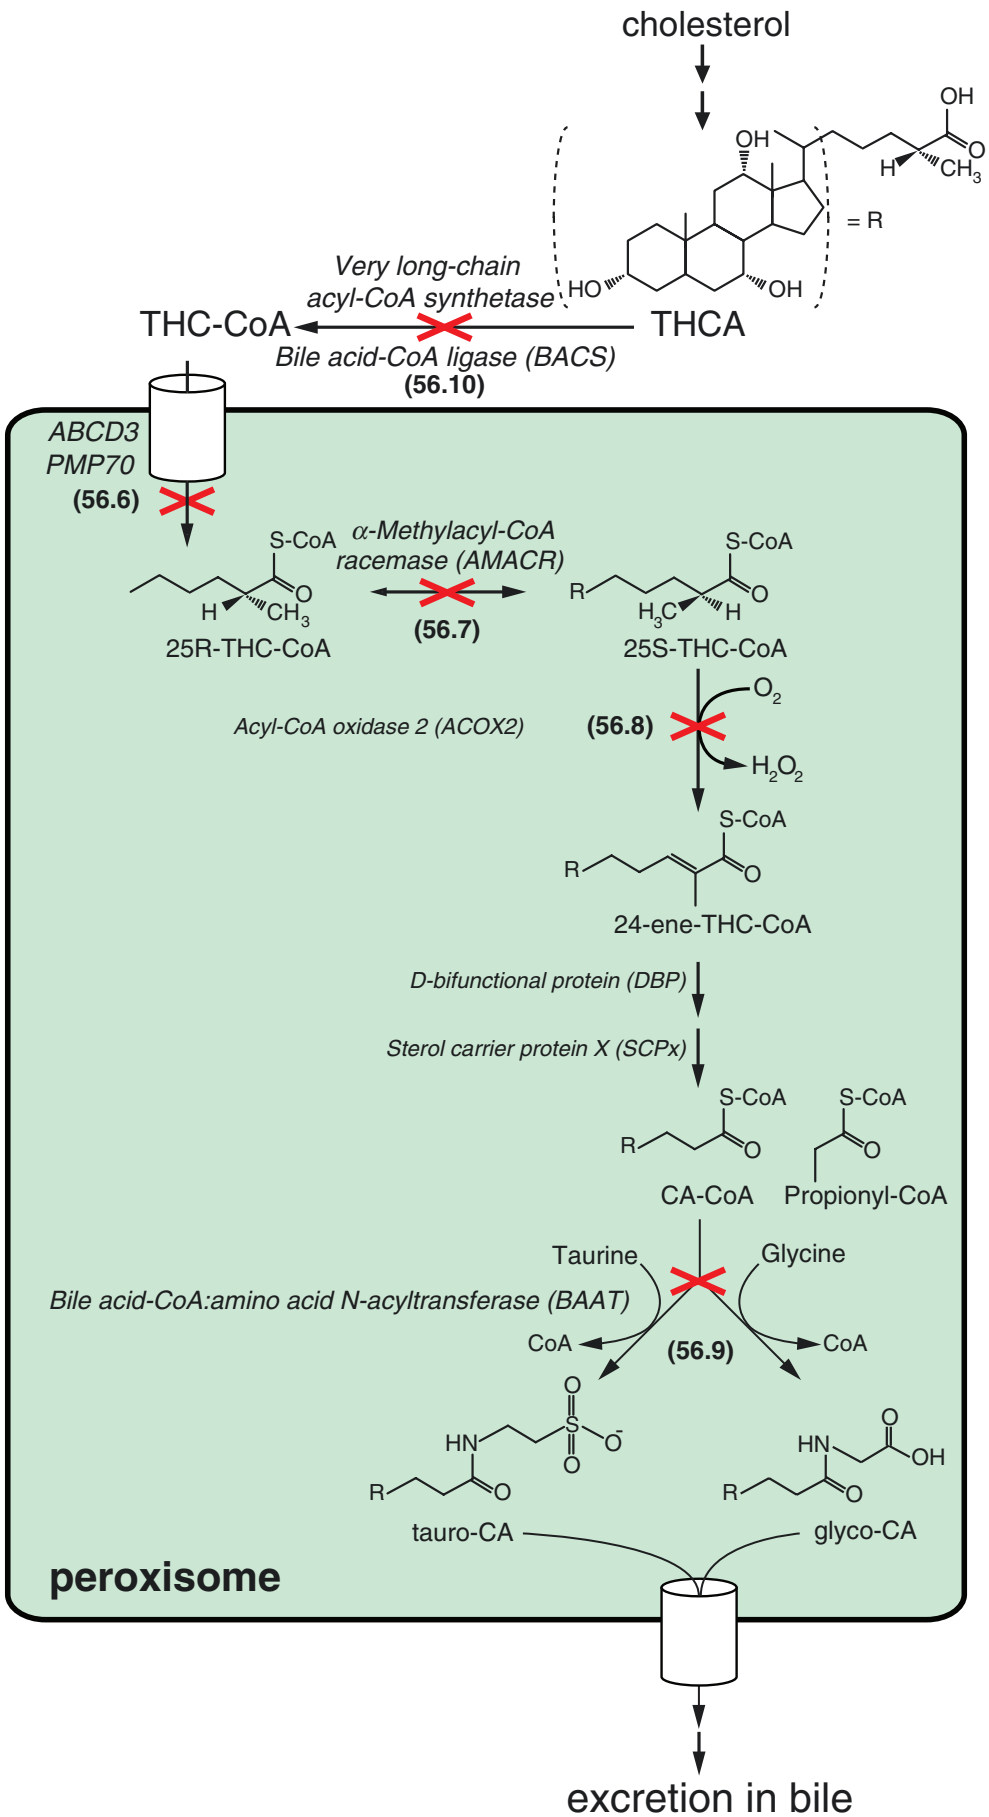

Fig. 56.2 Schematic representation of the enzymes and bile acid intermediates of the peroxisomal steps in bile acid biosynthesis. Known inborn errors discussed in this chapter are indicated by red crosses and the disease number between parentheses. In short, the C27-bile acid intermediate trihydroxycholestanoic acid (THCA) is formed via several enzymatic steps from cholesterol and then activated to CoA-ester at the endoplasmic reticulum. Subsequently, THC-CoA is transported into the peroxisome via the transporter PMP70/ABCD3 after which the side chain is cleaved via peroxisomal β-oxidation generating choloyl-CoA (CA-CoA) followed by amidation via bile acid-CoA: amino acid *N*-acyltransferase (BAAT)

Signs and Symptoms

Only four patients including two siblings with peroxisomal acyl-CoA oxidase 2 (ACOX2) deficiency have been described so far (Vilarinho et al. 2016; Monte et al. 2017; Ferdinandusse et al. 2018). One patient with a complicated clinical presentation, who died at the age of 5 months, is not included because the patient most likely suffered from another defect underlying the clinical presentation (Ferdinandusse et al. 2018). This patient did have persistently but slightly increased ALAT levels like the other ACOX2 patients

Only two siblings with BACS deficiency have been described (Chong et al. 2012). One sibling has remained asymptomatic. The symptomatic sibling also had a homozygous mutation in the gene encoding the bile salt export pump (BSEP)

Reference Values

Traditionally, urine cholanoid profiles measured by GC-MS were used to investigate a possible bile acid biosynthesis defect. When abnormal metabolites were found, follow-up GC-MS analyses were performed in plasma and/or urine with or without chemical/enzymatic deconjugation to confirm the findings. For details about these procedures, we refer the reader to the previous version of this book, Chapter 34 (Lemonde et al. 2014). Given the established and general use of bile acid analysis by (UPLC)-ESI-MS, we focus on this technique for the diagnosis of bile acid disorders.

As the solubility of the (accumulating) bile acid metabolite greatly determines in which body fluids they are best analyzed, we advise the analysis of cholanoid profiles = bile acid analysis in both plasma (qualitative and quantitative) and urine (qualitative) as this yields the best diagnostic result. Depending on the abnormal metabolites found, MS/MS can be performed to help confirm peak identities by parent/daughter analyses, e.g., m/z 74 for glycine conjugates, m/z 80 for taurine conjugates, m/z 97 for sulfates, and m/z 85 for glucuronides. The advent of high-resolution mass spectrometry with exact mass possibilities, especially with automated fragmentation, will enable better and faster identification of bile acid metabolites, but this equipment is not yet routinely used for diagnostics (Vaz and Ferdinandusse 2017). Anticipating this for the near future, we have included monoisotopic masses in Table below.

Quantitative reference values for bile acid profiles—routine for plasma but less relevant for urine—vary between laboratories as standardization of bile acid measurements is not yet in place and few laboratories offer this service. We therefore chose to concentrate on the presence/absence of metabolites instead of listing quantitative reference and pathological values. For quantitative bile acids/salts in plasma, laboratories generally provide method- and population-specific reference ranges.

Bile acids, bile acid conjugates, and bile alcohols found in urine and plasma of normal and cholestatic[a] individuals by ESI-MS

Nominal mass	Monoisotopic mass	Compound name	Urine normal	Urine cholestasis	Plasma normal	Plasma cholestasis
391	391,2885	Dihydroxy-cholanoic acids (e.g., chenodeoxycholic acid)		±		±

[a]Cholestasis is defined here as hypercholemia (as seen in the laboratory analysis) and can therefore have different clinical etiologies. In cholestatic young children, monohydroxylated species of primary bile acids (m/z 480 and m/z 530) can be more abundant than the primary acids themselves

Pathological Values

Table 'Bile acids, bile salts, and bile alcohols found in urine and plasma of patients with bile acid synthesis disorders as analyzed by ESI-MS' shows bile acid metabolite changes in both plasma and urine for different bile acid synthesis disorders. In general, most metabolite changes are observed both in urine and plasma where, depending on the solubility and renal excretion of the accumulating metabolites, these can be more predominant in urine or plasma. If relevant, this is indicated. Depending on the disorder, the profile can vary considerably and in some disorders may even be without obvious abnormalities. *CYP7A1* deficiency (56.1), for example, is not in table 'Bile acids, bile salts, and bile alcohols found in urine and plasma of patients with bile acid synthesis disorders as analyzed by ESI-MS' as a normal cholanoid profile is observed, except that possibly relatively more CDCA than CA is present because of upregulation of the CDCA production via the acidic/alternative pathway.

Diagnostic Flowcharts

Bile acid synthesis defects should be considered, and screened for, in all patients with unexplained jaundice or cholestasis, hepatitis, liver fibrosis or cirrhosis, gallstones, deficiencies in fat-soluble vitamins (e.g., rickets or bleeding problems), hypercholesterolemia, tendon xanthomas, chronic diarrhea or steatorrhea, cataracts, and unexplained neurological disease (e.g., ataxia, spastic paraplegia, neuropathy, cognitive decline, epilepsy). Screening for bile acid synthesis defects should especially, but not exclusively, be considered in patients with cholestasis with low to normal γGT, or low to normal total bile acids. Also patients with genetic variants in the bile acid synthesis pathway genes, detected during, e.g., whole exome and whole genome sequencing, should be screened/confirmed biochemically. Biochemical screening for bile acid synthesis defects is performed in both urine and plasma, preferably using (UPLC-)ESI-MS. For interpretation of the results, see tables 'Plasma cholestanol concentration and % cholestanol', Bile acids, bile acid conjugates, and bile alcohols found in urine and plasma of normal and cholestatica individuals by ESI-MS and 'Bile acids, bile acid conjugates, and bile alcohols found in urine and plasma of normal and cholestatica individuals by ESI-MS'.

Plasma cholestanol concentration and % cholestanol[a]

	Age < 100 days	Age > 100 days	Cholestatic
Cholestanol (μmol/l)	2.8–19	3.5–10	Can be elevated
% Cholestanol[b]	0.12–0.72	0.1–0.28	Normal

[a]Reference values indicative only
[b]Cholestanol concentration/cholesterol concentration * 100%

Specimen Collection

Test	Conditions	Material	Handling
Plasma cholanoid profile	No bile acid therapy	Plasma/ serum 0.2–1.0 ml	Ambient temp. 12 h, 4 °C for 48 h, –20 °C for >6 months
Urine cholanoid profile	No bile acid therapy	Spot urine ≥0.5 ml	As above
Plasma cholestanol	No bile acid therapy	Plasma/ serum 0.2–1.0 ml	As above

Prenatal Diagnosis and DNA Testing

Routine specific DNA testing for bile acid biosynthesis defects is not widely available, but the underlying genetic basis can be identified with next-generation sequencing techniques. Now that these NGS techniques become more available, it is likely that the number of patients identified with a bile acid biosynthesis defect will increase. Prenatal diagnosis can be done using genetic analysis.

[a]56.2 Urine is a better specimen than plasma; biomarker peaks are more pronounced in urine

[b]56.3 Urine is a suitable specimen; plasma less so but corroborates the urine results. Liver disease can mimic a 5β-reductase deficiency profile; however, in these cases, the primary bile acids are usually elevated reflecting cholestasis. Because of the existence of a 5α-reductase, the accumulating C27–3-oxo-Δ4 steroids can be converted to so-called allo-(5α)-bile acids which can account for more than 20% of the total (Setchell et al. 1988). Because the allo-bile acids are isobaric (same molecular mass) to their corresponding natural (5β) bile acids, the diagnosis of 5β-reductase can be missed. When in doubt, perform genetic analysis of the *AKR1D1* gene

[c]56.4 27-Hydroxycholesterol and 25-hydroxycholesterol are additional biomarkers that are grossly elevated (not many laboratories measure these); m/z 453 and m/z 510 are more prominent in urine

[d]56.5 Profile in urine is shifted to more hydroxylated bile alcohol glucuronides (higher m/z). In plasma, m/z 611 (cholestanetetrol glucuronide) is prominent, and m/z 613 is much lower, which in non-CTX liver disease is higher than m/z 611. In urine, m/z 627 (cholestanepentol glucuronide) is the most predominant bile alcohol glucuronide. An additional biomarker for CTX is plasma cholestanol and % cholestanol (from cholesterol). Both are elevated when compared to reference values mentioned. Especially in young children, cholestanol concentration is only slightly elevated, if at all. Bile alcohol glucuronides either in plasma or urine are superior biomarkers for CTX. In addition to these secondary metabolites in CTX, primary metabolites that accumulate are 7α-hydroxycholesterol, 7α-hydroxy-cholest-4-en-3-one, and 7α,12α-dihydroxy-cholest-4-en-3-one

[e]56.7 Sole accumulation of the 25R-isomers of DHCA and THCA. R/S species can usually be separated on UPLC-MS method if appropriate standards are available

Treatment

In general, standard medical or surgical care is indicated in case of gallstones, cataracts, and epilepsy. Substitution of fat-soluble vitamins A, D, E, and K is indicated in cases of symptomatic, proven deficiency. Patients developing acute liver failure or end-stage liver disease need to be evaluated for liver transplantation.

Bile Acid Supplementation

Supplementation with CA and/or CDCA has a stabilizing or proven curative effect in several bile acid synthesis defects; in other defects, there are indications of beneficial effects. In general, UDCA supplementation does not have beneficial effects in the bile acid synthesis defects, as it does not exert negative feedback on the first step of the synthesis cascade, at the level of cholesterol 7α-hydroxylase. Therefore, UDCA does not inhibit the formation of bile acid intermediates and derivatives that are considered the source of pathology in these diseases. In addition, combining UDCA with CA or CDCA probably competes for the ileal reuptake and enterohepatic recirculation of CA or CDCA and could thus reduce the effectivity of CA/CDCA supplementation (Heubi et al. 2018). Finally, UDCA appears to be an FXR antagonist and therefore does not suppress bile acid synthesis (Mueller et al. 2015). After initiation of treatment with CDCA or CA, patients should be monitored with liver enzymes and clinical-neurological examination until the bile acid analyses normalize and remain normal. Bile acid therapy is lifelong.

CTX (56.5) Treatment

Most available data using primary bile acid therapy, accumulated over decades, is for CDCA treatment in the context of CTX. The natural history of CTX is progressive neurodegeneration, most probably due to neurotoxicity of the accumulation of the by-product cholestanol. Long-term treatment with CDCA (10–15 mg/kg/day with a maximum of 750 mg/day in adults) normalizes plasma cholestanol concentrations within months, reduces the urinary excretion of bile alcohols, and stabilizes or improves the neurological symptoms; xanthomas disappear during treatment. Early initiation of therapy improves the outcome (Amador M del et al. 2018; Yahalom et al. 2013; Stelten et al. 2019). In a retrospective Japanese study, the percent decrease of cholestanol by combination therapy of CDCA and statin (59.3%) was not superior to that by CDCA monotherapy (77.6%), and so the efficacy of statin add-on therapy to CDCA remains uncertain (Sekijima et al. 2018). Low-density lipoprotein (LDL) apheresis reduces cholestanol, but the longer-term clinical efficacy is unclear (Berginer and Salen 1994).

Adverse outcomes have been described for the pregnancies and children of untreated CTX mothers, without providing final clarity on the teratogenicity or toxicity of the disease or cholestanol concentrations, nevertheless (Berginer et al. 1988). Developmental toxicity studies in rats, hamsters, and primates showed an absence of teratogenic effects, but CDCA treatment of pregnant rhesus monkeys and baboons (at 5–120 mg/kg/day for rhesus monkey; at 18–38 mg/kg/day for baboons) produced liver pathology in the developing fetus. Pathological effects on adrenals and kidneys were also seen in rhesus monkey fetuses. Maternal effects in the rhesus monkeys, but not baboons, included diarrhea, emesis, weight loss, and reduction in food consumption (Leadiant 2017). According to GeneReviews, it is advised to not interrupt CDCA treatment during pregnancy (Federico et al. 2016). Additional data on the risk of CTX for the fetus, and the risk of CDCA treatment during pregnancy, will be necessary to determine which is preferable.

Bile Acid Treatment in Other Bile Acid Synthesis Defects

Oral bile acid therapy appears safe; most reported adverse effects are liver toxicity (in some cases attributed to overdosing CDCA) and diarrhea. The success of CDCA and CA for patients with multiple defects in the bile acid biosynthetic pathway is well documented (Clayton 2011). The two most prevalent bile acid synthesis defects, according to a survey in 21 countries, are 3β-hydroxy-Δ5-C27-steroid oxidoreductase (3β-HSOR) deficiency (56.2) (n = 55) and Δ4–3-oxosteroid 5β-reductase deficiency (56.3) (n = 8) (Jahnel et al. 2017). In both these diseases, convincing long-term CA treatment effects at a dose of 15 mg/kg/day have been reported (3β-HSOR, 56.2: n = 13; 5β-reductase, 56.3: n = 2) (Matarazzo et al. 2018). Hepatitis, cholestasis, and even fibrosis/cirrhosis were reversed by CA treatment. Patients grew to adulthood in good health, while the natural history of the disease is an evolution to liver failure and transplantation. Safety of CA treatment during pregnancy seems good, given that ten uneventful pregnancies in five mothers on CA were reported (Matarazzo et al. 2018).

CA treatment failures have been reported in patients with oxysterol 7α-hydroxylase deficiency (CYP7B1) deficiency (SPG5, 56.5), while combination therapy with CDCA and statins appeared beneficial (Marelli et al. 2018).

Very few systematic data are available for the deficiencies of PMP70/ABCD3 (56.6), AMACR (56.7), and ACOX2 (56.8). In AMACR deficiency, primary bile acid therapy with CA is effective in normalizing liver enzymes and preventing the onset of neurologic symptoms in the infant, coupled with

dietary restriction of phytanic acid and pristanic acids, which are necessary to prevent neurotoxicity from their accumulation in the brain (Heubi et al. 2018). In view of the rarity of PMP70/ABCD3 ($n = 1$) and ACOX2 ($n = 3$) deficiency, it is hard to make treatment recommendations for these disorders.

A notable exception to the effectivity of CA and CDCA supplementation is the amidation defects (56.9 and 56.10). As conjugation of the primary bile acids CA and CDCA with glycine or taurine is defective in these diseases, they are only responsive to treatment with conjugated bile acids, as was shown for treatment with glycocholic acid (glycine conjugated CA) recently (Heubi et al. 2015).

Part VII

Disorders of Tetrapyrroles

Disorders of Heme Metabolism

57

Ulrich Stölzel, Ilja Kubisch, Thomas Stauch, and Detlef Schuppan

Contents

Summary

Porphyrias are metabolic disorders of the heme biosynthesis. The location of the deficient enzyme within the heme biosynthetic pathway determines the pattern of the accumulated porphyrin precursors and/or porphyrins. Clinically, they can be differentiated into acute and non-acute porphyrias. Acute hepatic porphyrias (AHP) are characterized by overproduction of probably neurotoxic porphyrin precursors and porphyrins. Acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HCP), and Doss porphyria (ADP) belong to this group of metabolic disorders. The clinical presentation of acute hepatic porphyrias includes abdominal, psychiatric, neurological, and cardiovascular symptoms. They are diagnosed by an at least fourfold elevated urinary excretion of 5-aminolevulinic acid (ALA) and porphobilinogen (PBG) (except for ADP and lead poisoning (LP)). Besides symptomatic therapy with non-porphyrinogenic drugs, the combination of electrolyte correction, intensive monitoring, intravenous caloric supply (mainly glucose), and heme is established for treatment. Recently, in the Phase 3 ENVISION study in patients with AHP, givosiran, an RNAi therapeutic which targets liver mRNA encoding ALAS1 to reduce 5-ALA/PBG, ameliorates attacks and clinical manifestations.

Non-acute types are porphyria cutanea tarda (PCT), hepatoerythropoietic porphyria (HEP), erythropoietic protoporphyria (EPP), X-linked protoporphyria (XLP), and congenital erythropoietic porphyria (CEP). Accumulated porphyrins cause photosensitivity of the skin and in some cases severe liver damage. X-linked protoporphyria (XLP) represents a new type of protoporphyria, with 5-aminolevulinic acid synthase 2 gain of function leading to high concentrations of free protoporphyrin IX (PPIX). Treatment of PCT is based on iron depletion, the use of hydroxychloroquine (HCQ), and, in case of chronic hepatitis C virus (HCV) infection, antiviral therapy. Patients with EPP or XLP profit from treatment with an analogue of α-melanocyte-stimulating hormone that reduces sunlight sensitivity and inflammation. Further therapeutic developments directly address dysfunctional steps of the heme biosynthetic pathway.

Introduction

Porphyrias are a heterogeneous group of metabolic disorders, which are caused by a range enzyme deficiencies or defects due to mutations in genes along the heme synthesis pathway (Puy et al. 2010; Bonkovsky et al. 2013; Bissell et al. 2017; Stölzel et al. 2019) (Fig. 57.1). The majority of patients are carriers of heterozygous mutations. Some patients carry homozygous or compound heterozygous mutations resulting in a reduced enzyme activity. As customary, autosomal dominant disorders porphyrias can vary in penetrance and phenotype; moreover, there are considerable interactions between genetic and environmental factors. Moreover, they can result from combinations of genetic alterations (Lenglet et al. 2018) . In addition, there are considerable interactions between genetic and environmental factors.

PCT is the most common porphyria. Hepatic uroporphyrinogen decarboxylase (UROD) is reduced in all cases with PCT (acquired type 1 or familial type 2). Thus, a cross-sectional registry study comprising 4653 patients showed prevalence ratios of 91/26/9/4/2/1 for PCT/AIP/EPP/VP/HCP/CEP (Stölzel et al. 2019). Among AHPs, AIP is the most frequent type, followed by VP, HCP, and a rare autosomal recessive acute hepatic porphyria ADP (synonym: porphobilinogen synthase defect porphyria, Doss porphyria) which is biochemically very similar to lead poisoning (LP) (Doss et al. 1979) .

Clinically, acute (AIP, VP, HCP, ADP) and non-acute porphyrias (PCT, HEP, EPP, XLP, CEP) can be differentiated, while pathogenetically hepatic (PCT, HEP, AIP, VP, HCP, ALADP) and erythropoietic (EPP, XLP, CEP) porphyrias form two major groups. Dual porphyrias (biochemical findings of two porphyrias) are rare and have been confirmed by mutation analyses. Increased porphyrin precursors and porphyrins are also found in LP.

The clinical presentation of AHP and LP comprises abdominal, neuropsychiatric, and cardiovascular symptoms and hyponatremia, whereas chronic hepatic and erythropoietic porphyrias present with photodermatosis and occasionally severe liver damage. AHP is not just an "acute" disease as its name implies, but also has chronic manifestations that impact patients' lives (Gouya et al. 2020).

All porphyrias are diagnosed and differentiated by specific biochemical patterns of elevated porphyrins and porphyrin precursors in urine, feces, and blood (Bonkovsky et al. 2013; Bissell et al. 2017; Stölzel et al. 2019). AHPs are characterized by excessive accumulation and excretion of the porphyrin precursors 5-ALA (ADP, LP) or 5-ALA and PBG (AIP, VP, HCP) as well as porphyrins. In patients with PCT, but also in patients with HEP, levels of porphyrins are greatly increased in urine and plasma, with uro- and heptacarboxyporphyrins predominating. Increased levels of metal-free protoporphyrin (>4.500 nmol/l, controls <89 nmol/l) in hemolyzed anticoagulated whole blood confirm the diagnosis of EPP or XLP. Here, patients with XLP display a significantly higher proportion of zinc- to metal-free protoporphyrin (>25%) than patients with EPP (<15%).

Erythropoietic and hepatic porphyrias are genetically determined primary porphyrias, whereas clinically asymptomatic secondary porphyrinurias and porphyrinemias are not due to functional mutations of the heme synthetic pathway but caused by a number of different (e.g., metabolic, hepatic, or hematologic) diseases and dysfunctions.

In tyrosinemia type I, the nonfunctional fumarylacetoacetate hydrolase leads to succinylacetone that inhibits the enzyme ALA dehydratase.

Nomenclature

No.	Disorder	Alt name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM no.	Inheritance
57.1	X-linked sideroblastic anemia	Erythroid 5-aminolevulinate synthase deficiency	XLSA	*ALAS2*	Xp11.21	5-Aminolevulinate synthase 2	300751	XL
57.2	X-linked protoporphyria	Erythroid 5-aminolevulinate synthase gain of function	XLP	*ALAS2*	Xp11.21	5-Aminolevulinate synthase 2	300752	XL
57.3	5-Aminolevulinate dehydratase deficiency	Doss porphyria	ADP	*ALAD*	9q32	Delta-aminolevulinate dehydratase	612740	AR
57.4	Acute intermittent porphyria	Porphobilinogen deaminase deficiency	AIP	*HMBS*	11q23.3	Hydroxymethylbilane synthase	176000	AD
57.5	Congenital erythropoietic porphyria	Uroporphyrinogen III synthase deficiency	CEP	*UROS*	10q25.2–26.3	Uroporphyrinogen III synthase	263700	AR
57.6	Porphyria cutanea tarda types I, II and hepatoerythropoietic porphyria	Hepatic uroporphyrinogen decarboxylase deficiency	PCT/HEP	*UROD*	1p34	Uroporphyrinogen decarboxylase	176100	AD, AR
57.7	Hereditary coproporphyria	Coproporphyrinogen oxidase deficiency	HCP	*CPOX*	3q12	Coproporphyrinogen oxidase	121300	AD
57.8	Porphyria variegata	Protoporphyrinogen oxidase deficiency	VP	*PPOX*	1q22-q23	Protoporphyrinogen oxidase	176200	AD
57.9	Erythropoietic protoporphyria	Ferrochelatase deficiency	EPP	*FECH*	18q21.3	Ferrochelatase	177000	AD

Metabolic Pathways

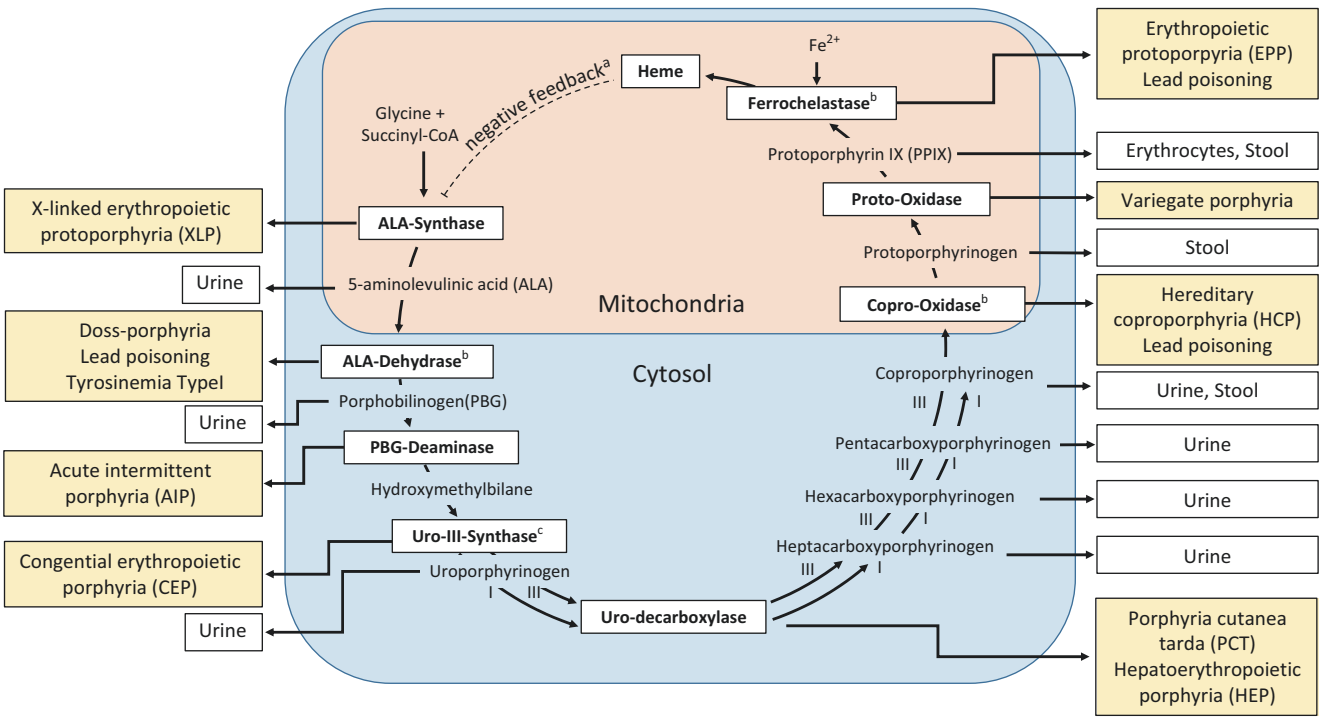

Fig. 57.1 Localization of characteristic enzyme defects of heme biosynthesis and in porphyrias, lead poisoning, and type I tyrosinemia. The porphyrinogens are excreted after their oxidation to porphyrins. (a) In the liver, the first heme synthetic enzyme ALAS1 is regulated via a negative feedback loop by the end product heme. In contrast, the rate-limiting bone marrow enzyme ALAS2 is regulated by iron and erythropoietin and not by heme. (b) Three enzymes involved in heme biosynthesis are compromised in lead poisoning. (c) The two isomers uroporphyrinogen I and III that are synthesized from hydroxymethylbilane are converted to coproporphyrinogen I and III, respectively. Only isomer III is utilized for heme synthesis. The nonfunctional isomer I is excreted via the hepatobiliary and renal routes in feces and urine, respectively (Modified from Ref. Stölzel et al. 2019)

Signs and Symptoms

Table 57.1 X-linked sideroblastic anemia[a]

System	Symptoms and Biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Hematological	Anemia, microcytic, hypochromic			+	+	+

Overview on Symptomatology

Disorder	Leading clinical symptoms	Onset of symptoms	Prevalence
57.1 X-linked sideroblastic anemia	Anemia		
57.2 X-linked protoporphyria	Photosensitivity/liver disease/anemia	Childhood	Rare
57.3 ALA-dehydratase deficiency Lead poisoning	Abdominal and neurological symptoms Abdominal and neurological symptoms/anemia/lead blue line (Burton's line)	Childhood Childhood/adolescence	Very rare Rare
21.1 Tyrosinemia type 1	Failure to thrive, abdominal and neurological symptoms, liver dysfunction	Early childhood	Rare
57.4 Acute intermittent porphyria	Abdominal and neurological symptoms/hyponatremia	After puberty (female>male)	1: 100,000
57.5 Congenital erythropoietic porphyria	Photosensitivity: Blisters, erosions, mutilations/ anemia/hemolysis/hepatosplenomegaly/erythrodontia	Neonatal/childhood	Very rare
57.6 Porphyria cutanea tarda I, II, Hepatoerythropoietic porphyria	Liver disease/skin fragility/photosensitivity/ hypertrichosis	Late adolescence	20: 100,000 Very rare
57.7 Hereditary coproporphyria	Abdominal and neurological symptoms, photosensitivity	After puberty (adolescence And senescence)	0.1: 100,000
57.8 Porphyria variegate	Abdominal and neurological symptoms, photosensitivity	After puberty (adolescence And senescence)	0.3: 100,000
57.9 Erythropoietic protoporphyria	Photosensitivity, some patients develop liver disease	Infancy/childhood	1: 100,000

Enzyme Defects along the Heme Biosynthesis in Porphyrias, Regulated Induction of ALAS1, and Major Clinical Manifestation

Disorder in heme synthesis	Enzyme	Induction of ALAS1	Major clinical manifestation			
			Neurovisceral	Cutaneous	Anemia	Liver
X-linked sideroblastic anemia (57.1)	ALAS2	–			++

[c]Tyrosinemia is not described in detail; the reader is referred to Sect. 21.1

Reference Ranges

Urinary Excretion of Porphyrin Precursors and Porphyrins

	24-h urine collection	Urine spot sample
Analyte	Referred to the total excretion volume	Referred to excreted creatinine
ALA	<49 µmol/day	<2.6 mmol/mol, BZ 2.6–6.8
PBG	<7.5 µmol/day	<1.0 mmol/mol, BZ 1.0–2.2
Uroporphyrin	<33 nmol/day	<4.5 µmol/mol
Coproporphyrin I	<51 nmol/day	<7.0 µmol/mol
Coproporphyrin III	<102 nmol/day	<14.0 µmol/mol
Total porphyrins	<209 nmol/day	<26.7 µmol/mol

BZ border zone

Fecal Porphyrin Excretion

Analyte	Upper limit of reference
Coproporphyrin I	<26 nmol/g dry weight
Coproporphyrin III	<11 nmol/g dry weight
Protoporphyrin	<95 nmol/g dry weight

Erythrocytic Porphyrins

Analyte	Upper limit of reference
Zinc protoporphyrin IX	<385 nmol/l or < 40µmol/mol heme
Free protoporphyrin IX	<89 nmol/l

Diagnostic Flowcharts

Acute hepatic porphyrias	Porphyria cutanea tarda	Protoporphyrias
Patients after puberty	Adult patients Age > 18 years	Children or adolescents
• Unexplained gastrointestinal complaints (colic, vomiting, subileus) • Neuropsychiatric symptoms (paresthesia, seizures, paresis, depression, anxiety, hallucination) • Cardiovascular symptoms (tachycardia, hypertension) • Red-colored urine without erythrocytes or hemoglobin • Serum hyponatremia	• Blister-forming dermatosis on light-exposed skin areas • Increased skin vulnerability • Hyper- and hypopigmentation on light-exposed skin • Hypertrichosis of the cheeks, temples, and eyebrows; often associated with: – Iron overload – HCV infection – HIV infection – Alcohol consumption – Hormone (replacement) therapy – Toxic agents, e.g., hexachlorobenzene	• Burning pain • Erythema/redness on light-exposed skin areas • Angioedema-like swelling on the face, on the back of the hands, and on the forearms • Often microcytic anemia
Key diagnostic features		
> Fourfold elevated ALA and PBG in urine	ALA and PBG in urine normal, elevated total porphyrins in urine with uroporphyrin > coproporphyrin	ALA and PBG in urine normal, metal-free erythrocyte protoporphyrin increased in blood

Diagnosis and differential diagnosis of porphyrias rely on biochemical, quantitative determinations of porphyrin precursors and porphyrins in urine, stool, plasma, and heparinized blood. The simplified three scenarios (acute hepatic porphyrias, porphyria cutanea tarda, protoporphyrias) are helpful in clinical practice. Think of porphyria in patients with unexplained abdominal and neuropsychiatric symptoms and/or photosensitivity. Use key diagnostic features. (Modified from Ref. Stölzel et al. 2019)

Specimen Collection

Test	Material	Handling
First-line diagnostic tests		
Fluorescence scan	1 ml serum, plasma (heparin, EDTA)	Light protected and cool
5-Aminolevulinic acid Porphobilinogen (porphyrin precursors)	5 ml urine (spot sample or 24-h collection)	Light protected and cool
Porphyrins	5 ml urine (spot sample or 24-h collection), 5 g feces	Light protected and cool
Free protoporphyrin	3 ml EDTA blood or	
Zinc protoporphyrin	Heparinized blood	Light protected and cool
Second-line diagnostic tests		
Enzyme activity tests	5 ml heparinized blood or ACD blood	Cool, not frozen
Molecular genetic assays	EDTA blood or	–
Genomic DNA	Isolated DNA	
cDNA	EDTA blood	Rapid sample transport (<12 h)

Treatment

Acute Porphyrias (ALADP; 57.3, AIP; 57.4, HCP; 57.7, VP; 57.8)

Generally, patients need to be admitted to an intensive care unit, to receive pain treatment and caloric support (mainly glucose infusion) and to have their electrolyte abnormalities corrected. Porphyrinogenic medications and other triggers need to be identified and discontinued (Stölzel et al. 2019). AHP requires specific therapies (see table below).

1. Discontinuation of porphyrinogenic drugs and intensive medical monitoring	www.drugs-porphyria.org and see Fig. 57.2
2. Caloric support (carbohydrates, protein) And heme treatment:	Intravenous and/or oral carbohydrates as preferred source of energy; beware of dilutional hyponatremia; serum sodium, magnesium, and phosphate must be monitored daily For severe cases, neurologic manifestations and associated hyponatremia: Heme arginate (e.g., Normosang^{R}), 3 mg/kg body weight/day in 100 ml human albumin (5%–20%), infused in 15 min, for up to four consecutive days
3. Symptom measures: For pain: For tachycardia and hypertension: For restlessness or vomiting: For symptoms of ileus: For respiratory relief: For infections: For recurrent attacks and chronic symptoms: Physiotherapeutic measures from the very beginning	 Acetylsalicylic acid, morphine derivatives, gabapentin Propranolol, metoprolol, valsartan Chlorpromazine, lorazepam, ondansetron Neostigmine Assisted or controlled ventilation (possibly tracheotomy) Penicillin, cephalosporins, imipenem, gentamicin, amikacin, vancomycin Givosiran (Givlaari^{R}) 2.5 mg/kg body weight, s.c., monthly

Givosiran silences hepatic ALAS1-mRNA, normalizes ALA und PBG overproduction, and significantly reduces pain, the days of administered heme, and annualized rate of porphyria attacks. Givosiran is given once monthly subcutaneously. Modified from Ref. (Stölzel et al. 2019)

Heme therapy is clearly indicated when neurological symptoms occur (Bonkowsky et al. 1971). Usually, these and other symptoms begin to improve within 48 h of early-on intravenous administration of heme (Normosang®, Orphan Europe, Puteaux, France, Europe, and elsewhere; Panhematin®, Recordati Rare Diseases, Lebanon, NJ, United States, Mexico, and elsewhere). Heme is a feedback inhibitor of the rate-limiting hepatic enzyme ALAS1 at the transcriptional level. While being effective in most cases, lack of response can be due to insufficient dosing (<3 mg/kg/day), symptoms that are not caused by porphyria, late start of therapy, or chronified porphyria-related pathology, which includes irreversible neurological damage. Heme therapy is also effective in LP and ALADP. Prophylactic treatment with heme in fixed intervals, e.g., up to weekly in severe cases, is justified for patients with recurrent attacks (defined as more than three per year). However, regular heme infusions over prolonged periods have significant side effects, especially iron overload and venous damage and obliteration caused by heme degradation products that bind to clotting factors, platelets, and endothelial cells. These patients require an intravenous port for blood sampling and intravenous heme therapy. Administration of heme bound to albumin is an easy measure to reduce intravenous heme toxicity (see table above). We dilute the heme arginate in 100 ml of human albumin (5–20%). After infusion into a large vein or the port, physiological saline is infused for 15 min to reduce local toxicity. In rare cases that require highly frequent heme infusions, because of severe clinical manifestations, the accumulating heme can activate heme oxygenase 1, which results in accelerated heme degradation and loss of feedback inhibition of ALAS1. This can explain the more than fourfold increase of reported AIP patients that experience recurrent attacks since the introduction of heme therapy in 1985

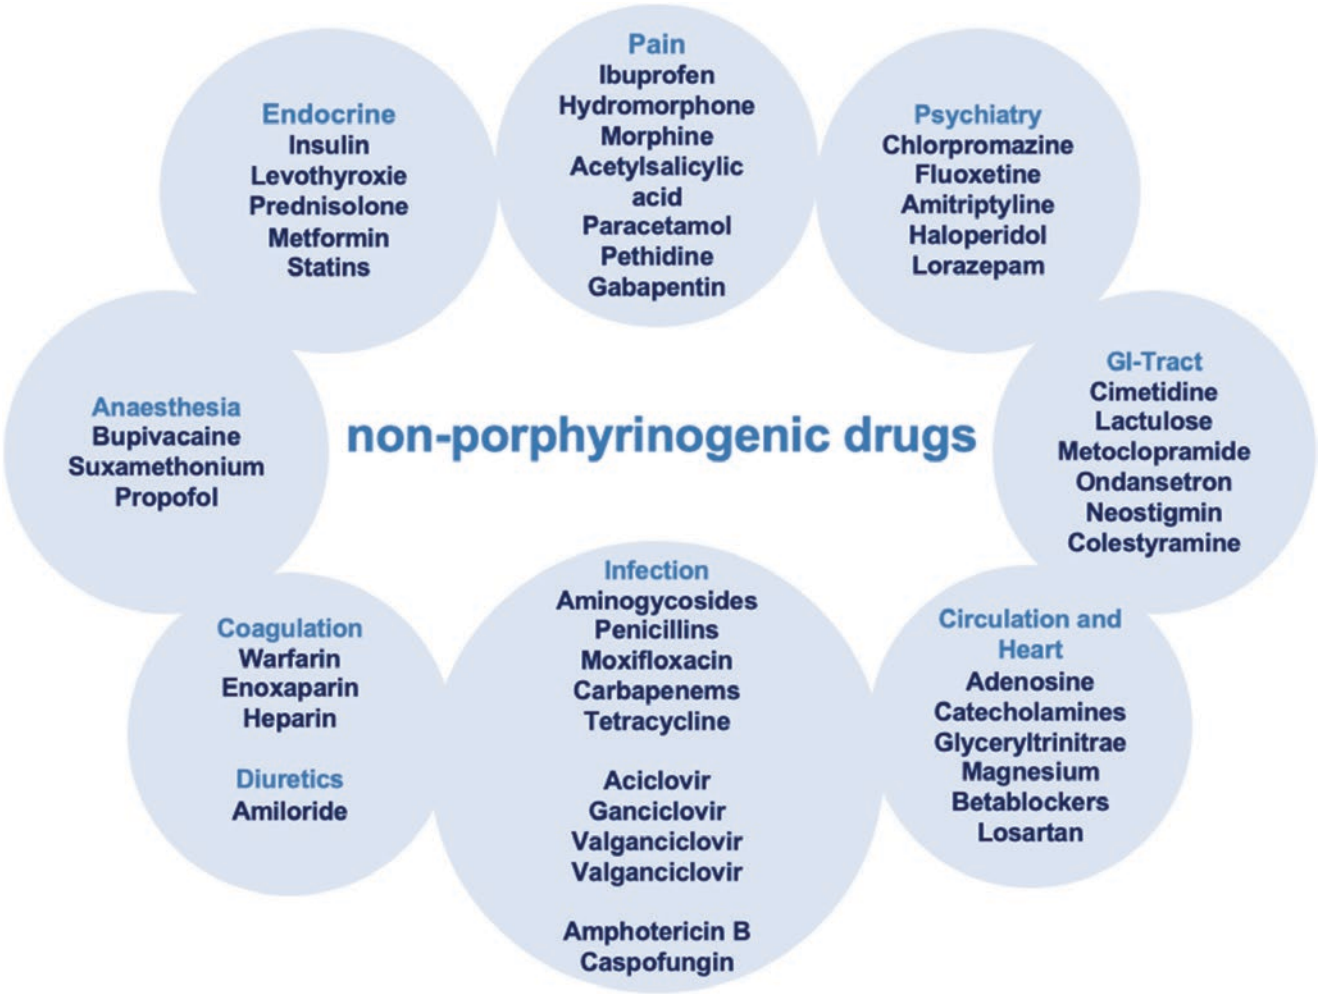

Fig. 57.2 Non-porphyrinogenic drugs

(from 4/230 in 1985 to 40/536 in 2008), but improved survival with heme therapy may also have contributed (Schmitt et al. 2018). Taken together, if feasible, high-frequency heme therapy should be avoided.

Sufficient caloric support (especially with carbohydrates and protein) is a central basic therapy for AHP. Attacks are often induced by low caloric intake and worsened by nausea and vomiting (Doss et al. 1985). The infused glucose inhibits the peroxisome proliferator-activated receptor-γ (PPAR-γ) coactivator-1α that otherwise upregulates transcription of ALAS1 (Handschin et al. 2005). Glucose combined with insulin may be more effective than glucose alone, but controlled studies are lacking. A too rapid glucose infusion may lead to a dangerous refeeding syndrome, promoting, e.g., hyponatremia. Therefore, patients with hyponatremia should first receive heme therapy followed by careful glucose infusion.

Pain, another component of the vicious cycle, needs to be treated immediately and rigorously prevented. Well-tolerated drugs used by us are opiates and gabapentin. They do not induce hepatic ALAS1 and are excreted via the kidneys. Mild acute hepatic porphyria cases should be treated with pain medication and caloric support alone. Figure 57.2 lists safe drugs, based on numerous experimental studies, pharmacological data, and clinical reports (Stölzel et al. 2009). We recommend to consult the International Guidelines (www.drugs-porphyria.org, www.porphyria-europe.com).

In women with acute porphyria, pregnancy is in general not at risk, although progesterone potently induces liver heme production. However, pregnancy-associated vomiting and subsequent caloric deficiency should be normalized promptly by caloric supply with parenteral nutrition. For those women suffering from frequent attacks related to menstrual cycle, gonadotropin-releasing hormone analogues, combined subsequently with low-dose estrogen patch to suppress menopausal symptoms, can be helpful.

Ultimately, in severe and complicated disease, liver transplantation was shown to cure the disease (Seth et al. 2007). Complete normalization of porphyrin metabolism after liver transplantation proves that acute porphyrias are diseases of the liver.

Small interfering RNA (givosiran, Givlaari®, Alnylam, USA) silences hepatic ALAS1-mRNA, normalizes ALA und PBG overproduction (Tschudy et al. 1965), and significantly reduces the annualized rate of porphyria attacks (Balwani et al. 2020). After 12 months of follow-up, 62% of patients on givosiran were attack-free. Safety profile was acceptable. However, 10 (11%) and 16 (17%) of the treated patients had renal and/or hepatic adverse events, respectively.

Overall, the rigorous elimination of precipitating factors in daily life remains the mainstay of prevention and therapy. Avoiding porphyrinogenic medication, including alcohol, smoking, and physical stress, is of major importance, as well as a balanced diet with a high percentage of carbohydrates. Patients with acute porphyria should take special care to avoid infections and other diseases, and the porphyrin precursors ALA and PBG should be monitored. We recommend liberal vaccination.

Porphyria Cutanea Tarda/Hepatoerythropoietic Porphyria (PCT I, II/HEP; 57.6)

Vitamin D supplementation and adequate sun protection is indispensable. The skin should not be exposed to intensive artificial light sources. Patients are advised to avoid known precipitating factors, especially alcohol and smoking, that upregulate CyP450 enzymes and thus the heme synthetic machinery. Alcohol further contributes by downregulating hepcidin, which increases iron resorption and enhances oxidative stress. Women must discontinue hormonal contraception or replacement therapy. Photoprotection, phlebotomy, and treatment with hydroxychloroquine (HCQ) (100 mg twice per week, respectively) are effective first-line therapies (Kordac and Semrádová 1973). Phlebotomy is employed to remove excess iron. Initially, a biweekly phlebotomy up to 500 ml is performed and monitored by serum ferritin concentrations (target value near the lower limit of normal) to avoid iron deficiency. When phlebotomy is not possible, such as in severe anemia, oral iron chelators or low-dose HCQ can be given. Phlebotomy and low-dose HCQ are also effective baseline therapies for the majority of patients with PCT, with comparable efficacy. HCQ can mobilize cellular porphyrin aggregates with subsequent elimination mainly via the urine. With HCQ, urinary porphyrin excretion usually increases at least twofold, and skin photosensitivity can worsen during the first 3 months, but then starts to decrease, followed by clinical remission which is accompanied by normalization of elevated liver enzyme activities in 95% of patients. Long-term HCQ therapy can lead to retinopathy, requiring (baseline and annual) regular ophthalmologic monitoring. Patients with PCT and iron overload related to HFE mutations should preferentially undergo phlebotomy (Stölzel et al. 2003). In general, in patients with increased serum ferritin, the combination of phlebotomy with low-dose HCQ shortens the time of remission. Even advanced liver damage and siderosis, such as in patients that are homozygous for the HFE C282Y mutation, can regress after combined phlebotomy and HCQ therapy.

In patients with chronic HCV infection, treatment with iron depletion combined with highly effective antiviral therapy induces rapid clinical and biochemical remission (Combalia et al. 2017).

Treatment should be discontinued once urinary porphyrin levels stabilize around 400 nmol/day (normal <209 nmol/day). Such mild porphyrinuria usually persists during clinical remission. Still, biochemical and clinical relapse occurred in 36% and 20% of patients in the first year after discontinuation of HCQ or phlebotomy, respectively (Salameh et al. 2018).

Erythropoietic Protoporphyrias (EPP/XLP 57.1/57.9)

EPP and XLP require effective sun protection, including protection from intensive artificial light sources. Conventional sunscreens are insufficient, since photosensitivity is mainly due to visible blue light (Soret band: near 400 nm). Appropriate skin protectants contain zinc oxide or titanium oxide. Since sunlight exposure triggers pain, patients quickly learn and adopt light protection measures. Vitamin D substitution (1000–2000 U of D3 daily) is necessary. Afamelanotide (Scenesse®, Clinuvel Pharmaceuticals, Melbourne, VIC, Australia), an α-melanocyte-stimulating hormone analogue, promotes skin pigmentation independent of sunlight via the activation of the melanocyte melanocortin-1 receptor and improves sunlight protection and tolerance (Langendonk et al. 2015).

In uncontrolled observational studies, ursodeoxycholic acid appears to increase hepatic clearance, and cholestyramine may bind excess protoporphyrin IX (PPIX) in the gut to interrupt its enterohepatic circulation. Excess metal-free PPIX has also been removed by plasma exchange in the treatment of liver failure or for prevention of hepatic decompensation. Erythrocytapheresis may be useful, since patients' red blood cells contain high amount of toxic PPIX. Moreover, iron depletion should be beneficial, since iron stimulates ALAS2. Patients with advanced cholestasis or cirrhosis should receive liver transplants. Before liver transplantation, excess circulating PPIX must be removed. During transplantation, but also during other abdominal surgeries, the use of special yellow filters prevents light-induced damage of visceral organs. Unfortunately, and in contrast to patients with AHP, liver transplantation does not cure patients with EPP or XLP, where the excessively elevated PPIX originates from the bone marrow. Consequently, allogeneic hematopoietic stem cell transplantation has led to a PPIX reduction of up to 85% and a resolution of inflammatory liver damage, regardless of prior liver transplantation.

Patients with EPP or XLP are not sensitive to numerous drugs, as are patients with AHP. Paradoxical on a first glance,

iron substitution can decrease PPIX concentrations and improve symptoms in patients with XLP, which can be explained by iron serving as secondary substrate to promote conversion of toxic PPIX to heme by FECH (Landefeld et al. 2016). In contrast, EPP is exacerbated by iron substitution, since iron induces the bone marrow enzyme ALAS2 (Barman-Aksoezen et al. 2017). In this line, mild iron deficiency may rather protect patients with EPP. Should iron substitution in patients with EPP be necessary, as in cases of severe anemia, it should be done during the darker seasons with low-intensity sunlight. There is some hope for gene therapeutic approaches to EPP.

Congenital Erythropoietic Porphyria (CEP; 57.5)

As in EPP and XLP, baseline treatment and prevention for CEP are light protection and vitamin D supplementation. Some patients with anemia have benefited from splenectomy. The indication for splenectomy must be personalized, since clinical presentation is highly variant, with different degrees of splenomegaly, anemia, and thrombocytopenia. Allogeneic hematopoietic stem cell transplantation is curative and should be performed at younger age. A single case was reported, where iron depletion with deferasirox improved photosensitivity, likely by reducing the activity of ALAS2. This mechanism is supported by another case, where an ALAS2 gain-of-function mutation increased the severity of CEP. Furthermore, proteasome inhibitors or chemical chaperones could stabilize the otherwise dysfunctional UROS variants to increase their activity, reduce porphyrin accumulation, and ameliorate skin photosensitivity in CEP patients.

Inherited Disorders of Bilirubin Metabolism

58

Namita Roy-Chowdhury, Chandan Guha, and Jayanta Roy-Chowdhury

Contents

Summary

Bilirubin is the breakdown product of heme, which is the iron-containing tetrapyrrole moiety of hemoglobin, myoglobin, and several enzymes. Heme cleavage, catalyzed by microsomal heme oxygenases, gives rise to biliverdin, which is reduced to bilirubin by biliverdin reductase. As an antioxidant, bilirubin provides health benefits at low concentrations, but at very high concentrations, it can cause bilirubin-induced neurological damage (BIND). Binding to plasma albumin, rapid uptake by hepatocytes, UGT1A1-mediated conjugation with glucuronide, and ATP-dependent pumping into bile canaliculi maintain low plasma concentrations of bilirubin, preventing its tissue toxicity. A fraction of bilirubin glucuronides formed in periportal hepatocytes is pumped out into sinusoidal blood and undergoes reuptake by hepatocytes located downstream to sinusoidal blood flow. Inherited disorders causing excessive bilirubin production, reduced glucuronidation, defective canalicular excretion, or abnormal reuptake can cause hyperbilirubinemia. Newborns have transient hyperbilirubinemia that normally resolves in 1–2 weeks, but can be prolonged or exacerbated by breastfeeding, delayed UGT1A1 maturation, or several inherited disorders of bilirubin metabolism. Mutations of *UGT1A1* gene that cause complete or partial loss of the

enzyme activity (Crigler-Najjar syndromes, types 1 and 2, respectively) increase specifically the unconjugated fraction of plasma bilirubin. A common polymorphism of *UGT1A1* promoter causes mild and harmless increase of plasma bilirubin (Gilbert syndrome). Both conjugated and unconjugated bilirubin fractions are increased in disorders of canalicular organic anion excretion (Dubin-Johnson syndrome) or reuptake of bilirubin glucuronides (Rotor syndrome). A group of monogenic disorders, termed progressive familial intrahepatic cholestasis, cause hyperbilirubinemia not by specifically perturbing the bilirubin excretory pathway, but through extensive liver injury.

Introduction

Bilirubin is the breakdown product of the heme (ferroprotoporphyrin IX) moiety of hemoproteins. Hemoglobin, derived from senescent erythrocytes, contributes 80% of the daily bilirubin production of approximately 4 mg/kg body weight in normal adults. Reticuloendothelial cells in the spleen and bone marrow are major sites of bilirubin production. The remainder comes from rapidly turning over hepatic hemoproteins, such as cytochrome P450s, catalase, peroxidase, and tryptophan pyrrolase, a small free hemoglobin pool, and the slowly turning over myoglobin. Heme degradation begins with the oxidation of the α-methene bridge carbon by microsomal heme oxygenase isoforms 1 and 2 (HO-1 and HO-2) by a reaction requiring oxygen and a reducing agent, such as NADPH. HO inhibition by non-metabolized "dead-end" inhibitors, such as tin-protoporphyrin or tin-mesoporphyrin, reduces serum bilirubin levels in neonates (Kappas and Drummond 1995). Oxidation of the α-methene bridge carbon of the ferroprotoporphyrin ring converts it to the linear tetrapyrrole, biliverdin, releasing 1 mol each of CO and iron. Heme breakdown can be quantified from CO exhaled in breath. CO regulates vascular tone in the liver and other organs, such as the heart under stressful conditions. The iron molecule is reutilized.

HO-1, encoded by the *HMOX1* gene, is ubiquitous and inducible by protoheme IX and oxidative/electrophilic stress signals. HO-1 is cytoprotective against oxygen radicals both directly and through its products, biliverdin and bilirubin. Induction of intestinal HO-1 protects against ischemia-reperfusion injury and bacterial lipopolysaccharides, as well as injury caused by indomethacin, trinitrobenzene sulfonic acid, and dextran sulfate. The physiological importance of HO-1 is highlighted by extensive endothelial injury, causing consumption coagulopathy, microangiopathic hemolytic anemia, low serum bilirubin, hyperlipidemia, and growth retardation observed in a patient with inherited frameshift mutation of *HMOX1* (Yachie et al. 1999). HO-2 is expressed mainly in the brain, and its induction in response to anoxia may be protective during ischemic attacks.

Two biliverdin reductase isozymes, BVRA and BVRB, reduce biliverdin to bilirubin. The *BVRB* gene, located at chromosome 19.q13, is expressed during early embryogenesis and primarily reduces biliverdin IXβ, the product of fetal heme-IXβ. *BVRA*, located on chromosome 7 (pter>q22), is expressed later and mediates the reduction of biliverdin IXα, the product of adult heme-IXα (O'Brien et al. 2015). The N-terminal domains of both isozymes contain catalytic sites for biliverdin reduction. The C-terminal region of BVRA (but not BVRB) contains a basic leucine zipper (bZiP) domain, which functions as a transcription factor that binds the antioxidant response element (ARE) and hypoxia response elements (HRE), and recruits the transcription factor, Nrf2. Nrf2 induces HO-1, thereby protecting against oxidative injury. Additionally, BVRA is an insulin receptor substrate and interacts with both major arms of insulin signalling, namely, the PI3-kinase/Akt and the IRK/IRS/PI3-kinase/MAPK pathways (Choi et al. 2013).

The antioxidant activity of bilirubin may be particularly important during the neonatal period, when intracellular availability of other antioxidants is low. Also there is accumulating evidence for the physiological benefit of bilirubin in adults. At relatively low serum bilirubin concentrations, an inverse relationship has been reported between bilirubin levels and the incidence of ischemic heart disease (Breimer et al. 1995), colon cancer (Zucker et al. 2004), abdominal visceral obesity, and metabolic syndrome (Choi et al. 2013). On the other hand, clinicians are more concerned with abnormal elevation of serum bilirubin, as an indicator of acquired hepatobiliary diseases, hemolysis, or a number of inherited disorders, which are the focus of this chapter. Bilirubin toxicity manifests primarily as bilirubin-induced neurological damage (BIND), caused by unconjugated bilirubin. BIND most commonly occurs when there is exaggerated neonatal jaundice. It can also occur in adults with severe inherited UGT1A1 deficiency, as seen in Crigler-Najjar syndrome type 1.

Bilirubin chemistry: Bilirubin IXα is a linear tetrapyrrole, the two dipyrrolic halves of which are joined by a central

methene bridge. The propionic acid side chain of each dipyrrolic half is internally hydrogen-bonded to the pyrrolic and lactam sites on the opposite dipyrrolic half (Bonnet et al. 1976), thereby engaging all polar groups. This renders bilirubin water-insoluble. Bilirubin remains in solution by binding to plasma albumin. In clinical laboratories, bilirubin is measured using the van den Bergh reaction (Van den Bergh and Muller 1916), in which diazo reagents attack the central methane bridge, generating two moles of azodipyrrole. Unconjugated bilirubin reacts slowly because of the inaccessibility of the central methene bridge due to hydrogen bonding. Disruption of hydrogen bonds by adding chemical accelerators makes the reaction rapid and complete ("total" bilirubin). In conjugated bilirubin, glucuronidation of the propionic acid carboxyls disrupts the hydrogen bonds, allowing the diazo reagents to react rapidly without accelerators ("direct-reacting" bilirubin).

Hepatic metabolism and elimination: Non-covalent binding to plasma albumin keeps unconjugated bilirubin in solution, preventing its tissue toxicity and renal excretion. Normally, albumin is in ~3-fold molar excess to bilirubin. As some metabolites and drugs can interfere with albumin binding, measurement of reserve bilirubin binding capacity may be needed for assessing BIND risk, particularly in premature infants. Peroxidase treatment, gel chromatography, electrophoretic analysis, and direct fluorimetry can be used for unbound bilirubin determination (Ahlfors et al. 2007). Conjugated bilirubin binds less tightly to albumin, and the unbound fraction is excreted in urine. Prolonged conjugated hyperbilirubinemia results in covalent binding of bilirubin to albumin (delta-bilirubin), delaying its clearance from plasma.

In liver sinusoids, bilirubin dissociates from albumin and undergoes facilitated diffusion into hepatocytes, where it is retained by binding to cytosolic glutathione S-transferases. Microsomal uridinediphosphoglucuronate glucuronosyltransferase type 1 (UGT1A1) catalyzes the transfer of glucuronic acid from UDP-glucuronate to bilirubin, forming mono- and diglucuronides. Glucuronidation makes bilirubin water-soluble, reduces its toxicity, and enables its secretion into bile canaliculi by the ATP-consuming pump, ABCC2 (also termed MRP2) (Fig. 58.1). A fraction of the bilirubin glucuronides is secreted into sinusoidal blood by ABCC3 and undergoes reuptake by hepatocytes located downstream to the blood flow via organic anion transporting polypeptides OATP1B1 (SLC01B1) and OATP1B3 (SLC01B3). This process increases bilirubin excreting capacity of the liver by recruiting additional hepatocytes to this process (see under Rotor syndrome).

Bilirubin glucuronides secreted into bile are degraded by intestinal bacteria into urobilinogen, stercobilinogen, and related products. Urobilinogen is partly reabsorbed from the intestine and undergoes enterohepatic circulation, but a small fraction is excreted in urine. Urobilinogen is colorless; but its yellow oxidation product, urobilin, contributes to the normal color of urine and stool.

To adapt to the demand for increased bilirubin clearance, such as during elevated bilirubin production due to hemolysis, bilirubin uptake, conjugation, and excretion need to be coordinately upregulated. Several nuclear receptors, including CAR and PXR, mediate coordinated regulation of these processes (Roy-Chowdhury et al. 2003).

Measurement of serum bilirubin has been used as a test for liver function and disease for many decades. In clinical laboratories, the fraction of bilirubin that reacts with diazo reagents rapidly without addition of a chemical "accelerator" is termed "direct"-reacting bilirubin. Total bilirubin is determined in the presence of an accelerator. The "indirect" bilirubin fraction is determined by subtracting the direct fraction from total bilirubin (Van den Bergh and Muller 1916). Direct bilirubin slightly overestimates the conjugated bilirubin fraction. More accurate measurements are possible using high-pressure liquid chromatography (HPLC) or thin-layer chromatography (TLC). By chromatographic analysis, approximately 4% of serum bilirubin is conjugated. When necessary, it is also possible to analyze bile pigments excreted in duodenal bile by HPLC. Inherited disorders of bilirubin metabolism can be classified into hyperbilirubinemia (a) due to exclusive increase in the unconjugated serum bilirubin fraction and (b) those associated with both conjugated and unconjugated bilirubin fractions (Nomenclature Table).

Nomenclature

No.	Disorder	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM no.

Metabolic Pathways

Effective biliary excretion of unconjugated bilirubin internalized into hepatocytes requires its conversion to polar conjugates by conjugation of one or both of its carboxyl groups with the glucuronic acid moiety transferred from UDP-glucuronic acid by the microsomal enzyme UDP-glucuronosyltransferase isoform 1A1 (UGT1A1). Absence or reduction of UGT1A1-mediated glucuronidation results in accumulation of unconjugated bilirubin in hepatocytes, which diffuses out into the sinusoidal blood. This results in an increase in the unconjugated fraction of serum bilirubin, along with reduction of the conjugated bilirubin fraction. Thus, the hyperbilirubinemia is contributed solely by unconjugated bilirubin, which is measured by subtracting the direct-reacting fraction from total bilirubin.

Following glucuronidation, conjugated bilirubin is pumped into bile across the biliary canaliculus by ABCC2, while a smaller component secreted into liver sinusoidal blood undergoes reuptake via sinusoidal organic anion transporters OATPB1 and OATPB3. Inherited disorders of canalicular secretion or sinusoidal reuptake cause Dubin-Johnson syndrome or Rotor syndrome, respectively. These disorders cause conjugated hyperbilirubinemia, without significant liver injury. Several other inherited disorders, termed progressive familial intrahepatic cholestasis, cause hyperbilirubinemia as a part of severe liver injury and cholestasis.

Signs, Symptoms, and Treatment

Inherited Disorders of Bilirubin Metabolism Associated with Increase of Exclusively Unconjugated Serum Bilirubin

UGT1A1-mediated glucuronidation is essential for effective excretion of bilirubin into the bile. Three inherited disorders

Table 58.1 Signs and symptoms of Crigler-Najjar syndrome type 1

System	Symptoms and signs	Neonatal	Infancy	Childhood	Adolescence	Adulthood
Conjunctiva, mucous membranes, skin	Yellow discoloration (jaundice)	++	+++	+++	+++	+++
Central nervous system	Abnormal eye movements	++	±	±	±	±
	Convulsions	±	++	++	+++	++
	Drowsiness, high-pitched crying	++	±			
	Inability to gaze upward	±	++	++	++	+
	Reduced muscle tone or muscle stiffness, choreoathetoid movements	+	++	++	+++	++
	Temperature instability	+	±			
Hearing	Loss of hearing	±	±	±	+	+
Routine laboratory tests	ALT, AST, alkaline phosphatase	n	n	n	n	n
	Serum bilirubin (all unconjugated)	425–500 μmol/L at 96 h	340–510 μmol/L	340–510 μmol/L	340–600 μmol/L	340–600 μmol/L
Special laboratory tests	Chromatographic analysis of pigments in duodenal bile				Only unconjugated bilirubin	Only unconjugated bilirubin
Pharmacological tests	Phenobarbital administration for 1 week			Total bilirubin reduced by <25%	Total bilirubin reduced by <25%	

result in various degrees of unconjugated hyperbilirubinemia from absence or reduction of UGT1A1 activity (Tables 58.1 and 58.2). The UGT1A locus, located at chromosome 2q37, consists of 4 exons (e2–e5) located at the 3′ end and a series of 12 additional exons (e1A1–e1A12) upstream (5′) to these exons. The bilirubin-conjugating enzyme, UGT1A1 is encoded by the UGT1A1 mRNA, which consists of five exons (exon e1A1 and e2-5). Notably, e2-5 also participate in mRNAs for several other UGT1A isoforms. Complete absence of UGT1A1 activity due to nonsense or missense coding region mutations of the UGT1A1 or splice site mutations leading to aberrant splicing of the RNA transcript results in Crigler-Najjar syndrome type 1 (DNA Testing Table). Lack of UGT1A1-mediated glucuronidation of bilirubin results in failure of biliary excretion and accumlation of unconjugated bilirubin in blood (Fig. 58.1). Crigler-Najjar syndrome type II is a milder disorder caused by missense coding region mutations that results in amino acid substitutions that markedly reduce the catalytic activity of UGT1A1 (DNA Testing Table). Finally, Gilbert syndrome is caused by reduced expression of catalytically normal UGT1A1 due to a common promoter variation consisting of insertion of TA dinucleotide in the TATAA box upstream to the UGT1A1 translation initiation site. Gilbert syndrome is associated with mild and/or intermittent unconjugated hyperbilirubinemia.

Comparison of inherited unconjugated hyperbilirubinemia syndromes

Features	Crigler-Najjar syndrome type 1 (CN1)	Crigler-Najjar syndrome type 2 (CN2)	Gilbert syndrome (GS)
Serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase	Normal	Normal	Normal
Pigments excreted in bile	Small amounts of unconjugated bilirubin	Increased proportion of bilirubin monoglucuronide (>10%)	Increased proportion of bilirubin monoglucuronide (>10%)
Hepatic bilirubin-UGT1A1 activity	Undetectable	Detectable but markedly reduced	Approximately 30% of normal
Effect of phenobarbital administration	No significant reduction of serum bilirubin	Reduction of serum bilirubin by <25% (with rare exceptions)	Normalization of serum bilirubin
Prevalence	Rare: <1 in 1,000,000	Rare: <1 in 1,000,000	Clinically in 3–5% of most populations. Genotypically ~9% in most populations
Prognosis	BIND unless vigorously treated. Cured by liver transplantation	BIND is uncommon, but occurs rarely	Innocuous, but may increase the toxicity of certain drugs.

BIND bilirubin-induced neurologic dysfunction

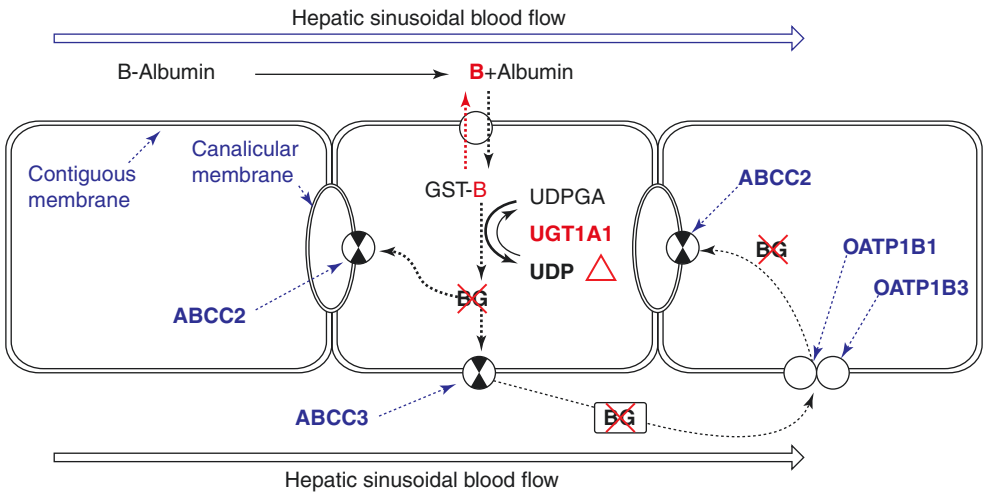

Fig. 58.1 Metabolic pathway of bilirubin disposal: Unconjugated bilirubin [B] enters hepatic sinusoids bound to serum albumin. At the sinusoidal surface of hepatocytes, bilirubin dissociates from albumin and is internalized by facilitated diffusion. In hepatocyte cytosol, bilirubin remains in solution bound to glutathione S-transferases [GSTs]. In the endoplasmic reticulum, UGT1A1 catalyzes the transfer of glucuronic acid from UDP-glucuronic acid (UDPGA) to bilirubin, forming bilirubin mono- and diglucuronides [BGs]. BGs are pumped out into the bile canaliculus by the ATP-consuming pump ABCC2, as well as by electrogenic mechanisms. A fraction of the BGs is pumped out into hepatic sinusoidal blood by ABCC3 and undergoes reuptake by hepatocytes located downstream to the blood flow via OATP1B1 and OATP1B3 and is subsequently excreted into the bile canaliculus by ABCC2

Crigler-Najjar Syndrome Type 1 (CN1)

Signs and Symptoms: This rare autosomal recessive disorder was originally described by Crigler and Najjar in six infants from three families (Crigler and Najjar 1952). The patients exhibited lifelong severe unconjugated hyperbilirubinemia resulting in bilirubin-induced neurological damage (BIND). Five of the 6 original cases died by 15 months of age, and the remaining patient lived for 15 years. Since then, several hundred CN1 patients have been reported in all races. With routine early implementation of phototherapy and plasmapheresis during acute hyperbilirubinemic crisis, many CN1 patients now survive beyond adolescence, but they remain at the risk of developing BIND around puberty or early adulthood (Wolkoff et al. 1979).

CN1 babies have normal serum bilirubin at birth, because during fetal life, bilirubin is cleared by the placenta. Serum bilirubin levels change from hour to hour after birth, and BIND risk depends on both the rate of rise and peak concentrations of bilirubin. Age-related curves have been constructed to correlate BIND risk to age-related bilirubin levels in newborns (Maisels 2015). In nearly all babies, serum bilirubin increases to above normal adult levels between 24 and 96 h of age. In healthy full-term newborns in Europe and North America, the 50th percentile for total serum bilirubin is 137–154 μmol/L (8–9 mg/dL), and the 95th percentile is about 257–300 μmol/L (15–17.5 mg/dL). In newborns with CN1 not treated with phototherapy or exchange transfusion, bilirubin levels at 96 h of age can exceed 425–510 μmol/L (25–30 mg/dL), at which levels penetration of the blood-brain barrier by bilirubin can lead to kernicterus with acute, and subsequently chronic, BIND, characteristically manifesting as choreoathetoid cerebral palsy and auditory neuropathy causing dyssynchrony with or without hearing loss. Normally, after 96 h, serum bilirubin declines rapidly. CN1 is suspected when serum bilirubin levels fail to normalize in 1 week despite phototherapy with or without plasmapheresis. Jaundice is usually the only initial presenting feature, although some patients may already exhibit signs of BIND. In older children maintained on phototherapy, a small amount of unconjugated bilirubin is excreted in bile, increasing the incidence of pigment gallstones and the risk of biliary obstruction.

Serum bilirubin levels usually range from 340 to 425 μmol/L, but may reach 850 μmol/L (Crigler and Najjar 1952) during intercurrent illness or if phototherapy is missed. Serum bilirubin is all unconjugated and tightly bound to albumin; therefore, bilirubinuria is absent. Bile samples obtained by duodenal intubation or endoscopy show the presence of small amounts of unconjugated bilirubin (Wolkoff et al. 1979). Fecal urobilinogen excretion is reduced, but the stool color remains normal (Crigler and Najjar 1952). As the bile canalicular transport mechanism remains normal, the biliary tree is visualized normally by cholecystographic agents, and bromosulfophthalein and indocyanine green are cleared normally from plasma after intravenous injection (Crigler and Najjar 1952) (See Table 58.1).

Liver biopsy is not usually required for the diagnosis. In infants, liver histology is normal, except for bilirubin plugs in bile canaliculi and bile ducts (Crigler and Najjar 1952; Maisels 2015). Older children may develop hepatic fibrosis. A recent study of 22 CN1 patients undergoing liver transplantation showed various degrees of liver fibrosis in 41% of the explanted livers (Mitchell et al. 2018). The fibrosis was not correlated with the presence of gallstones, and there was no evidence of portal hypertension.

Abnormalities of Hepatic UGT1A1. Hepatic UGT1A1 activity toward bilirubin is virtually absent in CN1. Depending

on the site of mutation, additional UGT1A isoforms may be catalytically inactive, so that glucuronidation of phenolic substrates may also be reduced (Bosma et al. 1992).

Treatment*:* Goal of the treatment of CN1 is to maintain serum bilirubin concentrations below neurotoxic levels. Liver transplantation is curative, but commits the patient to prolonged immunosuppressive therapy. Following is a brief discussion of the treatment modalities.

Phototherapy. Daily phototherapy is the standard maintenance therapy for reducing plasma unconjugated bilirubin (Maisels 2015). Banks of fluorescent lamps or more light-emitting diode (LED) lamps are used along with shielding the eyes. Exposure of the skin to light converts bilirubin IX_{α}-ZZ to its photoisomers that are excreted in bile. In newborns, use of phototherapy is based on age-related serum bilirubin concentrations: 260 μM at age 24–48 h, 310 μM at 49–72 h, and 340 μM at 72 h. If intensive phototherapy does not reduce serum bilirubin by at least 1–2 mg/dL within 4–6 h, plasmapheresis is considered (see below). By the age of 3 or 4 years, efficiency of phototherapy declines because of the thickening of skin, pigmentation, and reduction of surface area relative to body mass, requiring readjustment of the intensity and duration of phototherapy.

Plasmapheresis. If despite intensive phototherapy, serum bilirubin levels exceed the target levels described above by 85 μM, plasmapheresis is added to continued intensive phototherapy (Maisels 2015). Intensive phototherapy needs to be continued for several days because removal of albumin-bound bilirubin from blood mobilizes bilirubin from tissue stores to plasma, leading to secondary increase of bilirubin levels.

Orthotopic Liver Transplantation. Presently, the transplantation of whole liver or a liver lobe is the only available curative therapy for CN1 (Mazariegos et al. 2014). Liver transplantation has dramatically improved the prognosis of CN1 patients, although it commits the patient to prolonged immunosuppression.

Experimental Therapies

Heme oxygenase inhibition: Non-iron metalloporphyrins are dead-end heme oxygenase inhibitors (Kappas and Drummond 1995). Serum bilirubin concentrations were modestly reduced after tin-mesoporphyrin injection (0.5 μmol/kg, three times a week for 13–23 weeks) in two 17-year-old male CN1 patients. However, the duration of effect and safety of this treatment have not been established.

Hepatocyte transplantation: Hepatocytes have a high reserve UGT1A1 activity. Therefore, partial restitution of the enzyme activity in livers of CN1 patients should enable therapeutically significant reduction of serum bilirubin. After evaluation of the efficiency of hepatocyte transplantation in UGT1A1-deficient Gunn rats (Polgar et al. 2017), isolated allogeneic human hepatocytes were transplanted into the liver of an adolescent CN1 patient. Transplantation of 7.5×10^9 hepatocytes by infusion into the portal vein via a percutaneously placed catheter reduced serum bilirubin levels by about 50% and permitted reduction of the duration of phototherapy (Fox et al. 1998). Bilirubin glucuronides were detectable in duodenal bile samples for up to two and a half years, but after 2 years, serum bilirubin gradually increased to pretransplantation levels, requiring auxiliary liver transplantation, which normalized serum bilirubin levels (J. Roy-Chowdhury, personal communication). These results in this study and experience derived from a number of hepatocyte transplantations for CN1 performed by several investigators indicated that the number of hepatocytes that can be transplanted at a time, without causing prolonged portal hypertension, is insufficient for fully obviating the requirement for continued phototherapy (Iansante et al. 2018). Therefore, novel strategies are being explored to expand the mass of the engrafted hepatocytes. As the liver to body weight ratio is regulated tightly by physiological mechanisms, the engrafted hepatocytes can proliferate significantly only by replacing the mutant host hepatocytes by cell competition. Liver repopulation has been achieved in Gunn rats by preparative regional irradiation of the liver, combined with a variety of mitotic stimuli (Zhou et al. 2012). Partial hepatic irradiation enhanced both initial hepatocyte engraftment and subsequent proliferation of the donor hepatocytes, resulting in complete normalization of serum bilirubin levels (Zhou et al. 2012). Preparative irradiation for hepatocyte transplantation has been evaluated in non-human primates and in a patient with phenylketonuria (Soltys et al. 2016).

Gene Therapy. To reconstitute the missing hepatic UGT1A1 activity, gene therapy is being evaluated through (a) ex vivo gene therapy, consisting of transduction of primary hepatocytes using viral vectors, followed by transplantation into the liver, and (b) systemic administration of viral or non-viral vectors to express wild-type UGT1A1 in host hepatocytes in vivo. After initial validation in animal experiments, a clinical trial using recombinant adeno-associated viral vectors has been initiated for CN1 patients and (c) targeted gene editing by homologous recombination (Asp et al. 2019).

Targeted gene editing by homologous recombination is being explored using three different strategies (Asp et al. 2019): (a) gene repair to correct mutations, insertions, or deletions or (b) insertion of a UGT1A1 transcription unit at a genomic "safe haven" (such as the AAV-S1 site on human chromosome 19) or (c) insertion of a promoterless UGT1A1 open reading frame (orf) downstream to a highly expressed gene (e.g., albumin) to take advantage of the strong endogenous promoter. Homologous recombination is augmented by generating a nuclease-mediated DNA break which recruits DNA repair proteins at the break site. This can be achieved by expressing a peptide-nuclease fusion protein, e.g., zinc-finger nuclease (ZFN) or transcription activator-like effector nuclease (TALEN). Alternatively, site-directed DNA break can be generated using the CRISPR system, in which a nuclease, such as Cas9, can be guided to the site of interest and activated using a guide strand RNA. In in vivo experiments, usually recombinant adeno-associated viral vectors are used to express the transgenes for inducing targeted DNA breaks, as well as for delivering the DNA strand for homologous recom-

bination. Interestingly, expression from the albumin promoter is so efficient that a low level of homology-directed insertion of the UGT1A1 open reading orf 3′ to the albumin coding sequences is sufficient to reduce serum bilirubin levels in *Ugt1A1* gene-deleted jaundiced mice.

Crigler-Najjar Syndrome Type 2 (CN2, Also Termed Arias Syndrome)

Signs and Symptoms: Arias described a milder variant of Crigler-Najjar syndrome (Arias 1962) in which serum bilirubin usually ranges from 136 to 306 μmol/L (see Table 58.1), but can increase to 500 μmol/L during intercurrent illness, general anesthesia, or prolonged fasting. Kernicterus is unusual, but can occur during episodes of exacerbated hyperbilirubinemia (Arias 1962). As in CN1, the inheritance shows autosomal recessive pattern, and jaundice due to increased plasma unconjugated bilirubin is the main presenting feature. As there is some residual UGT1A1 activity, CN2 can be usually differentiated from CN1 by induction of UGT1A1 by phenobarbital administration. Also in contrast to CN1, bile contains a significant amount of bilirubin glucuronides. Whereas normal human bile contains predominantly bilirubin diglucuronide, in CN2 and Gilbert syndrome (see below), bilirubin monoglucuronide exceeds 30% of total bilirubin in duodenal bile (normal, ~10%). Liver biopsy is not necessary for diagnosis, but when performed shows normal histology. Hepatic UGT1A1 activity toward bilirubin is usually reduced to 10% normal.

Treatment*:* The baseline level of hyperbilirubinemia in CN2 patients does not increase the BIND risk sufficiently to require routine phototherapy. However, highly stressful situations, such as severe infections, major surgery, or prolonged fasting, can increase bilirubin concentrations to dangerous levels. In these cases, the patients can be treated on a short-term basis with phototherapy or, rarely, plasmapheresis. In special situations, phenobarbital may be used to reduce serum bilirubin levels.

