Handbook *of*
Atomic, Molecular,
and Optical Physics

Drake
Editor

2nd Edition

Springer Handbooks

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword

Atomic, molecular, and optical physics (AMO physics) encompasses the foundational knowledge of atomic physics and essential concepts and data for molecular and optical physics. AMO physics provides the tools for understanding the full gamut of atomic, ionic, and molecular collisions that is essential for astronomy and astrophysics. Knowledge from AMO physics overflows into neighboring fields: nuclear physics, material science, biophysics, geo-physics, and atmospheric science. AMO science is crucial to the understanding of climate change.

AMO physics has undergone dramatic advances since the last edition of the AMO Handbook. The discovery of ultracold atoms has led to new tools for many-body physics. Cavity quantum electrodynamics has opened avenues into field theory and quantum information processing. Advances in experimental techniques have revolutionized metrology and enabled a new generation of atomic frequency standards that have reached precision of parts in 10^{19} . A metrological revolution has taken place: all the basic units of science have been redefined in terms of quantum measurements.

Fundamental tests continue to flourish. Atoms now serve as tools for manipulating photons, quantum information theory and quantum communication have advanced, and the search for physics beyond the Standard Model has been carried forward. The discovery of gravitational waves by LIGO was enabled by advances in quantum optics from the AMO community, and the observation of radiation by matter as it falls through the event horizon of a black hole was made possible by synchronizing signals from observatories around the world using atomic clocks at their limit of accuracy.

The Table of Contents of this new edition of the *Springer Handbook of Atomic, Molecular, and Optical Physics* reflects the broad scope of AMO physics today. Its 91 chapters, written by experts and carefully reviewed, are an essential resource for physicists in academic, industrial, and federal research laboratories.

With the changing style in scientific publishing and library practice, browsing has become increasingly difficult. All the more reason to have access to the *Springer Handbook of Atomic, Molecular and Optical Physics*, for which browsing is almost irresistible.

January, 2021

Daniel Kleppner

Foreword to the First Edition by Herbert Walther

The *Handbook of Atomic, Molecular and Optical (AMO) Physics* gives an in-depth survey of the present status of this field of physics. It is an extended version of the first issue to which new and emerging fields have been added. The selection of topics thus traces the recent historic development of AMO physics. The book gives students, scientists, engineers, and other interested people a comprehensive introduction and overview. It combines introductory explanations with descriptions of phenomena, discussions of results achieved, and gives a useful selection of references to allow more detailed studies, making the handbook very suitable as a desktop reference.

AMO physics is an important and basic field of physics. It provided the essential impulse leading to the development of modern physics at the beginning of the last century. We have to remember that at that time not every physicist believed in the existence of atoms and molecules. It was due to Albert Einstein, whose work we commemorate this year with the world year of physics, that this view changed. It was Einstein's microscopic view of molecular motion that led to a way of calculating Avogadro's number and the size of molecules by studying their motion. This work was the basis of his PhD thesis submitted to the University of Zurich in July 1905 and after publication became Einstein's most quoted paper. Furthermore, combining kinetic theory and classical thermodynamics led him to the conclusion that the displacement of a microparticle in Brownian motion varies as the square root of time. The experimental demonstration of this law by Jean Perrin three years later finally afforded striking proof that atoms and molecules are a reality. The energy quantum postulated by Einstein in order to explain the photoelectric effect was the basis for the subsequently initiated development of quantum physics, leading to a revolution in physics and many new applications in science and technology.

The results of AMO physics initiated the development of quantum mechanics and quantum electrodynamics and as a consequence led to a better understanding of the structure of atoms and molecules and their respective interaction with radiation and to the attainment of unprecedented accuracy. AMO physics also influenced the development in other fields of physics, chemistry, astronomy, and biology. It is an astonishing fact that AMO physics constantly went through periods where new phenomena were found, giving rise to an enormous revival of this area. Examples are the maser and laser and their many applications, leading to a better understanding of the basics and the detection of new phenomena, and new possibilities such as laser cooling of atoms, squeezing, and other nonlinear behaviour. Recently, coherent interference effects allowed slow or fast light to be produced. Finally, the achievement of Bose–Einstein condensation in dilute media has opened up a wide range of new phenomena for study. Special quantum phenomena are leading to new applications for transmission of information and for computing. Control of photon emission through specially designed cavities allows controlled and deterministic generation of photons opening the way for a secure information transfer.

Further new possibilities are emerging, such as the techniques for producing attosecond laser pulses and laser pulses with known and controlled phase relation between the envelope and carrier wave, allowing synthesis of even shorter pulses in a controlled manner. Furthermore, laser pulses may soon be available that are sufficiently intense to allow polarization of the vacuum field. Another interesting development is the generation of artificial atoms, e.g.,

quantum dots, opening a field where nanotechnology meets atomic physics. It is thus evident that AMO physics is still going strong and will also provide new and interesting opportunities and results in the future.

Herbert Walther

Preface

The field of atomic, molecular, and optical physics is the oldest part of modern physics, and yet it provides the foundation upon which all the rest is built. The previous edition of the *Springer Handbook of Atomic, Molecular, and Optical Physics* was published in 2005, which was the International Year of Physics celebrating the *Annus mirabilis* of Einstein exactly 100 years earlier. 2005 also marked another in a long sequence of Nobel Prizes awarded for work in the area of AMO physics, this time to Roy Glauber, John Hall, and Ted Hänsch for their work on quantum optics and high-precision measurement. The sequence continued with the 2012 prize being awarded to Serge Haroche and David Wineland for their work on measuring and manipulating individual quantum systems, and the 2018 prize to Arthur Askin for the development of optical tweezers, and Gérard Mourou and Donna Strickland for high-intensity ultrashort laser pulses. Most recently, the Nobel Prize in Physics for 2022 was awarded jointly to Alain Aspect, John F. Clauser and Anton Zeilinger for experiments with entangled photons, establishing the violation of Bell inequalities, and pioneering quantum information science. The 2015 Prize for neutrino oscillations and the 2017 Prize for gravitational waves also made essential use of the techniques of AMO physics for their success. 2015 was also the International Year of Light, where the ever-expanding power and versatility of lasers played a prominent role; this continues to provide a unifying theme for much of AMO physics.

The intent of this Handbook is to provide a ready reference for the principal ideas, techniques, and results that are common to all these areas of research where exciting advances continue apace. The success of the previous 2005 edition and advances in the field provide the motivation for the current revised edition, with the expectation that it will continue as a standard reference source for the field. Many of the topics have not changed significantly since the previous edition was published, such as angular momentum algebra (Chap. 2), perturbation theory (Chap. 5), second quantization (Chap. 6), and the properties of hydrogenic wave functions (Chap. 9), and so these chapters are still the same (except for minor corrections). However, most of the other chapters have been extensively revised, and in some cases completely rewritten. In the search for new physics beyond the Standard Model, it has become increasingly evident that high-precision atomic physics measurements at low energy can be used to supplement, or in some cases extend, what can be learned from high-energy particle accelerators. Entirely new chapters are included on searches for dark matter and an electron electric dipole moment (EDM), and tests of Lorentz invariance and general relativity. The major previous sections on lasers, laser interactions with matter, and quantum optical tests of the foundations of physics remain of central importance in the revised edition, along with the various forms of spectroscopy. The sections on scattering phenomena, both theoretical and experimental, have been augmented to include a new chapter on ultracold Rydberg atom collisions, and another on quantum defect theory. The section on applications remains as important and timely as ever, with extensively updated chapters on aeronomy and global change. Chapter 1 on units and constants has been completely transformed by the redefinition of Planck's constant, Avogadro's number, Boltzmann's constant, and the elementary charge as defined physical constants with zero uncertainty.

The preparation of the original Handbook and the current revision would not have been possible without the help and advice of many people throughout the AMO physics commu-

nity. To name just a few, I am particularly indebted to Thomas Kirchner, Klaus Bartschat, and Jonathan Tennyson for their help and advice on revisions to the section on scattering theory, and to Pierre Meystre and Bruce Shore for their advice and guidance in extending and restructuring the section on quantum optics. Marianna Safronova provided valuable input on searches for new physics beyond the Standard Model.

We regret that the following authors, all giants in the field, from the previous edition are no longer with us. In order of their appearance in the previous edition, they are James D. Louck, Robert N. Hill, William C. Martin, Anthony F. Starace, M. Raymond Flannery, Philip Burke, Bernd Crasemann, Stig Stenholm, Alexander Dalgarno, Alan Garscadden, Hans Bichsel, Mitio Inokuti, John M. Brown, Lorenzo J. Curtis, Kenneth Evenson, Gordon Feldman, Thomas Fulton, Axel Schenzle, Paul Feldman, and Michael R. Strayer.

Work on the current revision project began in February, 2016, and so it has been nearly seven years in the making. Much of the day-to-day work involved corresponding with over 100 authors and keeping track of the status of each of the 91 chapters as they passed through an external review process followed by revisions. In many cases, it also involved actively helping authors solve problems with their \LaTeX source code and establishing good lines of communication with each author concerning the content of other related chapters. All of this would not have been possible without the very capable help of the three Editorial Assistants who worked on various stages of the project: Jacklyn Bizarre, Shawn Steven, and Fatemeh Hamdizadeh. Their tireless efforts and energy contributed greatly to the successful completion of the project. I would also like to acknowledge the very capable assistance of the Springer Handbook Coordinators: Veronika Hamm, Heather King, and Judith Hinterberg. I owe a great debt of gratitude to all of these people in making this revised edition of the *Springer Handbook of Atomic, Molecular and Optical Physics* a reality. I am especially grateful for the love and support of my wife, Mary Louise, and my children Susan and Peter. I hope that the present edition will continue to serve as a valuable resource for many years to come.

November, 2022

Gordon W.F. Drake

Preface to the First Edition

The year 2005 has been officially declared by the United Nations to be the International Year of Physics to commemorate the three famous papers of Einstein published in 1905. It is a fitting tribute to the impact of his work that the *Springer Handbook of Atomic, Molecular, and Optical Physics* should be published in coincidence with this event. Virtually all of AMO Physics rests on the foundations established by Einstein in 1905 (including a fourth paper on relativity and his thesis) and his subsequent work. In addition to the theory of relativity, for which he is best known, Einstein ushered in the era of quantum mechanics with his explanation of the photoelectric effect, and he demonstrated the influence of molecular collisions with his explanation of Brownian motion. He also laid the theoretical foundations for all of laser physics with his discovery (in 1917) of the necessity of the process of stimulated emission, and his discussions of the Einstein–Podolsky–Rosen Gedanken experiment (in 1935) led, through Bell’s inequalities, to current work on entangled states and quantum information. The past century has been a Golden Age for physics in every sense of the term.

Despite this history of unparalleled progress, the field of AMO Physics continues to advance more rapidly than ever. At the time of publication of an earlier Handbook published by AIP Press in 1996 I wrote “The ever increasing power and versatility of lasers continues to open up new areas for study.” Since then, two Nobel Prizes have been awarded for the cooling and trapping of atoms with lasers (Steven Chu, Claude Cohen-Tannoudji, William D. Phillips in 1997), and for the subsequent achievement of Bose–Einstein condensation in a dilute gas of trapped atoms (Eric A. Cornell, Wolfgang Ketterle, Carl E. Wieman in 2001). Although the topic of cooling and trapping was covered in the AIP Handbook, Bose–Einstein condensation was barely mentioned. Since then, the literature has exploded to nearly 2500 papers on Bose–Einstein condensation alone. Similarly, the topics of quantum information and quantum computing barely existed in 1995, and have since become rapidly growing segments of the physics literature. Entirely new topics such as “fast light” and “slow light” have emerged. Techniques for both high precision theory and measurement are opening the possibility to detect a cosmological variation of the fundamental constants with time. All of these topics hold the promise of important engineering and technological applications that come with advances in fundamental science. The more established areas of AMO Physics continue to provide the basic data and broad understanding of a great wealth of underlying processes needed for studies of the environment, and for astrophysics and plasma physics.

These changes and advances provide more than sufficient justification to prepare a thoroughly revised and updated *Atomic, Molecular and Optical Physics Handbook* for the Springer Handbook Program. The aim is to present the basic ideas, methods, techniques and results of the field at a level that is accessible to graduate students and other researchers new to the field. References are meant to be a guide to the literature, rather than a comprehensive bibliography. Entirely new chapters have been added on Bose–Einstein condensation, quantum information, variations of the fundamental constants, and cavity ring-down spectroscopy. Other chapters have been substantially expanded to include new topics such as fast light and slow light. The intent is to provide a book that will continue to be a valuable resource and source of inspiration for both students and established researchers.

I would like to acknowledge the important role played by the members of the Advisory Board in their continuing support of this project, and I would especially like to acknowledge the talents of Mark Cassar as Assistant Editor. In addition to keeping track of the submissions and corresponding with authors, he read and edited the new material for every chapter to ensure uniformity in style and scientific content, and he composed new material to be added to some of the chapters, as noted in the text.