Gilbert Syndrome

Signs and Symptoms: This very common disorder associated with mild, fluctuating, and occasionally intermittent unconjugated hyperbilirubinemia was described by Gilbert and Lereboullet in 1901 (Gilbert and Lereboullet 1901). More than a century later, Bosma and colleagues showed that Gilbert syndrome is caused by the insertion of a TA dinucleotide into the TATAA element in the proximal promoter of *UGT1A1* (Bosma et al. 1995). Gilbert syndrome is usually diagnosed incidentally in young adults from routine blood tests or during investigation of unrelated illnesses. Mild icterus is the only positive physical finding, and serum bilirubin is predominantly unconjugated. Bilirubin levels can be within normal limits, and are only elevated intermittently. In the absence of coexisting hemolytic conditions, e.g., glucose-6-phosphate dehydrogenase deficiency, or stressful situations, serum bilirubin usually remains below 51 μmol/L. Hyperbilirubinemia is exacerbated during intercurrent illness, stress, fasting, or menstruation. Not uncommonly, patients with known diagnosis of Gilbert syndrome erroneously ascribe fatigue and abdominal discomfort caused by other conditions to Gilbert syndrome. Incidence of pigment gallstones is higher in subjects with Gilbert syndrome than in general population. Liver biopsy is not necessary for diagnosis, but, when performed, shows normal histology.

Gilbert syndrome is one of the most common inherited disorders (Roy-Chowdhury et al. 2019). Clinical diagnosis of Gilbert syndrome has been reported in 3–7% of most populations, although prevalence of homozygous promoter variance (~9%) indicates that all cases are clinically diagnosed. Gilbert syndrome is diagnosed more frequently in males (Roy-Chowdhury et al. 2019), who have a higher baseline bilirubin levels. Increased erythrocyte mass during puberty with consequent increase in bilirubin production and inhibition of bilirubin glucuronidation by endogenous steroid hormones may make the diagnosis clinically apparent at adolescence.

Gilbert syndrome is diagnosed in individuals with mild unconjugated hyperbilirubinemia, but otherwise normal liver serology and no evidence of hemolysis. However, coexistent hemolytic disorders can make jaundice clinically obvious, bringing the patient to medical attention. Liver biopsy is not indicated for the diagnosis, but, when performed, shows reduced hepatic UGT1A1 activity (approximately 30% of normal) (Arias and London 1957). Where the diagnosis is in question, genetic analysis can be performed from a small amount of whole blood sample, usually submitted as a filter paper blot. Homozygosity for a TA dinucleotide insertion into the TATAA element within the proximal promoter region of UGT1A1 establishes the diagnosis. Chromatographic analysis of bile collected by duodenal aspiration via endoscopy shows an increased proportion of bilirubin monoglucuronide (>10%), reflecting reduced hepatic UGT1A1 activity. Reduction of caloric intake to 400 kcal/day for 2 days or nicotinic acid administration may make jaundice clinically detectable in Gilbert syndrome, but since these "challenges" also increase serum bilirubin in normal subjects, they do not provide definitive diagnosis.

Gilbert syndrome is not only innocuous; mild serum bilirubin elevation may have significant health benefits as suggested by reduced incidence of obesity and metabolic syndrome (Choi et al. 2013), ischemic coronary artery disease (Breimer et al. 1995), and colon cancer (Zucker et al. 2004). However, reduced UGT1A1 expression can affect glucuronidation and excretion of certain drugs (Roy-Chowdhury et al. 2019). Gilbert syndrome is associated with a high incidence of diarrhea in patients treated with the anticancer drug, irinotecan (Iyer et al. 1998). Oxidative intermediates of acetaminophen are associated with its drug toxicity. There is conflicting evidence in literature for reduced glucuronidation of these oxidative metabolites in subjects with the UGT1A1*28 allele.

Treatment. No treatment is necessary for Gilbert syndrome.

Inherited Disorders of Bilirubin Metabolism Associated with Predominantly Conjugated Hyperbilirubinemia

By chromatographic measurement, about 4% of serum bilirubin is conjugated, although diazo-based measurements in clinical laboratories overestimate the proportion to some extent (Roy-Chowdhury et al. 2019). Proportion of conjugated bilirubin increases in conditions where bilirubin glucuronides formed in hepatocytes are pumped out to plasma because of bile duct obstruction, inflammatory or ischemic liver injury, as well as inherited disorders of bile canalicular transport or failure of reuptake of bilirubin glucuronides transported out of the hepatocytes into sinusoidal blood. In addition, a number of cholestatic disorders termed progressive familial intrahepatic cholestasis can lead to various degrees of liver injury. In this chapter we will describe in brief two inherited disorders of bilirubin metabolism that cause accumulation of both conjugated and unconjugated bilirubin in plasma, without causing significant liver injury, Dubin-Johnson syndrome (Table 58.2) and Rotor syndrome (Table 58.3), and five inherited types of progressive familial intrahepatic cholestasis that cause hyperbilirubinemia in the context of significant liver injury.

Dubin-Johnson Syndrome (Table 58.2)

Signs and Symptoms: Dubin-Johnson syndrome is characterized by chronic or intermittent conjugated hyperbilirubinemia and grossly pigmented, but otherwise histologically normal liver. Mild jaundice is the only consistent presenting feature. Usually, the patients are otherwise asymptomatic, but vague abdominal pain and hepatosplenomegaly occur in some cases (Dubin 1958; Shani et al. 1970). Serum bile acid levels are nearly normal (Dubin 1958), and in contrast to chronic cholestatic disorders, pruritus is absent. Serum bilirubin levels increase during intercurrent illness, intake of oral contraceptives, and pregnancy (Iyer et al. 1998). Diagnosis is usually made in young adults. In some cases, the condition is identified during pregnancy or contraceptive use (Dubin 1958; Shani et al. 1970). Dubin-Johnson syndrome is innocuous, but the diagnosis is important, because increased serum conjugated bilirubin levels suggest inflammatory or cholestatic hepatobiliary diseases.

Serum bilirubin levels usually range from 34 to 85 μmol/L, but levels as high as 340–425 μmol/L have been reported in rare situations. More than half of serum bilirubin is direct-reacting, and bilirubin is excreted in urine. Liver serology, including ALT, AST, and alkaline phosphatase, is normal. In contrast to other cholestatic conditions, serum bile acid levels are normal in adult patients with Dubin-Johnson syndrome (Shani et al. 1970). As the functional defect involves hepatocellular canalicular excretion for multiple organic anions, other than most bile acids, oral cholecystography does not visualize the gallbladder even using the contrast material at "double dose." Intravenous administration of meglumine iodipamide (Biligrafin) may enable visualization of the gallbladder after 4–6 h (Roy-Chowdhury et al. 2019).

Organic Anion Transport. A large variety of organic anions, including bilirubin glucuronides, but not most bile acids are pumped out into the bile canaliculus from the hepatocyte against a concentration gradient by an energy-consuming ATP-dependent protein ABCC2 or MRP2 (Fig. 58.2) (Roy-Chowdhury et al. 2019; Shani et al. 1970). Much of the information on the function of Abcc2 has come from studies in the jaundiced TR^- rat strain (Paulusma et al. 1996). In this rat strain, biliary excretion of sulfated or glucuronidated bile acids was found to be deficient. Consistent with this, in a subsequent multicenter study, neonates with Dubin-Johnson syndrome were found to have significantly increased serum total

Table 58.2 Signs and symptoms of Dubin-Johnson syndrome

System	Symptoms and signs	Neonatal	Infancy	Childhood	Adolescence	Adulthood
Conjunctiva, mucous membranes, skin	Yellow discoloration (jaundice) Increased jaundice during pregnancy and contraceptive use	±	±	+	++	++ +
Abdominal pain	Vague upper abdominal pain				±	±
Routine laboratory tests	ALT, AST, alkaline phosphatase, γ-glutamyl transpeptidase	+				
	Elevated serum bilirubin (predominantly conjugated)	+	±	+	++	++
	Plasma bile salt elevation	+	±			
Special laboratory tests	Urinary coproporphyrinogen chromatography: Increased proportion of isoform I	+	+	++	+++	+++
Oral cholecystography	Non-visualization even with double dose of contrast			+	+	+
Liver biopsy	Macroscopic: Black liver			+	++	+++
	Microscopic: Dark brown pigments			+	++	+++
Pharmacological tests	Plasma bromosulfophthalein clearance: Normal at 45 min, secondary rise at 90 min			+	++	++

Table 58.3 Signs and symptoms of Rotor syndrome

System	Symptoms and signs	Neonatal	Infancy	Childhood	Adolescence	Adulthood
Conjunctiva, mucous membranes, skin	Yellow discoloration (jaundice)	±	±	+	++	++ +
Routine laboratory tests	ALT, AST, alkaline phosphatase, γ-glutamyl transpeptidase					
	Elevated serum bilirubin (predominantly conjugated)	±	±	+	++	++

Liver biopsy	No pigmentation	n	n	n	n	n
Pharmacological tests	Plasma bromosulfophthalein retention at 45 min, no secondary rise			+	++	++

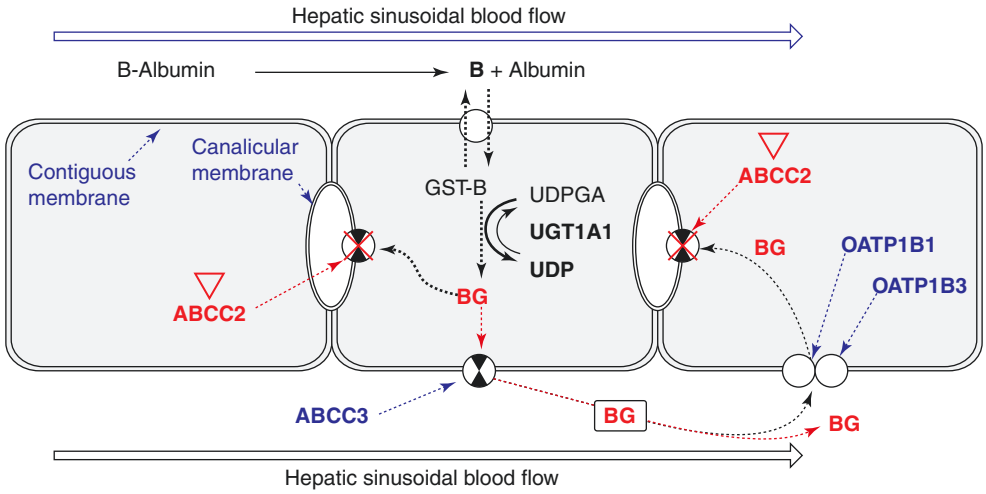

Fig. 58.2 Dubin-Johnson syndrome is caused by mutations of the bile canalicular ATP-utilizing pump, ABCC2. This protein is involved in pumping a large number of organic anions into the bile canaliculus, including bilirubin glucuronides (BGs), but not including most bile salts. Conjugated bilirubin retained in the hepatocytes is pumped out across the sinusoidal surface membrane of hepatocytes by alternative pumps, such as ABCC3, resulting in an increase in the conjugated fraction of serum bilirubin

bile acid levels (Togawa et al. 2018). Despite the lack of ABCC2, serum bilirubin is only mildly elevated, suggesting additional pathways of excretion of bilirubin conjugates in bile. In addition, accumulated organic anions within the hepatocytes upregulate the expression of ABCC11 and ABCC3 at the basolateral surface of the hepatocytes. These and possibly additional ATP-consuming pumps may transport both unconjugated and conjugated bilirubin from the hepatocyte to plasma (Roy-Chowdhury et al. 2019).

Urinary Coproporphyrin Excretion. In normal adults approximately 75% of the urinary coproporphyrin is isomer III, the precursor of heme. The remaining is coproporphyrin I. In Dubin-Johnson syndrome, over 80% of total urinary coproporphyrin is isomer I, but total urinary coproporphyrin excretion is normal (Kaplowitz et al. 1972). In neonates, the proportion of urinary coproporphyrin I is higher than in adults, but not as high as in Dubin-Johnson syndrome. The relationship of the abnormal urinary porphyrin excretion pattern to defective organic anion transport is not known. Together with consistent clinical presentation, the urinary coproporphyrin excretion pattern is diagnostic of Dubin-Johnson syndrome.

As indicated in Fig. 58.2, the uptake mechanism at the sinusoidal surface of hepatocytes is unaffected in Dubin-Johnson syndrome. Consistent with this, after intravenous injection of the organic anion BSP (bromosulfophthalein), initial decline of plasma BSP concentration is nearly normal for 45 min, but, in most patients, there is a secondary increase in plasma BSP concentration at 90 min because of the reflux of glutathione-conjugated BSP from hepatocytes into the circulation (Roy-Chowdhury et al. 2019). However, such secondary rise of plasma BSP can also occur in other cholestatic disorders (Roy-Chowdhury et al. 2019). Therefore, the BSP clearance pattern is not pathognomonic of Dubin-Johnson syndrome.

Liver Histology: The liver is black in color, which is a distinguishing characteristic of Dubin-Johnson syndrome. Light microscopy reveals a dense brown pigment (Fig. 58.3). After intravenous infusion of ^{3}H-epinephrine into mutant Corriedale sheep (an animal model for Dubin-Johnson syn-

drome), radioactivity is incorporated into the pigment, which may consist of polymers of epinephrine metabolites (Roy-Chowdhury et al. 2019). Following liver regeneration after massive hepatocellular death, the pigment is cleared from the liver, but reaccumulates slowly after recovery.

Treatment*:* No treatment is required for Dubin-Johnson syndrome.

Rotor Syndrome (Table 58.3)

Signs and Symptoms: Rotor syndrome is characterized by lifelong mild hyperbilirubinemia without evidence of hemolysis (Rotor et al. 1948). Elevation of serum bilirubin levels is predominantly due to increase in the conjugated bilirubin fraction. Serum ALT, AST, alkaline phosphatase, and other routine blood biochemistries are normal (Table 58.3). In these respects, the clinical phenotype resembles that of Dubin-Johnson syndrome. However, in contrast to Dubin-Johnson syndrome, there is no pigmentation accumulation in the liver. Liver histology is normal. Rotor syndrome is harmless (Kaplowitz et al. 1972), but the diagnosis is important because, as in Dubin-Johnson syndrome, increased serum conjugated bilirubin fraction may suggest inflammatory or cholestatic hepatobiliary diseases. Rotor syndrome is rare, but has been reported in several races.

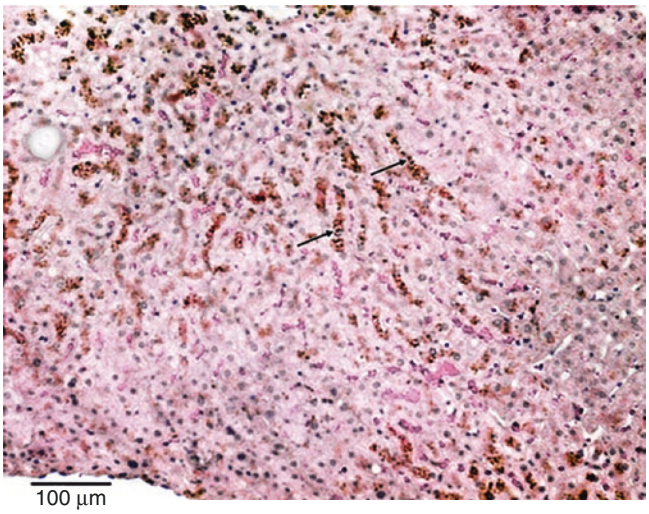

Fig. 58.3 Hematoxylin/eosin staining of liver section in a patient with Dubin-Johnson syndrome. The liver architecture and histology are normal, except for dark brown pigments (arrows) predominantly in centrizonal (Zone 3) hepatocytes

Organic Anion Excretion. In contrast to Dubin-Johnson syndrome, canalicular secretion of organic anions is normal in Rotor syndrome, but the reuptake of bilirubin glucuronides and several other conjugated substances by hepatocyte sinusoidal membranes is defective as result of complete deficiency of two organic anion transport proteins, OATP1B1 and OATP1B3 (Fig. 58.4) (Roy-Chowdhury et al. 2019; van de Steeg et al. 2012). As in many acquired liver diseases, and in contrast with Dubin-Johnson syndrome, over 25% of injected BSP is retained in serum at 45 min, and there is no secondary rise of plasma BSP level (Roy-Chowdhury et al. 2019). Plasma clearance of intravenously administrated unconjugated bilirubin and ICG is also delayed. In contrast to the findings in Dubin-Johnson syndrome, bile canalicular export pumps are normal in Rotor syndrome; therefore, the gallbladder is visualized by oral cholecystography (Fig. 58.4).

Urinary Coproporphyrin Excretion. Total urinary coproporphyrin excretion in Rotor syndrome is increased two- to fivefold over normal. Approximately 65% of the urinary cop-

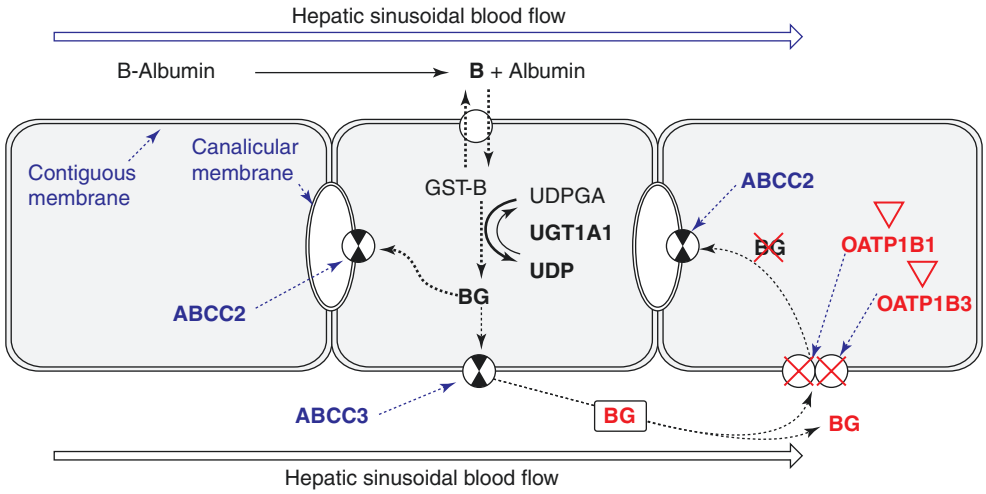

Fig. 58.4 Rotor syndrome is caused by simultaneous deficiency of the organic anion transporters OATP1B1 and OATP1B3 at the sinusoidal membrane of hepatocytes. While the majority of bilirubin glucuronides (BGs) formed by the action of UGT1A1 is normally secreted into the bile canaliculus, a fraction is pumped out into the hepatic sinusoidal blood by ABCC3. This fraction of bilirubin glucuronides undergoes reuptake by hepatocytes located downstream to the blood flow via OATP1B1 and OATP1B3 (encoded by the *SLC01B1* and *SLC01B3* genes, respectively). Lack of bilirubin glucuronide reuptake results in mild conjugated hyperbilirubinemia

roporphyrin has been reported to be isomer I (Roy-Chowdhury et al. 2019). This pattern is similar to that found in many other hepatobiliary disorders, but is distinct from that seen in Dubin-Johnson syndrome (see above). However, in two brothers with characteristic clinical features of Rotor syndrome, over 80% of urinary coproporphyrins was isomer I (Roy-Chowdhury et al. 2019), raising doubts about the utility of urinary coproporphyrin analysis in distinguishing Rotor from Dubin-Johnson syndrome.

Treatment*:* No treatment is required for Rotor syndrome.

Progressive Familial Intrahepatic Cholestasis. These conditions do not affect the bilirubin throughput pathway directly, but result in elevation of both serum unconjugated and conjugated bilirubin levels as a result of hepatocellular injury. Five life-threatening monogenic disorders, collectively termed progressive familial intrahepatic cholestasis (PFIC-1, PFIC-2, PFIC-3, PFIC-4, PFIC-5), can cause cholestasis, associated with severe liver injury, affecting the secretion of bile acids or other components of bile into the bile canaliculi. It is likely that additional gene mutations causing PFIC will be discovered. Some mutations of the genes associated with the PFIC syndromes cause only partial loss of function, resulting in a milder phenotype of the diseases, namely, benign recurrent intrahepatic cholestasis (BRIC) or mild chronic liver disease, resulting in delayed liver fibrosis or cirrhosis. Inherited cholestatic diseases including the PFIC syndromes have been reviewed recently (Henkel et al. 2019), and a brief discussion follows.

Progressive Familial Intrahepatic Cholestasis Type 1 (Table 58.4)

Signs and Symptoms*:* Progressive familial intrahepatic cholestasis type 1 (PFIC 1) was originally described in an Amish Mennonite family and was named Byler's disease, after the family name of the first patient (Roy-Chowdhury et al. 2019; Henkel et al. 2019). It has been also termed Greenland-Eskimo familial cholestasis. PFIC-1 is associated with severe life-threatening cholestatic liver disease along with extrahepatic manifestations. Abnormality of aminophospholipid transfer from the outer leaflet of plasma membrane to the inner leaflet results in hyperbilirubinemia and accumulation of bile salts in plasma. Infants often present with jaundice, pruritus, and hepatosplenomegaly. When the disease is severe, cholestasis is persistent and progressive resulting in development of portal hypertension in early childhood. Although serum ALT and AST are elevated, γ-glutamyl transpeptidase (GGT) level remains normal. Severe extrahepatic manifestations, such as profound diarrhea, poor growth, short stature, pancreatic insufficiency, elevated sweat chloride, and sensorineural deafness (Henkel et al. 2019; Clayton et al. 1969), distinguish this disease from other inherited cholestatic disorders. The liver shows canalicular cholestasis with biliary plugs, giant cell transformation, paucity of bile ducts, and lobular disarray. The bile has a granular appearance.

Treatment: As with all forms of PFIC, no definitive medical therapies are available. Supportive measures include improving nutritional deficiencies by caloric, fat (mainly

Table 58.4 Signs and symptoms of progressive familial intrahepatic cholestasis type 1

medium chain triglycerides), and vitamin supplementation. Ursodeoxycholic acid (UDCA) is administered to replace the hydrophobic bile salt pool, as well as to induce bile salt excretory protein (BSEP) and MDR3 expression. UDCA administration usually improves pruritus (Roy-Chowdhury et al. 2019; Henkel et al. 2019).

Surgical Interruption of Bile Salt Reabsorption: When medical therapy is insufficient, surgical procedures aimed at interruption of enterohepatic recycling of bile acids have been used for the treatment of PFIC. Partial external biliary diversion (cholecysto-jejunal cutaneous fistula) or ileal bypass can reduce pruritus and improve growth rate in many cases. More recently, partial internal biliary diversion (PIBD) has been utilized by creating a neo-conduit between the gallbladder and the colon to prevent reabsorption of bile acids in the terminal ileum (Clayton et al. 1969). In addition to relieving pruritus, these procedures have been reported to reduce plasma bile acid and bilirubin levels.

Liver Transplantation: Patients with a refractory course and those who have developed end-stage liver disease require liver transplantation. It should be noted that diarrhea associated with PFIC-1 may persist or even worsen after liver transplantation. Furthermore, the allograft may develop steatosis and fibrosis, and in some cases ileal diversion has been performed at the time of liver transplantation to prevent hepatic steatosis. (Gunaydin et al. 2016).

Progressive Familial Intrahepatic Cholestasis Type 2 (PFIC-2) (Table 58.5)

This condition results from defective transport of bile acids from hepatocytes into the bile canaliculi, leading to hepatotoxicity from accumulated bile salts. Deficiency of bile salts in the intestinal lumen results in fat indigestion and malabsorption.

Signs and Symptoms: Affected infants initially present with jaundice. Pruritus develops at 4–5 months of age. Hepatomegaly and growth retardation due to malabsorption of fat and fat-soluble vitamins may also be apparent. Extrahepatic symptoms are less pronounced than in FIC1 deficiency, but the disease often progresses to portal hypertension within the first year of life (Henkel et al. 2019). Typically, serum aminotransferase levels are over twice the upper limit, and both conjugated and unconjugated bilirubin are elevated. But serum GGT levels remain normal (Henkel et al. 2019).

Liver biopsy typically shows evidence of canalicular cholestasis, hepatocellular disarray, and lobular and portal fibrosis (Roy-Chowdhury et al. 2019; Henkel et al. 2019). Up to 15% of PFIC-2 patients develop liver malignancy (hepatocellular carcinoma and cholangiocarcinoma), which can occur in children as early as at 13 months of age (Knisely et al. 2006). Therefore, PFIC-2 patients need to be screened for liver cancer by serum α-fetoprotein (AFP) level and abdominal ultrasonography every 6–12 months.

Treatment: Medical treatment is primarily supportive and includes nutritional supplementation and antipruritic agents. Enhancers of the residual cell surface BSEP such as 4-phenylbutyrate have been promising. Surgical interruption of the enterohepatic circulation ameliorates pruritus but not progression of liver injury (Wang et al. 2017). In general, patients with some residual BSEP function have better prognosis than those with severely dysfunctional or absent BSEP (Roy-Chowdhury et al. 2019; Henkel et al. 2019).

Liver transplantation: Liver transplantation has been performed in PFIC-2 patients with a severe course and in those who develop tumor. However, some recipients develop alloreactive antibodies specific to the extracellular loop of the BSEP protein, which may cause an immune-mediated recur-

rence of BSEP disease in the allograft, which may respond to standard immunosuppression, although refractory disease recurrence may require B-cell-depleting antibody therapy and allogeneic hematopoietic stem cell transplantation (Krebs-Schmitt et al. 2019). Some patients have required repeat liver transplantation (Krebs-Schmitt et al. 2019).

Progressive Familial Intrahepatic Cholestasis Type 3 (PFIC-3) (Table 58.6)

PFIC-3 results from defects of energy-consuming transport of phosphatidylcholine from the inner lipid leaflet of the bile canaliculus to the outer leaflet. This process normally replenishes the phospholipid in the outer leaflet, which is continuously removed by high concentrations of bile acid in the bile canaliculi. Failure of phosphatidylcholine replenishment results in chronic bile salt-mediated injury of the canalicular membrane and small bile ducts (Roy-Chowdhury et al. 2019; Henkel et al. 2019).

Signs and Symptoms*:* PFIC-3 has been diagnosed in some cases in the first months of life or in children, but patients usually present in late adolescence or even adulthood (Schatz et al. 2018). Those diagnosed in childhood present with pruritus at about 1 year of age, and most have hepatosplenomegaly, portal hypertension, and jaundice at presentation. Children and adolescents may initially present with variceal bleeding, without significant prior symptoms. Many patients in the pediatric age group also have growth restriction, reduced bone density, and learning disability (Schatz et al. 2018). Adult patients can present with slowly progressive disease, cholelithiasis, drug-induced cholestasis, or benign recurrent intrahepatic cholestasis (also see below under BRIC).

In contrast to other PFICs, GGT is typically elevated at presentation, despite relatively milder elevation of serum bilirubin and transaminases.

Portal fibrosis and bile duct proliferation with mild giant cell hepatitis are usually seen early in the course of the disease with occasional intraductal cholelithiasis (Roy-Chowdhury et al. 2019; Henkel et al. 2019). MDR3 is often absent by immunohistochemical staining, but may be visualized when there are functional protein defects. Both hepatoma and cholangiocarcinomas may be found.

Treatment: Supportive management includes nutritional supplements and antipruritic agents. Liver transplantation offers the only definitive therapy.

Benign Recurrent Intrahepatic Cholestasis (BRIC) presents with recurrent episodes of cholestasis in adolescence or early adulthood, characterized by both conjugated and unconjugated hyperbilirubinemia, malaise, anorexia, pruritus, weight loss, and malabsorption. During the attacks that last weeks to months, laboratory tests are typical of cholestasis without severe hepatocellular injury (Biempica et al. 1967). The cholestatic episodes are followed by a complete clinical, biochemical, and histological resolution. In individual patients, the clinical features and duration of the episodes resemble those in previous attacks. Liver biopsy shows noninflammatory intrahepatic cholestasis without fibrosis, even after multiple episodes. During remission, the liver appears normal by light and electron microscopy (Roy-Chowdhury et al. 2019; Biempica et al. 1967). Interestingly, this relatively benign disorder is also caused by certain missense mutations of the *ATP8B1, ABCB11*, or *ABCB4* genes (BRIC-1, BRIC-2, and BRIC-3, respectively).

Table 58.6 Signs and symptoms of progressive familial intrahepatic cholestasis type 3

Progressive Familial Intrahepatic Cholestasis Type 4 (PFIC-4)

In a multi-institution collaborative study, 33 children with severe chronic cholestatic liver disease but with low GGT for the degree of cholestasis were found to have no mutations of either *ABCB11* or *ATP8B1*, which cause PFIC-1 or PFIC-2, respectively. Therefore, these patients were designated as having PFIC-4. Subsequently, histological analysis showed deficiency of the tight junction protein 2 (TJP2) (Henkel et al. 2019; Sambrotta et al. 2014).

Signs and Symptoms: Infants present with severe liver disease during the first few months of life. Although only a small number of patients have been reported so far, retrospective re-classification suggests that TJP2 deficiency may be more common than previously thought.

Increased serum bilirubin and transaminase levels indicate severe liver injury, but as in PFIC-1 and PFIC-2, serum GGT levels are normal or low for the degree of cholestasis. Histological examination of the liver shows evidence of intracellular cholestasis and giant cell transformation. Immunohistochemical staining reveals absence of TJP2. Hepatocellular carcinoma was found at presentation in several infants (Zhou et al. 2015).

Treatment: As the liver injury and cholestasis are severe from the onset, 9 of the 12 initially reported patients have undergone liver transplantation. Two others who did not receive liver transplantation have survived, but have developed portal hypertension (Henkel et al. 2019; Zhou et al. 2015).

Progressive Familial Intrahepatic Cholestasis Type 5 (PFIC-5) (Table 58.7)

This is a rare disease caused by abnormality of the nuclear receptor FXR, which in turn regulates BSEP. So far five patients have been reported in literature (Henkel et al. 2019; Gomez-Ospina et al. 2016).

Signs and Symptoms: All reported patients with this defect presented in the neonatal period and rapidly progressed to end-stage liver disease with coagulopathy and hyperammonemia.

Serum ALT and AST are initially normal, and as in PFIC 1, 2, and 4, GGT remains normal. Serum bile acid levels are elevated and AFP levels can be very high. With the onset of end-stage liver disease, coagulopathy that is not reversed by vitamin K and hyperammonemia occur (Henkel et al. 2019).

Histologically, the liver shows evidence of intralobular cholestasis with ductular reaction, hepatocellular ballooning, giant cell transformation, and fibrosis with progression to micronodular cirrhosis.

Treatment: Of the five patients reported in literature, three underwent liver transplantation. However two of the transplant recipients showed steatosis in the graft organ on follow-up.

Table 58.7 Signs and symptoms of progressive familial intrahepatic cholestasis type 5

System	Symptoms and signs	Neonatal	Infancy	Childhood	Adolescence	Adulthood

Reference Values

Age	Serum total bilirubin (μmol/L)	Serum unconjugated bilirubin (μmol/L)[a]	Serum conjugated bilirubin (μmol/L)[a]	Total plasma bile acids (μmol/L)
Newborn				
At birth	1.71–25	1.2–17.5	0.51–7.5[a]	3.85–6.32 (isomer I: 25%)
At 96 hr				
50th percentile	137–154	124–139[a]	13–15[a]	
96th percentile	257–300	251–270	26–30[a]	
Infant	1.71–17	1.21–12[a]	0.5–5.1[a]	6.61–9.43 (isomer I 25%)
Adult	1.71–20.5	1.21–14.5[a]	0.5–6.0[a]	0.28–6.50 (isomer I 25%)

[a]By methods using diazo reagents, which overestimate conjugated bilirubin. By chromatographic measurements, approximately 4% of total serum bilirubin in normal adults is conjugated

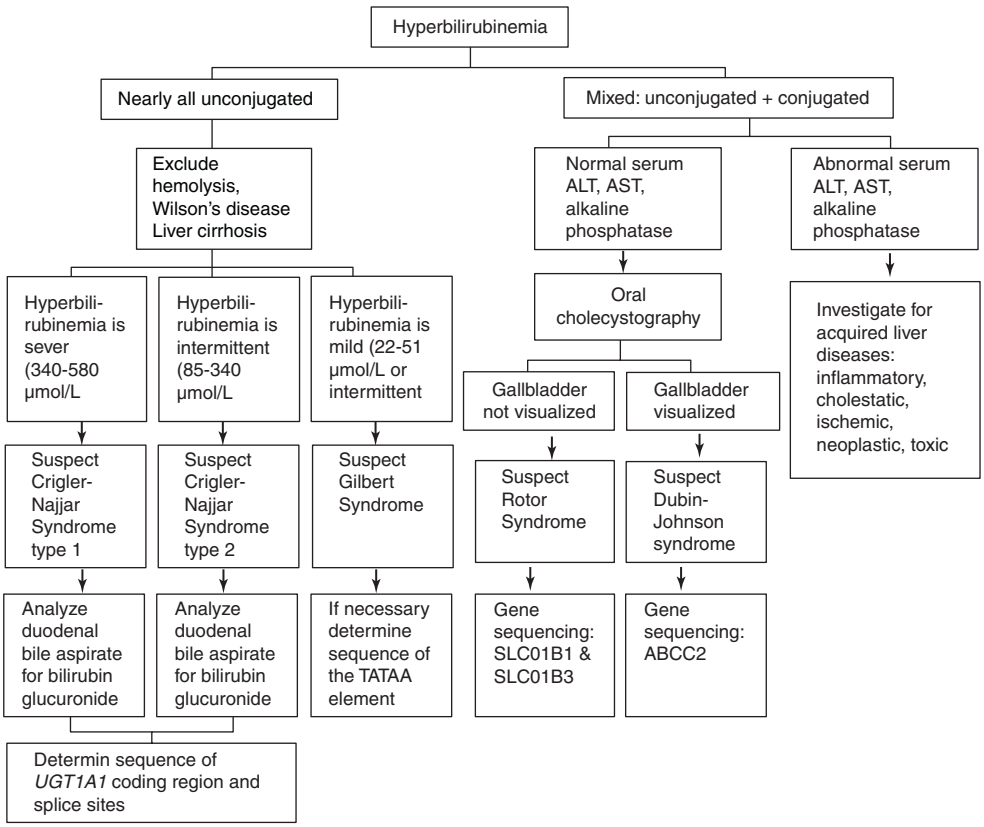
Pathological Values

Disorder	Serum unconjugated bilirubin (μmol/L)	Serum conjugated bilirubin (μmol/L)[a]	Plasma bile acids (μmol/L)	Total urine coproporphyrin (μmol/L) (% isomer-I)
Crigler-Najjar type 1	340–600	0[a]		
Crigler-Najjar type 2	136–306	>4% of total[a]		
Gilbert syndrome	15–51	>4% of total[a]		
Dubin-Johnson syndrome	9–35	25–50	0.28–6.50[b]	0.28–6.50 (isomer I: 80%)
Rotor syndrome			20–33	16–33 (isomer I: ~50%)

[a]Conjugated bilirubin values obtained by chromatographic analysis. Diazo reagent-based assays show artifactually higher proportions of conjugated ("direct-reacting") bilirubin

[b]Neonates with Dubin-Johnson syndrome may have abnormally high serum bile acid levels

Diagnostic Flowchart



Specimen Collection

Test	Sample requirement	Special handling/storage
Bilirubin: • Total • conjugated • unconjugated	Serum sample, at least 0.5 ml	Protect from bright light Analysis to be completed by: • room temperature: 2 days • 0–4.0 °C: 3 days • frozen (−20 °C): 14 days
Plasma bile acid	Anticoagulated blood (EDTA or heparin) At least 0.2 ml	Analysis to be completed by: • Room temperature: 1 day • 0–4.0 °C: 3 days • Frozen (−20 °C): 7 days

Prenatal Diagnosis

Disorder	Material	Timing (post-conception)
Crigler-Najjar syndrome type 1	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks
Crigler-Najjar syndrome type 2	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks
Progressive familial intrahepatic cholestasis type 1 (PFIC-1)	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks
PFIC-2	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks
PFIC-3	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks
PFIC-4	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks
PFIC-5	• Amniotic fluid (30 ml) collected by amniocentesis • Chorionic villus sampling	16–20 weeks (or later) 11–14 weeks

DNA testing

Disorder	Gene	Comments
Crigler-Najjar syndrome type 1 (CN1)	*UGT1A1*	Insertions, deletions, or single nucleotide mutations (nonsense or missense) within any of the five exons comprising the coding region of UGT1A1 can result in complete or near-complete loss of UGT1A1 activity. Genetic lesions within exon 1 affect only UGT1A1, but lesions within exons 2–5 affect all UGT isoforms expressed from the UGT1A locus. Intronic lesions leading to splicing abnormalities can also cause CN1
Crigler-Najjar syndrome type 2 (CN2)	*UGT1A1*	CN2 is caused by nonsynonymous missense mutations within coding region of UGT1A1 that lead to a single amino acid substitution, causing reduction of UGT1A1 catalytic activity to ~10% of normal
Gilbert syndrome (GS)	*UGT1A1*28*	GS is caused by homozygosity for the insertion of a TA dinucleotide within the TATAA element 29 nt 5′ of the translation initiation site of UGT1A1. The GS-type promoter reduces UGT1A1 expression to ~30% of normal. Because of the high frequency of the GS promoter in general population, it may coexist with other genetic disorders. In heterozygote carriers of CN1 or CN2, presence of a GS promoter in the allele with normal coding region reduces UGT1A1 expression, resulting in an intermediate level of jaundice
Dubin-Johnson syndrome (DJS)	*ABCC2*	Genetic lesions within the coding region include insertions, deletions (in-frame or frameshift), non-sense mutations, or nonsynonymous single nucleotide transitions. In addition, splice site mutations within introns may result in exon skipping
Rotor syndrome	*SLC01B1; SLC01B3* (digenic)	The Rotor syndrome phenotype requires simultaneous genetic lesions within the coding regions of both *SLC01B1*and *SLC01B3*. In addition, inversion of exon 4 of *SLC01B3* has been reported
Progressive familial intrahepatic cholestasis type 1 (PFIC-1) and benign recurrent intrahepatic cholestasis (BRIC-1)	*ATP8B1*	Nonsense mutations, nonsynonymous nucleotide transitions, small (three-base) or large deletions, a seven-base duplication, and intronic mutations leading to splicing abnormality of ATP8B1 pre-mRNA have been reported to cause PFIC1. Patients are homozygotes or compound heterozygotes In BRIC-1, *ATP8B1* point mutations are nonsynonymous
PFIC-2 and BRIC-2	*ABCB11*	Nonsense mutations, small insertions, or deletions leading to truncated protein, and single nonsynonymous mutations within the ABCB11 coding region can cause PFIC-2. In addition, intronic mutations and a synonymous mutation predicted to affect splicing have been reported In BRIC-2, *ABCB11* point mutations are nonsynonymous.
PFIC-3 and BRIC-3	*ABCB4*	A large number of nonsynonymous, nonsense, or frameshift mutations and short insertions within the coding region of the ABCB4 gene have been reported to affect the function of various domains of ABCB4 (bile canalicular “flopase”) In BRIC3, the point mutations are nonsynonymous.
PFIC-4	*TJP2*	Patients are homozygotes or compound heterozygotes for a variety of genetic lesions of *TJP2*. Small deletions (1–4 bases) within exons, causing frameshift, and a nonsense mutation have been described. Intronic mutations can result in deletions ranging from 2-nt to 11 entire exons
PFIC-5	*NR1H4*	Patients are homozygotes or compound heterozygotes for nonsense mutations, in-frame insertions, or large deletions (37.2 kb) spanning exons 1 and in the *NR1H4* gene

Contents

Summary

The term autophagy derives from the Greek word autóphagos, which means "self-eating" or "self-digestion." Autophagy is a fundamental and highly conserved intracellular pathway that in its most basic sense involves the delivery of cytoplasmic cargo to the lysosome for degradation. The Nobel Laureate in Physiology and Medicine in 1974, Christian de Duve, introduced this term to describe the self-eating function of lysosomes in degrading intracellular debris, including damaged organelles (mitochondria, endoplasmic reticulum membranes, ribosomes), and other cellular components such as larger protein aggregates (Harnett et al. 2017). Based on different modes of cargo delivery to lysosomes, three subtypes of autophagy have been defined: macro-autophagy, micro-autophagy, and chaperone-mediated autophagy. In macro-autophagy, cargo is transported inside double-membrane vesicles (or autophagosomes) which are delivered to and fused with lysosomes to form the autolysosome. In micro-autophagy, the cytosolic cargo is trapped in small vesicles formed by invagination of the lysosomal membrane. In chaperone-mediated autophagy, substrates are selectively targeted by hsp70 to the microvesicles and delivered by the receptor protein LAMP2 for lysosomal degradation.

Introduction

The term autophagy derives from the Greek word autóphagos, which means "self-eating" or "self-digestion." Autophagy is a fundamental and highly conserved intracellular pathway that in its most basic sense involves the delivery of cytoplasmic cargo to the lysosome for degradation. The Nobel Laureate in Physiology and Medicine in 1974, Christian de Duve, introduced this term to describe the self-eating function of lysosomes in degrading intracellular debris, including damaged organelles (mitochondria, endoplasmic reticulum membranes, ribosomes), and other cellular components such as larger protein aggregates (Harnett et al. 2017). Based on different modes of cargo delivery to lysosomes, three subtypes of autophagy have been defined: macro-autophagy, micro-autophagy, and chaperone-mediated autophagy. In macro-autophagy, cargo is transported inside double-membrane vesicles (or autophagosomes) which are delivered to and fused with lysosomes to form the autolysosome. In micro-autophagy, the cytosolic cargo is trapped in small vesicles formed by invagination of the lysosomal membrane. In chaperone-mediated autophagy, substrates are selectively targeted by hsp70 to the microvesicles and delivered by the receptor protein LAMP2 for lysosomal degradation.

Besides its key function in degradative pathways, autophagy contributes to biosynthetic and secretory processes and is associated with a wide range of physiological processes including embryogenesis, adaptation to changed metabolic requirements and stress, cellular remodeling and quality control of organelles, tumor suppression, pathogen elimination, immune and inflammatory responses, and aging. Macro-autophagy plays a major role and as a pathway can be divided into six consecutives steps—initiation, nucleation, elongation, closure, maturation, and fusion—closely related to the cascade activation of the AuTophaGy-related (or ATG) genes. The whole process is under the tight control of pathways crucial for cellular metabolic control such as the mTOR and AMPK pathways and requires tight regulation of each step, fine-tuning at the substrate level, and crosstalk with other vesicular and cellular trafficking machineries. The term "selective autophagy" refers to the specificity of autophagy for certain cargos that in mammalian cells include peroxisomes ("pexophagy"), mitochondria ("mitophagy"), the endoplasmic reticulum ("reticulophagy"), lysosomes ("lysophagy"), pathogens ("xenophagy"), lipid droplets ("lipophagy"), ferritin ("ferritinophagy"), and glycogen ("glycophagy") (Gatica et al. 2018).

Given its crucial role in many essential cellular processes, the involvement of autophagy has been implicated in a wide range of human diseases, manifesting as organ-specific or as systemic disorders, including infections; cancer; neurodegenerative, cardiovascular, autoimmune, and inflammatory disorders; chronic liver disease; myopathies; obesity and metabolic syndrome; diabetes; and even aging. In the specific field of metabolic diseases, a secondary involvement of autophagy has been reported in lysosomal storage disorders and, more recently, also in urea cycle defects and organic acidurias (Luciani et al. 2020; Settembre et al. 2013; Soria and Brunetti-Pierri 2019).

The advent of next-generation sequencing has allowed the discovery of several disorders primarily affecting the genes of the autophagy machinery, and these single gene disorders, recently named congenital disorders of autophagy, represent an emerging category of inborn errors of metabolism (Ferreira et al. 2021; García-Cazorla and Saudubray 2018; Teinert et al. 2020).

Despite a growing interest over the last years in congenital disorders of autophagy, a consensus in the classification of autophagy-related diseases is still missing (Fig. 59.1) (Ferreira et al. 2021; García-Cazorla and Saudubray 2018; Levine and Kroemer 2019; Stamatakou et al. 2020; Teinert et al. 2020; Zatyka et al. 2020).

Nomenclature

In this chapter, we propose a new classification of congenital disorders of autophagy, which includes 25 genetic disorders responsible for over 30 different OMIM phenotypes, the number of which will likely increase with genomic disease discovery. These genetic defects that primarily involve the different steps of the autophagy machinery are clinically heterogeneous yet invariably present with a characteristic involvement of the CNS and the peripheral nervous system. Given their post-mitotic nature, neurons are highly sensitive to the accumulation of toxic proteins and damaged organelles and are therefore highly dependent on the autophagy machinery to maintain their homeostasis even already from early embryonic and perinatal stages (Fassio et al. 2020). This dependency makes autophagy a key player for early neurogenesis and central nervous system development, neuronal polarity, and synaptic function. Neurological signs include developmental delay, intellectual disability, ataxia, epilepsy, myopathies, psychiatric manifestations, pyramidal dysfunction, neuropathy, sensorineural deafness, and various manifestations of neurodegeneration, including parkinsonism. Neuroimaging often reveals corpus callosum agenesis or hypoplasia, cerebral and cerebellar atrophy, and, in some cases, a characteristic brain iron accumulation. Non-neurological manifestations include ocular, skeletal, respiratory, renal, hepatic, gastrointestinal, cardiac, cutaneous, and immunological abnormalities and dysmorphic, i.e., storage-like, features in certain conditions.

Metabolic Pathway

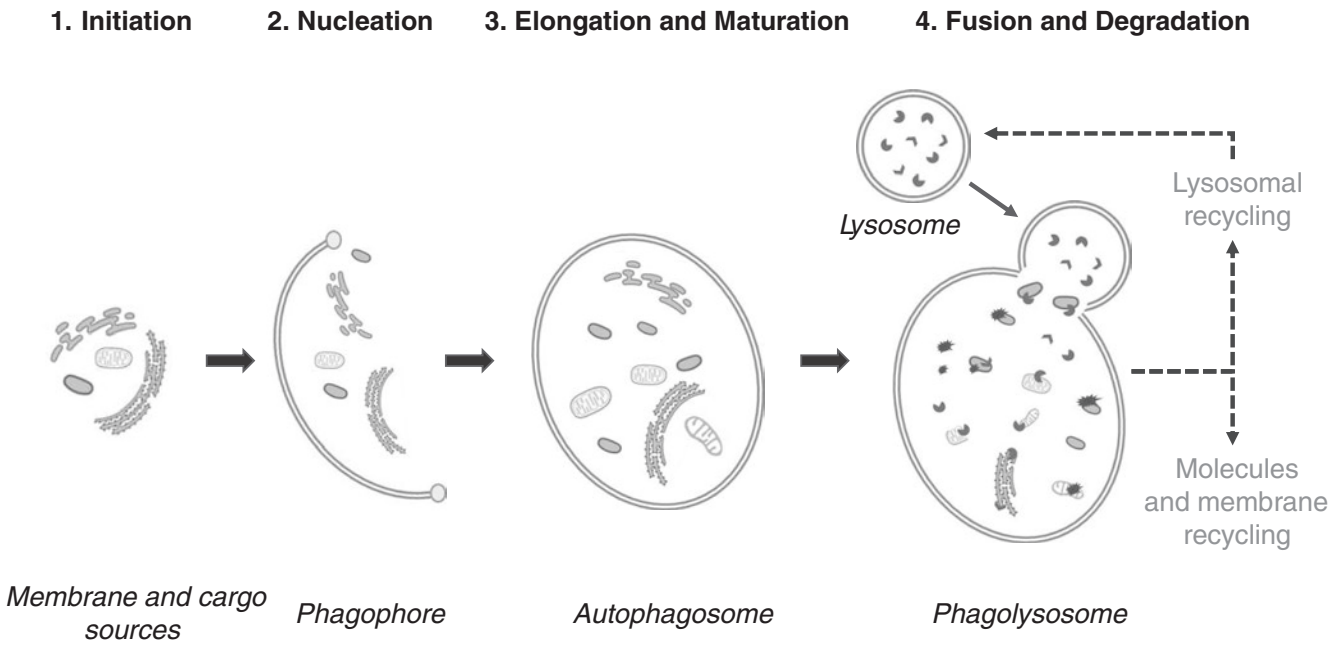

Fig. 59.1 Schematic illustration of the main steps of Macroautophagy

Signs and Symptoms

Based on the main clinical presentation, congenital or monogenic disorders of autophagy can be grouped into different subtypes: multisystem diseases, hereditary spastic paraplegia, amyotrophic lateral sclerosis, Parkinson disease, neurodegeneration with brain iron accumulation, Charcot-Marie-Tooth disease, and other complex neurodegenerative diseases.

Multisystem Disease

Four diseases, Vici syndrome, Yunis-Varon syndrome, spinocerebellar ataxia 20 (SCARS20), and TBCK deficiency, present with multisystemic clinical storage-like pictures, affecting the central nervous system and other organs and systems.

Vici syndrome (59.1, AR, MIM 615068), caused by autosomal recessive mutations in *EPG5*, was initially described as a new syndrome characterized by agenesis of the corpus callosum, skin and hair hypopigmentation, cataracts, cleft lip and palate, cardio/myopathy, and immunodeficiency. After this first report, numerous other cases were described, and the genetic cause, mutations in *EPG5*, a gene encoding ectopic P granules protein 5 (EPG5) playing a key role in the autophagy machinery, was reported in 2013 (Cullup et al. 2013). EPG5 deficiency causes impaired fusion of autophagosomes with lysosomes and subsequent accumulation of autophagosomes. The disease has a pan-ethnic distribution and over 60 patients are known (Byrne et al. 2016). In addition to a wide range of other multisystem features, EPG5 deficiency causes a complex immunological dysfunction, with selective involvement of memory B cells, whose pathophysiology implicates a perturbation of the cell signaling cascade mediated by toll-like receptor 7 and 9 affecting both innate and adaptive immunity (Piano Mortari et al. 2018).

Yunis-Varon syndrome (59.32, AR, MIM 609390; and 59.33, AR, MIM 604632) has been reported in association with two different genetic defects of autophagy, *FIG4* and *VAC14*, coding for two proteins involved in the conversion of phosphoinositide PI(3)P to PI(3,5)P and causing a perturbation in the homeostasis of cellular vacuoles containing LAMP1 and LAMP2 proteins (Campeau et al. 2013; Lines et al. 2017). This syndrome shares some similarities with Vici syndrome such as corpus callosum agenesis/hypoplasia, cardio/myopathy, cataract, cleft lip and palate, and tissue lysosomal storage. An abnormal urine oligosaccharide profile has been reported in Yunis-Varon syndrome. Mutations in *FIG4* and *VAC14* have also been associated with additional clinical manifestations. For *FIG4*, other associated phenotypes include bilateral temporo-occipital polymicrogyria (59.29, AR, MIM 609390) (Baulac et al. 2014), amyotrophic lateral sclerosis type 11 (59.30, AD, MIM 609390) (Nguyen et al. 2019), and Charcot-Marie-Tooth disease type 4 J (59.31, AR, MIM 609390) (Nicholson et al. 2011), while mutations in *VAC14* have been reported in a Leigh-like disease with childhood-onset striato-nigral degeneration (59.34, AR, MIM 604632) (Lenk et al. 2016).

Spinocerebellar ataxia 20 (59.3, AR, 616105) is an autosomal recessive disorder due to mutations in *SNX14*, encoding a protein involved in phosphatidylinositol (3,5)-bisphosphate metabolism and maturation of the autophagy pathway, resulting in a dysfunction of lysosome-autophagosome fusion (Akizu et al. 2015). Patients present between birth and 1 year of age with developmental delay and hypotonia, with development of age-dependent cerebellar atrophy. Coarse facial features similar to those of mucopolysaccharidosis and other lysosomal storage disorders, seizures, hepatosplenomegaly, skeletal abnormalities, hypertrichosis, nystagmus, and hearing loss represent additional clinical signs. An abnormal pattern of urine oligosaccharides and elevated excretion of glycosaminoglycans have been observed in some patients.

Mutations in *TBCK*, encoding for TBC1-domain-containing kinase, a protein implicated in the mTOR pathway, cause a complex storage-like disease with autophagosomal-lysosomal dysfunction (59.23, AR, MIM 616899) (Bhoj et al. 2016; Beck-Wödl et al. 2018). The main phenotypic features described in over 30 patients reported to date include distinctive facial features with bitemporal narrowing, macroglossia, severe motor and cognitive delay, seizures, hypo/areflexia, generalized hypotonia, endocrinological abnormalities, dysgenesis of the corpus callosum, and cerebellar atrophy. Autopsy where performed revealed lipofuscin-like storage material in CNS neurons; storage deposits in astrocytes and microglia; PAS-positive deposits in the pons, cerebellum, spleen, and liver in two sibs; and GM2-ganglioside storage in spinal motor neurons in another patient (Strømme et al. 1997), all showing normal total glycosaminoglycans and oligosaccharide profiles in urine.

Hereditary Spastic Paraplegia

Hereditary spastic paraplegias (HSPs) are a heterogeneous group of neurodegenerative diseases, inherited in an autosomal dominant, autosomal recessive, or X-linked manner, characterized by retrograde degeneration of the long corticospinal motor neuron axons, resulting in progressive lower limb spasticity, weakness, reduced vibration sense, and urinary incontinence. To date, HSPs encompass more than 80 loci and over 60 genes, with some labeled complex HSPs, presenting additional phenotypic features, in particular cerebellar signs and cognitive impairment. Spastic gait genes (SPG) are involved in several cellular pathways, including ER and vesicle trafficking, mitochondrial regulation, myelination, lipid metabolism, and autophagy. Thus far, eight different inherited defects of autophagy have been implicated in hereditary spastic paraplegia. These include SPG11 (59.4, AR, MIM 610844), SPG15 (59.7, AR, MIM 612012), and SPG47 (59.20, AR, MIM 607245), SPG48 (59.8, AR, MIM 613653), SPG49 (59.9, AR, MIM 615000), SPG50 (59.21, AR, MIM 602296), SPG51 (59.22, AR, MIM 607244), and SPG52 (59.19, AR, MIM 607243) (Ebrahimi-Fakhari et al. 2018; Hirst et al. 2015; Oz-Levi et al. 2012; Vantaggiato et al. 2019). All these disorders can be classified as complex HSPs and are clinically characterized by lower limb spasticity, developmental delay/mental retardation, and, frequently, corpus callosum and white matter abnormalities. Additional findings often include cerebellar atrophy, seizures, ataxia, neuropathy, dysmorphic features, psychiatric manifestations, retinopathy, and deafness. SPG11 and SPG15, which are clinically indistinguishable, are the most frequent form of complex HSPs. *SPG11* encodes spatacsin, a protein involved in autophagosome maturation, and mutations in *SPG11* have been associated also with Charcot-Marie-Tooth disease type 2X (59.5, AR, MIM 610844) and to amyotrophic lateral sclerosis type 5 (59.6, AR, MIM 610844) (Montecchiani et al. 2016; Orlacchio et al. 2010). SPG15 is due to mutation in the *ZFYVE26* gene, coding for spastizin, also involved in autophagosome maturation (Vantaggiato et al. 2019). SPG49 is caused by mutations in the *TECPR2* gene, encoding tectonin beta-propeller repeat-containing protein 2, which interacts with ATG8 in phagophore membrane elongation (Oz-Levi et al. 2012). SPG47, SPG50, SPG51, and SPG52 are caused by mutations in genes that encode the subunits of adaptor-protein 4, involved in autophagosome turnover and resulting in impaired autophagic degradation of protein aggregates (Ebrahimi-Fakhari et al. 2018). These "adaptinopathies," together with SPG48, caused by mutation in a gene encoding a subunit of adaptor protein 5 (Hirst et al. 2015), represent a specific subtype of complex HSPs. Interestingly, spastizin and spatacsin physically interact and have similar subcellular distributions and co-localize with adaptor protein 5 in a multiprotein complex expressed in endosomes and lysosomes and are involved in autophagosome-endosome fusion.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is an invariably fatal neurodegenerative disease involving neurons controlling voluntary muscles. ALS is characterized by the progressive degeneration of motor neurons in the spinal cord and brain, which leads to neuromuscular denervation, atrophy, and paralysis of voluntary skeletal muscles and ultimately to death. ALS is most commonly a sporadic disease, but approximately 5%–10% of cases are familial. Six genetic defects affecting the autophagy pathway cause different forms of amyotrophic lateral sclerosis often associated with frontotemporal dementia (Nguyen et al. 2019): ALS 2, ALS 2 deficiency (59.24, AR, 606352); ALS 3, SQSTM1 deficiency (59.15, AD, MIM 601530); ALS 4, TBK1 deficiency (59.10, AD, MIM 604834); ALS 5, spatacsin deficiency (59.6, AR, MIM 610844), involved in autophagosome matu-

ration; ALS 11, FIG4 deficiency (59.30, AD, MIM 609390); and ALS 17, CHMP2B deficiency (59.38, AD, MIM 609512). Besides ALS, other phenotypic manifestations have been reported in association with these genetic defects: distal myopathy with rimmed vacuoles (59.16, AD, MIM 601530) (Bucelli et al. 2015), neurodegeneration, ataxia, dystonia, and gaze palsy (59.17, AR, MIM 601530) (Haack et al. 2016), and Paget disease of bone 3 (59.18, AD, MIM 601530) (Laurin et al. 2002) with mutations in *SQSTM1*; spastic paraplegia (59.4, AR, MIM 610844) (Vantaggiato et al. 2019) with mutations in *SPG11*; primary lateral sclerosis juvenile (59.25, AR, MIM 606352) and infantile-onset ascending spastic paralysis (59.26, AR, MIM 606352) with mutations in *ALS2* (Eymard-Pierre et al. 2002); bilateral temporo-occipital polymicrogyria (59.29, AR, 609390) (Baulac et al. 2014), Charcot-Marie-Tooth disease type 4 (59.31, AR, MIM 609390) (Nicholson et al. 2011), and Yunis-Varon syndrome (59.32, AR, 609390) (Campeau et al. 2013), with mutations in *FIG4*; and frontotemporal dementia without ALS (59.39, AS, MIM 609512) with mutations in *CHMP2B* (Skibinski et al. 2005).

Parkinson Disease

Three genes of the autophagy machinery, *PARK2* (59.13, AR, MIM 602544) (Kitada et al. 1998), *PINK1* (59.14, AR, MIM 608309) (Valente et al. 2004), selectively affecting mitochondria target cargos (mitophagy), and *DCTN1* (59.27, AD, MIM 601143) (Konno et al. 2017), cause autosomal recessive and dominant forms of Parkinson disease. *PINK1* encodes a mitochondrially located serine/threonine kinase which phosphorylates parkin, encoded by *PARK2*, and ubiquitin to regulate mitophagy. *DCTN1* gene encodes the subunit $p150^{Glued}$ of the protein complex dynactin, which participates with dynein in autophagosome-lysosome fusion, playing a key role in retrograde axonal transport. *DCTN1* mutations, which cause pathological protein accumulation and aggregation in neurons, were identified in patients with Perry syndrome (59.28, AD, MIM 601143), a rare hereditary neurodegenerative disease characterized by dominantly inherited parkinsonism, psychiatric symptoms, weight loss, and central hypoventilation (Konno et al. 2017). *DCTN1* variants have also been found in patients with distal hereditary motor neuropathy type VIIB (59.27, AD, MIM 601143) and other neurodegenerative phenotypes, such as amyotrophic lateral sclerosis, with or without frontotemporal dementia, and a progressive supranuclear palsy (PSP)-like syndrome (Konno et al. 2017).

Neurodegeneration with Brain Iron Accumulation

Neurodegeneration with brain iron accumulation (NBIA) comprises a group of disorders characterized by abnormal accumulation of iron in the basal ganglia, most often in the globus pallidus and/or substantia nigra. NBIA 5 (59.2, XLD, MIM 300526), also known as beta-propeller protein-associated neurodegeneration (BPAN), is due to X-linked dominant mutations in *WDR45*, a gene involved in autophagosome formation and elongation by binding phosphatidylinositol 3-phosphate (Haack et al. 2012). The characteristic features of the disease include childhood-onset developmental delay with slow motor and cognitive gains; little to no expressive language; seizures of various types, prominent in childhood but may resolve in adolescence; autistic-like behavioral abnormalities; motor dysfunction; and ataxia, hypotonia, and spasticity, progressing into dystonia-parkinsonism and dementia, with a biphasic disease course. MRI can feature hypomyelination and a thin corpus callosum.

Charcot-Marie-Tooth Disease

Charcot-Marie-Tooth (CMT) disease comprises a heterogeneous group of progressive hereditary sensory and motor neuropathy with onset between the 5th and the 15th year of age. Patients present with muscle weakness, walking difficulties, abnormal gait, pes cavus, and progressive distal-muscle wasting of lower and upper limbs. Charcot-Marie-Tooth disease has been associated with some genetic defects linked to autophagy, including *SPG11* (CMT 2x, 59.5, AR 610844) (Montecchiani et al. 2016), involved in autophagosome maturation, *RAB7A* (CMT 2b, 59.11, AD, MIM 602298) (Verhoeven et al. 2003), *FIG4* (CMT 4 J, 59.31, AR, MIM 609390) (Nicholson et al. 2011), and *DNM2* which has also been implicated in a form of centronuclear myopathy (CNM) (59.36, AD, MIM 602378) (Bitoun et al. 2005). Remarkably, the extremely rare form of CNM due to mutations in *MTMR14* (59.35, AD, MIM 611089) (Tosch et al. 2006), encoding myotubularin-related protein 14, also causes a dysregulation of autophagy in relation to an abnormal metabolism of phosphoinositides, a group of phospholipids that play a critical role in the control of organelle and membrane traffic. Interestingly, also myotubularin, the gene implicated in X-linked myotubular myopathy, the X-linked form of CNM, plays a crucial role in the regulation of PI3P levels.

Other Complex Neurodegenerative Diseases

Mutations in *ATG5*, coding for ATG protein 5 which plays a key role in the elongation process of phagophore, cause spinocerebellar ataxia 25 (59.12, AR, MIM 604261), a childhood-onset disorder with walking difficulties, ataxia, nystagmus, variable degrees of intellectual disability, pyramidal signs, and cerebellar hypoplasia, with evidence of a reduced autophagic flux (Kim et al. 2016).

Diagnosis

The diagnosis of an autophagy-related disorder should be prompted by a characteristic combination of features as outlined above. Mutation analysis via targeted Sanger or exome analysis is the only reliable method of diagnosis of an autophagy-related disorder. Non-specific laboratory changes, such as abnormalities of urinary oligosaccharides profile or increased GAG, have been reported in a few disorders presenting with a multisystem storage-like disease, such as Yunis-Varon syndrome (59.32; 59.33) and spinocerebellar ataxia 20 (59.3) (Akizu et al. 2015; Dworzak et al. 1995).

Treatment

There are currently no approved therapies available for inherited disorders of autophagy; therefore, current treatment is limited to symptomatic and supportive management. However, there are several therapeutic modalities under investigation (Morel et al. 2017; Maiuri and Kroemer 2019; Yang et al. 2013).

Lipidoses: The Sphingolipidoses, Lysosomal Acid Lipase Deficiency, and Niemann-Pick Type C

60

Carla Hollak

Contents

Abstract

Metabolic disorders that affect the lysosomal degradation of complex carbohydrates, lipids, and proteins are associated with a wide variety of clinical symptoms. The lipidoses are the most common of the lysosomal storage disorders and are increasingly recognized in adults with a more attenuated phenotype. At the severe end of the clinical spectrum, neurological symptoms are frequently seen and go along with significant brain pathology. The high abundance of sphingolipids in the brain partially explains the major neurodegenerative effect of disturbed sphingolipid breakdown. For most of the sphingolipidoses, new treatments have emerged, which provides hope for the future of patients, in particular for those with non-neurological disease, such as renal and cardiac disease in Fabry disease and hepatosplenomegaly with bone symptoms in Gaucher disease. Neurological disease has so far been very difficult to manage, although hematopoietic stem cell transplantation in metachromatic leukodystrophy and gene therapy approaches hold promise for the future as well.

Introduction

This chapter deals with lysosomal lipid storage disorders, in particular the sphingolipidoses, Niemann-Pick type C disease, and lysosomal acid lipase deficiency. The mucolipidoses

and the neuronal ceroid lipofuscinoses are described elsewhere (cross refs).

Sphingolipids are catabolized by hydrolases in lysosomes, followed by sequential removal of the degraded components. The various enzymes participating in this degradative pathway include galactosidases, hexosaminidases, neuraminidase (sialidase), glucosidases, sphingomyelinase (a phosphodiesterase), sulfatase, and ceramidase (an amidase). Specific activator proteins, saposins, or sphingolipid activator proteins (SAPs) are needed for sphingolipid degradation. These small, nonenzymatic glycoproteins bind the respective hydrolases and can support connection of lipids accessible to the hydrolases. Apart from deficient activities of lysosomal enzymes, defects in saposins can also give rise to sphingolipid storage disorders. Lysosomal cholesterol accumulation occurs as the main feature of lysosomal acid lipase deficiency and Niemann-Pick disease type C. Lysosomal acid lipase normally hydrolyzes cholesteryl esters and triglycerides to generate free fatty acids and cholesterol, while in Niemann-Pick disease type C, a defect in NPC1 or NPC2 proteins hampers transport of cholesterol out of the lysosomal/endosomal compartment, which in addition leads to secondary accumulation of sphingolipids.

Depending on the defect, different cells can be the target of lysosomal storage: macrophages are a frequent target, but neuronal cells, endothelial cells, cardiomyocytes, etc. can be affected. This results in a wide variety of symptoms: from neuronal damage to visceral enlargement or renal insufficiency. In addition, the type of mutation will lead to different residual enzyme activities, which importantly determines the age of onset of symptoms. However, genotype-phenotype relationships are generally poor especially for the late-onset disorders resulting in a wide variety of signs and symptoms, even within families. Clearly modifier genes or epigenetic or environmental factors influence the clinical manifestations in the majority of disorders. Many of these factors have so far not been identified, which may hamper family counseling and interpret results of screening. Treatment options have rapidly evolved over the last two decades, with more success to target visceral symptoms than neurological features. Intravenous enzyme replacement therapy is now available for several disorders, and oral substrate reduction therapy is authorized for Gaucher disease and under investigation for Fabry disease, while a first chaperone treatment is now available for the latter. In addition, hematopoietic stem cell transplantation has a place for metachromatic leukodystrophy, and several gene therapy options are currently explored. The different disorders, their characteristic features, guidelines for follow-up, and treatments are discussed separately below.

Gangliosidoses: GM1, GM2 (Sandhoff and Tay-Sachs Diseases), and Galactosialidosis

The Gangliosidoses

The general clinical hallmark of the gangliosidoses is neurodegeneration, due to accumulation of substrates in the central nervous system. GM1 gangliosidosis is caused by deficiency of β-galactosidase due to a mutation in *GLB1*. This gene is also mutated in Morquio type B, with a completely different phenotype, indicating different substrate binding sites, protein folding-relevant sites, or subdomains in the enzyme (Sandhoff and Harzer 2013). GM1 gangliosidosis encompasses a spectrum of clinical phenotypes, depending on the age of onset: a rapidly progressive infantile form (most common) with early developmental delay followed by severely progressive neurological disease with blindness, deafness, and death by 1–2 years of age. These children have visceral disease as well with hepatosplenomegaly, coarse features, and corneal clouding; the late infantile or juvenile form is characterized by a slower course with loss of developmental milestones; in adults a variant is described mainly with extrapyramidal manifestations (Brunetti-Pierri and Scaglia 2008). GM2 gangliosidosis is caused by deficiency of β-hexosaminidase or in very exceptional cases due to a defect in the GM2 activator protein. The enzyme has two isoforms, A and B: HEXA, encoded by *HEXA*, has α and β subunits, and isoenzyme HEXB consists of two β subunits encoded by *HEXB*. Tay-Sachs disease is caused by *HEXA* mutations, while Sandhoff disease is caused by HEXB mutations (Bley et al. 2011). Similar to GM1 disease, GM2 gangliosidosis has different phenotypes: infantile, juvenile, and adult forms. The infantile form is characterized by hyperacusis and visual impairment, developmental regression, and seizures. The juvenile form has a slower progressive course with psychomotor retardation. The adult form presents mostly with either cerebellar or anterior motor neuron involvement. Affected individuals may also develop psychotic episodes (Neudorfer et al. 2005).

Galactosialidosis clinically resembles GM1 gangliosidosis. In this disorder, a secondary deficiency of acid β-galactosidase is present, together with deficiency in sialidase and a specific sulfatase, all caused by mutations in *CTSA* encoding the protective protein/cathepsin A (PPCA). A defect in this protein hampers the stabilization of the enzymes, resulting in deficiency of their activities. For an appropriate diagnosis of GM1 gangliosidosis, a differentiation with galactosialidosis needs to be made on the basis of enzyme activities or molecular analysis.

Krabbe Disease

Krabbe disease (globoid cell leukodystrophy) is a rare, autosomal recessively inherited sphingolipid storage disorder

with a neurological phenotype. As a result of deficiency of galactocerebrosidase, galactolipids including galactocerebroside and psychosine (the lyso compound, i.e., galactosylsphingosine) accumulate in the brain. In particular galactosylsphingosine is toxic for oligodendrocytes and leads to severe white matter involvement of the peripheral and central nervous system. Mutations in the gene for the lysosomal enzyme galactocerebrosidase (GALC) result in different residual activity with accordingly variable clinical disease manifestations, although phenotype-genotype correlations are imperfect. The most severe cases of early infantile disease manifest with ataxia, spasticity, rapid psychomotor decline, and early death, usually before the age of 2 years. This form is associated in a high percentage of European and Mexican patients with one specific mutation (Rafi et al. 1995). Juvenile and adult patients have a more variable and attenuated course with differences in onset and progression of ataxia, spasticity, peripheral neuropathy, and sometimes loss of vision and dementia. Imaging of the brain may be normal for a long time in attenuated cases (Bajaj et al. 2002).

For counseling purposes and selection of infantile cases for hematopoietic stem cell transplantation, neonatal screening programs have been set up (Kwon et al. 2018).

Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD) is an autosomal recessive disease caused by mutations in the arylsulfatase A (ARSA) leading to a deficiency of the enzyme, which is involved in the breakdown of sulfatide. Accumulation of sulfatide and related compounds affects the central and peripheral nervous system, which leads to demyelination. MLD is clinically characterized by progressive neurological decay: based on the age of onset three sybtypes can roughly be distinguished (Gomez-Ospina [Internet], n.d.). A late infantile form manifests before the age of 2,5 years and has a rapidly progressive course with loss of motor function and early death. The juvenile form starts between 2,5 and 16 years and the adult form beyond 16 years of age. This group has variable progression of disease, with adults remaining mildly symptomatic for years. In the latter group, psychiatric symptoms may be a first manifestation of the disorder. In those less severe phenotypes, hematopoietic cell transplantation (HCT) can arrest progression of disease, especially when patients are pre-symptomatic or very early symptomatic. Characteristic white matter lesions on MRI may even improve after transplantation, although peripheral neuropathy will persist. Recently, visceral symptoms have been described as well, mainly in relation to the gastrointestinal tract, specifically the occurrence of gallbladder polyps (van Rappard et al. 2016a, b). Atypical presentations have been described in relation to saposin B deficiency with flaccid paralysis and gallbladder abnormalities as well (Madaan et al. 2019).

Gaucher Disease, Saposin C Deficiency, and Limp2 Deficiency

The lysosomal enzyme β-glucocerebrosidase (β-GCase) is involved in the degradation of the natural glycosphingolipid glucocerebroside (or glucosylceramide; GC) into glucose and ceramide (Brady et al. 1966). Deficient activity of this enzyme causes Gaucher disease. The enzyme β-GCase is activated by saposin C, which is derived from proteolytic cleavage of prosaposin. Deficiency of saposin C results in a decrease in β-GCase and gives rise to a clinical variant of Gaucher disease with neuronopathic features (Christomanou et al. 1986). More recently, another disease subtype associated with deficiency of β-GCase in skin fibroblasts, but not in leukocytes, has been described. In this disorder, lysosomal integral membrane protein type 2 (LIMP-2) is deficient. This protein has been shown to be the mannose-6-phosphate-independent trafficking receptor for β-GCase (Reczek et al. 2007), which may result in tissue-dependent decreases in intralysosomal β-GCase activities (Berkovic et al. 2008; Balreira et al. 2008). Clinically this disorder was previously described as action myoclonus renal failure syndrome.

Gaucher Disease

Gaucher disease has first been described by Philippe Gaucher in 1882 and is now recognized as one of the most prevalent lysosomal storage disorders. Its inheritance is autosomal recessive and the disease is panethnic, but there are some ethnic predilections. In Western countries, type I Gaucher disease or the non-neuronopathic variant is most common and has a high prevalence in the Ashkenazi Jewish population of 1 in 850 (Zimran and Elstein 2010). In general, the prevalence is believed to be around 1 in 75,000 (Meikle et al. 1999; Poorthuis et al. 1999), but it is likely that this is an underestimation since milder variants remain undiagnosed. The neuronopathic variants are extremely rare, with variable ethnic background, although clusters of these patients have been described in Norrbotten (Sweden), in Poland, and in the Jenin Arab population (Vellodi et al. 2009).

Type 1 Gaucher disease has a wide phenotypic variability. In general, the buildup of undegraded GC in macrophages results in hepatosplenomegaly, bone marrow involvement, cytopenia, and skeletal disease (Grabowski 2008). Most patients with this disorder present with unexplained thrombocytopenia and splenomegaly. More exceptionally, the first symptoms can be related to skeletal involvement, such as painful bone crises or avascular necrosis. Although the majority is diagnosed during adolescence/adulthood, severe

manifestations may already be present during early childhood. Spleens can become massively enlarged, which necessitated splenectomy before enzyme replacement therapy was available (Beutler 1988). After splenectomy, these patients are vulnerable to septicaemia and progressive skeletal, liver, and pulmonary disease. Once extreme bone marrow infiltration has occurred, the risk for bone complications increases (Hollak et al. 2001). This can be shown by a reduction in fat signal in the bone marrow on MRI. Skeletal complications include avascular necrosis, specifically of the femoral head but also in other joints, pathological fractures, and bone crises. These crises resemble the acute bone pain seen in sickle cell disease and can only be managed by supportive measures such as morphinomimetics. Imaging of the skeleton shows characteristic, although not pathognomonic, features including osteopenia, sclerosis, Erlenmeyer flask deformities of the femurs, lytic lesions, and fractures (Maas et al. 2002). On MRI, decrease in fat signal and sometimes areas with high water signal can be seen. This last feature does not always indicate acute disease. Early AVN and infarcts can also be recognized on MRI. While severe, progressive disease in children and young adults has been described, on the other end of the clinical spectrum, a diagnosis of Gaucher disease can be made as a coincidental finding in an otherwise healthy person. The very mild patients have usually little disease progression (Beutler et al. 1995). Gaucher disease type 1 is also associated with other conditions, including a higher risk for malignancies, specifically multiple myeloma. As a large proportion (up to 20%) of adult Gaucher disease patients have a monoclonal protein, it is clear that there is an increased risk and patients should be monitored for this (De Fost et al. 2008). In addition, several cases of hepatocellular carcinoma have been reported, presumably associated with advanced liver involvement. Pulmonary hypertension and renal and cardiac involvement have all been reported. The increased risk for these conditions should be kept in mind during clinical follow-up. Individual factors that put patients at risk for these complications are currently under investigation. Another intriguing association is that of Parkinson's disease, not only in patients but also in carriers of a *GBA1* mutation: in fact, recent research indicates that *GBA1* mutations are the most common known genetic risk factor for Parkinson's disease and dementia with Lewy bodies. The clinical phenotype of carriers and patients with Gaucher disease and Parkinson's disease resembles sporadic Parkinson's disease, but with an earlier onset and more severe course (Ryan et al. 2019.)

Type 2 and 3 Gaucher disease are the neuronopathic Gaucher disease forms which are traditionally distinguished based upon the onset of neurological disease and the rate of deterioration. Type 2 patients always present with very early developmental delay and a rapidly fatal course. However, an early diagnosis can also be made in a type 3 patient, and considerable overlap of disease manifestations between type 2 and 3 disease exists. Therefore, neuropathic forms are increasingly regarded as a phenotypic continuum (Hruska et al. 2008). Since management decisions will be made primarily based upon the course of progression, Vellodi and coworkers have suggested using the terms "acute" and "chronic" (Vellodi et al. 2009) instead of type 2 and type 3. Acute neuropathic disease then refers to onset at <1 year of age with progressive neurological features including bulbar and pyramidal signs and cognitive impairment. Chronic neuropathic disease encompasses all patients with neurological disease manifestations in the context of Gaucher disease, who do not have the acute form (Vellodi et al. 2009). The chronic neuropathic disease group harbors several variants: the subtype living in Northern Sweden (Norrbotten) with relatively mild neurological features but extensive visceral disease is sometimes referred to as type 3a, to distinguish these from patients with more prominent neurological features, including myoclonic epilepsy (type 3b). Another atypical variant of chronic neuropathic disease is referred to as type 3c and has first been reported in a group of Jenin Arab patients (Abrahamov et al. 1995). Homozygosity for the D409H mutation in these patients is associated with valvular heart disease with cardiovascular calcifications in addition to oculomotor apraxia and mild visceromegaly.

Saposin C Deficiency or Prosaposin Deficiency

Patients with saposin C deficiency or prosaposin deficiency have been described with clinical features of neuronopathic Gaucher disease, including the characteristic horizontal ophthalmoplegia, epilepsy, and pyramidal and cerebellar signs (Pampols et al. 1999), but also non-neuronopathic variants with extensive visceral involvement have been described (Tylki-Szymanska et al. 2007). Diagnosis can be difficult as β-GCase activity is normal. The clinical presentation, presence of Gaucher cells, high levels of chitotriosidase, and storage of glucosylceramide will point to the direction of saposin C deficiency. Molecular analysis of *PSAP* can confirm the diagnosis. Treatment with substrate reduction therapy (miglustat, Zavesca ™) has been attempted but did not have any effect (Tylki-Szymańska et al. 2011).

LIMP2 Deficiency

Patients diagnosed with action myoclonus-renal failure syndrome have been identified as carrying a mutation in *SCARB2/LIMP2*. Several non-sense mutations in this gene have been shown to impair trafficking of β-GCase to the lysosome. Deficiency of active β-GCase that differs between tissues can hamper a diagnosis, as only fibroblasts and not leukocytes

have low activity. Molecular analysis needs to be performed for a final diagnosis. The diversity in β-GCase deficiency throughout the body gives a totally different clinical picture, although some of the neurological features resemble those found in neuronopathic Gaucher disease. In addition to myoclonus epilepsy, demyelinating peripheral neuropathy, hearing loss, and dementia can occur in the presence or absence of renal failure (Dibbens et al. 2016). However, no visceromegaly is present, and no evidence of systemic storage of glucosylceramide is established in bone marrow and kidney biopsies, which is in agreement with the presence of normal chitotriosidase activities (Chaves et al. 2011).

Combined Saposin Deficiency

Prosaposin (PSAP) deficiency is caused by mutations in *PSAP* that codes for the 65–70 kDa prosaposin protein, which is the precursor for four sphingolipid activator proteins, saposins A–D. This ultra-rare disorder can have features of severe Gaucher disease or metachromatic leukodystrophy and has a rapidly fatal course. Lysolipid analysis has revealed elevated levels of globotriaosylsphingosine (LysoGb3) and glucosylsphingosine (GlSph) in some cases (Motta et al. 2016).

Fabry Disease

The enzyme α-galactosidase A (aGalA) is deficient in Fabry disease, which results in storage of glycosphingolipids, mainly globotriaosylceramide (ceramide trihexoside, CTH, Gb3), in multiple cell types (Schiffmann 2015). Most involved are cells of the vascular system, including endothelial and smooth muscle cells. Storage can also be found in podocytes in the kidney, cardiomyocytes, sweat glands, and peripheral nerves. Fabry disease is X-linked, with severe manifestations in male patients without any residual aGalA activity. In carrier females and in non-classical male patients, the disease is much more variable. Variants in males have been described in which only the heart or kidney is involved. It is important to discriminate between classical and non-classical disease as well as in males and females, as for each of these subgroups, the natural disease course is different (Arends et al. 2017). In classically affected males, severe pain in hands and feet caused by acroparesthesia is one of the earliest symptoms starting in the first or second decade of life. Some children may have severe abdominal pain as well or unexplained periods of fever. Angiokeratoma may start to appear at the same age, located primarily in the genital area and around the umbilicus (Germain 2010). Gradually, further storage in the kidney, heart, and brain results in end-organ damage: proteinuria is one of the first signs of kidney involvement and is associated with further deterioration in both kidney and heart (Wanner et al. 2010). The heart may become extremely hypertrophic, with areas of fibrosis. Already at an early stage, most patients have bradycardia or other rhythm disturbances, and many need to receive a pacemaker or ICD later in life (Germain 2010). White matter lesions in the brain are believed to represent small vessel involvement, and there is an increased risk of stroke/TIA. Hearing loss, both acute and chronic, is probably also related to ischemia in the brain and has frequently been reported in Fabry disease. Classically affected males usually develop kidney disease, while this is more exceptional in non-classical males and classical females. In general, the life expectation of classically affected males is reduced with around 20 years (Schiffmann et al. 2009). In non-classical males and classical females, cardiac manifestations and brain white matter lesions are the most prominent features. These symptoms usually develop very gradually but may lead to a reduced life expectation of around 10 years (MacDermot et al. 2001), although there is probably some bias in studies reporting on this, since many asymptomatic females may remain undiagnosed or are not regularly followed in the clinic.

The disease is panethnic, with an estimated birth prevalence of classically affected patients of ~1:40,000 (Desnick 2003). However, awareness for the disease after the introduction of enzyme replacement therapy has resulted in the identification of large groups of individual carrying a *GLA*-mutation. For example, neonatal screening and screening in "high-risk" populations have shown an abundance of *GLA* variant of unknown significance (van der Tol et al. 2014; Spada et al. 2006; Hwu et al. 2009). To avoid anxiety and unnecessary treatment or inappropriate counseling, a diagnosis should only be made based on solid criteria, which may need additional testing, for example histology (Smid et al. 2014). The European Fabry Working Group recently launched an independent database which is freely accessible and provides guidance on genetics, biochemical parameters, and diagnostic criteria (http://www.fabrygenphen.com/).

Farber Disease

Farber disease is an autosomal recessive disorder caused by mutations in the acid ceramidase gene (*ASAH1*) leading to a deficiency of the lysosomal enzyme acid ceramidase (AC). The disorder is extremely rare with less than 100 patients described in the world. Ceramide accumulation can be found in the central nervous system as well as in the skin, kidney,

liver, and lungs, leading to a complex and often difficult-to-diagnose phenotype. Main clinical manifestations are neurological and rheumatological. A triad of subcutaneous nodules, joint swellings/arthritis, and a hoarse or weak voice impairment is suggestive of the disease, but this is not present in all cases (Levade et al. 2017).

Onset is usually in infancy with a progressive and lethal course. Most patients die during childhood, at a median age of 3 years (Zielonka M, Garbade SF, Kölker S, Hoffmann GF, Ries M. A cross-sectional quantitative analysis of the natural history of Farber disease: an ultra-orphan condition with rheumatologic and neurological cardinal disease features. Genet Med. 2018 Apr;20(5):524–530).

NP-C usually presents with both visceral and neurological manifestations at a wide range of ages. Due to the variability in symptoms, which may be subtle and aspecific, a diagnosis of NP-C is often delayed. A neonatal form with severe jaundice and hepatosplenomegaly can be the first sign of the disease, but since this is often temporary and not immediately followed by systemic or neurological manifestations, the diagnosis may be missed. At a later age, subtle or more prominent hepatosplenomegaly can be present, but the neurological symptoms are more prominent and devastating, including vertical supranuclear gaze palsy, cerebellar ataxia, seizures, and progressive dementia.

Niemann-Pick Diseases

The Niemann-Pick disease group encompasses two distinct entities: acid sphingomyelinase-deficient Niemann-Pick disease (ASMD) resulting from mutations in *SMPD1* and Niemann-Pick disease type C (NP-C) including also type D, resulting from mutations in either *NPC1* or *NPC2* (Vanier 2013). These rare autosomal recessively inherited disorders have a wide spectrum of phenotypical manifestations with mainly neurovisceral characteristics.

Traditionally, ASMD has been classified as Niemann-Pick disease (NPD) types A (NPD A) and B (NPD B). NPD A has mainly neurological features starting in infancy followed by a rapidly progressive course, usually lethal before the age of 3 years. Patients with NPDB may have an intermediate phenotype (or variant NPDB) with both visceral and neurological symptoms starting and progressing during childhood. These patients frequently die early, usually from respiratory failure or liver failure. Older patients typically lack neurological symptoms and may have variable degrees of hepatosplenomegaly, thrombocytopenia, interstitial lung disease, and an abnormal, atherogenic, lipid profile. In these attenuated patients, the disease may remain stable during adult life (Hollak et al. 2012a, b). Studies are performed for a better understanding of symptom diversity and the natural history across the disease spectrum, which is needed to improve disease recognition, timely diagnosis, and appropriate disease management (McGovern et al. 2017).

Lysosomal Acid Lipase Deficiency

Lysosomal acid lipase deficiency (LAL-D) is an extremely rare, autosomal recessive disorder caused by lysosomal acid lipase deficiency as a result of mutations in *LIPA*. LAL hydrolyzes cholesteryl esters and triglycerides to generate free fatty acids and cholesterol in lysosomes. As a consequence of the deficiency, storage of cholesteryl esters in macrophages and hepatocytes occurs, giving rise to hepatosplenomegaly and liver dysfunction. Residual enzyme activity determines the clinical severity: in Wolman's disease no residual activity is present leading to a severe disorder that presents during infancy with failure to thrive, diarrhea, malabsorption, hepatomegaly, and hepatic failure and involvement of the adrenal glands. These infants have a rapidly devastating course with death occurring in the first year of life. On the other end of the phenotypic spectrum is cholesteryl ester storage disease, ranging from early dyslipidemia, hepatomegaly, and cirrhosis to minimal symptoms without progression in adults (Pericleous et al. 2017).

While misdiagnosis as non-alcoholic fatty liver disease (NAFLD), non-alcoholic steatohepatitis (NASH), or other causes of dyslipidemia and cirrhosis may occur, recent screening studies have shown that the extreme rarity of LALD of around 1 in 175,000 does not justify screening in dyslipidemia cohorts or only as second tier in non-obese patients with fatty liver (Carter et al. 2019).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM No.
60.1	GM1 gangliosidosis	Beta-galactosidase-1 deficiency		*GLB1*	3p22.3	Beta-galactosidase	230500
60.2	Sandhoff disease	GM2 gangliosidosis O-variant		*HEXB*	5q13.3	Beta-subunit of hexosaminidase	268800
60.3	Tay-Sachs disease	GM2 gangliosidosis B-variant	TSD	*HEXA*	15q23	Alpha-subunit of hexosaminidase	272800
60.4	GM2 gangliosidosis AB variant	GM2 activator deficiency		*GM2A*	5q33.1	GM2 activator	272750
60.5	Galactosialidosis	Protective protein/cathepsin A deficiency	GSL	*CTSA*	20q13.12	Protective protein/cathepsin A	256540

60.16	Lysosomal acid lipase deficiency	Wolman disease, cholesteryl ester storage disease	CESD	*LIPA*	10q23.31	Acid lipase	278000

Metabolic Pathway

Glycosphingolipids and sphingolipids are components of cell membranes. They are formed of ceramide, a molecule formed of sphingosine and long-chain fatty acids. After synthesis in the ER, glucose and carbohydrates are added to ceramide in a series of modification steps in the Golgi apparatus before the newly synthesized glycosphingolipids reach membrane compartments by vesicular membrane transport. Glycosphingolipids comprise gangliosides, and cerebrosides, named according to the composition of their sugar chain, and sulfatides in case of sulfation of cerebrosides. Sphingomyelin is a sphingolipid composed of ceramide and phosphocholine or phosphoethanolamine instead. The degradation of glycosphingolipids and sphingolipids is driven by a stepwise degradation through a series of specific hydrolases in the lysosome after their transport via the endosomal pathway. Hydrolase defects result in accumulation and lysosomal storage of substrates, thereby leading to cell pathology. Membrane-rich tissues or tissues with a high membrane turnover, e.g., myelin in the central and peripheral nervous system or cells of the reticuloendothelial system like macrophages with a high amount of glycosphingolipids and sphingolipids, are prone to an early cellular dysfunction in case of a hydrolase defect. This primarily affects the CNS, liver, and spleen to a variable extent in every disease due to the different content of defined glycosphingolipids and sphingolipids in cell membranes. A detailed pathway of the lysosomal degradation of sphingolipids is given in Fig. 60.1 (Schulze et al. 2009; Kolter and Sandhoff 2006; Kolter et al. 2002).

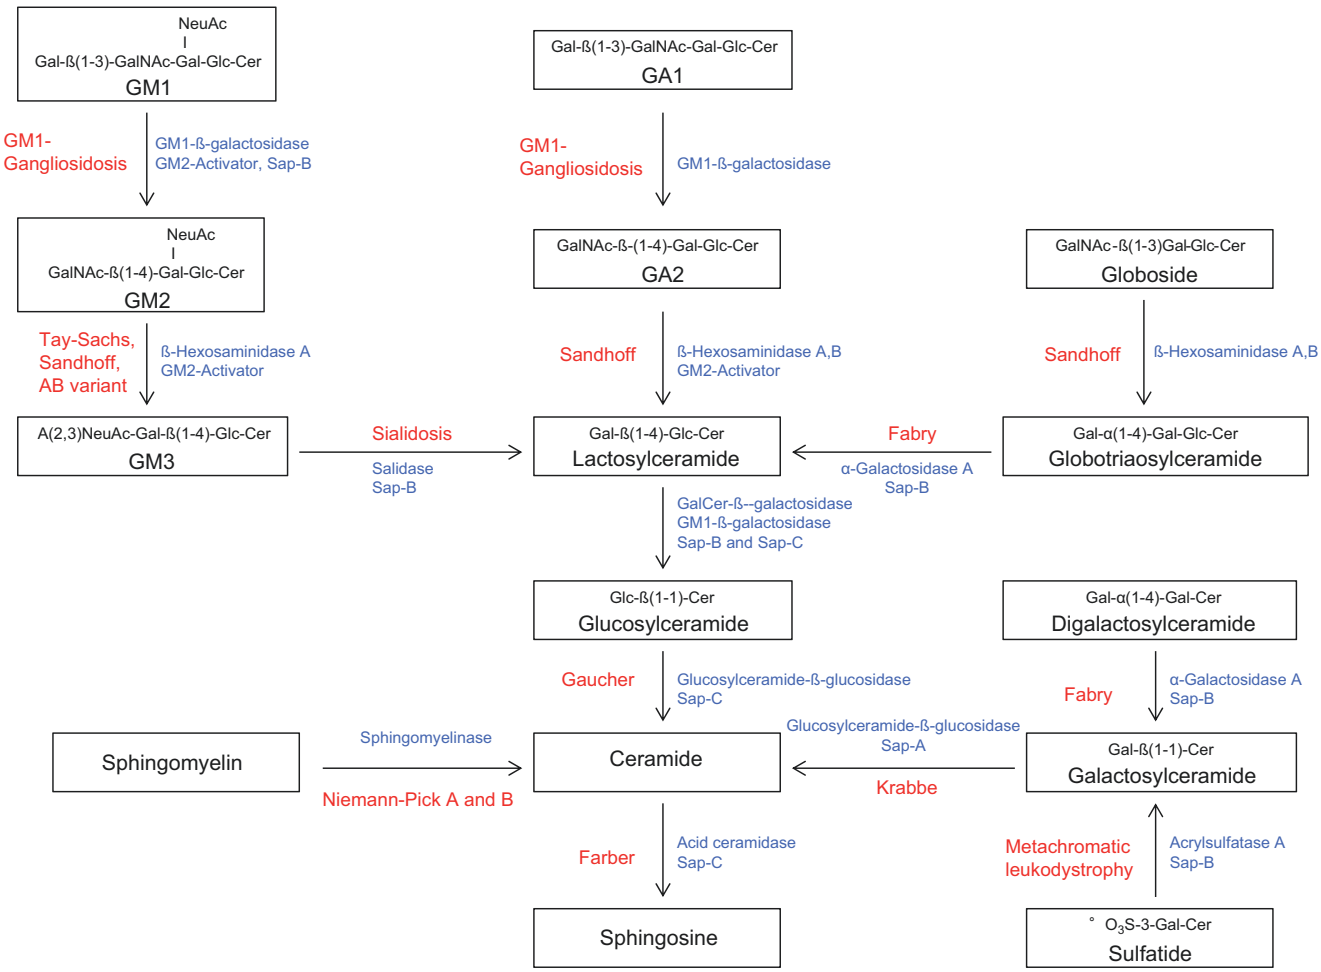

Fig. 60.1 Degradation pathway of sphingolipids. The major metabolites are framed, the enzymes and activator proteins that catalyze the degradation step are colored *blue*, and the disorders resulting from the corresponding enzyme defect are highlighted in *red*

Single lysosomal hydrolase deficiencies comprise disorders like gangliosidosis, galactosialidosis, Krabbe disease, metachromatic leukodystrophy, Gaucher disease, Fabry disease, Farber disease, lysosomal acid lipase deficiency, and Niemann-Pick disease types A and B or acid sphingomyelinase deficiency (ASMD).

In gangliosidosis the deficiency of β-galactosidase leads to the disease pattern of GM1 gangliosidosis (Wenger et al. 1978; D'Azzo et al. 1982; Galjart et al. 1988), and the deficiency of hexosaminidase subunit alpha and beta as well as the deficiency of GM2 activator leads to the phenotype of Tay-Sachs disease (B variant), Sandhoff disease (0 variant), and AB variant of GM2 gangliosidosis (Adams and Green 1986; Beck et al. 1998; Hendriksz et al. 2004). Galactosialidosis is characterized by combined deficiency of β-galactosidase and neuraminidase (sialidase) activity due to a defect in the protective protein/cathepsin A (PPCA). PPCA stabilized and routed the β-galactosidase/neuraminidase complex on their way from endoplasmic reticulum to lysosome and protected them against rapid proteolysis (Abaroa et al. 2011). While β-galactosidase cleaves β-galactosyl residues from GM1-gangliosides, glycoproteins, and glycosaminoglycans, neuraminidase (sialidase) cleaves sialic acid mainly *N*-acetylneuraminic acid from glycoproteins. PPCA itself has a catalytic deaminase/esterase activity on neuropeptides, but this activity is presumably irrelevant for the pathophysiology of galactosialidosis disease.

In mammalian neuronal tissue, there are two isoenzymes of β-hexosaminidase, and each isoenzyme consists of two polypeptide chains. β-Hexosaminidase A is a heterodimer (α/β), whereas β-hexosaminidase B is a homodimer (β/β). Only the β-hexosaminidase A is able to cleave *N*-acetyl-d-glucosamine and *N*-acetyl-d-galactosamine from GM2 gangliosides in presence of GM2 activator, a substrate-specific cofactor. Due to this fact, there are three genes that can lead to impaired GM2 ganglioside hydrolysis: *HEXA* which encodes β-hexosaminidase A subunit-α, *HEXB* which encodes β-hexosaminidase A/B subunit-β, and *GM2A* which encodes the GM2 activator. Mutations of HEXA lead to impaired β-hexosaminidase A activity with normal β-hexosaminidase B activity in Tay-Sachs disease (B variant). Mutations of HEXB lead to impaired β-hexosaminidase A and B activity in Sandhoff disease (0 variant). And at last mutations in *GM2A* lead to failure of GM2 activator in GM2 gangliosidosis AB variant.

In Krabbe disease cerebroside beta-galactosidase catabolizes galactosylceramide to ceramide and galactosylsphingosine to sphingosine. The degradation step further requires the saposin A protein that presents the substrate to the enzyme. Mutations in *GALC* encoding cerebroside beta-galactosidase lead to impaired enzymatic function with storage of galactosylceramide in the pathognomonic "globoid cells," macrophages with storage material, in the CNS as well as toxic galactosylsphingosine in oligodendrocytes and Schwann cells (Wenger et al. 2000).

Arylsulfatase A (ASA) conducts the desulfation of 3-O-sulfogalactosyl-containing glycolipids. 3-O-sulfogalactosyl-containing glycolipids are mainly present in the myelin sheaths of central and peripheral nervous system. The desulfation requires the combined action of ASA and saposin B, a non-enzymatic protein, supposed to present the substrate to ASA, similar to the action of saposin A and cerebroside beta-galactosidase (see above). Deficiency of either ASA activity, which is much more common, or saposin B causes metachromatic leukodystrophy (Gieselmann and Krageloh-Mann 2010; Grossi et al. 2008).

Farber disease is a rare disorder due to the deficiency of the lysosomal hydrolase acid ceramidase with accumulation of undegraded ceramide. An accumulation of macrophages and histiocytes in different tissues as well as ceramide accumulation in brain cells defines the histopathology.

Wolman disease and the milder phenotype cholesteryl ester storage disease are due to the deficiency of lysosomal acid lipase, which is needed to cleave cholesteryl esters in various tissues. The deficiency results in a massive accumulation of cholesteryl esters and triglycerides in lysosomes of most body tissues (Scriver 2002).

Deficiency of lysosomal acid sphingomyelinase in Niemann-Pick type A and B that catalyzes the degradation of sphingomyelin to ceramide and phosphocholine results in the accumulation of sphingomyelin and other lipids in the monocyte-macrophage system. Residual enzymatic activity of sphingomyelinase is much more reduced in patients presenting with the severe form type A compared to milder activities in patients with type B, displaying a more attenuated course of disease.

Besides single lysosomal hydrolase deficiencies leading to glycosphingolipid and sphingolipid storage in lysosomes, the group of sphingolipidoses comprises diseases due to deficiencies of activator proteins, defects of posttranslational modification of lysosomal hydrolases, and lipid trafficking, primarily displaying the clinical picture of sphingolipidosis or in combination with clinical signs of mucopolysaccharidosis (Klima et al. 1993; Vielhaber et al. 1996; Dierks et al. 2009). For the function of different lysosomal hydrolases in the degradation of cerebrosides and gangliosides, the so-called saposins, a group of intralysosomal activator proteins, are a prerequisite. Defective saposin proteins lead to lyso-

somal hydrolase dysfunction and substrate accumulation resulting in a nearly identical clinical phenotype (Spiegel et al. 2005; Christomanou et al. 1986).

In case of mucolipidosis, a defect in the posttranslational glycosylation of lysosomal hydrolases results in a missorting of lysosomal hydrolases to the extracellular space (Tiede et al. 2005). This is further discussed in the chapter on mucopolysaccharidoses (cross ref).

Niemann-Pick type C (NPC) is caused by mutations in *NPC1* or *NPC2*. The disease is caused by a defect in the very complex coordinated action of *NPC1* or *NPC2* with regard to intralysosomal transport and efflux of cholesterol (Wheeler et al. 2019).

Combined saposin deficiency is characterized by the absence of all four types of saposin (saposins A–D) and already manifests in the newborn period with hypotonia, myoclonus, and hepatosplenomegaly. Patients usually develop generalized brain atrophy and epileptic seizures and die during infancy. As in the case of the isolated saposin deficiencies, the enzymatic activities of lysosomal enzymes (e.g., glycosylceramidase, galactosylceramidase, and ceramidase) may be normal in leukocytes but are reduced in cultured fibroblasts. In addition, increased urinary excretion of glycosphingolipids, such as globotriaosylceramide, is found. The diagnosis is confirmed by detection of (often truncating) mutations in *PSAP*.

Signs and Symptoms

Table 60.1 GM1-gangliosidosis

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Cardiomyopathy	±	±	±		
CNS	Brain atrophy (MRI)	++	++	+		
	Dystonia	±	±	++	++	++
	Gait disturbance			±	++	++
	Hypotonia	+++	+++	+		
	Intellectual disability	+++	+++	++	±	±
	Leukodystrophy (MRI)	++	++	+	+	+
	Seizures	++	++	++		
	Spasticity	+++	+++	++	±	±
	Speech disturbances			±	++	++
	Startle response, exaggerated	++	++	+		
Digestive	Ascites, edema	±				
	Hepatosplenomegaly	++	++	±		
Eye	Cherry-red spot	++	++	±		
	Corneal clouding	+	+	±	±	±
	Optic atrophy	++	++	±	±	±
Hematological	Vacuolated lymphocytes	+	+	+	+	+
Musculoskeletal	Coarse facial features	++	++	+		
	Dysostosis multiplex	++	++	±		
	Gingival hypertrophy, macroglossia	++	+	±		
Laboratory findings	LysoGM1	↑	↑	n-↑		
	Molecular analysis	+	+	+	+	+
	Mucopolysaccharides (unsaturated keratan sulfate)	↑	↑	↑		
	Oligosaccharides (U)	↑↑↑	↑↑↑	↑↑	↑	↑

There is no involvement of peripheral nerve system.

Table 60.2 Sandhoff disease

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Ataxia		±	±	++	++
	Brain atrophy (MRI)		++	++	+	+
	Choreoathetosis				++	++
	Dementia		+++	++	+	+
	Dystonia				++	++
	Hypotonia		+++	++	+	+
	Leukodystrophy (MRI)		++	++	±	±
	Mental deterioration		+++	++	±	±
	Seizures		±	±	+	+
	Spasticity		+++	+++	+	+
	Speech disturbances		+++	++	++	++
	Startle response, exaggerated		+++	++	+	+
	Visual evoked potential		↓↓↓	↓↓↓		
Digestive	Hepatosplenomegaly		±	±	±	±
Eye	Cherry-red spot		++	++	±	±
	Vision, impaired		++	++	+	+
Genitourinary	Urinary incontinence		++	++	+	+
Hematological	Vacuolated lymphocytes		+	+	+	+
Musculoskeletal	Doll-like face		++	++		
	Macrocephaly			++	+	+
	Muscle weakness		+++	+++	++	++
Laboratory findings	Beta-hexosaminidase activity A + B[a]	↓↓↓	↓↓↓	↓↓↓	↓↓	↓
	Beta-hexosaminidase activity A[a]	↓↓↓	↓↓↓	↓↓↓	↓↓	↓
	LysoGM2	↑	↑	n-↑		
	Molecular analysis	+	+	+	+	+
	Oligosaccharides (U)		↑↑↑	↑↑↑	↑↑↑	↑↑↑

[a]Enzyme activity is measured with synthetic substrates without need of GM2-activator

Table 60.3 Tay-Sachs disease

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Ataxia		±	±	++	++
	Dementia		+++	++	±	±
	Dystonia				++	++

(continued)

Table 60.3 (continued)

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Laboratory findings	Beta-hexosaminidase activity A + B[b]	n-↑	n-↑	n-↑	n-↑	n-↑
	Beta-hexosaminidase activity A[b]	↓↓↓	↓↓↓	↓↓↓	↓↓	↓↓
	LysoGM2	↑	↑	n-↑		
	Molecular analysis	+	+	+	+	+
	Oligosaccharides (U)	↑↑	↑↑↑	↑↑↑	↑↑↑	↑↑↑

There is no neonatal form of Tay-Sachs disease
Chronic/adult form is clinical related to an atypical Friedreich's ataxia (spinoqcerebellar ataxia); juvenile form is clinical related to juvenile spinal muscular atrophy (Kugelberg-Welander syndrome)
[a]Seizures develop in infancy with disease duration time
[b]Enzyme activity is measured with synthetic substrates without need of GM2-activator

Table 60.4 GM2-gangliosidosis AB variant

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
CNS	Megalencephaly		++	+		
	Mental deterioration		+++	++		
	Muscular hypotonia		++	++		
	Psychiatric symptoms			+++		
	Spasticity		++	++		
	Speech disturbances		+++	++		
	Startle response, exaggerated		+++	+		
Eye	Cherry-red spot		++	++		
	Vision, impaired		++	++		
Genitourinary	Urinary incontinence		++	++		
Laboratory findings	Beta-hexosaminidase activity A	n-↑	n-↑	n-↑		
	Molecular analysis	+	+	+		
	Oligosaccharides (U)	n-↑	n-↑	n-↑		
	Oligosaccharides (U)	↑↑	↑↑↑	↑↑↑		

All forms of GM2-gangliosidosis AB variant are infantile; no chronic forms described
There is no possibility to measure the functionality of GM2-activator, so in clinical suspicion of GM2-gangliosidosis with normal activity of β-hexosaminidases, Molecular analysis of GM2A should be done

Table 60.5 Galactosialidosis

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)
Cardiovascular	Cardiomyopathy	+++	±	+	+	+
	Valvular thickening	±	+++

60.6	Krabbe disease-like disorder due to saposin A deficiency	Low galactocerebrosidase activity in L	L	L, FB	A, CV
60.7	Metachromatic leukodystrophy	Sulfatides (U)	L, FB	L, FB	A, CV
60.7	Metachromatic leukodystrophy-like disorder due to saposin B deficiency	Sulfatides (U)	–	L, FB	A, CV
60.8	Gaucher disease	Glucosylsphingosine[b], chitotriosidase (S)	L, FB	L, FB	A, CV
60.9	Gaucher disease-like disorder due to saposin C deficiency	Chitotriosidase (S)	–	L, FB	A, CV
60.10	Action myoclonus-renal failure syndrome	–	L, FB	L, FB	A, CV
60.11	Combined saposin deficiency	–	L, FB	L, FB	A, CV
60.12	Fabry disease	Globotriaosylsphingosine (lysoGb3)	L, S FB	L, FB	A, CV
60.13	Farber disease	C26-ceramide	FB	L, FB	A, CV
60.14	Niemann-Pick disease types A or B	Lysosphingomyelin (lysoSM)	L, FB	L, FB	A, CV
60.15	Niemann-Pick disease type C1	Oxysteroles, LysoSM-509/LysoSM Chitotriosidase (S), vacuolated lymphos	–	L, FB	A, CV
60.15	Niemann-Pick disease type C2	Oxysteroles, LysoSM-509/LysoSM Chitotriosidase (S), vacuolated lymphos	–	L, FB	A, CV
60.16	Lysosomal acid lipase deficiency	High LDL cholesterol, low HDL cholesterol; vacuolated lymphos	L	L, FB	A, CV

GAGs Glycosaminoglycans, *L* Leukocytes, *S* Serum/plasma, *FB* Fibroblasts, *A* Amniotic fluid cells, *CV* Chorionic villi, *EM* Electron microscopy, *lymphos* lymphocytes

[a]Sialyloligosaccharides in amniotic fluid supernatant

[b]Lysogalactosylceramide and lysoglucosylceramide (glucosylsphingosine) are measured as lysohexosylceramide

Diagnosis and Reference Values

The diagnostic work-up of the sphingolipidoses should begin with the clinical assessment of the patients and should consider the general classification. The characteristic combination of symptoms determines the further diagnostic investigations as outlined in the diagnostic flowcharts (see Fig. 60.2). Depending on the disorder and signs as shown in the tables, these may comprise full blood count and smear, fundoscopy, cardiac assessment (ECG/ECHO), skeletal status (X-ray), cranial MRI, and electrophysiology (VEP, SEP, ERG).

Specific tests for sphingolipidoses, LAL deficiency, and NPC should be performed in specialized laboratories. Diagnostic procedures include specific enzyme assays of lysosomal hydrolases in plasma, leukocytes, or fibroblasts as well as quantitative

analysis of metabolites, mostly in plasma, serum, urine, or CSF. In case the disorder is not associated with an enzyme deficiency or in order to confirm the diagnosis, DNA mutational analysis in the affected gene should be performed. DNA testing is also important in cases where enzymatic diagnosis is already made for counseling purposes, which may include prediction of phenotypes. For further details on specific investigations, see Table 'Specific laboratory investigations for the diagnostic work-up of sphingolipidoses'. For reference values see corresponding lysosomal Tables.

Diagnostic Flowchart

Figure 60.2 shows a diagnostic follow-up of patients presenting with visceral symptoms, mainly hepatosplenomegaly, and with or without neurological presentation. In the case of a multisystem disease with one or more of the specific symptoms in the figure, a further work-up can be performed with screening panels followed by specific enzyme and molecular analysis.

Pathological Values

Specific laboratory investigations for the diagnostic work-up of sphingolipidoses are given below. Of note, dried blood spots (DBS) are increasingly used for screening purposes. However, enzyme assays based upon DBS alone are not always reliable and should be confirmed with other specific tests including enzyme analysis in plasma, leukocytes, or fibroblasts and molecular analysis. Studies have shown that many of the biomarkers can also be determined from blood spots. Again, confirmation by state-of-the-art enzymatic and genetic studies is always necessary to avoid misdiagnosis resulting in erroneous treatment and counseling decisions.

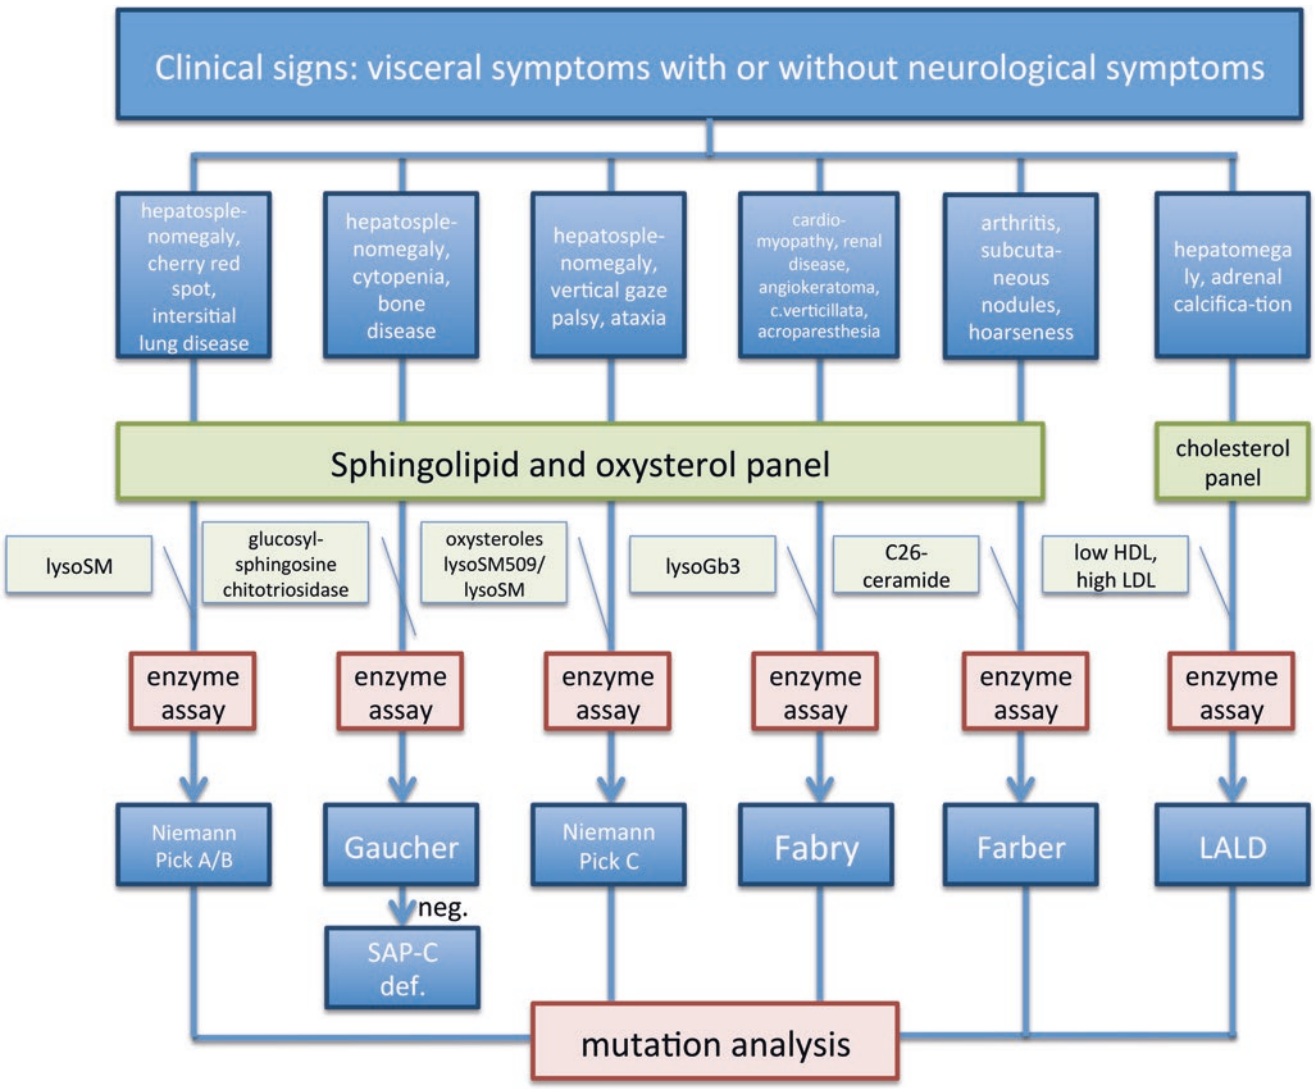

Fig. 60.2 Diagnostic follow-up based upon presenting symptoms

A screening panel consisting of the lysosphingolipids lysoglobotriaosylceramide (LysoGb3), lysohexosylceramide (LysoHexCer: both lysoglucosylceramide and lysogalactosylceramide), lysosphingomyelin (LysoSM), and its carboxylated analogue lysosphingomyelin-509 (LysoSM-509) and oxysterols cholestane-3β,5α,6β-triol and 7-ketocholesterol by UPLC-MS/MS and chitotriosidase activity can be used for a rapid screening to identify lipid storage disorders (Voorink-Moret et al. 2018). Specific elevations, i.e., without overlap between controls and other lipid storage disorders, can be used: LysoSM levels in acid sphingomyelinase deficiency (Niemann-Pick disease type A/B), LysoGb3 levels in males with classical phenotype Fabry disease, and LysoHexCer (i.e., lysoglucosylceramide/lysogalactosylceramide) in Gaucher and Krabbe diseases. In Niemann-Pick diseases, oxysterols were elevated, but LysoSM-509/LysoSM ratio was specifically abnormal in Niemann-Pick disease type C. In Gaucher disease type I, chitotriosidase was grossly elevated while only mildly elevated in all other lipid storage disorders. For GM1 and GM2, lysolipids have also been found to be elevated but only in infantile cases (Pettazzoni et al. n,d). In Farber disease the ceramide C26:0 and especially its isoform 1 are a highly sensitive and specific biomarker (Cozma et al. 2017).

Treatment and Follow-Up

GM1/GM2 Gangliosidosis, Galactosialidosis, and Sandhoff and Tay-Sachs Diseases

In order to replace the deficient enzyme, allogeneic hematopoietic stem cell transplantation has been attempted in both GM1 and GM2 gangliosidoses with disappointing results: in a child with infantile GM1 gangliosidosis. However, despite complete normalization of white blood cell β-galactosidase levels, the patient continued to deteriorate neurologically (Shield et al. 2005). Also for galactosialidosis it has been shown that bone marrow transplantation in mice can fully correct the systemic organ pathology but not the neurological phenotype (Zhou et al. 1995).

In some patients with GM1 gangliosidosis, treatment with the iminosugar N-butyldeoxynojirimycin, miglustat, an inhibitor of glycolipid synthesis, is reported to have some beneficial effect, but without a control group, it is difficult to ascertain its value (Deodato et al. 2017). Based upon its ability to reduce the generation of complex glycolipids, miglustat was also tried in GM2 gangliosidosis. However, no clear effect of miglustat in Sandhoff disease has been observed, and a clinical trial of late-onset Tay-Sachs patients failed.

The most promising therapeutic intervention at this moment is gene therapy: adeno-associated viruses (AAV) seem to have the greatest potential to treat the nervous system because most serotypes preferentially transduce neurons after intraparenchymal injection. Currently intravenous gene transfer with an AAV9 vector is studied for GM1 gangliosidosis, and gene therapy trials for Tay-Sachs and Sandhoff disease are underway. Similar gene transfer therapies are currently being studied for galactosialidosis.

For late-onset patients with relatively milder mutations, pharmacological chaperones, such as pyrimethamine for GM2 gangliosidosis, which enhance residual enzyme activity may be an option. So far no clinical successes have been established (Clarke et al. 2011).

Krabbe Disease

Hematopoietic stem cell transplantation appeared to be successful in asymptomatic infantile patients or slowly progressive later-onset forms of disease. Demyelination and neurological deterioration were prevented or arrested, respectively (Krivit et al. 1998; Escolar et al. 2005). While initially bone marrow was used as a source, nowadays umbilical cord blood is applied for transplants. Since only presymptomatic transplantation may lead to remyelination of the central nervous system, Krabbe disease has been implemented for newborn screening in New York. However, HSCT is not a cure, and ethical issues towards newborn screening have been raised recently because of the identification of uncertain phenotypes based upon GALC enzyme levels (Ehmann and Lantos 2019). Therapeutic approaches using virus-mediated gene transfer and a combination of gene transfer and stem cell transplantation were performed in a mouse model of Krabbe disease (Biffi et al. 2012). Currently preclinical studies are performed to investigate gene transfer for Krabbe disease using AAV-based vectors. No treatment is available for saposin A deficiency.

Supportive care requires a multidisciplinary approach, including measures to manage pain, spasticity, and seizures, prevent infections, and support nutrition. Disease management recommendations are provided by Escolar et al. (Escolar et al. 2016).

Metachromatic Leukodystrophy/Saposin B Deficiency

Only supportive treatment is available for late-infantile MLD caused by ASA deficiency. Stem cell transplantation, even at an early stage of disease, has been mainly proven ineffective. For juvenile and adult forms of MLD caused by ASA defi-

ciency, hematopoietic stem cell transplantation is able to stabilize cerebral demyelination and arrests or slows disease progression, but without influence on the peripheral nervous system. ERT trials are taking place in animal models (Batzios and Zafeiriou 2012; Matthes et al. 2012; Biffi et al. 2008). Gene therapy trials using a lentiviral vector to transfer a functional *ARSA* into hematopoietic stem cells are currently conducted with promising preliminary results (Sessa et al. 2016). Additional gene therapy trials using AAV-based vectors are under investigation. Enzyme replacement therapy through intrathecal administration of the recombinant ARSA is piloted in a phase ½ study that was completed in 2017. Further results are awaited.

There is no treatment available for MLD due to saposin B deficiency (Landrieu et al. 1998).

As for Krabbe disease, supportive care managing pain and spasms as well as nutrition is the cornerstone of treatment of these patients, especially when they are not eligible for transplantation. A specific concern is the risk for gallbladder polyps that may evolve to carcinoma, even in transplanted patients, requiring follow-up and surgical intervention in some cases (van Rappard et al. 2016a, b).

Gaucher Disease

Before enzyme replacement therapy became available, the treatment of a Gaucher disease patient has been symptomatic (Beutler 1988). Splenectomy was performed usually in case of grossly enlarged spleens, leading to infarcts, abdominal discomfort, or severe cytopenia secondary to hypersplenism. After splenectomy, cytopenia is usually immediately resolved. However, the patient is at risk for further liver involvement, hepatopulmonary syndrome, and pulmonary hypertension. In addition, splenectomized patients more frequently develop bone crises and pathological fractures (Mikosch and Hughes 2010). Also, absence of the spleen puts them at a higher risk of septicemia from pneumococci and other encapsulated bacteria. Thus, splenectomy should be avoided whenever possible. Bone crises usually present as acute, circumscript, severe, persistent pain in a long bone, pelvis, or spine, often with signs of inflammation. No other treatment than supportive care with bed rest and nonsteroidal anti-inflammatory drugs or morphine is available. Orthopedic procedures such as joint replacement in case of avascular necrosis are sometimes necessary. Bleeding has been a major problem related to thrombocytopenia, thrombocytopathy, and decreased clotting factors (Hollak et al. 1997). Coagulation studies, including PT and aPTT, need to be performed around every surgical procedure or pregnancy. Supplementation with coagulation factors or plasma may be indicated. For patients with severe skeletal disease, especially those with fractures and osteoporosis, bisphosphonates have been used. While they lead to an increase in bone density, the clinical relevance of this treatment is unclear. Also, new evidence points towards decreased osteoblast activity rather than increased bone loss, and prolonged bisphosphonate therapy may further impair bone remodelling (Van Dussen et al. 2011).

Hematopoietic Stem Cell Transplantation (HSCT)

Allogeneic bone marrow transplantation or HSCT has been used specifically in the past to treat neuronopathic Gaucher disease (Ringdén et al. 1995). The aim of this approach is to replace hematopoietic stem cells with healthy donor cells secreting normal enzyme. Since enzyme replacement therapy does not reach the central nervous system, HSCT may still be an option for patients with chronic neuronopathic disease. However, this procedure is rarely performed nowadays considering the high risk and the beneficial effects of ERT. Updated outcomes of patients transplanted in the past showed that HSCT had no potential to completely prevent the development of neurological damage since patients developed epilepsy over time (Machaczka 2013).

Enzyme Replacement Therapy (ERT)

The prospects of patients with type 1 Gaucher disease have improved dramatically with the advent of ERT. Intravenous administration, usually once every 2 weeks, of recombinant β-GCase (Cerezyme, Genzyme Corp., MA) has proven to result in reversal of most disease manifestations (Barton et al. 1991). In patients with advanced liver, lung, or bone disease, the effectiveness is more limited. But in those initiating therapy before irreversible damage has occurred, the responses are very good. Many dosing regimens have been explored, with higher doses generally leading to more robust responses (Grabowski et al. 2009). However, individualization of dosing has become standard practice, since doses between 15 and 60 U/kg eow may all produce sustained responses. It needs to be emphasized that many patients do not need to be treated as they have very mild, nonprogressive disease manifestations (Beutler et al. 1995). The precise criteria to start ERT in type 1 Gaucher disease are not unequivocal. Some believe that most patients need ERT, while others tend to be more conservative. In general, children with symptoms are always treated, while adults with stable disease and mild splenomegaly without severe platelet count (e.g., below 60 × 109/L) and without severe bone marrow infiltration may remain untreated. Currently, the risk factors for late complications, such as multiple myeloma, osteoporosis, or liver/lung disease, are unknown. Whether early initiation of ERT can prevent this is unclear and needs to be investigated. Patients with the acute neuronopathic form of Gaucher disease do not benefit from ERT, and it is now generally accepted that these should not be treated (Vellodi et al. 2009). In a very young patient with neurological symptoms,

it may be difficult to decide whether this represents an acute or a chronic form. In such a case, it may be an option to discuss temporary treatment with the option to stop when the course of disease is rapidly progressive (Vellodi et al. 2009). In patients with the chronic neuronopathic form, ERT may certainly alleviate the symptoms related to hepatosplenomegaly and partially also skeletal disease. However, there is no evidence that ERT has reversed, stabilized, or slowed the progression of neurological involvement. Detailed recommendations for treatment are provided in the consensus paper by Vellodi et al. (2009). In type 3c, ERT is usually not indicated, as these patients do not have extensive visceral disease. Over the last years, new ERTs have been developed. Currently, velaglucerase (VPRIV, Shire HGT) has also received marketing authorization in the EU and the USA, whereas taliglucerase (Uplyso, Protalix/Pfizer) has been approved by the FDA only (Zimran et al. 2010, 2011). All these enzymes have shown effectiveness, and choices for treatment will probably depend on whether there are any potential differences in effectiveness or safety, as well as reimbursement strategies and costs.

Substrate Reduction Therapy (SRT) and Gene Therapy

An alternative approach is based on small molecules that inhibit substrate synthesis. The authorized treatment is miglustat (*N*-butyl deoxynojirimycin, Zavesca, Actelion/Janssen). As mentioned before, this compound is an iminosugar, which inhibits the glucosyltransferase involved in the first step in the formation of complex glycosphingolipids. The rationale is that the reduction in substrate is balanced against the residual β-GCase activity, which ultimately results in degradation of stored glycolipids. Indeed, miglustat results in reductions in liver and spleen size and gradual improvements in hemoglobin and platelet counts (Cox et al. 2000). The limitations of miglustat are the inferior effects in relation to ERT and unpleasant, mainly gastrointestinal, side effects. With the authorization of a second-generation substrate inhibitor, eliglustat (Lukina et al. 2010), with a more favorable safety and efficacy profile, miglustat is rarely used for type 1 Gaucher disease. While miglustat failed in type 3 Gaucher disease (Schiffmann et al. 2008), newer SRTs such as venglustat (Sanofi/Genzyme) are currently under development that have the ability to cross the blood-brain barrier and can be used in neuropathic Gaucher disease. Preclinical data on gene therapy for type 1 Gaucher disease with lentiviral or liver-directed AAV-based vectors have been promising, and clinical trial programs are about to start.

Follow-Up and Monitoring of Gaucher Disease

Follow-up should in principle be individualized, as the heterogeneity of the disease and a number of associated conditions precludes strict protocolized follow-up. However, recommendations for follow-up of patients with Gaucher disease have been previously published (Charrow et al. 2004; Baldellou et al. 2004; Grabowski 2004; Zimran 2011). For neuronopathic disease, a helpful scheme for follow-up of neurological symptoms has been published (Vellodi et al. 2009). Some of the recommendations for follow-up in non-neuronopathic Gaucher disease refer to earlier-defined therapeutic goals (Pastores et al. 2004). It should be kept in mind that these goals are in fact mean responses in blood counts, liver and spleen volumes, and skeletal parameters, rather than clinically meaningful endpoints. Dose adjustment should be made on an individual basis rather than on achievement of these goals. For example, in patients with very large spleens, platelet responses will initially be very slow, and in the absence of clinically relevant bleeding episodes, there is no justification for a dose increase (Hollak et al. 2012a, b). In general, bleeding, severe anemia, and symptomatic organomegaly are alleviated within 12–24 months. Of importance is that good clinical responses are always accompanied by substantial decreases in chitotriosidase (Aerts et al. 2005) or in deficient patients, in CCL18/PARC, ACE, or ferritin levels. Absence of a response in these parameters indicates failure of treatment. Table 'Follow-up and monitoring of non-neuronopathic (type 1) Gaucher disease' shows the minimal recommended follow-up procedures. Because of the increased risk for multiple myeloma, pulmonary hypertension, Parkinson's disease, and perhaps other conditions such as diabetes, it may be wise to include relevant physical, laboratory, or imaging parameters in the follow-up (Zimran 2011). Skeletal imaging should preferably be performed with MRI, as this allows the assessment of the degree of bone marrow involvement. Serial follow-up with skeletal X-rays is unnecessary and exposes patients at high levels of radiation (Poll et al. 2002). DEXA scanning has difficulties in interpreting results in pediatric patients and in adults with sclerotic lesions may also give false outcomes. However, in those with milder disease, regular follow-up to detect early osteopenia or osteoporosis is of importance (Hughes et al. 2019).

Fabry Disease

Multidisciplinary care for a Fabry disease patient is usually required because of the complexity of the manifestations (Desnick et al. 2003). Since the natural disease course differs between man and women and classically and non-classically affected patients (Arends et al. 2017), management needs to be tailored to the patients' needs. Adequate pain management and early treatment with ACE inhibitors or angiotensin receptor blockers may be needed in case of proteinuria or cardiac symptoms (Jain and Warnock 2011). The use of aspirin is mostly recommended, certainly after TIA or stroke, but whether use of antiplatelet therapy prevents new white mat-

ter lesions is unknown. Cardiovascular risk factors independent of Fabry disease are likely to influence the disease course and deserve adequate identification and strict treatment, including hypertension, diabetes, and hypercholesterolemia. Those with rhythm disturbances, frequently bradycardia and AV blocks with ventricular escape tachycardias, may experience syncope. Those patients carry a risk for acute cardiac death and need cardiological monitoring (Pierre-Louis et al. 2009). Patients with end-stage renal failure may benefit greatly from kidney transplantation. The graft survival is not different compared with other patients with renal failure (Ojo et al. 2000).

Enzyme Replacement Therapy

In 2001, two recombinant enzymes were approved for use in Fabry disease: agalsidase alpha (Replagal®) and agalsidase beta (Fabrazyme®), referred to as enzyme replacement therapy (ERT). While these enzymes are produced in different cell systems, their biochemical properties are very similar. They have been investigated in different doses: agalsidase beta at 1.0 mg/kg eow and agalsidase alpha at 0.2 mg/kg eow. The first placebo-controlled trials showed some beneficial effect on reduction of storage in endothelial cells and improvement in pain, with stable parameters of renal and cardiac disease (Eng et al. 2001; Schiffmann et al. 2001; Hughes et al. 2008). In a phase IV placebo-controlled trial, treatment with agalsidase beta resulted in a reduction of Fabry-related complications in patients with advanced disease at baseline (Banikazemi et al. 2007). However, complications can still occur during treatment, specifically in patients with advanced disease (Schiffmann et al. 2006; Germain et al. 2007; Weidemann et al. 2009). The occurrence of antibodies may also influence the clinical outcome, as has been recently shown (Lenders et al. 2018; van der Veen et al. 2019). Antibodies almost exclusively emerge in male patients, in particular those without any residual enzyme activity. Their presence is frequently associated with infusion-associated reactions such as chills and fever. This can usually be managed by premedication with corticosteroids and/or slowing down of the infusion rate. Benefits of ERT have also been reported in children, but whether early treatment can prevent the occurrence of late complications is still unknown. There is increasing consensus that not all patients will benefit, and therefore start and stop criteria have been developed and should be regularly evaluated (Biegstraaten et al. 2015).

More recently migalastat and oral chaperone treatment has been authorized for treatment of Fabry disease patients with amenable mutations (Germain et al. 2016). Only a subset of patients, mainly non-classical, have amenable mutations. For which patients this oral alternative is an effective option needs further study, including the reliability of the amenability assay, as some switch patients may show biochemical evidence of disease progression (Lenders et al. 2019). Many questions are thus still unanswered regarding the appropriate use of Fabry treatments. A major concern in this respect is that screening initiatives (neonatal or screening in high-risk groups) may reveal many individuals with variants of unknown significance that may be misdiagnosed as Fabry cases. A diagnosis should be carefully considered before costly and burdensome treatments are recommended.

Alternative or Investigational Treatments for Fabry Disease

New enzyme replacement therapies are being developed that hopefully will have less immunological side effects and a better biodistribution. Of these, pegunigalsidase, a pegylated dimer of aGal-A, is a promising agent as shown in a phase 1/2 study (Schiffmann et al. 2019.) A moss-derived enzyme with a different glycosylation and therefore biodistribution, perhaps better targeting kidney cells, is also investigated in Fabry disease patients (Hennermann et al. 2019).

Other small molecules, specifically substrate inhibitors (see Gaucher disease), are under investigation. Currently lucerastat (*N*-butyl deoxygalactonojirimycin, Idorsia) is investigated in Fabry disease and has shown to be safe (Guérard et al. 2018). Its effectiveness is now studied in a phase 3 trial. In addition, a new oral substrate inhibitor is developed by Sanofi/Genzyme, venglustat, for treatment of Fabry disease but also for neuropathic Gaucher disease and Parkinson's disease. Gene therapy has been successfully used in animal models of Fabry disease. As for Gaucher disease, lentiviral or liver-directed AAV-based vectors are currently explored in clinical trials of adult Fabry disease patients. All these developments hold great promise for the future, but results of safety and efficacy studies have to be awaited.

Follow-Up and Monitoring of Fabry Disease

As discussed before, Fabry disease is extremely variable. Hence an individualized approach is the cornerstone of management and follow-up. ERT is usually initiated in symptomatic patients, but those who are asymptomatic should receive follow-up as well. Early recognition of organ failure and adequate and timely initiation of appropriate therapy are important. ERT is probably of limited effectiveness in advanced cases, and benefits should be outweighed against the burden of frequent intravenous administration and costs (Biegstraaten et al. 2015). In advanced cases, follow-up schedules need to be extended based on the most severe end-organ damage, following general practice guidelines for patients with renal or cardiac failure. A proposal for follow-up measures is shown in Table 'Follow-up and monitoring of Fabry disease'.

Farber Disease

There is no effective treatment for Farber disease at this moment. Hematopoietic stem cell transplantation (HSCT) has been explored in Farber disease showing some improvement in peripheral manifestations but without effect on the central nervous system (Ehlert et al. 2018). Enzyme replacement therapy with recombinant human ACDase (rhACDase) is not yet in clinical phase of development, but is currently being investigated as potential treatment. Finally, gene therapy strategies hold promise for the treatment of ACDase deficiency. Gene therapy was performed in mouse models showing long-term expression of ACDase for up to 13 weeks (Ramsubir et al. 2008). An ex vivo strategy with transduction of hematopoietic stem cells seems an attractive approach as well. No clinical trials have so far started in Farber disease.

Niemann-Pick Type a or B

For patients with Niemann-Pick A and B, supportive therapy to treat the pulmonary manifestations or liver disease is still the mainstay of treatment. Splenectomy is rarely done as it aggravates the liver and lung disease, but may be required in case of extensive enlargement and infarcts or rupture. Standard lipid-lowering agents are indicated for the treatment of ASMD-associated lipid abnormalities in adult patients. Bronchoalveolar lavage has been tried in some cases of extreme pulmonary involvement to relieve symptoms, but its effect is unclear.

Hematopoietic stem cell transplantation (HSCT) has not been very successful, with several patients succumbing due to peritransplant complications (Schuchman and Wasserstein et al. 2015).

Enzyme replacement therapy (ERT) with recombinant human ASM (Sanofi/Genzyme) is currently explored in a phase 3 clinical study. In a 26-week phase 1 study, decreases in spleen and liver volumes and sphingomyelin accumulation in liver biopsies have been observed (Wasserstein et al. 2015).

Niemann-Pick Disease Type C

Treatment of NPC should involve symptom management, employing disease-modifying agent(s) when available. Several supportive therapies for neurological symptoms are listed in an extensive review from the International Niemann-Pick Disease Registry (INPDR) (Geberhiwot et al. 2018). Bone marrow transplantation in a child with NPC did not improve neurological deterioration (Hsu et al. 1999), whereas trials with hematopoietic stem cell transplantation are in progress in an animal model of NPC (Seo et al. 2011). In infantile-onset NPC presenting with jaundice and hepatosplenomegaly, liver transplantation can be a temporary life-saving measure, but the outcome is poor due to neurological deterioration, despite miglustat therapy (Yamada et al. 2019).

Substrate reduction therapy with miglustat is the only authorized treatment for NPC so far. A randomized controlled trial of 12-month duration reported improvements or stabilization of saccadic eye movements, and in later cohort studies, neurological symptoms including swallowing have been reported to improve or stabilize (Pineda et al. 2018). In a retrospective study in France, patients with less severe neurological disability had a better outcome while using miglustat. Since the disease course is very variable, and with the lack of an untreated comparator, it remains unclear whether this is due to a milder disease course or a neuroprotective effect of miglustat (Nadjar et al. 2018). Current consensus states that only patients with milder phenotypes and early neurological disease should receive treatment (Geberhiwot et al. 2018).

New treatments are arimoclomol, a small-molecule co-inducer of heatshock proteins, which is currently in phase 2/3 trial, and cyclodextrins. The latter compounds are small oligosaccharide rings that can capture cholesterol, a specific mixture of which was piloted in a phase 1/2a clinical trial with intrathecal administration followed by a phase 2/3 clinical trial. In addition, phase 1 clinical studies utilizing high-dose intravenous administration of different cyclodextrins are currently executed. N-Acetyl-L-leucine, which is an amino acid used traditionally for vertigo as well as several causes of ataxia, is also evaluated in NPC.

The INPDR has proposed a schedule for follow-up on a regular basis including neurocognitive, ophthalmological, audiological, and swallowing assessments (Geberhiwot et al. 2018).

Lysosomal Acid Lipase Deficiency

HMG-CoA reductase inhibitors are given in cholesteryl ester storage disease to prevent early complications of atherosclerosis. HSCT and liver transplantation have been employed with successes in some patients but also with disease recurrence and complications in others (Bernstein et al. 2018).

Currently, ERT with recombinant human acid lipase (Alexion) is authorized to treat patients of all ages, including infants with Wolman disease, where it has shown to improve survival and growth (Jones et al. 2017). In attenuated phenotypes with significant and progressive disease, ERT can improve cholesterol profiles and liver enzymes and volume and hopefully prevent liver failure. Older patients with very mild phenotypes and minimal symptoms may remain stable and probably do not require treatment (Burton et al. 2015).

Follow-up and Monitoring

Follow-up and monitoring of non-neuronopathic (type 1) Gaucher disease

Assessment		Untreated	Treated	
Schedule		Every 12–24 months	Every 3 months during the first year, every 6 months thereafter	Every 12 months during the first 2–4 years, on an individual basis thereafter
Physical examination		X	X	X
Laboratory	Ab testing[b]			X
	ACE	X		X
	CBC	X	X	X
	Chitotriosidase or CCL18/PARC[a]	X	X	X
	Ferritin	X		X
	Glucosylsphingosine	X	X	X
	Liver enzymes	X		X
	M-protein	X		X
Imaging	DEXA scan[d]	X		X
	Liver and spleen volume (MRI, US)			
	Skeletal MRI	X		X
	Skeletal X-rays[c]	X		X
QoL scores		X		X

[a]CCL18/PARC is recommended in case of chitotriosidase deficiency
[b]Testing for antibodies should be done at baseline and after 12 months. If negative, this should only be repeated in case of infusion-associated reactions or lack of response
[c]Skeletal X-rays are recommended to be made only once, to serve as baseline; follow-up X-rays should only be made upon clinical indication (Maas et al. 2002)
[d]DEXA scans should be performed at baseline and on an individual basis thereafter

Follow-up and monitoring of Fabry disease

Assessment		At first visit	Untreated	Treated	
			Every 12–24 months	Every 3 months during the first year, every 6 months thereafter	Every 12 months during the first 2–4 years, on an individual basis thereafter
Physical examination	General Neurological[a]	X	X	X	X
Laboratory	24 h urinary protein	X	X	X	
	Ab testing				X[c]
	Cholesterol profile[b]	X			
	Creatinine/eGFR	X	X	X	
	Electrolytes	X			X
	Gb3/lysoGb3			X	
Imaging	Brain MRI[d]	X			X
	Cardiac MRI or	X	X		
	US[d]		X		X
Others	Audiogram	X	X		X
	EKG	X	X		X
	Ocular examination	X			
	Qol scores	X	X		X

[a]At first visit, the presence of angiokeratoma and small fiber neuropathy should be investigated
[b]Cholesterol profile and other cardiovascular risk factors should be recorded carefully at first visit and followed on an individual basis
[c]Testing for antibodies should be done at baseline and after 12 months. If negative, this should only be repeated in case of infusion-associated reactions or lack of response
[d]MRI or US of the heart and MRI of the brain in adults only or upon clinical indication in children

Introduction

Neuronal ceroid lipofuscinoses (NCLs) are a heterogeneous group of inherited neurodegenerative diseases characterized by the lysosomal accumulation of autofluorescent material, revealed upon electron microscopy of neurons and many other cell types. The autofluorescent storage material is most commonly represented by subunit c of mitochondrial ATP synthase and sphingolipid activator proteins A and C. Nearly all of the NCL diseases can be subdivided in different clinical forms by age of onset and severity due to residual activity of the corresponding enzyme.

The overall incidence of the NCL is estimated to be 1:20.000. The disorders primarily affect the cerebral gray matter. Signs and symptoms vary widely between the forms, but generally the major clinical symptoms include psychomotor regression, movement disorder, myoclonic epilepsy, progressive loss of vision, behavioral disturbance, and cognitive decline leading to dementia. The early-onset forms of NCL are characterized by severe brain atrophy, decerebration, and premature death. Five clinical groups—congenital, infantile, late infantile, juvenile, and adult—refer to the age of disease onset and are caused by mutations in at least 13 different genes (see Table 61.1). Three enzymes have been recognized as responsible, when deficient, of NCL cases: palmitoyl-protein thioesterase 1 (*PPT1*), tripeptidyl-peptidase 1 (*TPP1*), and cathepsin D (CTSD).

CLN9 is not genetically defined yet. *SGSH* gene mutations usually cause mucopolysaccharidosis type IIIA. SGSH mutations that are associated with high residual sulfamidase activity may also cause adult onset of NCL.

Most NCL diseases are inherited in an autosomal recessive manner. As by current knowledge, only the CLN4B follows an autosomal dominant inheritance. There is a rough genotype-phenotype correlation in the sense that several missense mutations with minor residual enzymatic activity in the palmitoyl protein thioesterase 1 (CLN1), the tripeptidyl peptidase 1 (CLN2), and cathepsin D (CLN10) are correlated with protracted clinical courses (Das et al. 2001; Steinfeld et al. 2004, 2006).

Nomenclature

NCL Phenotypes Classified by Age at Onset

The *congenital NCL* (CLN10) begins in utero and is associated with intrauterine growth retardation and fetal microcephaly. At birth, affected infants show intractable seizures, spasticity, and central apnea. These newborns usually survive only days, seldom weeks.

The *infantile NCL* is a rapidly progressive form and presents between 6 and 18 months with hyperexcitability, muscular hypotonia, psychomotor retardation, myoclonic seizures, visual failure, and microcephaly. Later, by the age of 3 years, loss of motor abilities, increasing spasticity, and lack of environmental contact comprise the clinical picture.

The *classical late infantile NCL* is characterized by normal development to the age of 2 years, followed by developmental delay, motor regression, myoclonic seizures, and visual failure. After the onset of symptoms, the disease progresses in a program-like manner over 2–3 years leading to chair boundness, spasticity, blindness, and dementia (Steinfeld et al. 2002).

The *juvenile NCL* is characterized by progressive visual failure beginning at the age of 4–9 years, followed by developmental delay, motor regression, myoclonic seizures, and visual failure. Cognitive decline and motor deterioration follow and finally lead to death in the third or fourth decades. Seizures are a variable feature. Atypical juvenile forms (CLN2 and CLN5) initially present with motor symptoms and behavioral problems before they develop visual disturbance.

The *variant forms of late infantile NCL* have clinical presentations intermediate between the classical late infantile and juvenile forms.

The *adult* NCL is distinguished from the other NCL types by the absence of visual failure and an onset at 20–30 years of age with mild progression (Mole et al. 2005, Mole and Williams 2010).

The diagnostic work-up of the NCL should begin with the clinical assessment of the patients and should mainly consider the presence of major neurodegeneration (Mole and Williams 2001). The assessment of the specific combination of symptoms is important to determine the further diagnostic investigations that commonly comprise full blood count and smear, fundoscopy, cardiac assessment (ECG/ECHO), skeletal status (X-ray), brain MRI, and electrophysiology (VEP, SEP, ERG). Specific tests should be performed in specialized laboratories. Diagnostic procedures include quantitative analysis of metabolites in body fluids (urine, serum, CSF) and fibroblasts as well as specific assays of lysosomal hydrolases. DNA mutation analysis in the affected gene should be performed to confirm the diagnosis. DNA testing is particularly important for prenatal diagnosis. More specific information are available in the following specific sessions.

Tripeptidyl-Peptidase 1 Deficiency (NCL2)

Physiopathology

The lipopigment pattern seen most often in CLN2 consists of "curvilinear" profiles. Patients with CLN2 are deficient in a pepstatin-insensitive lysosomal peptidase called tripeptidyl peptidase 1 (TTP1). TTP1 removes tripeptides from the N-terminal of polypeptides. The mechanism by which failure to cleave these N-terminal peptides leads to neuronal degeneration of the hippocampus, cortical interneurons, cerebellum, and thalamocortical neurons with consequent neuronal death is still poorly understood.

Table 61.1 Ceroid lipofuscinosis, neuronal, 2

	Lysosomal tripeptidyl-peptidase-1 (fibroblasts)	↓↓↓	↓↓↓	↓↓↓	↓↓↓	↓↓↓
	Lysosomal tripeptidyl-peptidase-1 (leukocytes)	↓↓↓	↓↓↓	↓↓↓	↓↓↓	↓↓↓

Laboratory and instrumental examinations (NCL2)

Histologic findings (electron microscopic findings)	Electron microscopy ultrastructural studies in peripheral blood lymphocytes or other tissues (conjunctiva, skin, or other tissues) show the presence of the curvilinear profiles (CVB). Histologic findings include neuronal loss and the presence of distended neurons with granular PAS-positive material
Enzyme activity	Tripeptidyl peptidase 1 (TPP1) levels can be measured in leukocytes, cultured fibroblasts, dried blood spots, and saliva. Fibroblast TPP1 activity is approximately 17,000 micromoles of amino acids produced per hour per mg of protein The TPP1 activity in CLN2 is less than 4% of normal
Molecular genetic testing	Molecular genetic testing of TPP1 gene. More than 90 mutations of TPP1 are known. The common mutations are p. Arg208Ter and c.509-1G>C; the others are uncommon or private mutations
Instrumental tests	*Electroencephalography:* Abnormal EEG with spikes in the occipital region in response to photic stimulation at 1–2 Hz *Electroretinography:* Electroretinogram (ERG) is usually abnormal at presentation and becomes undetectable soon thereafter. On occasion, the ERG may be normal at presentation *Visual evoked potential:* Abnormally enhanced for a long period and diminish in the final stage of the disease *Somatosensory evoked potential:* Progressive attenuation in all NCLs is seen in somatosensory evoked potential studies *MRI and MR spectroscopy:* Progressive cerebellar and cerebral atrophy with normal basal ganglia and thalami. In a study, Dyke et al. elaborate a multiparametric disease severity score, correlating with the patient's age and disease duration; it is obtained from the combination of the whole-brain apparent diffusion coefficient (ADC), the volume percentage of CSF, and N-acetylaspartate-to-creatine metabolite ratios and const. They determined that children in the study with CLN2 began to differ from controls at age 5 years *Positron emission tomography:* a severe, generalized hypometabolism is seen
Other tests	*Neurologic examination* *Developmental/cognitive and educational assessment* *Ophthalmic examination:* Ophthalmic scale may serve as an objective marker of LINCL (late infantile neuronal ceroid lipofuscinosis) severity and disease progression *A total disability score* is derived by summing up the single scores for motor, visual, and verbal functions *A Weill Cornell LINCL (late infantile neuronal ceroid lipofuscinosis) scale,* based on neurologic, ophthalmologic, and CNS imaging, has been developed, which correlate with age and time since the onset of initial clinical manifestations

Prevention

Prenatal diagnosis is an option in patients with family history of CLN2 or known carriers. It can be done through electron microscopic examination of uncultured amniocytes for typical curvilinear bodies and through mutation analysis.

Genetic counseling should be offered to family members, and the risk of CLN2 should be assessed for subsequent pregnancies.

Neuronal Ceroid Lipofuscinosis Type 3

Physiopathology

In CLN3 NCL, mutations in CLN3 gene, coding for a protein involved in lysosomal function, in particular in microtubule-dependent, anterograde transport of late endosomes and lysosomes, have been found. These mutations result in a substantial decrease in mRNA expression and stability. Consequently, several cellular processes are affected, such as

Table 61.2 Ceroid lipofuscinosis, neuronal, 3

Laboratory and instrumental examinations (CLN3)

Histologic findings (electron microscopic findings) and laboratory tests	The analysis of *blood smears* through light microscopy reveals the presence of lymphocyte vacuoles *Electron microscopy ultrastructural studies* in peripheral blood lymphocytes or other tissues (conjunctiva, skin, or other tissues) show the presence of vacuoles and the storage of lipopigment with a "fingerprint" profile. The fingerprint profile can have three different appearances: pure within a lysosomal residual body; in conjunction with curvilinear or rectilinear profiles; and as a small component within large membrane-bound lysosomal vacuoles. The combination of fingerprint profiles within lysosomal vacuoles is a regular feature of blood lymphocytes from patients with CLN3 *Histological studies* reveal severe widespread neuronal degeneration resulting in retinal atrophy and in massive loss of brain substance, the selective necrosis of stellate cells in layers II and III and loss of pyramidal cells in layer V, and the accumulation of lipofuscin in neuronal perikaryon and in the thyroid *Muscle biopsy:* In muscle tissue, autophagic vacuoles and intermyofibrillar and subsarcolemmal accumulation of electrodense material are seen on biopsy (in some patients) *Biochemical abnormalities* include the accumulation of subunit C of the ATP synthase complex (SCMAS) in the lysosomes of patients *Lymphoblast cell analysis:* Enhanced levels of α-synuclein oligomers and gangliosides GM1, GM2, and GM3 and reduced levels of sphingomyelin and autophagy in CLN3 disease lymphoblast cells compared with normal cells CLN3-deficient cells display defects in the ARF1-Cdc42 pathway and actin-dependent events
Enzyme activity	Not applicable
Molecular genetic testing	*Molecular genetic testing* of CLN3 gene

Instrumental tests	*Electroencephalography:* The EEG shows nonspecific disorganization and spike-and-slow-wave complexes *Electroretinography:* Abnormal early ERG shows loss of photoreceptor function *Visual evoked potential:* Abnormal early with delayed latency *Somatosensory evoked potential:* Progressive attenuation *Magnetic resonance imaging (MRI) and MR spectroscopy:* Cerebral atrophy and cerebellar atrophy are seen usually after age 15 years. Progressive hippocampal atrophy is one of the characteristic features of brain atrophy in CLN3 in adolescence *Longitudinal MRI* shows that the annual rate of the gray matter loss in adolescent CLN3 patients is as high as 2.4% *In voxel-based morphometric study,* marked reduction in the gray matter volume of the dorsomedial thalami in particular and decreased white matter volume of the corona radiata are seen *Positron emission tomography (PET):* Hypometabolism, earliest in the calcarine area
Other tests	*Neurologic examination* *Ophthalmologic examination* (early in the course of disease may reveal macular changes only; gradually, typical signs of pan-retinal degeneration develop, such as pigmentary changes in the retinal periphery, vascular attenuation, and optic nerve pallor) *Developmental/cognitive and educational assessment* *Use of the multimodal clinical rating instrument, the Unified Batten Disease Rating Scale (UBDRS)*, to assess motor, behavioral, and functional capabilities of patients with juvenile onset

lysosomal pH, endocytosis, autophagy, transport of proteins from the TGN, cell proliferation, apoptosis, and synaptic transmission. Nevertheless, it is still not clear what precise biological function(s) CLN3 regulates and what is the mechanism of such regulation (Anil B. Mukherjee et al. 2019).

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Neuronal Ceroid Lipofuscinosis Type 4 (Parry Type) (CLN4B)

Physiopathology

In CLN4B NCL, the DNAJ homolog subfamily C member 5 (DNAJC5) is deficient. DNAJC5 functions in many cellular processes by regulating the ATPase activity of 70-kd heat-shock proteins. In particular cysteine string protein alpha (CSPα) encoded by the DNAJC5 gene plays critical acting as a chaperone to facilitate correct folding of proteins.

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Neuronal Ceroid Lipofuscinosis Type 5

Physiopathology

The lipopigment patterns observed most often in CLN5 comprise mixed combinations of "granular," "curvilinear," and "fingerprint" profiles. The functions of these soluble lysosomal glycoproteins are still unknown, but it seems to play a role in endosomal sorting.

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Neuronal Ceroid Lipofuscinosis Type 6

Physiopathology

CLN6 encodes a protein of unknown function with seven transmembrane domains localizing to the endoplasmic reticulum (ER). It has been reported that CLN6 has a role in the regulation of cellular acidification, endocytosis, and autophagy, but how the altered function of this gene leads to the accumulation of biometals and how this defect leads to CLN6 disease pathogenesis must still be clarified.

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Neuronal Ceroid Lipofuscinosis Type 7

Physiopathology

In NCL 7, the major facilitator superfamily domain of the CLN7 gene containing protein-8 (MFSD8), an acid membrane protein that belongs to the major facilitator superfamily of transporter proteins (active permeases), is deficient. The precise role of this protein is still not well understood, but active permeases function as transporters of sugars, sugar phosphates, drugs, inorganic and organic cations, amino acids, and neurotransmitters across membranes, so mutations in gene cause depletion of soluble proteins in the lysosomes that in turn impairs the reactivation of mTOR signalling, thus being responsible for impaired anabolic regulator of cell growth and metabolism. The protein likely localizes to lysosomal membranes. MFSD8 is ubiquitously expressed at a very low level; only in the liver, heart, and pancreas its expression is consistently higher.

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Neuronal Ceroid Lipofuscinosis Type 8

Physiopathology

The CLN8 gene encodes a transmembrane protein belonging to a family of proteins containing TLC domains, which are postulated to function in lipid synthesis, transport, or sensing. The protein localizes to the endoplasmic reticulum (ER) and may recycle between the ER and ER-Golgi intermediate compartment. The exact function is still not clear, but it is known that CLN8 protein belongs to the TRAM-

Laboratory and instrumental examinations (CLN8)

Histologic findings and laboratory tests (electron microscopic findings) and laboratory tests	*Electron microscopy studies of tissue specimens* (5–10 mL of heparinized whole blood (lymphocytes)) or tissue biopsies (now usually of skin, but previously of conjunctiva or other tissues) show intracellular accumulation of granular storage material and autofluorescent lipopigment in neurons Intracellular curvilinear profiles on ultrastructural analysis Lymphocytes are not usually vacuolated
Enzyme activity	Not applicable
Molecular genetic testing	Molecular analysis to confirm the diagnosis
Instrumental tests	*Neurologic examination with developmental/cognitive and educational assessment* *EEG* shows abnormalities *MRI* shows cerebral and cerebellar atrophy, progressive *Somatosensory evoked magnetic field (SEF) studies* within normal limits *Magnetic resonance imaging* shows slight to moderate cerebellar atrophy and might reveal slightly enlarged cerebral sulci
Other tests	*Clinical examination* *Family history*

Cathepsin D Deficiency (NCL Type 10)

Physiopathology

The CLN10 gene encodes cathepsin D, a lysosomal aspartic protease belonging to the pepsin superfamily. Cathepsin D is important for neuronal stability and maintenance of the extracellular environment. It is associated with several physiological processes such as protein degradation, autophagy, and apoptosis since it hydrolyzes a wide variety of substrates including the extracellular matrix proteins fibronectin and laminin. So far, the in vivo substrates of this enzyme have not been clearly identified although it has been reported that CTSD catalyzes the cleavage of α-synuclein, a protein associated with Parkinson's disease.

Alterations in a macroautophagy-lysosomal degradation pathway appear to mediate neurodegeneration in this disease.

Prevention

Prenatal testing is possible in pregnancies at increased risk if biochemical studies in the proband have revealed deficient activity of the enzyme CTSD, or if the disease-causing mutation(s) have been identified in the proband and parents. In these instances, testing is performed on fetal cells obtained by chorionic villus sampling (CVS) at about 10–12 weeks' gestation or amniocentesis usually performed at about 15–18 weeks' gestation. (Gestational age is expressed as menstrual weeks calculated either from the first day of the last normal menstrual period or by ultrasound measurements.)

Preimplantation genetic diagnosis (PGD) may be an option for some families in which the disease-causing mutations have been identified.

Progranulin Deficiency (NCL Type 11 Recessive)

Physiopathology

The CLN11 gene encodes progranulin (PGRN), originally described as a growth factor that regulates wound healing, vasculogenesis, and tumor growth. Within the central nervous system, GRN-mRNA is expressed in a variety of cell types including neuron, microglia, astrocytes, and endothelial cells. It has been suggested that signaling pathways downstream of Akt may also be activated by progranulin. In macrophages, granulins, cleaved from PGRN, bind to CpG oligodeoxynucleotides in lysosomes, enabling Toll-like receptor-9 signaling. Mutations in the PGRN gene are responsible for frontotemporal lobar degeneration with distinct neuropathological features consisting of ubiquitin-positive protein aggregates in the nucleus and cytoplasm of cortical neurons related to the lysosomal dysfunction. The role of PGRN in this disease is anyway still not clear, and more research is needed to advance our understanding of the induced pathogenesis.

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Laboratory and instrumental examinations (CLN11)

Histologic findings and laboratory tests (electron microscopic findings) and laboratory tests	*Electron microscopy ultrastructural studies* in peripheral blood lymphocytes or other tissues (conjunctiva, skin, or other tissues) show the presence of numerous "fingerprint profiles" *Measurement of plasma progranulin levels*: undetectable in the homozygous patients and about 50% decreased in the heterozygous parents Presence of non-vacuolated lymphocytes
Enzyme activity	Not applicable
Molecular genetic testing	*Molecular genetic testing* of GRN gene
Instrumental tests	*Electroencephalography* showed generalized polyspike wave discharges *Electroretinography* showed severe attenuation of both rod and cone responses *Magnetic resonance imaging (MRI)* showed cerebellar atrophy Visual evoked potential (VEP): polyphasic VEP waveform suggesting hyperexcitability of the occipital cortex *Somatosensory evoked potential*: progressive attenuation in all NCLs *Visual evoked potential (VEP):* polyphasic VEP waveform suggesting hyperexcitability of the occipital cortex
Other tests	*Neurologic examination* *Ophthalmologic examination* *Developmental/cognitive and educational assessment*

ATP13A2 Deficiency (NCL Type 12)

Physiopathology

The ATP13A2 gene encodes a member of the P5 subfamily of ATPases which transports inorganic cations as well as other substrates. In most human tissues, ATP13A2-mRNA is detectable, but it is expressed at a high level in the ventral midbrain, including substantia nigra, and to a lesser extent in the kidney and skeletal muscle. Interestingly, oxidative stress is found to increase the expression of the CLN12/ATP13A2-mRNA. This protein is highly expressed in neurons and is predicted to function as a cation pump, playing a role as a cation transporter regulating Mn2+, Zn2+, and Mg2+ homeostasis with H+ ion concentration in the cell. Being cation regulation and homeostasis vital for neuronal function including intra- and intercellular signaling, dysfunction of the ATP13A2 may be responsible for the dysregulated neurotransmission and eventual dementia characteristic of this disease. Indeed, accumulation of zinc and mitochondrial dysfunction are established etiological factors that contribute to Parkinson's disease; however, their underlying molecular mechanisms are largely unknown.

Mitochondrial dysfunction and autophagy are centrally implicated in Parkinson's disease (PD). It has been suggested that ATP13A2 helps maintain optimal pH in lysosomes where ceramide is also metabolized. The apoptosis that appears to cause NCLs is associated with increased levels of ceramide, which might have also been linked to α-synuclein deposition, contributing to PD pathogenesis. It may be that ATP13A2 helps regulate ceramide metabolism, such that significant changes inATP13A2 activity may contribute to the pathogenesis of both PD and NCLs.

Table 61.11 Ceroid lipofuscinosis, neuronal, 12

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Psychiatric	**Behavioral disorder**				+	++

Laboratory and instrumental examinations (CLN12/PARK9)

Histologic findings and laboratory tests (electron microscopic findings) and laboratory tests	*Light and electron microscopy ultrastructural studies:* Light and electron microscopic investigations of intracellular storage that, when performed in the logical order shown, lead straight and economically to adequate molecular genetic confirmation Presence of non-vacuolated lymphocytes
Enzyme activity	Not applicable
Molecular genetic testing	*Sequences analysis* ATP13A2
Instrumental tests	*EEG* shows nonspecific disorganization and spike-and-slow-wave complexes *Computed tomography and MRI* reveal cerebral and, to a lesser degree, cerebellar atrophy in the later stages (age > 15 years) *Ophthalmologic examination* may reveal macular changes only; gradually, typical signs of pan-retinal degeneration develop: pigmentary changes in the retinal periphery, vascular attenuation, and optic nerve pallor *ERG* shows loss of photoreceptor function early on *Developmental/cognitive and educational assessment*: Speech disturbances (festinating stuttering, often mislabelled as echolalia) and slow decline in cognition occur around the time of onset of seizures. Behavioral problems, extrapyramidal signs, and sleep disturbance occur in the second decade *Cardiological assessment*: Cardiac involvement late in the disease, progressive cardiac involvement with repolarization disturbances, ventricular hypertrophy, and sinus node dysfunction
Other tests	*Medical genetics consultation* *Psychiatric examination*: Psychiatric problems including disturbed thoughts, attention problems, somatic complaints, and aggressive behavior

Prevention

Prenatal testing is possible in pregnancies at increased risk if the disease-causing mutation(s) have been identified in the proband and parents. In these instances, testing is performed on fetal cells obtained by chorionic villus sampling (CVS) at about 10–12 weeks' gestation or amniocentesis usually performed at about 15–18 weeks' gestation.

Cathepsin F Deficiency (NCL Type 13)

Physiopathology

Kufs disease type B can be due to variants to the *DNAJC5* and cathepsin F (CTSF) genes with *CTSF* mutations accounting for a minority of cases of type B Kufs. Mutations in cathepsin F as the causative gene for autosomal recessive Kufs disease type B have been only recently identified. When the *CTSF* gene is mutated, it cannot produce cathepsin F, an enzyme that cuts proteins in the lysozyme. CTSF is a cysteine protease synthesized in the ER. CTSF is tagged with mannose 6-phosphate residues in the cis-Golgi and transported by CI-M6PR to the late endosomal/lysosomal compartment. CTSF is highly expressed in cerebrocortical, hippocampal, and cerebellar neurons. By cutting proteins, cathepsin F can modify the function of the proteins as well as help break them down. Dysfunction leads to incomplete breakdown of proteins. Once again, lipopigments build up, and brain function is decreased as the neuron cells.

Prevention

Prenatal testing for pregnancies at increased risk is possible if the disease-causing mutation(s) have been identified in the family.

Table 61.12 Ceroid lipofuscinosis, neuronal, 13

Laboratory and instrumental examinations (CLN13)

Histologic findings and laboratory tests (electron microscopic findings) and laboratory tests	*Histologic findings:* Electron microscopy ultrastructural studies in peripheral blood lymphocytes or other tissues (conjunctiva, skin, or other tissues) often show the presence of fingerprint profiles Abundant autofluorescent material is found in the cytoplasm of neurons of the cerebral cortex, thalamus, striatum, brainstem nuclei, and Purkinje cells. This storage material is immunoreactive for ubiquitin and contained fingerprint profiles
Enzyme activity	*Measurement of enzymatic activity of cathepsin F (CTSF)* in leukocytes and cultured skin fibroblast cells
Molecular genetic testing	*Molecular genetic testing* on CTSF gene
Instrumental tests	*Brain MRI* showed diffuse cerebral atrophy
Other tests	

Neuronal Ceroid Lipofuscinosis Type 14

Physiopathology

KCTD7 gene (potassium channel tetramerization domain containing 7) encodes a member of the potassium channel tetramerization domain-containing protein family. Family members are identified on a structural basis and contain an amino-terminal domain similar to the T1 domain present in the voltage-gated potassium channel. Mutations in this gene have been associated with progressive myoclonic epilepsy-3, a clinically defined epileptic syndrome that manifests as myoclonic seizures and progressive neurological dysfunction before age 2 years and accompanied by developmental regression. Alternative splicing results in multiple transcript variants. KCTD7 encoded protein is a highly conserved soluble cytosolic protein localized in various organs indicating that it plays a role in the hyperpolarization of the cell membrane via interaction with a component of the ubiquitin ligase complex. It also directly interacts with Cullin-3, a component of E3 ubiquitin-protein ligases, for degradation by ubiquitin proteasome system. Missense mutations in the KCTD gene found in CLN14 disease disrupt KCTD7-Cullin-3 interactions, suggesting a role in the impairment of the cellular degradative process.

Prevention

No data.

Ceroid Lipofuscinosis, Neuronal, 1

Physiopathology

The neuronal ceroid lipofuscinoses (NCLs; CLNs) are a clinically and genetically heterogeneous group of neurodegenerative disorders characterized by the intracellular accumulation of autofluorescent lipopigment storage material in different patterns.

The lipopigment pattern seen most often in CLN1 is referred to as granular osmiophilic deposits (GROD), with characteristic accumulation of saposins A and D.

In CLN1 NCL, a lysosomal enzyme, palmitoyl protein thioesterase 1 (PPT1), is deficient. PPT1, which removes fatty acyl groups from cysteine residues on fatty acid-modified proteins, remains in the endoplasmic reticulum, where it is inactive, causing saposins A and D to accumulate in the lysosomes.

Table 61.13 Ceroid lipofuscinosis, neuronal, 14

System	Symptoms and biomarkers	Neonatal (birth–1 month)	Infancy (1–18 months)	Childhood (1.5–11 years)	Adolescence (11–16 years)	Adulthood (>16 years)

Laboratory and instrumental examinations (CLN1)

Histologic findings (electron microscopic findings)	Electron microscopy ultrastructural studies in peripheral blood lymphocytes or other tissues (conjunctiva, skin, or other tissues) show the presence of autofluorescent granular osmiophilic deposits (GROD) with characteristic accumulation of saposins A and D Not vacuolated lymphocytes Almost complete loss of cortical neurons
Enzyme activity	Deficient activity of palmitoyl-protein thioesterase 1 (PPT-1) encoded by PPT1 evidenced by fluorimetric assay based on the fluorochrome 4-methylumbelliferone in leukocytes, dry blood samples, cultured skin fibroblast cells, amniotic fluid cells, or chorionic villi
Molecular genetic testing	Targeted analysis for pathogenic variants Sequence analysis for assessment of sequence variants Deletion/duplication analysis
Instrumental tests	*Electroencephalography:* Electroencephalographic characteristics seen in CLN1 NCL include lack of attenuation of posterior dominant rhythm to eye opening, loss of sleep spindles, progressive background abnormality, and attenuation with the background flat by age 3 years *Electroretinography*: Unrecordable at age 3 years *Visual evoked potential*: Unrecordable at age 4 years *Somatosensory evoked potential*: Progressive attenuation in all NCLs *Magnetic resonance imaging (MRI):* Mild cerebral atrophy that progresses after 4 years, decreased T2 signal intensity in the thalami, callosal thinning, periventricular rims of hyperintensity that progress to diffuse white matter hyperintensity on T2, and cerebellar atrophy after age 3 years *Magnetic resonance (MR) spectroscopy:* Almost complete loss of N-acetylaspartate (metabolite present only in neurons), reduction in creatine- and choline-containing compounds (i.e., markers for glial membrane turnover), elevation of myoinositol (i.e., a glial marker), elevation of lactate in gray and white matter

Current Treatment Strategies

Being the NCL inherited metabolic disorders, any therapeutic approach will need to be strictly connected to the primary metabolic defect. For the majority of NCLs, so far, there is no specific treatment, and current disease management is mainly aimed at controlling the symptoms rather than "curing" the disease.