List of Tables

Table 1.1	Exact quantities and their symbols, numerical values, and units in the SI	4
Table 1.2	Selected constants as well as atomic and natural units based on the 2018 CODATA adjustment of the fundamental constants [5]. The first two columns describe the quantity and its mathematical symbol. The third and fourth columns give its numerical value and unit. For quantity X the number in parenthesis in the numerical value is the combined statistical and systematic one-standard-deviation uncertainty $u(X)$ in the last two digits of the numerical value. Finally, the last column gives the relative standard uncertainty $u_r(X) = u(X)/ X $. The unit u is the atomic mass unit, one-twelfth of the mass of a ^{12}C atom	6
Table 2.1	The solid and spherical harmonics \mathcal{Y}_{lm} and the tensor harmonics \mathcal{T}_{μ}^k (labeled by $k = l$ and $\mu = m$) for $l = 0, 1, 2, 3$, and 4	65
Table 2.2	The $3-j$ coefficients for all M 's = 0 or $J_3 = 0, \frac{1}{2}$	65
Table 2.3	The $3-j$ coefficients for $J_3 = 1, \frac{3}{2}, 2$	65
Table 2.4	The $6-j$ coefficients for $d = 0, \frac{1}{2}, 1, \frac{3}{2}, 2$, with $s = a + b + c$	66
Table 3.1	Generators of the Lie groups for the atomic l shell. The subscripts i and j run over all $4l + 2$ states of a single electron	73
Table 3.2	Dimensions D of the irreducible representations (IR's) of various Lie groups	74
Table 3.3	Eigenvalues of Casimir's operator C for groups used in the atomic l shell	74
Table 3.4	The states of the d shell	76
Table 10.1	Atomic structure programs	166
Table 10.2	Atomic scattering programs	166
Table 10.3	Molecular structure programs	167
Table 10.4	Molecular and heavy particle scattering programs	167
Table 10.5	GNU autotools table	169
Table 10.6	Types of FORTRAN compilers	170
Table 10.7	Types of mixing techniques of languages	171
Table 10.8	Types of third-party libraries	172
Table 10.9	Testing harnesses (frameworks)	172
Table 11.1	Atomic structure hierarchy in LS coupling and names for groups of transitions between structural entities	179
Table 11.2	Allowed J -values for l_j^N equivalent electrons (jj) coupling	180
Table 11.3	Ground levels and ionization energies for neutral atoms	184
Table 11.4	Selection rules for discrete transitions	187
Table 11.5	Conversion relations between S and A_{ki} for forbidden transitions	188
Table 11.6	Wavelengths λ , upper energy levels E_k , statistical weights g_i and g_k of lower and upper levels, and transition probabilities A_{ki} for persistent spectral lines of neutral atoms. Many tabulated lines are resonance lines (marked "g"), where the lower energy level belongs to the ground term	190
Table 11.7	Some transitions of the main spectral series of hydrogen	194

Table 11.8	Values of Stark-broadening parameter $\alpha_{1/2}$ of the H_β line of hydrogen (486.1 nm) for various temperatures and electron densities	195
Table 12.1	Formulas for the radial integrals $I_0(a, b, c; \alpha, \beta) = \langle r_1^a r_2^b r_{12}^c e^{-\alpha r_1 - \beta r_2} \rangle_{\text{rad}}$ and $I_0^{\text{log}}(a, b, c; \alpha, \beta) = \langle r_1^a r_2^b r_{12}^c \ln r_{12} e^{-\alpha r_1 - \beta r_2} \rangle_{\text{rad}}$. $\psi(n) = -\gamma + \sum_{k=1}^{n-1} k^{-1}$ is the digamma function, ${}_2F_1(a, b; c; z)$ is the hypergeometric function, and $s = a + b + c + 5$. Except as noted, the formulas apply for $a \geq -1$, $b \geq -1$, $c \geq -1$	203
Table 12.2	Nonrelativistic eigenvalue coefficients ε_0 and ε_1 for helium	206
Table 12.3	Eigenvalue coefficients ε_2 for helium	207
Table 12.4	Values of the reduced electron mass ratio μ/M , including binding energy corrections	207
Table 12.5	Nonrelativistic eigenvalues $E = \varepsilon_0 + (\mu/M)\varepsilon_1 + (\mu/M)^2\varepsilon_2$ for helium-like ions (in units of e^2/a_μ)	208
Table 12.6	Expectation values of various operators for He-like ions for the case $M = \infty$ (in a.u.)	208
Table 12.7	Total ionization energies for ${}^4\text{He}$, calculated with $R_M = 3\,289\,391\,006.600\text{MHz}$	209
Table 12.8	QED corrections to the ionization energy included in Table 12.7 for the S and P -states of helium (in MHz)	210
Table 12.9	Quantum defects for the total energies of helium with the ΔW_n term subtracted [Eq. (12.56)]	211
Table 12.10	Formulas for the hydrogenic expectation value $\langle r^{-j} \rangle \equiv \langle nl r^{-j} nl \rangle$ in terms of $G_p^{nl} = \frac{2^p Z^p (2l-p+2)!}{n^{p+1} (2l+p-1)!}$, $f_p^l = \frac{(l+p)!}{(l-p)!}$	212
Table 12.11	Oscillator strengths for helium. The factor in brackets gives the finite mass correction, with $y = \mu/M$	214
Table 12.12	Singlet-triplet mixing angles for helium	215
Table 14.1	Relativistic ground state binding energy $-E_{\text{gs}}/Z^2$ and finite nuclear size correction $\delta E_{\text{nuc}}/Z^2$ (in a.u.) of hydrogenic atoms for various magnetic fields B (in units of 2.35×10^5 T). δE_{nuc} should be added to E_{gs}	226
Table 14.2	Relativistic binding energy $-E_{2S, -1/2}$ for the $2S_{1/2}$ ($m_j = -\frac{1}{2}$) and $-E_{2P, -1/2}$ for the $2P_{1/2}$ ($m_j = -\frac{1}{2}$) excited states of hydrogen (in a.u.) in an intense magnetic field B (in units of 2.35×10^5 T)	226
Table 14.3	Relativistic corrections $\delta E = (E - E_{\text{NR}})/ E_{\text{R}} $ to the nonrelativistic energies E_{NR} for the ground state and $n = 2$ excited states of hydrogen in an intense magnetic field B (in units of 2.35×10^5 T). The numbers in brackets denote powers of 10	227
Table 14.4	Relativistic dipole polarizabilities for the ground state of hydrogenic atoms	228

Table 22.1	The effective quantum number and quantum defect parameters of the $2snd$ Rydberg series in Be	318
Table 22.2	Observed and Hartree–Fock ionization potentials for the ground states of neutral atoms, in eV.	318
Table 22.3	Classification of replacements from the $1s^2 2s$ ground state of Li. The $1s$ and $2s$ orbitals are occupied, and all the other orbitals are virtual orbitals, vl	319
Table 22.4	Comparison of theoretical and experimental energies for Be $1s^2 2s^2 {}^1S$ in hartrees. All theoretical values include some form of extrapolation	322
Table 22.5	Comparison of CAS-MCHF and PCFI total energies (in hartrees) for the ground state of beryllium with increasing orbital active sets. NCSF corresponds to the size M of the CSF expansion Eq. (22.17)	323
Table 22.6	Convergence of transition data for the $1s^2 2s^2 2p^2 P^\circ \rightarrow 1s^2 2s 2p^2 {}^2D$ transition in boron with increasing active set	324

Table 22.7	Specific mass shift parameter and electron density at the nucleus as a function of the active set	327
Table 22.8	MCHF hyperfine constants (in MHz) for the $1s^2 2s 2p \ ^1P^o$ state of B II . . .	328
Table 23.1	Relativistic angular density functions	344
Table 23.2	Nonrelativistic angular density functions	344
Table 23.3	Spectroscopic labels and angular quantum numbers	345
Table 23.4	Radial moments $\langle \rho^s \rangle$	348
Table 23.5	j^N configurational states in the seniority scheme. The multiplicity of each unresolved degenerate state is indicated by a superscript	357
Table 26.1	Test of sum rule in Eq. (26.15) for the lowest $\text{He}^- (1s 2s^2 \ ^2S)$ autodetachment state [5]. Projection operators are based on a 4 term Hylleraas ϕ_0 and the variational form of v_α given below. Values of other constants are given in [5]	397
Table 26.2	Comparison of methods for calculating the energy of the lowest $\text{He}^- (1s 2s^2 \ ^2S)$ autodetachment state. The QHQ results are denoted $(\hat{E} - E_0)_{\text{Quasi}}$ for the quasi-projection method and $(E - E_0)_{\text{Complete}}$ for the complete projection method [5]. The entries labeled <i>Other results</i> give the full resonant energy. Units are eV	397
Table 26.3	Energies \mathcal{E}_s of the $\text{He}(2s 2p \ ^1P^0)$ autoionization states below $\text{He}^+ (n = 2)$ threshold from the variational calculations of <i>O'Malley</i> and <i>Geltman</i> [11]. Units are Ry; N is the number of terms in the trial function	397
Table 26.4	Comparison of high-precision calculations with the experiment for the resonance parameters of the $\text{He}(^1P^0)$ resonances below the $n = 2$ threshold. For photoabsorption, the appropriate Rydberg constant is $R_M = R_\infty / (1 + m/M)$ [19]. The value used here is $R_M = 13.603833$ eV, and $E_0 = -79.0151$ eV [6]	399
Table 26.5	Comparison of resonance parameters (in eV) obtained from different methods for calculating $^1D^e$ states in H^-	401
Table 26.6	Singlet autoionization states of He of $S, P, D,$ and F angular momentum below the $n = 2$ threshold of He^+ . Results are in eV relative to the ground state energy of $\text{He} = -5.8074475$ Ry	401
Table 26.7	Triplet autoionization states of He of $S, P, D,$ and F angular momentum below the $n = 2$ threshold of He^+ . Results are in eV relative to the ground state energy of $\text{He} = -5.8074475$ Ry	401
Table 26.8	Singlet and triplet autoionization states of Ps^- . Results are in eV relative to the ground state energy of $\text{Ps} = 0.5$ Ry	401
Table 26.9	$^3P^e$ states of Ps^- . Results are in eV relative to the ground state energy of $\text{Ps} = 0.5$ Ry	402
Table 26.10	Odd parity $^{1,3}P$ states of Ps^- . Resonance positions are with respect to the ground state energy of $\text{Ps} = 0.5$ Ry	402
Table 26.11	Resonance energies \mathcal{E}_F (Ry) and widths (eV) for 1P states of He below the $n = 2$ threshold (-1 Ry) of He^+	403
Table 26.12	$^3P^e$ shape resonances in Ps^- . Results are in eV relative to the ground state energy of $\text{Ps}^- = -0.5$ Ry	403
Table 29.1	Coefficients for the QED contributions to the electron anomaly. The coefficients $A_1^{(2n)}$ and functions $A_2^{(2n)}(x)$, evaluated at $x = x_{e\mu} \equiv m_e/m_\mu$ and $x_{e\tau} \equiv m_e/m_\tau$ for the muon and tau leptons, respectively, are listed with two significant digits for ease of comparison; summed values $C_e^{(2n)}$, based on the 2014 CODATA adjustment, are listed as accurately as needed for the tests described in this article. Missing values indicate that their contribution to the electron anomaly is negligible	437

Table 29.2	Theoretical contributions and total value for the g -factor of hydrogenic carbon 12 based on the 2014 CODATA recommended values of the constants and corresponding theory. The total g -factor has a relative uncertainty of 1.3×10^{-11}	441
Table 29.3	Theoretical contributions and total value for the g -factor of hydrogenic silicon 28 based on the 2014 CODATA recommended values of the constants and corresponding theory. The total g -factor has a relative uncertainty of 8.5×10^{-10}	441
Table 29.4	List of contributions and their main dependence on fundamental constants to the hydrogen transition frequencies ordered by appearance in the text. The first two columns give the section in Sec. 29.7.1 in which the contribution is described in detail and the name of the contribution, respectively. The fundamental-constant dependence of a contribution in the third column is given in terms of the Hartree energy $E_h = m_e c^2 \alpha^2$ and four dimensionless variables with values small compared to one: the fine-structure constant α , the proton charge radius divided by the reduced Compton wavelength r_p/λ_C , and the mass ratios m_e/m_μ and m_e/m_p . The last column gives the order of magnitude of each of the contributions in Hz for the $1S_{1/2}-2S_{1/2}$ transition	443
Table 29.5	Values of the Bethe logarithms $\ln k_0(n, \ell)$. Missing entries correspond to states for which no experimental measurements are available	443
Table 29.6	Values of the function $G_{SE}(\alpha)$. Missing entries correspond to states for which no experimental measurements are available	445
Table 29.7	Values of the function $G_{VP}^{(1)}(\alpha)$. No experimental data is available for missing entries. Zero values indicate that their contributions are negligibly small	445
Table 29.8	Values of B_{61} used in the 2014 CODATA adjustment. Zero values indicate that their contributions are negligibly small	445
Table 29.9	Values of B_{60} used in the 2014 CODATA adjustment. The uncertainties of B_{60} for S-states are explained in the text	445
Table 30.1	Accurately measured atomic transition frequencies and their fractional uncertainty ([9, 12] and references therein). These transitions have been used in evaluations of temporal variation of fundamental constants	453
Table 30.2	Magnetic moments and relativistic corrections for atoms involved in microwave standards. The relativistic sensitivity κ is defined in Sec. 30.2.3. Here, μ is an actual value of the nuclear magnetic moment, μ_N is the nuclear magneton, and μ_S stands for the Schmidt value of the nuclear magnetic moment; the nucleon g factors are $g_p/2 \simeq 2.79$ and $g_n/2 \simeq -1.91$	454
Table 30.3	The frequencies of different transitions in neutral atoms and ions, applied or tried for precision spectroscopy, and their sensitivity to variations in α due to relativistic corrections	455
Table 30.4	Model-independent laboratory constraints on the possible time variations of natural constants [41, 42]	457
Table 30.5	Progress in constraining a possible time variation of the fundamental constants: the results of 2004 (following [43, 44]), 2008 (following [45]), and of 2014 using data summarized in [42] but following [43, 44] (see [41] for details). Here, ρ is the correlation coefficient $\rho(\partial \ln \alpha / \partial t, \partial \ln \{R_\infty\} / \partial t)$	457

Part A
Mathematical Methods

Part A gathers together the mathematical methods applicable to a wide class of problems in atomic, molecular, and optical physics. The application of angular momentum theory to quantum mechanics is presented. The basic tenet that isolated physical systems are invariant to rotations of the system is thereby implemented into physical theory. The powerful methods of group theory and second quantization show how simplifications arise if the atomic shell is treated as a basic structural unit. The well-established symmetry groups of quantum mechanical Hamiltonians are extended to the larger compact and noncompact dynamical groups. Perturbation theory is introduced as a bridge between an exactly solvable problem and a corresponding real one, allowing approx-

imate solutions of various systems of differential equations. The consistent manner in which the density matrix formalism deals with pure and mixed states is developed, showing how the preparation of an initial state, as well as the details regarding the observation of the final state, can be treated in a systematic way. The basic computational techniques necessary for accurate and efficient numerical calculations essential to all fields of physics are outlined, and a summary of relevant software packages is given. The ever-present one-electron solutions of the nonrelativistic Schrödinger equation and the relativistic Dirac equation for the Coulomb potential are then summarized. A summary of the computer software available for atomic and molecular physics calculations is included.

Abstract

We describe atomic and natural units relevant for the atomic, molecular, and optical physics described in this book. For nonrelativistic models of atoms and molecules absorbing and emitting photons atomic units are appropriate. In this system, energies and lengths are expressed in terms of the Hartree energy and Bohr radius, respectively. Relativistic models are required for precision quantum electrodynamics-based determinations of energy levels of hydrogen and other light atoms and molecules. Natural units are then the most appropriate, and energies and length are expressed in the rest energy of the electron and the reduced Compton wavelength, respectively. Finally, we present values for an abbreviated list of fundamental constants taken from the CODATA (Committee on Data for Science and Technology) adjustment of fundamental constants based on data published or made available before the end of 2018.

Keywords

atomic units · fine structure constant · fundamental constants · International System of Units (SI) · natural units

1.1 Introduction

In science we communicate measurements of quantities or observables in terms of a product of a numerical value and a unit, where the unit is a particular example of the quantity. For example, the spin of an electron is $(1/2)\hbar$, where $1/2$ is the numerical value, and the reduced Planck constant \hbar is the unit or example angular momentum. Equivalently, the spin of the electron is $0.527\,285\dots\times 10^{-34}$ J s in the International System of Units (SI) [1]. More digits for the numerical value can be easily found now that the Planck constant is exactly defined in the SI. In fact, seven exact constants define the seven SI base units second, meter, kilogram, Coulomb, kelvin, and lumen [1]. The names and values of these constants are given in Table 1.1. It was only on World Metrology Day, 20 May 2019, that the Planck constant, elementary charge, Boltzmann constant, and the Avogadro constant were given their exact value in the SI. See [2] for a review of the ideas that led to this redefinition.

The example in the previous paragraph shows that some units are more convenient than others. We tend to prefer units where the numerical value of the measured quantity is of order 1. Preferred units for a system follow from its Hamiltonian H in a process that makes H as well as all operators and constants appearing in H dimensionless. Operators can correspond to particle spins, positions, and momenta but also fields in quantum field theories.

In this chapter, we derive atomic and natural units as they appear in atomic, molecular, and optical physics. For a different view of units in the field of electromagnetism, we recommend the appendix on units and dimensions of [3]. We also present a list of relevant fundamental constants.

1.2 Atomic Units

We derive atomic units starting from the nonrelativistic Hamiltonian for an electron with charge $-e$ and mass m_e

Table 1.1 Exact quantities and their symbols, numerical values, and units in the SI

Quantity	Sym.	Value	Unit
Hyperfine transition frequency of ^{133}Cs	$\Delta\nu_{\text{Cs}}$	9 192 631 770	Hz
Speed of light in vacuum	c	299 792 458	m s^{-1}
Planck constant ^a	h	$6.626\,070\,15 \times 10^{-34}$	J Hz^{-1}
	\hbar	$1.054\,571\,817 \dots \times 10^{-34}$	J s
Elementary charge	e	$1.602\,176\,634 \times 10^{-19}$	C
Boltzmann constant	k	$1.380\,649 \times 10^{-23}$	J K^{-1}
Avogadro constant	N_{A}	$6.022\,140\,76 \times 10^{23}$	mol^{-1}
Luminous efficacy	K_{cd}	683	lm W^{-1}

^a The energy of a photon with frequency ν expressed in unit Hz is $E = h\nu$ in J. The unitary time evolution of the state of this photon is given by $\exp(-iEt/\hbar)|\varphi\rangle$, where $|\varphi\rangle$ is the photon state at time $t = 0$, and time is expressed in unit s. The ratio Et/\hbar is a phase.

bound to an infinitely heavy point-like source with charge $+Ze$, possibly absorbing and emitting transverse photons. Following [4] we use the Coulomb gauge and assume that the charges are contained in a large cubic box with periodic boundary conditions and length L on each side. Here, e is the (positive) elementary charge, and Z is a positive integer. Hence, we have

$$H = \frac{(\vec{p} + e\vec{A}_{\perp}(\vec{r}))^2}{2m_e} - \frac{1}{4\pi\epsilon_0} \frac{Ze^2}{r} + \sum_j \hbar\omega_j \left[a_j^{\dagger} a_j + \frac{1}{2} \right], \quad (1.1)$$

where \vec{r} and \vec{p} are the position and momentum operators of the electron, respectively, and the commutation relations $[r_i, p_j] = i\hbar\delta_{ij}$ for vector components i and j hold. The source is located at $\vec{r} = \vec{0}$, ϵ_0 is the vacuum electric permittivity, and δ_{ij} is the Kronecker delta. For simplicity, we have omitted the Zeeman interaction of the electron spin coupling to a magnetic field.

The last term of Eq. (1.1) describes the photon-field Hamiltonian, where operators a_j and a_j^{\dagger} annihilate and create photons, respectively. For index j , photons are specified by polarization $\vec{\epsilon}_j$ and wavevector \vec{k}_j . The components of the wavevector are integer multiples of $2\pi/L$. By construction $\vec{\epsilon}_j$ and \vec{k}_j are perpendicular to each other, and the frequency of photon j is $\omega_j = c|\vec{k}_j|$, where c is the speed of light in vacuum. Operators a_j and a_j^{\dagger} satisfy the commutation relations $[a_i, a_j^{\dagger}] = \delta_{ij}$. Finally, the transverse vector field operator $\vec{A}_{\perp}(\vec{r})$ ¹ is given by

$$\vec{A}_{\perp}(\vec{r}) = \sum_j \sqrt{\frac{\hbar}{2\epsilon_0\omega_j L^3}} \left[a_j \vec{\epsilon}_j e^{i\vec{k}_j \cdot \vec{r}} + a_j^{\dagger} \vec{\epsilon}_j e^{-i\vec{k}_j \cdot \vec{r}} \right]. \quad (1.2)$$

Similar expressions for the transverse electric $\vec{E}_{\perp}(\vec{r})$ and magnetic $\vec{B}(\vec{r})$ field operators can be written down. The con-

¹ A transverse vector field $\vec{F}_{\perp}(\vec{r})$ in position space \vec{r} is a field such that its Fourier representation $\vec{F}_{\perp}(\vec{k})$ is perpendicular to \vec{k} for all wavevectors \vec{k} . Magnetic fields are transverse vector fields in any gauge and subscript \perp is often dropped.

stants ϵ_0 , c , and the vacuum magnetic permeability μ_0 are not independent. They satisfy

$$c^2 = \frac{1}{\mu_0\epsilon_0}. \quad (1.3)$$

We are now ready to make the Hamiltonian dimensionless. We assume that there exists a convenient length scale a_0 and write for the position operator of the electron $\vec{r} = \vec{x} a_0$, where operator \vec{x} is dimensionless. An equally valid interpretation of $\vec{x} a_0$ is that \vec{x} is a vector of numerical values, and a_0 is the unit for position. The commutation relation for \vec{r} and \vec{p} imply $\vec{p} = -i\hbar\nabla_r$, where ∇_r is the gradient or nabla vector differential operator in \vec{r} , and thus $\vec{p} = -i\nabla_x \hbar a_0^{-1}$. The wavevector and frequency of the photon field are made dimensionless with $\vec{k}_j = \vec{q}_j a_0^{-1}$ and $\omega_j = |q_j| c a_0^{-1}$. The components of \vec{q}_j are integer multiples of $2\pi/\ell$, where $L = \ell a_0$. Thus, the units of electron momentum, photon wavevector, and frequency are $\hbar a_0^{-1}$, a_0^{-1} , and $c a_0^{-1}$, respectively.

To summarize, Eq. (1.1) becomes

$$H = \frac{\hbar^2}{m_e a_0^2} \frac{1}{2} \left(-i\nabla_x + \frac{e a_0}{\hbar} \vec{A}_{\perp}(\vec{x} a_0) \right)^2 - \frac{e^2}{4\pi\epsilon_0 a_0} \frac{Z}{x} + \hbar c a_0^{-1} \sum_j |q_j| \left[a_j^{\dagger} a_j + \frac{1}{2} \right]. \quad (1.4)$$

A comparison of the energies of the first two terms suggests that we choose a_0 such that

$$\frac{\hbar^2}{m_e a_0^2} = \frac{e^2}{4\pi\epsilon_0 a_0} \equiv E_h, \quad (1.5)$$

and, thus,

$$a_0 = \frac{4\pi\epsilon_0 \hbar^2}{m_e e^2}. \quad (1.6)$$

The reference quantities E_h and a_0 or the atomic units of energy and length are better known as the Hartree energy and the Bohr radius, respectively. The Rydberg frequency cR_{∞} is defined by $cR_{\infty} = E_h/2h$.

In atomic units the vector potential is made dimensionless with the choice

$$\vec{A}_\perp(\vec{x} a_0) \equiv \vec{\mathcal{A}}_\perp(\vec{x}) \frac{\hbar}{e a_0}, \quad (1.7)$$

so that the Hamiltonian reads

$$H = \left\{ \frac{1}{2} \left(-i \nabla_x + \vec{\mathcal{A}}_\perp(\vec{x}) \right)^2 - \frac{Z}{x} + \sum_j \frac{1}{\alpha} |q_j| \left[a_j^\dagger a_j + \frac{1}{2} \right] \right\} E_h, \quad (1.8)$$

where the dimensionless fine-structure constant α is

$$\alpha = \frac{e^2}{4\pi\epsilon_0 \hbar c}, \quad (1.9)$$

and $1/\alpha$ is the numerical value of the speed of light in vacuum in atomic units. Specifically, the unit of velocity is $\hbar/m_e a_0$.

1.3 Natural Units

Natural units follow from Dirac's relativistic description of the negatively-charged electron bound to an infinitely-heavy point charge in the presence of transverse photons. Thus, in the Coulomb gauge, we have

$$H_{\text{rel}} = \beta m_e c^2 + c \vec{\alpha} \cdot (\vec{p} + e \vec{A}_\perp(\vec{r})) - I_4 \frac{1}{4\pi\epsilon_0} \frac{Z e^2}{r} + \sum_j \hbar \omega_j \left[a_j^\dagger a_j + \frac{1}{2} \right], \quad (1.10)$$

where $\vec{\alpha}$ and β are four dimensionless mutually anticommuting four-component Dirac matrices with $\alpha_i^2 = \beta^2 = I_4$, and I_4 is the four-component identity matrix. The definition for the transverse vector potential $\vec{A}_\perp(\vec{r})$ remains that of Eq. (1.2). For our purpose of defining natural units, we can ignore interpretations of the positive and negative energy solutions of the Dirac equation as well as effects such as virtual electron-positron pairs, which will be present in the complete quantum electrodynamic (QED) theory.

This relativistic Hamiltonian can be made dimensionless by assuming the length unit λ_C and $\vec{r} = \vec{x} \lambda_C$ with similar expressions for box size L , momentum \vec{p} , and photon wavevector and frequency \vec{k}_j and ω_j . Then we find

$$H_{\text{rel}} = \beta m_e c^2 + \hbar c \lambda_C^{-1} \vec{\alpha} \cdot \left(-i \nabla_x + \frac{e \lambda_C}{\hbar} \vec{\mathcal{A}}_\perp(\vec{x} \lambda_C) \right) - \frac{e^2}{4\pi\epsilon_0 \lambda_C} \frac{Z}{x} + \hbar c \lambda_C^{-1} \sum_j |q_j| \left[a_j^\dagger a_j + \frac{1}{2} \right], \quad (1.11)$$

and, by comparing the energies of the first two terms, choose λ_C such that

$$m_e c^2 = \hbar c \lambda_C^{-1}, \quad (1.12)$$

or

$$\lambda_C = \frac{\hbar}{m_e c}. \quad (1.13)$$

The reference quantities $m_e c^2$ and λ_C or the natural units of energy and length are the energy equivalent of the electron rest mass and the reduced Compton wavelength, respectively. We also note that $\lambda_C = \alpha a_0$ and $E_h = \alpha^2 m_e c^2$.

In natural units the transverse vector potential is not made dimensionless from its appearance in the Hamiltonian but rather from rewriting its definition in Eq. (1.2) in terms of the reduced Compton wavelength. In fact, we choose

$$\vec{A}_\perp(\vec{x} \lambda_C) \equiv \sqrt{4\pi\alpha} \vec{\mathcal{A}}_\perp(\vec{x}) \frac{\hbar}{e \lambda_C}, \quad (1.14)$$

where

$$\vec{\mathcal{A}}_\perp(\vec{x}) = \sum_j \sqrt{\frac{1}{2|q_j| \ell^3}} \left[a_j \vec{\epsilon}_j e^{i \vec{q}_j \cdot \vec{x}} + a_j^\dagger \vec{\epsilon}_j e^{-i \vec{q}_j \cdot \vec{x}} \right] \quad (1.15)$$

by inspection. The transverse vector field $\vec{\mathcal{A}}_\perp(\vec{x})$ only depends on geometric quantities related to the periodic boundary conditions in the cubic box of length $L = \ell \lambda_C$ and not on α or the charge of the electron. Finally, the Hamiltonian in Eq. (1.11) reads

$$H_{\text{rel}} = \left\{ \beta + \vec{\alpha} \cdot \left(-i \nabla_x + \sqrt{4\pi\alpha} \vec{\mathcal{A}}_\perp(\vec{x}) \right) - I_4 \frac{Z\alpha}{x} + \sum_j |q_j| \left[a_j^\dagger a_j + \frac{1}{2} \right] \right\} m_e c^2, \quad (1.16)$$

where the fine-structure constant now appears in the strength of the minimal coupling $\vec{\alpha} \cdot \vec{\mathcal{A}}_\perp(\vec{x})$ of the electron with the photons and in the Coulomb term of the Hamiltonian. The numerical value of the speed of light in vacuum is one in natural units. In fact, the unit of velocity is $\hbar/m_e \lambda_C = c$.

1.4 Fundamental Constants

In Table 1.2 we present an abbreviated list of values for fundamental constants based on the 2018 adjustment of fundamental constants as published by the CODATA taskgroup [5]. The table also gives values for atomic and natural units for a range of quantities, such as charge, speed, and time. The two most accurately known constants are the g -factor of a free electron and the Rydberg frequency $c R_\infty$ (or, equivalently, the Hartree energy) with relative uncertainties of 1.7×10^{-13} and 1.9×10^{-12} , respectively. The least well-known quantity in the table is the proton root-mean-square (rms) charge radius r_p with a relative uncertainty of

Table 1.2 Selected constants as well as atomic and natural units based on the 2018 CODATA adjustment of the fundamental constants [5]. The first two columns describe the quantity and its mathematical symbol. The third and fourth columns give its numerical value and unit. For quantity X the number in parenthesis in the numerical value is the combined statistical and systematic one-standard-deviation uncertainty $u(X)$ in the last two digits of the numerical value. Finally, the last column gives the relative standard uncertainty $u_r(X) = u(X)/|X|$. The unit u is the atomic mass unit, one-twelfth of the mass of a ^{12}C atom

^a The full description of m^{-1} is cycles or periods per meter and that of m is meter per cycle (m/cycle). The scientific community is aware of the implied use of these units. It traces back to the conventions for phase and angle and the use of unit Hz versus cycles/s. No solution has been agreed upon.