The only specific treatment available for NCL is cerliponase alfa for neuronal ceroid lipofuscinosis type 2 (CLN2, also known as tripeptidyl peptidase 1 [TPP1] deficiency). Cerliponase alfa is an enzyme replacement therapy (ERT) approved by the FDA in April 2017 and by the CE in June 2017, to slow the loss of ambulation in symptomatic pediatric patients aged 3 years or older with late infantile neuronal CLN2. Recent studies confirm that the decline in motor and language functions is decreased in patients treated with alfa cerliponase compared to their historical controls (Schulz et al. 2018).

The drug requires weekly intraventricular administration via a reservoir surgically implanted under the scalp. The recommended dosage for cerliponase alfa is 300 mg (10 mL solution) administered every other week by intraventricular infusion.

Standard anticonvulsant drugs to control seizures in NCLs to terminate clinical and electrical seizure activity as rapidly as possible and to prevent seizure recurrence (from Goldenberg 2010)

Drug	Chemical name	Molecular weight	Brand and other names	Indication	Action	Mechanism of action
Carbamazepine	5H-Dibenz[b, f] azepine-5-carboxamide	236.27	(Tegretol, Carbatrol, Epitol, Equetro)	Treatment of complex partial seizures (To control generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and for preventing and treating seizures occurring during or following neurosurgery)	May reduce polysynaptic responses and block post-tetanic potentiation	Reduction of sustained, high-frequency, repetitive neural firing
Oxcarbazepine	10,11-Dihydro-10-oxo-5H-dibenz[b,f] aze-pine-5-carboxamide	252.27	(Trileptal)	Anticonvulsant Monotherapy for adults and in children 4 to 16 years of age with partial seizures and as adjunctive therapy for children 2 years of age and older and for adults and children 2 to 16 years of age with partial seizures	May block voltage-sensitive sodium channels, inhibit repetitive neuronal firing, and impair synaptic impulse propagation	Increased potassium conductance and modulation of high-voltage activated calcium channels

Drug	Chemical name	Molecular weight	Brand and other names	Indication	Action	Mechanism of action
Valproic	-N-propyl acetic acid	144	Acid (Depakote, Depakene, Depacon, Stavzor)	Status epilepticus: primary generalized tonic-clonic seizures Partial and generalized seizures and is indicated as monotherapy and adjunctive therapy for complex partial seizures, which begin in a limited area of the brain. These seizures may occur either in isolation or in association with other types of seizures	Increase brain concentrations of GABA.1	Not established
Gabapentin	1-(Aminomethyl) cyclohexaneacetic acid	171.24	(Neurontin)	Status epilepticus: Adjunctive therapy for patients older than 12 years of age with partial seizures with and without secondary generalization Adjunctive therapy for pediatric patients 3–12 years of age with partial seizures Nerve pain	Mimic the neurotransmitter GABA	Not established
Topiramate	2,3:4,5-Di-O-isopropylidene-β-d-fructopyranose sulfamate	339.36	(Topamax)	Primary generalized tonic-clonic seizures Adjunctive therapy for adult and pediatric patients 2 to 16 years of age with partial-onset seizures Initial monotherapy in patients 10 years of age and older with partial-onset or primary generalized tonic-clonic seizures	Potentiate the inhibitory activity of the neurotransmitter GABA. In addition, topiramate may block glutamate activity	Not well established: Probable inhibition of voltage-dependent sodium channels; may increase activity of the neurotransmitter GABA at some subtypes of the GABAA receptor, and antagonize the AMPA/kainate subtype of the glutamate receptor, and inhibit the carbonic anhydrase enzyme, particularly isozymes II and IV
Tiagabine	(−)-(R)-1-[4,4-Bis(3-methyl-2-thienyl)-3-butenyl]nipecotic acid HCl	412.0	(Gabitril)	Adjunctive therapy in adults and children 12 years of age and older with partial seizures	Enhanced activity of GABA	Not well established: It is believed to be related to recognition sites associated with the GABA uptake carrier, therefore blocking GABA uptake into presynaptic neurons and thus increasing the quantity of GABA available for receptor binding on the surfaces of postsynaptic cells

Drug	Chemical name	Molecular weight	Brand and other names	Indication	Action	Mechanism of action
Felbamate	2-Phenyl-1,3-propanediol dicarbamate	238.24	(Felbatol)		Weak inhibitory effects on GABA receptor binding and benzodiazepine receptor binding	Antagonist at the strychnine-insensitive glycine recognition site of the N-methyl-D-aspartate (NMDA) receptor-ionophore complex
Midazolam	8-Chloro-6-(2-fluorophenyl)-1-methyl-4H-imidazo[1,5-a][1,4] benzodiazepine	325.8	(Versed)	Emergency management of seizures Sleep problems	Anxiolytic, amnestic, hypnotic, anticonvulsant, and sedative action	Binding to the benzodiazepine receptor at the GABA receptor-chloride ionophore complex in the central nervous system (CNS). It induces an increase in the opening of chloride channels and membrane hyperpolarization and increases the inhibitory effect of GABA in the CNS. Midazolam may also interfere with the reuptake of GABA, thereby causing accumulation of GABA in the synaptic cleft
Phenobarbital	5-Ethyl-5-phenylpyrimidine-2,4,6(1H,3H,5H)-trione	232.24	(Solfoton, Luminal)	Seizures that occur in neonates and in the first year of life Both generalized tonic-clonic seizures and partial seizures in patients of all ages Phenobarbital is used to treat status epilepticus (continuous seizures with impaired consciousness between episodes)	Potentiated inhibitory neurotransmission	Increased duration of time that GABA-mediated chloride channels remain open and reduced neurotransmitter release from nerve terminals, probably due to effect on calcium channels Decreased excitatory neurotransmission due to a reduced effect of glutamate
Valproate	2-Propylpentanoic acid	144.21	(Convulex, Depakote, Epilim, Stavzor, and others)	Tonic-clonic seizures Mioclonus	Anticonvulsant effect	Not well established: It seems to be due to the blockade of voltage-gated sodium channels and increased brain levels of gamma-aminobutyric acid (GABA)
Zonisamide	1,2-Benzisoxazole-3-methanesulfonamide	212.23	(Zonegran)	Adjunctive therapy for treating partial seizures in adults	Reduces sustained high-frequency repetitive firing of action potentials and prevents the spread of seizure discharge across cells	Not well established, probable inactivation of voltage-sensitive sodium channels and inhibition of low-threshold T-type calcium channels in neurons

Drug	Chemical name	Molecular weight	Brand and other names	Indication	Action	Mechanism of action
Levetiracetam	(−)-(S)-α-Ethyl-2-oxo-1-pyrrolidine acetamide	170.21	(Keppra, Keppra XR, Spritam)	Adjunctive therapy for partial-onset seizures and epilepsy in adults and children 4 years of age and older Myoclonic seizures in adults and adolescents 12 years of age and older with juvenile myoclonic epilepsy And primary generalized tonic-clonic seizures in adults and children 6 years of age and older with idiopathic generalized epilepsy	May selectively prevent hypersynchronization of epileptiform burst firing and propagation of seizure activity	Modulation of synaptic neurotransmitter release through binding to the synaptic vesicle protein SV2A in the brain

Drugs used to control myoclonia and spasticity

Drug	Chemical name	Molecular weight	Brand and other names	Indication	Action	Mechanism of action
Baclofen	4-Amino-3-(4-chlorophenyl) butyric acid	213.661	Lioresal	Myoclonia and spasticity	GABA agonist used as a skeletal muscle relaxant	Reduces the release of excitatory neurotransmitters and substance P by binding to the GABA-B receptor
Tizanidine	5-Chloro-4-(2-imidazolin-2-yl-amino)-2,1,3-benzothiadiazole monohydrochloride	253.71	Zanaflex	Myoclonia and spasticity	Central alpha-2-adrenergic receptor agonist	Reduces spasticity by increasing presynaptic inhibition of motor neurons
Piracetam	2-(2-Oxopyrrolidin-1-yl) acetamide	142.156	Nootropil	Adult patients suffering from myoclonus of cortical origin	Neuroprotective and anticonvulsant	Piracetam's mode of action in cortical myoclonus is as yet unknown

Other helping supportive means of utmost importance in these chronic diseases characterized by a multiplicity of symptoms and affected systems include chest physiotherapy, nasogastric or gastric tube feeding in the later stages of the disease, orthopedic treatment, speech therapy, and psychological and transition (Kohlschütter et al. 2019). In particular physical and occupational therapies are routinely used to aid in the retention of physical abilities (Neverman et al. 2015).

Some antiepileptic drugs like carbamazepine, phenytoin, and vigabatrin can exacerbate myoclonia. These drugs should therefore be avoided especially in the late infantile NCL types that commonly manifest a high prevalence of myoclonic seizures, although they can improve control of tonic-clonic seizures when these are refractory to other medications. Clinical distinction among NCL forms is therefore important for the therapeutic choice (Augustine et al. 2015).

Drug to be avoided

Drug	Chemical name	Molecular weight	Brand and other names	Indication	Action	Mechanism of action
Carbamazepine	5H-Dibenz[b, f] azepine-5-carboxamide	236.27	(Tegretol, Carbatrol, Epitol, Equetro)	Treatment of complex partial seizures (To control generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and for preventing and treating seizures occurring during or following neurosurgery)	May reduce polysynaptic responses and block post-tetanic potentiation	Reduction of sustained, high-frequency, repetitive neural firing
Phenytoin	Sodium 5,5-diphenyl-2, 4-imidazolidinedione	274.3	(Dilantin, Phenytek)	Status epilepticus: For controlling generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and for preventing and treating seizures occurring during or following neurosurgery	Selective block of high-frequency neuronal activity	Suppression of the sodium action potential through a voltage-dependent blockade of membrane sodium channels (Yaari et al. 1986)
Vigabatrin	4-Amino-5-hexenoic acid	129.16	(Sabril, Vigadrone)	It is used in patients who have already been treated with other medicines that did not work well. For treating complex partial seizures in adults and children 10 years of age and older and infantile spasms in children	Increased concentrations of GABA in the CNS	The precise mechanism of the antiseizure effect is unknown, but it is believed to result from its action as an irreversible inhibitor of GABA transaminase (GABA-T), the enzyme responsible for the metabolism of the inhibitory neurotransmitter GABA

Recently also the use and effectiveness of Lamotrigine have been debated since it may worsen myoclonus in the early stages of CLN2 disease, late infantile (Shorvon, et al. 2019).

Lamotrigine	3,5-Diamino-6-(2,3-dichlorophenyl)-as-triazine	256.09	(Lamictal)	Adjunctive therapy for partial seizures, and primary generalized tonic-clonic seizures Neuralgic pain	Diminished neuronal activity	Inhibition of the release of glutamate and also inactivation of voltage-sensitive sodium channels, with stabilization of the neuronal membrane

Emerging Causal Treatment

Several major therapeutic options are under investigations: The majority - enzyme replacement therapy; gene therapy; bone marrow transplantation; neural stem cell therapy; and molecular or pharmacological chaperone therapy—are aimed at reducing the levels of the compounds that accumulate in the lysosomes.

- **Enzyme replacement therapy (ERT):** It usually consists in the regular intravenous infusions of a recombinant form of the defective enzyme which is then scavenged by affected cells, endocytosed, and incorporated into lysosomes restoring functional activity. Unfortunately, ERT does not cross the blood-brain barrier, thus hindering effective treatment of CLNs with CNS involvement. Therefore, it is necessary to inject the enzyme to the cerebrospinal fluid, either directly into the lateral ventricles or by intrathecal injection (needle in the back). ERT is currently available for CLN2 and under study for CLN1.
- **Gene therapy** is currently only utilized in animal models. Multiple viral vectors have been used to accomplish in vivo gene transfer, such as herpesviruses, lentiviruses, adeno-associated viruses (AAV), adenoviruses (Ad), and others. Gene therapy approaches have shown promising results in animal models of various NCLs with improvements already made in vectors used for delivery of the genes. Importantly recent findings indicate that early ther-

apy (i.e., presymptomatic) provides best results (Kohlschütter et al. 2019).

- **Bone marrow transplant (BMT):** It consists in using donor bone marrow-derived cells as a source of enzyme. Studies in animal models as well as in a few infants have so far not showed satisfactory results. Nevertheless, BMT in combination with gene therapy provides an unprecedented increase in lifespan as well as dramatic improvement on functional and histological parameters (Macauley et al. 2012).
- **Molecular or pharmacological chaperone therapy (protein chaperone therapy, PCT):** It consists in the use of small molecule compounds to assist the folding of mutated enzymes, therefore restoring their catalytic activity. This type of therapy is still highly experimental, but testing in cell culture models has shown promising results. Currently, no pharmacological chaperones have been tested in NCL cell lines or animal models except one study in lymphoblast lines from patients with CLN1where increase in PPT1 activity was showed (Dawson et al. 2010). Currently, no other pharmacological chaperones have been tested in NCL cell lines or animal models.
- **Stem cell transplant (SCT):** It is useful for the enzymatic deficiencies and it can intravenous transplantation of different types of donor cells. Generally it consists of healthy hematopoietic stem cells (usually from bone marrow, sometimes from cord blood) or neural stem cells (nerve cells). The newly produced enzymes can be taken up by the enzyme-deficient cells (cross-correction), or in certain cases stem cells can also have the capacity to differentiate and replace the person's own (diseased) cells. Both types have been used in animal models and clinical trials. Unfortunately, this therapy showed to have minimal effects on disease progression and to be largely ineffective against LINCL and JNCL. Nevertheless, this is not an approach to be eliminated since more promising outcomes have been obtained using HSC, specifically bone marrow treatment, in combination with gene therapy in Ppt1 −/− mice where neurodegeneration in the brain was attenuated, even if not in the retina (Arrant et al. 2018).
- **Substrate reduction therapy (SRT):** It consists in the oral administration of a drug capable of inhibiting/reducing the rate of production of the substrate reducing the metabolic load on the lysosome. Clinical trials that studied the effect of combining cysteamine bitartrate and N-acetylcysteine to treat INCL have been performed, but no effect on the progression of the disease was shown even if the treatment succeeded in reducing the amount of storage material in peripheral leucocytes and parents reported less irritability and increased concentration.

Nowadays CLN1, CLN2, CLN3, and CLN6 are the diseases for which the current therapeutic approaches have reached preclinical or clinical trials (see Table below). Both small and large animal models of various forms of NCLs are being developed. These animal models are likely to be very useful for the preclinical evaluation of novel therapeutic strategies.

Moving Towards Effective Therapeutic Strategies

For ongoing trial for NCL see ClinicalTrials.gov.

Mucolipidoses, Multiple Sulfatase Deficiency, and Cathepsin K and C Deficiency

62

Contents

Summary

Mucolipidosis type II/III (ML II/III) and multiple sulfatase deficiency (MSD) share clinical features with the mucopolysaccharidoses. Both ML II/III and MSD result from enzymatic defects that affect the post-translational modification of lysosomal enzymes. In ML II/III the mannose-6-phosphate marker, essential for routing lysosomal enzymes towards the lysosomes, is lacking. This leads to the excretion of lysosomal enzymes in plasma where they are unable to execute their function. In MSD lysosomal sulfatases, as well as sulfatases from the endoplasmic reticulum and Golgi complex, cannot be activated due to the inability to modify a conserved cysteine residue at the active site. In mucolipidosis type IV (ML IV), lysosomal dysfunction is caused by the deficiency of transient receptor potential channel mucolipin-1 (TRPML1), a nonselective cation channel present in late endosomal and lysosomal membranes necessary for autophagy, vesicular trafficking, and mTOR and TFEB signaling. Neurological dysfunction and visual impairment are the most predominant clinical features; skeletal abnormalities are not seen in ML IV. Deficiency of the lysosomal enzymes cathepsin K (pycnodysostosis) and C (Papillon–Lefèvre or Haim–Munk syndrome) presents both with a very distinct clinical picture. Cathepsin K is important for bone resorption and extracellular matrix remodeling. Its deficiency results in stunted growth, facial dysmorphism, osteopetrosis, and dental abnormalities. In cathepsin C deficiency, premature loss of both deciduous and permanent teeth due to periodontitis in combination with palmoplantar keratosis is the main clinical feature.

All disorders are ultra-rare and have autosomal recessive inheritance. Their clinical spectrum is not yet fully

known, and patients are likely still underdiagnosed. No specific biomarkers are available that can lead to the diagnosis. All disorders have in common that no curative treatments are available and specialized multidisciplinary supportive care is needed to minimize the disease burden and provide an adequate quality of life.

Introduction

In this chapter different lysosomal storage disorders are described that do not necessarily share a mutual pathophysiological mechanism, but do cause lysosomal dysfunction and have overlap in clinical presentation. In both mucolipidosis type II and III (ML II/III) and in multiple sulfatase deficiency (MSD), the deficiency of an extra-lysosomal enzyme results in the deficiency of lysosomal enzymes. In mucolipidosis type IV, lysosomal dysfunction is caused by a defect in a cation channel in the membrane of lysosomes, and both cathepsin K and C deficiency are lysosomal proteases whose deficiency results in a distinct clinical picture. We will briefly introduce all disorders separately.

Mucolipidoses: **mucolipidosis type II** (ML II; **I-cell disease** OMIM#252500) and **mucolipidosis type III α/β** or **γ** (**pseudo-Hurler dystrophy**, ML III α/β; OMIM#252600, ML III γ; OMIM#252605) are rare autosomal recessive lysosomal storage disorders (Maroteaux and Lamy 1966; Leroy and Martin 1975). The birth prevalence in the Netherlands is less than 1 per 100.000. In ML II and ML III, there is absent or reduced activity of the membrane-bound enzyme **UDP-*N*-acetyl glucosamine-1-phosphotransferase** (GlcNAc-1-phosphotransferase), a hexameric complex, with three subunits; α2, β2 (*GNPTAB*), and γ2 (*GNPTG*). **GlcNAc-1-phosphotransferase** is responsible for the first step in the phosphorylation of enzyme-conjugated mannose residues to form mannose-6-phosphate (Reitman and Kornfeld 1981). Mannose-6-phosphate serves as the recognition marker for the targeting of more than 70 newly synthesized soluble lysosomal enzymes to the lysosome. Absence or reduced presence of this marker results in secretion of lysosomal enzymes in the plasma, where they are unable to execute their function and substrates, such as glycosaminoglycans (GAGs) and (glyco)sphingolipids, accumulate in the lysosome. The clinical picture of ML II and ML III mostly resembles that of the mucopolysaccharidoses and much less that of the sphingolipidoses and other lysosomal storage disorders. There is a clinical spectrum with severely affected patients (MLII) at one end of the spectrum and milder patients at the other end (ML III). There is also an "intermediate" phenotype with features of both ML II and ML III patients (Cathey et al. 2010). The patients with the most severe form of ML II are already severely affected at birth and develop rapidly progressive airway, cardiac, skeletal, and nervous system disease, resulting in death in early childhood. The ML III α/β patients present with a broader clinical phenotype ranging from severely affected patients that die in childhood to milder affected patients displaying primarily skeletal symptoms, who survive into adulthood (Cathey et al. 2010). ML III γ patients have a milder phenotype with onset in early school age, but are phenotypically not distinguishable from the ML III α/β patients (Nampoothiri et al. 2019).

In **mucolipidosis type IV** (ML VI; OMIM#252650), another ultra-rare autosomal recessive disorder predominantly present among Ashkenazi Jews (Bargal et al. 2001), mutations in *MCOLN1*, which encodes for the transient receptor potential cation channel, mucolipin-1 subfamily member 1 (**TRPML1**), lead to lysosomal dysfunction (Clapham et al. 2001). This channel is distributed in the membranes of late endosomes and lysosomes in all tissues, with the highest expression in the brain, kidney, liver, spleen, and heart (Cheng et al. 2010). It is nonselective permeable to several cations. Abnormal flux of calcium probably is the most important in the lysosomal dysfunction in ML IV, resulting in dysregulation of autophagy, vesicular trafficking, and mammalian target of rapamycin (mTOR) and transcription factor EB (TFEB) signaling (Boudewyn and Walkley 2019). Patients with ML IV do not have the typical dysmorphic features, as seen in ML II/III. Patients can have severe psychomotor delay (slowly progressive over time) due to neuronal dysmyelination, hypotonia which gradually progresses to spasticity during childhood, speech deficits, retinal degeneration, and optic atrophy causing visual impairment. Other symptoms are cornea clouding, achlorhydria with increased gastrin secretion and iron deficiency anemia, and kidney disease and failure, which finally leads to a shortened life span in the patients (Boudewyn and Walkley 2019). Most of them are still alive at least in the first two to three decades; thereafter, it is still unknown. From the patients that died in the second decade, the cause of death was not exactly known (Bargal et al. 2001).

Multiple sulfatase deficiency: **multiple sulfatase deficiency** (MSD; OMIM #272200), an ultra-rare disorder with autosomal recessive inheritance, was first described in 1964 by Austin et al. (Austin et al. 1964) and results from the deficiency of **formylglycine-generating enzyme (FGE)** due to mutations in *SUMF1* (sulfatase-modifying factor 1). Only approximately 100 cases have been described to date, but MSD is most likely still underdiagnosed due to the broad clinical spectrum seen in patients. FGE plays a crucial role in the post-translational activation of sulfatases by modifying a conserved cysteine residue into formylglycine at the active site, necessary for the catalytic activity of sulfatases. Its deficiency therefore affects the activity of all known 17 sulfatases, including 8 lysosomal sulfatases, of which 6 are associated with well-characterized lysosomal storage

disorders (i.e., **metachromatic leukodystrophy** (OMIM #250100), **mucopolysaccharidoses types II** (OMIM #309900), **III A** (OMIM #252900) **and D** (OMIM #252940), **IV A** (OMIM #253000), **and VI** (OMIM #253200)), 1 in the endoplasmatic reticulum associated with **X-linked ichthyosis** (OMIM #308100), and 1 in the Golgi complex associated with **chondrodysplasia punctata type I** (OMIM #302950). The clinical phenotype of MSD can be very heterogeneous and is dependent on FGE protein stability and residual enzyme activity and the degree the different sulfatases are affected. Four clinical subtypes can be distinguished based on the main presenting symptoms and age of symptom onset: a neonatal, severe late infantile, mild late infantile, and juvenile form of MSD (Ahrens-Nicklas et al. 2018).

Cathepsin K deficiency (pycnodysostosis): **pycnodysostosis** (OMIM #265800) is an ultra-rare, prevalence is estimated at one to three per million, **osteochondrodysplasia** with autosomal recessive inheritance (Bizaoui et al. 2019). It was first described in 1962 (Maroteaux and Lamy 1962), and since a few hundred cases have been published, the most well-known being the French painter Henri de Toulouse-Lautrec (Markatos et al. 2018). Pycnodysostosis is caused by the deficiency of lysosomal **cathepsin K** encoded by *CTSK*. Cathepsin K belongs to the papain-like cysteine protease family and is mainly expressed in osteoclasts where it plays a central role in bone resorption by degrading collagen type I. Cathepsin K is also expressed in other tissues where it is involved in extracellular matrix remodeling, adipogenesis, thyroxine liberation, and peptide hormone regulation (Novinec and Lenarcic 2013). Its deficiency causes a distinct clinical phenotype characterized by short stature and the formation of hard and dense bones with thick cortices (osteopetrosis), resulting in frequent fractures and skeletal problems including dysplasia of the cranium, mandible, clavicle, and distal phalanges. In addition, dental abnormalities are frequently seen including dental crowding, delayed eruption of permanent teeth, enamel hypoplasia, and hypercementosis (Xue et al. 2011; Wen et al. 2016).

Cathepsin C deficiency: **cathepsin C deficiency** is best known as **Papillon–Lefèvre syndrome** (PLS; OMIM #245000) characterized by a severe early-onset periodontitis, resulting in the premature loss of both deciduous and permanent teeth, and palmoplantar keratosis. It is also associated with **Haim–Munk syndrome** (HMS; OMIM #245010), which resembles PLS but in addition also exhibits arachnodactyly, acro-osteolysis, and onychogryphosis (Hart TC et al. 2000). PLS is an ultra-rare disorder with an estimated prevalence of approximately one to four per million and autosomal recessive inheritance (Machado et al. 2019). Cathepsin C, encoded by *CTSC* and also known as **dipeptidyl peptidase 1**, also belongs to the papain-like cysteine protease family and is ubiquitously expressed. By removing dipeptides from the N-terminus of its substrates, it has a major role in the activation of pro-inflammatory granule-associated serine proteases, which degrade various extracellular matrix compounds causing tissue damage and chronic inflammation. It also has been suggested to play an important role in epithelial differentiation and desquamation, which could explain the palmoplantar keratosis seen in patients (Korkmaz et al. 2018). Besides the characteristic severe periodontitis and palmoplantar keratosis, patients have a higher susceptibility to infections, especially skin, respiratory, and urinary tract infections, and may exhibit a delay in somatic development, keratosis pilaris, and hyperhidrosis.

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Inheritance	Affected protein	OMIM no.
62.1	Mucolipidosis type II	I-cell disease	ML II	*GNPTAB*	12q23.3	AR	UDP-*N*-acetyl glucosamine-1-phosphotransferase (GlcNAc-PTase)	252500
62.2	Mucolipidosis type III alpha, beta	Pseudo-hurler	ML III α, β	*GNPTAB*	12q23.3	AR	UDP-*N*-acetyl glucosamine-1-phosphotransferase (GlcNAc-PTase)	252600

Metabolic Pathways

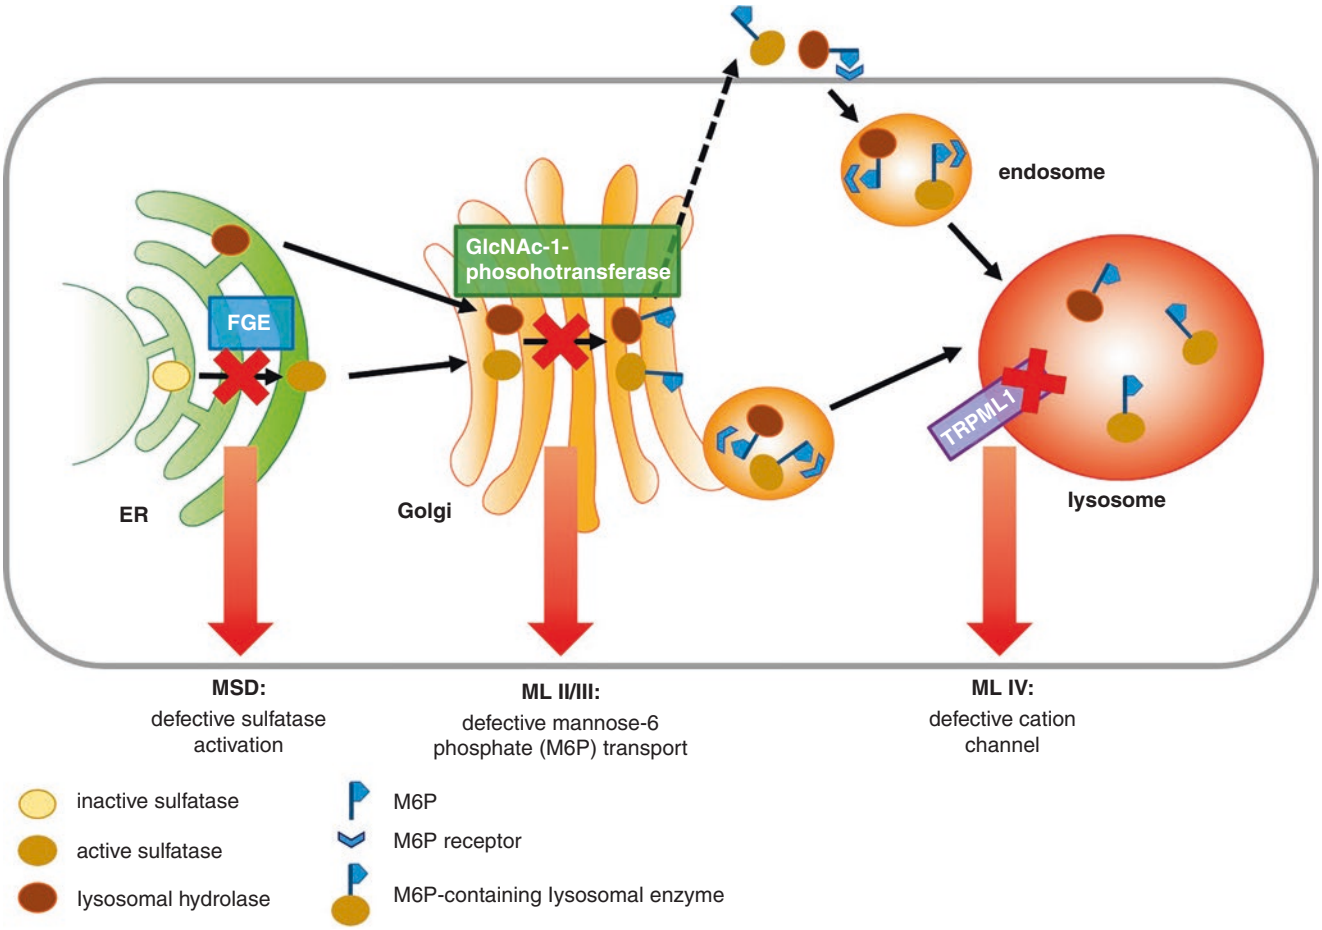

Fig. 62.1 Intracellular lysosomal enzyme processing and trafficking. After production more than 70 lysosomal enzymes are transported from the ER to the Golgi complex where a mannose-6-phosphate residue is added by UDP-*N*-acetyl glucosamine-1-phosphotransferase (GlcNAc-1-phosphotransferase), defective in mucolipidosis type II/III (ML II/III), which serves as a key targeting signal for the intracellular routing of enzymes towards lysosomes. In addition, lysosomal sulfatases need to be activated by formylglycine-generating enzyme (FGE), defective in multiple sulfatase deficiency (MSD), in the ER before transportation to the Golgi complex. The TRPML1 cation channel present in the membranes of late endosomes and lysosomes, defective in mucolipidosis type IV, is essential for the nonselective flux of cations, necessary for regulation of lysosomal autophagy and vesicular trafficking and mammalian target of rapamycin (mTOR) and transcription factor EB (TFEB) signaling

Reference Values

For the diagnosis of mucolipidosis type II/III and cathepsin C deficiency, the following enzymatic assays are used (normal ranges may vary between laboratories). Please see Chaps. 60 "Lipidoses" and 64 "Mucopolysaccharidoses" for details on the different sulfatase assays which can be used for the diagnosis of multiple sulfatase deficiency.

No.	Disorder	Enzyme(s)	Material	Normal range	Reference

Pathological Values

The diagnosis of mucolipidoses (ML), multiple sulfatase deficiency (MSD), and cathepsin K and C deficiency is based on enzymatic analysis and/or molecular analysis. No specific diagnostic biomarkers are known for these disorders, although biochemical abnormalities are seen: urinary **glycosaminoglycans** (GAGs) excretion can be increased in ML II and III as well as in MSD. Urinary **sulfatides** may be increased in MSD, in ML II, bound **sialic acid** is elevated in urine. As these can also be normal in ML and MSD, they cannot be used to exclude these disorders. In ML and MSD, as well as in attenuated forms of cathepsin K and C deficiency, the clinical phenotype may be less distinct. These forms are more likely to be diagnosed through untargeted molecular analysis, especially with exome sequencing since this is now more widely used in patients with an unexplained clinical phenotype.

Mucolipidoses: for ML II/III first-level diagnostic procedures include measurement of the activity of several lysosomal enzymes including β-hexosaminidase A, β-hexosaminidase A+B, α-L-fucosidase, β-D-glucuronidase, α-D-mannosidase, and β-D-galactosidase in plasma and/or fibroblasts, where these enzymes are elevated in plasma and decreased in fibroblasts. In addition, GlcNAc-1-phophotransferase activity can be measured in fibroblasts. Finally, molecular analysis of *GNPTAB* (ML II and III α, β) or *GNPTG* (ML III γ) can be performed. Genotype-phenotype correlations in the MLII/III are difficult to establish due to the high proportion of individual mutations and the variable expressivity in patients carrying the same mutation (Velho et al. 2019).

ML IV can only be diagnosed by molecular analysis of *MCOLN1*. Increased **gastrin** secretion and **iron deficiency anemia** are indicative for ML IV and can support the diagnosis.

Multiple sulfatase deficiency: the diagnosis of MSD is based on demonstrating reduced activity of at least two sulfatases in leucocytes or fibroblasts as patients can be missed if only one sulfatase is assayed (Schlotawa et al. 2011). Hereafter, the diagnosis should be confirmed with molecular analysis by demonstrating a pathogenic alteration on both alleles of *SUMF1*. Several specific genotype–phenotype correlations have been established, where mutations strongly affecting protein stability and residual enzyme activity are associated with a more severe clinical phenotype (Sabourdy et al. 2015).

Cathepsin K deficiency (pycnodysostosis): the distinct clinical and radiographic features of pycnodysostosis are the most important clues towards diagnosis. Detecting acro-osteolysis in combination with increased bone density upon radiological evaluation is almost pathognomonic of the disorder. The diagnosis can only be confirmed by molecular analysis of *CTSK* demonstrating pathologic alterations on both alleles. Until now genotype–phenotype relations have not been established (Bizaoui et al. 2019). *CTSK* mutations have also been detected in patients with a more attenuated osteopetrosis phenotype without the distinct clinical features of pycnodysostosis and should therefore be considered in all patients with unexplained osteopetrosis (Schlotawa et al.

2011). Differentiating pycnodysostosis from other forms of osteopetrosis is important as the latter may benefit from early hematopoietic stem cell transplantation whereas this has no proven benefit in pycnodysostosis (Bizaoui et al. 2019).

Cathepsin C deficiency: as with cathepsin K deficiency, the distinct clinical features of palmoplantar hyperkeratosis and periodontitis seen in Papillon–Lefèvre syndrome offer the most important clues for cathepsin C deficiency. An enzymatic assay for cathepsin C has been described (Hart PS et al. 2000), but is not widely available. Diagnosis should be confirmed with molecular analysis of *CTSC*. To date 89 disease-causing mutations have been described, all affecting the heavy chain of cathepsin C which is essential for its tetramer formation and protein function. No consistent genotype–phenotype relations have been established (Machado et al. 2019).

Treatment and Follow-Up

All lysosomal disorders discussed in this chapter are multisystem diseases for which no curative treatments are available. Multidisciplinary supportive treatment is therefore essential, as well as palliative care for the patients with a shortened life span. Supportive treatment and developments in innovative treatment approaches are discussed below.

Supportive Treatment

Mucolipidoses: as the clinical phenotype of ML II/III patients is similar to the patients with mucopolysaccharidosis (MPS), the multidisciplinary supportive care described for MPS patients in Chap. 64 can also be used for patients with ML II/III. Patients with ML II are poor feeders with stunted growth and are often overfed. Most children need nasogastric tube feeding and dietary support. Patients with ML III have skeletal problems and often develop secondary osteoarthritis (more severe than observed in MPS patients), necessitating **surgical orthopedic interventions** relatively early in life.

Orthopedic follow-up is necessary, with involvement of the care of a rehabilitation specialist and occupational therapist. ML III patients experience bone pain due to secondary osteoarthritis and osteopenia causing microfractures. Adequate pain management is important in this patient group, which may require an expert in **pain management**. **Bisphosphonates** have been given to ML III patients (Robinson et al. 2002; Zolkipli et al. 2005; Kerr et al. 2011; Kobayashi et al. 2011). Their effect on bone pain remains unclear. Since long-term use of these drugs suppresses bone turnover and consequently may have a negative effect on final height, they may be of limited use in ML III.

For patients with ML IV, neurological and pediatric follow-up is important. There is a psychomotor delay in all the patients, and in infancy patients are hypotonic, which gradually progresses to spasticity during childhood. All patients develop visual impairment due to corneal clouding, strabismus, myopia, retinal degeneration, and/or optic atrophy, for which they need ophthalmologic follow-up. It has been noted that many patients in the second to third decades of life suffer from kidney disease and kidney failure, which needs follow-up by a nephrologist (Boudewyn and Walkley 2019). Patient with ML IV can have iron deficiency anemia for which they need iron supplementation, which must be monitored over time by measuring iron and hemoglobin levels in the blood.

Multiple sulfatase deficiency: the clinical spectrum in MSD is highly variable. Therefore, a tailor-made multidisciplinary approach is required in each patient in order to support motor function, prevent secondary complications, and maintain an adequate quality of life. Most patients have musculoskeletal problems, including dysostosis multiplex, contractures, and muscle tone dysregulation and/or muscle weakness, requiring the involvement of a physiotherapist and rehabilitation specialist as well as pharmacological management of tone abnormalities. A specialized dermatologist is needed to treat ichthyosis. Other potential clinical issues requiring specialized care include symptoms related to GAG accumulation in different tissues as seen in MPS; see details in Chap. 64. Patients should be seen at regular time intervals (every 3–6 months is suggested depending on the disease burden) to monitor the progression of the disease and its complications, preferably using standardized outcome measures in order to obtain more knowledge about the natural course of MSD. For more details and a comprehensive guideline on treatment and follow-up in MSD, see Ahrens-Nicklas et al. 2018 (Ahrens-Nicklas et al. 2018).

Cathepsin K deficiency (pycnodysostosis): as pycnodysostosis is primarily a bone disease and patients are prone to fractures, (parents of) patients should be instructed to avoid activities that increase the risk of fractures. Nevertheless, most patients require at least one surgical intervention in their life span (Bizaoui et al. 2019). As bone remodeling is impaired due to the osteoclastic dysfunction, open reduction with internal fixation (direct bone healing) is advised over external fixation with casting (indirect bone healing) in fracture management (Grewal et al. 2019). It should be noted there is an increased risk of developing osteomyelitis with all surgical procedures as bone blood supply in pycnodysostosis is decreased. An important aspect of the disease is upper airway obstruction due to the mandibular and/or maxillary hypoplasia, the long soft palate, and possible laryngomalacia. This can lead to severe obstructive apnea requiring a nasopharyngeal tube and/or noninvasive ventilation and possibly surgical interventions, during childhood. Patients can be very difficult to intubate, and airway management should be carefully evaluated before any procedure requiring general anesthesia is scheduled. Dental hygiene and management are essential as patients are prone to develop severe caries with the dental abnormalities seen in pycnodysostosis; patients should be seen by a (specialized) dentist at least once a year. Patients may exhibit a Chiari malformation related to the cranial dysplasia; it is therefore advised to do a cerebral MRI in all patients after diagnosis. Finally, as stunted growth is important in pycnodysostosis, supplementation of **growth hormone** can be considered and was reported to be effective in 40% of the patients (Bizaoui et al. 2019).

Cathepsin C deficiency: management in Papillon–Lefèvre syndrome focuses on the preservation of permanent teeth in young patient by controlling factors that contribute to the destruction of the periodontium. This requires frequent (every 3 months) specialized dentist care aimed at prevention and early treatment of periodontitis with oral hygiene instruc-

tions using **chlorhexidine gluconate** 0.2% mouth rinses and antibiotic treatment when necessary. Development of pyogenic liver and skin abscesses due to bacteremia is a complication of periodontitis seen in PLS because of impairment of the immune system. Renal and cerebral abscesses have also been described. Deciduous teeth should be extracted when they have a poor prognosis and cause a potential problem for the eruption of permanent teeth. Extraction of permanent teeth with advanced periodontal disease is also required. In order to preserve chewing function, dental prostheses are needed involving fabrication of partial or complete dentures with an age-specific approach. Management of the dermatological manifestations seen in PLS requires the involvement of a specialized dermatologist. The mainstay of treatment is anti-inflammatory emollients; keratolytics, such as **salicylic acid** and **topical steroids**; and **oral retinoids**, which have been shown to improve both dental and cutaneous lesions of PLS. Retinoids decrease the total keratin content of keratinocytes, are involved in the regulation of growth and differentiation of epithelial cells, and may have a positive effect on inflammation by stimulating both humoral and cellular immunity. Prescribers should be aware of adverse effects which include dryness of lips, mild pruritus, transient hair loss, and elevated serum triglycerides and liver enzymes due to liver toxicity and teratogenicity. Long-term use of retinoids can cause bone toxicity with growth disturbances due to premature epiphyseal closure and traumatic fractures (Sreeramulu et al. 2015; Korkmaz et al. 2018).

Innovative Treatments

Mucolipidoses: in ML II patients, hematopoietic stem cell transplantation (HSCT) has been explored but was proven ineffective (Lund et al. 2014). As in both ML II/III and ML IV, a transmembrane protein is involved, it is highly unlikely that this approach would be effective (Boudewyn and Walkley 2019). In patients with lysosomal storage diseases, an inflammatory component, arising from the accumulation of lysosomal storage products, contributes to the pathophysiology. Reducing this inflammatory response could be a possible target of treatment. This may be achieved by drugs such as pentosan polysulfate (PPS), as this drug has shown to improve range of motion and reduce pain in MPS I patients in a short-term study (Hennermann et al. 2016). Recently, a proof of concept for the development of an anti-sense oligonucleotide to induce exon skipping of exon 19 in *GNPTAB*, in order to overcome the deleterious effect of the most common c.3503_3504del mutation in ML II, was reported (Matos et al. 2020). Some clinical aspects, like bone disease, in ML II are less likely to be treated with this approach, as they have their origin in fetal development.

Multiple sulfatase deficiency: combined rAAV9 gene therapy, where a single injection of this vector was given both systemic and in the cerebral ventricles, was shown to result in a widespread transduction of tissues, leading to the activation of sulfatases, a near complete clearance of glycosaminoglycans (GAGs), a decrease in inflammation in both the central nervous system and visceral organs, and an improvement in behavior and survival of *SUMF1* knockout mice (Spampanato et al. 2011). Further work on the development of gene therapy for MSD has not been reported. Currently, there is no evidence to support the use of HSCT in MSD (Tan et al. 2019).

Cathepsin K deficiency (pycnodysostosis): to our knowledge no innovative treatment approaches for pycnodysostosis are under development. This may be related to the fact that enzyme replacement treatment strategies are known to be less effective for skeletal disease manifestations. Hematopoietic stem cell transplantation has been proven effective in several genetic forms of osteopetrosis, but its therapeutic potential in pycnodysostosis remains yet to be shown (Bizaoui et al. 2019).

Cathepsin C deficiency: autophagic flux has been shown to be impaired in Papillon–Lefèvre syndrome and is suggested to play an important role in PLS pathophysiology. Providing recombinant cathepsin C to fibroblasts of PLS patients partially restored autophagic flux, reduced lysosomal membrane permeability, and improved the fibroblast growth rate (Bullon et al. 2018). This suggests that enzyme replacement therapy and gene therapy approaches may be of interest in PLS.

Oligosaccharidoses and Sialic Acid Disorders

63

Michael Beck and Zoltan Lukacs

Contents

Summary

Oligosaccharidoses comprise a group of disorders which show glycoprotein excretion in urine and diminished activity of lysosomal enzymes that are involved in the degradation of sugar side chains (Tables 63.1–63.14). Among those are glycosylasparaginase deficiency (aspartylglucosaminuria), α-L-fucosidase deficiency (fucosidosis), α- and β-mannosidase deficiency (α- and β-mannosidosis), α-*N*-acetylgalactosaminidase deficiency (Kanzaki and Schindler disease), and neuraminidase deficiency (siali-

dosis) (Fig. 63.1). In contrast to the latter, where the degradation of glycosides is impaired, disorders of sialic acid (= N-acetyl neuraminic acid, Neu5Ac) metabolism are based on different mechanisms: A defect of sialin, a transporter protein of the lysosomal membrane, leads to accumulation of sialic acid within the lysosomes and clinical consequences, namely to Salla disease and the more severe form, free sialic acid storage disorder (Fig. 63.2). Sialuria, inclusion body myopathy and a defect of N-acetylneuraminic acid synthase (NANS) are due to a disturbance of sialic acid biosynthesis. In patients with a deficiency of N-acetylneuraminate pyruvate lyase (NPL) the degradation of sialic acid is impaired. Oligosaccharidoses and sialic acid disorders are rare and present a wide phenotypic spectrum. Detection of oligosaccharides in urine and enzyme activity measurements in leukocytes or fibroblasts is usually diagnostic. Free sialic acid has to be assessed by HPLC. For final confirmation a molecular genetic test should be carried out. To date mainly palliative therapies can be provided.

Introduction

The term oligosaccharidoses comprises a group of disorders that are caused by defective degradation of protein-bound sugar side chains as a result of deficiency in certain lysosomal enzymes. Hurler-like symptoms, skeletal abnormalities, hearing impairment, and neurological symptoms are common features of most of these conditions. As it is common to all lysosomal storage disorders, a broad phenotypic heterogeneity is observed within each of the oligosaccharidoses, ranging from a severe neonatal to a milder adult form, making the clinical diagnosis often difficult.

In sialidosis the enzyme neuraminidase is deficient. In vivo this enzyme is found within a multienzyme complex consisting of protective protein/cathepsin A (PPCA), neuraminidase and β-galactosidase. Cathepsin A stabilizes this structure, and a defect of that protein leads to the disease galactosialidosis in which both neuraminidase and ß-galactosidase are deficient. Clinically galactosialidosis resembles sialidosis.

The diseases named after Schindler and Kanzaki represent different phenotypic expressions of α-*N*-acetylgalactosaminidase (α-NAGA) deficiency. However, it seems that α-NAGA deficiency alone cannot explain the phenotypic variation among patients with the same mutation. The first two brothers described by Schindler et al. (Schindler et al. 1989) had clinical signs of neuroaxonal dystrophy, a neurodegenerative disorder that is now known to be caused by mutations of the *PLA2G6* gene. Therefore it must be suggested that mutations in this gene have caused neuroaxonal dystrophy in the original patients with Schindler disease (Westaway et al. 2007). And also in other patients with α-NAGA deficiency, no clear correlation between residual enzyme activity and the severity of symptoms exists. Therefore, most likely other factors or genes contribute to this clinical heterogeneity (Bakker et al. 2001).

In contrast to oligosaccharidoses, where the degradation of sugar side chains is impaired, other pathogenetic mechanisms are responsible for sialic acid disorders. A defect of sialin, a specific carrier protein of the lysosomal membrane that transports sialic acid out of the lysosomes, leads to progressive accumulation of this compound in the cell, resulting in the allelic disorders free sialic acid storage disease and Salla disease. Free sialic acid storage disease represents the severe infantile form, characterized by global developmental delay, hepatosplenomegaly, cardiomegaly, and early death. The less severe adult form is named Salla disease after a geographic region in Finland where the patients' families have lived. Patients with Salla disease show a broad phenotypic spectrum ranging from mild cognitive dysfunction and ataxia to an intermediate severe form characterized by coarse facial features, intellectual disability, hypotonia, and hepatosplenomegaly (Barmherzig et al. 2017).

The biosynthesis of sialic acid is a complex process in which the enzyme UDP-GlcNac 2-epimerase/ManNAc kinase (GNE) plays an essential role as the master regulator. This enzyme consists of two independent functional domains, an N-terminal domain covering the epimerase activity and a C-terminal domain responsible for ManNAc kinase activity. In the initial step of sialic acid synthesis, the active site of UDP-GlcNac 2-epimerase converts UDP-GlcNAc into ManNAc. The activity of UDP-GlcNac 2-epimerase is regulated by allosteric feed-

back inhibition by CMP-sialic acid, the final product of the synthetic pathway.

Two disorders are known in GNE deficiency: hereditary inclusion body myopathy (or Nonaka myopathy; autosomal recessive) and sialuria (autosomal dominant). Sialuria is a genetic defect of the feedback inhibition of UDP-GlcNac 2-epimerase resulting in cytoplasmic accumulation and urinary excretion of large amounts of free sialic acid. Characteristic clinical signs of sialuria include developmental delay, mildly coarse features, hepatomegaly, and prolonged neonatal jaundice (Ferreira et al. 2018). Until now, only nine patients with sialuria have been described (Martinez et al. 2018).

The C-terminal domain of UDP-GlcNac 2-epimerase/ManNAc kinase converts ManNAc into ManNAc-6-phosphate. Mutations of this domain, but in some cases also of the epimerase domain, lead to the autosomal recessive adult-onset hereditary inclusion body myopathy (HIBM), also called distal myopathy with rimmed vacuoles or Nonaka myopathy. In affected patients progressive muscle weakness and limb atrophy are the leading clinical signs. This is associated with muscle hyposialylation. A unique feature of hereditary inclusion body myopathy is the sparing of the quadriceps muscles, even in advanced stages of the disease.

Since both disorders hereditary inclusion body myopathy and sialuria represent defects in the biosynthesis of sialic acid, an important component of the glycosylation machinery, they are also classified as congenital disorders of glycosylation (CDG) (Ferreira et al. 2018).

As the next step in the sialic acid biosynthetic pathway, ManNAc-6-phosphate is converted to N-acetylneuraminic acid (Neu5Ac) by N-acetylneuraminic acid synthase (NANS) and N-acetylneuraminic acid phosphatase (NANP), respectively. Finally, Neu5Ac is transported to the nucleus and there activated to CMP-sialic acid by the enzyme cytidine monophosphate N-acetylneuraminic acid synthase (CMAS). CMP-sialic acid is transferred to the Golgi apparatus by the specific transporter SLC35A1 for sialylation of gangliosides and glycoproteins (Willems et al. 2016).

A genetic defect of the enzyme N-acetylneuraminic acid synthase (NANS) leads to a disorder characterized by severe developmental delay, intellectual disability, skeletal dysplasia, and coarse facial features (van Karnebeek et al. 2016; van Karnebeek et al. 2017). In the affected patients, the urine concentration of N-acetylmannosamine is increased, but not of sialic acid.

Wen et al. have detected a defect not in the biosynthesis, but in the degradation of sialic acid in two siblings who presented with dilated cardiomyopathy, proximal myopathy, and sensorineural hearing loss. In these patients compound heterozygous mutations in the gene *NPL* have been found that codes for the enzyme N-acetylneuraminate pyruvate lyase NPL (Wen et al. 2018). And a defect of this enzyme that is responsible for the degradation of sialic acid to N-acetylmannosamine and pyruvate leads to significant sialic aciduria, but not to accumulation of sialic acid in fibroblasts.

For the diagnosis of oligosaccharidoses and sialic acid disorders usually thin-layer chromatography (TLC) combined with enzyme measurement and/or mutation analysis is employed. Free sialic acid will not prominently show on thin-layer chromatography, and therefore a dedicated high-performance-liquid-chromatography method is necessary to assess the concentration of sialic acid in urine and possibly fibroblasts. More recently, tandem-mass spectrometry (TMS) has been applied for the determination of oligosaccharides and sialic acid. However, as the differentiation of sugar moieties by TMS is difficult, TLC will probably remain the screening method of choice for the time being. N-Acetylmannosamine has been measured by NMR-spectroscopy.

Finally, molecular genetic testing by using modern methods such as next-generation sequencing will become more important for the diagnosis of these rare disorders.

Unfortunately, despite progress in therapies for many lysosomal storage diseases, the oligosaccharidoses and sialic acid disorders still lack an effective treatment; only for patients affected by alpha-mannosidosis enzyme replacement therapy has become available. However, further understanding of disease mechanism and phenotypic differences between patients with the same mutation may help to pave the way to novel therapies and better care for the patients.

Metabolic Pathways

Lysosomal enzymes that cleave sugar residues from glycoproteins are deficient in oligosaccharidoses (Fig. 63.1). In aspartylglucosaminuria, glycosylasparaginase shows diminished activity (Fig. 63.1, step 2). This enzyme requires prior hydrolysis of both peptide bonds joined to the asparagine (Asn). This is achieved by lysosomal cathepsins. In addition, the enzyme is inhibited by fucose that is bound to the core reducing end of N-acetylglucosamine (Fig. 63.1, step 1). This special property explains why most of fragments that accumulate in fucosidosis are glycopeptides that retain the Asn residue (Aronson Jr. 1999). In α-mannosidosis oligosaccharides containing α-1–3 and α-1–6 linkages accumulate, while in β-mannosidosis the disaccharide Man-β1-4GlcNAc is the major storage material (Fig. 63.1, step 4α/β). For α-NAGA deficiency the major compounds are sialylglycopeptides of the O-linked type. However, they seem not to be the primary lysosomal storage product (Keulemans et al. 1996). Sialidosis is characterized by increased amounts of sialylated oligosaccharides and glycoproteins (Fig. 63.1, step 3).

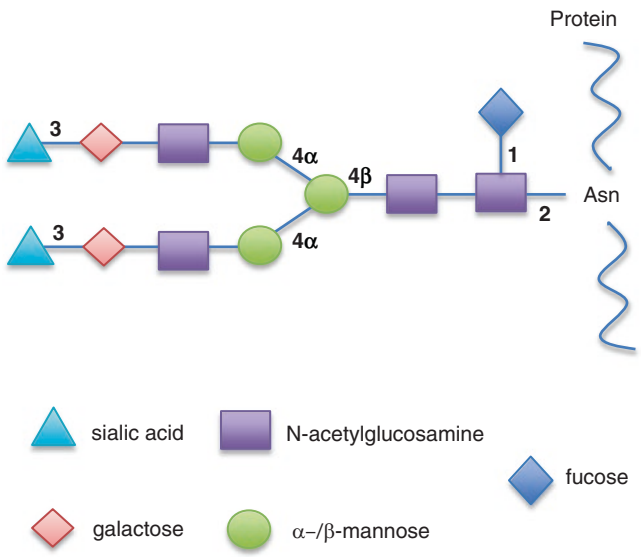

Fig. 63.1 Degradation of complex oligosaccharides. Liberation of the glycoside from the protein by lysosomal cathepsins is followed by a sequential degradation of the sugar moieties (steps 1–4). Galactose and N-acetylglucosamine are cleaved by β-galactosidase and hexosaminidase, respectively, between steps 3 and 4

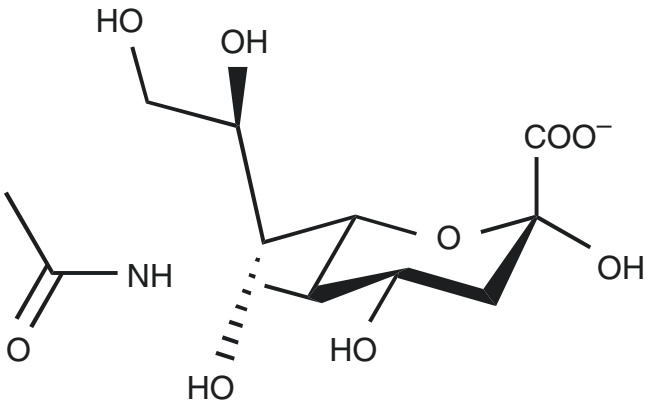

Fig. 63.2 Sialic acid (N-acetyl neuraminic acid, Neu5Ac)

In Salla disease, a defect in the membrane transporter protein, sialin, impairs efflux of sialic acid (Fig. 63.2) from the lysosomes, so that this compound accumulates in the cell.

Reference Values

Reference values for analysis of the specific enzymes deficient in the respective disorders and free sialic acid. Activities are usually independent of age and gender. Ranges are listed according to methods and materials used.

Entry	Protein	Method	Material	Range (unit)
1	AGU	2-AADG[a]	Fibroblasts	45–333 (nmol/min*g)

[a]2-Acetamido-*N*-(L-aspart-4′-oyl)-2-deoxy-β-glucopyranosylamine
[b]*L*-Aspartic acid β-(7-amido-4-methylcoumarin)
[c]p-Nitrophenyl-α-L-fucopyranoside
[d]4-Methylumbelliferyl-α-L-fucoside
[e]A polymorphism is responsible for enzyme activities of approx. 25% of the control mean in ca. 10% of the population. This affects only measurements in fibroblasts and plasma. Activity in leukocytes remains unaffected (Willems et al. 1999)
[f]4-Methylumbelliferyl-α-D-mannopyranoside
[g]In affected individuals the residual activity is found to be between 5 and 15% of normal activity. This may be due to the fact that other mannosidases are present and can contribute some activity. Following immunoprecipitation, only 0.1–1.3% of the normal activity has been detected (Malm and Nilssen 2008)
[h]4-Methylumbelliferyl-β-D-mannopyranoside
[i]4-Methylumbelliferyl-α-*N*-acetylgalactosaminide
[j]4-Methylumbelliferyl-α-neuraminide
[k]Enzyme is labile to sonication and freezing. Activity in leukocytes is approx. Tenfold lower than in fibroblasts. For this reason, leukocyte activity measurement is not recommended for diagnosis in sialidosis
[l]Free sialic acid has been determined by HPLC
[m]N-Acetylmannosamine has been determined by NMR spectroscopy (van Karnebeek et al. 2016; 2017)

Diagnostic Flowcharts
(Figs. 63.3, 63.4 and 63.5)

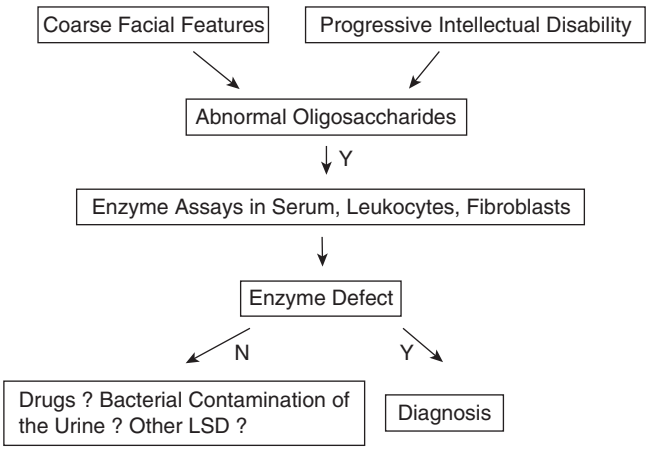

Fig. 63.3 Flowchart for the diagnosis of oligosaccharide storage disorders

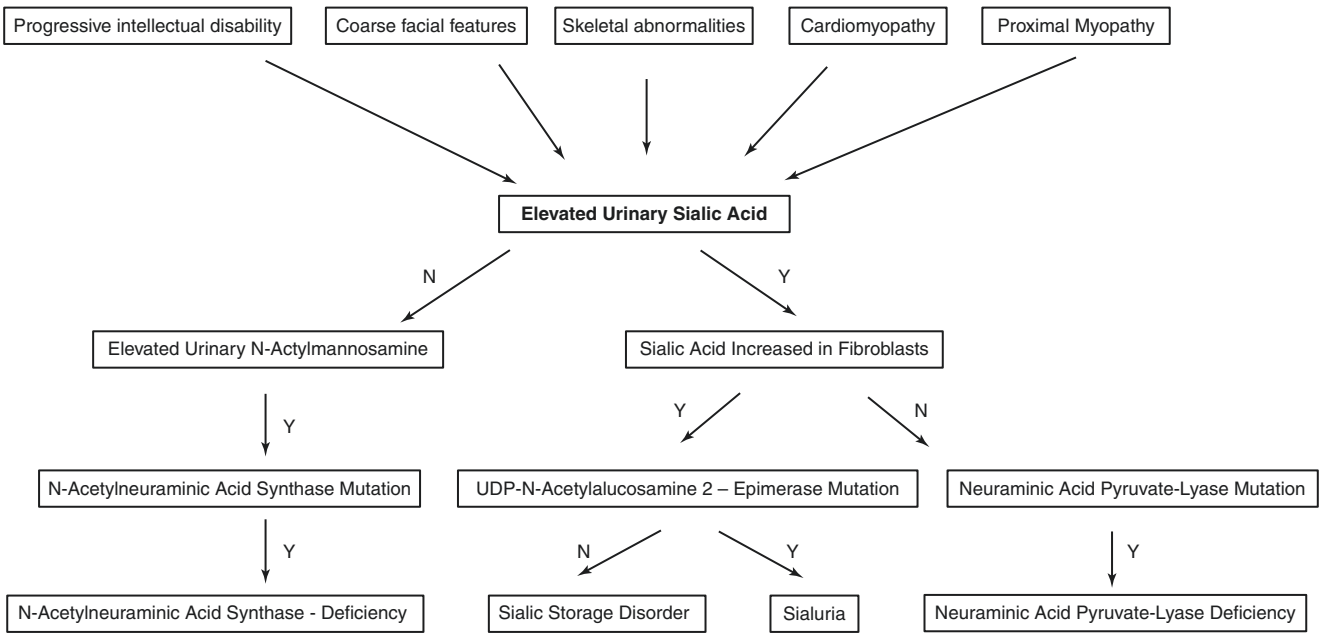

Fig. 63.4 Flowchart for the diagnosis of sialic acid disorder and sialuria

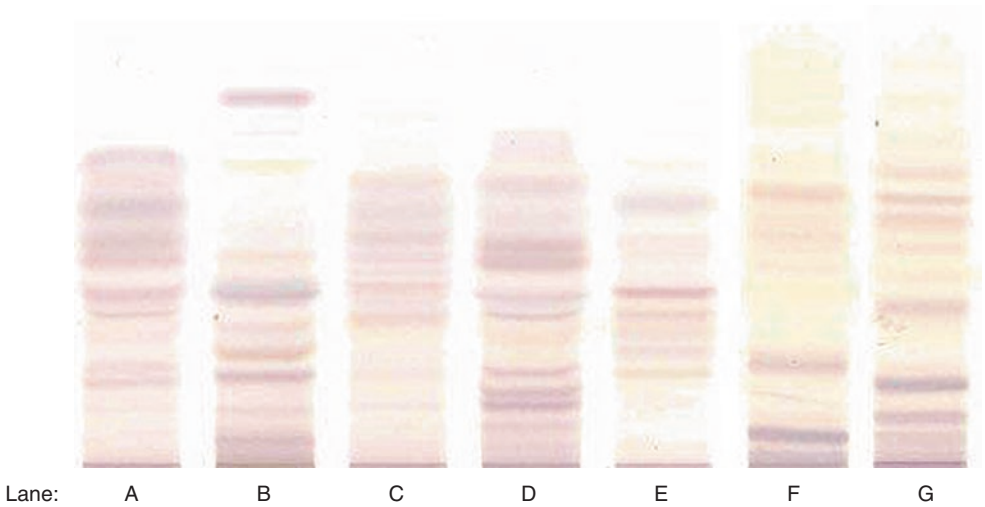

Fig. 63.5 Oligosaccharides in urine analyzed by thin-layer chromatography provide a simple tool for a primary biochemical diagnosis. This figure shows examples of certain oligosaccharidosis (urines kindly provided by Prof. Beck, Mainz, Germany). Urines from patients with the following disorders have been analyzed: GM2-gangliosidosis, Sandhoff type (lane *A*), fucosidosis (lane *B*), GM1-gangliosidosis, patient 1 (lane *C*), aspartylglucosaminuria (lane *D*), mannosidosis (lane *E*), sialidosis (lane *F*), GM1-gangliosidoses, patient 2 (lane *G*)

Specimen Collection

For enzyme analysis either fibroblasts, leukocytes/lymphocytes, plasma or dried blood spots can be used, depending on the enzyme that should be determined. Fibroblasts should be taken by specialized staff in a hospital environment. They can be shipped in sterile growth medium or, if shipping time does not exceed 1–2 days, in physiological NaCl solution (also sterile). For leukocytes and lymphocytes whole blood is required (usually approx. 5 mL). Shipping time should be kept to a minimum (less than 3 days). Nevertheless, the likelihood of hemolysis increases with prolonged shipping time. Plasma samples should be shipped after centrifugation and removal of any cell pellet to avoid contamination with hemolyzed cells during shipment. Dried blood specimens can be prepared either from tubes of whole blood or directly from venous/capillary blood. In the case of newborns, the usual procedures for taking newborn screening samples can also be followed. It is especially important that samples are prepared swiftly after the blood has been taken. In addition, they should be dried at room temperature (ca. 20°C) over night before shipment. The stability of enzymes varies widely in dried condition, so that timely shipping and analysis are always preferable.

Oligosaccharides and sialic acid are analyzed from urine. Spontaneous urine samples (ca. 3–5 mL) can be shipped without additives at room temperature, provided no bacterial contamination is present. Otherwise, samples should be shipped on dry ice.

Prenatal Diagnosis

Preferably, prenatal diagnosis should be performed by molecular genetic testing, especially if mutations from an index patient in the family are already known. Enzyme testing of amniotic cells is also possible. However, it has to be checked whether maternal cells are present and thus may contribute to enzyme activity. In addition, interpretation of low enzyme activity becomes problematic in cases of heterozygote carriers, especially as only a few laboratories have a significant number of normal controls to determine a statistically reliable reference range. In any case, requirements and the possibility of prenatal enzyme testing should be checked with the specialized laboratory before shipment of samples. As in all autosomal-recessive disorders with a known disease-causing mutation, also in lysosomal storage disorders, a preimplantation diagnosis can be performed.

DNA Testing

In aspartylglucosaminuria the *AGA* gene is comprised of nine exons. About 30 different *AGA* mutations have been observed around the world. Due to a founder effect, the incidence of aspartylglucosaminuria is very high in Finland, with one major allele, named AGU_{FIN}, that is composed of the disease-causing substitution Cys163Ser and the Arg161Gln exchange that does not affect the enzymatic activity (Pande et al. 2018).

Fucosidosis is caused by mutations in the *FUCA1* gene that is composed of eight exons spanning approximately 23 kbp. To date, more than 30 mutations in the FUCA1 gene associated with the disease have been reported (Saleh-Gohari et al. 2018).

To our best knowledge, only 22 cases of β-mannosidosis in 18 families have been described worldwide. In the ß-mannosidosis gene *MANBA* that consists of 17 exons, so far 18 disease-causing variants have been reported including both null and missense mutations (Blomqvist et al. 2019).

The α-*N*-acetylgalactosaminidase gene *NAGA* consists of 9 exons coding for 411 amino acids. An overview of mutations is given by Bakker et al. (Bakker et al. 2001).

Sialidosis is caused by mutations in the *NEU1* gene that consists of 6 exons and codes for a protein of 368 amino acid moieties. So far, more than 40 mutations within the *NEU1* gene have been identified in patients with sialidosis type I and II (Khan and Sergi 2018).

Salla disease is caused by mutations in the *SLC17A5* gene that codes for a lysosomal membrane transporter (sialin). The disease is mainly found in Finland, where the missense mutation Arg39Cys is responsible for 95% of cases. An overview of mutations is given by Barmherzig et al. (Barmherzig et al. 2017).

Mutations in the *CTSA* gene lead to the lysosomal storage disorder galactosialidosis that is characterized by the combined deficiency of ß-galactosidase and neuraminidase. More than 30 *CTSA* mutations are known until now (Aldamiz-Echevarria et al. 2018).

The enzyme UDP-GlcNac 2-epimerase/ManNAc kinase (GNE) that plays an essential role in the biosynthesis of sialic acid is encoded by the *GNE* gene on chromosome 9p13.3. Mutations of the *GNE* gene are responsible for two different disorders (See Introduction): Heterozygous missense variants at the allosteric site, specifically at Arginine 294 and Arginine 297, result in sialuria. A new heterozygous pathogenic variant (Asp84His) has been detected in a 2-year-old boy who was diagnosed with sialuria (Martinez et al. 2018).

Mutations elsewhere in the *GNE* gene, which lead to decreased sialylation, are responsible for the hereditary inclusion body myopathy, also called distal myopathy with rimmed vacuoles or Nonaka myopathy. In a study performed by Mori-Yoshimura et al. in order to examine the correlation between genotype and phenotype in 71 patients with genetically confirmed GNE myopathy, it was found that patients with a homozygous mutation in the N-acetylmannosamine kinase domain had an earlier disease onset and exhibited a more severe phenotype compared to compound heterozygous individuals with mutations in the uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc) 2-epimerase and N-acetylmannosamine kinase domains (Mori-Yoshimura et al. 2012).

Treatment Summary

As until now no specific treatment is available for almost all patients affected by an oligosaccharidosis or sialic acid disorder, they will require significant supportive therapy even in cases where specific therapies are effective, for example, in α-mannosidosis for which enzyme replacement therapy has been approved. The supportive care given should be custom tailored to each disease and each patient, based on the organs affected and the degree of severity of this involvement.

Standard Treatment

As oligosaccharidoses and sialic acid disorders are multisystemic diseases, the affected individuals often need surgical procedures. The anesthetic management of these patients, however, is often complicated by airway problems such as difficult laryngoscopy secondary to dysmorphic facial features, thoracic deformities, and impaired visualization of the vocal cords (Hallas et al. 2011). In those cases, intubation by fiber-optic laryngoscopy is strongly recommended in order to prevent the necessity of performing a tracheostomy. Preoperative examination should be carefully performed to rule out the presence of cardiomyopathy and hepatosplenomegaly. Epileptic seizures are not uncommon in oligosaccharidoses; they should be treated according to

general therapeutic guidelines; in aspartylglucosaminuria patients carbamazepine has been shown to be very effective (Arvio and Mononen 2016). In a 15-year-old sialidosis patient, severe myoclonic seizures could be successfully treated with perampanel, a non-competitive, selective glutamate receptor antagonist (Hu et al. 2018). In fucosidosis, the occurrence of dystonic symptoms has been observed that did not respond to drugs that are commonly used for the treatment of dystonia such as carbamazepine, L-dopa, anticholinergics, or baclofen (Gordon et al. 1995).

Enzyme replacement therapy is now available for α-mannosidosis. In patients treated with the recombinant human α-mannosidase enzyme velmanase alfa, biochemical and functional improvements were seen for up to 4 years (Lund et al. 2018).

Experimental Treatment

Substrate Supplementation

Several mouse models of GNE myopathy have been developed that recapitulate the pathological changes of the human disease. To elucidate whether inclusion body myopathy can be treated by sialic acid supplementation, 6′-sialyllactose or free sialic acid was orally given to GNE myopathy mice. After several weeks of treatment in 6′-sialyllactose-treated mice, spontaneous locomotion activity improved, while in sialic acid-treated mice, just a slowing down of disease progression could be observed (Yonekawa et al. 2014). As this and other animal studies provided a proof of concept of substrate replacement, clinical trials with substrate supplementation in GNE myopathy patients have been initiated.

In a human placebo-controlled, double-blind, single-ascending dose study, 22 subjects suffering from GNE myopathy received N-acetyl-D-mannosamine (ManNAc), the first committed precursor in the sialic acid biosynthetic pathway, at single doses of 3 g, 6 g, or 10 g or placebo. The administration of a single dose of ManNAc resulted in a significant and sustained increase in plasma free sialic acid. In subjects who received a dose of 6 g or 10 g, the sialic acid levels remained above baseline 2 days post-dose (Xu et al. 2017).

Free sialic acid was considered as a therapeutic agent in GNE myopathy and other disorders of sialic acid metabolism. However, as orally administered sialic acid is rapidly cleared from the circulation via the kidney, an extended release formulation of sialic acid (aceneuramic acid extended release; Ace-ER) was developed to achieve a continuous elevated substrate concentration in serum and thereby to attain sufficient muscle uptake (Argov et al. 2016). To investigate the efficacy and safety of Ace-ER, a phase 3, double-blind, placebo-controlled study was performed in 89 patients with GNE myopathy. Clinical endpoints were changes in muscle strength of upper and lower extremity and knee extensor strength. After 48 weeks of treatment with 6 g/day Ace-ER, muscle strength did not differ between the Ace-ER and the placebo group (Lochmüller et al. 2019). The authors come to the conclusion that in future studies the clinical heterogeneity and the rate of progression of the disease need more attention when planning clinical trials in patients with GNE myopathy.

Substrate supplementation may be effective also in other disorders of sialic acid metabolism: A knockdown of *NPL* (N-acetylneuraminate pyruvate lyase deficiency) in zebra fish resulted in skeletal myopathy and cardiac edema, and these abnormalities could be rescued by treatment of embryos with N-acetylglucosamine or N-acetylmannosamine, the catabolic products of NPL (Wen et al. 2018). Knockdown of *NANS* (N-acetylneuraminic acid synthase deficiency) in zebra fish embryos leads to an abnormal skeletal phenotype that can be rescued by exogenously added sialic acid (van Karnebeek et al. 2016; van Karnebeek et al. 2017).

Enzyme Replacement Therapy

Enzyme replacement therapy has been studied in several animal models of oligosaccharide storage disorders: Dunder and co-workers have given mice affected by aspartylglucosaminuria different dosages of recombinant glycosylasparaginase at the age of 1 week. In the mice who have received the highest amount of enzyme, a reduction of the storage material aspartylglucosamine was observed not only in the visceral organs but also in the brain tissue (Dunder et al. 2010).

Kondagari et al. evaluated the effect of intracisternal infusions of recombinant α-fucosidase on neuropathological findings in the naturally occurring dog model of fucosidosis (Kondagari et al. 2015). The procedure resulted in improvement in almost all measures of neurodegeneration and inflammation in several brain regions. These animal studies may pave the way for clinical trials using recombinant fucosidase.

Chaperones

An efficient mechanism exists in each cell that controls correct folding of newly synthesized enzymes. As misfolded enzymes are degraded by proteasomes, they cannot reach the Golgi apparatus for further maturation. Specific molecules, named *chaperones*, help the proteins to be folded into the appropriate confirmation. Missense mutations that affect accurate folding of lysosomal enzymes prevent them from reaching the lysosome, so that they cannot fulfill their function. Small pharmacological molecules are able to correct the folding of mutant enzymes and increase their enzymatic activities.

O'Leary et al. used fibroblasts from sialidosis patients in order to examine the efficacy of the immunosuppressant (Celastrol) and a proteosomal inhibitor (MG132) to rescue mutant enzymes with altered conformation. In their study they demonstrated that MG132 could reduce the accumulation of gangliosides, but Celastrol diminished sialidase activity. The combination of both, MG132 and Celastrol, however, resulted in a significant increase in specific sialidase activity beyond that of the enzyme activity measured in normal fibroblasts (O'Leary and Igdoura 2012). This study points to a potential therapeutic strategy for the treatment of sialidosis.

Hematopoietic Stem Cell Transplantation (HSCT)

Hematopoietic stem cell transplantation (HSCT) was the first approach for the treatment of lysosomal storage disorders. Previously, bone marrow has been traditionally the graft source for this procedure. However, in the last years, more and more patients have been treated with unrelated donor umbilical cord blood transplant, allowing rapid and increased access to transplantation. Krivit et al. analyzed the clinical results of HSCT in over 500 patients with a peroxisomal or lysosomal storage disorder. This study included also individuals with α-mannosidosis, fucosidosis, and aspartylglucosaminuria (Krivit 2004). In those disorders HSCT did not lead to a significant clinical improvement, most probably as the patients were older and had already irreversible organ damage. Arvio et al. reported five patients with aspartylglucosaminuria in whom HSCT was not successful; therefore the authors do not recommend this treatment of patients with this lysosomal storage disorder (Arvio et al. 2001). Some positive were seen in fucosidosis patients who underwent bone marrow transplantation; however, considering the transplantation-related risk, this therapeutic option should be recommended for patients only at an early stage of disease (Jiang et al. 2017).

Gene Therapy

As lysosomal storage disorders in general represent well-characterized single gene disorders and in addition are not subject to complex regulation mechanisms, they are excellent candidates for therapy by gene transfer. In addition, an enzyme activity of only 15%–20% of the normal level is sufficient for clinical efficacy (Sands and Davidson 2006). A gene can be delivered to the organism by two ways, the ex vivo and the in vivo technique. For ex vivo therapy, stem cells of the patient are transfected with the gene and thereafter returned to the body. This technique was used in a study with a mouse model of galactosialidosis, in which the animals received hematopoietic progenitor cells transduced with a retroviral vector overexpressing the protein protective/cathepsin A (PPCA) that is deficient in galactosialidosis. The procedure resulted in a complete correction of systemic organ damage and in an improvement of CNS pathology (Leimig et al. 2002). The results support the use of this approach for the treatment of patients affected by a galactosialidosis.

The in vivo technique was studied in α-mannosidosis cats that received an intracisternal infusion of adeno-associated virus type 1 (AAV1) expressing the feline α-mannosidase gene. The lifespan of the treated animals was significantly prolonged, the α-mannosidase activity was increased, and the neuropathology showed a reduction of storage material within the whole brain (Yoon et al. 2016).

Gene Editing

The elegant and easy-to-manage gene editing system CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats/CRISPR-associated protein 9) seems to represent a conceivable therapeutic option for patients affected by a lysosomal storage disorder. This sophisticated technique that is able to selectively target genes containing deleterious mutations and correct the disease-causing mutations is currently used in human pluripotent stem cells taken from patients to correct several genetic diseases and will be probably soon applied in clinical studies in patients with a lysosomal storage disorder (Christensen and Choy 2017).

Besides the CRISPR/Cas9 system, two other gene editing techniques have been developed, namely, zinc finger nucleases (ZFNs) and transcription activator-like effector nucleases (TALENs) (Schneller et al. 2017). These alternative gene editing tools, however, have some disadvantages in comparison with the CRISPR/Cas9 technique.

When and how the results of the experiments with pluripotent stem cells can be transferred to clinical trials cannot be answered now, as this transformation requires the development of quality assays, demonstration of safety and efficacy of new gene therapy protocols, and, last but not least, the approval and consensus of the scientific and biomedical communities (Giugliani et al. 2017).

The Mucopolysaccharidoses

64

Giancarlo Parenti and Roberto Giugliani

Contents

Summary

The mucopolysaccharidoses (MPS) are a group of inborn errors of metabolism caused by the deficiency of lysosomal hydrolases that degrade glycosaminoglycans (GAGs). These disorders are associated with a progressive accumulation of different types of GAGs within the cells of various organs and are characterized by somatic manifestations (facial dysmorphisms, hepatosplenomegaly, cardiac, respiratory, and skeletal involvement) and neurological, hematologic, and ocular symptoms. These manifestations are variably associated in each disorder. In most cases the disease phenotypes encompass a spectrum ranging from severe to attenuated clinical forms. Initial clinical assessment should include the evaluation of different organs and systems. Biochemical and genetic investigations are an important part of the diagnostic process and include the analysis of GAGs, the demonstration of a specific enzyme defect, and the identification of mutations in the relevant gene. Neonatal screening programs for selected MPS types have been implemented in some countries. Carrier detection and prenatal diagnosis are possible. Management of any MPS requires supportive care and multidisciplinary treatment. Specific treatment is available for several MPS, based on different approaches. Hematopoietic stem cell transplantation is indicated for MPS IH patients under the age of 2 years who have normal or near-normal developmental scores, but is not standard practice in other MPS types. Enzyme replacement therapy (ERT) is currently available for MPS I, MPS II, MPS IVA, MPS VI, and MPS

VII. ERT results in improvement of somatic manifestations and of motor performance and in reduced urinary GAG excretion. However, other clinical features, particularly those related to central nervous system involvement, respond to a lesser extent to therapy. Newer therapeutic approaches involving the use of small molecules, ERT with enzymes that bypass the blood-brain barrier, intrathecal or intracerebroventricular enzyme delivery, and gene therapy/gene editing approaches are still in preclinical or clinical development.

Introduction

The mucopolysaccharidoses (MPS) are a broad group of lysosomal storage diseases, classically caused by the deficiency of lysosomal hydrolases that degrade the glycosaminoglycans (GAGs). These disorders are associated with a progressive accumulation of different types of GAGs within the cells of various organs, ultimately compromising their function. The cumulative incidence of these disorders varies between approximately 1.5 and 4.5 in 100,000 live births/year, depending on ethnicity (Kobayashi 2019).

The pathophysiology of MPS is complex. Recent studies suggest that the clinical manifestations of these disorders not only are the direct effects of GAG storage but also derive from a cascade of secondary events, triggered by storage, that ultimately lead to dysfunction or inappropriate activation of different cellular processes and pathways (Parenti and Fraldi 2018). These events include secondary storage of substrates unrelated to the defective enzyme; abnormal composition of membranes, impaired vesicle fusion and trafficking; impairment or block of autophagy; oxidative stress; dysregulation or activation of signaling pathways; and abnormalities of calcium homeostasis. These abnormalities are emerging as key factors in the pathophysiology of the MPS and may represent potential new targets of therapies. Particular attention has been paid to the impairment of autophagy, a catabolic pathway that mediates the degradation of macromolecules and organelles in lysosomes. The autophagic pathway was shown to be affected in the MPS (Pshezhetsky 2016; Shapiro et al. 2014; Settembre et al. 2008), with a block or reduction of the autophagic flux and consequent autophagosome accumulation. Both the impairment of the autophagic flux and activation of inflammation have been recognized as important pathogenic factors for neurodegeneration, one of the most debilitating manifestations of MPS (Martins et al. 2015).

The major manifestations of disease differ depending on the specific deficiency and on the turnover of substrates. Therefore, the clinical presentation and approach to therapy is different across the various disease types. The clinical presentation of the MPS is broad. They are characterized by somatic manifestations (facial dysmorphisms, hepatosplenomegaly, cardiac, respiratory, and skeletal involvement) and neurological, hematologic, and ocular symptoms. These manifestations are variably associated in each disorder. In most cases the disease phenotypes encompass a spectrum ranging from severe to attenuated clinical forms.

Because of the multisystem involvement in these patients, initial clinical assessment should rely on the evaluation of different organs and systems, and the involvement of a multidisciplinary team, including neurologist, ophthalmologist, ENT specialist, cardiologist, orthopedic surgeon, hematologist, and pulmonologist, is recommended. Imaging and functional studies are also valuable.

Biochemical investigations are needed to confirm the specific diagnosis, and genetic analyses, which are important for phenotype prediction, carrier detection, and prenatal diagnosis, may be required for diagnosis confirmation. These include the analysis of GAGs, the demonstration of a specific enzyme defect, and the identification of mutations in the relevant gene.

The evidence that earlier introduction of therapy improves the disease outcome supports the expansion of neonatal screening for selected MPS, which has already been introduced in some countries. Carrier detection, aiming to genetic counseling and/or family planning, is especially important in the X-linked recessive MPS II. This requires identification of the family mutation to investigate potential carriers, although in some cases this could be made by pedigree analysis. Prenatal diagnosis is possible either by assay of enzyme activity or by molecular analysis. As for other genetic conditions, preimplantation genetic diagnosis is also possible in the MPS.

Management of all MPS requires both supportive care and specific treatment. Supportive care should be based on multidisciplinary treatment of a variety of systemic complications and personalized in individual patients. Specific treatment is based on different approaches, depending on the MPS subtype. Hematopoietic stem cell transplantation (HSCT) has been performed in several MPS types, with variable results, being its most consistent indication MPS IH patients under the age of 2–3 years who have normal or near-normal developmental scores. Data of HSCT in MPS VI are also encouraging (Turbeville et al. 2011). Mortality and morbidity risks associated to HSCT are not negligible and should be taken into account.