2.2×10^{-3} . In fact, r_p extracted from precision spectroscopy on the hydrogen atom and on muonic-hydrogen, where the electron is replaced by a muon, are marginally discrepant.

The fine-structure constant α , vacuum electric permittivity ϵ_0 , and vacuum magnetic permeability μ_0 are dependent. They are related through Eqs. (1.3) and (1.9) and, since in the SI the values for \hbar , e , and c are exact, one of α , ϵ_0 , or μ_0 fixes the other two. In current state-of-the-art experiments that constrain these constants, the dimensionless fine-structure constant is measured or the most conveniently extracted. In fact, the CODATA adjustment uses α as an adjusted constant, and values for ϵ_0 and μ_0 are derived from Eqs. (1.3) and (1.9). Finally, the mass of the electron follows from $m_e = E_h/\alpha^2 c^2$. Its relative uncertainty is twice that of α as the relative uncertainty of the Hartree energy is much better known.

Abstract

Angular momentum theory is presented from the viewpoint of the group $SU(1)$ of unimodular unitary matrices of order 2. This is the basic quantum mechanical rotation group for implementing the consequences of rotational symmetry into isolated complex physical systems and gives the structure of the angular momentum multiplets of such systems. This entails the study of representation functions of $SU(2)$, the Lie algebra of $SU(2)$ and copies thereof, and the associated Wigner–Clebsch–Gordan coefficients, Racah coefficients, and $3n-j$ coefficients, with an almost boundless set of interrelations, and presentations of the associated conceptual framework. The relationship of $SU(2)$ to the rotation group in physical 3-space R^3 is given in detail. Formulas are often given in a compendium format with brief introductions on their physical and mathematical content. A special effort is made to interrelate the material to the special functions of mathematics and to the combinatorial foundations of the subject.

Keywords

angular momentum algebra · invariant operator · coupling scheme · symmetry relation · tensor operator · Wigner–Eckart theorem · Lie algebra · Racah coefficients · Clebsch–Gordan coefficients · rotation group

Angular momentum theory in its quantum mechanical applications, which is the subject of this section, is the study of the group of 2×2 unitary unimodular matrices and its irreducible representations. It is the mathematics of implementing into physical theory the basic tenet that isolated physical systems are invariant to rotations of the system in physical 3-space, denoted R^3 , or, equivalently, to the orientation of a Cartesian reference system used to describe the system. That it is the group of 2×2 unimodular matrices that is basic in quantum theory in place of the more obvious group of 3×3 real, orthogonal matrices representing transformations of the coordinates of the constituent particles of the system, or of the reference frame, is a consequence of the Hilbert space structure of the state space of quantum systems and the impossibility of assigning overall phase factors to such states because measurements depend only on the absolute value of transition amplitudes.

The exact relationship between the group $SU(2)$ of 2×2 unimodular unitary matrices and the group $SO(3, R)$ of 3×3 real, proper, orthogonal matrices is an important one for keeping the quantum theory of angular momentum, with its numerous conventions and widespread applications across all fields of quantum physics, free of ambiguities. These notations and relations are fixed at the outset.

Presentation of a point in R^3 :

$$\begin{aligned} \mathbf{x} &= \text{col}(x_1, x_2, x_3) && \text{column matrix,} \\ \mathbf{x}^T &= (x_1, x_2, x_3) && \text{row matrix,} \\ X &= \begin{pmatrix} x_3 & x_1 - ix_2 \\ x_1 + ix_2 & -x_3 \end{pmatrix} && \begin{aligned} &2 \times 2 \text{ traceless Hermitian matrix;} \\ &\text{Cartan's representation.} \end{aligned} \end{aligned}$$

A one-to-one correspondence between the set R^3 of points in 3-space and the set H^2 of 2×2 traceless Hermitian matrices is obtained from $x_i = \frac{1}{2} \text{Tr}(\sigma_i X)$, where the σ_i denote the matrices (Pauli matrices)

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (2.1)$$

Mappings of R^3 onto itself:

$$\begin{aligned} \mathbf{x} &\rightarrow \mathbf{x}' = R\mathbf{x}, \\ X &\rightarrow X' = UXU^\dagger, \end{aligned}$$

where \dagger denotes Hermitian conjugation of a matrix or an operator.

Two-to-one homomorphism of $SU(2)$ onto $SO(3, R)$:

$$\begin{aligned} R_{ij} &= R_{ij}(U) = \frac{1}{2} \text{Tr}(\sigma_i U \sigma_j U^\dagger), && (2.2) \\ \begin{pmatrix} \xi \\ \mathbf{x}' \end{pmatrix} &= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & & & \\ 0 & R(U) & & \\ 0 & & & \end{pmatrix} \begin{pmatrix} \xi \\ \mathbf{x} \end{pmatrix} \\ &= A^\dagger (U \times U^*) A \begin{pmatrix} \xi \\ \mathbf{x} \end{pmatrix}, && (2.3) \end{aligned}$$

where ξ is an indeterminate, A is the unitary matrix given by

$$A = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & -i & 0 \\ 0 & 1 & i & 0 \\ 1 & 0 & 0 & -1 \end{pmatrix},$$

$U \times U^*$ denotes the matrix direct product, and $*$ denotes complex conjugation. There is a simple unifying theme in almost all the applications. The basic mathematical notions that are implemented over and over again in various contexts are: group action on the underlying coordinates and momenta of the physical system and the corresponding group action

in the associated Hilbert space of states; the determination of those subspaces that are mapped irreducibly onto themselves by the group action; the Lie algebra and its actions as derived from the group actions, and conversely; the construction of composite objects from elementary constituents, using the notion of tensor product space and Kronecker products of representations, which are the basic precepts in quantum theory for building complex systems from simpler ones; the reduction of the Kronecker product of irreducible representations into irreducibles with the associated Wigner–Clebsch–Gordan and Racah coefficients determining not only this reduction but also having a dual role in the construction of the irreducible state spaces themselves; and, finally, the repetition of this process for many-particle systems with the attendant theory of $3n-j$ coefficients. The universality of this methodology may be attributed to being able, in favorable situations, to separate the particular consequences of physical law (e.g., the Coulomb force) from the implications of symmetry imposed on the system by our underlying conceptions of space and time. Empirical models based on symmetry that attempt to identify the more important ingredients underlying observed physical phenomena are also of great importance.

The group actions in complex systems are often modeled after the following examples for the actions of the groups $SO(3, \mathbf{R})$ and $SU(2)$ on functions defined over the two-sphere $S^2 \subset \mathbf{R}^3$:

Hilbert space:

$$V = \{f | f \text{ is a polynomial satisfying } \nabla^2 f(\mathbf{x}) = 0\} .$$

Inner or scalar product:

$$(f, f') = \int_{\text{unit sphere}} f^*(\mathbf{x}) f'(\mathbf{x}) dS ,$$

where $f(\mathbf{x}) = f(X)$ for \mathbf{x} presented in the Cartan matrix form X .

Group actions:

$$\begin{aligned} (O_R f)(\mathbf{x}) &= f(R^{-1}\mathbf{x}), & \text{each } f \in V, \\ & & \text{each } \mathbf{x} \in \mathbf{R}^3, \\ (T_U f)(X) &= f(U^\dagger X U), & \text{each } f \in V, \\ & & \text{each } X \in \mathbf{H}^2. \end{aligned}$$

Operator properties:

- O_R is a unitary operator on V ; that is, $(O_R f, O_R f') = (f, f')$.
- T_U is a unitary operator on V ; that is, $(T_U f, T_U f') = (f, f')$.

- $R \rightarrow O_R$ is a unitary representation of $SO(3, \mathbf{R})$; that is, $O_{R_1} O_{R_2} = O_{R_1 R_2}$.
- $U \rightarrow T_U$ is a unitary representation of $SU(2)$; that is, $T_{U_1} T_{U_2} = T_{U_1 U_2}$.
- $O_{R(U)} = T_U = T_{-U}$ is an operator identity on the space V .

One parameter subgroups:

$$\begin{aligned} U_j(t) &= \exp(-it\sigma_j/2), \quad t \in \mathbf{R}, \quad j = 1, 2, 3; \\ R_j(t) &= R(U_j(t)) = \exp(-itM_j), \\ & \quad t \in \mathbf{R}, \quad j = 1, 2, 3; \end{aligned}$$

where

$$\begin{aligned} M_1 &= i \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, & M_2 &= i \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \\ M_3 &= i \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \end{aligned} \quad (2.4)$$

Infinitesimal generators:

$$\begin{aligned} L_j &= i(dO_{R_j(t)}/dt)_{t=0}, \\ L_j &= i(dT_{U_j(t)}/dt)_{t=0}, \\ (L_j f)(\mathbf{x}) &= -i \left(x_k \frac{\partial}{\partial x_l} - x_l \frac{\partial}{\partial x_k} \right) f(\mathbf{x}), \\ & \quad j, k, l \text{ cyclic in } 1, 2, 3. \end{aligned} \quad (2.5)$$

Historically, the algebra of angular momentum came about through the quantum rule of replacing the linear momentum \mathbf{p} of a classical point particle, which is located at position \mathbf{r} , by $\mathbf{p} \rightarrow -i\hbar\nabla$, thus replacing the classical angular momentum $\mathbf{r} \times \mathbf{p}$ about the origin of a chosen Cartesian inertial system by the angular momentum operator:

$$\mathbf{L} = -i\mathbf{r} \times \nabla \quad (\text{in units of } \hbar). \quad (2.6)$$

The quantal angular momentum properties of this simple one-particle system are then to be inferred from the properties of these operators and their actions in the associated Hilbert space. This remains the method of introducing angular momentum theory in most textbooks because of its simplicity and historical roots. It also leads to focusing the developments of the theory on the algebra of operators in contrast to emphasizing the associated group transformations of the Hilbert space, although the two viewpoints are intimately linked, as illustrated above. Both perspectives will be presented here.

2.1 Orbital Angular Momentum

The model provided by orbital angular momentum operators is the paradigm for standardizing many of the conventions and relations used in more abstract and general treatments. These basic results for the orbital angular momentum operator $L = -i \mathbf{r} \times \nabla$ acting in the vector space V are given in this section both in Cartesian coordinates $\mathbf{x} = \text{col}(x_1, x_2, x_3)$ and spherical polar coordinates:

$$\mathbf{x} = (r \sin \theta \cos \phi, r \sin \theta \sin \phi, r \cos \theta),$$

$$0 \leq r < \infty, \quad 0 \leq \phi < 2\pi, \quad 0 \leq \theta \leq \pi.$$

2.1.1 Cartesian Representation

Commutation relations:

Cartesian form:

$$[L_1, L_2] = iL_3, \quad [L_2, L_3] = iL_1,$$

$$[L_3, L_1] = iL_2.$$

Cartan form:

$$[L_3, L_+] = L_+, \quad [L_3, L_-] = -L_-,$$

$$[L_+, L_-] = 2L_3.$$

Squared orbital angular momentum:

$$L^2 = L_1^2 + L_2^2 + L_3^2 = L_-L_+ + L_3(L_3 + 1)$$

$$= L_+L_- + L_3(L_3 - 1)$$

$$= -r^2\nabla^2 + (\mathbf{x} \cdot \nabla)^2 + (\mathbf{x} \cdot \nabla).$$

L^2, L_3 form a complete set of commuting Hermitian operators in V with eigenfunctions

$$\mathcal{Y}_{lm}(\mathbf{x}) = \left[\frac{2l+1}{4\pi} (l+m)!(l-m)! \right]^{\frac{1}{2}}$$

$$\times \sum_k \frac{(-x_1 - ix_2)^{k+m} (x_1 - ix_2)^k x_3^{l-m-2k}}{2^{2k+m} (k+m)! k! (l-m-2k)!},$$

where $l = 0, 1, 2, \dots$; $m = l, l-1, \dots, -l$.

Homogeneous polynomial solutions of Laplace's equation:

$$\mathcal{Y}_{lm}(\lambda \mathbf{x}) = \lambda^l \mathcal{Y}_{lm}(\mathbf{x}),$$

$$(\mathbf{x} \cdot \nabla) \mathcal{Y}_{lm}(\mathbf{x}) = l \mathcal{Y}_{lm}(\mathbf{x}),$$

$$\nabla^2 \mathcal{Y}_{lm}(\mathbf{x}) = 0.$$

Complex conjugate:

$$\mathcal{Y}_{lm}^*(\mathbf{x}) = (-1)^m \mathcal{Y}_{l,-m}(\mathbf{x}).$$

Action of angular momentum operators:

$$L_{\pm} \mathcal{Y}_{lm}(\mathbf{x}) = [(l \mp m)(l \pm m + 1)]^{\frac{1}{2}} \mathcal{Y}_{l,m \pm 1}(\mathbf{x}),$$

$$L_3 \mathcal{Y}_{lm}(\mathbf{x}) = m \mathcal{Y}_{lm}(\mathbf{x}),$$

$$L^2 \mathcal{Y}_{lm}(\mathbf{x}) = l(l+1) \mathcal{Y}_{lm}(\mathbf{x}).$$

Highest weight eigenfunction:

$$L_+ \mathcal{Y}_{ll}(\mathbf{x}) = 0, \quad L_3 \mathcal{Y}_{ll}(\mathbf{x}) = l \mathcal{Y}_{ll}(\mathbf{x}),$$

$$\mathcal{Y}_{ll}(\mathbf{x}) = \frac{1}{2^l l!} \left(\frac{(2l+1)!}{4\pi} \right)^{\frac{1}{2}} (-x_1 - ix_2)^l.$$

Generation from highest weight:

$$\mathcal{Y}_{lm}(\mathbf{x}) = \left(\frac{(l+m)}{(2l)!(l-m)!} \right)^{\frac{1}{2}} L_-^{l-m} \mathcal{Y}_{ll}(\mathbf{x}).$$

Relation to Gegenbauer and Jacobi polynomials:

$$\mathcal{Y}_{lm}(\mathbf{x}) = r^{l-|m|} \mathcal{Y}_m(x_1, x_2)$$

$$\times [(2l+1)(l+m)!(l-m)!/2]^{\frac{1}{2}}$$

$$\times H_{l,|m|}(x_3/r),$$

$$H_{l\lambda}(z) = \frac{(2\lambda)!}{2^{\lambda} \lambda!} C_{l-\lambda}^{\lambda+\frac{1}{2}}(z) = \frac{(l+\lambda)!}{2^{\lambda} l!} P_{l-\lambda}^{(\lambda, \lambda)}(z),$$

$$0 \leq \lambda \leq l = 0, 1, 2, \dots,$$

where the $\mathcal{Y}_m(x_1, x_2)$ are homogeneous polynomial solutions of degree $|m|$ of Laplace's equation in 2-space, \mathbf{R}^2 :

$$\mathcal{Y}_m(x_1, x_2) = \begin{cases} (-x_1 - ix_2)^m / \sqrt{2\pi}, & m \geq 0, \\ (x_1 - ix_2)^{-m} / \sqrt{2\pi}, & m \leq 0. \end{cases}$$

(Sect. 2.1.2 for the definition of Gegenbauer and Jacobi polynomials.)