Enzyme replacement therapy (ERT) with recombinant human enzymes has been approved for MPS I, MPS II, MPS IVA, MPS VI, and MPS VII. ERT reduces urinary GAG excretion and results in improvement of somatic manifestations and functional performance. However, some disease features (as heart valves pathology) respond to a lesser extent to therapy, and the inability of the recombinant enzymes to cross the blood-brain barrier limits its effect on the CNS. Strategies to address these important limitations and to facilitate recombinant enzyme delivery to the central nervous system are currently under development.

Other therapeutic approaches for the treatment of the MPS include substrate reduction, modulation of inflammation, gene therapy, and genome editing, among others, and are still under preclinical and clinical evaluation.

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM no.
64.1	Hurler-Scheie disease	Alpha-Iduronidase deficiency	MPS I	*IDUA*	4p16.3	Alpha-Iduronidase	607014, 607015, 607016
64.2	Hunter disease	Iduronate 2-sulfatase deficiency	MPS II	*IDS*	Xq28	Iduronate 2-sulfatase	309900
64.3	Sanfilippo A disease	Heparan-N-sulfatase deficiency	MPS IIIA	*SGSH*	17q25.3	Heparan-N-sulfatase	252900
64.4	Sanfilippo B disease	N-acetyl-alpha-D-glucosaminidase deficiency	MPS IIIB	*NAGU*	17q21	N-acetyl-alpha-D-glucosaminidase	252920
64.5	Sanfilippo C disease	Acetyl-CoA alpha-glucosaminide acetyltransferase deficiency	MPS IIIC	*MPS3C*	8p11.1	Acetyl-CoA alpha-glucosaminide acetyltransferase	252930
64.6	Sanfilippo D disease	N-Acetylglucosamine-6-sulfatase deficiency	MPS IIID	*GNS*	12q14	N-Acetylglucosamine-6-sulfatase	252940
64.7	Morquio A disease	N-Acetylgalactosamine-6-sulfatase deficiency	MPS IVA	*GALNS*	16q24.3	N-Acetylgalactosamine-6-sulfatase	253000
64.8	Morquio B disease	Beta-galactosidase deficiency	MPS IVB	*GLB1*	3p21.33	Beta-galactosidase	253010
64.9	Maroteaux-Lamy disease	N-Acetylgalactosamine-4-sulfatase deficiency	MPS VI	*ARSB*	5q11-q13	N-Acetylgalactosamine-4-sulfatase	253200
64.10	Sly disease	Beta-Glucuronidase deficiency	MPS VII	*GUSB*	7q21.11	Beta-Glucuronidase	253220
64.11	Natowicz disease	Hyaluronidase deficiency	MPS IX	*HYAL1*	3p21.31	Hyaluronidase	601492
64.12	MPS plus	–	MPSPS	*VPS33A*	12q24.3	Vacuolar protein sorting-associated protein 33A	61730

Metabolic Pathway

The degradation of GAGs is performed through the sequential action of lysosomal hydrolases. As the majority of these enzymes are either exoglycosidases (they cleave the sugar moiety at the end of the oligosaccharide chains) or sulfatases, a deficiency of one of these activities results in a block of further degradation of GAGs. The degradation pathways of HS, KS, and DS are shown in Fig. 64.1.

Signs and Symptoms

The major and evocative clinical features of MPS include somatic manifestations (facial dysmorphism, hepatosplenomegaly, cardiac, respiratory, and skeletal involvement) and neurological, hematologic, and ocular symptoms. These disease manifestations are variably associated in each disorder. The combination of the clinical features may be an important clue for the differential diagnosis in a patient in whom a MPS is suspected.

In most cases the disease phenotypes encompass a spectrum ranging from early-onset (severe) to late-onset (attenuated) clinical forms. The clinical presentation of each disease is reported in Tables 64.1, 64.2, 64.3, 64.4, 64.5, 64.6, 64.7, 64.8, 64.9, 64.10, 64.11, and 64.12 (signs and symptoms).

Patients with the severe form of MPS I (Hurler disease, MPS IH), MPS II (Hunter disease), and MPS VI (Maroteaux-Lamy disease) generally present with facial dysmorphism and persistent respiratory disease in the early years of life. Many patients will have undergone surgical procedures for recurrent otitis media, removal of tonsils and/or adenoids, and hernia repair before the diagnosis is established. Infants with MPS III (Sanfilippo A, B, C, or D disease) present with cognitive difficulties and then develop a profound behavioral disturbance. The behavior disorder is characteristic and often leads to the diagnosis. Somatic features are less pronounced in these patients. Children with MPS IVA (Morquio disease, type A) have normal cognitive functions but are affected by severe spondyloepiphyseal dysplasia, which in most patients leads to extreme short stature, deformity of the chest, marked shortening and instability of the neck, and joint laxity. MPS IVB (Morquio disease, type B) has similar features of the skeletal dysplasia of MPS IVA but is much more variable in its effects; MPS VII (Sly disease) often presents as nonimmune hydrops fetalis. Those patients who survive or who present later resemble patients

[a]MPS I presents with wide variability. Traditionally, phenotypes were described as Hurler (severe, MPS IH) and Scheie (attenuated, MPS IS), with an intermediate, Hurler-Scheie (MPS IH/S) in between. From the clinical perspective, the classification in severe and attenuated types makes more sense. The severe phenotype is quite well defined and corresponds to the Hurler syndrome. The attenuated phenotype is a spectrum of presentations that range from the severe end of the Hurler-Scheie phenotype, which could have some cognitive involvement, to the mild end of the Scheie phenotype that has limited clinical impact

with MPS I with respect to clinical phenotype and supportive management. Potentially life-threatening manifestations, such as tracheal compression and aortic dilatation, have been reported in some MPS. Cognitive impairment is a feature of MPS III and of the severe forms of MPS I, MPS II, and MPS VII. Patients with the rare MPS IX (Natowicz disease) show a clinical picture limited to joint involvement and proliferative synovitis (Imundo et al. 2011). The recently described MPSPS (MPS Plus) has an early presentation with coarse face, dysostosis multiplex, respiratory difficulty, visceromegaly, neurological involvement, and other severe manifestations (Kondo et al. 2017).

The phenotype of patients with attenuated forms of MPS I (MPS IH/S and MPS IS, Hurler-Scheie or Scheie disease, respectively), MPS II, and MPS VI is much more difficult to predict, and treatment needs in this group of patients may be very variable. The MPS disorders in general present as a continuum of clinical involvement, and even patients with the most attenuated forms of Scheie syndrome may have severe disabilities, requiring major medical and surgical interventions.

Diagnostic Flowcharts

The diagnosis workup for MPS is complex and relies on clinical evaluation and multiple laboratory tests.

The first step in the diagnostic workup of MPS is the clinical evaluation of patients and first-level diagnostic procedures (x-ray, blood smear, eye examination, ECG, cardiac ECHO, etc.; see Fig. 64.2).

Laboratory tests to complete the diagnosis should be performed in laboratories with specific expertise. These procedures usually start by the search for metabolites (quantitative and qualitative analysis of urinary GAGs; Fig. 64.3) using colorimetric methods and/or tandem mass spectrometry procedures; the assay of GAGs in blood is being developed and may play a role in MPS screening and diagnosis; enzyme assay of specific hydrolases in dried blood spots, plasma, leucocytes, or fibroblasts; and molecular analysis of the relevant gene (usually in DNA samples from peripheral blood, but DNA can be obtained also from other sources). Molecular analysis may be based on next-generation sequencing of multiple genes, including the ones involved in other lysosomal processes (Di Fruscio et al. 2015).

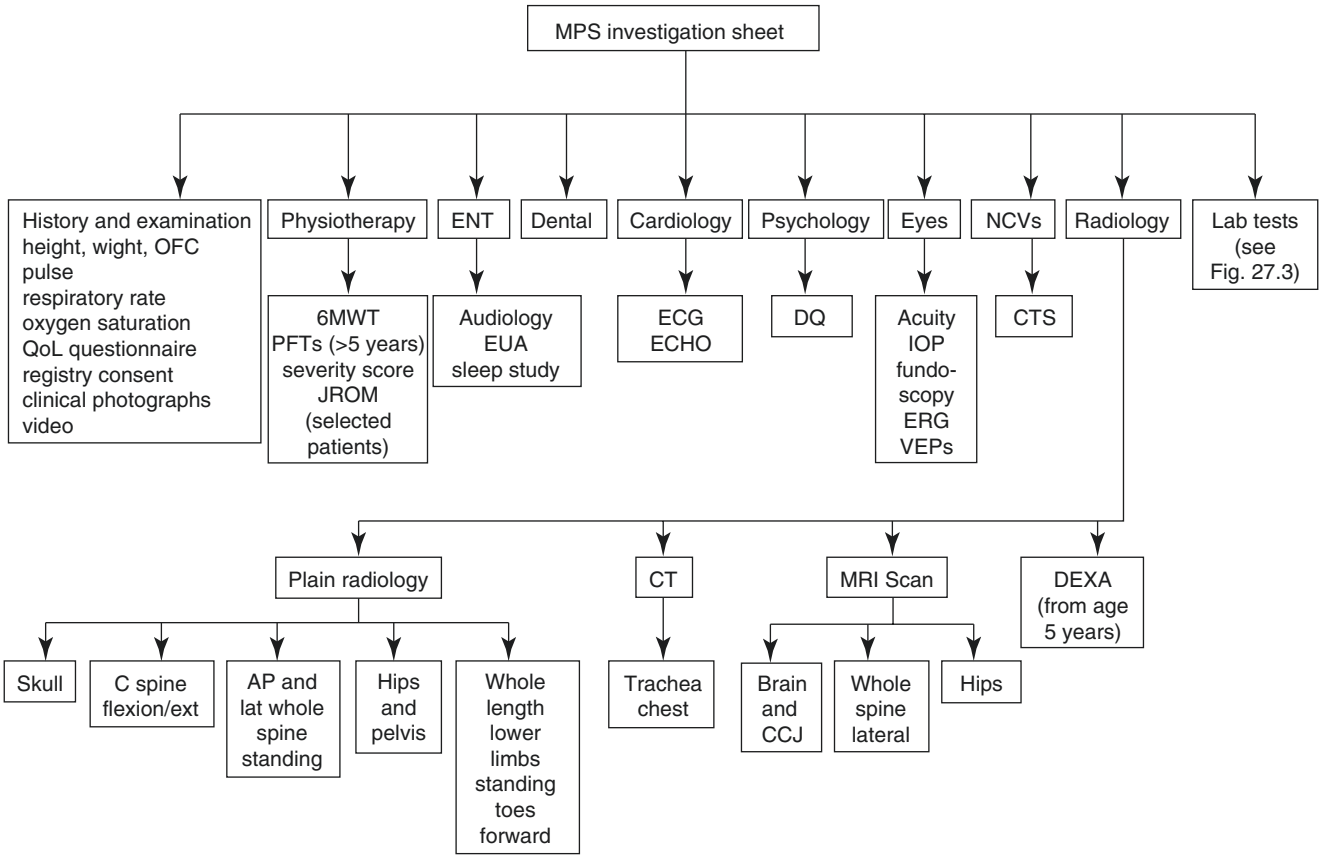

Fig. 64.2 The MPS investigation sheet. History, clinical examination, and imaging studies are associated with evaluation of multisystem involvement and laboratory tests to confirm the diagnosis

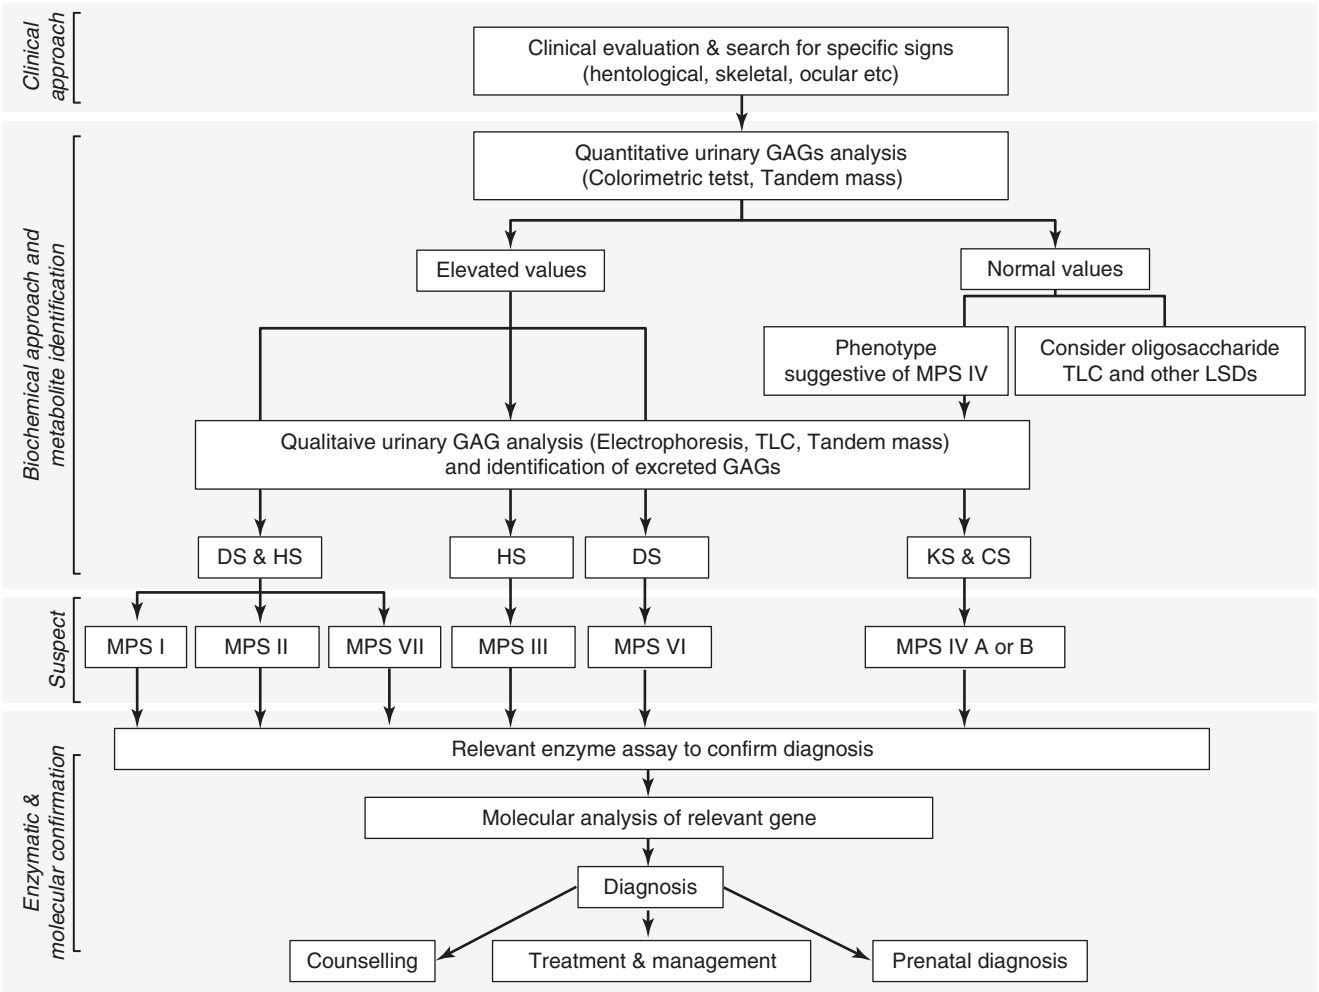

Fig. 64.3 The assay of urinary GAGs and the identification of specific excretion patterns, performed by thin-layer chromatography (TLC), electrophoretic separation, or tandem mass spectrometry (depending on the availability of these techniques in the laboratory), help to select the specific enzyme(s) to be tested in the appropriate sample. Enzyme assays in dried blood spots or plasma are considered screening methods that should be validated by the enzyme assay in leucocytes or fibroblasts and/or by genetic analysis. The diagnosis should be confirmed by molecular analysis of the relevant gene. *LSDs* Lysosomal storage diseases

Specimen Collection

No.	Disorder	Metabolite analysis (GAGs)	Enzyme assay	Molecular characterization[a]
64.1	MPS I	U[b]	D[c], P[d], L[e], FB[f]	B
64.2	MPS II	U	D, P, L, FB	B
64.3	MPS IIIA	U	L, FB	B
64.4	MPS IIIB	U	D, P, L, FB	B
64.5	MPS IIIC	U	L, FB	B
64.6	MPS IIID	U	L, FB	B
64.7	MPS IVA	U	D, L, FB	B
64.8	MPS VIB	U	D, L, FB	B
64.9	MPS VI	U	D, L, FB	B
64.10	MPS VII	U	D, P, L, FB	B
64.11	MPS IX	–	P	B
64.12	MPSPS	U, P	–	B

U Urine, *D* dried blood spots, *P* plasma, *S* serum, *B* blood, *L* leucocytes, *FB* fibroblast

[a]For all diseases DNA can be obtained from other sources (e.g., fibroblasts)

[b]Urine should be kept frozen (positive screening for MPS may be missed due to diluted urine specimens – low creatinine concentration, proteinuria, and medications; heparan sulfate may be increased in non-MPS diseases)

[c]Dried blood spots should be collected in a protein saver filter paper and dry at room temperature for at least 4 hours and then placed preferably in a plastic bag with desiccant; could be transported at room temperature; and should be stored at refrigerator until analysis, noting that the activity of some enzymes, as GALNS, is time-sensitive

[d]Fibroblasts are obtained by skin biopsy, obtained under sterile conditions, and kept in culture medium or saline solution at room temperature until the culture is started; after harvested, fibroblasts could be stored frozen

[e]Plasma could be obtained preferably by collection of blood with EDTA, so the material could be used for the measurement of GAGs, when available; transport the blood at room temperature or refrigerated until plasma is obtained; the plasma sample could be stored frozen (−20°C)

[f]Leucocytes and lymphocytes could be obtained from blood collected with EDTA, as it could allow assay of GAGs; blood should be kept at room temperature or refrigerated (do not freeze) until isolation of leucocytes or lymphocytes, which should be performed no more than 48–72 h after collection; after isolation, leucocytes and lymphocytes could be stored frozen

Prenatal Diagnosis

No.	Disorder	Enzyme assay	Genetic testing
64.1	MPS I	α-Iduronidase	*IDUA*
64.2	MPS II	Iduronate-2-sulfatase	*IDS*
64.3	MPS IIIA	Heparan-N-sulfatase (sulfamidase)	*SGSH*
64.4	MPS IIIB	α-N-acetylglucosaminidase	*NAGU*
64.5	MPS IIIC	Acetyl-CoA:α-glucosaminide N-acetyltransferase	*MPS3C*
64.6	MPS IIID	N-acetyl glucosamine-6-sulfatase	*GNS*
64.7	MPS IVA	N-Acetylgalactosamine-6-sulfatase	*GALNS*
64.8	MPS VIB	β-Galactosidase	*GLB1*
64.9	MPS VI	N-Acetylgalactosamine-4-sulfatase	*ARSB*
64.10	MPS VII	β-Glucuronidase	*GUSB*
64.11	MPS IX	Hyaluronidase	*HYAL1*
64.12	MPSPS	Not available	*VPS33A*

Enzyme analysis and genetic testing can be performed in chorionic villi or amniocytes. Iduronate sulfatase enzyme assay can also be performed in amniotic fluid

Functional tests of hyaluronidase and VPS33A for prenatal diagnosis are not reported in the literature. For both disorders genetic testing can be performed

Neonatal Screening

Neonatal screening for MPS is technically feasible, and its implementation largely depends on the evidences of benefits of its diagnosis in newborns. This is clear for MPS IH, and so the newborn screening for MPS I became part of the "Recommended Uniform Screening Panel" (RUSP) in the United States (http://www.hrsa.gov/advisorycommittees/mchbadvisory/heritabledisorders/recommendedpanel/index.html) in 2016 and is now routine in several US states (https://www.newsteps.org/), in Taiwan (Chan et al. 2019; Chuang et al. 2018), and in a growing number of regions, including regular schemes and pilot programs (Taylor et al. 2019a, b; Bronstein et al. 2019; Burlina et al. 2018; Bravo et al. 2017; Navarrete-Martínez et al. 2017; Burton et al. 2017).

Screening for MPS II is in place in Taiwan since 2015 (Chuang et al. 2018) and the US state of Illinois since 2017 and will probably expand to other states and countries in the short term (Joseph et al. 2018).

Screening for other MPS, which is technically possible, is under consideration for MPS IVA, MPS VI, and MPS VII, which have specific therapy available (Donati et al. 2018; Liu et al. 2017). Screening for MPS III still needs that specific therapies become available in order to move to practice (Yi et al. 2018; Kuiper et al. 2018).

The present newborn screening techniques are based on the measurement of specific enzymes, by tandem mass spec-

trometry (Gelb 2018; Schielen et al. 2017; Gelb et al. 2017) or digital microfluidics (Sista et al. 2011; Millington et al. 2010). Postanalytical tools can help to reduce false-positive rates regardless of the methodology chosen for the enzyme assay (Minter Baerg et al. 2018; Gelb 2018).

However, the possibility of measuring GAGs in dried blood spots is being tested (Maccari et al. 2018; Kubaski et al. 2017) and if approved may bring the possibility of detecting almost all MPS cases with just one assay (Saville et al. 2019).

Newborn screening with genetic analyses is also being developed and may become an alternative technology for the detection of not only MPS but also of a large number of other treatable diseases; however currently major concerns with this type of analyses are due to new variants or variants of unknown significance (VUS) (Donati et al. 2018).

Treatment

Because of the multisystem involvement in these patients, treatment is multidisciplinary and encompasses both the specific and general management elements.

Supportive Treatment

Irrespective of the type, the management of all MPS requires supportive care and multidisciplinary treatment of a variety of systemic complications.

Regular evaluation at a major center with special interest and expertise in the management of the diseases is important in the coordination of interdisciplinary input and to coordinate multispecialty treatment strategies. In addition to the neurological complications experienced by many, distortion and narrowing of the upper airway and deformities of the chest present potential fatal anesthetic risks for most patients with MPS. Even the most trivial procedures requiring general anesthesia should be done at centers with anesthetists who are experienced with MPS disorders (Moretto et al. 2018; Madoff et al. 2019).

Because of the progressive nature of the diseases, individuals with MPS need to be evaluated regularly in order to identify potential problems early at a time when intervention would decrease morbidity, prevent premature mortality, and enhance the quality of life of affected patients. Every patient with MPS is unique; therefore, treatment options need to be individually based.

The table summarizes the types of problems experienced by patients with MPS disorders and strategies for their management.

Supportive treatment of mucopolysaccharidoses

System	Problem	Intervention
Cardiovascular	Cardiomyopathy	Anti-heart failure medication
	Valve lesions	Anti-heart failure medication; valve replacement
	Coronary artery disease	None
CNS	Hydrocephalus	Ventriculoperitoneal shunt
	Atlantoaxial instability	Surgical decompression or fusion of cervical spine
	Cervical myelopathy	Surgical decompression or fusion
	Seizures	Anticonvulsant medication
	Behavior problems	Behavior management, medication
	Sleep disturbance	Medication
	Mental retardation	Appropriate educational support and interventions
Digestive	Hepatosplenomegaly	None
	Umbilical and inguinal hernias	Surgical repair
	Swallowing problems	Pureed diet; small, frequent meals; gastrostomy
	Drooling	Hyoscine glycopyrrolate, Botox injections
	Diarrhea	Antimotility medication
Ear	Recurrent otitis media	Antibiotic therapy; ENT surgery [a]
	Sensorineural deafness	Hearing aids
Eye	Corneal clouding	Avoid direct sunlight; corneal transplantation
	Glaucoma	Topical beta-blockers; trabecular surgery
	Retinal dystrophy	None
Musculoskeletal	Degenerative hip dysplasia	Analgesics; orthopedic surgical correction
	Kyphosis or kyphoscoliosis	Bracing or orthopedic surgical correction
	Joint contractures	Physiotherapy and orthoses
	Genu valgum deformities	Osteotomies
Respiratory	Upper airway obstruction	ENT surgery [a]
	Obstructive sleep apnea	Oxygen therapy, CPAP, or BiPAP
	Restrictive lung disease	Oxygen therapy, CPAP, or BiPAP
Dental	Caries, dental abscess	Oral hygiene; dental extraction
Peripheral nerve	Carpal tunnel syndrome	Surgical decompression

ENT Ears, nose, throat, *CPAP* continuous positive airway pressure
[a]Including various combinations of tonsillectomy, adenoidectomy, myringotomy, the insertion of ventilation tubes, and tracheostomy

Specific Treatment

Hematopoietic Stem Cell Transplantation (HSCT)

In patients with MPS IH under the age of 2–3 years who have normal or near-normal developmental scores (DQ > 70), HSCT should be considered, using either HLA-matched bone marrow or umbilical cord blood cells as the donor cells (Taylor et al. 2019a, b). The best results are achieved with HLA-matched sibling donors, although using heterozygous carriers as donors should be avoided. Successful engraftment is associated with resolution of hepatosplenomegaly and upper airway obstruction. Corneal clouding usually resolves slowly, but never completely. Intraocular pressures may decrease. Cardiac manifestations attributable to muscle involvement are corrected, but valvular abnormalities are resistant to HSCT and often progress. Improvements in joint mobility are routinely experienced, and growth may approach normal rates for children of the same age. However, some skeletal abnormalities, especially abnormalities of the spine, do not respond to HSCT, and most severely affected children still require major orthopedic interventions. HSCT has been used occasionally to treat other MPS types, with controversial findings. The most consistent results, other than in young MPS IH patients, is in MPS VI (Turbeville et al. 2011), although it has been not routinely used where ERT is available due to the mortality and morbidity risks associated to the transplantation, which also limits its use in attenuated forms of MPS I. Limited data are available on HSCT in other MPS (Kubaski et al. 2017; Selvanathan et al. 2018; Taylor et al. 2019a, b).

Enzyme Replacement Therapy

ERT has been demonstrated in randomized, double-blind, placebo-controlled studies to produce improvements in general performance, joint mobility, pulmonary function, and exercise tolerance in patients with MPS I (laronidase), MPS II (idursulfase), MPS IVA (elosulfase alfa), MPS VI (galsulfase), and MPS VII (vestronidase alfa). These enzymes are licensed in the European Union, United States, and several other countries to treat the non-neurological aspects of the specific MPS.

As there is no evidence that any of the replacement proteins cross the blood-brain barrier in significant amounts, an approach based on repeated intrathecal ERT has been used in MPS I (Muñoz-Rojas et al. 2008) and MPS VI patients (Muñoz-Rojas et al. 2010) and later further tested in clinical trials on MPS I (ClinicalTrials.gov Identifier: NCT02232477), MPS II (ClinicalTrials.gov Identifier: NCT00920647), and MPS IIIA (ClinicalTrials.gov Identifier: NCT01299727), but so far is not an approved therapeutic approach. Intracerebroventricular ERT is presently in development for MPS II and for MPS III B.

Another approach to provide enzyme to the CNS is the use of fusion proteins that could bypass the blood-brain barrier. A fusion protein combining laronidase and the antibody for the insulin receptor was tested in MPS I patients (Giugliani et al. 2018), and a similar product with idursulfase is in clinical trial for MPS II. Another fusion protein, combining idursulfase with the antibody for the transferrin receptor, was developed to treat MPS II (ClinicalTrials.gov Identifier: NCT02262338) and is presently in clinical development, with a similar approach being planned also for MPS I (ClinicalTrials.gov Identifier: NCT02371226).

Other Therapeutic Approaches

The treatment of MPS is rapidly evolving and other therapeutic approaches are currently under evaluation.

Small molecules have been considered in the treatment of MPS I. Genistein was proposed as a substrate reduction therapy that could bring benefit to neuronopathic MPS as MPS III and the severe forms of MPS I and MPS II (de Ruijter et al. 2012; Marucha et al. 2011; Kloska et al. 2011). Despite good results in preclinical studies and safety demonstrated in clinical trials (Kim et al. 2013), no benefits to MPS patients were clearly demonstrated so far. Rhodamine B was also proposed as drug that could lead to substrate inhibition (Roberts et al. 2007). Ataluren was proposed as a stop-codon read-through strategy which could improve the outcome on severe MPS I patients (Hein et al. 2004), but no successful clinical use was reported so far. Odiparcil, a drug that makes GAGs (especially dermatan sulfate) more soluble and could reduce its storage (Myers et al. 2008), is under evaluation in a clinical trial (ClinicalTrials.gov Identifier: NCT03370653). Pentosan polysulfate was proposed to reduce inflammation (Hennermann et al. 2016; Simonaro et al. 2016), suspected to be one of the major players in MPS pathology.

Gene therapy is in clinical development for several types of MPS (MPS I, MPS II, MPS IIIA, MPS IIIB, and MPS VI), using different vectors (adeno-associated virus, lentivirus) and different administration routes (intravenous, intrathecal, intraparenchymal).

The results of clinical trials of gene therapy for MPS IIIA and IIIB have been published (Tardieu et al. 2014; Tardieu et al. 2017). Adeno-associated virus-mediated intraparenchymal gene therapy resulted in stabilized or delayed disease progression, particularly in patients treated at earlier ages.

Genome editing, which is also in clinical trials (MPS I and MPS II), may become another therapeutic alternative in the future (Ho et al. 2018).

Different therapeutic options may be available for the same disorder, and the appropriate treatment should be considered in individual patients.

Patients with severe central nervous system involvement (MPS III, Sanfilippo disease) or severe bone dysplasia (MPS IVA, Morquio disease) present particular challenges to management, as current therapies are poor in correcting the effects of the genetic lesion in the brain and bone, respectively.

Treatment of mucopolysaccharidoses by ERT

No.	Disorder	Age	Medication	Dosage	Route and frequency
64.1	MPS I	All	Laronidase	100 U/kg	IV weekly
64.2	MPS II	All	Idursulfase	0.5 mg/kg	IV weekly
64.7	MPS IVA	All	Elosulfase alfa	2 mg/kg	IV weekly
64.9	MPS VI	All	Galsulfase	1 mg/kg	IV weekly
64.10	MPS VII	All	Vestronidase alfa	4 mg/kg	IV every two weeks

Therapeutic options for mucopolysaccharidoses

No.	Disorder	HSCT	ERT	Small molecules	Gene therapy
64.1	MPS I	+	+	Preclinical studies	Clinical development
64.2	MPS II	(+)	+	Preclinical studies	Clinical development
64.3	MPS IIIA				Clinical development
64.4	MPS IIIB		Clinical development		Clinical development

64.12	MPSPS				

Follow-Up and Monitoring

The objectives of monitoring patients with MPS disorders are:

1. To provide ongoing support for the patient and family.
2. To anticipate complications, identify them early when they occur, and treat them in order to decrease morbidity.
3. To monitor specific therapies, such as HSCT and ERT, to assess their effectiveness, and, in the case of ERT, to manage infusion reactions which may occur.

Recommended follow-up and monitoring of MPS disorders

		Initial	Every 6 months	Every 12 months	Every 2 years
General	Medical history and physical examination[a]	*	*		
Neurological	Neurological examination	*	*		
	Developmental assessment	*		*	
	MRI of brain	*			*
	MRI of spine	*			*
Ophthalmologic[b]	Visual acuity	*		*	
	Retinal examination	*		*	
	Corneal examination	*		*	
Auditory	ENT consultation	*		*	
	Audiometry	*		*	

		Initial	Every 6 months	Every 12 months	Every 2 years
Cardiac	Chest radiograph (for heart size)	*		*	
	ECG	*			*
	Echocardiogram	*			*
Respiratory	Pulmonary function tests[c]	*	*		
	Sleep study	*		*	
Gastrointestinal	Spleen and liver volumes[d]	*			*
Musculoskeletal	Skeletal radiographs[e]	*			*
Laboratory studies[f]	Enzyme assay[g]	*			
	Urinary GAG level	*	*		
	Urine analysis	*	*		
	Antibody testing	*[h]	*		

[a]Including measurement of height, weight, head circumference, and blood pressure

[b]Including measurement of intraocular pressures

[c]Forced vital capacity (FVC) and 1-s forced expiratory volume (FEV_1)

[d]Best measured by MRI or CT scan

[e]AP and lateral views of the skull, PA view of the chest, lateral views of the spine (including the cervical spine), AP view of the hips and pelvis, single AP view of both hands together. In the case of MPS IV, include lateral views of the neck in flexion and extension to assess stability of the atlantoaxial joint and a single AP view of the upper cervical spine through the open mouth to assess the integrity of the odontoid process. These studies are primarily for the assessment of disease in children; the menu and schedule for radiographic studies in adults would be more limited, emphasizing the assessment of osteoarthritis

[f]In patients who have undergone hematopoietic stem cell transplantation (HSCT), leucocytes alpha-l-iduronidase assays and VNTR analyses on DNA extracted from peripheral blood should be done monthly from the time of transplantation and then every 6 months to assess engraftment

[g]For assessment of response to enzyme replacement therapy or HSCT

[h]To be performed initially 3 months after the start of ERT

Summary

Infantile nephropathic cystinosis is an autosomal recessive disorder caused by mutations in the *CTNS* gene that encodes for cystinosin, a lysosomal cystine/H^+ symporter. With time, cystine accumulation leads to cell dysfunction in various tissues. The kidneys are initially more involved. Most patients are asymptomatic at birth but present in the first or second

year of life with failure to thrive, polyuria, dehydration, and/or rickets, which are secondary to the renal Fanconi syndrome. With very few exceptions, all patients have corneal cystine crystals by 18 months of age that can help in recognizing the disease. The diagnosis of cystinosis is based on the detection of increased leukocyte cystine levels and demonstration of mutations in the *CTNS* gene (detection rate > 95%). In Northern Europe, 75% of mutated alleles carry a 57-kb deletion; all other types of mutations, generally resulting in a complete or severe loss of function of the cystinosin protein, have been described.

Introduction of cysteamine treatment in the late 1980s and improvements in dialysis and renal transplantation have considerably improved the prognosis of cystinosis. Cysteamine significantly delays progression to end-stage renal kidney disease, but cannot prevent it in most cases. The majority of patients live well into adulthood but, if not appropriately treated with cysteamine, develop other symptoms related to cystine accumulation in various tissues. These include retinal degeneration, hypothyroidism, diabetes mellitus, exocrine pancreatic insufficiency, pubertal retardation and gonadal dysfunction, restrictive pulmonary disease, myopathy, neurological deterioration, and liver involvement. Two milder forms of the disease, namely, juvenile cystinosis and ocular cystinosis, caused by mutations that allow residual function of the cystinosin protein, have also been reported. These patients present with milder symptoms later in childhood or with isolated corneal cystine depositions.

Introduction

Cystinosis is an inherited autosomal recessive disease caused by mutations in the *CTNS* gene, which encodes for cystinosin, a cystine/H^+ symporter that is primarily expressed at the lysosomal membrane (Kalatzis et al. 2001). The *CTNS* gene is located on chromosome 17p13 and was cloned in 1998 (Town et al. 1998). To date, more than 140 different mutations have been identified with a detection rate that exceeds 95% (David et al. 2019).

The *CTNS* gene is composed of 12 exons and spans 23 kb. Cystinosin is composed of 367 amino acids that form a 7-transmembrane domain cotransporter with 2 lysosomal targeting motifs (Cherqui et al. 2001). The most common mutation, accounting for 75% of the affected alleles in Northern Europe, is a 57-kb deletion that removes the first nine exons and part of exon 10 of the *CTNS* gene, the upstream 5′ region of the *CARKL* gene, and the first two non-coding exons of the *TRPV1* gene (Nesterova and Gahl 2017). The function of the *CARKL* gene has been identified in the phosphorylation of sedoheptulose, an intermediate metabolite of the pentose phosphate pathway. The transient receptor potential channel vanilloid subfamily member 1 (*TRPV1*) encodes for an ion channel that is primarily expressed in sensory nerves and is activated by a wide range of chemical stimuli. Patients with a homozygous 57-kb deletion have elevated blood and urinary levels of sedoheptulose. The contribution of the *CARKL* and *TRPV1* genes to the pathogenesis of the disease in patients with homozygous 57-kb deletion has not been fully studied. No major differences in the clinical evolution, however, have been reported when comparing these patients to patients carrying other *CTNS* gene mutations (Wilmer et al. 2010). These include smaller deletions, insertions, nonsense mutations, missense mutations, mutations within the promoter region, and splice site mutations. Intronic mutations affecting normal splicing have also been reported in families whose standard genetic testing failed to identify mutations in one or both alleles, indicating that cystinosis is a monogenic disorder and that intronic regions should be analyzed when no mutations are found in the *CTNS* coding sequence (Taranta et al. 2010; David et al. 2019).

A transcript variant originating from an alternative splicing of exon 12 has been reported and was shown to be expressed also in other cell compartments, including the plasma membrane (Taranta et al. 2008). The contribution of this isoform to the physiopathology of the disease is not known yet (Wilmer et al. 2010).

The incidence of cystinosis varies among countries between 0.5 and 1.0/100,000 live births; several founder mutations have been observed in different geographic regions, such as the 57-kb deletion that originated in Germany around A.D. 500 (Nesterova and Gahl 2017). In its most frequent form, termed infantile nephropathic cystinosis (MIM 219800), children are usually asymptomatic at birth and develop normally during the first 2–3 months of life. They generally present around the age of 6 months with failure to thrive, vomiting, constipation, polyuria, excessive thirst, dehydration, and sometimes rickets (Nesterova and Gahl 2017; Elmonem et al. 2016). These symptoms are the consequence of the renal Fanconi syndrome, which is characterized by excessive urinary losses of water, amino acids, phosphate, uric acid, bicarbonate, glucose, sodium, potassium, low-molecular-weight proteins, and other solutes. Untreated children develop chronic renal failure during early childhood that progresses to end-stage kidney disease in the first decade of life. Patients with cystinosis have a

characteristic facial appearance. Typically, Caucasian children have blond hair, although children from other ethnic groups may retain normal or near-normal pigmentation. With time, cystine crystals deposit in the cornea and are nearly always observed by 18 months of age (Tsilou et al. 2002). They may cause photophobia and chronic inflammatory changes of the anterior chamber, if not treated.

The diagnosis of cystinosis is based on the measurement of leukocyte cystine levels by tandem mass spectrometry or HPLC. Abnormal results need to be confirmed by molecular analysis of the *CTNS* gene. Leukocyte cystine levels are increased up to 100-fold in affected individuals compared with control subjects; levels in heterozygous carriers are only slightly increased.

Since the late 1980s, improvements in dialysis and renal transplantation and the introduction of treatment with the cystine-depleting agent cysteamine have considerably prolonged the life expectancy of patients with cystinosis (Markello et al. 1993; Van Stralen et al. 2011). However, they have also revealed hitherto long-term complications resulting from cystine accumulation in other tissues. These include retinal degeneration, hypothyroidism, diabetes mellitus, exocrine pancreatic insufficiency, pubertal retardation and gonadal dysfunction, restrictive pulmonary disease, myopathy, neurological deterioration, and liver involvement (Gahl et al. 2007; Nesterova and Gahl 2013; Brodin-Sartorius et al. 2012). A few female patients have given birth to normal healthy children, but nearly all tested male patients with infantile cystinosis are infertile. Most late-onset complications improve or are prevented by cysteamine (Gahl et al. 2007; Nesterova and Gahl 2013; Brodin-Sartorius et al. 2012). Corneal cystine crystals do not respond to oral cysteamine and require topical administration. Cysteamine treatment should be optimized by regular measurements of leukocyte cystine levels that allow adapting the dose to target levels (Levtchenko et al. 2004).

Renal transplantation is a well-established treatment for patients reaching end-stage renal disease. Transplanted cystinotic patients have longer renal survival, probably because they have a lower risk of rejection (Van Stralen et al. 2011). They require, nonetheless, standard immunosuppression. Although cysteamine has considerably improved the outcome, progression to end-stage kidney diseases usually cannot be prevented beyond the second or third decade of life (Van Stralen et al. 2011; Nesterova and Gahl 2013).

Early recognition of complications, optimization of nutritional intake, early treatment of Fanconi syndrome and rickets, and growth hormone therapy have also considerably improved the clinical outcome.

In addition to the infantile form, two other milder variants have been identified (Nesterova and Gahl 2017). These include the "juvenile" or "intermediate" form (MIM 219900), which is usually diagnosed during childhood or adolescence and is characterized by less severe renal symptoms, and a third form that has been reported primarily in adults and is characterized by isolated ocular symptoms and is termed "ocular" or "non-nephropathic" cystinosis (MIM 219750).

The severity of the disease co-segregates within family members with very few exceptions. *In vitro* studies of residual cystine transport activity have shown that infantile cystinosis generally results from severe mutations leading to complete loss of function of cystinosin (David et al. 2019).

To date, the physiopathology of cell damage in cystinosis has not been fully elucidated. *In vitro* and *in vivo* studies have shown that cystinotic cells are more prone to apoptosis; abnormalities in glutathione and ATP metabolism, as well as defects in intracellular trafficking and mTOR signaling and impaired autophagy, have been reported (Wilmer et al. 2010; Cherqui and Courtoy 2017; Festa et al. 2018).

Nomenclature

No.	Disorder name	Alternative disorder names	Disorder abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM #
65.1	Infantile nephropathic cystinosis		–	*CTNS*	17p13	Cystinosin	219800
65.2	Juvenile cystinosis	Intermediate form	–	*CTNS*	17p13	Cystinosin	219900
65.3	Non-nephropathic cystinosis	Ocular form	–	*CTNS*	17p13	Cystinosin	219750

Metabolic Pathways

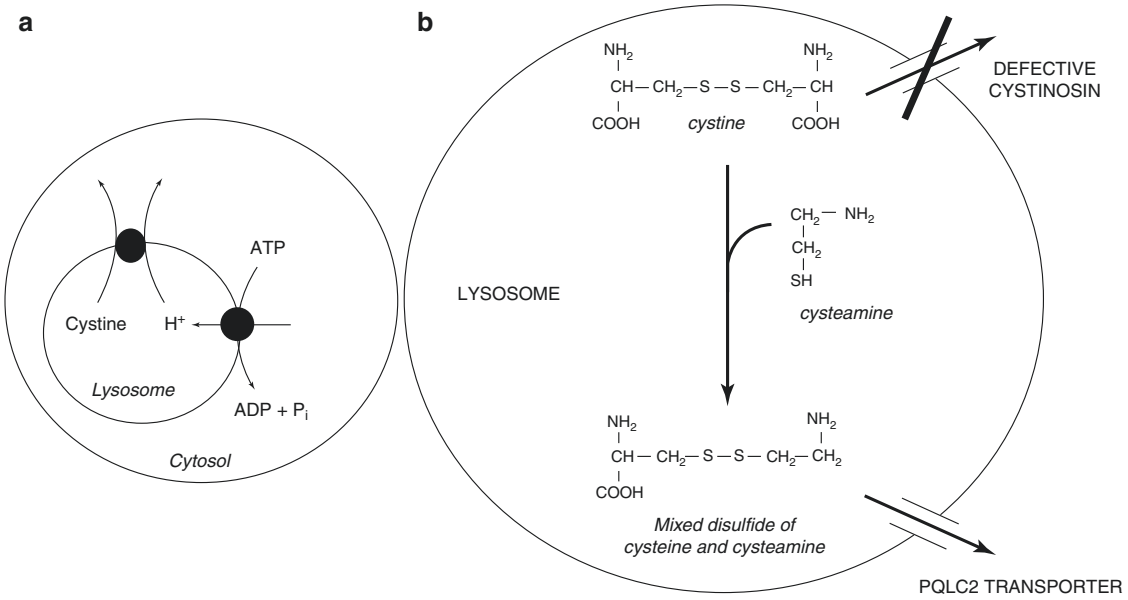

Fig. 65.1 *Panel* (**a**). Cystinosin is a lysosomal cystine carrier. Cystine efflux from lysosomes is dependent on the proton gradient generated by the vacuolar H^+ ATPase. *Panel* (**b**). Mechanism of action of cysteamine. In the presence of cystine, cysteamine forms a mixed disulfide molecule resembling lysine, which is more soluble than cystine and exits the lysosome through a PQLC2 transporter

Patients with juvenile cystinosis present with symptoms similar to the infantile form, but usually at older age. Renal Fanconi syndrome is usually less pronounced. Non-nephropathic cystinosis 65.3 are exceptional patients that only have corneal cystine crystals.
Patients with ocular cystinosis present only with ocular complaints related to corneal cystine crystals, but not with systemic symptoms
[a]Patients have usually a kidney transplant at that age; symptoms and routine biochemical parameters depend on the graft function
[b]Biochemical features of renal Fanconi syndrome decrease during the decline of the GFR. Urinary features of renal Fanconi syndrome mostly persist even at advanced stages of renal failure and after renal transplantation if the diuresis of the native kidneys is still present
[c]Cystine measurements in cultured fi broblasts (FB) are not recommended routinely. The diagnosis of cystinosis should be confi rmed by molecular diagnosis of the *CTNS* gene

Reference Values

Reference values for leukocyte cystine

Cystine (WBC)	<0.1–0.2 nmol cystine/mg protein[a]
Cystine (PMN)	<0.1–0.2 nmol cystine/mg protein[a]

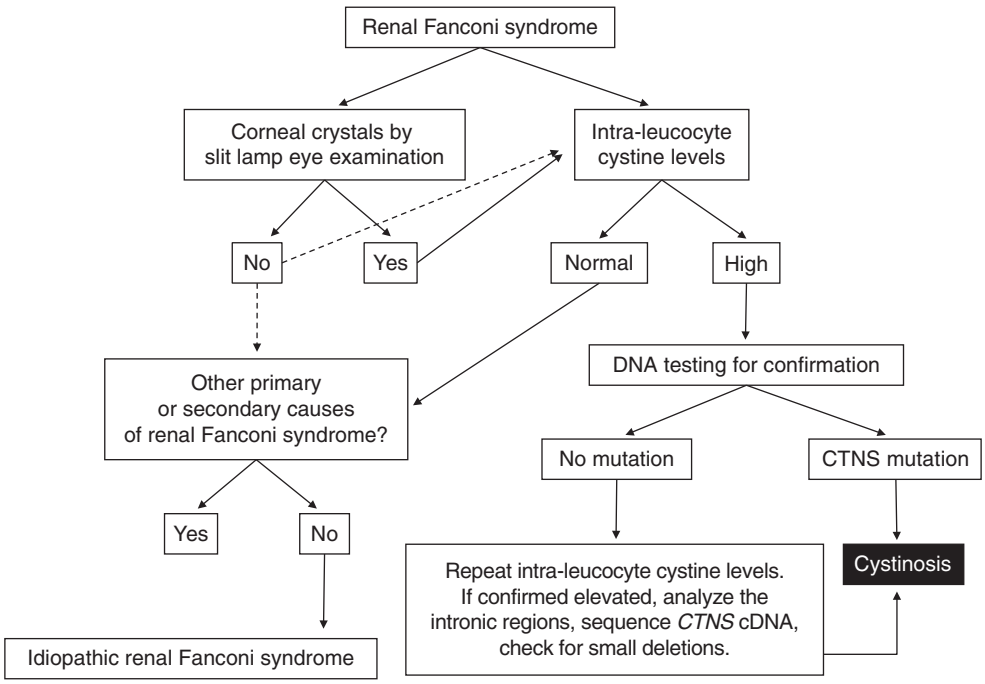
Conversion factor ½ cystine/mg protein = 2× cystine/mg protein
[a]Cystine is sometimes expressed as nmol ½ cystine/mg protein

Pathological Values

Pathological values for leukocyte cystine

Cystine (PMN)	Heterozygotes	0.09–0.65 nmol cystine/mg protein
	Patients at diagnosis	>2 nmol cystine/mg protein
	Patients under cysteamine therapy	<0.6 nmol cystine/mg protein
Cystine (WBC)	Heterozygotes	0.05–0.5 nmol cystine/mg protein
	Patients at diagnosis	>2 nmol cystine/mg protein
	Patients under cysteamine therapy	<0.5 nmol cystine/mg protein

Diagnostic Flowchart



Specimen Collection

Leukocyte cystine measurement is a particularly sensitive test that should be performed in certified laboratories. Each laboratory should produce its own reference values for healthy subjects, heterozygotes carriers, patients at diagnosis, and patients under cysteamine treatment.

Blood is usually collected in heparin or citrate tubes according to the laboratory recommendation; results are significantly influenced by the type of anticoagulant. After collecting blood samples, specimens should be processed as soon possible. The pre-analytic phase is the most delicate part of the analysis. Cystine is currently measured by tandem mass spectrometry (MS-MS) and, less frequently, by high-performance liquid chromatography (HPLC). Results are usually normalized per mg of proteins. Sample contamination with other non-leukocyte proteins (e.g., erythrocyte ghosts) may result in falsely low values. Measurements performed on the granulocyte fraction after Ficoll fractionation are more reliable than measurements on the entire leukocyte population, because granulocytes contain significantly more lysosomes than lymphocytes.

Prenatal Diagnosis

Fetal DNA sequencing allows accurate prenatal diagnosis. In the past, cystine measurements were performed on cultured amniotic cells, but this approach has been abandoned.

Treatment Summary

Oral cysteamine bitartrate efficiently depletes lysosomes from cystine (Fig. 65.1) at a recommended dose of 1.3–1.9 g/m^2/day given at 6-hour intervals (Markello et al. 1993; Elmonem et al. 2016; Gahl et al. 2007). A delayed release preparation is also available in some countries, allowing treatment every 12 hours at a dose that is usually 80% of the regular cysteamine bitartrate dose (Langman et al. 2016). Treatment should be started as soon as the diagnosis is made and continued lifelong. Trough levels should be used to monitor leukocyte cystine levels (Levtchenko et al. 2004). Side effects of cysteamine are mostly restricted to gastrointestinal discomfort, bad breath, and sweat odor. Gastric tolerance can be improved by proton pump inhibitors. Noncompliance because of foul odor and strict administration schedules (especially for standard cysteamine bitartrate) occur frequently, particularly in adolescents, and often correspond to worsening clinical symptoms and prognosis.

Symptomatic therapy includes prescription of appropriate fluid and electrolyte intake, adequate nutrition, and prevention of rickets. Patients with cystinosis should always have free access to water; prolonged heat exposure should be avoided. Young children frequently require tube feeding. Renal tubular waste is significantly reduced by indomethacin (1–3 mg/kg/day in 2–3 separate doses), but this therapy can be nephrotoxic; it can be, however, particularly useful in the first years of life. The doses of potassium, sodium, bicarbonate, and phosphate supplements should be regularly adapted; 1,25-dihydroxycholecalciferol should be prescribed very early to prevent rickets. Carnitine supplementation is recommended in some centers (Veys et al. 2017).

Treatment with recombinant growth hormone improves growth of children that are growth retarded despite cysteamine therapy and adequate metabolic control. Other complications such as hypothyroidism, diabetes, or hypogonadism are treated with L-thyroxin, insulin, or testosterone, respectively. ACE inhibitors can decrease albuminuria and may delay progression of renal failure; however, they may also cause hypotension and impair renal function in patients that are fluid and salt depleted. They should be used therefore with caution, preferably not in conjunction with indomethacin; the dose should be reduced or stopped during the hot weather season (Veys et al. 2017).

Experimental Treatment

The FDA has approved in 2019 a clinical trial in humans for the use of autologous hematopoietic stem cells after gene repair (https://clinicaltrials.gov, trial no. NCT03897361), based on encouraging results obtained in a cystinosis mouse model (Rocca and Cherqui 2018). Up to six subjects will undergo in this phase I/II trial autologous hematopoietic stem cell transplantation after ex vivo gene modification with a pCCL-CTNS lentiviral vector to express CTNS gene.

Summary

The peroxisomal disorders comprise a heterogeneous group of genetic diseases either caused by a defect in peroxisome biogenesis or in one of the metabolic functions of peroxisomes. Diagnosis of patients affected by a certain peroxisomal disorder can be simple if the clinical signs and symptoms of the patient involved are suggestive as in Zellweger syndrome. Through the years, however, we have seen a tremendous increase in the phenotypic variability among patients with a peroxisomal disorder which makes diagnosis on clinical grounds increasingly difficult. The availability of a set of highly sensitive metabolite biomarkers, which can be measured in a small blood sample, followed by enzyme studies and flux analysis of the different peroxisomal pathways in fibroblasts has been of great importance in this respect. Moreover, these biochemical markers and assays remain instrumental for the confirmation of the pathogenicity of DNA variants of uncertain significance identified through whole exome and whole genome sequencing, which have taken over as first-line diagnostic test, at least in several centers around the world. Despite the progress in the clinical and laboratory diagnosis of peroxisomal patients, much less progress has been made with respect to the treatment options. For some disorders there is curative treatment for some aspects of the disease. For instance, the leukodystrophy of XALD responds to hematopoietic cell transplantation (HCT), either heterologous from a matched donor or autologous employing lentiviral gene therapy. Another peroxisomal disorder for which therapeutic options are truly on the horizon is hyperoxaluria Type 1 for which different therapeutic trials are underway.

Introduction

The peroxisomal disorders (PDs) represent a heterogeneous group of genetic diseases in man caused either by a defect in the biogenesis of peroxisomes or an impairment in one of its metabolic functions. Zellweger syndrome (ZS) is generally considered to be the prototype of the group of peroxisomal disorders, and studies on ZS in the early 1980s have laid the basis for our current knowledge about peroxisomes, at least to a significant extent. This applies to the resolution of the basic principles of peroxisome biogenesis as well as the identification of the various metabolic pathways in peroxisomes which often started with some metabolic abnormality first identified in ZS patients. Indeed, it was the finding of elevated very-long-chain fatty acids, the bile acid intermediates di- and trihydroxycholestanoic acid and phytanic acid which led to the discovery of the pathways of fatty acid beta-oxidation, bile acid synthesis, and alpha-oxidation in peroxisomes. The same is true for the discovery of the role of peroxisomes in ether phospholipid biosynthesis. Studies on ZS have also set the stage for the discovery of the various biomarkers we now have for the proper laboratory diagnosis of patients with a PD. Moreover, these biomarkers have been very instrumental in identifying all the different PDs and the recognition of their tremendous clinical heterogeneity. In this chapter we will describe our current state of knowledge about PDs as listed in Table below.

Nomenclature

No.	Disorder	Alternative name 1	Alternative name 2	Disease abbreviation	Gene symbol	Chromosomal localization	Mode of inheritance	Affected protein	OMIM no
66.1.1	Zellweger spectrum disorder	Peroxisome biogenesis disorder	Zellweger syndrome Neonatal adrenoleukodystrophy Infantile Refsum disease	ZSD	*PEX1*	7q21.2	AR	PEX1	602136

Metabolic Pathways

Peroxisome Biogenesis

Peroxisomes were long thought to be solely derived from pre-existing peroxisomes through a mechanism of growth and division and would therefore belong to the group of non-autonomous cell organelles just like mitochondria. However, it is now clear that peroxisomes are in fact semi-autonomous organelles which may form de novo from a special subcompartment of the endoplasmic reticulum or by growth and division of pre-existing peroxisomes. Importantly, all peroxisomal proteins albeit matrix or membrane proteins are synthesized on free polyribosomes and are directed to the peroxisome through specific targeting signals which are an integral part of each peroxisomal protein. Peroxisomal matrix proteins for instance are targeted to peroxisomes via one of the two different targeting signals (see Legend to Fig. 66.1) named peroxisome targeting signal (PTS) 1 and 2. These two PTS sequences are recognized by their cognate receptors PEX5 and PEX7, respectively, and the cargo-loaded receptors are subsequently recognized by the peroxisomal protein import machinery followed by transfer of the matrix proteins across the peroxisomal membrane and recycling of the unloaded receptors back into the cytosol (Fig. 66.1). The complexity of peroxisome biogenesis as briefly outlined above immediately explains why so many different proteins collectively named PEX proteins are required to maintain peroxisome biosynthesis and also explains why the disorders of peroxisome biogenesis are so genetically heterogeneous as discussed later. For a review on peroxisome biogenesis, see Waterham et al. (2016).

Metabolic Functions of Peroxisomes

Peroxisomes in humans catalyze a great number of different metabolic functions (for reviews see Wanders et al. (2016) and Van Veldhoven (2010)), but so far defects in only a few of these metabolic pathways have been identified, which is why we have chosen to limit our discussion to the pathways described below:

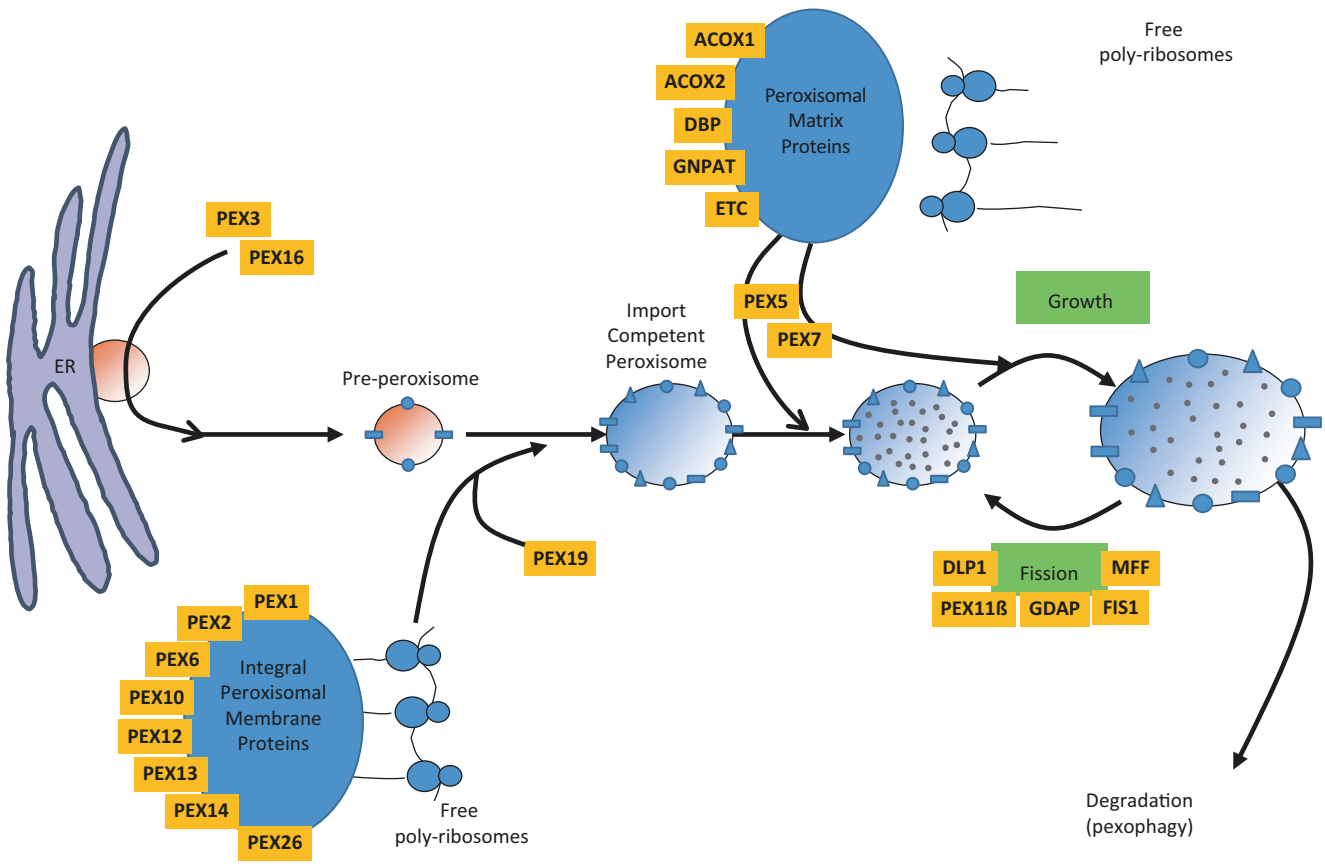

Fig. 66.1 Schematic diagram showing the essential features of peroxisome biogenesis in humans. In short, peroxisomes may be formed by one of the two different pathways, which include a de novo pathway whereby a pre-peroxisome is formed from a special subcompartment of the endoplasmic reticulum as mediated by PEX3 and PEX16. Hereafter the peroxisomal membrane proteins that are all synthesized on free polyribosomes are inserted into the pre-peroxisomal membrane so that an import-competent peroxisome arises able to accept the peroxisomal matrix proteins, which are also all synthesized on free polyribosomes. In the second pathway, peroxisomes are formed by growth and division of pre-existing peroxisomes. Abbreviations used: *ACOX1* acyl-CoA oxidase 1, *ACOX2* acyl-CoA oxidase 2, *DBP* D-bifunctional protein, *GNPAT* glycerone-3-phosphate acyltransferase, *DLP1* dynamin-like protein 1, *MFF* mitochondrial fission factor, *FIS1* fission 1, *GDAP1* ganglioside-induced differentiation-associated protein 1

Fatty Acid Oxidation

The majority of dietary fatty acids (FAs) is oxidized by mitochondria with only a minor role for peroxisomes. Nevertheless, peroxisomes do play an indispensable role in cellular fatty acid homeostasis since they catalyze the oxidation of a range of different FAs which cannot be degraded by mitochondria. These include:

(a) Very-long-chain FAs, notably hexacosanoic acid (C26:0), which are derived from dietary sources but mostly from chain elongation of shorter-chain saturated FAs.

(b) Pristanic acid (2,6,10,14-tetramethylpentadecanoic acid), which is to some extent derived from dietary sources but mostly originates from phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) which upon alpha-oxidation produces pristanic acid.

(c) Di- and trihydroxycholestanoic acid (DHCA and THCA) which are intermediates in the biosynthesis of the primary bile acids cholic acid and chenodeoxycholic acid.

(d) Tetracosahexaenoic acid (C24:6w3), which upon beta-oxidation in peroxisomes yields docosahexaenoic acid (C22:6w3).

(e) Other FAs including long-chain dicarboxylic fatty acids, etc. (Fig. 66.2).

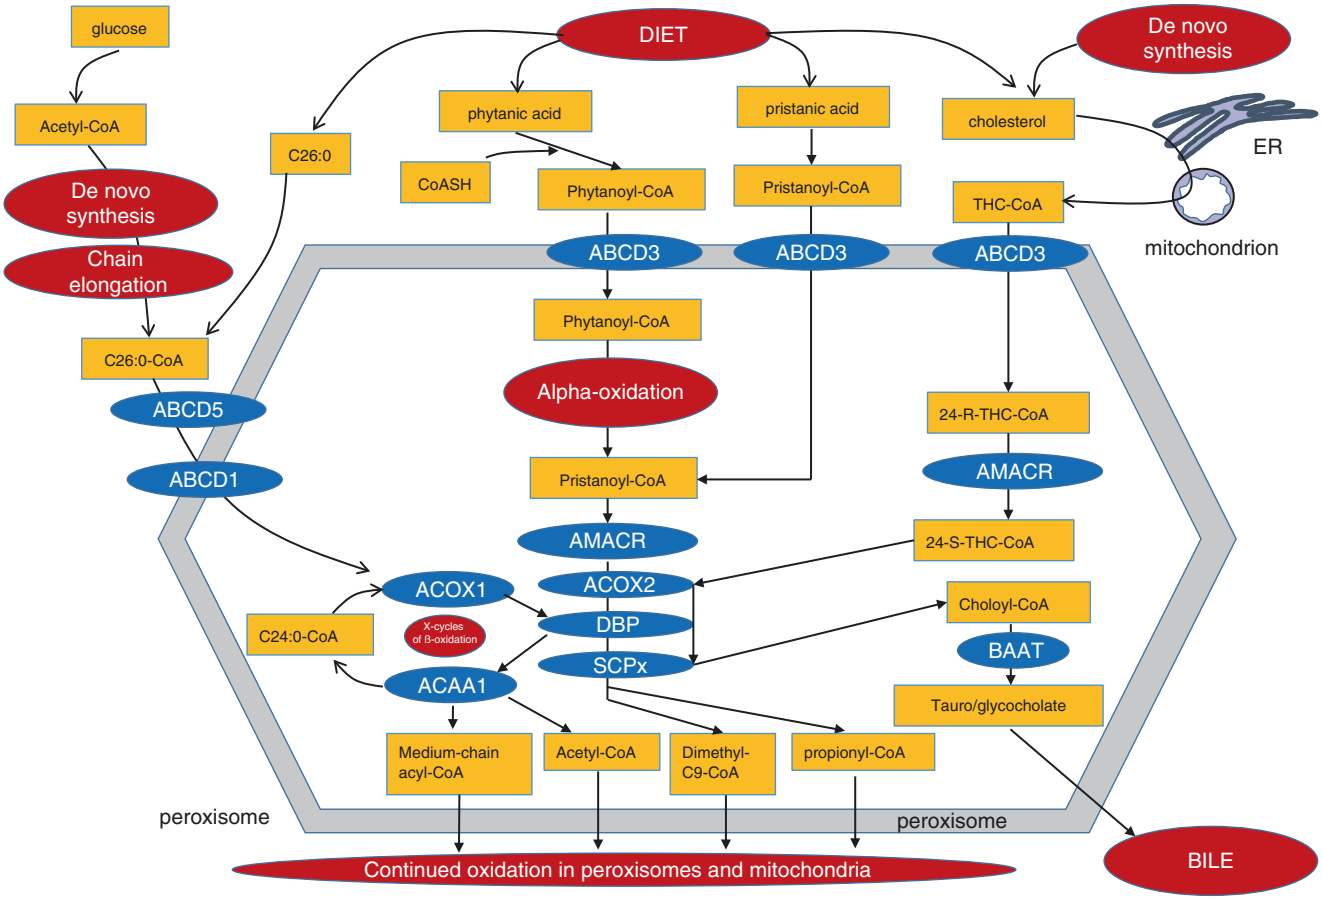

Fig. 66.2 Schematic diagram showing the essential features of the peroxisomal fatty acid beta-oxidation machinery. The main substrates oxidized in peroxisomes include (1) very-long-chain FAs with C26:0 as typical example which is either derived from exogenous, dietary sources or synthesized de novo from acetyl-CoA via the FAS complex followed by chain elongation; (2) pristanic acid which cannot be synthesized endogenously but is only derived from exogenous, dietary sources either directly or indirectly via alpha-oxidation of phytanic acid which also comes from dietary sources only; and (3) di- and trihydroxycholestanoic acid as derived from cholesterol via a series of enzymes localized in different subcellular compartments including the mitochondrion, cytosol, and endoplasmic reticulum. The actual beta-oxidation machinery is different for each of the three substrates as indicated in Fig. 66.2 except that the enzyme DBP (D-bifunctional protein) is involved in the beta-oxidation of all three substrates. The end products of the beta-oxidation of C26:0 and pristanic acid are acetyl-CoA, propionyl-CoA, and several medium-chain acyl-CoAs, which are then shuttled to the mitochondrion for full oxidation to CO2 and H2O via one of the two different routes including a free-acid route and a carnitine-mediated pathway. In case of di- and trihydroxycholestanoic acid, the end products are choloyl-CoA and chenodeoxycholoyl-CoA which then undergo transamination via the peroxisomal enzyme BAAT (bile acid-CoA: amino acid N-acyltransferase) to give rise to tauro/glycocholic acid and tauro/glycochenodeoxycholic acid, which are then transported out of the peroxisome to end up in the bile

Ether Phospholipid Biosynthesis

Ether phospholipids (EPLs) are a special class of phospholipids which differ from their more well-known sister molecules the diacylphospholipids in one major aspect, which is the presence of an ether bond rather than an ester bond at the sn-1 position of the glycerol backbone (see Fig. 66.3). Furthermore, EPLs catalyze a number of unique functions in human physiology different from diacylphospholipids. Importantly, peroxisomes play an indispensable role in the synthesis of EPLs since the characteristic ether bond is generated by a unique peroxisomal enzyme named alkylglycerone-3-phosphate synthase (AGPS, formerly called alkylDHAP synthase (ADHAPS)), which, if deficient, causes one of the different forms of rhizomelic chondrodysplasia punctata (RCDP). Figure 66.3 depicts the ether phospholipid biosynthesis pathway and the enzymes plus the deficiencies involved (see Braverman and Moser 2012).

Fatty Acid Alpha-Oxidation

Fatty acids with a methyl group at the 3-position, like in phytanic acid 3,7,11,15-tetramethylhexadecanoic acid, cannot undergo beta-oxidation because of the location of the methyl group at the 3-position and first require one round of alpha-oxidation to turn the 3-methyl FA into the corresponding 2-methyl FA which in case of phytanic acid is pristanic acid.

Figure 66.4 shows the alpha-oxidation pathway. Refsum disease is so far the only peroxisomal disorder in which the alpha-oxidation pathway is affected due to mutations in the gene coding for the first enzyme of the pathway phytanoyl-CoA hydroxylase (see Wanders et al. 2011).

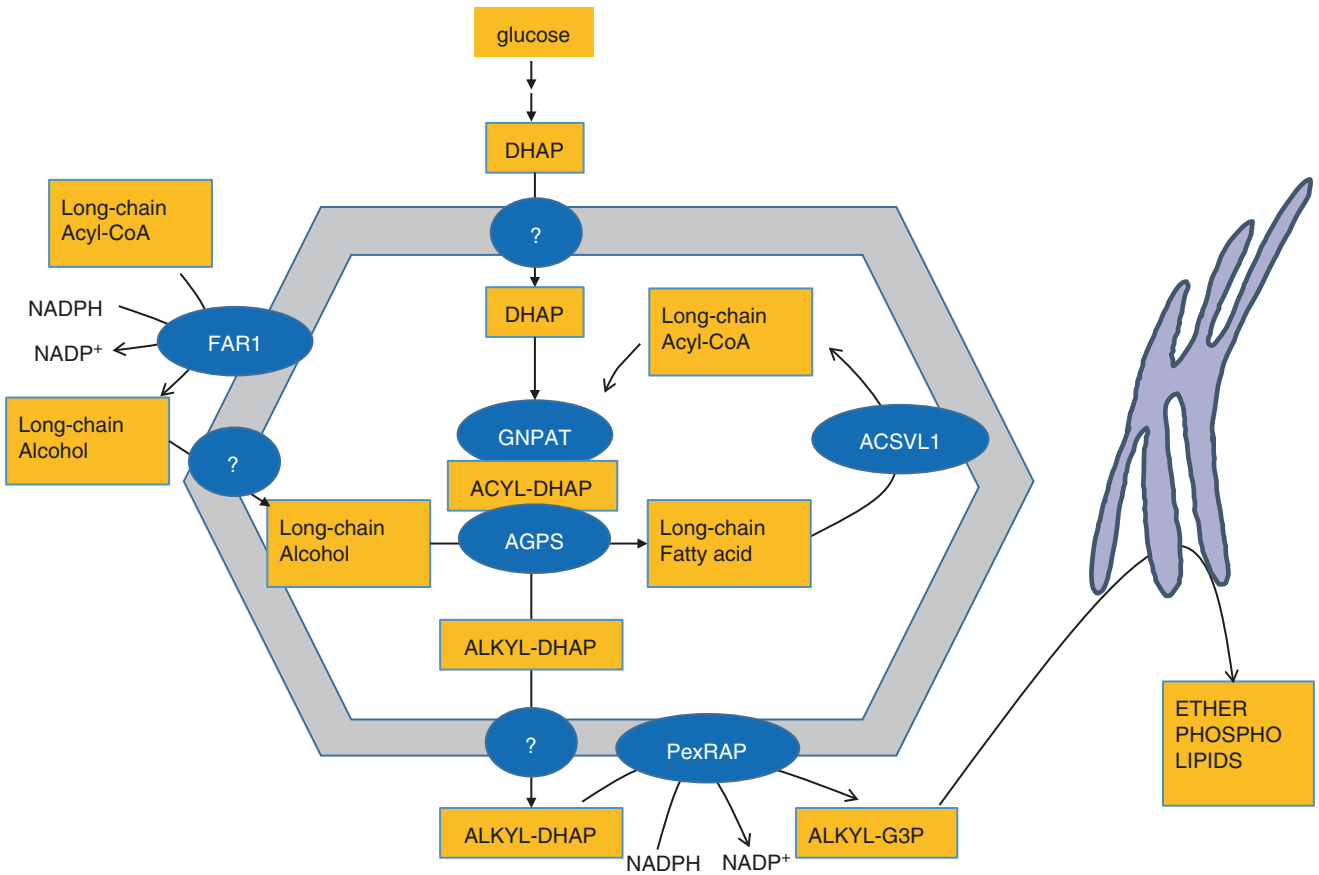

Fig. 66.3 Schematic diagram showing the essential features of the ether phospholipid biosynthesis pathway. Peroxisomes play a key role in the synthesis of ether phospholipids by virtue of the fact that the enzyme responsible for the introduction of the characteristic ether bond (AGPS, alkyl glycerone 3-phosphate synthase) is strictly peroxisomal. The long-chain alcohol required in the AGPS reaction is provided by the enzyme fatty acyl-CoA reductase of which there are two isoforms, FAR1 and FAR2. Furthermore, the enzyme GNPAT (glycerone-3-phosphate acyltransferase) provides the other substrate for the AGPS reaction, which is acylglycerone 3-phosphate. The end product of the peroxisomal part of the ether phospholipid biosynthetic machinery is alkyl-DHAP, which is converted into alkyl-G3P via the enzyme PexRAP and then transported to the ER where the subsequent steps take place. The importance of each of the individual steps involved in ether phospholipid synthesis is exemplified by the fact that deficiencies of GNPAT, AGPS, and FAR1 give rise to (rhizomelic) chondrodysplasia punctata

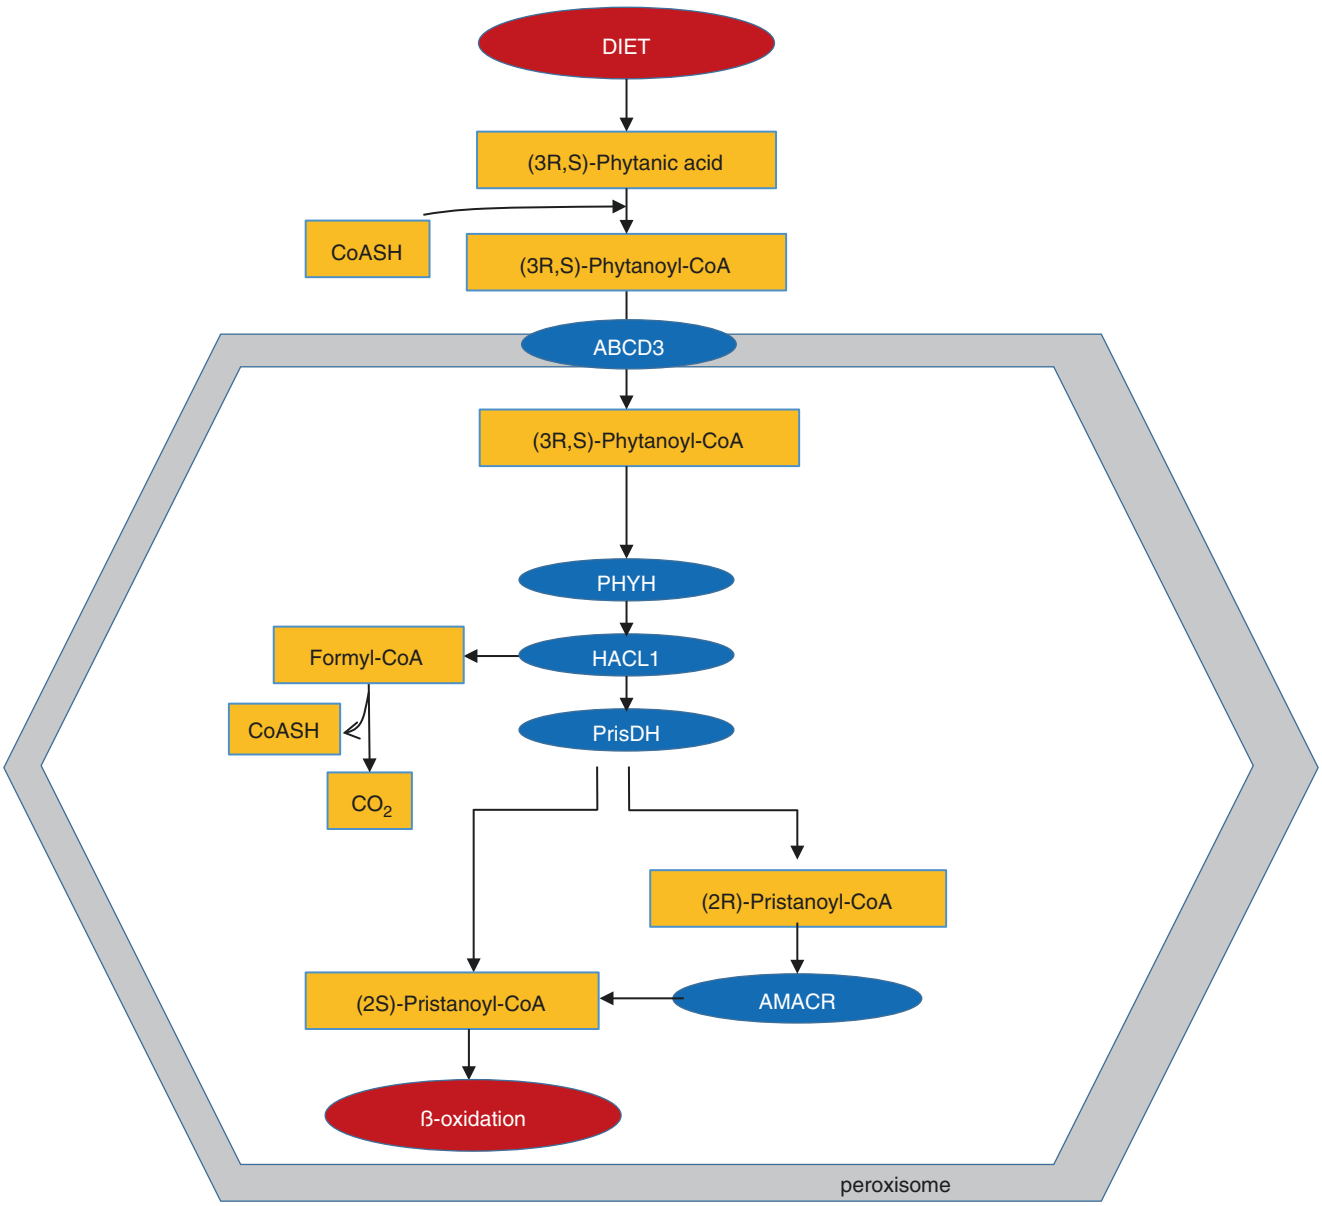

Fig. 66.4 Schematic diagram showing the essential features of the fatty acid alpha-oxidation pathway in humans. Phytanic acid cannot be synthesized endogenously but is derived from dietary sources only. Phytanic acid first undergoes activation to the corresponding coenzyme A ester, i.e., phytanoyl-CoA, which then enters the peroxisome via the half-ABC transporter ABCD3. Once inside, phytanoyl-CoA is converted into 2-hydroxyphytanoyl-CoA by the enzyme phytanoyl-CoA hydroxylase (PHYH) after which the enzyme hydroxyacyl-CoA lyase 1 (HACL1) splits the molecule into two parts including formyl-CoA plus pristanal, followed by dehydrogenation of pristanal to pristanic acid which then undergoes activation to the corresponding coenzyme-A ester to yield pristanoyl-CoA which can then enter the beta-oxidation machinery. In vivo, phytanic acid occurs as a racemic mixture of two different stereoisomers including (3R,7R,11R,15)-tetramethylhexadecanoic acid and (3S,7R,11R,15)-tetramethylhexadecanoic acid which are both substrates for the alpha-oxidation system, thus yielding (2S,6R,10R,14)-pristanoyl-CoA and (2R,6R,10R,14)-pristanoyl-CoA. The latter pristanoyl-CoA requires the enzyme AMACR to convert the (2R)-form into the (2S)-form because the beta-oxidation machinery only accepts (2S)-acyl-CoAs as substrate

Glyoxylate Metabolism

Peroxisomes play a key role in the metabolism of glyoxylate: the ultimate detoxification of glyoxylate is catalyzed by the peroxisomal enzyme alanine glyoxylate aminotransferase (AGXT), which, if deficient, causes hyperoxaluria Type 1. Glyoxylate is generated from different precursors including hydroxyproline and glycolate, and its toxicity is due to the fact that, if not immediately detoxified by AGXT, glyoxylate is converted into oxalate which precipitates into calcium oxalate in multiple tissues including the kidneys (Fig. 66.5).

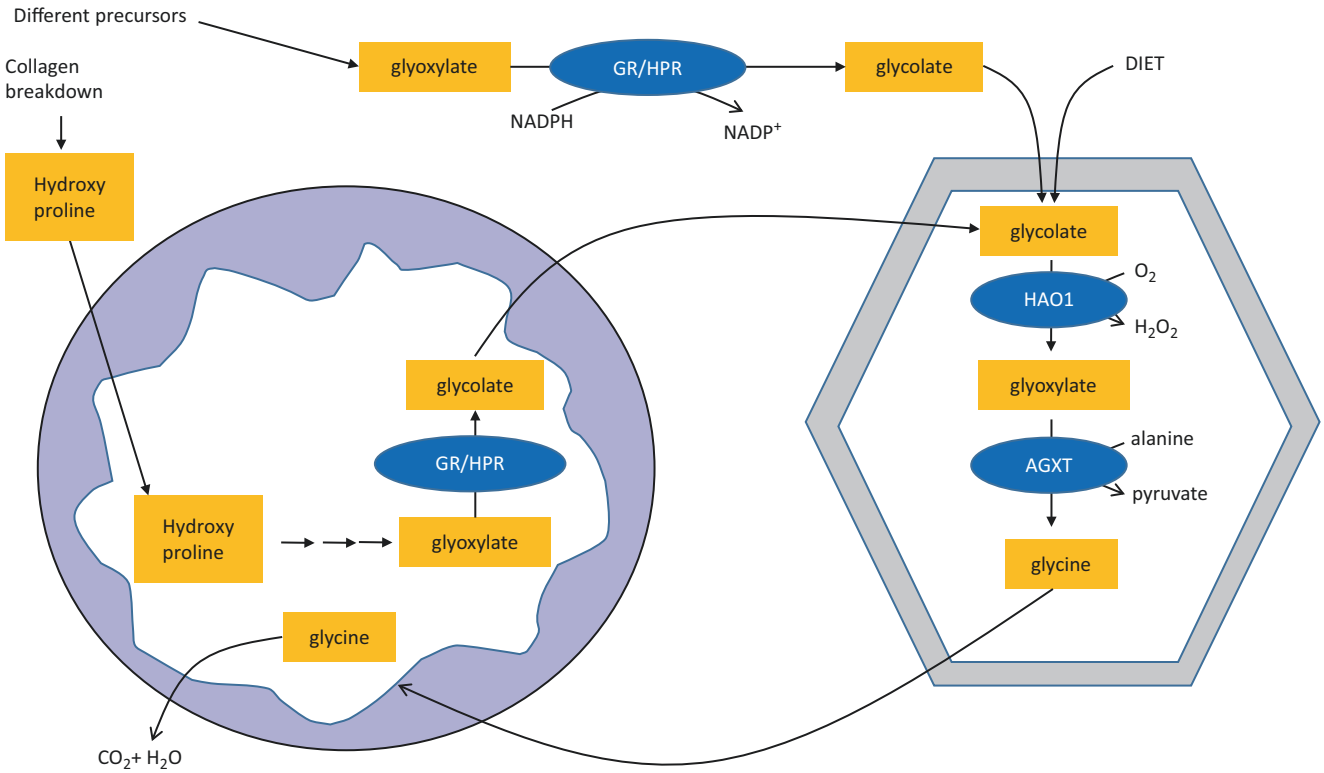

Fig. 66.5 Essential features of the glyoxylate detoxification pathway in humans. Glyoxylate is a highly toxic molecule since it readily undergoes oxidation to oxalate as mediated by the ubiquitous enzyme lactate dehydrogenase followed by precipitation of oxalate as calcium oxalate in different tissues including the kidneys. Peroxisomes play a crucial role in glyoxylate detoxification by virtue of the fact that the enzyme alanine glyoxylate aminotransferase (AGXT) is strictly peroxisomal. Two of the primary precursors of glyoxylate in humans are hydroxyproline, which is generated in lysosomes upon breakdown of collagen, and glycolate, derived from plant-derived foodstuffs. Shown is the complicated crosstalk between different subcellular compartments with the peroxisome as ultimate site of final glyoxylate detoxification by converting glyoxylate into glycine

Bile Acid Synthesis

Peroxisomes also play an indispensable role in the synthesis of the primary bile acids cholic acid and chenodeoxycholic acid from cholesterol in the liver (Vaz and Ferdinandusse 2017). The final steps in the formation of bile acids from di- and trihydroxycholestanoic acid to chenodeoxycholic acid and cholic acid, respectively, occur exclusively in peroxisomes. Furthermore, the formation of the taurine and glycine derivatives of cholic acid and chenodeoxycholic acid also takes place solely in peroxisomes.

Additional Peroxisomal Pathways

Peroxisomes are involved in various additional metabolic pathways including the oxidation of L-pipecolic acid, hydrogen peroxide metabolism, and other pathways not detailed here.

Signs and Symptoms

From a clinical point of view, the PDs listed in Nomenclature Table can be subdivided into different subgroups based on the similarity in clinical signs and symptoms including:

A. The Zellweger spectrum disorders (PD66.1.1–66.1.12), acyl-CoA oxidase 1 deficiency (PD66.4), and D-bifunctional protein deficiency (PD66.6).
B. The rhizomelic chondrodysplasia punctata spectrum (PD:66.2.1–66.2.5).
C. X-linked adrenoleukodystrophy (PD66.3).
D. Refsum disease (PD66.8.1 and PD66.8.2).
E. Hyperoxaluria Type 1 (PD66.11).
F. The disorders of bile acid biosynthesis including acyl-CoA oxidase 2 deficiency (PD66.5), BAAT deficiency (PD66.10), PMP70 deficiency (PD66.11), and racemase deficiency (PD66.9).

G. The peroxisomal fission defects including PEX11 beta deficiency (PD66.13), DLP1 deficiency (PD66.14), MFF deficiency (PD66.15), FIS1 deficiency (PD66.16), and GDAP1 deficiency (PD66.17).
H. The separate disorder, ACBD5 deficiency (PD66.7).

We will restrict discussion of the signs and symptoms to the main groups of peroxisomal disorders including the ZSDs, RCDPs, XALD, Refsum disease, and AMACR deficiency (see Table below).

Zellweger Spectrum Disorders (PD66.1, PD66.4, PD66.6, PD66.7, and PD 66.13)

The prototype of the Zellweger spectrum disorders (ZSDs) is Zellweger syndrome (ZS), which is a multisystem disorder dominated by (1) typical craniofacial dysmorphic features including a high forehead, a large anterior fontanelle, hypoplastic supraorbital ridges, and epicanthic folds; (2) profound developmental delay and neurological abnormalities including severe hypotonia and seizures; and (3) liver dysfunction

Possible symptoms related to age in peroxisomal disorders

	System	Symptoms	ZSD[a]	RCDP	ALD	RD	AMACR
Neonatal period	Neurological	Hypotonia	+				
		Seizures	+				
		Spastic paresis		+			
	Vision	Cataract	+	+			
		Glaucoma, retinitis pigmentosa	+				
	Hearing	Sensorineural hearing loss	+				
	Musculoskeletal	Enlarged fontanel	+

AMACR, α-Methylacyl-CoA racemase deficiency, *RCDP* rhizomelic chondrodysplasia punctata, *RD* Refsum disease (classic), *ALD* adrenoleukodystrophy

[a]Includes Zellweger spectrum disorders (ZSDs), peroxisomal acyl-CoA oxidase type 1 (ACOX1) deficiency, and D-bifunctional protein (DBP) deficiency

along with additional aberrations in multiple organs. Apart from ZS with its neonatal onset and early fatal course, milder variants have been identified originally labeled under the names neonatal adrenoleukodystrophy and infantile Refsum disease. Since the realization that we are dealing with a disease spectrum rather than distinct, well-defined phenotypes, the collective term Zellweger spectrum disorders (ZSDs) has been coined. Roughly three main phenotypic groups can be discerned based on age of presentation: (1) the neonatal-infantile presentation, essentially resembling the classic Zellweger syndrome with severe hypotonia, seizures, failure to thrive, liver dysfunction, and craniofacial dysmorphism; (2) the childhood presentation characterized by failure to thrive, developmental delay, liver dysfunction, adrenal insufficiency, and less profound hypotonia and craniofacial dysmorphism; and (3) the adolescent-adult presentation with visual and hearing impairment as most consistent symptoms, developmental delay, and in some cases cerebellar ataxia and neuropathy at the time of presentation (see Table above).

Importantly, the group of Zellweger spectrum disorders also includes the single peroxisomal enzyme deficiencies acyl-CoA oxidase 1 deficiency (PD66.4) and D-bifunctional protein deficiency (PD66.6) because of the marked similarity in the clinical signs and symptoms (Ferdinandusse et al. 2006; Ferdinandusse et al. 2007). Patients with the single peroxisomal enzyme deficiency ACBD5 deficiency (PD66.7) and the peroxisomal fission defect PEX11 beta deficiency (PD66.13) which have been described in only a few patients so far, are also showing symptoms resembling the Zellweger spectrum (Ferdinandusse et al. 2017; Ebberink et al., 2012). This has major implications for the laboratory diagnosis of patients as discussed later (for reviews see Argyriou et al. (2016) and Klouwer et al. (2015, 2017)).

Rhizomelic Chondrodysplasia Punctata (RCDP) Spectrum (PD66.2.1–5)

The RCDP spectrum is a clinically heterogeneous group with, at the severe end of the spectrum, patients showing severe growth retardation, proximal shortening of the extremities, contractures, spasticity, severe developmental delay, and cataracts. Life expectancy is considerably reduced. At the other end of the spectrum are patients with mild to moderate developmental delay, cataracts, and bone dysplasia but no rhizomelic shortening. It is important to note that many patients with the mild phenotype reach adulthood and that progression of disease is common (with progressive deterioration of joint and spinal cord compression at the craniocervical junction) (Poll-The, personal observation). The characteristic biochemical abnormality in RCDP patients is the deficiency of plasmalogens, which can either be caused by a (partial) deficiency in peroxisome biogenesis (PEX7 and PEX5) or by a deficiency of one of the enzymes involved in the synthesis of plasmalogens (GNPAT, AGPS, and FAR1) (see Braverman and Moser 2012).

X-Linked Adrenoleukodystrophy (PD66.3)

Patients with XALD are normal at birth. Although patients are traditionally classified in distinct "phenotypes", XALD should be considered as a progressive neurodegenerative disease. In male patients, adrenal failure is often the first symptom and can occur in (early) childhood but also in adulthood (lifetime prevalence is about 80%) (Huffnagel et al. 2019a). A progressive gait disorder and incontinence due to spinal cord disease (with involvement of predominantly the pyramidal tracts and the dorsal columns) develop on average in the third decade in males (Engelen et al. 2012; Huffnagel et al. 2019b) and the fifth decade in females (Huffnagel et al. 2019c; Engelen et al. 2014). About 60% of males will develop a progressive leukodystrophy (about 40% in childhood) (de Beer et al. 2014). Hematopoietic cell transplantation (HCT) (either heterologous or, more recently, autologous after ex vivo lentiviral gene therapy) is available as treatment for the leukodystrophy in an early stage (preferably with few lesions on MRI of the brain and without symptoms) (Miller et al. 2011; Eichler et al. 2017).

Refsum Disease (PD66.8)

Refsum disease is due to a deficiency of the peroxisomal enzyme phytanoyl-CoA hydroxylase (Fig. 66.4) and is characterized by anosmia and early-onset retinitis pigmentosa in virtually all patients with variable combinations of cerebellar ataxia, polyneuropathy, sensorineural hearing loss, ichthyosis, skeletal abnormalities, and cardiac arrhythmias. The clinical picture of Refsum disease is usually that of a slowly developing retinopathy and progressive neuropathy with severe motor weakness and muscular wasting especially of the lower extremities (see Wierzbicki et al. 2002 and Wanders et al. 2011).

Hyperoxaluria Type 1 (PD66.11)

Hyperoxaluria Type 1 is caused by a deficiency of the peroxisomal enzyme alanine glyoxylate aminotransferase (AGXT). This leads to the accumulation of glyoxylate which is then converted to oxalate by the enzyme lactate dehydrogenase. Oxalate precipitates as calcium oxalate in all tissues including the kidneys with all the consequences involved as discussed elsewhere in detail in Chap. 67.

Disorders of Peroxisomal Bile Acid Biosynthesis (PD66.5, PD66.9, PD66.10, and PD66.11)

The disorders of peroxisomal bile acid biosynthesis include PMP70 deficiency (PD66.11), acyl-CoA oxidase 2 deficiency (PD66.5), 2-methylacyl-CoA racemase deficiency (PD66.9), and bile acid-CoA: amino acid N-acyltransferase (BAAT) deficiency (PD66.10) in increasing order of incidence. The first two disorders have only been described in only a few patients (1 and 3, respectively) with divergent clinical signs and symptoms not detailed here. AMACR deficiency has been described in about ten patients, again with various symptoms. The childhood form of AMACR deficiency presents with the typical features reminiscent of the bile acid deficiency phenotype (see Chap. 40) dominated by variable liver abnormalities which may progress into liver failure if untreated, fat malabsorption with steatorrhea and growth retardation, and fat-soluble vitamin deficiency leading to coagulation defects and rickets. Apart from this severe childhood form, we have recently identified several patients with AMACR deficiency, who showed a much more slowly developing phenotype characterized by developmental delay, neuropathy, intellectual disability, seizures, spastic paresis, as well as cataract, retinitis pigmentosa, and rhabdomyolysis (see Table above). Furthermore, based on a previously reported specific MRI pattern of the brain suggestive for AMACR deficiency (Haugarvoll et al. 2013), our clinic recently identified five adult patients, who all had an unremarkable childhood, developed retinitis pigmentosa in early adulthood and peripheral neuropathy after the fourth decade (M. Engelen, personal observation). All five patients had increased transaminases and one patient developed hepatocellular carcinoma. We also follow three children that were identified because of increased transaminases but are otherwise asymptomatic (Poll-The and Engelen, personal observation). It is possible this is the typical disease course of AMACR; however, more observations are needed.

Since AMACR plays a key role in the degradation of both pristanic acid and the bile acid intermediates di- and trihydroxycholestanoic acid, there is accumulation of all these metabolites in plasma from AMACR-deficient patients. BAAT deficiency has been described more frequently and is caused by a deficiency of the peroxisomal enzyme bile acid-CoA: amino acid N-acyltransferase (BAAT) deficiency, which leaves di- and trihydroxycholestanoic acid unconjugated and leads to a deficiency of the conjugated forms of the primary bile acids cholic acid and chenodeoxycholic acid which results in steatorrhea, coagulopathy, rickets, and jaundice, which are all features observed in patients affected by one of the classic bile acid synthesis deficiencies (see Heubi et al. 2018). These disorders are dealt with in more detail in Chap. 40 by Vaz et al. (see also Vaz and Ferdinandusse 2017).

Reference Values

The laboratory diagnosis of peroxisomal disorders involves the analysis of only a limited set of biomarkers including the analysis of very-long-chain fatty acids or rather C26:0-lysoPC, phytanic acid, pristanic acid, and di- and trihydroxycholestanoic acid in plasma, pipecolic acid in urine, and plasmalogens in erythrocytes. In literature many different methods have been described for these metabolites either measured individually or in combination. Indeed, we analyze the very-long-chain fatty acid, phytanic acid, and pristanic acid levels in a single assay essentially as described in Vreken et al. (Vreken et al. 1998) although we now prefer to analyze C26:0-lysoPC because of its superior sensitivity (see Klouwer et al. 2017). The analysis of di- and trihydroxycholestanoic acid is part of a much more elaborate analysis which involves the analysis of all bile acids, bile acid conjugates, and bile alcohols as discussed in detail in Chap. 40 by Vaz et al. The best diagnostic markers next to di- and trihydroxycholestanoic acid coming out of this analysis include tetrahydroxycholestanoic acid, C29-dicarboxylic cholestanoic acid, tauro-trihydroxycholestanoic acid, and tauro-tetrahydroxycholestanoic acid.

Plasmalogen analysis in erythrocytes can best be done using the method originally described by Bjorkhem et al. (Bjorkhem et al. 1986) as modified by Dacremont and Vincent (Dacremont and Vincent 1995) although plasmalogen analysis can also be done using lipidomics technology (see Herzog et al. 2018).

Table below lists the reference values for the various metabolites described above.

Reference values of peroxisomal biomarker metabolites

Biomarker	Reference level
Plasma (P), erythrocyte (E), dried blood spot (D)	
C26:0-lysoPC (D)	<72 nmol/L
C26:0 (P)	0.45–1.32 μmol/L
C26:0/C22:0 (P)	0.0–0.02
Phytanic acid (P)	0.5–9.9 μmol/L
Pristanic acid (P)	0.1–3.0 μmol/L
Pipecolic acid (P)	0.1–7.0 μmol/L
Dihydroxycholestanoic acid (P)	0.0–0.0 μmol/L
Tetrahydroxycholestanoic acid (P)	0.0–0.1 μmol/L
Plasmalogens (E)	
C16:0-dimethylacetal	6.8–11.9%
C18:0-dimethylacetal	10.6–24.9%

Pathological Values

Table below lists the different peroxisomal biomarker metabolites and their levels in blood from patients affected by one of the peroxisomal disorders illustrated in Nomenclature Table.

Peroxisomal biomarker metabolites and their levels in blood, urine, or erythrocytes from patients affected by one of the peroxisomal disorders shown in Nomenclature Table

Peroxisomal biomarker	Type of peroxisomal disorder										
	Zellweger spectrum disorders			Rhizomelic chondrodysplasia punctata types 1–5					Single enzyme deficiencies

Diagnostic Flowcharts

The flowcharts for the Zellweger spectrum disorders (Fig. 66.6), rhizomelic chondrodysplasia punctata (Fig. 66.7), X-linked adrenoleukodystrophy/adrenomyeloneuropathy in males and females (Fig. 66.8), and Refsum disease (Fig. 66.9) are shown below. Metabolite analysis is the first essential step in the laboratory diagnosis of the different peroxisomal disorders, and, when abnormal, the results obtained immediately guide the way to the identification of the enzyme defect and subsequent molecular analysis to pinpoint the molecular defect in the gene involved. In recent years there has been a shift in the laboratory diagnosis of patients away from metabolite analysis as first-line diagnostic method thanks to the revolutionary developments of different sequencing methods. As a consequence whole exome and/or whole genome sequencing has gained popularity as first-line test in patients suspected to suffer from an inborn error of metabolism, which includes the peroxisomal disorders. It should be stressed that functional studies, including metabolite analyses, enzymatic assays, and/or metabolic pathway flux analysis, remain of key importance for the interpretation of whole exome/whole genome data especially when the mutations identified are novel and have not been

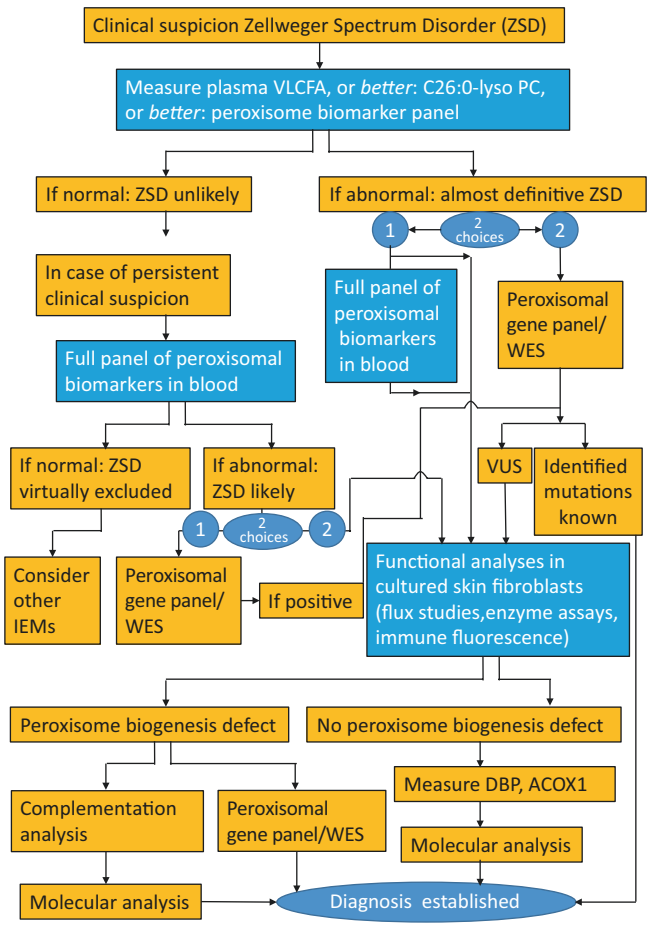

Fig. 66.6 Diagnostic flowchart for patients suspected to suffer from a Zellweger spectrum disorder (ZSD)

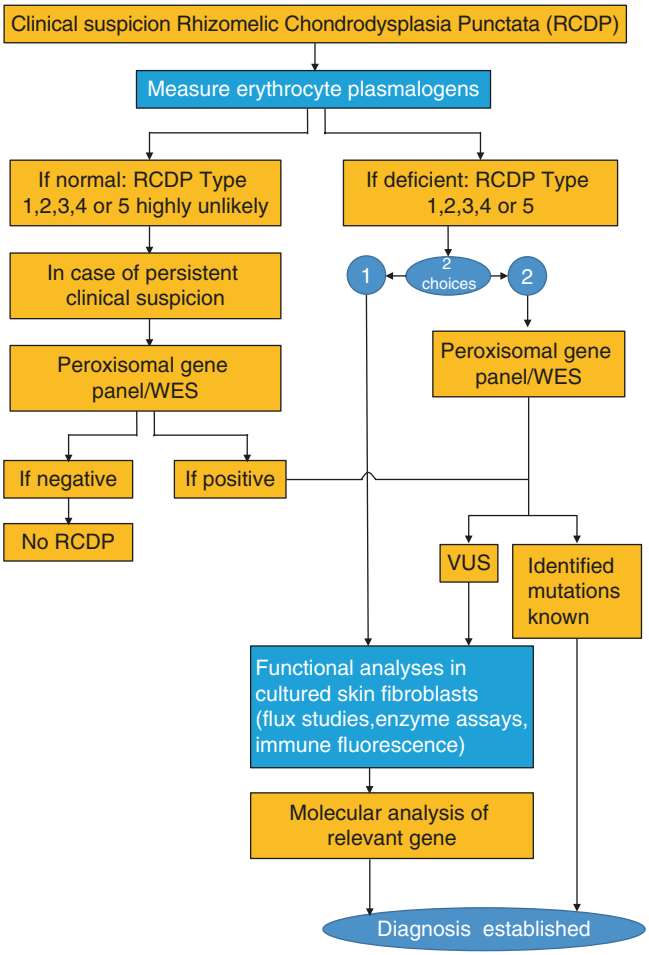

Fig. 66.7 Diagnostic flowchart for patients suspected to suffer from (rhizomelic) chondrodysplasia punctate

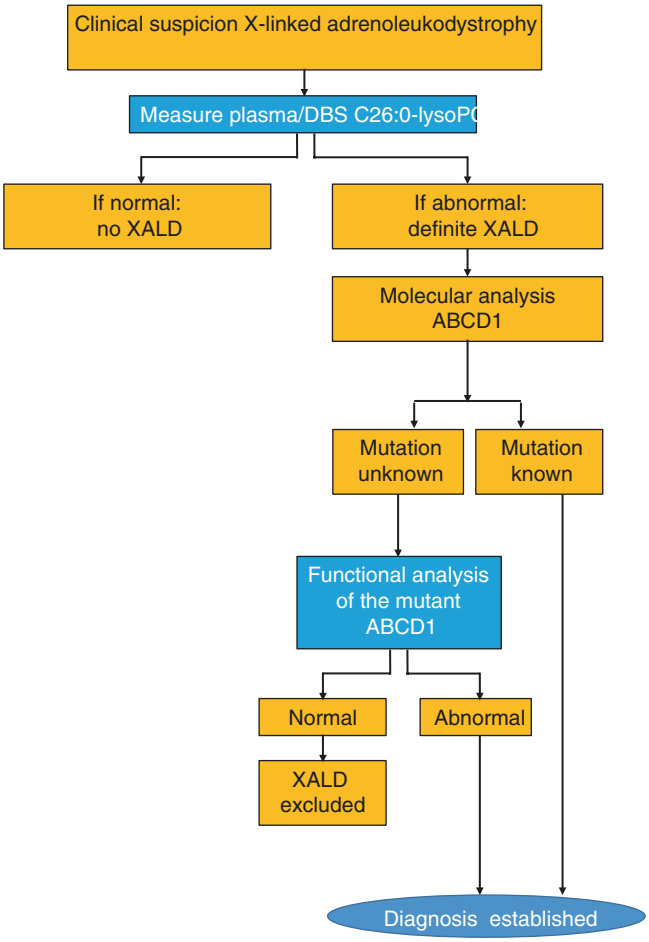

Fig. 66.8 Diagnostic flowchart for patients suspected to suffer from X-linked adrenoleukodystrophy/adrenomyeloneuropathy

described in literature before (see Ferdinandusse et al. 2016).

Loading Tests

No loading tests have been described in literature for any of the PDs shown in Nomenclature Table.

Specimen Collection

Very-long-chain fatty acids, phytanic acid, pristanic acid, and di- and trihydroxycholestanoic acid should all be measured preferably in EDTA plasma (or serum) and, if possible, in samples taken from patients after 1-night fasting. From the same blood sample, erythrocytes can be prepared for subsequent analysis of plasmalogens and DHA. Although glycolate and oxalate are mostly measured in urine, these metabolites can also be measured in plasma samples, which is especially relevant for some hyperoxaluria Type 1 patients (see Chap. 67 on hyperoxaluria).

Prenatal Diagnosis

In the past, prenatal diagnostic methods have been developed for all PDs using biochemical methods including the analysis of specific metabolites, enzyme activity measurements, and immunoblot analysis, but these methods have become relatively obsolete thanks to the progress in molecular techniques. Indeed, molecular analysis of the gene involved is now the method of choice for the prenatal diagnosis of all PDs except in rare cases in which the molecular defect has not been established with certainty. In few patients with a clear-cut peroxisomal defect on biochemical grounds, the gene involved has remained unidentified, whereas in few other cases, molecular analysis has only identified one heterozygous mutation in the index patient.

DNA Testing

Because it is not possible to predict from the biochemical and clinical phenotype of a patient with ZSD which of the known 13 *PEX* genes is defective, different approaches have

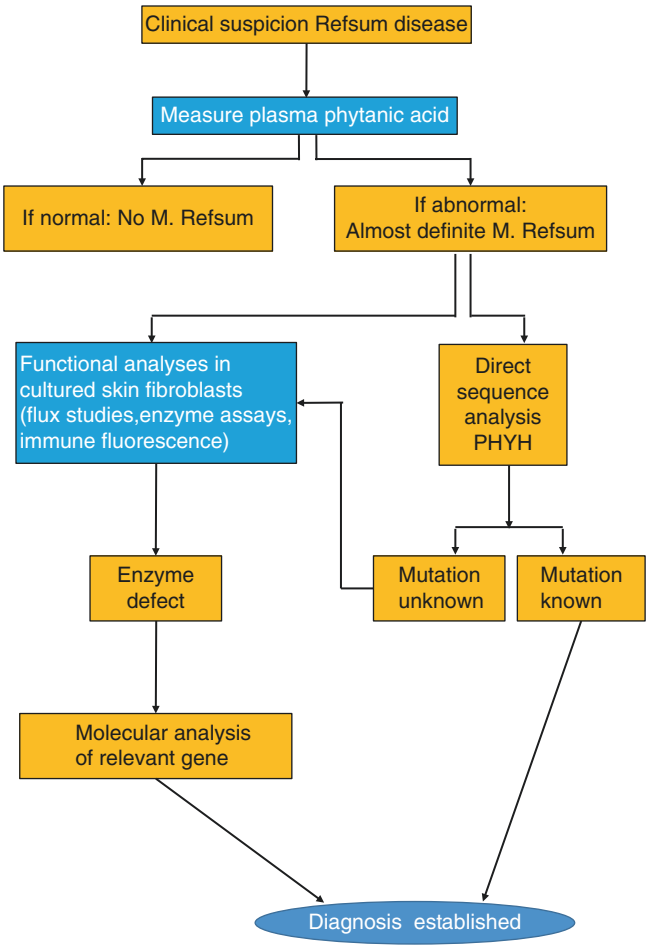

Fig. 66.9 Diagnostic flowchart for patients suspected to suffer from Refsum disease

been developed to rapidly identify the affected gene. This includes *PEX* cDNA transfection complementation assays followed by sequencing of the implicated *PEX* gene and parallel sequencing of multiple genes involved in peroxisome biogenesis and maintenance, either by means of diagnostic peroxisomal gene panels or by exome sequencing (Waterham et al. 2016).

Genetic confirmation of patients suspected from any of the single enzyme defects (based on clinical presentation and/or biochemical parameters) is performed by sequencing of the encoding genes.

Genetic confirmation of patients suspected from a peroxisomal fission defect (usually after observing abnormal peroxisomal morphology upon microscopy) is performed by sequencing of the candidate genes, including DLP1, MFF, FIS1, GDAP1, and the PEX11B genes.

The identification of mutations causing a peroxisomal disorder enables carrier testing in relatives of patients and allows early prenatal testing or preimplantation genetic diagnosis in families with a recurrence risk for such disorders.

Treatment Summary

For many of the PDs, no curative treatment has been described so far, which implies that treatment options are restricted to symptomatic and supportive care only (see Tables below).

Supportive treatment of ZSD, DBP, acyl-CoA oxidase 1 deficiency

System	Problem	Intervention
Nervous system	Seizures	Anti-epileptic drugs
	Behavioral problems	Antipsychotics, behavioral management
	Intellectual disability	Educational support and intervention
	Drooling	Anti-cholinergic medication, botulinum toxin injection in salivary glands, surgical removal of submandibular salivary
	Neuropathy	Management of complications, referral to rehabilitation physician if severe
	Ataxia	Physical therapy, referral to rehabilitation physician
Eye	Retinopathy	Glasses
	Cataract	Lens replacement
Ear	Hearing impairment	Hearing aids
Dental	Enamel hypoplasia, caries	Oral hygiene, dental referral
Digestive	Dysphagia	Speech therapist; gastrostomy tube placement
	Steatorrhea	Surveillance of malabsorption; elemental formulas may be better tolerated

Therapeutic options for Zellweger spectrum disorders

Defect/deficiency	Medication/diet	Dosage
Low levels of fat-soluble Vitamins (A, D, E)	Vitamin A, D, E	Depending on plasma levels
Vitamin K-dependent coagulopathy	Vitamin K (phytomenadione)	Up to 1 mg/day or more
Accumulation of bile acid intermediates (di- and trihydroxycholestanoic acids)	Cholic acid	10–20 mg/kg/day
Phytanic acid accumulation	Dietary restriction of phytanic acid with adequate caloric intake	Reduce following products: Dairy products, fish
Hyperoxaluria and/or kidney stones	Sufficient fluid intake and citrate therapy	
Adrenal insufficiency	Adrenal hormone replacement	

Supportive treatment of rhizomelic chondrodysplasia punctata spectrum

System	Problem	Intervention
Nervous system	Seizures	Anti-epileptic drugs
	Intellectual impairment	Educational support and intervention
	Spastic paresis	Spasmolytics, referral to rehabilitation physician
Eye	Cataract	Lens replacement
Digestive	Dysphagia	Gastrostomy tube placement
Cardiovascular	Congenital heart defects	Appropriate support and intervention
Musculoskeletal	Contractures	Physical therapy
Respiratory	Respiratory tract infections	Prophylactic antibiotics
Skin	Ichthyosis	Hydrating creams

Therapeutic options for rhizomelic chondrodysplasia punctata spectrum

Defect/deficiency	Medication/diet	Dosage
Phytanic acid accumulation	Dietary restriction of phytanic acid intake	Reduce following products: Dairy products, fish

Supportive treatment of XALD males

System	Problem	Intervention
Nervous system	Behavioral problems	Behavioral management, psychiatric consultation
	Myeloneuropathy (adult man), myelopathy with spastic paraparesis, incontinence, and sexual dysfunction	Supportive care by rehabilitation medicine and urologist, physical therapy, treatment of spasticity, neuropathic pain, and bladder issues

Therapeutic options for XALD males

Defect/deficiency	Medication/diet
Adrenal insufficiency	Adrenal hormone replacement
Neurologic dysfunction	Hematopoietic stem cell or bone marrow transplants
	Autologous hematopoietic stem cell gene therapy (phase IV study)

Supportive treatment of Refsum disease

System	Problem	Intervention
Nervous system	Ataxia	Physical therapy, referral to rehabilitation physician
	Neuropathy	Management of complications, referral to rehabilitation physician if severe
Eye	Retinitis pigmentosa	Glasses
	Cataract	Lens replacement
Ear	Hearing impairment	Hearing aids
Smell	Anosmia	None
Cardiovascular	Arrhythmia, cardiomyopathy	Antiarrhythmic drugs and other cardiac medication
Skin	Ichthyosis	Hydrating creams

Therapeutic options for Refsum disease

Defect/deficiency	Medication/diet	Dosage
Phytanic acid accumulation	Dietary restriction of phytanic acid intake	
	Plasmapheresis, lipopheresis	
	Avoidance of sudden weight loss	Appropriate caloric intake

Zellweger Spectrum Disorders

The symptomatic and supportive care options for ZSD patients include treatment of adrenal insufficiency (Berendse et al. 2014); seizures; low levels of fat-soluble vitamins A, D, and E; vitamin K-dependent coagulopathy; hearing and visual impairment; kidney stones due to hyperoxaluria; and dental abnormalities. Because supplementation of cortisone may be associated with severe side effects such as growth suppression and osteoporosis, only patients with a true insufficiency as established by means of an ACTH stimulation test qualify for this therapy. For hearing and visual impairments, ophthalmologists and ENT specialists can sometimes provide symptomatic treatment. In exceptional cases, cataract removal in infancy is advised.

Patients with renal calcium oxalate stones due to hyperoxaluria should be treated with citrate to prevent the formation of these stones. No evidence that ZSD patients benefit from a phytanic acid low diet is available at this point; therefore a phytanic acid-restricted diet is not advised when patients have only slightly increased phytanic acid levels. Some patients will need a gastrostomy tube to provide adequate intake of calories. On top of the symptomatic measures described above, several therapeutic options have been tried in the past. This includes a dietary therapy based on docosahexaenoic acid supplementation to patients to correct the deficiency of DHA in ZSD patients. Despite initial claims of a beneficial effect of DHA, a randomized, double-blind placebo-controlled trial in ZSD patients failed to show improvements of visual function and growth despite the increased DHA levels in plasma (Paker et al. 2010). Cholic acid therapy has also been advocated to be beneficial for ZSD patients, although recent clinical studies were unable to support this claim.

Rhizomelic Chondrodysplasia Punctata

Also for the different RCDPs, treatment is only supportive and symptomatic. This may include cataract extraction in order to restore some vision, physical therapy to prevent contractures, and anti-epileptic drugs. Dietary restriction of phytanic acid as described for Refsum disease may be beneficial for RCDP

patients especially in the milder forms dominated by ataxia and bone dysplasia (Smeitink et al. 1992) when phytanic acid levels are high. Inspired by the work of Brites and coworkers in a mouse model for RCDP Type 1 (Brites et al. 2011), alkylglycerol supplementation therapy has been tried in several RCDP patients with inconclusive results, which warrant additional work (Poll-The, personal communication).

XALD

Corticosteroid replacement therapy is of crucial importance in every XALD patient with adrenal insufficiency. Indeed, if untreated, patients may succumb to adrenal crises. HLA-matched hematopoietic stem cell transplantation using HLA-matched donor or cord blood can stabilize or even reverse the cerebral demyelination at least to some extent when the procedure is performed at an early stage of the disease (Miller et al. 2011). More recently, following the initial encouraging work by Cartier and Aubourg (Cartier et al. 2009), Eichler and coworkers have shown that autologous hematopoietic stem cell gene therapy using a lentiviral vector may well be the treatment of choice especially when a matching HLA donor is missing (Eichler et al. 2017). These new developments are especially important since XALD has been included in several neonatal screening programs around the world.

Refsum Disease

Owing to the pathogenic role of excessive phytanic acid accumulation and its strict dietary source, therapeutic measures are aimed at lowering phytanic acid levels. Serial plasmapheresis or lipid apheresis should be initiated promptly if levels are excessively high as in some patients with levels >1000 micromol/L (normal levels = <15 micromol/L). Lipid apheresis can be done serially over a long period of time and usually is well tolerated. The mainstay of therapy in Refsum patients, however, is dietary restriction of phytanic acid which implies elimination of dairy products as well as certain fish and other ingredients from the diet (Baldwin et al. 2010). With long-term treatment and depending on the dietary compliance, patients do show stabilization or even improvement of the neuropathy, ataxia, and cardiac arrhythmias, whereas the retinitis pigmentosa, deafness, and anosmia seem more refractory.

Hyperoxaluria Type 1 (See Chap. 67)

Disorders of Peroxisomal Bile Acid Synthesis Including ACOX2 Deficiency, PMP70 Deficiency, AMACR Deficiency, and BAAT Deficiency

So far only few patients have been described with deficiencies at the level of PMP70/ABCD3 (PD66.7), ACOX2 (PD66.5), and AMACR deficiency (PD66.12). Like all disorders of bile acid biosynthesis, the peroxisomal defects in bile acid synthesis also qualify for oral bile acid therapy, although evidence of clinical benefit is very limited in this subgroup. As discussed in more detail by Vaz et al. in Chap. 40, the mainstay of the treatment of BAAT-deficient patients involves supplementation of conjugated bile acids like glycocholic acid rather than unconjugated cholic acid or chenodeoxycholic acid as in the other bile acid synthesis defects.

Standard Treatment Tables

Tables above show the supportive and therapeutic options for the main peroxisomal disorders including the Zellweger spectrum disorders, rhizomelic chondrodysplasia punctata, XALD, and Refsum disease.

Experimental Treatment

There are no experimental treatment options studied at present, but retinal gene therapy for mildly affected ZSD patients is considered based on successful preliminary work in a mouse model for Zellweger syndrome (Argyriou et al., unpublished) and gene therapy and substrate deprivation therapy in hyperoxaluria Type 1, which is discussed in Chap. 67.

Follow-Up and Monitoring

Zellweger Spectrum Disorders

Follow-up should be aimed at screening for treatable complications as described in paragraph 66.11. This includes periodic blood withdrawal to assess adrenal function, fat-soluble vitamin levels, phytanic acid level, liver enzymes, and coagulation parameters. Screening for kidney stones should be done by performing abdominal ultrasound in combination with measuring urine oxalate levels to detect hyperoxaluria. Additional recommendations for follow-up and monitoring include regular assessment of growth and nutritional status and periodic ophthalmologic, audiological, neurological, and dental evaluation. Depending on the specific symptoms an individual patient is experiencing, additional follow-up may be indicated.

Rhizomelic Chondrodysplasia Punctate

Recommendations for follow-up include regular assessment of growth and nutritional status and periodic ophthalmo-

logic, cardiac, dental, orthopedic, and neurological evaluation including seizure frequency. Periodic blood withdrawal to assess phytanic acid levels is advised.

XALD

Follow-up for male patients is recommended every 6 months from the age of 2–12 years and yearly from that age to monitor for complications and initiate timely treatment. Visits are preferably organized in a specialized clinic with a (pediatric) neurologist and endocrinologist. Aside from clinical evaluation, an MRI of the brain is done and an ACTH stimulation test (in those patients that have not developed adrenal failure) (Engelen et al. 2012). When lesions with gadolinium enhancement develop on the MRI, HCT treatment is advised. HCT is not recommended for patients with a symptomatic leukodystrophy or extensive lesions on MRI of the brain (Loes score of 9 or higher) (Miller et al. 2011). For the myelopathy of adulthood (that also occurs in those patients who received HSCT for cerebral ALD), there is currently no disease modifying or curative treatment, and only supportive care is available. Women with ALD do not develop adrenal failure or cerebral ALD and yearly follow-up is therefore not necessary.

Refsum Disease

The following evaluations are recommended to be performed on a regular basis: ophthalmologic, audiological, cardiac, and neurological assessment and testing for anosmia. Weight and plasma phytanic acid levels should be evaluated at least on a yearly basis in order to adapt the diet and perform plasmapheresis and/or lipid apheresis.

Hyperoxaluria Type 1 (See Chap. 67)

Disorders of Bile Acid Biosynthesis (See Chap. 40).

Summary

Hyperoxaluria is one of the most important promoters of crystallization, which might induce a chronic inflammatory process if crystals are internalized in the tubular system, leading later to early end-stage renal failure (Kurts 2013; Beck et al. 2016). Urinary oxalate is mostly of endogenous origin, and only ~10% derive from the daily nutritional intake (Whittamore et al. 2019). Primary causes are distinguished from secondary ones: The autosomal recessive inherited primary hyperoxaluria (PH) types I, II, and III are defects of the glyoxylate metabolism leading to endogenous (primary) overproduction of oxalate (Hoppe

2012; Belostotsky et al. 2010). A significant number of hyperoxaluric patients, who would classify for PH, have yet unknown genetic basis of disease; thus, further types of PH are likely to exist (unclassified PH). Urinary excretion of oxalate is strongly elevated (>1 mmol/1.73 m^2 BSA/day, normal <0.5) in all forms of PH, resulting in recurrent stone formation and/or nephrocalcinosis and in progressive kidney damage leading to systemic calcium oxalate deposition (systemic oxalosis), primarily in PH type I (100%), but also in PH II (50%). Systemic oxalosis in PH I is a catastrophic situation that must be prevented by all means. Yet, diagnosis is all too often missed or delayed until end-stage renal failure occurs (in more than one third of adult patients). This is particularly unfortunate because progressive renal damage can be delayed or even prevented by early intervention (Garrelfs et al. 2021; Weigert et al. 2018). Secondary hyperoxaluria is due either to excessive oxalate or vitamin C intake (dietary hyperoxaluria), the latter being metabolized to oxalate, or to increased intestinal oxalate absorption (enteric, mostly based on chronic inflammatory bowel syndromes, Hoppe et al. 2003). Although the urinary oxalate excretion is usually <1 mmol/1.73 m^2 BSA/24 h, it may nevertheless lead to significant morbidity, i.e., to recurrent urolithiasis or progressive nephrocalcinosis with renal failure, especially in patients with Crohn's disease and ileocecal valve resections.

Introduction

Glyoxylate Reductase/Hydroxypyruvate Reductase (GRHPR) Deficiency

All currently known types of primary hyperoxaluria (PH I–III) are rare, autosomal recessive disorders of the glyoxylate metabolism (Hoppe 2012; Belostotsky et al. 2010). Primary hyperoxaluria type II (PH II) seems to be even more rare (under one tenth of the PH fraction) or remains markedly underdiagnosed. It is characterized by increased urinary excretion of oxalate and L-glyceric acid due to a defect in glyoxylate reductase/hydroxypyruvate reductase (GRHPR) activity (Cregeen et al. 2003). *GRHPR*, located on chromosome 9p11, is composed of 9 exons with >30 known causative mutations (Garrelfs et al. 2019). The clinical course of PH II is comparable, but generally more benign as compared to PH I, but symptoms may be clinically indistinguishable from PH I. CKD/ESRF occurs less frequently, has not been reported in childhood, but still affects about 50% of adults (Garrelfs et al. 2019).

4-Hydroxy-2-Oxoglutarate Aldolase 1 (HOGA1) Deficiency

Mutations in the seven exons spanning gene on chromosome 10 (*HOGA1*) were found to cause PH III (Belostotsky et al. 2010; Monico et al. 2011). *HOGA1* encodes for a mitochondrial 4-hydroxy-2-oxoglutarate aldolase. The findings of nonsense mutations in *HOGA1* suggested that a loss of function may lead to glyoxylate accumulation and hence the production of oxalate (Beck et al. 2013) by lactate dehydrogenase A. PH III patients also show increased urinary 4-hydroxy-2-oxoglutarate (HOG), which serves as a diagnostic biomarker together with urinary oxalate (PMID: 22771891). Also, dihydroxyglutarate and 4-hydroxyglutamate excretion is elevated. What may be extrapolated from the limited data available is the fact that this subtype is about to become the second most frequent form. Also adults presenting with recurrent kidney stones and CKD stages 2 or higher are observed in more than 20 % of patients. Although PH III so far has only two documented cases of ESRF, long term follow up data is still missing, but it is already clear that it is not as benign as it was initially reported (Monico et al. 2011, Ventzke et al. 2017).

Oxalate Transporter Deficiencies

In the intestine, oxalate is secreted by the soluble intestinal oxalate transporter (SLC26A6), and in the kidney, next to the fact that it is freely filtered, tubular secretion and reabsorption processes are regulated via SLC26A1 and SLC26A6, finally resulting in a net secretion (Knauf et al. 2011; Knauf et al. 2019). A reduced secretion of oxalate via SLC24A6 may therefore lead way to increased plasma oxalate levels and hence to elevated urinary oxalate excretion. This was reported in mice with a defect in SLC26A6, showing a defective interplay of net absorption of oxalate and net secretion, thus inducing hyperoxalemia and hyperoxaluria (Knauf et al. 2011). Next to that, mice who lack the sulfate anion transporter-1 (Sat1 or SLC26A1), which mediates intestinal oxalate transport, also have a phenotype of hyperoxalemia, hyperoxaluria, and calcium oxalate stones (Ko

et al. 2012). Also, in obese mice, a reduced active transcellular intestinal oxalate secretion was recently found, which induces sometimes severe hyperoxalemia and hyperoxaluria (Amin et al. 2018). Here, however, it has to be considered that data of mice studies are not always applicable to the human situation and that there are also conflicting results even for mice data using an equivalent research approach (here *SLC26A1* knockout mice with/without hyperoxalemia and hyperoxaluria) (Dawson et al. 2010; Whittamore et al. 2019).

Alanine-Glyoxylate Aminotransferase (AGT) Deficiency

In PH I, mistargeting or low/absent activity of liver-specific peroxisomal alanine-glyoxylate aminotransferase (AGT) causes massive hyperoxaluria (Danpure et al. 1989). PH I is the most frequent and most severe subtype. The underlying defective *AGXT* comprises 11 exons, located on chromosome 2q36–37 (Purdue et al. 1991). Diagnosis is mostly based on complete *AGXT* sequencing, with >200 mutations identified nowadays throughout the gene. Genetic testing in patients with suspected disease is now considered the gold standard for diagnosis. The disease prevalence is approximately two patients per million populations (van Woerden et al. 2003), but newer genomic data let us suspect that the prevalence is even higher (1:58,000, Hopp et al. 2015). The highly elevated urinary excretion of oxalate and glycolate (>1 mmol/1.73 m^2 body surface area/day, normal <0.5) causes renal calculi (medullary), nephrocalcinosis (NC), or both (Hoppe 2012). While the disease progresses and renal function declines, calcium oxalate crystals systemically deposit (Cochat and Rumsby 2013, Hoppe 2012), when plasma oxalate (Pox) and plasma calcium oxalate saturation (ßPCaOx) increase dramatically, both being inversely correlated with glomerular filtration rate (GFR) in patients with severely impaired renal function (Hoppe et al. 1999). CaOx supersaturation then leads to systemic CaOx crystal deposition and hence a multisystemic disorder with extreme morbidity. PH I patients show a substantial genetic, biochemical, and phenotypic heterogeneity ranging from end-stage renal failure (ESRF) already in infancy (infantile oxalosis) to a late onset or oligosymptomatic course in advanced adulthood. Unfortunately, most patients will develop ESRF over time, if no measures are taken. Systemic oxalosis in PH I is a catastrophic situation that must be prevented by all means. Yet, diagnosis is all too often missed or delayed until ESRF had occurred (in approx. a third of adult patients) (Zhao et al. 2016, Hopp et al. 2015, Mandrile et al. 2014). Early intervention can delay or even prevent progressive renal damage, though.

Secondary Hyperoxaluria

Distinction between PH and secondary hyperoxalurias may be difficult (Robijn et al. 2011). The latter is due either to excessive dietary oxalate intake (dietary hyperoxaluria); to massive vitamin C intake, which is metabolized to oxalate; or to increased intestinal oxalate absorption (enteric). Patients with intestinal disease have an increased risk of hyperoxaluria, particularly after bowel resection (short bowel syndrome), after bypass surgery, in chronic inflammatory bowel disease or cystic fibrosis, and in other malabsorption syndromes. Although the urinary oxalate excretion is usually <1 mmol/1.73 m^2 BSA/24 h, it may nevertheless lead to significant morbidity, i.e., to recurrent urolithiasis or progressive nephrocalcinosis with renal failure and also to systemic oxalosis subsuming multisystemic disorder like in PH I (Hoppe 2012). Therapy is primarily directed toward the underlying disease, but additional measures are still very important.

Hydroxyacid Oxidase 1 (HAO1) Deficiency

Up to now, there are only two reports presenting patients with HAO1 deficiency leading to either only elevated urinary glycolate excretion in two brothers (Frishberg et al. 2014) or an (unexplained) hyperoxaluria in another young patient (Clifford-Mobley et al. 2017, Frishberg et al. 2014). The first report of Frishberg et al. pointed out that GO (glycolate oxidase) inhibition by RNA interference treatment (see below) would be safe, as no hyperoxaluria would be expected after that blockage. We are now aware of three other families with homozygous HAO1 mutations leading to extremely elevated uinary glycolate, but also to some amount of hyperoxaluria!

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localization	Affected protein	OMIM no.
67.1	Primary hyperoxaluria type II	Glyoxylate reductase deficiency	PH 2	*GRHPR*	9p13.2	D-Glycerate dehydrogenase	260000
67.2	Primary hyperoxaluria type III	4-Hydroxy-2-oxoglutarate aldolase deficiency (mitochondrial)	PH 3	*HOGA1*	10q24.2	4-Hydroxy-2-oxoglutarate aldolase	613616
67.3	Oxalate transporter deficiency	Solute carrier transporter deficiencies	SLC	*SLC26A6* *SLC26A1*	3p21.31 4p16.3	SLC26A6 SAT1	610068 610130
67.4	Primary hyperoxaluria type I	Alanine-glyoxylate aminotransferase deficiency (peroxisomal)	PH 1	*AGXT*	2q36–37	Alanine-glyoxylate aminotransferase	259900
67.5	Hydroxyacid oxidase 1 deficiency	Glycolate oxidase deficiency; isolated glycolic aciduria	HAO	*HAO1*	20p12.3	Glycolate oxidase deficiency	605023

Secondary Hyperoxalurias

Disorder	Definition/comment
Dietary hyperoxaluria (normalized on low-oxalate diet)	Oxalate (U) > 0.5 mmol/1.73 m^2/day Elevated urinary oxalate/creatinine ratios (age specific)
Enteric, absorptive hyperoxaluria (inflammatory bowel diseases, malabsorption syndromes, post bowel resection; lack of intestinal oxalate-degrading bacteria like *Oxalobacter formigenes*)	Oxalate (U) > 0.5 mmol/1.73 m^2/day Elevated urinary oxalate/creatinine ratios (age specific)

Metabolic Pathways

Diagnostic Flowchart(s)

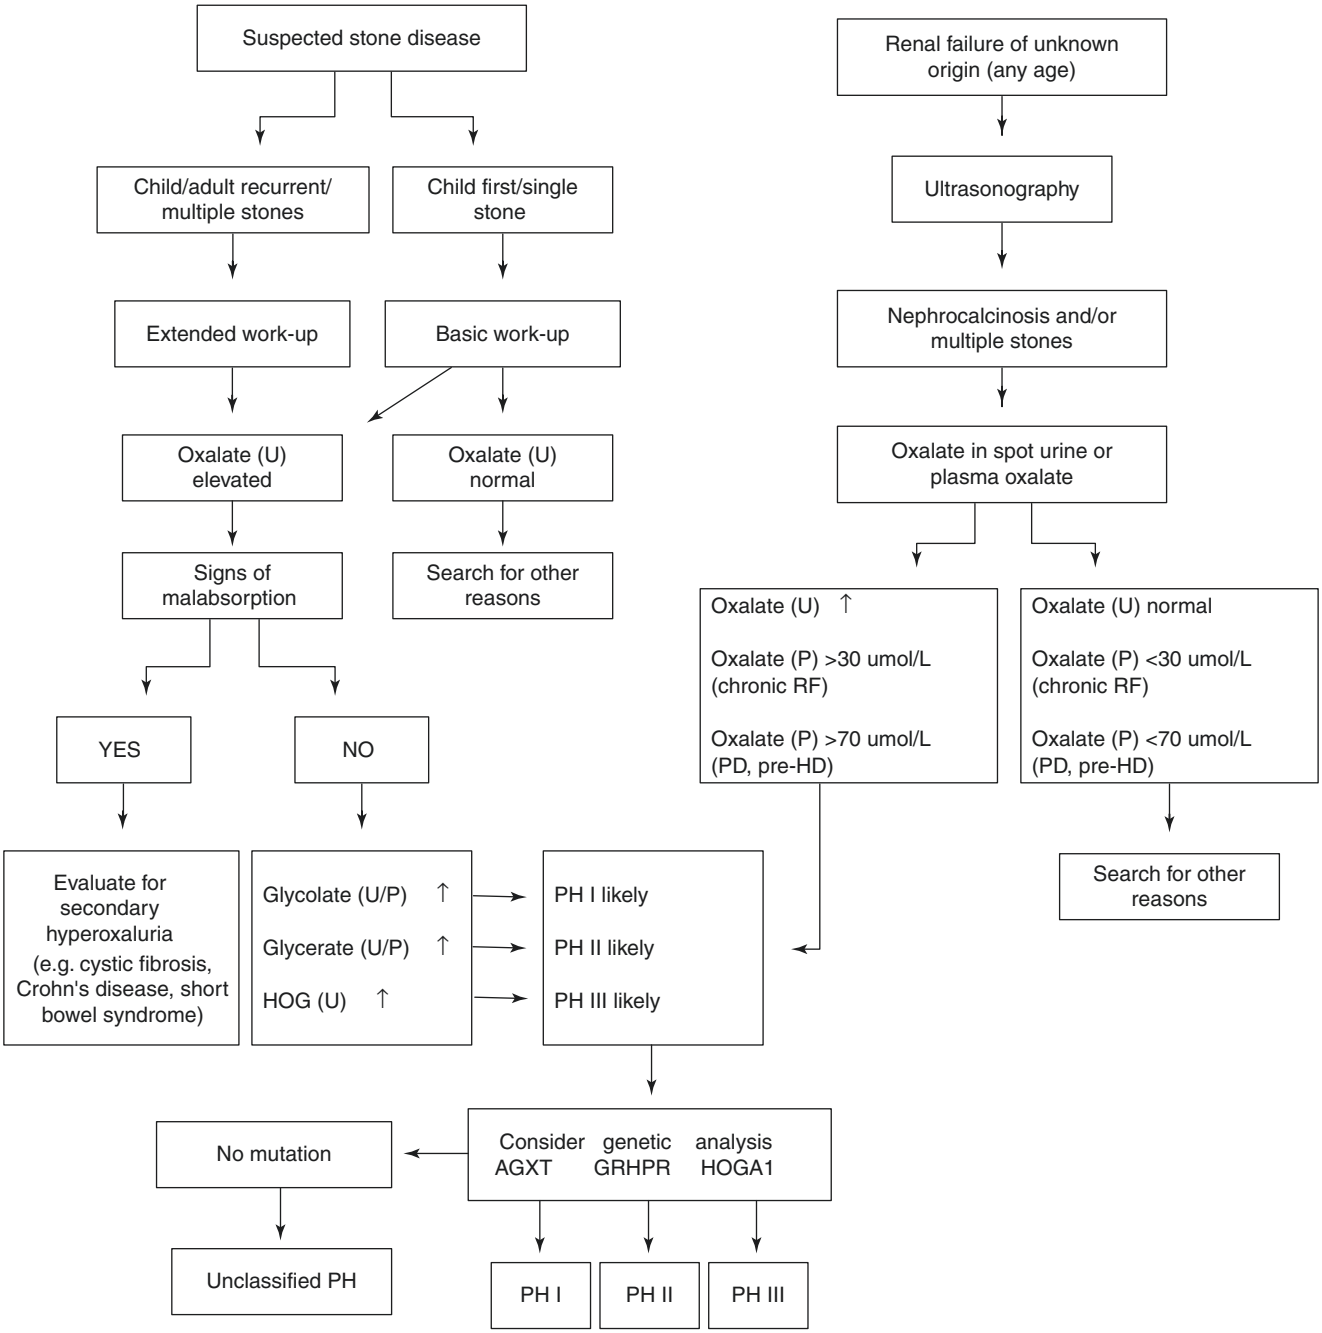

Fig. 67.2 Flowchart of diagnostic evaluation of hyperoxaluria

Specimen Collection

Metabolite	Material	Handling	Pitfalls
Oxalate	Urine	Immediately acidify with 0.02 ml, 6 mol/l HCl/ml to pH < 3. Dilute 20-fold with 0.3 mol/l boric acid	1. Excess alimentary oxalate or precursors (increased enteral uptake) 2. Vitamin B6 deficiency 3. Chronic renal failure 4. Parenteral nutrition in prematures 5. Alkaline pH aids spontaneous formation of oxalate from ascorbate 6. Precipitation of oxalate from urine sample before analysis
	Blood, heparinized	Keep ice-cold after collection Separate red cells and ultrafilter (cutoff 10,000 Da) 2 ml plasma onto 0.06 ml, 1 mol/l hydrochloric acid/ml. Dilute ultrafiltrate 1:1 with 0.3 mol/l boric acid. All steps at 4 °C. Store at −20 °C until analysis	
Glycolate	Urine	Immediately acidify with 0.02 ml, 6 mol/l HCl/ml to pH < 3. Dilute 20-fold with 0.3 mol/l boric acid	
	Blood, heparinized	Keep ice-cold after collection Separate red cells and ultrafilter (cutoff 10,000 Da) 2 ml plasma onto 0.06 ml, 1 mol/l hydrochloric acid/ml. Dilute ultrafiltrate 1:1 with boric acid. All steps at 4 °C. Store at −20 °C until analysis	
Glycerate	Urine	Immediately acidify with 0.02 ml, 6 mol/l HCl/ml to pH < 3. Dilute 20-fold with 0.3 mol/l boric acid	
HOG	Urine	Immediately acidify with 0.02 ml, 6 mol/l HCl/ml to pH < 3. Dilute 20-fold with 0.3 mol/l boric acid	

Prenatal Diagnosis and DNA Testing

	Amniotic fluid metabolites	Fetal liver biopsy (enzyme activity)	CV (enzyme activity)	DNA testing[a] (from CV or biopsy)
PH 1	Non-diagnostic	2 trimester	1 and 2 trimester	+
PH 2	Non-diagnostic			+
PH 3	Non-diagnostic			+

[a]In PH patients, genomic DNA sequencing or linkage analysis (if an index patient exist)

Treatment

The management greatly depends on the degree of renal function, especially in PH type I. About one third of patients with PH I respond to pharmacological doses of pyridoxine (Milliner et al. 1994), but the majority of patients only show a decline in urinary oxalate excretion of 30–50% (Hoyer-Kuhn et al. 2014). Normalization of urinary oxalate excretion is only achieved in some patients. In case of renal failure, the waiting time until transplantation must be kept as short as possible, as no form of dialysis is able to keep pace with the extreme amounts of endogenous oxalate production (Hoppe et al. 2008). Thus, systemic oxalosis develops, which greatly reduces the success of transplantation (Jamieson 2005). Isolated kidney transplantation in PH I is only a reasonable option in fully pyridoxine-responsive patients or, perhaps, in older patients. The transplantation treatment of choice in all other patients with PH I is combined liver-kidney transplantation or kidney after liver transplantation in those with a massive burden of systemic oxalate deposition. Preemptive liver transplantation as enzyme replacement therapy may be considered in patients with remaining stable kidney function (GFR >50 ml/min, Nolkemper et al. 2000); however, the timing of the transplantation is considered to be difficult. In PH type II, isolated kidney transplantation is the treatment of choice, as the underlying enzyme defect is not only located within the liver. However, combined liver-kidney transplantation was now also reported in PH II patients with problematic disease courses or after failed isolated kidney transplanta-

tion. A report in one adult patient showed that normal urinary oxalate and glycerate levels were achieved after 1-year follow-up (Dhondup et al. 2018). Currently, only two patients with PH III have reached end-stage renal failure (Hopp et al. 2015; Richard et al. 2017), although, to our knowledge, no transplantation has been considered for them to date.

Conservative and palliative measures are mandatory for patients diagnosed with PH. High fluid intake and crystallization inhibitors (sodium-potassium citrate) must be advised as soon as PH (of any type) is diagnosed or even suspected. In the last decade, many innovative therapeutic approaches have emerged aiming to tackle the disease from different perspectives: targeting the hepatic metabolism, the oxalate absorption in the gut, or the renal consequences of CaOx deposition. Currently, four drugs are being evaluated in human clinical trials or has already been licenced:

1. Oxabact® (OxThera AB, Stockholm, Sweden), phase III (NCT03116685): composed of *Oxalobacter formigenes*, a commensal anaerobic bacterium of the human intestinal tract that uses oxalate as its carbon source. Oral administration of Oxabact® reduces oxalate absorption, hence Uox, by activating the intestinal oxalate transporter SLC26A6, thus shifting the blood-lumen gradient concentration of oxalate toward its elimination through the feces (Hoppe et al. 2006; Hoppe et al. 2017). Therefore, Oxabact® would be applicable for all types of PH and secondary hyperoxaluria.
2. Oxlumo® (Lumasiran, Alnylam Pharmaceuticals, Boston, MA, USA), was recently approved from FDA and EMA for treatment of PH I. It is a small interference RNA (siRNA) against the *HAO1* gene, encoding for the liver-specific protein glycolate oxidase (GO). Blockade of GO reduces the formation of glyoxylate, upstream of the metabolic blockade by AGT deficiency, thus reducing the burden of oxalate produced in the liver and excreted through the kidneys (Liebow et al. 2017, Dutta et al. 2016, Martin-Higueras et al. 2016). In principle, this substrate reduction therapy is only useful for PH I patients. In the recently published paper a decline of 65.4% in urinary oxalate excretion was reported and most of the patients reached near-normal urinary oxalate values (Garrelfs et al. 2021).
3. DCR-PHXC/Nedosiran® (Dicerna Pharmaceuticals, Boston, MA, USA), phase II (NCT03847909): hepatic lactate dehydrogenase type V (LDH-A) inhibition by siRNA, which blocks the ultimate conversion of glyoxylate into oxalate, thus being suitable for treating at least PH I and PH II patients (Lai et al. 2018). In the recent PHYOX1 study, the safety and efficacy of medication were shown. A mean maximum reduction of 72% of urinary oxalate excretion was achieved in patients with PH I and of 49% in patients with PH II after a single dose of Nedosiran® (Hoppe et al. 2020). The pivotal trial (PHYOX2) is ongoing, but open label data from a long term follow up study (PHYOX3) of the patients being included in PHYOX1 shows normalization of urinary oxalate excretion in all patients (Coenen et al. 2020).
4. ALLN-177 (Allena Pharmaceuticals, Newton, MA, USA), phase II (NCT03391804): a recombinant oxalate decarboxylase that enzymatically degrades oxalate in the intestinal lumen. Because of an oxalate gradient toward the intestinal lumen, but without any intestinal transporter activation, it may help to secrete blood oxalate, which can then be further metabolized (Langman et al. 2016; Leumann et al. 2016). This medication is currently being evaluated in patients with secondary hyperoxaluria and also PH II and PH III. A recent study showed a 22.6% mean reduction of urinary oxalate excretion in patients with enteric hyperoxaluria (Lieske et al. 2019).

Many other drugs are still under evaluation at preclinical stage using animal models of disease (AAV vectors, CRISPR/Cas9, CRID3, R-7050, stiripentol, huAGT-RHEAM mRNA) (Salido et al. 2011; Le Dudal et al. 2019; Kukreja et al. 2019). Although some drugs may reach the market soon, no curative options are available nowadays beyond combined liver-kidney transplantation.

PH Type I (AGT Deficiency)

- New RNAi medication available (Oxluma, Alnylam Pharmaceuticals).
- Systematic evaluation of pyridoxine (vitamin B6) treatment, starting with 5 mg/kg body weight/day, increasing every 6 weeks by 5 mg until 20 mg/kg body weight/day, is necessary in all patients (Cochat et al. 2012). Reliable and repeated baseline values for Uox (in normal renal function) or Pox in chronic renal failure are essential. If reduction of Uox or Pox is >30%, continue with dose of best response in B6 trial. If no effect, discontinue pyridoxine. Beware of side effects (e.g., neuropathy).
- Reduce intake of vitamin C, vitamin D, and eventually dietary oxalate.

PH Type II (GRHPR Deficiency)

- No effect of pyridoxine to be expected.
- Possible benefit of liver transplantation in renal failure.
- Other measures as for PH I.

PH Type III (HOGA1 Deficiency)

- No benefit of pyridoxine to be expected.
- Only two patients with ESRD reported, but transplant option not yet determined.
- Other measures as for PH I.
- Dietary (low-hydroxyproline, low-oxalate) diet recommendable.

Oxalate Transporter Deficiencies and Secondary Hyperoxaluria

- Dietary intervention, low-oxalate diet.
- Avoid vitamin C intake.

Beware: Pitfalls in Hyperoxaluria

1. Urinary oxalate excretion and oxalate/creatinine ratios are falsely low in renal insufficiency because of oxalate retention.
2. Ascorbic acid is a precursor of oxalate and may interfere with oxalate determination. Vitamin C intake should be avoided.
3. Poor compliance is a serious problem in patients with hyperoxaluria who require long-term therapy.
4. Calcium restriction is contraindicated because it leads to enhanced intestinal oxalate absorption.
5. Renal replacement therapy by dialysis (hemo, peritoneal) should be avoided by all means or, at least, not be extended beyond 6 months in patients with primary hyperoxaluria. No form of dialysis is able to eliminate all oxalate generated; thus ongoing systemic deposition of calcium oxalate is inevitable.

Standard Protocol for Intercurrent Illness

Make sure patients get a high fluid intake at all times. Early intravenous fluid administration is indicated in case of severe diarrhea, vomiting, infection, and high fever. A medical emergency card with appropriate instructions is recommended for patients going abroad.

Contents

Summary

Congenital defects of glycosylation (CDG) are genetic diseases due to deficient glycosylation of glycoconjugates (glycoproteins, glycolipids) and to deficient synthesis of glycosylphosphatidylinositol anchors. Since the first clinical description, in 1980, of patients with a CDG, this disease family has shown an exponential expansion. At least 145 CDG have been reported. They can be divided into five groups: (1) defects in protein N-glycosylation, (2) defects in protein O-glycosylation, (3) defects in lipid glycosylation, (4) defects in multiple glycosylation pathways, and (5) defects in glycosylphosphatidylinositol anchor biosynthesis. In 2009, a novel, transparent CDG nomenclature was introduced that covers all (known and still to be discovered) CDG. It consists of the official gene symbol (unitalicized) followed by "-CDG." The majority of CDG patients show neurological disease associated with variable involvement of nearly all other organs. Only a few CDG are mono-organ diseases (e.g., ALG2-CDG, ALG14-CDG, GFPT1-CDG

(retina), EXT1/EXT2-CDG (cartilage), GNE-CDG (skeletal muscles), POFUT1-CDG (skin), POGLUT1-CDG (skin or skeletal muscles), SEC23B-CDG (erythrocytes), ST3GAL3-CDG (brain), TMEM199-CDG (liver), TUSC3-CDG (brain)). The known CDG present autosomal recessive inheritance except for ALG13-CDG, ATP6AP1-CDG, MAGT1-CDG, PIGA-CDG, SLC35A2-CDG, and SSR4-CDG (X-linked) and EXT1/EXT2-CDG, GANAB-CDG, POFUT1-CDG, POGLUT1-CDG, and PRKCSH-CDG (autosomal dominant). Some CDG can be diagnosed clinically such as EXT1/EXT2-CDG and the typical PMM2-CDG presentation. Two screening techniques are available: serum transferrin isoelectrofocusing (or similar techniques such as capillary zone electrophoresis) for the diagnosis of protein N-glycosylation disorders associated with sialic acid deficiency and serum apolipoprotein C-III isoelectrofocusing for the diagnosis of core 1 mucin-type O-glycans. Treatment possibilities are still frustratingly limited. An efficient therapy is available for only two CDG, namely, oral mannose for MPI-CDG and oral uridine for CAD-CDG. Since about 1–2% of the human genome is involved in glycosylation, it appears that a substantial number of CDG have still to be discovered. Elucidation of the basic defects of these CDG will increasingly require next-generation sequencing techniques such as whole exome and whole genome sequencing. Metabolomics and glycomics technology will reveal novel insights into the molecular basis of CDG.

Introduction

Congenital disorders of glycosylation (CDG) are genetic diseases caused by defective glycosylation of glycoproteins and glycolipids and defective synthesis of glycosylphosphatidylinositol anchors (reviews in Abu Bakar et al. (2018), Ferreira et al. (2018), Jaeken and Péanne (2017), Ng and Freeze (2018); reviews on specific aspects of CDG in Coman et al. (2008) (skeleton), Francisco et al. (2018b), Morava et al. (2009) (eyes), Marques-da-Silva et al. (2017b) (heart), Marques-da-Silva et al. (2017a) (liver), Monticelli et al. (2016) (immune system)). A novel CDG nomenclature was recently introduced that covers all (known and still to be discovered) CDG. It consists of the official gene symbol (unitalicized) followed by "-CDG" (Jaeken et al. 2009). Among the 145 known CDG, 118 are disorders of glycoprotein glycosylation. This CDG group comprises disorders of N-glycosylation, disorders of O-glycosylation, and disorders with a combined N- and O-glycosylation defect. C-Glycosylation defects have not yet been reported.

The N-glycosylation pathway encompasses three cellular compartments: the cytosol, the endoplasmic reticulum (ER), and the Golgi. It starts in the cytosol with the formation of the mannose donor GDP-mannose from fructose 6-phosphate, an intermediate of the glycolytic pathway. In the ER, the dolichol-linked oligosaccharide $GlcNAc_2Man_9Glc_3$ is assembled and subsequently transferred from dolichol to selected asparagines of nascent proteins. Still in the ER, this glycan starts to be processed by trimming off the three glucoses. This processing is continued in the Golgi by trimming off six mannoses and replacing them by two residues each of N-acetylglucosamine, galactose and finally sialic acid. O-Glycosylation is usually limited to the Golgi and has no processing pathway. The O-glycans are linked to the hydroxyl group of selected threonine and serine residues.

The first report on CDG was on patients who were subsequently shown to have an N-glycosylation disorder, phosphomannomutase 2 deficiency (PMM2-CDG) (Jaeken et al. 1980; Van Schaftingen and Jaeken 1995; Matthijs et al. 1997). It is a cytosolic assembly defect and turned out to be, by far, the most frequent N-glycosylation disorder with around 900 patients known worldwide. They show mild to severe neurological disease and variable involvement of many other organs. Dysmorphism ranges from mild and aspecific to a characteristic abnormal subcutaneous adipose tissue distribution with fat pads and nipple retraction. Mortality is about 20% in the first years of life (review in Grünewald 2009). The second most frequent N-glycosylation disorder is an ER assembly defect, glucosyltransferase 1 deficiency (ALG6-CDG). It is mainly a neurological disorder but usually milder than that of PMM2-CDG, with limb anomalies in some 10% of these patients (92 patients reported) (review in Morava et al. 2016). The third most reported N-glycosylation disorder is ALG1-CDG with 58 patients, also a predominant neurological disease (review in Ng et al. 2016). The fourth place is occupied by two CDG, on the one hand MAN1B1-CDG and on the other mannose phosphate isomerase deficiency (MPI-CDG), each with around 40 reported patients. MPI-CDG (review in Jaeken et al. 2014) is a remarkable disorder not only because of its pure hepatic-intestinal presentation but particularly because it is one of only two, more or less efficiently, treatable CDG (with oral mannose). The other is CAD-CDG, a defect in pyrimidine biosynthesis causing a deficiency in uridine diphosphate (UDP) (Koch et al. 2017). UDP monosaccharides are necessary for the transport of monosaccharides into the Golgi.

The protein N-glycosylation disorders can be divided into three groups: (1) defects in nucleotide-sugar biosynthesis (e.g., PMM2-CDG, MPI-CDG), (2) defects in lipid-linked oligosaccharide biosynthesis (e.g., DPAGT1-CDG, ALG1-CDG), and (3) defects in protein-linked oligosaccharide biosynthesis (e.g., MAN1B1-CDG, MGAT2-CDG).

A number of protein N-glycosylation disorders are associated with a protein O-glycosylation defect. These comprise defects in dolichol phosphate biosynthesis (e.g., DK1-CDG, SRD5A3-CDG), in dolichol phosphomannose synthesis (e.g., DPM1-CDG, DPM3-CDG), in dolichol phosphomannose utilization (MPDU1-CDG), in galactosylation (B4GALT1-CDG), in sialylation (SLC35A1-CDG), in fucosylation (SLC35C1-CDG), in ER-Golgi intermediate compartment proteins (SEC23B-CDG), and in other vesicular transport proteins (e.g., COG-CDG, ATP6V0A2-CDG). The latter two groups comprise defects in proteins that are not only involved in glycosylation but also in other functions (such as Golgi pH regulation). It has been proposed to name them "CDG-plus."

The protein O-glycosylation disorders can be divided on the basis of the monosaccharide which links the glycan to the protein. Seven groups have been described: (1) defects in O-xylosylglycan synthesis (e.g., XYLT1-CDG, B4GALT7-CDG, EXT1/EXT2-CDG, CHSY1-CDG); (2) defect in O-*N*-acetylglucosaminylglycan synthesis (EOGT-CDG); (3) defect in O-*N*-acetylgalactosaminylglycan synthesis (GALNT3-CDG); (4) defect in O-xylosyl/*N*-acetylgalactosaminylglycan synthesis (SLC35D1-CDG); (5) defects in O-mannosylglycan synthesis (e.g., POMT1/POMT2-CDG, POMGNT1-CDG, B3GALNT2-CDG, LARGE-CDG); (6) defects in O-fucosylglycan synthesis (POFUT1-CDG, B3GALTL-CDG, LFNG-CDG); and (7) defect in O-glucosylglycan synthesis (POGLUT1-CDG). Several of these diseases have also a descriptive name, based on their typical clinical presentation: multiple cartilaginous exostoses (EXT1/EXT2-CDG), familial tumoral calcinosis (GALNT3-CDG), Schneckenbecken dysplasia (SLC35D1-CDG), muscle-eye-brain disease (POMGNT1-CDG, POMT1/POMT2-CDG), and spondylocostal dysostosis type 3 (LFNG-CDG).

Most CDG present an autosomal recessive inheritance. ALG13-CDG, ATP6AP1-CDG, MAGT1-CDG, PIGA-CDG, SLC35A2-CDG, and SSR4-CDG are X-linked, and EXT1/EXT2-CDG, GANAB-CDG, POFUT1-CDG, POGLUT1-CDG, and PRKCSH-CDG display an autosomal dominant inheritance.

Essentially two techniques are available for CDG screening: serum transferrin isoelectrofocusing (IEF) detects protein N-glycosylation disorders associated with sialic acid deficiency (Jaeken et al. 1984), and serum apolipoprotein C-III IEF detects core 1 mucin-type O-glycosylation defects (Wopereis et al. 2003). Serum transferrin IEF can be replaced by other techniques such as capillary zone electrophoresis (Carchon et al. 2004). Serum transferrin IEF detects only about 50% of the known CDG. It does not pick up the O-glycosylation disorders that are not associated with an N-glycosylation defect, the lipid glycosylation defects, and the glycosylphosphatidylinositol (GPI) anchor synthesis defects, as well as defects in the N-glycosylation pathway that do not show a deficiency of sialic acid (PMM2-CDG due to a promotor defect, GMPPA-CDG, GMPPB-CDG, TUSC3-CDG, MOGS-CDG, GANAB-CDG, PRKCSH-CDG, FUT8-CDG, GNE-CDG, NANS-CDG, DHDDS-CDG, SLC35A1-CDG, SLC35A3-CDG, SLC35C1-CDG, SEC23B-CDG, PGM3-CDG). In case of an abnormal transferrin IEF profile, first an artifact, a protein polymorphism, and a secondary CDG (fructosemia, galactosemia, alcohol abuse, bacterial sialidase) should be excluded. Two types of abnormal transferrin IEF profiles can be distinguished: a type 1 pattern, characterized by an increase of di- and/or asialoprotein (CDG-I), and a type 2 pattern, characterized by an increase of tri-, di-, mono-, and/or asialoprotein (CDG-II). A type 1 pattern points to an assembly or transfer defect of the dolichol-linked glycan (in the cytosol or the ER). When there is a typical PMM2-CDG or MPI-CDG phenotype, measurement of the phosphomannomutase or mannose phosphate isomerase activity in fibroblasts or leukocytes is the next step, or direct mutation analysis of the involved genes. If there is no typical phenotype, next-generation sequencing (CDG gene panel analysis, WES, or WGS) is indicated. A type 2 pattern indicates a glycan processing defect (in the ER or the Golgi). If this is associated with a typical MAN1B1-CDG, MGAT2-CDG, or PGM1-CDG phenotype, mutation analysis is indicated, preceded or not by structural analysis of serum transferrin glycans. In the absence of a typical phenotype, CDG gene panel analysis, WES, or WGS should be performed. In order to know whether there is an associated O-glycosylation defect, apolipoprotein C-III IEF can be performed. When there is a normal serum transferrin IEF pattern but a strong clinical and/or biochemical suspicion (e.g., fat pads, cerebellar hypoplasia, and decreased coagulation factor XI (PMM2-CDG); intellectual disability with increased serum alkaline phosphatases (GPI anchor synthesis defect)), mutation analysis of the suspected gene or next-generation sequencing (using gene panels, WES, and/or WGS) should be performed (Francisco et al. 2018a).

The nomenclature and signs and symptoms tables are limited in this article to 124 CDG, namely, 30 disorders of N-linked glycosylation, 16 disorders of O-mannosylglycan synthesis, 1 disorder of O-*N*-acetylgalactosaminylglycan synthesis, 2 disorders of O-*N*-acetylglucosaminylglycan synthesis, 1 disorder of O-glucosylglycan synthesis, 2 disorders of O-fucosylglycan synthesis, 1 disorder of a galactosyltransferase-specific chaperone, 8 disorders of dolichol metabolism, 4 disorders of monosaccharide synthesis and interconversion, 1 disorders of nucleotide-sugar synthesis, 6 disorders of Golgi transport, 1 disorder of plasma membrane transport, 8 disorders of Golgi homeostasis, 24 disorders of glycosaminoglycan synthesis, and 19 GPI anchor synthesis disorders. N-Glycanase 1 deficiency (68.125) is not a CDG but a congenital disorder of deglycosylation (CDDG).

Diagnostic Flowchart

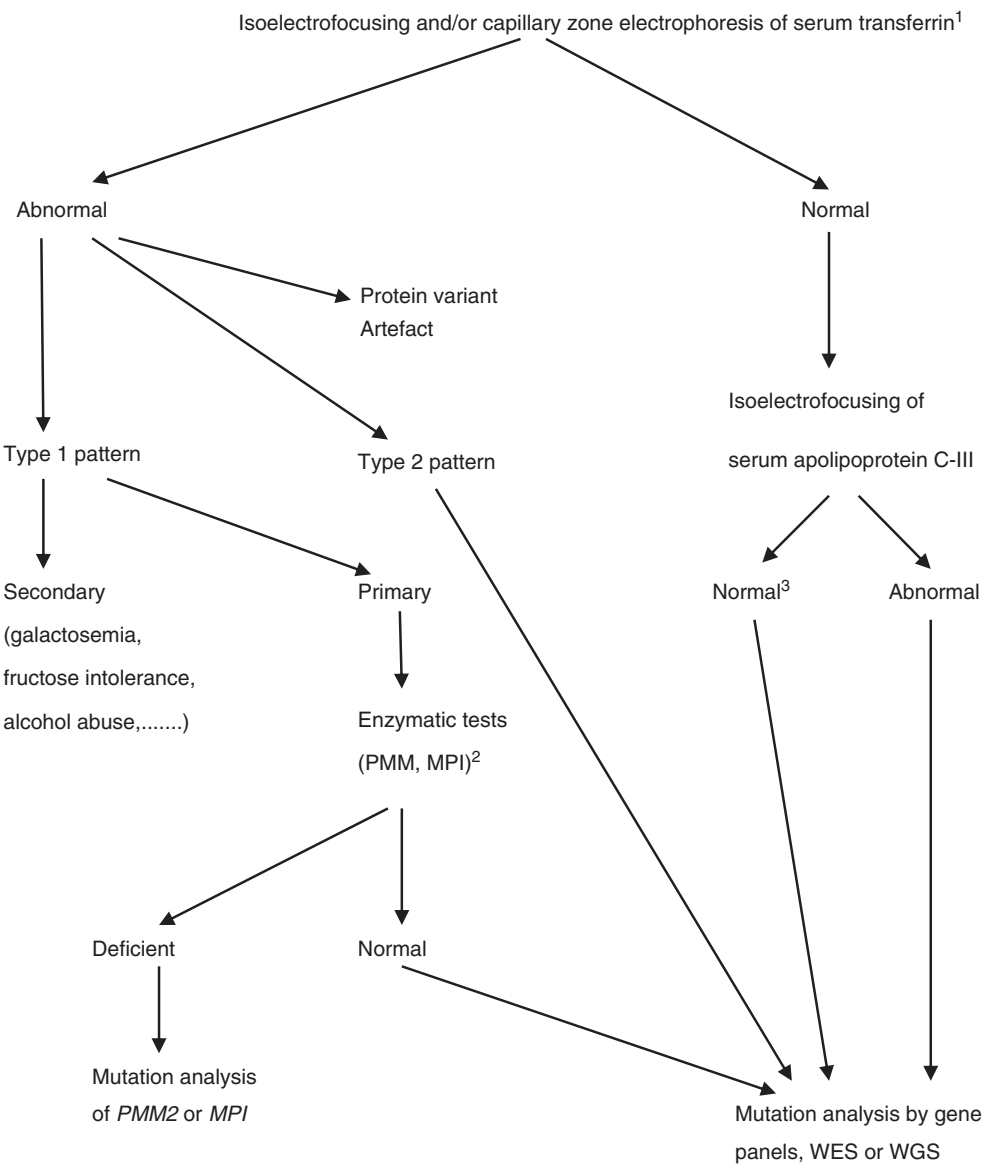

Fig. 68.2 Flowchart for the diagnosis of CDG

WES: whole exome sequencing (checking first established genes for CDG defects and afterwards candidate genes for CDG defects and/or all other genes).

WGS: whole genome sequencing (checking first established genes for CDG defects and afterwards candidate genes for CDG defects and/or all other genes).

1: In specialized centers for CDG diagnostics, glycomics MS assays have been developed and may be used for initial screening as well (Bakar et al 2018; Ashikov et al 2018).

2: Enzymatic tests may be performed when there is a typical PMM2-CDG or MPI-CDG phenotype.

3: In case of strong clinical suspicion of CDG, genetic testing is advocated.

Specimen Collection

Test	Precondition	Material	Handling	Pitfalls
Sialotransferrins		S	Frozen (–20 °C)	No EDTA plasma
Apolipoprotein C-III		S	Frozen (–20 °C)	
Phosphomannomutase		WBC, FB	Frozen (–20 °C)	
Phosphomannose isomerase		WBC, FB	Frozen (–20 °C)	

Prenatal Diagnosis

Disorder	Material	Timing, trimester
All (68.1–68.125)	CV sampling or cultured AFC	I, II

Prenatal diagnosis is performed by DNA diagnostics on genomic DNA when the genetic defect has been established in a particular family. Maternal contamination has to be excluded by haplotype (CA repeat) testing of the AFC and maternal blood.

DNA Testing

Disorder	Material	Methodology
All (68.1–68.125)	F, WBC	Direct sequencing of genomic DNA

Treatment

Besides the well-established symptomatic and supportive therapies for all CDG, there are very few specific/curative treatments: mannose for MPI-CDG, fucose for some patients with SLC35C1-CDG, benzoate for the neurological symptoms of PIGM-CDG, and uridine for CAD-CDG. Galactose is on trial for several CDG mainly PGM1-CDG, SLC35A2-CDG, and TMEM165-CDG. Also on trial is manganese for SLC39A8-CDG. A minority of patients with PMM2-CDG present recurrent stroke-like episodes, thromboses (probably at least in part due to hyperaggregability of blood platelets), and/or bleeding episodes. Guidelines for the preventive and curative treatment of these features are being established by the Paris MetabERN center. The same center also prepares guidelines for the hormonal treatment of pubertal problems in PMM2-CDG.

Standard Treatment

- **68.2** *Phosphomannose isomerase deficiency*
- Mannose circumvents the defective step because it can be directly converted to mannose-6-phosphate by hexokinases. Oral mannose, 0.2 g/kg of body weight per 4 h, is recommended. The clinical symptoms usually disappear rapidly, but it takes several months for the serum transferrin isoform pattern to improve or normalize.
- **68.114** *GDP-fucose transporter deficiency*
- Oral fucose, 150 mg/kg of body weight, five times a day, abolishes or prevents infections and normalizes neutrophil counts in some patients (depending on genotype).
- **68.85** *PIGM deficiency*
- Oral sodium phenylbutyrate (a histone deacetylase inhibitor), 20–30 mg/kg body weight, three times a day, has been given to three patients with a clearly beneficial effect on seizures and psychomotor development.