Orthogonal group action:

$$(O_R \mathcal{Y}_{lm})(\mathbf{x}) = \mathcal{Y}_{lm}(R^{-1} \mathbf{x}) = \sum_{m'} \mathcal{D}_{m'm}^l(R) \mathcal{Y}_{lm'}(\mathbf{x}),$$

where the functions $\mathcal{D}_{m'm}^l(R) = D_{m'm}^l(U(R))$ are defined in Sect. 2.3 for various parametrizations of R .

Unitary group action:

$$(T_U \mathcal{Y}_{lm})(X) = \mathcal{Y}_{lm}(U^\dagger X U)$$

$$= \sum_{m'} D_{m'm}^l(U) \mathcal{Y}_{lm'}(X),$$

where the functions $D_{m'm}^l(U)$ are defined in Sects. 2.2 and 2.3.

Orthogonality on the unit sphere:

$$\int_{\text{unit sphere}} \mathbf{Y}_{l'm'}^*(\mathbf{x}) \mathbf{Y}_{lm}(\mathbf{x}) dS = \delta_{l'l} \delta_{m'm} .$$

Product of solid harmonics:

$$\begin{aligned} \mathbf{Y}_{k\mu}(\mathbf{x}) \mathbf{Y}_{lm}(\mathbf{x}) &= \sum_{l'} \langle l' || \mathbf{Y}_k || l \rangle C_{m,\mu,m+\mu}^{lk l'} \mathbf{Y}_{l',m+\mu}(\mathbf{x}) \\ &= \sum_{l'} \langle l' || \mathbf{Y}_k || l \rangle \begin{pmatrix} l & k & l' \\ m & \mu & -m - \mu \end{pmatrix} \\ &\quad \times (-1)^{l'+m+\mu} \mathbf{Y}_{l',m+\mu}(\mathbf{x}) , \\ \langle l' || \mathbf{Y}_k || l \rangle &= r^{l+k-l'} \left(\frac{(2l+1)(2k+1)}{4\pi(2l'+1)} \right)^{\frac{1}{2}} C_{000}^{lk l'} , \\ \langle l' || \mathbf{Y}_k || l \rangle &= r^{l+k-l'} \left(\frac{(2l+1)(2k+1)(2l'+1)}{4\pi} \right)^{\frac{1}{2}} \\ &\quad \times (-1)^{l'} \begin{pmatrix} l & k & l' \\ 0 & 0 & 0 \end{pmatrix} , \end{aligned}$$

where $C_{m_1 m_2 m}^{l_1 l_2 l}$ and

$$\begin{pmatrix} l_1 & l_2 & l \\ m_1 & m_2 & -m \end{pmatrix} = \frac{(-1)^{l_1-l_2+m}}{\sqrt{2l+1}} C_{m_1 m_2 m}^{l_1 l_2 l}$$

denote Wigner–Clebsch–Gordan coefficients and 3– j coefficients, respectively (Sect. 2.7).

Vector addition theorem for solid harmonics:

$$\begin{aligned} \mathbf{Y}_{lm}(\mathbf{z} + \mathbf{z}') &= \sum_{k\mu} \left(\frac{4\pi(2l+1)!}{(2l-2k+1)!(2k+1)!} \right)^{\frac{1}{2}} C_{m-\mu,\mu,m}^{l-k,k,l} \\ &\quad \times \mathbf{Y}_{l-k,m-\mu}(\mathbf{z}) \mathbf{Y}_{k\mu}(\mathbf{z}') , \quad \mathbf{z}, \mathbf{z}' \in \mathbb{C}^3 , \\ C_{m-\mu,\mu,m}^{j-k,k,l} &= \left[\frac{\begin{pmatrix} l+m \\ k+\mu \end{pmatrix} \begin{pmatrix} l-m \\ k-\mu \end{pmatrix}}{\begin{pmatrix} 2l \\ 2k \end{pmatrix}} \right]^{\frac{1}{2}} . \end{aligned}$$

Rotational invariant in two vectors:

$$\begin{aligned} I_l(\mathbf{x}, \mathbf{y}) &= \frac{1}{2^l} \sum_k (-1)^k \begin{pmatrix} l \\ k \end{pmatrix} \begin{pmatrix} 2l-2k \\ l \end{pmatrix} \\ &\quad \times (\mathbf{x} \cdot \mathbf{y})^{l-2k} (\mathbf{x} \cdot \mathbf{x})^k (\mathbf{y} \cdot \mathbf{y})^k \\ &= (\mathbf{x} \cdot \mathbf{x})^{l/2} (\mathbf{y} \cdot \mathbf{y})^{l/2} C_l^{(1/2)}(\hat{\mathbf{x}} \cdot \hat{\mathbf{y}}) \\ &= \frac{4\pi}{2l+1} \sum_m (-1)^m \mathbf{Y}_{lm}(\mathbf{x}) \mathbf{Y}_{l,-m}(\mathbf{y}) , \end{aligned}$$

where $C_l^{(1/2)}(z)$ is a Gegenbauer polynomial (Sect. 2.1.2), and

$$\hat{\mathbf{x}} = \mathbf{x}/|\mathbf{x}| , \quad \hat{\mathbf{y}} = \mathbf{y}/|\mathbf{y}| , \quad \cos \theta = \hat{\mathbf{x}} \cdot \hat{\mathbf{y}} .$$

Legendre polynomials:

$$P_l(\cos \theta) = \frac{4\pi}{2l+1} \sum_m (-1)^m \mathbf{Y}_{l,-m}(\hat{\mathbf{y}}) \mathbf{Y}_{lm}(\hat{\mathbf{x}}) ,$$

$$\begin{aligned} \left(\frac{4\pi}{2l+1} \right)^{\frac{1}{2}} \mathbf{Y}_{l0}(\mathbf{x}) &= \frac{1}{2^l} \sum_k (-1)^k \begin{pmatrix} l \\ k \end{pmatrix} \begin{pmatrix} 2l-2k \\ l \end{pmatrix} \\ &\quad \times x_3^{l-2k} (\mathbf{x} \cdot \mathbf{x})^k \\ &= r^l P_l(x_3/r) . \end{aligned}$$

Rayleigh plane wave expansion:

$$\begin{aligned} e^{i\mathbf{k} \cdot \mathbf{x}} &= 4\pi \sum_{l=0}^{\infty} \sum_{m=-l}^l i^l j_l(kr) \mathbf{Y}_{lm}^*(\hat{\mathbf{k}}) \mathbf{Y}_{lm}(\hat{\mathbf{x}}) , \\ j_l(kr) &= \left(\frac{\pi}{2kr} \right)^{\frac{1}{2}} J_{l+1/2}(kr) . \end{aligned}$$

Relations in potential theory:

$$\begin{aligned} \mathbf{Y}_{lm}(\nabla) \left(\frac{1}{r} \right) &= \frac{(-1)^l (2l)!}{2^l l!} \frac{\mathbf{Y}_{lm}(\mathbf{x})}{r^{2l+1}} , \\ 1/R &= \sum_{l=0}^{\infty} I_l(\mathbf{x}, \mathbf{y}) / r^{2l+1} , \\ I_l(\mathbf{x}, \mathbf{y}) / r^{2l+1} &= \frac{(-1)^l}{l!} (\mathbf{y} \cdot \nabla)^l \left(\frac{1}{r} \right) . \end{aligned}$$

For $\mathbf{R} = \mathbf{x} - \mathbf{y}$, $r = (\mathbf{x} \cdot \mathbf{x})^{\frac{1}{2}}$, $s = (\mathbf{y} \cdot \mathbf{y})^{\frac{1}{2}}$,

$$1/R = \sum_l P_l(\cos \theta) \frac{s^l}{r^{l+1}} , \quad s \leq r , \quad \cos \theta = \hat{\mathbf{x}} \cdot \hat{\mathbf{y}} .$$

Rotational invariants in three vectors:

$$\begin{aligned} I_{(l_1 l_2 l_3)}(\mathbf{x}^1, \mathbf{x}^2, \mathbf{x}^3) &= \frac{(4\pi)^{3/2}}{[(2l_1+1)(2l_2+1)(2l_3+1)]^{\frac{1}{2}}} \\ &\quad \times \sum_{m_1 m_2 m_3} \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \\ &\quad \times \mathbf{Y}_{l_1 m_1}(\mathbf{x}^1) \mathbf{Y}_{l_2 m_2}(\mathbf{x}^2) \mathbf{Y}_{l_3 m_3}(\mathbf{x}^3) , \end{aligned}$$

where $\begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$ is a 3– j coefficient (Sect. 2.7).

$$\begin{aligned} I_{(l_1 l_2 l_3)}(\mathbf{x}^1, \mathbf{x}^2, 0) &= \delta_{l_1 l_2} \delta_{l_3 0} (-1)^{l_1} I_{l_1}(\mathbf{x}^1, \mathbf{x}^2) / (2l_1+1)^{\frac{1}{2}} . \end{aligned}$$

Product law:

$$I_{(l)}(\mathbf{x})I_{(k)}(\mathbf{x}) = \sum_{(j)} \left[\prod_{\alpha=1}^3 (-1)^{j_\alpha} (2j_\alpha + 1) \begin{pmatrix} l_\alpha & k_\alpha & j_\alpha \\ 0 & 0 & 0 \end{pmatrix} \times (\mathbf{x}^\alpha \cdot \mathbf{x}^\alpha)^{(l_\alpha + k_\alpha - j_\alpha)/2} \right] \begin{Bmatrix} l_1 & l_2 & l_3 \\ k_1 & k_2 & k_3 \\ j_1 & j_2 & j_3 \end{Bmatrix} I_{(j)}(\mathbf{x}),$$

where $l = (l_1, l_2, l_3)$, etc., $\mathbf{x} = (\mathbf{x}^1, \mathbf{x}^2, \mathbf{x}^3)$.

Coplanar vectors:

$$I_{(l)}(\mathbf{x}^1, \mathbf{x}^2, \alpha \mathbf{x}^1 + \beta \mathbf{x}^2) = \sum_{kl} \left(\frac{(2l_3 + 1)!}{(2l_3 - 2k)!(2k)!} \right)^{\frac{1}{2}} \times \alpha^{l_3 - k} \beta^k (-1)^{l_1 + l_3 + k} (2l + 1) \times \begin{pmatrix} l_3 - k & l_1 & l \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} k & l_2 & l \\ 0 & 0 & 0 \end{pmatrix} \begin{Bmatrix} l_3 - k & l_3 & k \\ l_2 & l & l_1 \end{Bmatrix} \times (\mathbf{x}^1 \cdot \mathbf{x}^1)^{(l_1 + l_3 - l - k)/2} (\mathbf{x}^2 \cdot \mathbf{x}^2)^{(l_2 + k - l)/2} \times I_l(\mathbf{x}^1, \mathbf{x}^2).$$

The bracket symbols in these relations are 6- j and 9- j coefficients (Sects. 2.9, 2.10).