Dangers/Pitfalls

- **68.2** Higher mannose doses can induce osmotic diarrhea. Some patients develop hemolytic jaundice under mannose therapy. The alternative is then liver transplantation.
- **68.114** Higher fucose doses can induce autoimmune neutropenia.

Experimental Treatment

- **68.105** *Phosphoglucomutase 1 deficiency*
- In pilot studies, oral galactose administration (1 g/kg per day) caused an improvement of liver transaminases, antithrombin and factor XI, endocrine parameters (to a variable degree), and glycosylation and a decreased frequency of rhabdomyolysis (review in Witters et al. 2017).
- **68.110** *CAD trifunctional protein deficiency*
- Oral uridine administration (100 mg/kg per day) abolished the epilepsy and the anemia, improved psychomotor development, and normalized UDP sugars in fibroblasts (Koch et al. 2017).
- **68.112** *UDP-galactose transporter deficiency*
- On oral galactose, seizures tend to improve. In one patient, glycosylation was nearly completely restored, but serum transaminases remained elevated (review in Witters et al. 2017).
- **68.116** *SLC39A8 deficiency*
- In two patients, oral $MnSO_4$ administration (15 and 20 mg/kg per day) considerably improved motor abilities, hearing, and other neurological functions and completely normalized enzyme dysfunctions (Park et al. 2018).
- **68.124** *Transmembrane protein 165 deficiency*
- In two patients, oral galactose administration caused a substantial improvement of N-glycosylation, endocrine function, and some coagulation parameters (Morelle et al. 2017).

Various

Cerebral Organic Acidurias

69

Stefan Kölker

Contents

Summary

A group of organic acidurias, including Canavan disease (*N*-acetylaspartic aciduria), glutaric aciduria type I, L-2-hydroxyglutaric aciduria and D-2-hydroxyglutaric aciduria types I and II, are characterised by a predominantly or even exclusively neurological presentation and have therefore been termed 'cerebral'. The clinical presentation frequently includes developmental delay, cognitive disability, movement disorder and epilepsy, resulting from acute and/or chronic pathological changes in various brain regions including grey matter (cortex, basal ganglia, cerebellum) and white matter (periventricular and subcortical). Unlike 'classic' organic acidurias (e.g. propionic and methylmalonic aciduria), acute metabolic decompensations with hyperammonaemia, metabolic acidosis and elevated concentrations of lactate and ketone bodies are uncommon for cerebral organic acidurias. Biochemically, these diseases are characterised by accumulation of characteristic organic acids, mostly dicarboxylic acids, in body fluids. At high concentrations, some of these may become neurotoxic. Since the blood–brain barrier has a low transport capacity for dicarboxylic acids, cerebral accumulation of dicarboxylic acids is facilitated. Impairment of brain energy metabolism is suggested to play a central role in the pathophysiology of this disease group. Metabolic treatment initiated in neonatally diagnosed patients with glutaric aciduria type I has significantly improved the neurological outcome, whereas current treatment strategies for the other cerebral organic acidurias are ineffective.

Introduction

Canavan disease (Van Bogaert–Bertrand disease, *N*-acetylaspartic aciduria), a debilitating and lethal leukodystrophy, is caused by an autosomal recessively inherited deficiency of aspartoacylase (aminoacylase 2) which is exclusively expressed in oligodendrocytes. Most patients have the infantile form which generally manifests at 2–4 months of age with head lag, muscular hypotonia and macrocephaly, progressing to marked developmental delay, seizures, optic nerve atrophy, progressive spasticity and opisthotonic posturing (Matalon et al. 1995). Death usually occurs in a few years. However, the initial symptoms may already start at or shortly after birth (neonatal form) or after the age of 5 years (juvenile form). Cranial MRI studies show diffuse or exclusively subcortical involvement of the white matter due to spongiform myelinopathy and involvement of the thalamus and globus pallidus. Diagnosis can be made by finding elevated *N*-acetylaspartate concentrations in urine using GC/MS analysis of organic acids. A decreased aspartoacylase activity in cultured skin fibroblasts and/or the identification of two disease-causing mutations in the *ASPA* gene localised on 17p13.2 confirms the diagnosis. *N*-Acetylaspartate is formed in neurons and hydrolysed to L-aspartate and acetate by oligodendrocytes. No effective treatment exists for Canavan disease. Lithium citrate decreases brain *N*-acetylaspartate concentrations (Assadi et al. 2010), and glyceryl triacetate treatment supplies the brain with acetate (Segel et al. 2011). Although this treatment is considered as safe, there is no proof for its therapeutic efficacy. Initial attempts of *ASPA* gene therapy have not met expectations (Leone et al. 2000). Recombinant adeno-associated virus-based gene therapy targeting astrocytes (Gessler et al. 2017), however, achieved complete and sustained rescue of the lethal phenotype in a mouse model of Canavan disease. Translation into clinical studies is pending.

Glutaric aciduria type I (glutaric acidaemia type I) is caused by an autosomal recessively inherited deficiency of glutaryl-CoA dehydrogenase, an FAD-dependent mitochondrial matrix enzyme. This enzyme is involved in the catabolic pathways of lysine, hydroxylysine and tryptophan, catalysing the oxidative decarboxylation of glutaryl-CoA to crotonyl-CoA. Transient muscular hypotonia and macrocephaly are often found in newborns. At this age, cranial MRI of affected individuals reveals temporal hypoplasia, dilated external CSF spaces, subependymal pseudocysts, myelination delay and an immature gyral pattern which all may improve or even resolve in early treated children (Harting et al. 2009). In the time interval between 3 and 36 (−72) months, however, most untreated patients develop a complex movement disorder best described as generalised dystonia superimposed on axial hypotonia (Gitiaux et al. 2008). These symptoms are the consequence of bilateral striatal injury which may occur acutely during acute encephalopathic crises precipitated by catabolism or insidiously without preceding crises (Kölker et al. 2006). Aside from striatal injury, MRI may show additional frontal atrophy and subdural haemorrhage. A few adolescent and adult patients with a late-onset form have been reported presenting with headaches, vertigo, reduced fine motor skills and white matter abnormalities (Harting et al. 2009). Patients can be identified in the first week of life by newborn screening using glutarylcarnitine as a diagnostic parameter. Glutarate and 3-hydroxyglutarate concentrations are increased in urine and other body fluids but may be (intermittently) normal in patients with a low-excreter phenotype. Therefore, a normal organic acid analysis result does not unequivocally exclude the diagnosis. Suspected diagnosis is confirmed by significantly decreased glutaryl-CoA dehydrogenase activity in leucocytes or fibroblasts and/or the identification of two disease-causing mutations in the *GCDH* gene localised on 19p13.13. Glutarate and 3-hydroxyglutarate concentrations are 100–1000-fold higher in the brain than in plasma which is caused by the very low efflux transport of dicarboxylic acids across brain capillary endothelial cells (Sauer et al. 2006). At high concentrations, accumulating dicarboxylic acids may become neurotoxic inhibiting energy metabolism (2-oxoglutarate dehydrogenase, dicarboxylate shuttle between astrocytes and neurons) and activating *N*-methyl-D-aspartate receptors. The development of prognostic relevant striatal injury can be prevented in the majority of children if the diagnosis is made and metabolic treatment is started neonatally (Heringer et al. 2010; Boy et al. 2018). Metabolic treatment according to a recently revised guideline includes a low lysine diet, carnitine supplementation and emergency treatment to counteract catabolism (Kölker et al. 2011; Boy et al. 2017a, b). Patients with a high- and low-excreter phenotype have the same risk of developing striatal injury and thus receive the same treatment (Kölker et al. 2006); however, the neurological long-term risk of individuals with high-excreter phenotype might be increased (Boy et al. 2017a, b). Regardless of therapy, some individuals develop mild to moderate degree chronic kidney disease starting at school age. The prognosis of this renal manifestation needs to be elucidated.

L-2-Hydroxyglutaric aciduria (L2HGA) is an autosomal recessive inborn error of metabolism, caused by mutations in the *L2HG dehydrogenase* (*L2HGDH*) gene. The *L2HGDH* gene product, i.e. L2HGDH, is an FAD-dependent membrane-bound enzyme responsible for the conversion of L-2-hydroxyglutarate (L2HG) into 2-ketoglutaric acid (2KG). The current opinion is that nonspecific mitochondrial formation of L2HG out of 2KG by L-malic dehydrogenase is the sole source of L2HG and that L2HGDH is an enzyme for metabolite repair (Van Schaftingen et al. 2009). L2HGA has an insidious onset starting in childhood with developmental delay, macrocephaly, epilepsy and cerebellar ataxia as clinical signs. In a minority of patients, the diagnosis is established in adulthood, but retrospective evaluation of the clinical course reveals an earlier subtle onset (Steenweg et al. 2010). MRI reveals disease-specific alterations characterised by predominantly subcortical cerebral white matter abnormalities and abnormalities of the dentate nucleus, globus pallidus, putamen and caudate nucleus (Steenweg et al. 2009). Metabolic investigations will reveal increased 2HG in the urinary organic acid screening, and subsequent chiral differentiation shows the increased excretion of exclusively L2HG. Apart from the massive increase of L2HG in all body fluids, a modest increase of CSF lysine is observed, while plasma lysine levels may be normal. Since the massive increase of L2HG is the major biochemical finding, pathology is likely to be explained by the pathologic levels of L2HG; however, lowered (peripheral) 2KG levels might also attribute to the disease. Currently, there is no established treatment protocol for L2HGA apart from two anecdotic reports mentioning positive effects of treatment with riboflavin and/or FAD.

D-2-Hydroxyglutaric aciduria (D2HGA) type I is one of the two subtypes of D2HGA and has an autosomal recessive pattern of inheritance. The disease is caused by mutations in the *D2HG dehydrogenase* (*D2HGDH*) gene, resulting in a deficiency of D-2-hydroxyglutarate (D2HG) dehydrogenase (Struys et al. 2005). This FAD-dependent mitochondrial enzyme converts D2HG, most likely formed by the action of hydroxyacid-oxoacid transhydrogenase (HOT), into 2KG. Although several hypothetical metabolic pathways for D2HG have been proposed, there is strong evidence that D2HG is directly and exclusively formed out of 2KG (Struys et al. 2004). The disease displays a strong clinical heterogeneity from severely affected individuals to asymptomatic individuals. However, frequently reported clinical findings are developmental delay, hypotonia and epilepsy. Usually, patients are first recognised by an increase of 2HG in the urinary organic acid screening. In contrast with L2HGA, these elevations can be modest. The increase of D2HG in all body fluids is the sole biochemical alteration in this disease, and the pathophysiology of the disease is likely to be explained by this. Currently, there is no treatment. However, it can be hypothesised that in individual cases, riboflavin supplementation might be beneficial.

D-2-Hydroxyglutaric aciduria (D2HGA) type II is the second form of D2HGA and is caused by a gain-of-function mutation in the *isocitrate dehydrogenase 2* (*IDH2*) gene (Kranendijk et al. 2010). Heterozygous mutations in IDH2 result in the formation of a neomorph enzyme which is able to efficiently convert 2KG into D2HG. This is in contrast with the normal action of IDH2, i.e. the conversion of isocitrate into 2KG. D2HGA type II has an autosomal dominant trait, and in the vast majority of patients, the mutation arose de novo. The degree of D2HG accumulation in D2HGA type II is higher than in type I, despite properly functioning D2HG dehydrogenase. Patients affected with D2HGA type II suffer from developmental delay, muscular hypotonia and epilepsy, and their clinical presentation is generally more severe than that of patients with D2HGA type I. Cardiomyopathy is frequently observed in D2HGA type II and absent in type I. Specific inhibition of the neomorph enzyme by a small molecule rescued cardiomyopathy and improved survival in a mouse model for D2HGA type II (Wang et al. 2016).

Nomenclature

No.	Disorder	Alternative name	Abbreviation	Gene symbol	Chromosomal localisation	Affected protein	OMIM no.
69.1	Canavan disease	Van Bogaert–Bertrand disease	CD	*ASPA*	17p13.2	Aspartoacylase (aminoacylase 2)	271900
69.2	Glutaric aciduria type I	Glutaric acidaemia type I	GA-I	*GCDH*	19p13.13	Glutaryl-CoA dehydrogenase	231670
69.3	L-2-Hydroxyglutaric aciduria	L-2-Hydroxyglutarate dehydrogenase deficiency	L2HGA	*L2HGDH*	14q21.3	L-2-Hydroxyglutarate dehydrogenase	236792
69.4	D-2-Hydroxyglutaric aciduria type I	D-2-Hydroxyglutarate dehydrogenase deficiency	D2HGA type I	*D2HGDH*	2q37.3	D-2-Hydroxyglutarate dehydrogenase	600721

Metabolic Pathways

Canavan Disease (Aspartoacylase Deficiency)

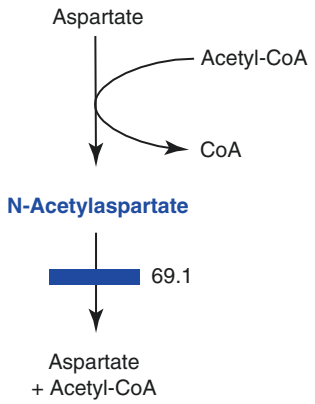

Fig. 69.1 Metabolic pathway of Canavan disease. *N*-Acetylaspartate is produced in neurons from L-aspartate and acetyl-CoA and is transported to oligodendrocytes where it is hydrolysed to L-aspartate and acetyl-CoA by aspartate aminoacylase 2. Inherited deficiency of this enzyme results in accumulation of *N*-acetylaspartate in patients with Canavan disease

Glutaric Aciduria Type I (Glutaryl-CoA Dehydrogenase Deficiency)

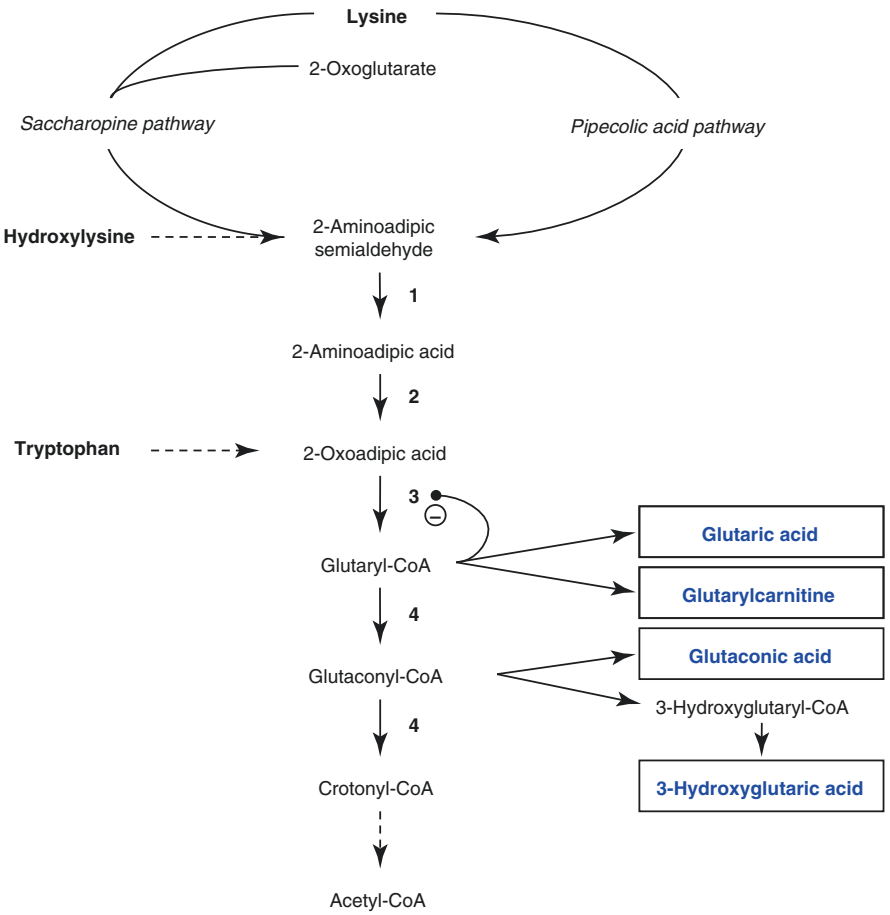

Fig. 69.2 Metabolic pathway of glutaric aciduria type I. Glutaryl-CoA is formed within the catabolic pathways of lysine, tryptophan and hydroxylysine. The quantitatively major precursor is lysine. Deficient activity of glutaryl-CoA dehydrogenase (4) results in variable accumulation of glutaric, 3-hydroxyglutaric and glutaconic acid as well as glutarylcarnitine, which are important for the diagnosis and can be determined in body fluids. Elevated glutaryl-CoA—similar to homologous succinyl-CoA—results in feedback inhibition of the TCA cycle enzyme 2-oxoglutarate dehydrogenase complex (3). *1*, 2-aminoadipic semialdehyde dehydrogenase (enzyme is deficient in pyridoxine-dependent epilepsy), *2*, 2-aminoadipate aminotransferase, *3*, 2-oxoglutarate dehydrogenase-like complex (enzyme complex contains three subunits: DHTKD1, a E1 component with substrate specificity for 2-oxoadipate, is deficient in 2-aminoadipic/2-oxoadipic aciduria; the E2 subunit is deficient in 2-oxoglutarate dehydrogenase complex deficiency; E3 subunit (lipoamide dehydrogenase), which is shared with pyruvate dehydrogenase and branched-chain oxoacid dehydrogenase complexes, is deficient in E3 deficiency, biochemically resembling maple syrup urine disease, 2-oxoglutarate dehydrogenase complex deficiency and pyruvate dehydrogenase complex deficiency, *4*, glutaryl-CoA dehydrogenase

L-2-Hydroxyglutaric Aciduria (L-2-Hydroxyglutarate Dehydrogenase Deficiency)

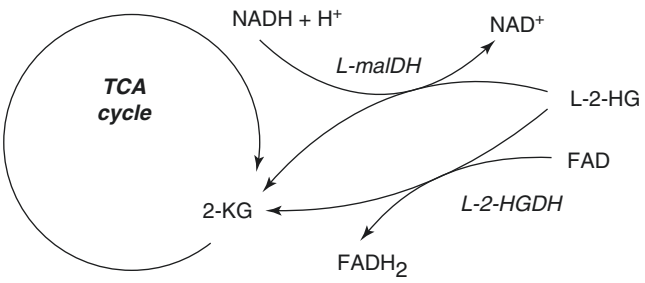

Fig. 69.3 Metabolic pathway of L-2-hydroxyglutaric aciduria. L-2-Hydroxyglutaric acid is formed by a nonspecific conversion of mitochondrial 2KG into L-2-hydroxyglutaric acid by the action of NADH-dependent l-malic acid dehydrogenase. L2HG dehydrogenase corrects for this metabolic imperfection by reconverting L2HG into 2KG

D-2-Hydroxyglutaric Aciduria Type I (D-Hydroxyglutarate Dehydrogenase Deficiency)

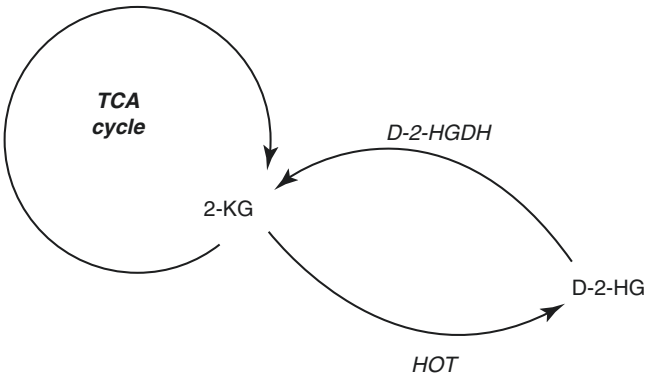

Fig. 69.4 Metabolic pathway of D-2-hydroxyglutaric aciduria type I. D-2-Hydroxyglutaric acid is formed out of mitochondrial 2KG by the action of hydroxyacid-oxoacid transhydrogenase (*HOT*). D2HG is reconverted into 2KG by D2HG dehydrogenase. This pathway is thought to play a role in GABA/GHB homeostasis

D-2-Hydroxyglutaric Aciduria Type II (Isocitrate Dehydrogenase 2 Deficiency)

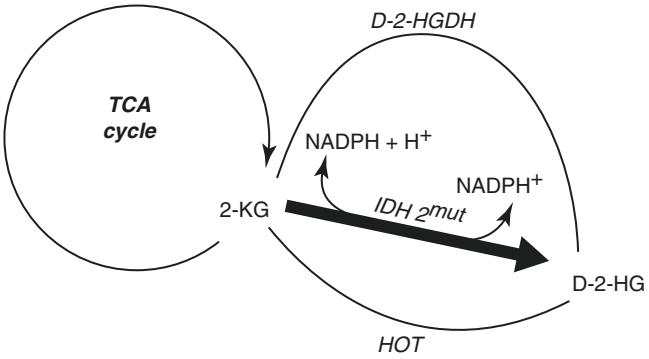

Fig. 69.5 Metabolic pathway of D-2-hydroxyglutaric aciduria type II. As a consequence of a heterozygous mutation in IDH2, the neomorph IDH2 enzyme produces vast amounts of D2HG, which exceed the capacity of D2HG dehydrogenase, an enzyme with a low K_m, and as a net result, D2HG accumulates. The neomorph IDH2 enzyme consumes both 2KG and NADPH, which might lead to their shortages

Signs and Symptoms

	mmol/mol creatinine	µmol/L	µmol/L
	448–11,305	99–757	30–172

Separation and individual quantification of the D- and L-isomer of 2HG by gas chromatography–mass spectrometry or liquid chromatography-tandem mass spectrometry

Diagnostic Flowchart(s)

N-Acetylaspartic Acid (NAA)

If neurological symptoms occur and/or neuroradiological abnormalities are found (→ **69.4** "Signs and Symptoms") which are characteristic for Canavan disease, the diagnostic process should be initiated by analysis of *N*-acetylaspartate (NAA) in urine. If increased NAA concentrations are found, the diagnosis can be confirmed by significantly decreased aspartoacylase activity in cultured skin fibroblasts and/or the identification of two disease-causing mutations in the *ASPA* gene.

Glutaric Aciduria Type I

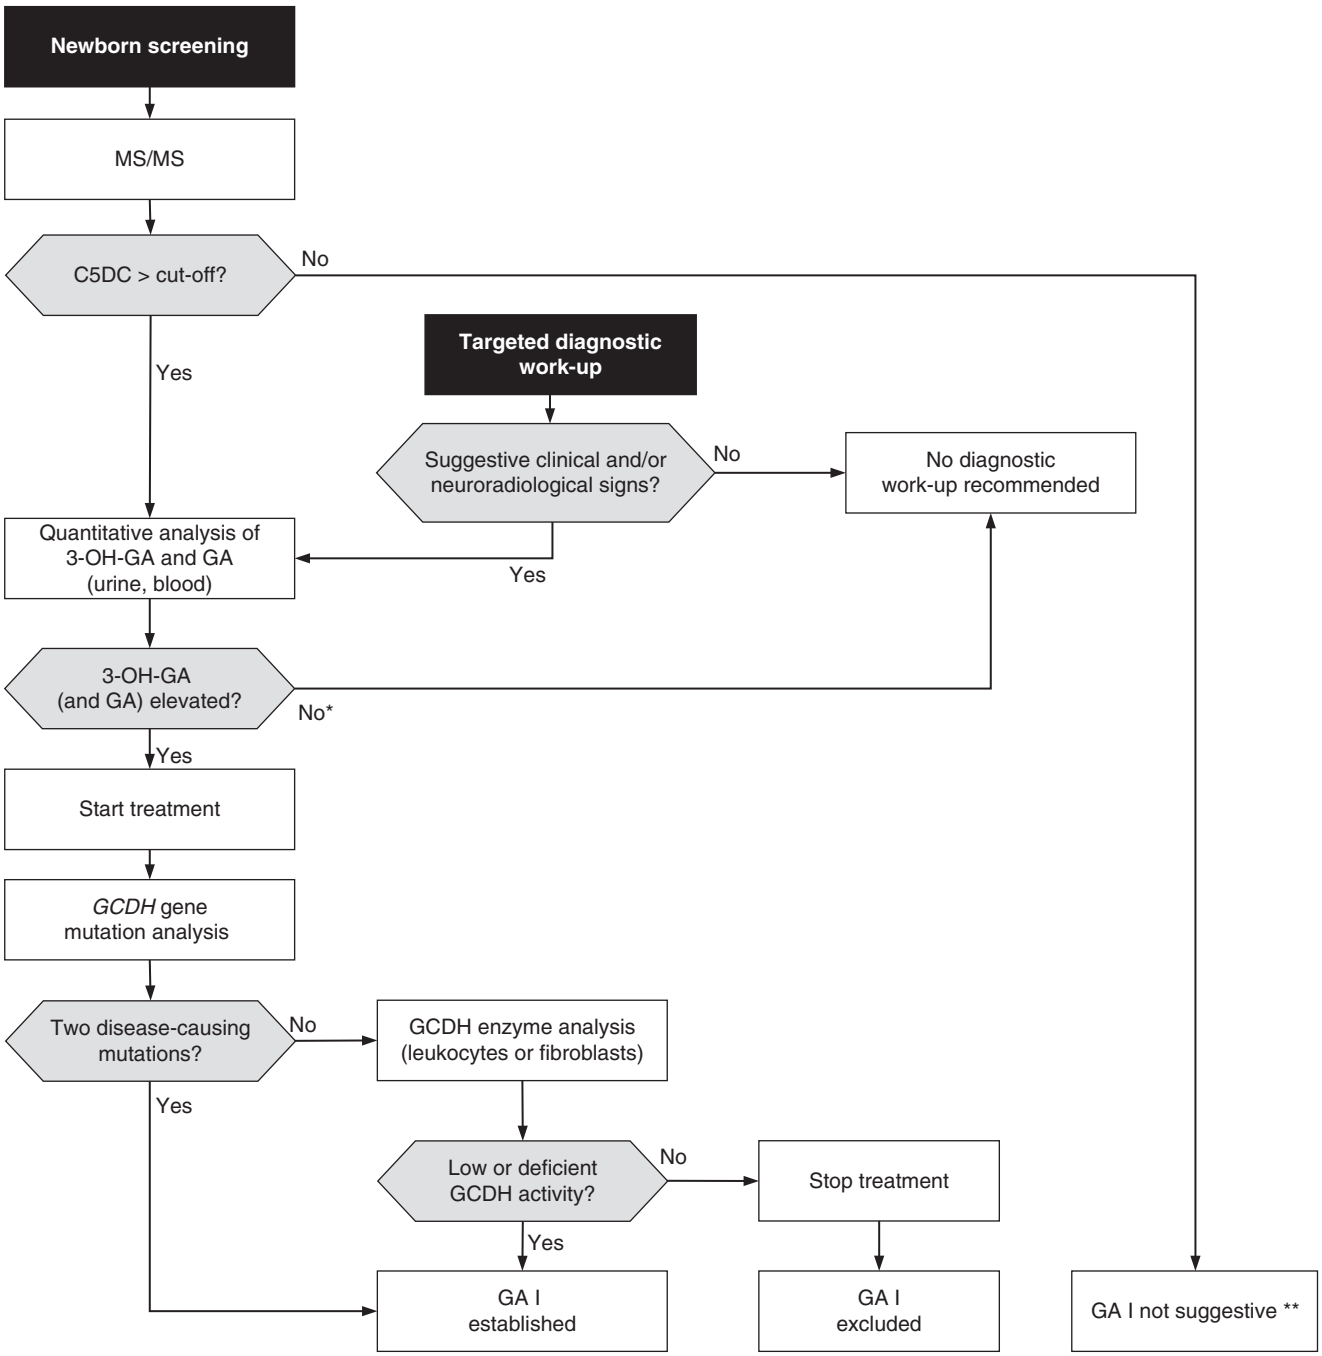

Fig. 69.6 Diagnostic flowchart for glutaric aciduria type I. (a) *Newborn screening* for glutaric aciduria type I (GA-I) is performed using tandem mass spectrometry (MS/MS). (b) *Targeted diagnostic work-up* should be started if diagnosis of GA-I is suspected or a positive family history is known. Note that a few patients with a low-excreting phenotype may show (intermittently) normal urinary excretion of 3-hydroxyglutaric acid (*3-OH-GA*) and glutaric acid (*GA*) (*). If an individual shows normal 3-OH-GA (and GA) concentrations in urine but presents with highly suspicious signs and symptoms for GA-I, it should be decided individually whether diagnostic work-up is continued (**)

L-2-Hydroxyglutaric Aciduria, D-2-Hydroxyglutaric Aciduria Type I and D-2-Hydroxyglutaric Aciduria Type II

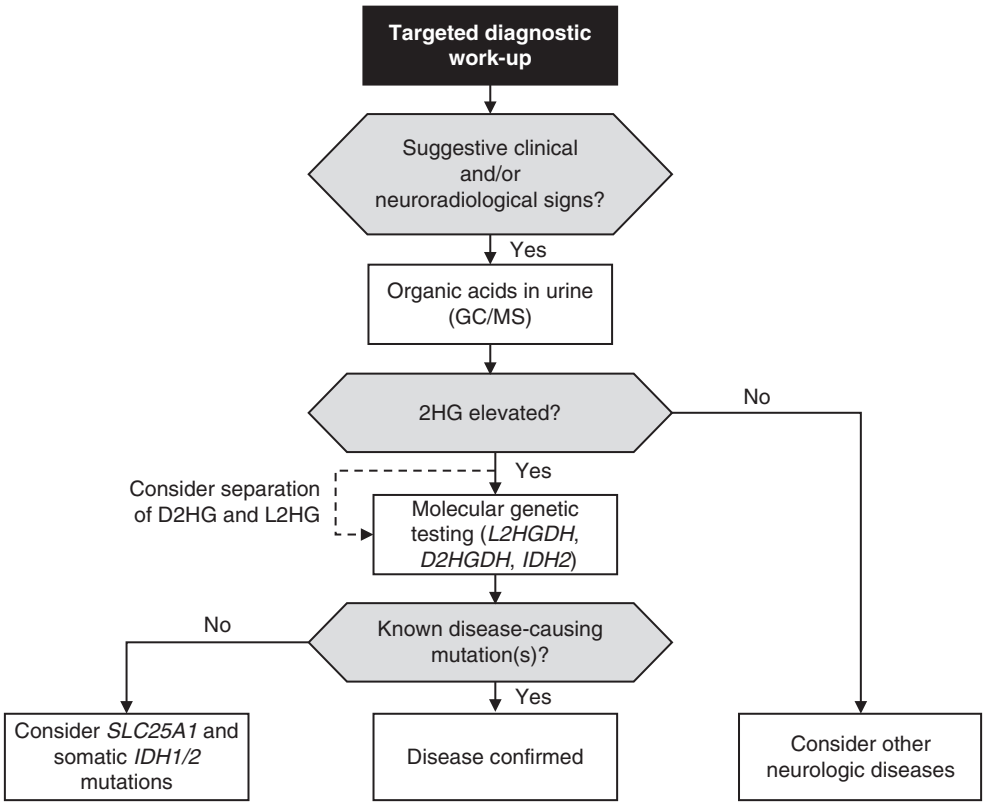

Fig. 69.7 Flowchart for diseases 69.3, 69.4 and 69.5. Elevated 2HG in GC/MS analysis of urinary organic acids is the biochemical hallmark of these diseases. According to discriminating biochemical (elevated CSF lysine and protein in L-2-hydroxyglutaric aciduria, elevated CSF GABA and elevated urinary 2-ketoglutarate in D-2-hydroxyglutaric aciduria), clinical (cardiomyopathy in D-2-hydroxyglutaric aciduria type II, progressive spasticity in L-2-hydroxyglutaric aciduria) and neuroradiologic parameters (pathognomonic MRI pattern of L-2-hydroxyglutaric aciduria), molecular genetic testing of *L2HGDH*, *D2HGDH* and *IDH2*, respectively, are often the next steps. However, enantiomeric separation and individual quantification of D2HG and L2HG may help to direct diagnostic work-up (dotted line). In case of negative molecular genetic tests, alternative diseases should also be considered including D-2−/L-2-hydroxyglutaric aciduria (caused by SLC25A1 deficiency), somatic gain-of-function mutations of the *IDH1* and *IDH2* genes in adult patients with gliomas or acute myeloid leukaemia or secondary increased D2HG in SSADH deficiency and GA-I

Specimen Collection

Disease no.	Symbol	Test	Preconditions	Material	Handling	Pitfalls
69.1	CD	Organic acids (NAA)	None	Urine	Keep frozen (−20 °C)	Compound has poor recovery in organic solvent extraction
69.2	GA-I	Quantitative amino acids	3.5–4 h postprandially, no dietary changes prior to the test	Plasma	Keep frozen (−20 °C)	
		Tryptophan	3.5–4 h postprandially, no dietary changes prior to the test	Plasma	Keep frozen (−20 °C)	Losses due to inappropriate deproteinisation
		Organic acids (3-OH-GA, GA)	None	Urine	Keep frozen (−20 °C)	Reliable identification of 3-OH-GA may require the use of a quantitative GC/MS method; differential diagnoses of elevated GA and 3-OH-GA include GA-II and GA-III, SCHAD deficiency and ketosis
		Carnitine status	None, also informs on adherence to carnitine supplementation	Plasma serum	Keep frozen (−20 °C)	
		Acylcarnitine profile (C5DC)	None	Dried blood spots Plasma	Plasma; keep frozen (−20 °C)	C5DC may be also elevated in GA-II, renal insufficiency, MCAD deficiency (pseudoglutarylcarnitinemia)
		Enzyme activity (GCDH)	None	Fibroblasts	RT	
				Leucocytes from heparinised blood	Keep frozen (−20 °C)	
69.3	L2HGA	Organic acids	None	Urine	Keep frozen (−20 °C)	For specific quantification of L2HG, enantiomeric separation, hyphenated to mass spectrometry, is required
	L2HGA	L2HG dehydrogenase activity	Isolation of cells according to specific protocol	Fibroblasts, lymphoblasts, lymphocytes	RT, pellets should be frozen	
69.4	D2HGA type I	Organic acids	None	Urine	Keep frozen (−20 °C)	For specific quantification of D2HG, enantiomeric separation, hyphenated to mass spectrometry, is required
	D2HGA type I	D2HG dehydrogenase activity	Isolation of cells according to specific protocol	Fibroblasts, lymphoblasts	RT, pellets should be frozen	
69.5	D2HGA type II	Organic acids	None	Urine	Keep frozen (−20 °C)	For specific quantification of D2HG, enantiomeric separation, hyphenated to mass spectrometry, is required. D2HG also accumulates GA-I and SSADH
	D2HGA type II	IDH2 gain-of-function assay	Isolation of cells according to specific protocol	Lymphoblasts	RT, pellets should be frozen	

3-OH-GA 3-hydroxyglutarate, *C5DC* glutarylcarnitine, *GA* glutarate, *GA-II* glutaric aciduria type II, *GA-III* glutaric aciduria type III, *GCDH* glutaryl-CoA dehydrogenase, *GC/MS* gas chromatography/mass spectrometry, *MCAD* medium-chain acyl-CoA dehydrogenase, *NAA* *N*-acetylaspartate, *SCHAD* short-chain 3-hydroxyacyl-CoA, *SSADH* succinic semialdehyde dehydrogenase deficiency

Prenatal Diagnosis

Disease no.	Symbol	Material	Timing trimester	Pitfalls
69.1	CD	Chorionic villi (accomplished)	I	Assay of aspartoacylase in amniocytes is not reliable. A combination of mutation analysis together with the exact quantitation of *N*-acetylaspartate in the amniotic fluid is recommended
		Amniotic fluid, amniocytes (accomplished)	II	
69.2	GA-I	Chorionic villi	I	
		Amniocytes, amniotic fluid	II	
69.3	L2HGA	Chorionic villi	I	
		Amniocytes, amniotic fluid	II	
69.4	D2HGA type I	Chorionic villi	I	
		Amniocytes, amniotic fluid	II	
69.5	D2HGA type II	Chorionic villi	I	Disease is usually caused by a heterozygous de novo mutation. Somatic and germline mosaicism in the parents cannot be excluded; thus, the recurrence risk for the parents is not zero. Therefore, prenatal diagnosis should always be offered
		Amniocytes, amniotic fluid	II	

In case of DNA-based prenatal diagnosis, maternal contamination should be excluded by VNTR marker analysis. Trimester one: only mutation analysis. Trimester two: a combination of metabolite and DNA investigations is recommended

DNA Testing

Disease no.	Symbol	Tissue	Methodology
69.1	CD	Lymphocytes, fibroblasts	Sequencing
69.2	GA-I	Lymphocytes, fibroblasts	Sequencing
69.3	L2HGA	Blood, lymphocytes, fibroblasts, lymphoblasts	Sequencing
69.4	D2HGA type I	Blood, lymphocytes, fibroblasts, lymphoblasts	Sequencing
69.5	D2HGA type II	Blood, lymphocytes, fibroblasts, lymphoblasts	Sequencing, targeted mutation analysis

Treatment Summary

Effective metabolic treatment has only been described for glutaric aciduria type I (low lysine diet, carnitine supplementation, emergency treatment). Riboflavin should be considered as a treatment option for patients with L-2-hydroxyglutaric aciduria aiming to activate residual enzyme activity. Treatment of patients' Canavan disease with lithium citrate, lowering brain *N*-acetylaspartate concentrations, and glycerol triacetate, supplying the brain with acetate, is considered as safe; however, it is yet unknown whether it improves the clinical outcome. Metabolic treatment for D-2-hydroxyglutaric aciduria types I and II has not yet been described.

Although effective treatment is only known for some cerebral organic acidurias, symptomatic and supportive treatment is important. This includes adequate supply with nutrient, minerals and micronutrients, physiotherapy, occupational therapy and pharmacotherapy of epilepsy and extrapyramidal movement disorder, among others. The therapeutic concept should be implemented after the assessment of individual needs and, subsequently, monitored and evaluated by an interdisciplinary team of specialists.

Emergency Treatment Table for All Disorders of Your Chapter (If Applicable) **and Medication Requirements** (A. Including Box After the Table, with Pitfalls and Important Information).

Diseases 69.1 and 69.3–69.5

No emergency treatment is available.

Disease 69.2 (GA-I)

Emergency treatment is thought to be the most effective component of the current treatment strategies to prevent acute striatal injury during infectious disease and for other causes of catabolism in glutaric aciduria type I (Heringer et al. 2010; Boy et al. 2018). It must be initiated before the onset of severe neurological signs, which already indicate the manifestation of neuronal damage. Therefore, during episodes that are likely to induce catabolism (e.g. infectious disease), emergency treatment should start without delay. Treatment should consist of frequent high carbohydrate feeds and increased carnitine supplementation, followed by high-dose intravenous glucose and carnitine (Kölker et al. 2011; Boy et al. 2017a, b). All patients with glutaric aciduria type I should be supplied with an emergency card. This concept should be strictly followed for the first 6 years of life. After this age, emergency treatment is individually adjusted.

Emergency treatment at home

A. Oral carbohydrates[a]	**Maltodextrin**			
Age (years)	%	Kcal/100 mL	KJ/100 mL	Volume (mL) per day orally
Up to 0.5	10	40	167	Min. 150/kg
0.5–1	12	48	202	120/kg
1–2	15	60	250	100/kg
2–6	20	80	334	1200–1500
B. Protein intake				
Natural protein	Stop for max. 24 (−48) h, and then reintroduce and increase stepwise until the amount of maintenance treatment is reached within 48 (−72) h			
AAM	If tolerated, AAM should be administered according to maintenance therapy			
C. Pharmacotherapy				
l-carnitine	Double oral carnitine supplementations			

According to Kölker et al. 2011; Boy et al. 2017a, b
[a]Solutions should be administered every 2 h day and night. Patients should be reassessed every 2 h. AAM, lysine-free, tryptophan-reduced amino acid mixtures

Emergency treatment in hospital (according to Kölker et al. 2011; Boy et al. 2017a, b).

A. Intravenous infusions		
Glucose	Age (years)	Glucose (g/kg per day IV)
	0–1	(12–)15
	1–3	(10–)12
	3–6	(8–)10
Insulin	If persistent hyperglycaemia >150 mg/dL (>8 mmol/L) and/or glucosuria occurs, start with 0.05 IE insulin/kg per h IV, and adjust the infusion rate according to serum glucose	
B. Protein intake		
Natural protein	Stop for max. 24 (−48) h, and then reintroduce and increase stepwise until the amount of maintenance treatment is reached within 48 (−72) h	
AAM	If tolerated, AAM should be administered orally or by nasogastric tube according to maintenance therapy	
C. Pharmacotherapy		
l-carnitine	100(−200) mg/kg per day IV	

AAM lysine-free, tryptophan-reduced amino acid mixtures.

Standard Treatment Table for All Disorders of Your Chapter (If Applicable) **and Medication Requirements** (A. Including Box After the Table, with Pitfalls and Important Information).

Diseases 69.1, 69.3, 69.4 and 69.5

No specific treatment is available.

Disease 69.2 (GA-I)

Disorder no.	Symbol	Age	Medication/diet	Dosage	Doses/day (*n*)
69.2	GA-I	<6 years	Carnitine	(50–)100 mg/kg per day	3
		>6 years	Carnitine	(30–)50 mg/kg per day	3
			Riboflavin[a]	100 mg	2
			Treatment of extrapyramidal movement disorders[b]		
			Antiepileptic treatment[c]		
			Diet (see below)		

[a]Riboflavin is not a recommended therapy in glutaric aciduria type I since riboflavin responsiveness seems to be very rare (if at all present) and no standard protocol exists to test it. There is no proven clinical benefit of riboflavin supplementation (Kölker et al. 2006)
[b]The complex movement disorder of symptomatic patients with glutaric aciduria type I is difficult to treat. Baclofen and benzodiazepines as monotherapy or in combination are often used as first-line drug treatment for focal and generalised dystonia. Intrathecal baclofen is used for additional therapy in individuals with generalised dystonia and spasticity. Trihexyphenidyl can be considered as second-line treatment for dystonia, particularly in adolescents and adults, and botulinum toxin A injections as additional therapy for severe focal dystonia (according to Kölker et al. 2011; Boy et al. 2017a, b)
[c]The risk of epilepsy is mildly elevated in glutaric aciduria type I. Dystonic and epileptic movements, however, may be confused with seizures. Indication, prescription and monitoring of antiepileptic treatment should be performed by a child neurologist or neurologist. Valproate is not recommended due to the theoretical risk of mitochondrial dysfunction and secondary carnitine depletion

Dietary treatment (low lysine diet, according to Kölker et al. 2011; Boy et al. 2017a, b).

Treatment	Dosage	Age				
		0–6 months	7–12 months	1–3 years	4–6 years	>6 years
Lysine (from natural protein)[a]	mg/kg per day	100	90	80–60	60–50	Controlled protein intake using natural protein with a low lysine content and avoiding lysine-rich food
Protein from amino acid mixtures[b]	g/kg per day	1.3–0.8	1.0–0.8	0.8	0.8	
Energy	Kcal/kg per day	100–80	80	94–81	86–63	
Micronutrients[c]	%	≥100	≥100	≥100	≥100	≥100

[a]The lysine/protein ratio (i.e. 2–9 mg lysine/100 mg protein) varies in natural food, and thus natural protein intake in children on a low lysine diet is dependent on the natural protein source

[b]Lysine-free, tryptophan-reduced amino acid mixtures should be supplemented with minerals and micronutrients as required to maintain normal levels. Safe intakes of essential amino acids are provided from natural protein and lysine-free, tryptophan-reduced amino acid supplements

[c]According to dietary recommendations

Dangers/Pitfalls

1. Dietary treatment needs to be adapted to the individual needs, in particular in dystonic patients. Overtreatment by protein restriction may result in malnutrition with essential nutrients.
2. Dysphagia is a frequent problem in dystonic patients. Tube feeding (via nasogastric tube or percutaneous gastrostomy) should be considered if oral food intake is inadequate.

Experimental Treatment

Disease no.	Symbol	Alternative therapies/experimental trials
69.1	CD	Lithium citrate
		Glycerol triacetate
		rAAV-based gene therapy (translational and preclinical studies)
69.2	GA-I	Arginine or homoarginine supplementation has yet only been studied in Gcdh-deficient mice, an animal model for GA-I, and in a small number of patients (arginine). The safety and efficacy of arginine supplementation as well as optimal dosage are unknown
69.3	L2HGA	Riboflavin supplementation
69.4	D2HGA type I	On the basis that D2HG dehydrogenase is an FAD-dependent enzyme, riboflavin supplementation is a therapeutic option
69.5	D2HGA type II	AGI-026, a mutant IDH2 protein inhibitor of the human IDH2R140Q-mutant enzyme, suppressed 2HG production, rescued cardiomyopathy and provided a survival benefit in Idh2R140Q mice (translational and preclinical studies)

3-Methylglutaconic Acidurias

70

Saskia B. Wortmann and Johannes A. Mayr

Contents

Summary

Increased urinary 3-methylglutaconic acid excretion is a relatively common finding in inborn errors of metabolism, especially in mitochondrial disorders. In most cases 3-methylglutaconic acid is only slightly elevated and accompanied by other (disease-specific) metabolites.

There is, however, a group of disorders with significantly and consistently increased 3-methylglutaconic acid excretion, where the 3-methylglutaconic aciduria is a hallmark of the phenotype and the key to diagnosis: inborn errors with 3-methylglutaconic aciduria as a discriminative feature (3-MGA-IEM). One should distinguish between "primary 3-methylglutaconic acidurias" formerly known as type I (3-methylglutaconyl-CoA hydratase deficiency, AUH defect) due to defective leucine catabolism and the—currently known— 11 "secondary 3-methylglutaconic acidurias." The latter should be further classified and named by their defective protein or the historical name as follows: TAZ-defect or Barth syndrome, SERAC1-defect or MEGDEL syndrome, AGK-defect or Sengers syndrome, OPA3-defect or Costeff syndrome, TMEM70, MICOS13, DNAJC19, TIMM50, and HTRA2 defect.

Introduction

The branched-chain organic acid 3-methylglutaconic acid (3-MGA) is an intermediate of the mitochondrial leucine catabolism. In the urine of healthy individuals, 3-MGA is found only in traces (<20 mmol/mol creatinine); in young infants it can be higher (up to 30 mmol/mol creatinine) as the creatinine is relatively lower due to lower muscle mass.

In patients with inborn errors with 3-methylglutaconic aciduria as a discriminative feature **(3-MGA-IEM)**, urinary 3-MGA concentrations can (intermittently) rise above 1000 mmol/mol creatinine (Wortmann et al. 2013a, b).

The leucine pathway shows the metabolic pathway of leucine. 3-MGA, 3-methylglutaric acid (3-MG), and 3-hydroxyisovaleric acid (3-HIVA) accumulate when the conversion of 3-methylglutaconyl-CoA to 3-hydroxy-3-methylglutaryl-CoA by the enzyme 3-methylglutaconyl-CoA hydratase (3-MGH, EC 4.2.1.18 encoded by *AUH*) is disturbed (Fig. 70.1) (Wortmann et al. 2010). This is the primary 3-methylglutaconic aciduria (3-MGA-uria) or AUH-defect, formerly known as 3-MGA-uria type I. **The urinary excretion of 3-MGA is generally higher in primary 3-MGA-IEM, AUH defect, than in all other (secondary) 3-MGA-IEM.** Patients with AUH defect excrete even higher amounts of urinary 3-MGA after a leucine-rich, or in general a protein-rich, meal (Table 70.12) (Wortmann et al. 2014). This is not the case in all other patients with 3-MGA-uria underlining that the excreted 3-MGA does not originate from leucine degradation. Another distinctive feature between primary and secondary 3-MGA-IEM is the elevation of 3-HIVA which is only seen in the AUH defect.

3-MGA-uria can be frequently seen (3% of all urine samples of patients with suspected IEM) in association with several IEM, such as organic acidurias, glycogen storage disorders, fatty acid oxidation disorders, and urea cycle disorders (Fig. 70.1 classification updated from) (Wortmann et al. 2013a, b). Therefore it is important to repeat urinary organic acid analysis in patients with 3-MGA-uria and to carefully interpret the other general clinical chemistry (blood gas analysis, glucose, lactate, ammonia, full blood counts, etc.) and metabolic screening tests (serum amino acids, acylcarnitines in dried blood spot, oligosaccharides in urine). This will allow to confirm that 3-MGA-uria is only an accompanying finding.

In another group of patients, 3-MGA-uria is only slightly and/or intermittently elevated, and 3-MGA-uria is a minor finding. The majority of patients in this group are patients with mitochondrial disorders where it is detected in about 11% of all patients. It is more frequently seen in ATPase-related disorders, with mitochondrial DNA depletion or deletion (e.g., Pearson syndrome), but not in patients with single respiratory chain complex deficiencies with exception of ATPase-related disorders (Wortmann et al. 2013a, b). As 3-MGA-uria is not found in all of these patients with the mentioned specific mitochondrial disorders, these disorders are discussed and not here.

Once 3-MGA-uria has been proven to be an isolated and consistently present finding, 3-MGA-uria as a major finding, the diagnosis of a 3-MGA-IEM can be made. One subgroup is formed by the disorders involving defective phospholipid biosynthesis (*TAZ*, *SERAC1*, *AGK*) (Clarke SL et al. 2013; Thiels C et al. 2016; Mass RR et al. 2017; Roeben B et al. 2018; Wortmann SB et al. 2015; Wortmann SB et al. 2012; Haghighi A et al. 2014; Mayr JA et al. 2012), all other 3-MGA-IEM share mitochondrial (membrane) dysfunction (*OPA3*, *DNAJC19*, *CLPB*, *HTRA2*, *TIMM50*, *TMEM70*, *MIC13*, Fig. 70.2) (Anikster et al. 2006; Ucar SK et al. 2017; Davey KM et al. 2006; Pronicka E et al. 2017; Wortmann SB et al. 2015; Kovacs-Nagy R et al. 2018; Shahrour MA et al. 2017; Magner M et al. 2015; Kishita Y et al. 2020). There are no additional (metabolic) clues that can help to further distinguish between the different types of 3-MGA-IEM with exception of the clinical features (see table on differential diagnosis at the section signs and symptoms). All 3-MGA-IEM show a distinctive pattern of signs and symptoms which allows to distinguish between them; however patients affected by the different 3-MGA-IEM show a spectrum within their subtype (Fig. 70.1).

Nomenclature

No.	Disorder_name	Alternative name	Gene symbol	Chromosomal location	Mode of Inheritance	Affected protein	OMIM No.
70.1	AUH deficiency	3-methylglutaconic aciduria type 1	*AUH*	9q22.31	AR	3-methylglutaconyl-CoA hydratase	600529
70.2	TAZ deficiency	Barth syndrome; Taffazin deficiency	*TAZ*	Xq28	XLR	Taffazin	300394
70.3	SERAC1 deficiency	3-methylglutaconic aciduria with dystonia, deafness, hepatopathy, encephalopathy, and Leigh-like syndrome (MEGDHEL)	*SERAC1*	6q25.3	AR	Serine active site-containing protein 1	614725
70.4	AGK deficiency	Sengers syndrome	*AGK*	7q34	AR	Acylglycerokinase	212350
70.5	OPA3 deficiency	Optic atrophy type 3 (dominant); 3-methylglutaconic aciduria type 3, Costeff syndrome (recessive)	*OPA3*	19q13.2–13.3	AD, AR		606580
70.6	DNAJC19 deficiency	Dilated cardiomyopathy with ataxia (DCMA syndrome); 3-methylglutaconic aciduria type 5	*DNAJC19*	3q26.33	AR	- DNAJ/HSP40 homolog, subfamily C, member 19	608977
70.7	CLPB deficiency	3-methylglutaconic aciduria type 7, with cataracts, neurologic involvement and neutropenia	*CLPB*	11q13.4	AR	- Caseinolytic peptidase B	616254
70.8	HTRA2 deficiency	3-methylglutaconic aciduria type 8	*HTRA2*	2p13.1	AR	- HTRA serine peptidase 2	606441
70.9	TIMM50 deficiency	3-methylglutaconic aciduria type 9	*TIMM50*	19q13.2	AR	Translocase of inner mitochondrial membrane 50	607381
70.10	TMEM70 deficiency	Transmembrane protein 70 deficiency	*TMEM70*	8q21.11	AR	Complex V assembly protein	612418
70.11	MICOS13 deficiency	MICOS complex subunit MIC13 deficiency	*MICOS13*	19p13.3	AR	MICOS complex, 13-KD subunit	618329

[a]All patients died (maximum age 13 months)

Reference Values

Metabolite	Reference value
3-Hydroxyisovaleric acid (U)	0–25 mmol/mol creatinine (0–2 month) 0–50 mmol/mol creatinine (2 months–2 years) 0–45 mmol/mol creatinine (2–10 years) 0–15 mmol/mol creatinine (10–18 years) 0–20 mmol/mol creatinine (> 18 years) (GCMS, TML laboratory, Radboud university, Nijmegen, NL)
3-Methylglutaconic acid (U)	0–20 mmol/mol creatinine (0–2 month) 0–15 mmol/mol creatinine (2 months–2 years) 0–10 mmol/mol creatinine (>2 years) (GCMS, TML laboratory, Radboud university, Nijmegen, NL)
3-Methylglutaric acid (U)	Absent, if present not quantified (GCMS, TML lab, Radboud University, Nijmegen, NL)

Pathological Values

Metabolite	Pathological value
3-Methylglutaconic acid (U)	20–40 mmol/mol creatinine: Suggestive for mitochondrial dysfunction as it can be seen in numerous inborn errors of metabolism > 40 mmol/mol creatinine: Suggestive for inborn error of metabolism with 3-methylglutaconic aciduria as discriminative feature

Leucine Loading Test

Indication: To distinguish between primary and secondary 3-methylglutaconic aciduria.

Procedure: Collect a urine portion for urinary organic acid analysis and a venous blood sample for serum amino acids. Give 100 mg/kg (max. 6 g) leucine powder orally, and repeat listed investigations 1 h after the leucine gift. Collect a 24-h urine sample for another urinary organic acid analysis.

Interpretation: Table below lists the typical findings before and after leucine loading in several 3-methylglutaconic acidurias. Only in primary 3-MGA_uria due to AU deficiency a clear increase in urinary 3-MGA occurs.

Results of the leucine loading tests in different 3-methylglutaconic acidurias

Defect	Elevated urinary 3-HIVA	Lowest urinary 3-MGA before loading (Ref < 20 mmol/mol creatinine)	Peak urinary 3-MGA after loading (Ref < 20 mmol/mol creatinine)	Ratio *cis:trans* isoforms of 3-MGA	Mean ratio (range, N patients)
AUH	+	400	2982	2:1	4.1 (3.9–4.5; *N* = 3)
TAZ	–	32	192	1:1	1.8 (1.1–5.3; *N* = 9)
OPA3	–	29	26	1:1	0.9 (*N* = 1)
SERAC1	–	60	234	1:1	1.3 (1.3–1.3; *N* = 2)
CLPB	–	52	53	1:1	1.0 (*N* = 1)
NOS	–	21	410	1:1	1 (0.5–1.1; *N* = 5)

3-HIVA 3-hydroxyisovaeleric acid, *3-MGA* 3-methylglutaconic acid

Specimen Collection

Urine for organic acid analysis should be analyzed immediately or frozen at –20 °C.

DNA Testing

All 3-MGA-IEM show a distinctive pattern of signs and symptoms which justifies single gene testing. In less clear presentations, the whole exome or genome sequencing (WES/WGS) is the method of choice. As both point mutations and deletion(s) in the mitochondrial DNA can cause disorders with unspecific 3-methylglutaconic aciduria, one should inquire at the genetic lab and make sure that the genetic test chosen covers these. Leucocyte-derived DNA from 3–5 ml EDTA blood (children, adults) will be enough for all mentioned genetic tests, and WGS can be performed in much less blood even from a dried blood spot.

Treatment Summary

AUH defect is a disorder of leucine catabolism. Acute deteriorations in relation to catabolism as in other intoxication-type IEM has not been described. The clinical manifestation is an adult-onset (fourth decade onwards) slowly progressive leukoencephalopathy with ataxia and spasticity (Wortmann et al. 2010). A leucine-restricted diet or a protein-defined (vegetarian) diet could be considered; data on this are lacking and will be difficult to obtain. In general, only a supportive treatment is available for all 3-MGA-IEM.

Biochemical Phenotypes of Questionable Clinical Significance

71

Contents

Abstract

Most of the many known inherited metabolic defects are associated with clinical disease; a few, however, are not—or their association with clinical disease is tenuous at best.

The latter include iminoglycinuria, hyperprolinemia type I, hydroxyprolinemia, histidinemia, urocanic aciduria, FIGLU-uria, trimethylaminuria, dimethylglycinuria, sarcosinemia, hyperlysinemia and saccharopinuria, 2-aminoadipic and 2-ketoadipic aciduria, glutaric aciduria type 3, hydroxykynureninuria, cystathioninuria, 3-methylcrotonylglycinuria and 2-methylglycinuria, as well as deficiencies of carnosinase, oxoprolinase, glycerol kinase, methionine adenosyltransferase, methylmalonyl-CoA epimerase, and short-chain acyl-CoA dehydrogenase (SCAD).

Only time will tell us if some of the disorders now considered pathogenic are not and if some of the former indeed cause clinical disease—perhaps in adulthood.

Stephen I. Goodman was deceased on October 30, 2020.

Introduction

It is noteworthy that one of the four inborn errors that comprise Garrod's tetrad is pentosuria, a biochemical abnormality whose primary clinical importance is its occasional misdiagnosis as diabetes mellitus. Several other inborn errors have little if any clinical relevance. In many of them, however, this realization has followed a lengthy period during which they were thought to cause disease, and in most cases, the problem has been one of sampling bias.

The first subject to be described with a novel inborn error is almost invariably screened because of clinical disease, and any biochemical abnormality that is detected may initially be thought of as linked to the clinical phenotype. In some cases, the perceived association is strengthened or weakened by studying other family members, particularly siblings, but in most cases the link between biochemical and clinical phenotype remains an open issue until, with the passage of time, more individuals with the defect are recognized. And this can take a long time. Biochemical phenotypes such as hydroxylysinemia (Goodman et al. 1972), phosphohydroxylysinuria (Dorland et al. 1990), and beta-mercapto-

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,

cysteine-lactate disulfiduria (Crawhall et al. 1968), despite their initial descriptions more than 20 years ago, are too infrequently reported to allow firm conclusions about pathogenicity.

Newborn screening programs have compressed the timeline considerably, and it is now possible to detect a biochemical defect in infancy and to follow its effect, if any, on clinical phenotype. Such programs have also identified many enzyme-deficient subjects who would likely not have come to clinical attention, such as the clinically unaffected females with 3-methylcrotonylglycinuria and glutaric acidemia type 1 whose infants tested positive for hydroxy-C5 carnitine ester and low carnitine, respectively.

This chapter will attempt to describe the biochemical phenotypes of some inborn errors whose clinical relevance is in question. Some, like hydroxykynureninuria, are primarily of historical importance, although recognition of an abnormal compound in amino or organic acid analysis can cause consternation to patient and physician alike. Much of what we write reflects the authors' personal views of what is now known about these conditions, and it may well be that a condition that we now think is of questionable clinical significance will on more intense and detailed study revert. An excellent example of the latter is hyperprolinemia type II, in which an early impression that patients tended to have seizures was confirmed and shown to be due to sequestering of vitamin B_6 by accumulated Δ^1-pyrroline-5-carboxylic acid. A continuing discussion of the topics will almost certainly keep the field alive and fascinating.

Disorders

Iminoglycinuria

Iminoglycinuria, i.e., increased amounts of proline, hydroxyproline, and glycine in urine, is most commonly seen in (premature) infants, when it is due to the immaturity of a shared renal tubular transporter for these amino acids. Iminoglycinuria due to tubular immaturity usually disappears by 1 year of age. It can also be seen in hyperprolinemia types I and II, when elevated proline in the glomerular filtrate saturates a transporter and competitively inhibits tubular reabsorption of glycine and hydroxyproline and when a transporter fails to operate properly due to mutation. The latter is called familial iminoglycinuria and is inherited as an autosomal recessive trait. Depending on which transporter is involved, the defect may also be expressed in the small intestine. Heterozygotes sometimes have hyperglycinuria without hyperglycinemia. While occasionally found in symptomatic individuals, familial iminoglycinuria is probably without clinical significance.

The condition is easily recognized on urine amino acid analysis by the increases in proline, hydroxyproline, and glycine, accompanied by a normal concentration of proline in blood. Hyperprolinemia type I (see below) and iminoglycinuria of the newborn are clinically benign, so the only clinically relevant condition that must be excluded in an individual with iminoglycinuria is hyperprolinemia type II. This is usually quite simple, as plasma proline is very high in hyperprolinemia type II, and Δ^1-pyrroline-5-carboxylic acid (P5C) and Δ^1-pyrroline-3-hydroxy-5-carboxylic acid (hydroxy-P5C) are increased in urine.

P5C and hydroxy-P5C in the urine appear as discrete peaks on amino acid analysis and also cause the urine to react positively with *o*-aminobenzaldehyde (Efron 1965). When using sodium citrate buffers, hydroxy-P5C elutes just after hydroxyproline, and P5C elutes just before proline (Goodman et al. 1974). The urine organic acid analysis of hyperprolinemia patients will reveal the presence of pyrrole-5-carboxylglycine, possibly the most accessible characteristic metabolite.

Hyperprolinemia Type I

Hyperprolinemia type I (HPI) is due to a defect in proline oxidase, a FAD-containing mitochondrial protein found mainly in the liver, kidney, and brain that converts proline to Δ^1-pyrroline-5-carboxylic acid (P5C). The condition was initially described in a patient with Alport-like renal disease (Schafer et al. 1962) and was subsequently reported in patients with a wide variety of renal and nonrenal manifestations, including eye abnormalities, developmental delay, and other neurologic manifestations. Evidence from subjects identified by newborn screening shows that HPI is usually benign (e.g., Fontaine et al. 1970), and the early association with clinical phenotypes is now thought to have been due to sampling bias although the reports about the association of this defect with various clinical problems such as epilepsia and schizophrenia are still appearing. The condition's primary importance is that it must be differentiated from hyperprolinemia type II, in which a defect in P5C dehydrogenase is often associated with intellectual disability and/or seizures.

The condition is easily recognized by finding increased proline (500–2000 μM; normal <420) on amino acid analysis of plasma, usually accompanied by increased proline, hydroxyproline, and glycine in urine. Iminoglycinuria is due to the saturation of the renal transporter for proline, hydroxy-

proline, and glycine by the increased proline in the glomerular filtrate.

Plasma proline concentrations in hyperprolinemia type II are often higher (>1300 μM), and the urine contains P5C, hydroxy-P5C, and pyrrole-5-carboxylglycine (see above).

Hydroxyprolinemia

Hydroxyprolinemia was described in 1962 (Efron et al. 1962) in association with intellectual disability and has since been described in several additional subjects with a variety of clinical manifestations and in several healthy hydroxyprolinemic siblings (Kim et al. 1997). In addition, one hydroxyprolinemic baby has been detected by newborn screening and continues to be clinically normal. It is now thought that, as with hyperprolinemia type I, deficiency of hydroxyproline oxidase does not cause clinical disease and that the early association with the disease was due to sampling bias.

As in proline oxidation, hydroxyproline is normally oxidized first to Δ^1-pyrroline-3-hydroxy-5-carboxylic acid by hydroxyproline oxidase and then to hydroxyglutamic semialdehyde by Δ^1-pyrroline-5-carboxylic dehydrogenase, the enzyme in the proline pathway that is deficient in hyperprolinemia type II.

Hydroxyprolinemia, which is inherited as an autosomal recessive trait, causes elevations of hydroxyproline in plasma and urine, without iminoglycinuria and with a normal excretion of peptide-bound hydroxyproline. Its diagnosis is relatively simple and depends on demonstrating high hydroxyproline in plasma (200–500 μM; normal <50) and urine.

Histidinemia

Histidinemia, first described in two siblings by Ghadimi et al. (1961), was thought in the past to cause speech defects as an almost specific clinical phenotype. As more subjects with the condition have been found, however, many of them by newborn screening programs, it has been learned that most enzyme-deficient individuals have normal intelligence and speech (Ishikawa 1987), and it is now thought that the condition is benign in most instances.

Histidine is deaminated to *trans*-urocanic acid by histidase (histidine ammonia-lyase), an enzyme found mainly in the liver and in the stratum corneum of the skin, but further metabolism of urocanic acid to 5-formyl-tetrahydrofolate and glutamate via imidazolone propionic acid and formiminoglutamic acid (FIGLU) appears to occur only in the liver. Histidinemia is caused by histidase deficiency. The enzyme defect is transmitted as an autosomal recessive trait.

Biochemical findings in histidinemia, which is the most common inborn error in Japan, include increased histidine in plasma, urine and cerebrospinal fluid, low concentrations of urocanic acid in blood and sweat, and increased concentrations of histidine metabolites such as imidazole pyruvic acid in urine. Enzyme-deficient subjects differ widely in their plasma histidine levels and tolerance to oral histidine loads, and this may well be due to differences in mutations and residual enzyme activity.

Histidine can be as high as 1500 μM (normal <150). The increased imidazole pyruvic acid in urine can usually be detected by the ferric chloride test or the Phenistix reagent strip. Diagnosis can be confirmed, if necessary, by demonstrating histidase deficiency in the skin and by mutation analysis (Kawai et al. 2005). Treatment with a histidine-restricted diet normalizes the biochemical phenotype but is not indicated for what is most likely a harmless condition.

Urocanic Aciduria

Urocanic aciduria, which is caused by a deficiency of urocanase, is characterized by increased urocanic acid in urine, with normal or slightly increased concentrations of histidine in plasma and urine. Said to be very rare, the condition is probably underdiagnosed because the increased urocanic acid cannot be detected by the usual methods used to screen for amino and organic acids in blood and urine. Older methods used thin-layer chromatography and staining with the Pauly reagent, but more specific HPLC methods have also been developed (e.g., Kuracka et al. 1996). Urocanic acid can appear in the HPLC analysis of urine purines and pyrimidines using UV detection. Alternatively, NMR analysis of a urine sample will readily detect an increased urocanic acid (UF Engelke, SSIEM-symposium Istanbul 2010). While initially diagnosed in retarded individuals, several children identified by newborn screening have developed normally without therapy, and the enzyme defect is now thought to be benign in most instances.

The condition is apt to be detected during the investigation of increased histidine in blood and/or urine, when increased urocanic acid is found in urine instead of the decrease expected in histidinemia, which is much more common. Diagnosis can be confirmed by demonstrating reduced enzyme activity in the liver or by molecular analysis of the *UROC1* gene (Espinós et al. 2009).

Glutamate Formiminotransferase-Cyclodeaminase Deficiency (FIGLU-Uria)

Increased excretion of formimino-L-glutamic acid (FIGLU), an intermediate in the oxidation of histidine, was first noted to result from an inherited deficiency of formiminotransferase-cyclodeaminase (FTCD) when amino acid analysis became routine when evaluating children with developmental disabilities. The compound does not react with ninhydrin but quickly breaks down to glutamate during many analytic procedures. FIGLU excretion is also increased in folic acid and B_{12} deficiency and in cblC disease (see Chaps. 21 and 29).

FTCD deficiency is a relatively common recessively inherited defect of histidine metabolism and has both severe and mild phenotypes, with the former characterized by megaloblastic anemia, intellectual disability, and elevated urine FIGLU following a histidine load. The mild phenotype includes high FIGLU in blood and urine without loading, and, if developmental delay is present, it is mild.

Elevated FIGLU is now most frequently encountered during analysis of plasma acylcarnitine esters (Malvagia et al. 2006). If folic acid deficiency and cblC disease are eliminated by appropriate studies, confirmation of the defect can be by enzyme analysis in the liver or by molecular analysis of the *FTCD* gene (Hilton et al. 2003). An additional diagnostic marker is urine hydantoin-5-propionic acid, a metabolite of imidazolone-propionic acid which is easily detected by urine organic acid analysis.

Carnosinase Deficiency and Homocarnosinosis

Formerly thought to be two conditions, carnosinase deficiency and homocarnosinosis are now thought to be variants of the same disorder. Carnosine is a dipeptide of β-alanine and histidine and is present in several human tissues, including the skeletal muscle and brain. Homocarnosine (γ-aminobutyryl-L-histidine) exists only in the brain and in amounts much larger than those of carnosine. Both dipeptides can be hydrolyzed by carnosinase (EC 3.4.13.20), an enzyme that is present in plasma and several tissues, including the brain, and encoded by the *CN1* gene on human chromosome 18. A closely related *CN2* gene is located near CN1 and encodes a much less specific dipeptidase that hydrolyzes carnosine only under non-physiological conditions (Teufel et al. 2003).

Carnosinemia and carnosinuria due to recessively inherited deficiency of carnosinase were initially described in patients with neurological disease (Perry et al. 1967) but have since been observed repeatedly in normal subjects. It is now thought that any relationship to clinical symptoms is fortuitous. Homocarnosinosis, which may be caused by a more severe deficiency of the same enzyme, is much less common and is characterized by increased homocarnosine (the major form of bound GABA) in the cerebrospinal fluid and increased carnosine in urine. It has been described only once, in a healthy 72-year-old woman and in three of her four children. All three children, but not their mother, had recessively inherited hereditary spastic paraplegia due to mutations in the *SPG11* gene (Sjaastad et al. 2018); the specific cause of the elevated CSF homocarnosine, however, remains obscure.

Persistent carnosinemia (0.005–0.03 μM; normal = not detected) and carnosinuria on a meat- (and therefore carnosine-) free diet strongly suggest a diagnosis of carnosinase deficiency, which is easily confirmed by enzyme assay. CSF homocarnosine in such individuals is normal, i.e., less than 15 μM. Because serum carnosinase also hydrolyzes anserine, a dipeptide of β-alanine and 1-methyl-L-histidine found in the skeletal muscle of birds and some mammals, normal subjects excrete 1-methylhistidine in urine after eating fowl. Carnosinase-deficient subjects do not, however, and instead excrete intact anserine. Because enzyme activity is low in infancy and increases gradually to achieve adult levels in adolescence, it is important to compare enzyme activity with appropriate age-matched control data.

A diagnosis of homocarnosinosis will initially be suggested by increased carnosine in urine, even on a meat-free diet, accompanied by elevated homocarnosine in cerebrospinal fluid (50–75 μM; normal <15). As in serum carnosinase deficiency, anserine is excreted intact after eating anserine-containing foods.

Trimethylaminuria

Trimethylaminuria is a recessively inherited condition in which absorbed trimethylamine (TMA), formed by gut bacteria from dietary precursors such as lecithin and choline, accumulates behind a defect in flavin-containing monooxygenase 3 (FMO3), the enzyme that oxidizes TMA to TMA N-oxide (TMAO). TMA is not toxic to tissues but is highly volatile, and FMO3-deficient subjects develop a pungent odor similar to that of rotting fish. Sometimes called "fish odor syndrome," the condition causes severe social stigmatization and psychological distress to the affected individuals and to their families.

Usually suspected because of the odor, diagnosis is made by demonstrating an abnormal ratio of TMA:TMAO in urine at rest or after a choline load; the latter is particularly useful when the odor is intermittent or mild and can consist most simply of a marine fish meal. The analysis of TMA and TMAO in urine can be quite cumbersome but a recently described

method using tandem mass spectrometry (Johnson 2008) appears to be simple, quick, and accurate. Alternatively, an in vitro NMR analysis of the urine will unequally demonstrate the presence of TMA (see below). There is normally much more TMAO in urine than TMA, so the TMAO:TMA + TMAO ratio in normal subjects exceeds 0.92. The ratio in severely enzyme-deficient subjects can be as low as 0.04.

Several polymorphisms as well as severe and mild mutations have been described in the *FMO3* gene, and the latter usually correlate with the severity of the metabolic block (Hernandez et al. 2003). Treatment is by restricting the intake of high choline- and lecithin-containing foods, in particular fish, dairy products, eggs, and chocolate, and eliminating bacterial TMA production by gut sterilization.

Dimethylglycinuria

Dimethylglycine (DMG) is formed by the transfer of a methyl group from betaine, a choline metabolite, to homocysteine, forming methionine. DMG is then converted to sarcosine by oxidative demethylation catalyzed by DMG dehydrogenase, a flavin-containing enzyme that requires folate as a cofactor. Sarcosine is converted to glycine by a similar and related enzyme. Electrons from the flavins of DMG and sarcosine dehydrogenase enter the respiratory chain via electron transfer flavoprotein (ETF) and ETF-ubiquinone oxidoreductase. Increased excretion of DMG has been observed in folate deficiency and in subjects receiving large doses of betaine as a therapeutic agent. Theoretically one should expect DMG to accumulate in the multiple acyl-CoA dehydrogenation defect (MADD, glutaric aciduria type II), but this has not been confirmed so far.

Dimethylglycinemia and -uria due to deficiency of dimethylglycine dehydrogenase has been observed only once, in an adult (Moolenaar et al. 1999) with a fishlike odor, chronic muscle fatigue, and increased serum creatine kinase. A search for trimethylamine in urine by ^{1}H-NMR spectroscopy instead detected an approximately 20-fold increase of DMG (450 mmol/mol creatinine; normal <26) and was confirmed by GC-MS of the trimethylsilyl derivative. DMG was increased 100-fold in plasma (221 μM; normal <5), and molecular analysis showed homozygosity for an inactivating mutation in the *DMGDH* gene (Binzak et al. 2001).

Except for the "fish odor," which is characteristic of dimethylglycine, the relationship between the enzyme deficiency and the rest of the clinical phenotype is not clear and may well be fortuitous. The diagnosis should probably be considered in the many patients with a fishlike odor who do not have trimethylamine oxidase deficiency.

Sarcosinemia

Sarcosine (monomethylglycine) is converted to glycine, with the oxidation of its methyl group to "active" formaldehyde by sarcosine dehydrogenase, a mitochondrial flavoprotein from which electrons enter the respiratory chain through electron chain flavoprotein (ETF) and ETF:ubiquinone oxidoreductase (ETF:QO). Like dimethylglycine dehydrogenase, the enzyme requires folate as a cofactor.

Sarcosinemia, a biochemical phenotype characterized by increased sarcosine in blood and urine, was first described in a 10-month-old child (Gerritsen and Waisman 1966) with intellectual disability and hypertonia and was subsequently reported in association with a variety of clinical phenotypes and a variable association with developmental issues. More recently it has been identified by newborn screening in developmentally normal subjects (Levy et al. 1984), and it is now thought that the biochemical phenotype is without clinical effect in most instances. The enzyme defect has not been demonstrated in affected individuals, but several pathogenic mutations have now been demonstrated in the *SARDH* gene (Bar-Joseph et al. 2012).

Increased sarcosine is also occasionally found in the multiple acyl-CoA dehydrogenation defect (MADD, glutaric aciduria type II), and it is important that the finding of increased sarcosine in blood and/or urine be followed by a careful search for the organic acids and/or acylcarnitine esters characteristic of GA2.

Not normally detectable in plasma or urine, plasma sarcosine levels in sarcosinemia range from 50 to 700 μM, and urine excretion ranges from 170 to 5080 mmol/mol creatinine.

Hyperlysinemia and Saccharopinuria

The initial steps in the mitochondrial oxidation of lysine in the liver and kidney are catalyzed by a single bifunctional enzyme, i.e., 2-aminoadipic semialdehyde synthase. The first reaction is a condensation of lysine with 2-ketoglutarate, carried out by lysine-2-ketoglutarate reductase, to form saccharopine, and the second, catalyzed by saccharopine dehydrogenase, releases glutamate and 2-aminoadipic semialdehyde. Recessively inherited mutations in the bifunctional enzyme cause familial hyperlysinemia when the first or both activities are deficient and saccharopinuria when appreciable residual activity is retained only in the first.

Although hyperlysinemia with and without saccharopinuria were initially recognized in mentally retarded children (Woody 1964; Carson et al. 1968), it soon became apparent that many patients with hyperlysinemia who were diagnosed

subsequently, some of whom were ascertained through newborn screening programs, were clinically normal and that the initial association of hyperlysinemia with neurodevelopmental abnormalities may well have been due to ascertainment bias (Dancis et al. 1983). This may also be true of saccharopinuria, in which the added metabolite is rapidly cleared by the kidney, but we do not know of a large study that has demonstrated this conclusively.

Plasma lysine in hyperlysinemia often exceeds 1000 μM (normal <250) and is accompanied by impressive lysinuria together with increased levels of the two N-acetyllysines and homocitrulline, sometimes with minimal saccharopinuria. While only two patients have been described with saccharopinuria, plasma lysine is lower than in familial hyperlysinemia, and urine saccharopine is much higher. The relationship of the enzyme defect to clinical manifestations is questionable in both disorders.

While saccharopinuria is difficult to miss—the compound runs as a 570 nm absorbing peak in the area of cystine on an amino acid analyzer—isolated hyperlysinemia and/or hyperlysinuria can represent a difficult diagnostic challenge. If elevated lysine is first detected in urine, plasma should be examined to ensure that it is due to overflow and not to the defects in renal transport that cause cystinuria and lysinuric protein intolerance. Hyperlysinemia must be distinguished from the secondary hyperlysinemia that occurs in infantile pyruvate carboxylase deficiency, where it is accompanied by hyperammonemia, lactic acidemia, and citrullinemia. A rarer cause of hyperlysinemia is mitochondrial NADP(H) deficiency due to *NADK2* mutations, which causes severe neurological disease and laboratory findings of mitochondrial dysfunction and dienoyl-CoA reductase deficiency (Houten et al. 2014).

2-Aminoadipic and 2-Ketoadipic Aciduria

2-Aminoadipic acid, an intermediate in lysine oxidation, is transaminated to 2-ketoadipic acid, which is then oxidatively decarboxylated to glutaryl-CoA by 2-ketoglutarate dehydrogenase (Hirashima et al. 1967) or by another enzyme similar to the dehydrogenases for pyruvate, branched-chain ketoacids, and 2-ketoglutarate.

Several subjects with recessively inherited 2-aminoadipic and/or 2-ketoadipic acidemia and aciduria have been described, most of them initially ascertained because of developmental delay and a variety of neurological manifestations. Because several siblings of these patients have been developmentally normal, and because a family is known in which all three biochemically affected subjects are clinically normal, it is now thought that clinical manifestations in these individuals are due to sampling bias and that the condition is benign. The condition is due to a variety of missense and nonsense mutations in *DHTKD1*, which encodes a peptide analogous to the E_1 subunits of pyruvate and 2-ketoglutarate dehydrogenases (Danhauser et al. 2012; Hagen et al. 2015; Stiles et al. 2016).

While a few individuals with 2-aminoadipic acidemia without 2-ketoadipic aciduria have been thought to be deficient in a 2-aminoadipic acid transaminase, one of them has also been shown to have mutations in *DHTKD1* (Hagen et al. 2015).

2-Aminoadipic acid concentrations in serum and urine have been 34–120 μM (normal <5) and 66–350 mmol/mol creatinine (normal <17), respectively. The urine concentration of 2-ketoadipic in one patient was 133 mmol/gm creatinine. Because similar amino and organic acid profiles have been observed in Reye-like episodes associated with various organic acidemias and other familial disorders (Elpeleg et al. 1990), diagnostic samples should be taken when the patients are not acutely ill.

The notion that 2-aminoadipic/2-ketoadipic (2AA/2KA) aciduria is harmless is hard to reconcile with the observation that Charcot-Marie-Tooth disease type 2 tracks with, and presumably caused by, heterozygosity for a nonsense mutation (pY485X) in *DHTKD1* in a large Chinese family (Xu et al. 2012), unless this mutation confers a new function on the *DHTKD1* gene product. Several other nonsense mutations have been described in individuals with 2-aminoadipic/2-ketoadipic aciduria, and to our knowledge, none of them (or their parents) have had similar neurological diseases. It is interesting to note that knockout mice homozygous for *DHTKD1* deficiency have 2-aminoadipic and 2-ketoadipic aciduria as well as a neurological phenotype not unlike human Charcot-Marie Tooth disease (Xu et al. 2018).

Glutaric Aciduria Type 3

Clinically significant disorders in the pathway of lysine (and tryptophan) oxidation include glutaric aciduria types 1 and 2 and pyridoxine dependent seizures and are discussed in Chaps. 32, 34 and 69. A condition in which glutaric acid is increased in blood and urine, but without accumulation of other organic acids and carnitine esters typical of glutaric aciduria types 1 and 2, has been called glutaric aciduria type 3.

This condition was first described in a child with β-thalassemia and attributed to the deficiency of peroxisomal glutaryl-CoA oxidase (Bennett et al. 1991) but has since been described in several clinically diverse situations and in

normal subjects, and the view has developed that, whatever the primary defect, the condition is benign.

The defect was mapped in three subjects in the Pennsylvania Old Order Amish, and homozygosity demonstrated for a missense mutation in *C7orf10*, which appears to encode a mitochondrial enzyme with a coenzyme A transferase domain (Sherman et al. 2008). Mutations in this gene were also present in several additional patients, and *these* included homozygosity for a chain-terminating mutation in the child whose defect had been thought initially to be in a peroxisomal oxidase. Because the enzyme product may esterify glutaric acid, it was suggested that the product of 2-ketoadipic dehydrogenase in the pathway of lysine oxidation is free glutaric acid, and not glutaryl-CoA. This seems unlikely in view of the relatively low glutaric acid excretion produced even by chain-terminating mutations in *C7orf10*, and it seems equally possible that the enzyme's primary function is to esterify free glutaric acid from other sources, such as gut bacteria.

Diagnosis, which is suspected by finding increased glutaric acid in blood and/or urine without the abnormal organic acids and carnitine esters found in glutaric aciduria types 1 and 2, can be confirmed by molecular analysis of *C7orf10*.

Hydroxykynureninuria

The oxidation of tryptophan in the liver proceeds through kynurenine, 3-hydroxykynurenine, and 3-hydroxyanthranilic acid to a branch point; most of the carbon skeleton is then oxidized to acetyl-CoA via 2-ketoadipic acid and glutaryl-CoA, but some is instead diverted to the biosynthesis of nicotinic acid and nicotinamide.

The conversion of 3-hydroxykynurenine to 3-hydroxyanthranilic acid by kynureninase is B_6 dependent, and renewed interest in vitamin deficiency and dependency states in the mid-1960s prompted an examination of tryptophan metabolites in patients with B_6-sensitive disorders and/or symptoms reminiscent of pellagra. Hydroxykynureninuria was first described (Komrower et al. 1964) in a mildly retarded 4-year-old girl with what had been thought to be a nicotinic acid deficiency in infancy. Xanthurenic acid, kynurenine, and 3-hydroxykynurenine were increased in urine and were increased by oral loading with L-tryptophan. A few children with similar metabolite excretion patterns have since been described without symptoms or with only mild pellagra-like findings, and it is now thought that the enzyme block is clinically relevant only if niacin intake is limited.