Cartan's vectors of zero length:

$$\begin{aligned} \boldsymbol{\alpha} &= (-z_1^2 + z_2^2, -i(z_1^2 + z_2^2), 2z_1 z_2), \\ \boldsymbol{\alpha} \cdot \boldsymbol{\alpha} &= \alpha_1^2 + \alpha_2^2 + \alpha_3^2 = 0, \\ \mathbf{z} &= (z_1, z_2) \in \mathcal{C}^2. \end{aligned}$$

Solutions of Laplace's equation using vectors of zero length:

$$\nabla^2(\boldsymbol{\alpha} \cdot \mathbf{x})^l = 0, \quad l = 0, 1, \dots$$

Solid harmonics for vectors of zero length:

$$\begin{aligned} (-1)^m Y_{l,-m}(\boldsymbol{\alpha}) &= \frac{(2l)!}{l!} \left(\frac{2l+1}{4\pi} \right)^{\frac{1}{2}} P_{lm}(z_1, z_2), \\ P_{lm}(z_1, z_2) &= \frac{z_1^{l+m} z_2^{l-m}}{\sqrt{(l+m)!(l-m)!}}. \end{aligned}$$

Orbital angular momentum operators for vectors of zero length:

$$\begin{aligned} \mathbf{J} &= -i(\boldsymbol{\alpha} \times \nabla_{\boldsymbol{\alpha}}), \\ J_+ &= z_1 \frac{\partial}{\partial z_2}, \quad J_- = z_2 \frac{\partial}{\partial z_1}, \\ J_3 &= \frac{1}{2} \left(z_1 \frac{\partial}{\partial z_1} - z_2 \frac{\partial}{\partial z_2} \right). \end{aligned}$$

Rotational invariant for vectors of zero length:

$$(\boldsymbol{\alpha} \cdot \mathbf{x})^l = \left(\frac{4\pi}{2l+1} \right)^{\frac{1}{2}} 2^l l! \sum_m P_{lm}(\mathbf{z}) Y_{lm}(\mathbf{x}).$$

Spinorial invariant under $\mathbf{z}^i \rightarrow U \mathbf{z}^i$ ($i = 1, 2, 3$):

$$\begin{aligned} &\sum_{m_1 m_2 m_3} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} P_{j_1 m_1}(\mathbf{z}^1) P_{j_2 m_2}(\mathbf{z}^2) P_{j_3 m_3}(\mathbf{z}^3) \\ &= [(j_1 + j_2 + j_3 + 1)!]^{-1/2} \\ &\quad \times \frac{(z_{12}^{12})^{j_1 + j_2 - j_3} (z_{12}^{31})^{j_3 + j_1 - j_2} (z_{12}^{23})^{j_2 + j_3 - j_1}}{[(j_1 + j_2 - j_3)!(j_3 + j_1 - j_2)!(j_2 + j_3 - j_1)!]^{\frac{1}{2}}}, \\ z_{12}^{ij} &= z_1^i z_2^j - z_1^j z_2^i. \end{aligned}$$

This relation is invariant under the transformation

$$\begin{aligned} \mathbf{z} \rightarrow U \mathbf{z} &= ((U \mathbf{z})_1, (U \mathbf{z})_2) \\ &= (u_{11} z_1 + u_{12} z_2, u_{21} z_1 + u_{22} z_2), \end{aligned}$$

where $U \in SU(2)$. Transformation properties of vectors of zero length:

$$\boldsymbol{\alpha} \rightarrow R \boldsymbol{\alpha}, \quad \boldsymbol{\alpha} = \text{col}(\alpha_1, \alpha_2, \alpha_3),$$

where $\mathbf{z} \rightarrow U \mathbf{z}$ and R is given in terms of U in the beginning of this chapter. Simultaneous eigenvectors of \mathbf{L}^2 and \mathbf{J}^2 :

$$\begin{aligned} \mathbf{L}^2(\boldsymbol{\alpha} \cdot \mathbf{x})^l &= l(l+1)(\boldsymbol{\alpha} \cdot \mathbf{x})^l, \quad l = 0, 1, \dots, \\ \mathbf{J}^2(\boldsymbol{\alpha} \cdot \mathbf{x})^l &= l(l+1)(\boldsymbol{\alpha} \cdot \mathbf{x})^l, \quad l = 0, 1, \dots \end{aligned}$$

2.1.2 Spherical Polar Coordinate Representation

The results given in Sect. 2.1.1 may be presented in any system of coordinates well-defined in terms of Cartesian coordinates. The principal relations for spherical polar coordinates are given in this section, where a vector in \mathbf{R}^3 is now given in the form

$$\begin{aligned} \mathbf{x} = r \hat{\mathbf{x}} &= r(\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta), \\ 0 &\leq \theta \leq \pi, \quad 0 \leq \phi < 2\pi. \end{aligned}$$

Orbital angular momentum operators:

$$\begin{aligned} L_1 &= i \cos \phi \cot \theta \frac{\partial}{\partial \phi} + i \sin \phi \frac{\partial}{\partial \theta}, \\ L_2 &= i \sin \phi \cot \theta \frac{\partial}{\partial \phi} - i \cos \phi \frac{\partial}{\partial \theta}, \end{aligned}$$

$$L_3 = -i \frac{\partial}{\partial \phi},$$

$$L_{\pm} = e^{\pm i \phi} \left(\pm \frac{\partial}{\partial \theta} + i \cot \theta \frac{\partial}{\partial \phi} \right),$$

$$L^2 = -\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) - \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2}.$$

Laplacian:

$$\mathbf{x} \cdot \nabla = r \frac{\partial}{\partial r},$$

$$\nabla^2 = \frac{1}{r^2} \left[\left(r \frac{\partial}{\partial r} \right)^2 + r \frac{\partial}{\partial r} - L^2 \right].$$

Spherical harmonics (solid harmonics on the unit sphere \mathcal{S}^2):

$$Y_{lm}(\theta, \phi) = (-1)^m \left(\frac{2l+1}{4\pi} (l+m)!(l-m)! \right)^{\frac{1}{2}} e^{im\phi}$$

$$\times \sum_k \frac{(-1)^k (\sin \theta)^{2k+m} (\cos \theta)^{l-2k-m}}{2^{2k+m} (k+m)! k! (l-2k-m)!}.$$

Orthogonality on the unit sphere:

$$\int_0^{2\pi} d\phi \int_0^{\pi} d\theta \sin \theta Y_{l'm'}^*(\theta, \phi) Y_{lm}(\theta, \phi) = \delta_{l'l} \delta_{m'm}.$$

Relation to Legendre, Jacobi, and Gegenbauer polynomials:

$$Y_{lm}(\theta, \phi) = (-1)^m \left(\frac{(2l+1)(l-m)!}{4\pi(l+m)!} \right)^{\frac{1}{2}}$$

$$\times P_l^m(\cos \theta) e^{im\phi},$$

$$P_l^m(\cos \theta) = \frac{(l+m)!}{l!} \left(\frac{\sin \theta}{2} \right)^m P_{l-m}^{(m,m)}(\cos \theta).$$

Jacobi polynomials:

$$P_n^{(\alpha,\beta)}(x) = \sum_s \binom{n+\alpha}{s} \binom{n+\beta}{n-s}$$

$$\times \left(\frac{x-1}{2} \right)^{n-s} \left(\frac{x+1}{2} \right)^s,$$

$$n = 0, 1, \dots,$$

where α, β are arbitrary parameters and

$$\binom{z}{k} = \begin{cases} z(z-1)\cdots(z-k+1)/k! & \text{for } k = 1, 2, \dots \\ 1 & \text{for } k = 0 \\ 0 & \text{for } k = -1, -2, \dots \end{cases}$$

Relations between Jacobi polynomials for $n + \alpha, n + \beta, n + \alpha + \beta$ nonnegative integers:

$$P_n^{\alpha,\beta}(x) = \frac{(n+\alpha)!(n+\beta)!}{n!(n+\alpha+\beta)!} \left(\frac{x+1}{2} \right)^{-\beta} P_{n+\beta}^{(\alpha,-\beta)}(x),$$

$$P_n^{\alpha,\beta}(x) = \frac{(n+\alpha)!(n+\beta)!}{n!(n+\alpha+\beta)!} \left(\frac{x-1}{2} \right)^{-\alpha} P_{n+\alpha}^{(-\alpha,\beta)}(x),$$

$$P_n^{\alpha,\beta}(x) = \left(\frac{x-1}{2} \right)^{-\alpha} \left(\frac{x+1}{2} \right)^{-\beta} P_{n+\alpha+\beta}^{(-\alpha,-\beta)}(x).$$

Nonstandard form (α arbitrary):

$$P_n^{(\alpha,\alpha)}(x) = \sum_s \frac{(-1)^s (\alpha+s+1)_{n-s} (1-x^2)^s x^{n-2s}}{2^{2s} s! (n-2s)!},$$

$$(z)_k = z(z+1)\cdots(z+k-1), \quad k = 1, 2, \dots;$$

$$(z)_0 = 1.$$

Gegenbauer polynomials ($\alpha > -1/2$):

$$C_n^{(\alpha)}(x) = \frac{(2\alpha)_n}{(\alpha+1/2)_n} P_n^{(\alpha-\frac{1}{2}, \alpha-\frac{1}{2})}(x)$$

$$= \sum_s \frac{(-1)^s (\alpha)_{n-s} (2x)^{n-2s}}{s! (n-2s)!}.$$

2.2 Abstract Angular Momentum

Abstract angular momentum theory addresses the problem of constructing all finite Hermitian matrices, up to equivalence, that satisfy the same commutation relations

$$[J_1, J_2] = iJ_3, \quad [J_2, J_3] = iJ_1, \quad [J_3, J_1] = iJ_2 \quad (2.7)$$

as some set of Hermitian operators J_1, J_2, J_3 appropriately defined in some Hilbert space; that is, of constructing all finite Hermitian matrices M_i such that under the correspondence $J_i \rightarrow M_i$ ($i = 1, 2, 3$) the commutation relations are still obeyed. If M_1, M_2, M_3 is such a set of Hermitian matrices, then $AM_1A^{-1}, AM_2A^{-1}, AM_3A^{-1}$, is another such set, where A is an arbitrary unitary matrix. This defines what is meant by equivalence. The commutation relations Eq. (2.7) may also be formulated as:

$$[J_3, J_{\pm}] = \pm J_{\pm}, \quad [J_+, J_-] = 2J_3,$$

$$J_{\pm} = J_1 \pm iJ_2, \quad J_+^{\dagger} = J_- \quad (2.8)$$

The squared angular momentum

$$J^2 = J_1^2 + J_2^2 + J_3^2 = J_- J_+ + J_3(J_3 + 1)$$

$$= J_+ J_- + J_3(J_3 - 1) \quad (2.9)$$

commutes with each J_i , and J_3 is, by convention, taken with \mathbf{J}^2 as a pair of commuting Hermitian operators to be diagonalized.

Examples of matrices satisfying relations Eq. (2.7) are provided by $J_i \rightarrow \sigma_i/2$ (the 2×2 Hermitian Pauli matrices defined in Eq. (2.1)) and $J_i \rightarrow M_i$ (the 3×3 matrices defined in Eq. (2.4)), these latter matrices being equivalent to those obtained from the matrices of the orbital angular momentum operators for $l = 1$.

One could determine all Hermitian matrices solving Eqs. (2.7) and (2.8) by using only matrix theory, but it is customary in quantum mechanics to formulate the problem using Hilbert space concepts appropriate to that theory. Thus, one takes the viewpoint that the J_i are linear Hermitian operators with an action defined in a separable Hilbert space \mathcal{H} such that $J_i : \mathcal{H} \rightarrow \mathcal{H}$.

One then seeks to decompose the Hilbert space into a direct sum of subspaces that are irreducible with respect to this action; that is, subspaces that cannot be further decomposed as a direct sum of subspaces that all the J_i leave invariant (map vectors in the space into vectors in the space). In this section, the solution of this fundamental problem for angular momentum theory is given. These results set the notation and phase conventions for all of angular momentum theory, in all of its varied realizations, and the relations are, therefore, sometimes referred to as standard. The method most often used to solve the posed problem is called the method of highest weights.

The solution of this problem is among the most important in quantum theory because of its generality and applicability to a wide range of problems. The space \mathcal{H} can be written as a direct sum

$$\mathcal{H} = \sum_{j=0, \frac{1}{2}, 1, \dots} \oplus n_j \mathcal{H}_j, \quad \text{each } \mathcal{H}_j \perp \mathcal{H}_{j'}, \quad j \neq j', \quad (2.10)$$

in which \mathcal{H}_j denotes a vector space of dimension $2j + 1$ that is invariant and irreducible under the action of the set of operators $J_i, i = 1, 2, 3$, and where the direct sum is over all half-integers $j = 0, \frac{1}{2}, 1, \dots$. There may be multiple occurrences, n_j in number, of the same space \mathcal{H}_j for given j , or no such space, $n_j = 0$, in the direct sum. Abstractly, in so far as angular momentum properties are concerned, each repeated space \mathcal{H}_j is *identical*. Such spaces may, however, be distinguished by their properties with respect to other physical observables, but not by the angular action of momentum operators themselves. The result, Eq. (2.10), applies to any physical system, no matter how complex, in which rotational symmetry, hence $SU(2)$ symmetry, is present, even in situations of higher symmetry where $SU(2)$ is a subgroup. Indeed, the resolution of the terms in Eq. (2.10) for vari-

ous physical systems constitutes *spectroscopy* in the broadest sense.

The characterization of the space \mathcal{H}_j with respect to angular momentum properties is given by the following results, where basis vectors are denoted in the Dirac bra-ket notation.

Orthonormal basis:

$$\{|jm\rangle | m = -j, -j + 1, \dots, j\}. \quad (2.11)$$

$$\langle jm' | jm \rangle = \delta_{m', m}. \quad (2.12)$$

Simultaneous eigenvectors:

$$\mathbf{J}^2 | jm \rangle = j(j + 1) | jm \rangle, \quad J_3 | jm \rangle = m | jm \rangle. \quad (2.13)$$

Action of angular momentum operators:

$$\begin{aligned} J_+ | jm \rangle &= [(j - m)(j + m + 1)]^{1/2} | jm + 1 \rangle, \\ J_- | jm \rangle &= [(j + m)(j - m + 1)]^{1/2} | jm - 1 \rangle. \end{aligned} \quad (2.14)$$

Defining properties of highest weight vector:

$$J_+ | jj \rangle = 0, \quad J_3 | jj \rangle = j | jj \rangle.$$

Generation of general vector from highest weight:

$$| jm \rangle = \left(\frac{(j + m)!}{(2j)!(j - m)!} \right)^{1/2} J_-^{j-m} | jj \rangle.$$

Necessary property of lowest weight vector:

$$J_- | j, -j \rangle = 0, \quad J_3 | j, -j \rangle = -j | j, -j \rangle.$$

Operator in \mathcal{H} corresponding to a rotation by angle ψ about direction $\hat{\mathbf{n}}$ in \mathbf{R}^3 :

$$\begin{aligned} T_{U(\psi, \hat{\mathbf{n}})} &= \exp(-i\psi \hat{\mathbf{n}} \cdot \mathbf{J}), \\ \hat{\mathbf{n}} \cdot \hat{\mathbf{n}} &= n_1^2 + n_2^2 + n_3^2 = 1, \\ \hat{\mathbf{n}} \cdot \mathbf{J} &= n_1 J_1 + n_2 J_2 + n_3 J_3, \\ U(\psi, \hat{\mathbf{n}}) &= \exp(-i\psi \hat{\mathbf{n}} \cdot \boldsymbol{\sigma}/2) \\ &= \sigma_0 \cos(\frac{1}{2}\psi) - i(\hat{\mathbf{n}} \cdot \boldsymbol{\sigma}) \sin(\frac{1}{2}\psi) \\ &= \begin{pmatrix} \cos(\frac{1}{2}\psi) - in_3 \sin(\frac{1}{2}\psi) & (-in_1 - n_2) \sin(\frac{1}{2}\psi) \\ (-in_1 + n_2) \sin(\frac{1}{2}\psi) & \cos(\frac{1}{2}\psi) + in_3 \sin(\frac{1}{2}\psi) \end{pmatrix} \\ &0 \leq \psi \leq 2\pi, \end{aligned} \quad (2.15)$$

where σ_0 denotes the 2×2 unit matrix.