The cumbersome paper and thin-layer chromatography methods once used to investigate the disorder are no longer necessary. Diagnosis is now possible by detecting increased urine xanthurenic acid on organic acid analysis; increased xanthurenic acid, kynurenine and 3-hydroxykynurenine in urine and plasma by HPLC; and/or mutations in the *KYNU* gene, which encodes kynureninase (Christensen et al. 2007).

Cystathioninuria

Even when first described in a 64-year-old mentally retarded woman (Harris et al. 1959) and attributed to a probable recessively inherited deficiency of γ-cystathionase, the B_6-requiring enzyme that cleaves cystathionine to 2-ketobutyrate and cysteine, the suspicion was that the metabolic abnormality was related only by chance to the clinical presentation. Large reviews suggest that the latter is indeed the case; a review of patients ascertained in a bias-free manner found very few with symptoms, and even fewer whose symptoms could not be attributed to another cause (Mudd et al. 2001).

Cystathionine is efficiently cleared by the kidney, and accumulation is much more easily detected in urine than in blood. Urine concentrations in enzyme-deficient individuals are up to 2200 mmol/mol creatinine (normal <0.5). Urine cystathionine is often increased in newborns (probably because liver γ-cystathionase appears late in fetal life), in B_6 deficiency, and in patients with functional neural tumors and hepatoblastomas, presumably because of an imbalance between production by cystathionine β-synthase and hydrolysis, and remethylation defects (Chap. 28).

Although rarely necessary, an inherited enzyme deficiency may be confirmed by molecular analysis of the *CTH* gene (Wang and Hegele 2003).

3-Methylcrotonylglycinuria

3-Methylcrotonyl-CoA is formed by oxidation of isovaleryl-CoA, an intermediate in leucine metabolism, and is normally converted to 3-methylglutaconyl-CoA by a biotin-requiring holocarboxylase. Deficiency of 3-methylcrotonyl-CoA carboxylase (3MCC) can be isolated or, in biotin deficiency, biotinidase deficiency and holocarboxylase synthase deficiency, combined with the deficiency of carboxylases specific for acetyl-CoA, propionyl-CoA, and pyruvate (see Chap. 30). 3MCC is probably an $\alpha_6\beta_6$ dodecamer (Huang et al. 2010), and 3MCC deficiency can be due to mutations in either subunit.

Most early descriptions of isolated enzyme deficiency were in infants and children with acute disease in infancy and in children with Reye-like symptoms, and there was

little doubt about the relevance of the biochemical defect to clinical disease until newborn screening by tandem mass spectrometry detected increased hydroxy-C5 carnitine in several infants whose mothers had asymptomatic enzyme deficiency. It is not yet clear how many individuals with isolated carboxylase deficiency develop symptoms, but none of the affected subjects picked up by newborn screening developed any symptoms (Arnold et al. 2008). Kindreds with multiple "healthy" affected sibs had been reported before (Mourmans et al. 1995).

Though an occasional patient with 3MCC deficiency has isolated 3-hydroxyisovaleric aciduria (Wolfe et al. 2007), most also have an easily detected peak of 3-methylcrotonylglycine, and the abnormal organic acid pattern is easily recognized, be it in an ill child or an asymptomatic female. While it appears that the defect can sometimes cause clinical disease, there is considerable disagreement about the management of the asymptomatic mother and/or newborn (Arnold et al. 2008).

2-Methylbutyrylglycinuria (2-Methylbutyryl-CoA Dehydrogenase Deficiency)

2-Methylbutyryl-CoA is an intermediate in the oxidation of isoleucine. It is produced by oxidative decarboxylation of 2-keto-3-methylvaleric acid and is normally oxidized to tiglyl-CoA by methylbutyryl-CoA dehydrogenase (SBCAD), one of the several mitochondrial flavin-containing dehydrogenases that pass electrons into the respiratory chain via ETF and ETF:ubiquinone oxidoreductase.

Deficiency of SBCAD was first observed in a 3-year-old boy with hypotonia and developmental delay and in his asymptomatic mother (Andresen et al. 2000). The parents were first cousins, and both mother and child were homozygous for the same missense mutation in the *SBCAD* gene. Subjects that were subsequently described have had a variety of clinical presentations, and many in fact have been completely normal. The enzyme deficiency is quite common in the Hmong population in the Midwest USA. A recent review of 12 non-Hmong enzyme-deficient subjects found that all 11 that had been detected by newborn screening were well; the oldest of them was 4 years of age (Alfardan et al. 2010). These findings suggest that the association between the biochemical phenotype and clinical disease is fortuitous.

The diagnosis in newborns is usually suspected when an elevated C5 acylcarnitine is found on screening by tandem mass spectrometry and is confirmed on urine organic acid analysis by finding a (usually) small peak of 2-methylbutyrylglycine (MBG), often with small amounts of isobutyrylglycine and ethylhydracrylic acid and without isovalerylglycine. It is important to note that the amount of MBG in urine in this condition is often 10- to 50-fold less than the amount of isovalerylglycine excreted in isovaleric acidemia. Inherited defects of *ETHE1* (ethylmalonic acid encephalopathy) may be accompanied by modestly elevated branched-chain acylglycines and should therefore be ruled out. While available, enzyme and molecular analysis is seldom indicated.

Oxoprolinase Deficiency

Excretion of large amounts of pyroglutamic acid (5-oxoproline) can be due to deficiency of glutathione synthetase, when it is invariably associated with clinical disease (Chap. 16). Rarely, however, it is due to the inherited deficiency of oxoprolinase, a condition with a much more benign clinical course. Oxoprolinase deficiency was first described in two siblings whose symptoms seemed unrelated to their enzyme block (Larsson et al. 1981) and has since been reported in six additional patients, many of whom have been entirely normal.

As in glutathione synthetase deficiency, a large peak of pyroglutamic acid (>2 mol/mol creatinine; normal <0.05) is seen on organic acid analysis. If not due to deficiency of glutathione synthetase, the diagnosis of oxoprolinase deficiency can be made by demonstrating enzyme deficiency in white blood cells or cultured fibroblasts or by molecular analysis of the *OPLAH* gene (Almaghlouth et al. 2011).

Glycerol Kinase Deficiency

Glycerol kinase phosphorylates glycerol to glycerol-3-phosphate. X-linked deficiency of this enzyme (GKD) was first described in two male siblings with increased glycerol in blood and urine, psychomotor retardation, osteoporosis, myopathy, and adrenal hypoplasia (Guggenheim et al. 1980). Subsequent evaluation of many additional patients has shown that glycerol kinase deficiency by itself is important only in its ability to give a falsely elevated estimation of serum triglyceride if the latter is measured by glycerol release after lipolysis, but not before. Clinical phenotypes associated with GKD deficiency are most often due to the fact that the GKD gene is closely linked to genes encoding ornithine transcarbamylase, congenital adrenal hypoplasia, and Duchenne muscular dystrophy, and the disease is often caused by deletions of several contiguous genes (McCabe 2001). Isolated GKD may be associated with mild fasting intolerance and

hyperketonemia in childhood, but causes no symptoms at all in adults (Sjarif et al. 2000).

GKD deficiency is usually diagnosed when organic acid analysis detects a large peak of glycerol in a patient being investigated for signs and symptoms due to deficiency of one of the adjacent genes or during evaluation for pseudohypertriglycerolemia. Subsequent investigations will vary depending on how and why it was detected. The enzyme defect is easily demonstrated in many tissues, including leukocytes and cultured fibroblasts, and molecular analysis of the *GKD* gene is also available.

Plasma glycerol in GKD deficiency is 1.8–8.3 mmol/L (normal <0.27), and in urine is 90–193 mmol/mmol creat (normal = not detected); the latter is sufficiently high to be seen on organic acid analysis despite its being poorly extracted into organic solvents. Increased urine glycerol may not be detected in the acidic fraction prepared by ion-exchange chromatography but will be seen instead in the neutral fraction. Further, glyceroluria due to GKD deficiency must be distinguished from that due to glycerol in a variety of oral, rectal, and intravenously administered medications, as well as direct glycerol contamination of blood and urine specimens.

Methionine Adenosyltransferase Deficiency

The initial reaction in the transsulfuration pathway through which methionine is converted to homocysteine and cysteine is the formation of S-adenosylmethionine (AdoMet) by methionine adenosyltransferase. Over 60 patients with inherited deficiency of this enzyme are known, many of them detected by high serum methionine on newborn screening. Most of these patients have remained free of symptoms, and the condition has long been thought to be benign (Gaull et al. 1981). The latter may not be true in all instances, as a few patients with more severe enzyme deficiencies have developed demyelinating disorders.

Plasma methionine in methionine adenosyltransferase deficiency can be as high as 2500 μM (normal <50), and, when detected, other causes of hypermethioninemia such as metabolic liver disease, tyrosinemia type I, cystathionine β-synthase deficiency, glycine N-methyltransferase deficiency, and citrin deficiency must be excluded (Mudd 2011).

Although the diagnosis is usually arrived at by exclusion, diagnosis can be confirmed by enzyme assay on the liver or by molecular analysis of *MAT1A*, which encodes the catalytic subunit of the two isoenzymes of methionine adenosyltransferase in the mammalian liver. Most of the mutations identified to date are transmitted as autosomal recessives, but one, p.Arg264His, causes reduced activity even when heterozygous and can cause the occasional situation in which hypermethioninemia is transmitted as an autosomal dominant (Blom et al. 1992).

Methylmalonyl-CoA Epimerase Deficiency

Inherited methylmalonic acidemia is usually due to decreased conversion of L-methylmalonyl-CoA to succinyl-CoA by methylmalonyl-CoA mutase; in some cases this is due to mutations of the *MUT* gene, which encodes the mutase, and in others it is due to defects in the biosynthesis of adenosylcobalamin, the mutase cofactor (Chap. 28). Very rarely, however, methylmalonic acidemia is due to deficiency of the epimerase (or racemase) responsible for the interconversion of D- and L-methylmalonyl-CoA.

Three individuals in two families have been reported with mild methylmalonic acidemia(uria) due to homozygosity for a nonsense mutation (p.Arg47Ter) in the *MCEE* gene (Bikker et al. 2006; Dobson et al. 2006). The lone patient in one family was a girl who at age 2 years had retarded motor development and signs of spasticity, possibly because she also had sepiapterin reductase deficiency (Bikker et al. 2006). There were two siblings in the other family: a girl who presented at 1 year of age with a single episode of severe ketoacidosis and who then remained symptom-free on daily hydroxycobalamin (1 mg po) and an older sister with congenital hydrocephalus, normal development, and no symptoms of metabolic disease.

Urine methylmalonic acid in these patients has been as high as 1500 mmol/mol creatinine (normal <10) but decreased considerably with age to approx. 50 mmol/mol creatinine. Suppression of gene expression in HeLa cells led only to a small reduction in pathway activity, suggesting that nonenzymatic conversion of D- to L- isomer contributes to flux through the pathway and perhaps explaining the relatively mild organic aciduria and symptoms even with a truncating mutation.

It now appears that epimerase deficiency is a relatively rare cause of methylmalonic aciduria and, since the diagnosis might have prognostic significance, molecular analysis of the *MMCE* gene may well become more widely used when evaluating patients detected in newborn screening programs.

SCAD Deficiency

Short-chain acyl-CoA dehydrogenase (SCAD) is one of the four chain length-specific acyl-CoA dehydrogenases involved in mitochondrial β-oxidation of fatty acids. Hexanoyl- and butyryl-CoA are its preferred substrates, and, like other members of the enzyme family, electrons from the en-

zyme flavin enter the respiratory chain at the level of coenzyme Q, and secondary SCAD deficiency therefore occurs in multiple acyl-CoA dehydrogenase deficiency. Like most of the other acyl-CoA dehydrogenases, the mature enzyme is in the mitochondrial matrix and exists as a tetramer of four identical subunits.

While inherited deficiencies of medium- and very long-chain acyl-CoA dehydrogenase cause clinical disease in most instances, it now appears that SCAD deficiency rarely if ever causes symptoms.

SCAD deficiency was initially identified in patients with carnitine deficiency and a variety of neurological or skeletal muscle problems (Roe and Ding 2001). Urine organic acid analysis often showed increased ethylmalonic acid, methylsuccinic acid and/or butyrylglycine, and acylcarnitine analysis an increase in the C4 ester. The diagnosis could be confirmed by enzyme assays on muscle or cultured fibroblasts, followed by identifying pathogenic mutations in the *ACADS* gene, and, while pathogenesis defied easy explanation, it was generally thought that SCAD deficiency caused disease in most instances but that the clinical phenotype was very diverse.

Follow-up of patients identified by newborn screening with tandem mass spectrometry has provided a quite different perspective. Newborn screening programs in Australia (Wilcken et al. 2009) and Massachusetts (Waisbren et al. 2008) have followed SCAD-deficient infants detected on the basis of an elevated C4 acylcarnitine in newborn blood spots and have found that most of them grow and develop normally. And in those that do not, a clinical disease can often be attributed to another cause. These data, which suggest that SCAD deficiency does not cause disease in the great majority of cases, have led several programs to stop screening for the disorder.

A diagnosis should not be made unless ethylmalonic encephalopathy and multiple acyl-CoA dehydrogenation defect (glutaric acidemia type II) have been excluded. While patients with the latter conditions often have additional organic acids, glycine esters, and carnitine esters in blood and urine, a molecular analysis of the relevant genes may be necessary to arrive at the proper diagnosis.

Signs and Symptoms

Concluding Remarks

The list of inborn errors of questionable clinical significance provided is almost certainly incomplete, as future clinical studies of patients detected by selective or newborn screening will show that some disorders do in fact cause disease in some patients, and that others do not. Further, newer diagnostic methods like whole genome analysis or exome sequencing will add novel disorders to the mix, and these too will have to undergo intensive analysis to decide if they are indeed clinically relevant.

Contents

Summary

Here we give an overview of the inborn errors of metabolism knowledge base, or IEMbase, a comprehensive electronic repository of the IEMs described in this book. Developed as a companion application to this textbook, IEMbase provides two key functions: first, it is a free and openly available repository of the features characterizing the different IEMs; second, it has an artificial intelligence (AI) search tool to aid the diagnosis of IEMs. Given the highly specialized knowledge necessary to accurately diagnose IEMs and the necessity for timely diagnosis, it is essential that all clinicians involved in IEM diagnoses have quick access to the disease-characterizing features of known IEMs. IEMbase fills this gap by providing a highly accessible tool to aid clinicians in overcoming the barriers to IEM diagnosis.

Introduction

Inborn errors of metabolism (IEMs) represent a large class of rare genetic disorders that result from congenital defects in metabolic pathways. While individually rare, as a group IEMs have a collective incidence rate higher than 1:1000. Early timely diagnosis is crucial for these disorders as early intervention has proven to be effective in improving the quality of life and preventing serious sequelae that if left untreated, can lead to end-organ damage and death. Technological advances

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*,
https://doi.org/10.1007/978-3-030-67727-5_72

in DNA sequencing and metabolomics have greatly improved our ability to detect, diagnose, and manage IEMs in recent years (Vernon 2015). However, with the large number of these disorders as well as the associated genetic and phenotypic heterogeneity, timely diagnosis can often be delayed (Hawkes et al. 2011). Nonspecialists often have challenges with the diagnosis and management of these disorders due to the large amount of specialist knowledge required (Hawkes et al. 2011).

IEMbase was created as an accessible digital application to store standardized information about IEMs taken from the IEM community knowledge base (Lee et al. 2018). The system is implemented as two complementary parts: a digital knowledge base of IEMs and a mini-expert AI to aid diagnosis. The regularly updated knowledge base is compiled by experts from the IEM community consisting of clinicians, geneticists, and scientists. It houses over 1000 disorders and their associated profiles, including information on relevant genomic, biochemical, and clinical markers. The mini-expert AI is designed to help with the diagnosis of IEMs. It allows users to input lists of biochemical and clinical phenotypes and to compare them quickly with the database of disorder profiles.

Knowledge Base

The specific steps regarding compilation and assembly of IEMbase have been previously described (Lee et al. 2018). For the purpose of this chapter, we will describe the components and content making up IEMbase, with a focus on the facilitating use of the system by potential users.

In its essence, IEMbase is a collection of disorder characterizing profiles for known IEMs. Each disorder profile stores known disorder names, causal gene information, and links to external databases. The links to external databases include OMIM (OMIM 2020), UniProt (UniProt Consortium 2019), NCBI Gene (Brown et al. 2015), GeneCards (Stelzer et al. 2016), Kyoto Encyclopedia of Genes and Genomes (KEGG 2020), National Institutes of Health Genetic Testing Registry (NIH 2020), and GeneReviews (Adam et al. 1993). Each disorder profile also contains a list of associated symptoms and biomarkers, information regarding the age of onset and severity of symptoms, as well as the pathological level(s) of associated biomarkers (Lee et al. 2018). Onset information is organized into five developmental categories: neonatal, infancy, childhood, adolescence, and adulthood. Severities of symptoms are denoted by plus signs, and pathological levels of biochemical markers are denoted by up/down arrows.

In the "backend" of the system, the disorder profiles and associated symptoms/biochemical markers are stored in a PostgreSQL database as three tables: disorders, biochemical/clinical phenotypes, and disorder-phenotype associations. As of April 2020, there are 1342 disorders, 3424 biochemical/clinical phenotypes, and 18,672 disorder-phenotype associations.

IEMbase is actively updated to reflect new information in the field. The first version of IEMbase was compiled as version 1.0.0. Regular updates have yielded new versions of the database, with the latest version at the time of writing (April 2020) being 1.4.3. Mobile Apps for Android and iOS are available in corresponding stores.

Mini-Expert

With over 1000 distinct IEMs in our database, several of which have overlapping symptoms and/or biochemical marker profiles, IEMbase includes an AI tool for diagnosing IEMs called the mini-expert. The mini-expert takes as input, a list of biochemical and clinical phenotypes. The system then uses a two-step algorithm to identify IEMs with matching profiles and presents them in ranked order (Fig. 72.1). Specific information regarding the algorithm for the mini-expert system is previously published (Lee et al. 2018).

Application Walkthrough

The IEMbase application is made of three parts: a search feature, a browsing feature, and the mini-expert. When the user enters the site at http://iembase.org they are presented a disclaimer. Once the user agrees, they are then redirected to the main page (Fig. 72.2); this page features a search bar and three buttons: browse, search, and mini-expert. This main page is identical to the search page.

Search

The search bar feature is found both on the main page and the search page. Using the search bar, the user can enter a disorder name, symptom, or gene name. The search feature will bring up a results page with all disorders that have a partial match with the search term entered (Fig. 72.3). Clicking the "more" button on a disorder from the results list will bring the user to the disorder view page, which will be discussed later in this walkthrough.

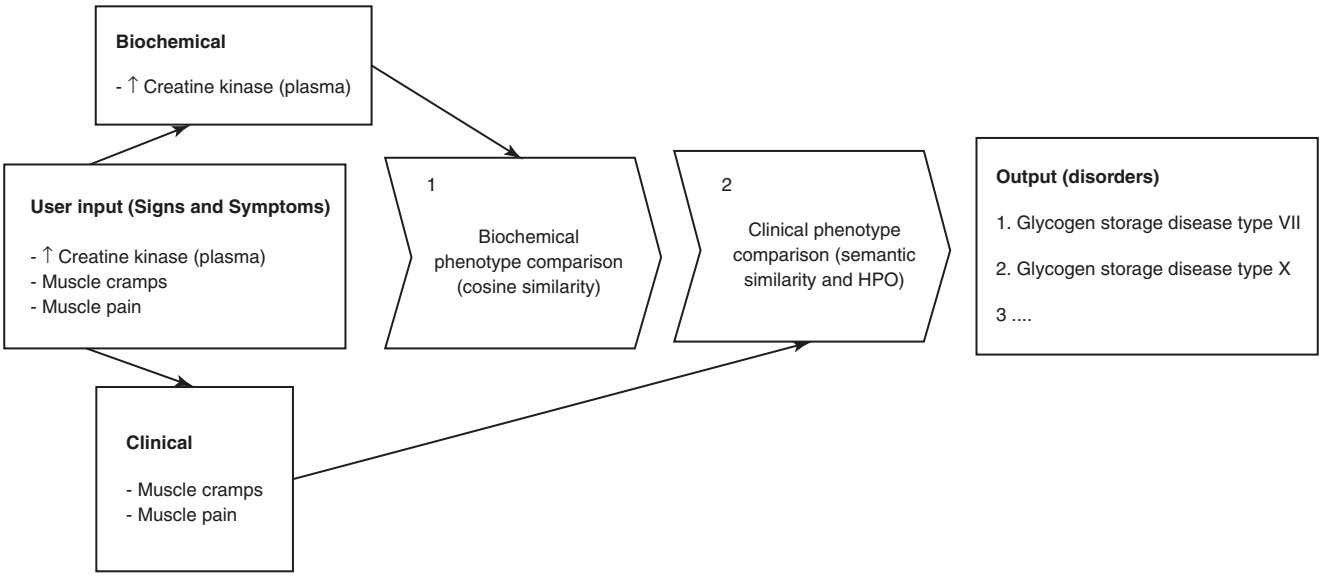

Fig. 72.1 Mini-expert algorithm flowchart. The user enters a list of signs and symptoms into the mini-expert. The biochemical signs entered are used in step 1 for comparison with the disorder profiles in the system using a cosine similarity measurement, while the clinical symptoms are compared in step 2 using a semantic similarity measurement. The mini-expert then outputs a ranked list of disorders matching the user input

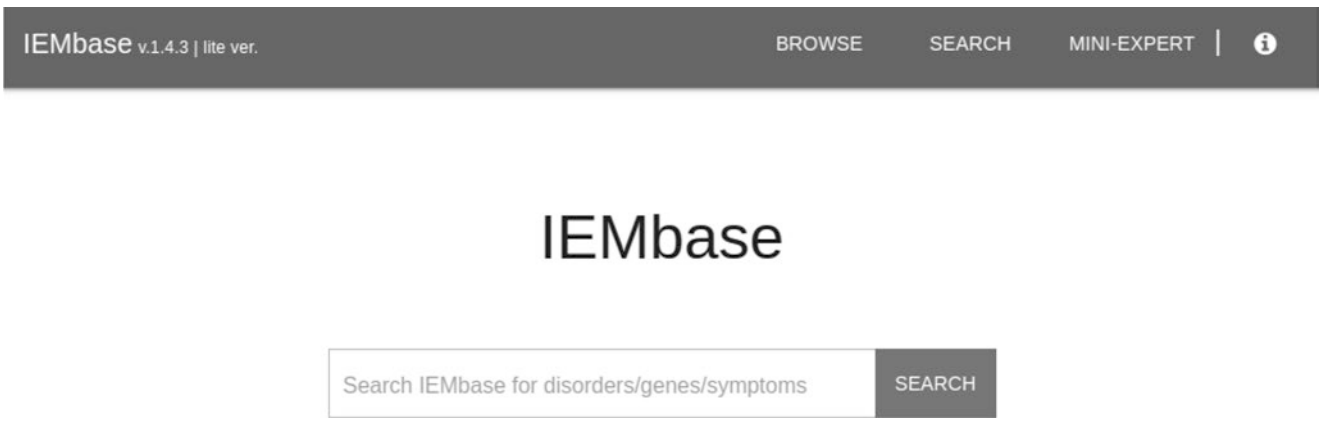

Fig. 72.2 Main page and search page. This page allows users to search IEMbase for a disorder but entering a partial name, gene symbol, or symptom

Browse

By clicking the browse button, the user navigates to the browsing page (Fig. 72.4). This page displays a dropdown list of all the IEMs stored in IEMbase organized by the disorder group, where the groupings are consistent with the textbook chapters. The user can expand different disorder groups and subgroups to look for specific disorders. By clicking a specific disorder, the user is redirected to that disorder's view page, which will be discussed in the next section.

The browse section also contains a search bar, which connects to a simplified search that only looks for substrings of a specific disorder name or disorder group name.

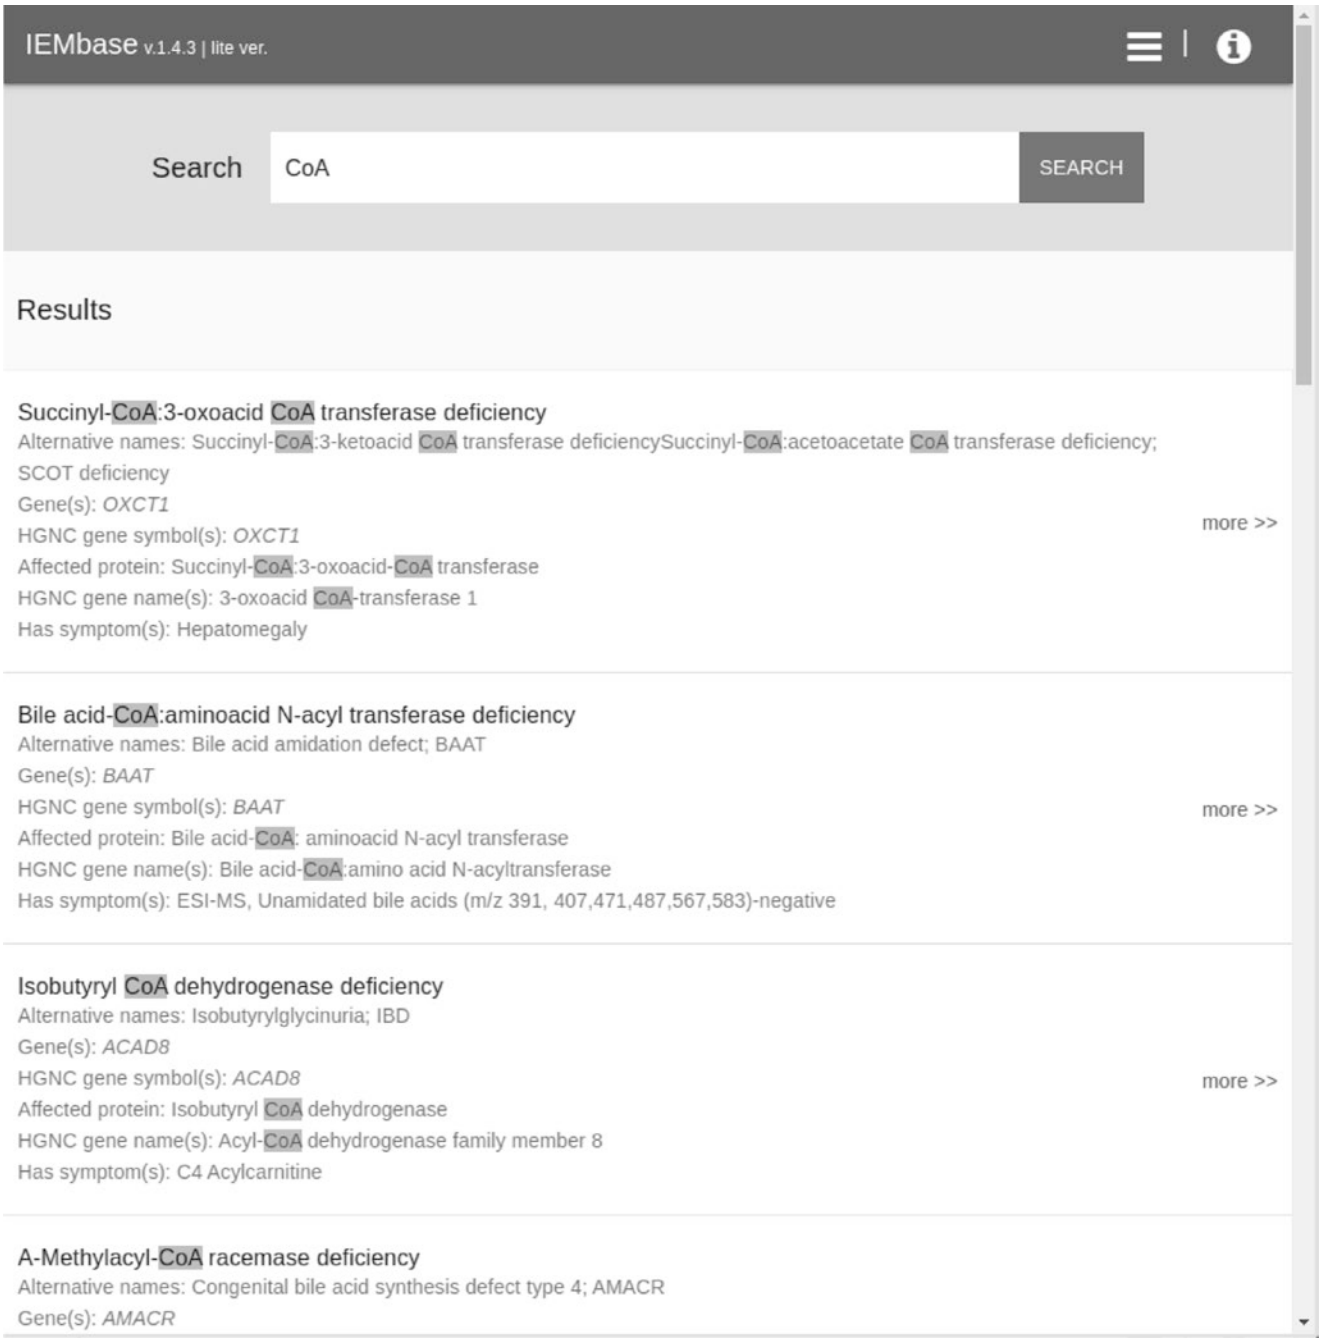

Fig. 72.3 Search results. After users enter a search term, the results returned include all disorders that have that search term in their summary. The summary consists of the disorder name and alternate names, associated gene(s), affected protein, and associated symptoms

Disorder View

When a user selects a disorder, either through the search or browse functions, they are redirected to that disorder's view page. This page has four sections: disorder information, clinical symptoms, biochemical markers, and gene information. The user can expand or hide each of these individual sections. Some parts of these sections have clickable features, such as the OMIM number, which redirect the user to relevant external databases.

Mini-Expert

When the user clicks on the mini-expert button, they are redirected to the mini-expert AI. The first page prompts the user to enter biochemical markers of clinical symptoms (Fig. 72.5). For biochemical markers the user can also specify the relative level by clicking on the up or down arrows. The user can then press the match button, which runs the AI and returns a ranked list of disorders that match the inputted features. The match-

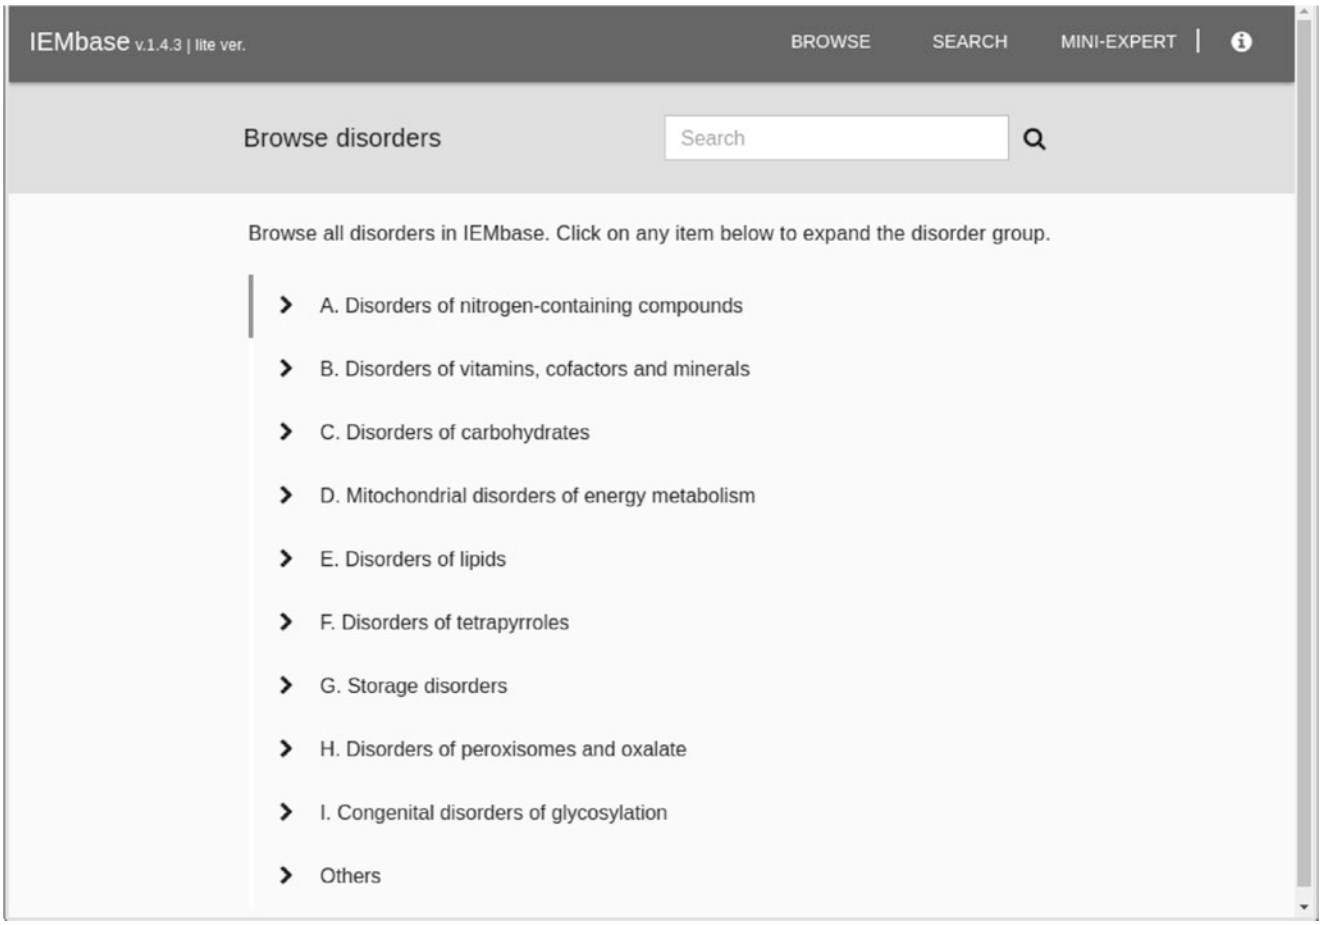

Fig. 72.4 Browse feature. The user is presented with a dropdown list of disorder groups. Clicking on any of these groups will expand them to show the specific subgroups and disorders under that category

ing algorithm prioritizes biochemical markers and will only work if at least one biochemical marker is input.

The result page (Fig. 72.6) has on the top a summary of the query and then panel options: results, differential diagnosis (DDX), biochemical tests, and gene panel. The DDX, biochemical tests, and gene panel options allow the user to select any subset of disorders from the results of the mini-expert, and it will then create a summary of the selected disorders depending on the option.

Future Directions

Over the long-term, IEMbase benefits most from the continuous effort of editors and experts to maintain the currency of the disorder characterizing profiles, and we are committed to continuous renewal.

Excluding technical updates, which are necessary for any informatics resource, we are exploring several innovations that may enhance the utility of IEMbase for users. We are attempting to incorporate the embedded display of information from external resources, such as the display within IEMbase of pathway diagrams from pathway databases. The system has largely focused on aiding diagnosis, but we are exploring how we could display information that is useful for clinicians planning treatment of patients. Finally, we are exploring improved AI and search functions that would allow results to be generated based on either verbal description of patient characteristics or submission of a transcribed medical record note.

Users are encouraged to provide feedback, particularly if there are features that would improve the utility of the IEMbase system.

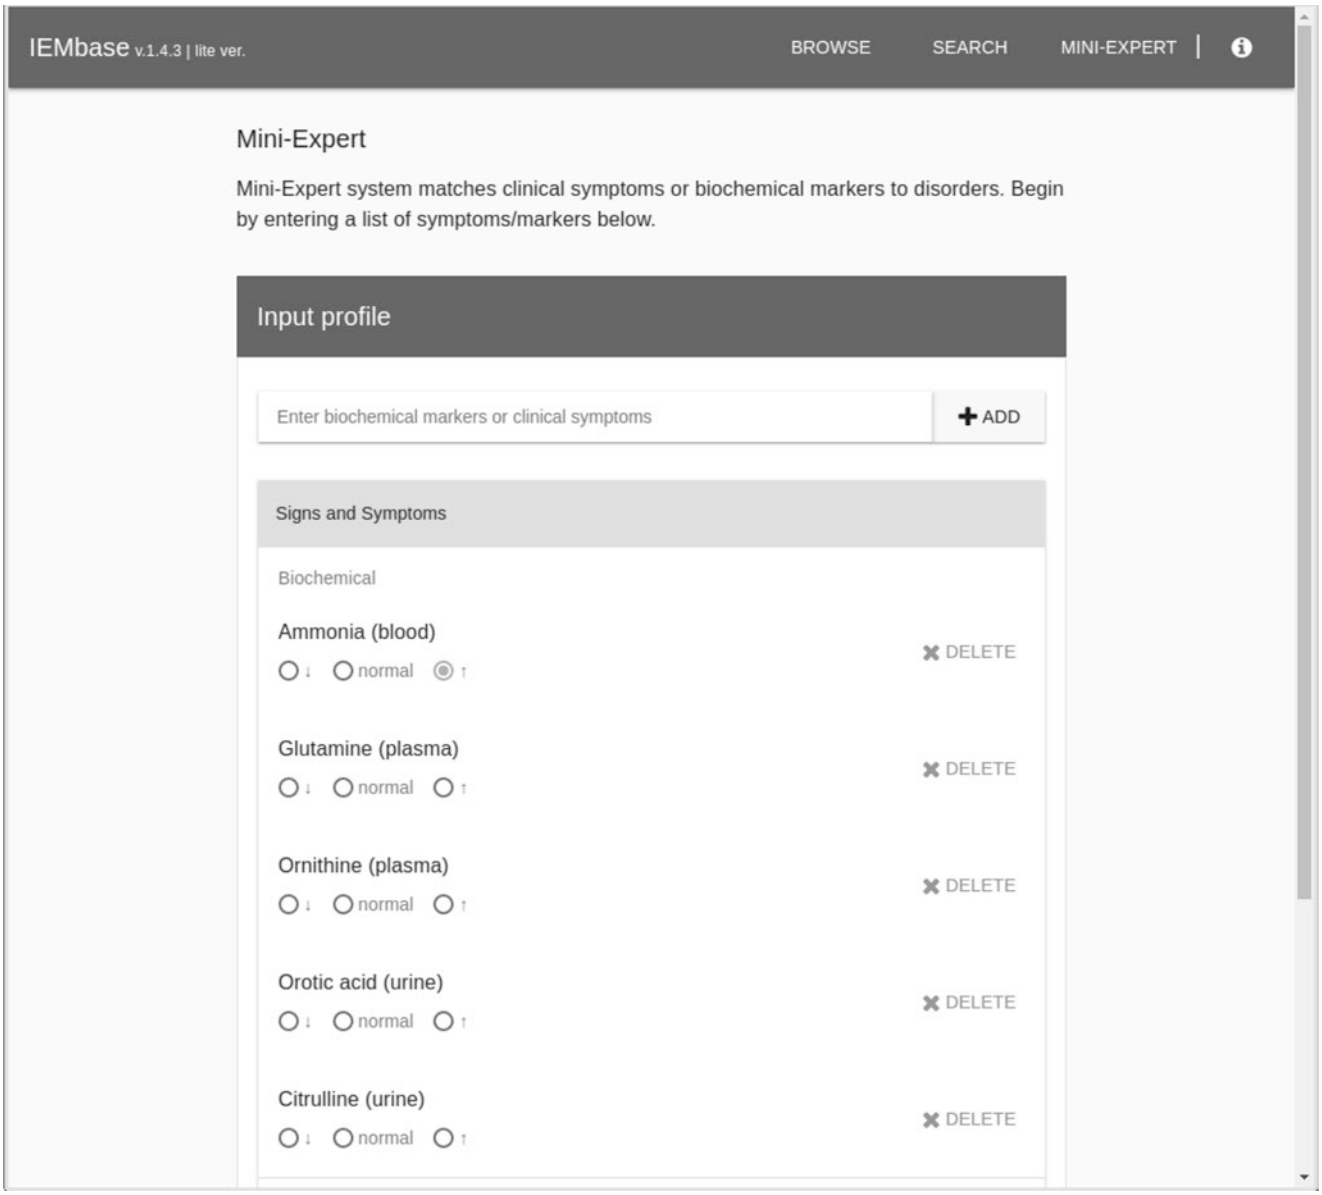

Fig. 72.5 Mini-expert input. The user can search for biochemical markers or clinical symptoms and can add them to the search query. For biochemical markers, the user can specify a level by selecting the up/down arrow or normal

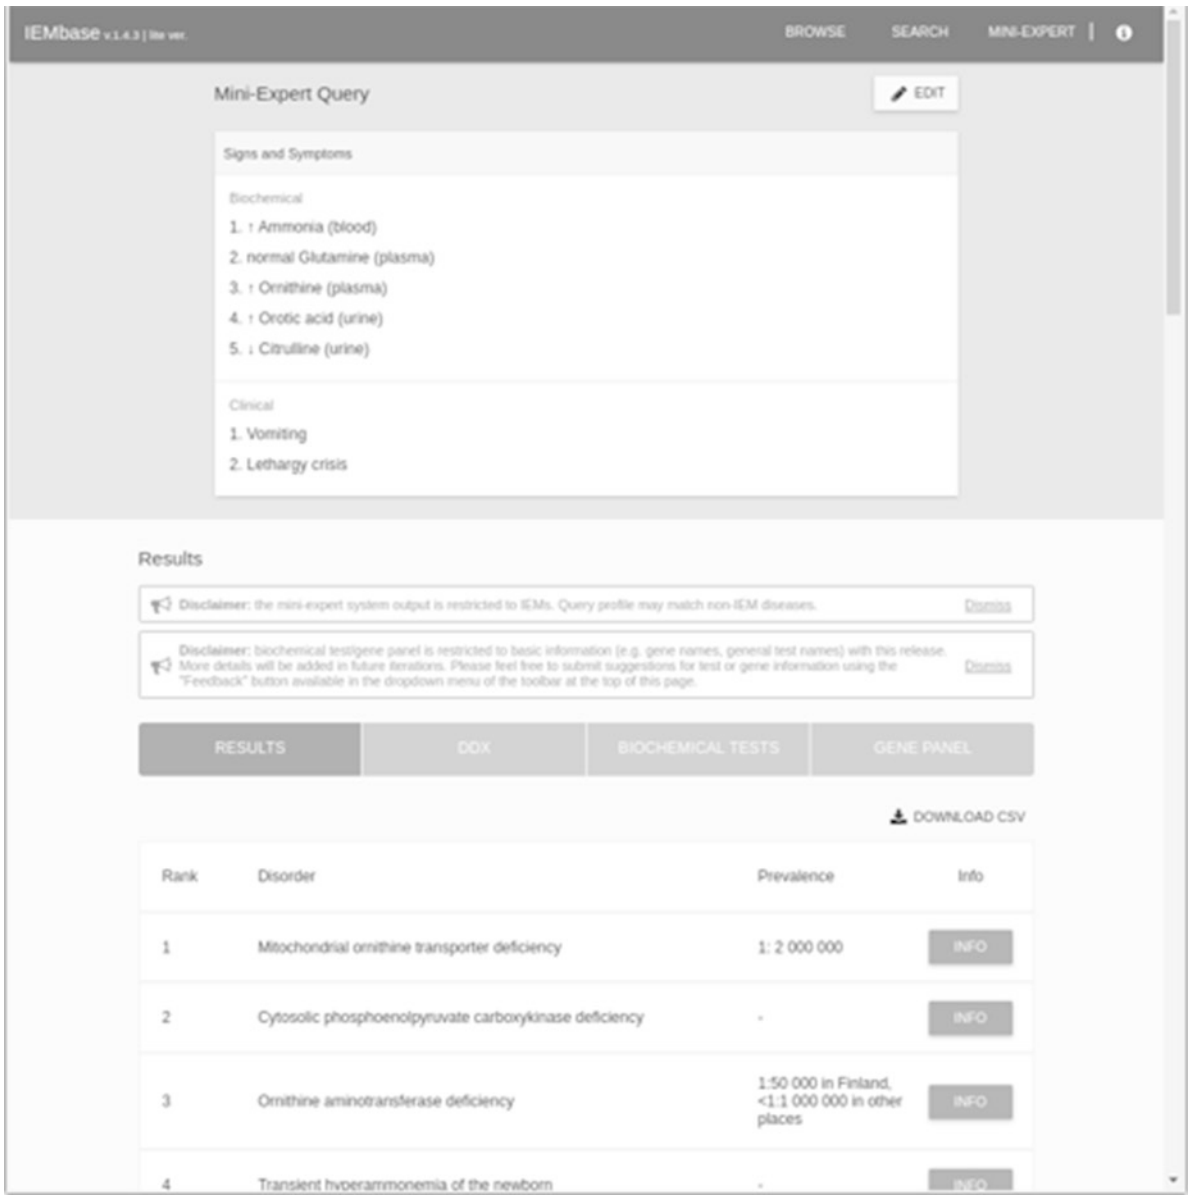

Fig. 72.6 Mini-expert results. The results from the mini-expert query consist of a summary of the query and a ranked list of matching disorders. There are three additional tabs, DDX, biochemical tests, and gene panel, which allow the user to create summary tables from the ranked results

WikiPathways: Integrating Pathway Knowledge with Clinical Data

73

Denise N. Slenter, Martina Kutmon, and Egon L. Willighagen

Contents

Summary

Throughout the chapters in this book, pathways are used to visualize how genetically inheritable metabolic disorders are related. These pathways provide common conceptual models which explain groups of chemical reactions within their biological context. Visual representations of the reactions in biological pathway diagrams provide intuitive ways to study the complex metabolic processes. In order to link (clinical) data to these pathways, they have to be understood by computers. Understanding how to move from a regular pathway drawing to its machine-readable counterpart is pertinent for creating proper models. This chapter outlines the various aspects of the digital counterparts of the pathway diagrams in this book, connecting them to databases and using them in data integration and analysis. This is followed by three examples of bioinformatics applications including a pathway enrichment analysis, a biological network extension, and a final example that integrates pathways with clinical biomarker data.

The original version of this chapter was previously published non-open access. A Correction to this chapter is available at https://doi.org/10.1007/978-3-030-67727-5_74

Introduction

The metabolic pathways in this book are common conceptual models which help us understand groups of chemical reactions within their biological context. These conversion reactions are catalyzed by enzymes and triggered by receptors or transporters, causing a wide variety of metabolites to be present in bodily fluids and tissues. Visual representations of the reactions in biological pathway diagrams provide intuitive ways to study complex metabolic processes. If we want to link clinical data to these pathways, we need pathways that can be understood by computers. By creating machine-readable versions of the pathways relevant for (rare) disorders, clinical data can be processed and analyzed in an automated fashion, allowing fast and visual interpretation (Kutmon et al. 2014a; Villaveces et al. 2015). However, modeling these pathways for data analysis comes with some challenges and limitations (Howe et al. 2008; Khare et al. 2016), which are discussed in this chapter in more detail.

Even though there is still a substantial amount of unexplored territory in human molecular biology, data on biological mechanisms, pathways, and related diseases has increasingly become available due to improvements in measurement and computational techniques. A crucial step to enable advanced data analysis is structuring and sharing the knowledge obtained from biological experiments. This chapter provides some examples of what types of data analysis can be performed with machine-readable pathways and related knowledge. More examples are available in literature, e.g., visualization of drug metabolism related expression changes (Jennen et al. 2010), integrating molecular interaction data (Herwig et al. 2016), and fully automatable processing steps of metabolomics data (Stanstrup et al. 2019). We hope to inspire the metabolic rare disease community to aid our quest in transforming, structuring, and collecting knowledge about molecular processes in machine-readable pathway models and databases. Finally, all these data acquisition and modeling steps will lead to a better understanding of the phenotype of a patient.

IEMBase and WikiPathways

The knowledge captured in the chapters of this book holds vital information on genetically inheritable metabolic diseases, genes, and proteins involved, metabolic biomarkers, pathways, relevant literature, diagnosis, and treatment. A great effort has been done digitizing most of this information in the IEMBase (www.iembase.org) (Lee et al. 2018), but one key element missing were machine-readable pathways, which are being added through a collaboration with the WikiPathways pathway database (www.wikipathways.org) (Kelder et al. 2012; Kutmon et al. 2016; Slenter et al. 2018). This database allows researchers to add machine-readable pathways, including literature references, and creates a traceable history of edits. The results are freely accessible and reusable by everyone in the world. Furthermore, adding a pathway to WikiPathways exposes the biological knowledge captured in the model via various other data formats (http://help.wikipathways.org) and tools (http://tools.wikipathways.org), allowing researchers to directly integrating the new knowledge within their tool of choice.

We aim to provide all pathways in the chapters of this book as machine-readable pathway models in WikiPathways. You can find the currently available pathways on http://iem.wikipathways.org.

Machine-Readable Metabolic Pathway Models

Researchers can use different tools to model machine-readable pathways from schematic drawings in publications. WikiPathways stores all pathways in the graphical pathway markup language (GPML), which can be drawn in PathVisio (www.pathvisio.org) (Kutmon et al. 2015). This format is flexible enough to allow modeling of detailed biological phenomena, while relying on a machine-readable structured backbone for automated data analysis. In the following subsections, we highlight relevant topics for creating pathways on genetically inheritable metabolic rare diseases. This information is complemented with an online step-by-step tutorial (academy.wikipathways.org).

Modeling Biological Entities

The biological entities in GPML-encoded pathways (e.g., gene products, proteins, and metabolites) are captured as *DataNodes* (Fig. 73.1a). These nodes have a textual label and biological type and can contain the following additional information: literature references, free text comments, and a unique database identifier (Fig. 73.1b). The textual label is the visible name of the entity while the type represents which biological entity is modeled: genes are modeled as *GeneProducts*, proteins and enzymes as *Proteins* and chemicals as *Metabolites* (Fig. 73.1a). Additional modeling options include *Complexes*, *Groups*, *RNAs*, (full) *Pathways*, and *States* such as posttranslational modifications (Fig. 73.1c). *DataNodes* can be connected to literature, ideally using PubMed identifiers. Another section allows users to add free text in the comment field, to explain additional details relevant for the pathway. Finally, a database identifier and the accompanying database (Fig. 73.1b) provides the framework required for data integration later (Figs. 73.4

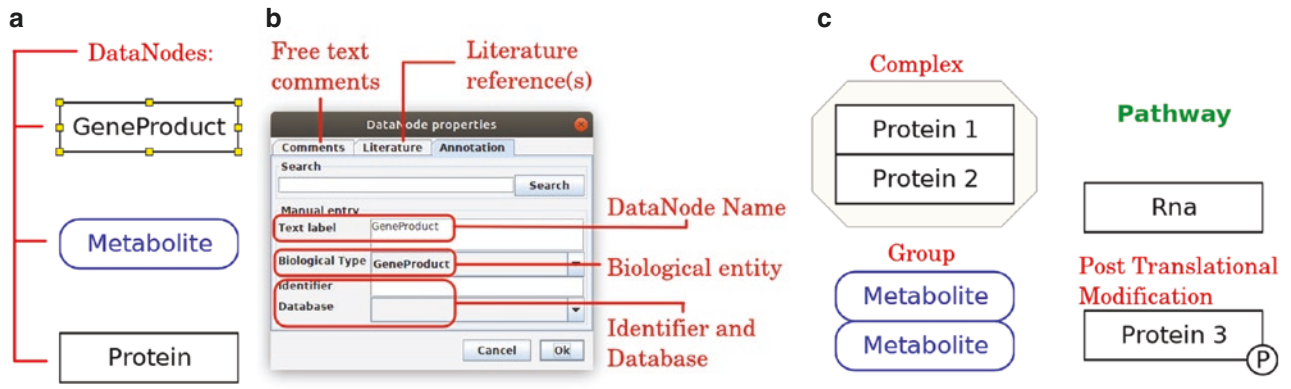

Fig. 73.1 Visualization of modeling properties for biological entities in PathVisio. (**a**) Main *DataNodes*, where the *GeneProduct* is selected (indicated with small yellow blocks). (**b**) Pop-up menu allowing connecting a *DataNode* to literature, identifier, and database. (**c**) Additional modeling options, where multiple *DataNodes* can be used to form *Complexes* and *Groups*. Nodes can also be used to point to other *Pathways* (including identifier) and *RNA*. *DataNodes* can also be extended with a *State* like posttranslational modifications

and 73.5). An online database identifier allows the retrieval of additional facts about the entity in the pathway. PathVisio makes use of the BridgeDb identifier mapping framework (www.bridgedb.org) (van Iersel et al. 2010) and can therefore support a variety of databases and mappings between them. Since these identifiers are crucial for data analysis, the next two sections discuss them in more detail.

Identifiers for Pathway Entities

There are many online resources storing information about the proteins, molecules, and interactions in pathways. Ideally, each element in the pathway is annotated with a specific identifier from one of the online databases. Because there are many different databases to choose from, we provide some general guidelines for the annotations of *DataNodes* and interactions in pathways.

Genes and proteins can be annotated with over 60 different databases. However, there are some subtle differences between what type of information is modeled in these databases. Ensembl (Cunningham et al. 2019) and NCBI (Entrez) Gene (Agarwala et al. 2018) focus on gene and transcript identifiers, while UniProt (UniProt Consortium 2019) models their data at a protein level. Therefore, one gene identifier in Ensembl could point to multiple UniProt entries. Enzyme commission numbers (EC-codes) (McDonald and Tipton 2014) can be very useful to annotate a group of enzymes which serve a similar biological function or to classify a chemical conversion to a specific reaction mechanism, without knowing the actual protein structure or gene involved. However, since this classification is not specific for one gene or protein, numerous mappings can be created which complicates data analysis. Thus, regarding identification of biological entities, the more specifically the identifier points to one entity, the more straightforward data can be connected to *GeneProduct* (Ensembl, NCBI Gene) and *Protein* (UniProt) *DataNodes*. For *Complexes* with multiple enzymes, each individual enzyme should receive a unique identifier from UniProt. In addition, distinctive isoforms could also have unique identifiers and be drawn as separate *DataNodes*.

Metabolites can be annotated with over 25 databases, where most of these databases have their own focus (nutrition, toxicology, human metabolism, medication) and possess different levels of chemical detail. These different levels can be quite relevant for the biological implications of these compounds and corresponding interactions, such as stereochemistry (e.g., chirality, isomers), protonation state, (de) phosphorylation, and tautomerization. For several pathways and reactions, the specific level can also be unknown, which is particularly the case for lipid pathways. These are more often considered to behave biologically similar when the head and tail of the lipid are comparable; however a small difference in number of double bonds or location thereof could lead to distinct biological behavior. Identifiers exist to be able to add groups of compounds as *Metabolite DataNodes* in pathways. Nevertheless, this does not solve the issue of straightforward data analysis as discussed for genes and proteins. We would therefore advise to use chemical identifiers which correspond to the known level of chemical detail, e.g., ChEBI (Hastings et al. 2016) for metabolites, DrugBank (Wishart et al. 2018) for drugs, and LIPID MAPS (Fahy et al. 2009) for lipids.

Interactions can currently be annotated with 14 databases, for which some allow easy integration with other resources. A good coverage of metabolic conversions between metabolites is provided by the Rhea database (Lombardot et al. 2019).

Interaction Types

As mentioned previously, interactions are separate elements within the pathway model. An interaction clearly connects two or more biological entities to depict a relationship between them. Understanding the biological meaning of a connection between different entities is needed to create accurate machine-readable models. PathVisio supports several types of interaction (standards): basic interactions, molecular interaction map (MIM) interactions (Luna et al. 2011), and the interaction types described in the systems biology graphical notation (SBGN) (van Iersel et al. 2012).

For the pathways in this book, we advise the application of MIM interactions, which include conversion and catalysis for reactions between metabolites and related enzyme(s) (Fig. 73.2a); stimulation and inhibition for signaling functions (Fig. 73.2b); transcription/translation for *GeneProduct* to *Protein* (Fig. 73.2c); modification for posttranslational or other modifications and binding for complex formation (Fig. 73.2d); and translocation for transport of metabolites between different cellular compartments (Fig. 73.2e).

Modeling Diseases and Interactions

Most pathways in this book clearly indicate which step(s) in a pathway are disease causing. This disease information can be added to pathways in several manners. First, diseases can be added to a pathway as text labels and connected to the related gene or protein. Second, a pathway can be tagged with terms from the Human Disease Ontology (Köhler et al. 2019) Pathway Ontology (Petri et al. 2014) and Cell Type Ontology (Diehl et al. 2016) on WikiPathways. The information enables systematic search and browse functionalities with clearly defined child-parent relationships; for example find all pathways, which are linked to the term "inborn error of metabolism pathway" (purl.bioontology.org/ontology/PW/PW:0001589) or all pathways linked to possible child terms. Third, genes and proteins are often linked to OMIM gene entries (Amberger et al. 2015) through BridgeDb, allowing navigation from a specific pathway to disease databases. Finally, including the disease name or class in the title of the pathway or description also helps searching for relevant pathways.

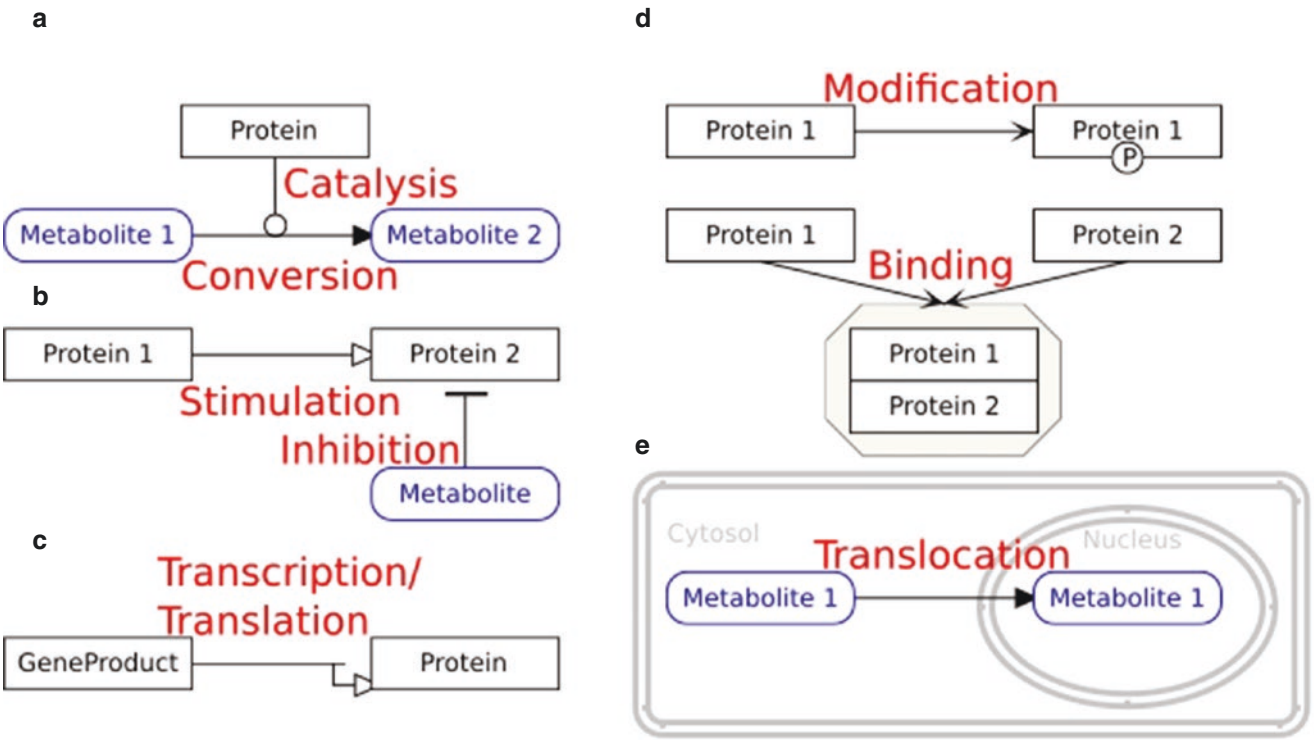

Fig. 73.2 Overview of MIM interaction types and how these can be used to connect biological entities in PathVisio. (**a**) *Metabolite* 1 is enzymatically converted to *Metabolite* 2, which is catalysed by a *Protein*. (**b**) *Protein* 1 stimulates *Protein* 2; *Protein* 2 is inhibited by a *Metabolite*. (**c**) A *GeneProduct* is transcribed and/or translated to a *Protein*. (**d**) top: A *Protein* undergoing a phosphorylation (P) Post-Translational-Modification (PTM); bottom: two *Proteins* binding together to form a complex. (**e**) A translocation from cytosol to nucleus for a *Metabolite*

Genetically Inheritable Metabolic Disorder Pathways on WikiPathways

A majority of the pathways in the chapters of this book are already available on WikiPathways (iem.wikipathways.org). As an example, Fig. 73.3 visualizes a complete example of a machine-readable version of the purine pathway (Chap. 13, WikiPathways:WP4792, www.wikipathways.org/instance/WP4792), which is linked to over 20 genetically inheritable diseases (available at WikiPathways:WP4224). Even though at first glance, this figure resembles the original drawing quite closely, all the individual metabolites, proteins, and biomarkers are annotated with identifiers and linked to databases, all interactions connect these elements together and have the appropriate MIM types. The following sections provide several examples on how these pathways can now be used for data analysis.

Using Pathway Models to Analyze Clinical Data

Pathways can be used to analyze various types of clinical data including whole exome sequencing (WES), transcriptomics and proteomics, genome-wide association studies (GWAS), metabolomics, or targeted chemical assay data. In this section, we provide several examples on how the created pathway models can be used for data analysis. Scripts and instructions for performing these analyses can be found online (bigcat-um.github.io/IEMPathwayAnalysis).

Pathway Analysis

The availability of pathways as machine-readable models enables us to visualize molecular data on the elements in the pathways and to perform advanced computational analysis including gene set enrichment and network analysis. While whole-genome sequencing is already well established in clinical practice, transcriptome analysis seems promising for diagnosing rare disease patients (Gonorazky et al. 2019).

Pathway analysis for transcriptomics data is a powerful tool to put the data into a biological context. As an example, we selected a publicly available transcriptomic dataset of patients with Lesch-Nyhan disease (LND) (geo:GSE24345, omim:300322) (Kang et al. 2011). The disease is caused by mutations in the *HPRT1* gene (ensembl:ENSG00000165704), producing the hypoxanthine phos-

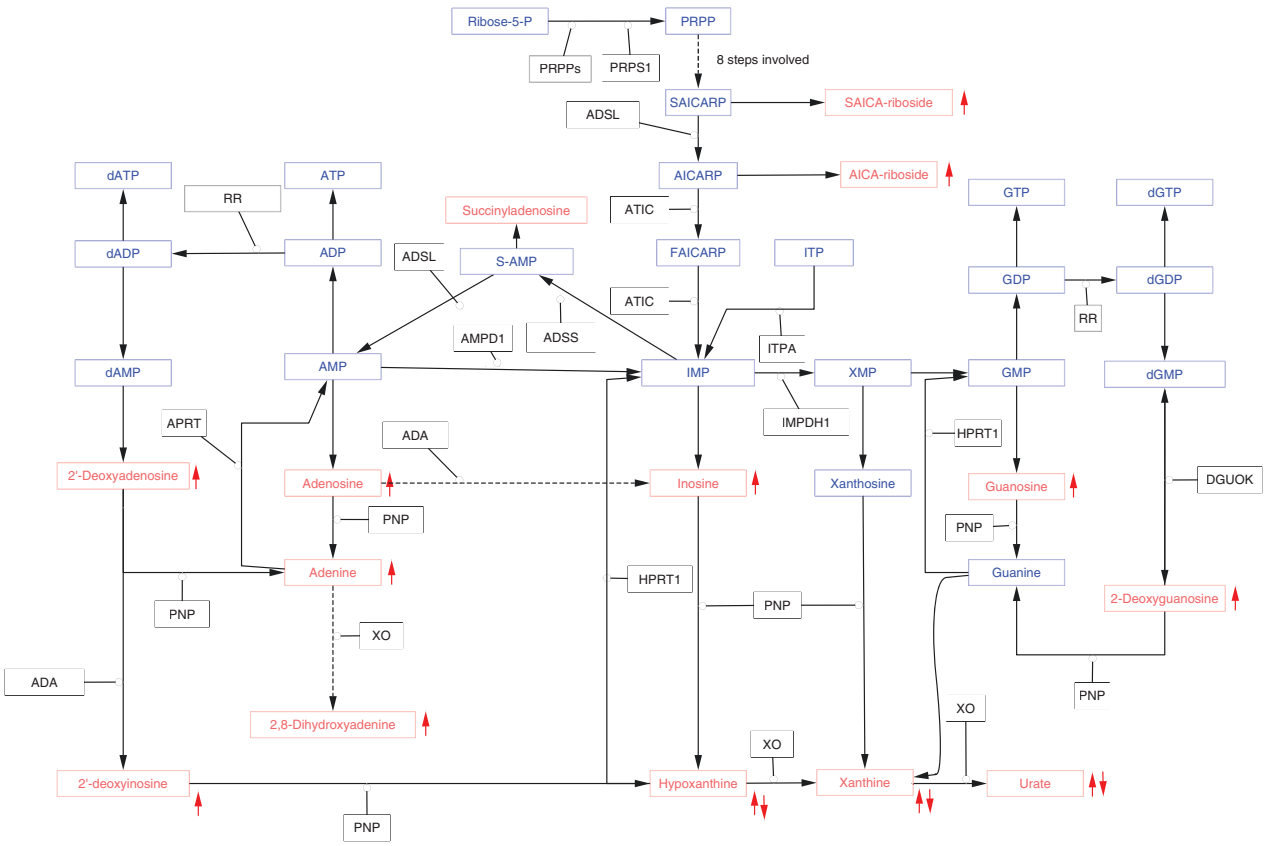

Fig. 73.3 Machine-readable version of the purine pathway, with metabolites in blue, proteins in black, and biomarker molecules in red (WikiPathways:WP4792)

phoribosyltransferase 1 enzyme (uniprot:P00492) which enables cells to recycle purines. After statistical analysis with GEO2R (Davis and Meltzer 2007), the differential gene expression data was visualized on the previously described purine pathway (Fig. 73.3) using the WikiPathways app in Cytoscape (apps.cytoscape.org/apps/wikipathways) (Kutmon et al. 2014b); see Fig. 73.4. Cytoscape (www.cytoscape.org) (Shannon et al. 2003) is a widely adopted network analysis and visualization software tool, and the WikiPathways app provides direct access to the WikiPathways pathway content. The log2 fold changes (difference in gene expression between patients and control group) are visualized as a gradient from blue (less expressed) over white (not changed) to red (more expressed). A strong downregulation of the *HPRT1* gene is immediately visible by the corresponding blue gene boxes. Based on this dataset, it seems that several of the other enzymes in the pathway (*PNP*, *APRT*, *PRPS1*) attempt to compensate for the lower transcript availability of HPRT1 and are upregulated in LND patients. Other enzymes, which are up- or downstream from the affected purine pathway, could also show changes relevant for the phenotype of the patient. Therefore, enrichment analysis on other pathway models can be used to assess the relevance of these pathways and find interesting affected processes in a certain dataset. Enrichment analysis showed several immune-related processes including the complement system as well as the Wnt signaling pathway affected in LND patients. Reimand et al. published a protocol that provides a description of pathway enrichment analysis and a practical step-by-step guide (Reimand et al. 2019).

Tutorial videos and R scripts for the data visualization (1A, Fig. 73.4) and pathway enrichment analysis (1B) can be found in the PathwayAnalysis folder on GitHub (bigcat-um.github.io/IEMPathwayAnalysis).

Pathways as a Source for Network Biology

Well-annotated pathway models are also an immensely useful source for network biology approaches. They can be used to extend biological pathways and networks (combinations of pathways) with additional knowledge, such as drug targets.

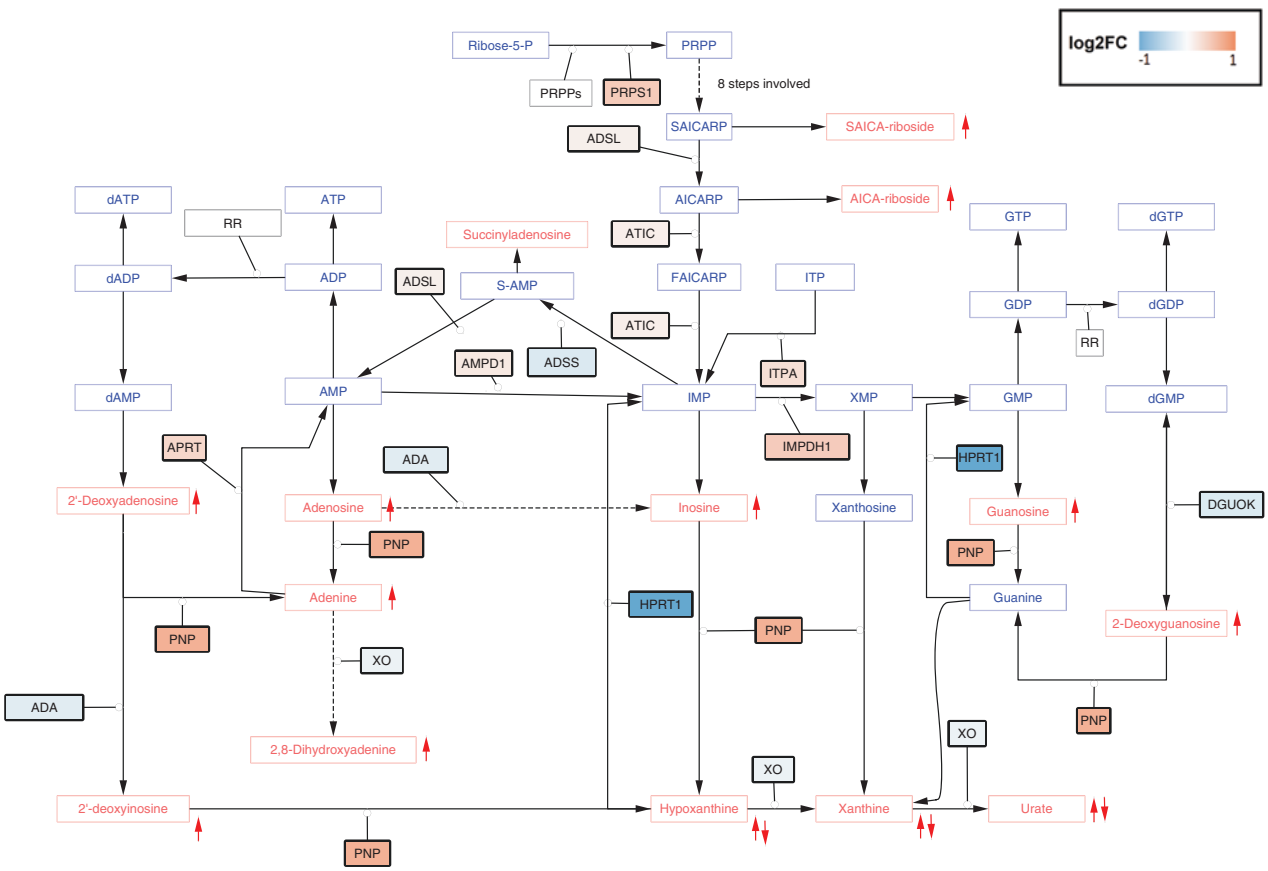

Fig. 73.4 Visualization of changes in gene expression in patients with Lesch-Nyhan disease in the purine metabolism pathway (WikiPathways: WP4792)

Using the WikiPathways app in Cytoscape, pathways can be visualized in two different views: the pathway view and the network view. The network view retains the existing biological interactions in the pathway only and applies an automatic layout allowing the pathways to be used for network analysis. Pathways can then be automatically enriched with additional information, e.g., regulatory mechanisms, known drugs, or disease annotations. The CyTargetLinker app for Cytoscape was specifically designed for this purpose (cytargetlinker.github.io) (Kutmon et al. 2019). In the following example, we will extend the purine metabolism pathway with approved drugs from DrugBank; see Fig. 73.5. The pathway contains fifteen enzymes, shown as rounded rectangles. In DrugBank, 21 drugs (shown as green diamonds) are reported to target one or more of these enzymes. Nine of the 15 enzymes are targeted by at least one drug, as shown in orange. The LND-causing gene *HPRT1* (highlighted with the red rectangle) is targeted by three drugs, azathioprine, mercaptopurine, and α-phosphoribosyl pyrophosphoric acid. The first two are immunosuppressants and inhibit *HPRT1*. The last molecule is a key substance in the biosynthesis of histidine, tryptophan, purine, and pyrimidine nucleotides and has unknown pharmacological action on *HPRT1*.

Tutorial videos and R scripts for the following example can be found in the Network Analysis folder on GitHub (bigcat-um.github.io/IEMPathwayAnalysis).

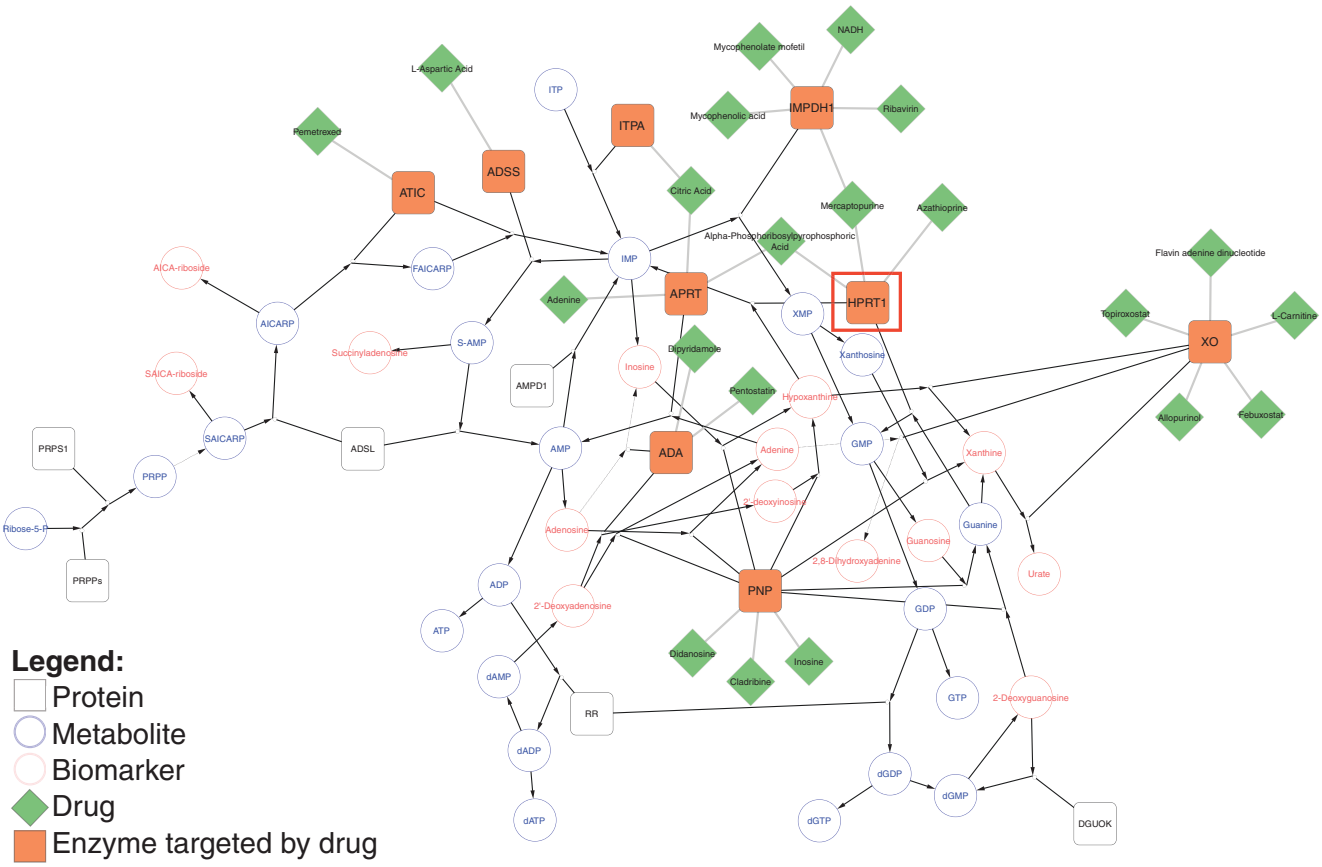

Fig. 73.5 Known drug-target interactions (from DrugBank) for the purine metabolism pathway

Linking Chemical (Biomarker) Data with RDF

The two examples in the previous sections work well for transcriptomics data. However, connecting metabolomics or chemical biomarker data to pathways can be challenging with the methods presented above, since the amount of data is significantly lower. Furthermore, as previously mentioned in Sect. 73.3.2, various levels of chemical detail exist within pathway models. To overcome these problems, we want to highlight another method to connect biomarkers data with pathways using an automated approach. The workflow for this example is visualized in Fig. 73.6a. One starts with chemical data from targeted (clinically validated) assays or with (un) targeted metabolomics data from mass spectrometry (MS) and/or nuclear magnetic resonance (NMR). After preprocessing of this data, for example, in R (Stanstrup et al. 2019), and annotation of relevant peaks with the corresponding chemical structure, one can also add an identifier from a (supported) database to the data. For subsequent data analysis steps, we used BridgeDb to link these identifiers to their corresponding InChIKey (a shortened version of the InChI) (Heller et al. 2015), which links the chemical structure to the original compound identifier in a machine-readable manner. The InChIKey consists of three parts (separated by a bar "-"); the first describes the general structure of a molecule, the second its stereochemistry, and the third the charge of the molecule. For example, "CKLJMWTZIZZHCS-REOHCLBHSA-M" is the InChIKey for L-aspartic acid monoanion, where the "M" stands for a −1 charge. In order to link these compounds to (metabolic) pathways, we will use a SPARQL query (Galgonek et al. 2016). This query is a structured method to ask questions to a database such as WikiPathways, which has been converted to the Resource Description Framework (RDF) format (Waagmeester et al. 2016). This RDF format unifies and harmonizes pathway data over all models, with several filtering and search options; data can be queried for specific species, *DataNodes*, literature, and more. Figure 73.6b provides an example of a SPARQL query where we investigated the occurrence of five compounds within the pathway models of WikiPathways. More details on the structure of the WikiPathways RDF and example queries are available on the Semantic Web portal: rdf.wikipathways.org. We also provide a beginners' tutorial on how to write SPARQL queries in the SPARQL folder on GitHub (bigcat-um.github.io/IEMPathwayAnalysis).

To visualize the concepts of SPARQL and data mapping, we chose the five naturally charged proteinogenic amino acids (positive charge: aspartic acid (Asp, D) and glutamic acid (Glu, E); negative charge: arginine (Arg, R), histidine (His, H), and lysine (Lys, K)). Lines 6–10 in Fig. 73.6b provide the InChIKeys for these compounds, which we will link to pathway data in line 15 (wp:bdbInChIKey ?inchikey). The results of the example query reveal in which pathways these compounds can be found, which are listed from lowest to highest (line 22) occurrence counts (line 4) in pathways, to find the most relevant pathways for further analysis. This results in 15 pathways, which all have one of these compounds present (RDF data release 2021-03-10). However, since pathways can be annotated with the uncharged form of these amino acids as well, we can also query all compounds

Fig. 73.6 Proposed workflow for data analysis of metabolic biomarkers with semantic web technologies. (**a**) Moving from chemical assay data to data interpretation using BridgeDb, SPARQL and Cytoscape. (**b**) Example of a SPARQL query on metabolic data in the WikiPathways RDF

with the same stereochemistry independent of change status, obtaining a more complete result. By changing the end of each compounds InChIKey to their neutral counterpart ("CKLJMWTZIZZHCS-REOHCLBHSA-M" becomes "CKLJMWTZIZZHCS-REOHCLBHSA-N") and changing line 15 to "rdfs:seeAlso ?inchikey," we obtain a total of 38 pathways, with 15 pathways containing 2 of the 5 amino acids (either in their neutral or charged form). This example is explained in more detail in the SPARQL folder on GitHub (bigcat-um.github.io/IEMPathwayAnalysis).

The next step in this workflow downloads the relevant pathways from WikiPathways in Cytoscape; see Sect. 73.4.1 and 73.4.2 for further details. When moving to a network tool, more advanced analysis approaches can be used. The chemical data can be visualized on the nodes in the network, while the edges (interactions between nodes) can be used to visualize fluxomic data (if available). After the data has been added, interpretation can be facilitated by additional features in Cytoscape, such as visualizing the chemical structure of the compounds, connecting several pathways (as networks) to obtain a more complete overview, adding other experimental data (e.g., transcriptomics; see Sect. 73.4.1), or expanding the network with biological knowledge from other databases (see Sect. 73.4.2).

Limitations

Every type of data analysis comes with its own set of limitations. For pathway analysis, the results depend on the coverage of the selected database (s), the mappings between identifiers from the dataset to the pathway knowledge, the statistics, and cut-off value used for the fold change to discover significant findings. Especially regarding this first issue, WikiPathways is a useful resource, since users can add missing information on pathways and interaction themselves, allowing them and others to use them directly in data analysis. Furthermore, the machine-readable model behind this database is flexible enough to accommodate the needs of researchers from the genetic inheritable metabolic disease research area. We hope that this chapter, as well as the created examples of machine-readable pathways from the figures in this book, provides other users inspiration to add more biological knowledge to databases. For more information on how to model these pathways, please visit help.wikipathways.org.

Conclusions

While regular pathway drawings are a great resource to visualize relevant biological interactions, these figures are not interactive and not directly reusable for data analysis. Understanding how to move from a regular pathway drawing to its machine-readable counterpart is pertinent for creating proper models. As shown in this chapter, having a digital pathway can link to reference databases and allows us to preform data integration and analysis. This will require some time and effort from the side of the user; however once these skills are mastered, adding new information is relatively easy, will decrease other research time needed for data analysis, and aid the research community as a whole.

Correction to: Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases

Correction to:

N. Blau et al. (eds.), *Physician's Guide to the Diagnosis, Treatment, and Follow-Up of Inherited Metabolic Diseases*, https://doi.org/10.1007/978-3-030-67727-5

The original version of the book was published with errors and was updated with the following corrections:

1. Chapter 73, WikiPathways: Integrating Pathway Knowledge with Clinical Data was previously published non-open access. It has now been changed to open access under a CC BY 4.0 license and the copyright holder updated to 'The Author(s)'. The book has also been updated with this change.
2. The affiliation of the fifth editor Dr. Clara D. M. van Karnebeek was updated to 'Departments of Pediatrics and Human Genetics, Emma Children's Hospital, Amsterdam University Medical Centers, Amsterdam, The Netherlands'.

The updated version of this book can be found at https://doi.org/10.1007/978-3-030-67727-5