Action of $T_{U(\psi, \hat{\mathbf{n}})}$ on \mathcal{H}_j :

$$T_U | jm \rangle = \sum_{m'} D_{m'/m}^j(U) | jm' \rangle, \quad (2.16)$$

in which $U = U(\psi, \hat{\mathbf{n}})$ and $D_{m'/m}^j(U)$ denotes a homogeneous polynomial of degree $2j$ defined on the elements

$u_{ij} = U_{ij}(\psi, \hat{n})$ in row i and column j of the matrix $U(\psi, \hat{n})$ given by Eq. (2.15). The explicit form of this polynomial is

$$D_{m'm}^j(U) = [(j+m)!(j-m)!(j+m)!(j-m)!]^{\frac{1}{2}} \times \sum_{\boxed{\alpha}} \frac{(u_{11})^{\alpha_{11}}(u_{12})^{\alpha_{12}}(u_{21})^{\alpha_{21}}(u_{22})^{\alpha_{22}}}{\alpha_{11}!\alpha_{12}!\alpha_{21}!\alpha_{22}!}. \quad (2.17)$$

The notation $\boxed{\alpha}$ symbolizes a 2×2 array of nonnegative integers with certain constraints:

$$\begin{array}{cc|cc} \alpha_{11} & \alpha_{12} & j+m' & \\ \alpha_{21} & \alpha_{22} & j-m' & \\ \hline j+m & j-m & & \end{array}.$$

In this array, the α_{ij} are nonnegative integers subject to the row and column constraints (sums) indicated by the (nonnegative) integers $j \pm m$, $j \pm m'$. Explicitly,

$$\begin{aligned} \alpha_{11} + \alpha_{12} &= j + m', & \alpha_{21} + \alpha_{22} &= j - m', \\ \alpha_{11} + \alpha_{21} &= j + m, & \alpha_{12} + \alpha_{22} &= j - m. \end{aligned}$$

The summation is over all such arrays. Any one of the α_{ij} may serve as a single summation index if one wishes to eliminate the redundancy inherent in the square-array notation. The form Eq. (2.17) is very useful for obtaining symmetry relations for these polynomials (Sect. 2.3.6).

Unitary property on \mathcal{H} :

$$\langle T_U \Psi | T_U \Psi \rangle = \langle \Psi | \Psi \rangle, \quad \text{each } \Psi \in \mathcal{H}.$$

Irreducible unitary matrix representation of $SU(2)$:

$$(D^j(U))_{j-m'+1, j-m+1} = D_{m'm}^j(U), \quad m' = j, j-1, \dots, -j; \quad m = j, j-1, \dots, -j, \quad (2.18)$$

denotes the element in row $j-m'+1$ and column $j-m+1$. Then, dimension of $D^j(U) = 2j+1$ and

$$\begin{aligned} D^j(U)D^j(U') &= D^j(UU'), \\ U &\in SU(2), \quad U' \in SU(2), \\ (D^j(U))^\dagger &= (D^j(U))^{-1} = D^j(U^\dagger). \end{aligned}$$

Kronecker (direct) product representation:

$$D^{j_1}(U) \times D^{j_2}(U)$$

is a $(2j_1+1)(2j_2+1)$ dimensional reducible representation of $SU(2)$. One can also effect the reduction of this representation into irreducible ones by abstract methods. The results are given in Sect. 2.7.

2.3 Representation Functions

2.3.1 Parametrizations of the Groups $SU(2)$ and $SO(3, \mathbf{R})$

The irreducible representations of the quantal rotation group, $SU(2)$, are among the most important quantities in all of angular momentum theory. These are the unitary matrices of dimension $2j+1$, denoted by $D^j(U)$, where this notation is used to signify that the elements of this matrix, denoted $D_{m'm}^j(U)$, are functions of the elements u_{ij} of the 2×2 unitary unimodular matrix $U \in SU(2)$. It has become standard to enumerate the rows and columns of these matrices in the order $j, j-1, \dots, -j$ as read from top to bottom down the rows and from left to right across the columns (see also Eq. (2.18)). These matrices may be presented in a variety of parametrizations, all of which are useful. In order to make comparisons between the group $SO(3, \mathbf{R})$ and the group $SU(2)$, it is most useful to parametrize these groups so that they are related according to the two-to-one homomorphism given by Eq. (2.2).

The general parametrization of the group $SU(2)$ is given in terms of the Euler–Rodrigues parameters corresponding to points belonging to the surface of the unit sphere \mathbf{S}^3 in \mathbf{R}^4 ,

$$\alpha_0^2 + \alpha_1^2 + \alpha_2^2 + \alpha_3^2 = 1. \quad (2.19)$$

Each $U \in SU(2)$ can be written in the form:

$$\begin{aligned} U(\alpha_0, \boldsymbol{\alpha}) &= \begin{pmatrix} \alpha_0 - i\alpha_3 & -i\alpha_1 - \alpha_2 \\ -i\alpha_1 + \alpha_2 & \alpha_0 + i\alpha_3 \end{pmatrix} \\ &= \alpha_0 \sigma_0 - i\boldsymbol{\alpha} \cdot \boldsymbol{\sigma}. \end{aligned} \quad (2.20)$$

The $R \in SO(3, \mathbf{R})$ corresponding to this U in the two-to-one homomorphism given by Eq. (2.2) is:

$$\begin{aligned} R(\alpha_0, \boldsymbol{\alpha}) &= \begin{pmatrix} \alpha_0^2 + \alpha_1^2 - \alpha_2^2 - \alpha_3^2 & 2\alpha_1\alpha_2 - 2\alpha_0\alpha_3 & 2\alpha_1\alpha_3 + 2\alpha_0\alpha_2 \\ 2\alpha_1\alpha_2 + 2\alpha_0\alpha_3 & \alpha_0^2 + \alpha_2^2 - \alpha_3^2 - \alpha_1^2 & 2\alpha_2\alpha_3 - 2\alpha_0\alpha_1 \\ 2\alpha_1\alpha_3 - 2\alpha_0\alpha_2 & 2\alpha_2\alpha_3 + 2\alpha_0\alpha_1 & \alpha_0^2 + \alpha_3^2 - \alpha_1^2 - \alpha_2^2 \end{pmatrix}. \end{aligned} \quad (2.21)$$

The procedure of parametrization is implemented uniformly by first parametrizing the points on the unit sphere \mathbf{S}^3 so as to cover the points in \mathbf{S}^3 exactly once, thus obtaining a parametrization of each $U \in SU(2)$. Equation (2.21) is then used to obtain the corresponding parametrization of each $R \in SO(3, \mathbf{R})$, where one notes that $R(-\alpha_0, -\boldsymbol{\alpha}) = R(\alpha_0, \boldsymbol{\alpha})$. Because of this two-to-one correspondence $\pm U \rightarrow R$, the domain of the parameters that cover the unit sphere \mathbf{S}^3 exactly once will cover the group $SO(3, \mathbf{R})$ exactly twice. This is taken into account uniformly by redefining the domain for $SO(3, \mathbf{R})$ so as to cover only the upper hemisphere ($\alpha_0 \geq 0$) of \mathbf{S}^3 .

In the active viewpoint (reference frame fixed with points being transformed into new points), an arbitrary vector $\mathbf{x} = \text{col}(x_1, x_2, x_3) \in \mathbf{R}^3$ is transformed to the new vector $\mathbf{x}' = \text{col}(x'_1, x'_2, x'_3)$ by the rule $\mathbf{x}' = \mathbf{R}\mathbf{x}$, or, equivalently, in terms of the Cartan matrix $X' = UXU^\dagger$. In the passive viewpoint, the basic inertial reference system, which is taken to be a right-handed triad of unit vectors $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3)$, is transformed by R to a new right-handed triad $(\hat{\mathbf{f}}_1, \hat{\mathbf{f}}_2, \hat{\mathbf{f}}_3)$ by the rule

$$\hat{\mathbf{f}}_j = \sum_i R_{ij} \hat{\mathbf{e}}_i, \quad i = 1, 2, 3,$$

so that $\hat{\mathbf{e}}_i \cdot \hat{\mathbf{f}}_j = R_{ij}$. In this viewpoint, the coordinates of one and the same point P undergo a redescription under the change of frame. If the coordinates of P are (x_1, x_2, x_3) relative to the frame $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3)$ and (x'_1, x'_2, x'_3) relative to the frame $(\hat{\mathbf{f}}_1, \hat{\mathbf{f}}_2, \hat{\mathbf{f}}_3)$, then

$$x_1 \hat{\mathbf{e}}_1 + x_2 \hat{\mathbf{e}}_2 + x_3 \hat{\mathbf{e}}_3 = x'_1 \hat{\mathbf{f}}_1 + x'_2 \hat{\mathbf{f}}_2 + x'_3 \hat{\mathbf{f}}_3,$$

so that $\mathbf{x}' = \mathbf{R}^T \mathbf{x}$.

Rotation about direction $\hat{\mathbf{n}} \in \mathcal{S}^2$ by positive angle ψ (right-hand rule):

$$(\alpha_0, \boldsymbol{\alpha}) = \left(\cos \frac{1}{2} \psi, \hat{\mathbf{n}} \sin \frac{1}{2} \psi \right), \quad 0 \leq \psi \leq 2\pi,$$

$$\begin{aligned} U(\psi, \hat{\mathbf{n}}) &= \exp\left(-i \frac{1}{2} \psi \hat{\mathbf{n}} \cdot \boldsymbol{\sigma}\right) \\ &= \begin{pmatrix} \cos \frac{1}{2} \psi - in_3 \sin \frac{1}{2} \psi & (-in_1 - n_2) \sin \frac{1}{2} \psi \\ (-in_1 + n_2) \sin \frac{1}{2} \psi & \cos \frac{1}{2} \psi + in_3 \sin \frac{1}{2} \psi \end{pmatrix}, \end{aligned}$$

$$\begin{aligned} R(\psi, \hat{\mathbf{n}}) &= \exp(-i\psi \hat{\mathbf{n}} \cdot \mathbf{M}), \quad 0 \leq \psi \leq \pi \\ &= I_3 - i \sin \psi (\hat{\mathbf{n}} \cdot \mathbf{M}) - (\hat{\mathbf{n}} \cdot \mathbf{M})^2 (1 - \cos \psi) \\ &= \begin{pmatrix} R_{11} & R_{12} & R_{13} \\ R_{21} & R_{22} & R_{23} \\ R_{31} & R_{32} & R_{33} \end{pmatrix}, \end{aligned}$$

$$\begin{aligned} R_{11} &= n_1^2 + (1 - n_1^2) \cos \psi, \\ R_{21} &= n_1 n_2 (1 - \cos \psi) + n_3 \sin \psi, \\ R_{31} &= n_1 n_3 (1 - \cos \psi) - n_2 \sin \psi, \\ R_{12} &= n_1 n_2 (1 - \cos \psi) - n_3 \sin \psi, \\ R_{22} &= n_2^2 + (1 - n_2^2) \cos \psi, \\ R_{32} &= n_2 n_3 (1 - \cos \psi) + n_1 \sin \psi, \\ R_{13} &= n_1 n_3 (1 - \cos \psi) + n_2 \sin \psi, \\ R_{23} &= n_2 n_3 (1 - \cos \psi) - n_1 \sin \psi, \\ R_{33} &= n_3^2 + (1 - n_3^2) \cos \psi. \end{aligned}$$

The unit vector $\hat{\mathbf{n}} \in \mathcal{S}^2$ can be further parametrized in terms of the usual spherical polar coordinates:

$$\begin{aligned} \hat{\mathbf{n}} &= (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta), \\ 0 &\leq \theta \leq \pi, \quad 0 \leq \phi < 2\pi. \end{aligned}$$

Euler angle parametrization:

$$\begin{aligned} U(\alpha\beta\gamma) &= e^{-i\alpha\sigma_3/2} e^{-i\beta\sigma_2/2} e^{-i\gamma\sigma_3/2} \\ &= \begin{pmatrix} e^{-i\alpha/2} \cos(\frac{1}{2}\beta) e^{-i\gamma/2} & -e^{-i\alpha/2} \sin(\frac{1}{2}\beta) e^{i\gamma/2} \\ e^{i\alpha/2} \sin(\frac{1}{2}\beta) e^{-i\gamma/2} & e^{i\alpha/2} \cos(\frac{1}{2}\beta) e^{i\gamma/2} \end{pmatrix}, \end{aligned}$$

$$0 \leq \alpha < 2\pi, \quad 0 \leq \beta \leq \pi \quad \text{or} \quad 2\pi \leq \beta \leq 3\pi, \\ 0 \leq \gamma < 2\pi,$$

$$U(\alpha, \beta + 2\pi, \gamma) = -U(\alpha\beta\gamma);$$

$$R(\alpha\beta\gamma) = e^{-i\alpha M_3} e^{-i\beta M_2} e^{-i\gamma M_3}$$

$$= \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos \beta & 0 & \sin \beta \\ 0 & 1 & 0 \\ -\sin \beta & 0 & \cos \beta \end{pmatrix}$$

$$\times \begin{pmatrix} \cos \gamma & -\sin \gamma & 0 \\ \sin \gamma & \cos \gamma & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$= \begin{pmatrix} \cos \alpha \cos \beta \cos \gamma & -\cos \alpha \cos \beta \sin \gamma & \cos \alpha \sin \beta \\ -\sin \alpha \sin \gamma & -\sin \alpha \cos \gamma & \\ \sin \alpha \cos \beta \cos \gamma & -\sin \alpha \cos \beta \sin \gamma & \sin \alpha \sin \beta \\ +\cos \alpha \sin \gamma & +\cos \alpha \cos \gamma & \\ -\sin \beta \cos \gamma & \sin \beta \sin \gamma & \cos \beta \end{pmatrix}$$

$$0 \leq \alpha < 2\pi, \quad 0 \leq \beta \leq \pi, \quad 0 \leq \gamma < 2\pi.$$

This matrix corresponds to the sequence of frame rotations given by

- rotate by γ about $\hat{\mathbf{e}}_3 = (0, 0, 1)$,
- rotate by β about $\hat{\mathbf{e}}_2 = (0, 1, 0)$,
- rotate by α about $\hat{\mathbf{e}}_3 = (0, 0, 1)$.

Equivalently, it corresponds to the sequence of frame rotations given by

- rotate by α about $\hat{\mathbf{n}}_1 = (0, 0, 1)$,
- rotate by β about $\hat{\mathbf{n}}_2 = (-\sin \alpha, \cos \alpha, 0)$,
- rotate by γ about $\hat{\mathbf{n}}_3 = (\cos \alpha \sin \beta, \sin \alpha \sin \beta, \cos \beta)$.

This latter sequence of rotations is depicted in Fig. 2.1 in obtaining the frame $(\hat{\mathbf{f}}_1, \hat{\mathbf{f}}_2, \hat{\mathbf{f}}_3)$ from $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3)$.

The four complex numbers

$$\begin{aligned} (a, b, c, d) \\ = (\alpha_0 + i\alpha_3, i\alpha_1 - \alpha_2, i\alpha_1 + \alpha_2, \alpha_0 - i\alpha_3) \end{aligned}$$

are called the Cayley–Klein parameters, whereas the four real numbers $(\alpha_0, \boldsymbol{\alpha})$ defining a point on the surface of the unit sphere in four-space, \mathcal{S}^3 , are known as the Euler–Rodrigues parameters. The three ratios α_i/α_0 form the homogeneous or symmetric Euler parameters.

Fig. 2.1 Euler angles. The three Euler angles $(\alpha\beta\gamma)$ are defined by a sequence of three rotations. Reprinted with the permission of Cambridge University Press, after [1]

2.3.2 Explicit Forms of Representation Functions

The general form of the representation functions is given in its most basic and symmetric form in Eq. (2.17). This form applies to every parametrization, it being necessary only to introduce the explicit parametrizations of $U \in SU(2)$ or $R \in SO(3, \mathbf{R})$ given in Sect. 2.3.1 to obtain the explicit results given in this section. A choice is also made for the single independent summation parameter in the α -array. The notation for functions is abused by writing

$$D^j(\omega) = D^j(U(\omega)),$$

$\omega =$ set of parameters of $U \in SU(2)$.

Euler–Rodrigues representation $[(\alpha_0, \boldsymbol{\alpha}) \in \mathcal{S}^3]$:

$$D_{m'm}^j(\alpha_0, \boldsymbol{\alpha}) = [(j+m')!(j-m')!(j+m)!(j-m)!]^{1/2} \\ \times \sum_s \frac{(\alpha_0 - i\alpha_3)^{j+m-s} (-i\alpha_1 - \alpha_2)^{m'-m+s}}{(j+m-s)!(m'-m+s)!} \\ \times \frac{(-i\alpha_1 + \alpha_2)^s (\alpha_0 + i\alpha_3)^{j-m'-s}}{s!(j-m'-s)!}. \quad (2.22)$$

Quaternionic multiplication rule for points on the sphere \mathcal{S}^3 :

$$(\alpha'_0, \boldsymbol{\alpha}')(\alpha_0, \boldsymbol{\alpha}) = (\alpha''_0, \boldsymbol{\alpha}''), \\ \alpha''_0 = \alpha'_0\alpha_0 - \boldsymbol{\alpha}' \cdot \boldsymbol{\alpha}, \\ \boldsymbol{\alpha}'' = \alpha'_0\boldsymbol{\alpha} + \alpha_0\boldsymbol{\alpha}' + \boldsymbol{\alpha}' \times \boldsymbol{\alpha}; \\ D^j(\alpha'_0, \boldsymbol{\alpha}')D^j(\alpha_0, \boldsymbol{\alpha}) = D^j(\alpha''_0, \boldsymbol{\alpha}'').$$

The $(\psi, \hat{\mathbf{n}})$ parameters:

$$\alpha_0 = \cos \frac{1}{2}\psi, \quad \boldsymbol{\alpha} = \hat{\mathbf{n}} \sin \frac{1}{2}\psi.$$

Euler angle parametrization:

$$D_{m'm}^j(\alpha\beta\gamma) = e^{-im'\alpha} d_{m'm}^j(\beta) e^{-im\gamma}, \\ d_{m'm}^j(\beta) = \langle jm' | e^{-i\beta J_2} | jm \rangle \\ = [(j+m')!(j-m')!(j+m)!(j-m)!]^{1/2} \\ \times \sum_s \frac{(-1)^{m'-m+s} (\cos \frac{1}{2}\beta)^{2j+m-m'-2s}}{(j+m-s)!s!(m'-m+s)!} \\ \times \frac{(\sin \frac{1}{2}\beta)^{m'-m+2s}}{(j-m'-s)!}. \quad (2.23)$$

Explicit matrices:

$$d^{1/2}(\beta) = \begin{pmatrix} \cos \frac{1}{2}\beta & -\sin \frac{1}{2}\beta \\ \sin \frac{1}{2}\beta & \cos \frac{1}{2}\beta \end{pmatrix}, \\ d^1(\beta) = \begin{pmatrix} \frac{1+\cos\beta}{2} & \frac{-\sin\beta}{\sqrt{2}} & \frac{1-\cos\beta}{2} \\ \frac{\sin\beta}{\sqrt{2}} & \cos\beta & \frac{-\sin\beta}{\sqrt{2}} \\ \frac{1-\cos\beta}{2} & \frac{\sin\beta}{\sqrt{2}} & \frac{1+\cos\beta}{2} \end{pmatrix}.$$

Formal polynomial form (z_{ij} are indeterminates):

$$D_{m'm}^j(Z) = [(j+m')!(j-m')!(j+m)!(j-m)!]^{1/2} \\ \times \sum_{\boxed{\boldsymbol{\alpha}}} \prod_{i,j=1}^2 (z_{ij})^{\alpha_{ij}} / (\alpha_{ij})!, \quad (2.24)$$

$$D^j(Z')D^j(Z) = D^j(Z'Z).$$

Boson operator form:

Put $a_i^j = z_{ij}$ ($i, j = 1, 2$) in Eq. (2.24). Let \bar{a}_i^j denote the Hermitian conjugate boson so that

$$[a_i^k, a_i^j] = 0, \quad [\bar{a}_i^k, \bar{a}_i^j] = 0, \quad [\bar{a}_i^k, a_i^j] = \delta^{kj} \delta_{li}.$$

Then the boson polynomials are orthogonal in the boson inner product:

$$\langle 0 | D_{\mu'\mu}^{j'}(\bar{A}) D_{m'm}^j(A) | 0 \rangle = (2j)! \delta_{j'j} \delta_{\mu'\mu'} \delta_{\mu\mu}.$$

2.3.3 Relations to Special Functions

Jacobi polynomials (Sect. 2.1.2):

$$d_{m'm}^j(\beta) = \left(\frac{(j+m)!(j-m)!}{(j+m')!(j-m')!} \right)^{1/2} \left(\sin \frac{1}{2}\beta \right)^{m-m'} \\ \times \left(\cos \frac{1}{2}\beta \right)^{m'+m} P_{j-m}^{(m-m', m+m')}(\cos \beta),$$

$$\begin{aligned} d_{m'm}^j(\beta) &= (-1)^{m'-m} d_{-m',-m}^j(\beta) \\ &= (-1)^{m'-m} d_{mm'}^j(\beta) = d_{mm'}^j(-\beta). \end{aligned}$$

Legendre polynomials:

$$\begin{aligned} D_{m0}^l(\beta) &= (-1)^m \left(\frac{(l-m)!}{(l+m)!} \right)^{\frac{1}{2}} P_l^m(\cos \beta) \\ &= \left(\frac{(l+m)!}{(l-m)!} \right)^{\frac{1}{2}} P_l^{-m}(\cos \beta). \end{aligned}$$

Spherical harmonics:

$$\begin{aligned} Y_{lm}(\beta\alpha) &= \left(\frac{2l+1}{4\pi} \right)^{\frac{1}{2}} e^{im\alpha} d_{m0}^l(\beta) \\ &= \left(\frac{2l+1}{4\pi} \right)^{\frac{1}{2}} D_{m0}^{l*}(\alpha\beta\gamma), \\ Y_{lm}^*(\beta\alpha) &= (-1)^m Y_{l,-m}(\beta\alpha). \end{aligned}$$

Gegenbauer polynomials:

$$\begin{aligned} d_{m0}^l(\beta) &= (-1)^m [(l+m)!(l-m)!]^{\frac{1}{2}} \\ &\times \frac{(2m)!}{m!} \left(\frac{\sin \beta}{2} \right)^m C_{l-m}^{(m+1/2)}(\cos \beta), \quad m \geq 0. \end{aligned}$$

Solutions of Laplace's equation in \mathbf{R}^4 (Sect. 2.5):

$$\begin{aligned} \nabla_4^2 D_{m'm}^j(x_0, \mathbf{x}) &= 0, \quad (x_0, \mathbf{x}) \in \mathbf{R}^4, \\ \nabla_4^2 &= \sum_{\mu=0}^3 \frac{\partial^2}{\partial x_\mu^2}. \end{aligned}$$

Replace the Euler–Rodrigues parameters $(\alpha_0, \boldsymbol{\alpha})$ in Eq. (2.22) by an arbitrary point $(x_0, \mathbf{x}) \in \mathbf{R}^4$.

2.3.4 Orthogonality Properties

Inner (scalar) product:

$$\begin{aligned} (\Psi, \Phi) &= \int d\Omega \Psi^*(\mathbf{x}) \Phi(\mathbf{x}), \\ d\Omega &= \text{invariant surface measure for } \mathbf{S}^3, \\ \int_{\mathbf{S}^3} d\Omega &= 2\pi^2. \end{aligned}$$

Spherical polar coordinate for \mathbf{S}^3 :

$$\begin{aligned} (\alpha_0, \boldsymbol{\alpha}) &= \\ (\cos \chi, \cos \phi \sin \theta \sin \chi, \sin \phi \sin \theta \sin \chi, \cos \theta \sin \chi), \\ 0 \leq \theta \leq \pi, \quad 0 \leq \phi < 2\pi, \quad 0 \leq \chi \leq \pi, \end{aligned}$$

$$d\Omega = d\omega \sin^2 \chi d\chi,$$

$$d\omega = d\phi \sin \theta,$$

$$d\theta = \text{invariant surface measure for } \mathbf{S}^2;$$

$$\begin{aligned} \int_0^{2\pi} d\phi \int_0^\pi d\theta \sin \theta \int_0^\pi d\chi \sin^2 \chi D_{m'm}^{j*}(\alpha_0, \boldsymbol{\alpha}) D_{\mu'\mu}^{j'}(\alpha_0, \boldsymbol{\alpha}) \\ = \frac{2\pi^2}{2j+1} \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu}. \end{aligned}$$

Coordinates $(\psi, \hat{\mathbf{n}})$ for \mathbf{S}^3 :

$$\begin{aligned} (\alpha_0, \boldsymbol{\alpha}) &= \left(\cos \frac{\psi}{2}, \hat{\mathbf{n}} \sin \frac{\psi}{2} \right), \\ 0 \leq \psi \leq 2\pi, \quad \hat{\mathbf{n}} \cdot \hat{\mathbf{n}} &= 1, \end{aligned}$$

$$d\Omega = dS(\hat{\mathbf{n}}) \sin^2 \frac{\psi}{2} \frac{d\psi}{2},$$

$$dS(\hat{\mathbf{n}}) = d\omega \text{ for } \hat{\mathbf{n}} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta),$$

$$\begin{aligned} \int dS(\hat{\mathbf{n}}) \int_0^{2\pi} \frac{d\psi}{2} \left(\sin \frac{\psi}{2} \right)^2 D_{m'm}^{j*}(\psi, \hat{\mathbf{n}}) D_{\mu'\mu}^{j'}(\psi, \hat{\mathbf{n}}) \\ = \frac{2\pi^2}{2j+1} \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu}, \end{aligned}$$

Euler angles for \mathbf{S}^3 ($SU(2)$):

$$\begin{aligned} (\alpha_0, \boldsymbol{\alpha}) &= \left(\cos \frac{\beta}{2} \cos \frac{1}{2}(\gamma + \alpha), \sin \frac{\beta}{2} \sin \frac{1}{2}(\gamma - \alpha), \right. \\ &\quad \left. \sin \frac{\beta}{2} \cos \frac{1}{2}(\gamma - \alpha), \cos \frac{\beta}{2} \sin \frac{1}{2}(\gamma + \alpha) \right), \end{aligned}$$

$$d\Omega = \frac{1}{8} d\alpha d\gamma \sin \beta d\beta, \quad (2.25)$$

$$\frac{1}{8} \int_0^{2\pi} d\alpha \int_0^{2\pi} d\gamma \int_0^\pi d\beta \sin \beta D_{m'm}^{j*}(\alpha\beta\gamma) D_{\mu'\mu}^{j'}(\alpha\beta\gamma)$$

$$\begin{aligned} + \frac{1}{8} \int_0^{2\pi} d\alpha \int_0^{2\pi} d\gamma \int_{2\pi}^{3\pi} d\beta \sin \beta D_{m'm}^{j*}(\alpha\beta\gamma) D_{\mu'\mu}^{j'}(\alpha\beta\gamma) \\ = \frac{2\pi^2}{2j+1} \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu}. \end{aligned} \quad (2.26)$$

Euler angles for hemisphere of \mathbf{S}^3 ($SO(3, \mathbf{R})$); j' and j both integral):

$$\begin{aligned} \int_0^{2\pi} d\alpha \int_0^{2\pi} d\gamma \int_0^\pi d\beta \sin \beta D_{m'm}^{j*}(\alpha\beta\gamma) D_{\mu'\mu}^{j'}(\alpha\beta\gamma) \\ = \frac{8\pi^2}{2j+1} \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu}. \end{aligned} \quad (2.27)$$

Formal polynomials Eq. (2.24):

$$\left(D_{m'm}^j, D_{\mu'\mu}^{j'} \right) = (2j)! \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu} ,$$

with inner product

$$\langle P, P' \rangle = P^* \left(\frac{\partial}{\partial Z} \right) P'(Z) |_{Z=0} ,$$

where $P^* \left(\frac{\partial}{\partial Z} \right)$ is the complex conjugate polynomial P^* of P in which each z_{ij} is replaced by $\frac{\partial}{\partial z_{ij}}$.

Boson polynomials:

$$\left\langle D_{m'm}^j \left| D_{\mu'\mu}^{j'} \right. \right\rangle = (2j)! \delta_{jj'} \delta_{m'\mu'} \delta_{m\mu} ,$$

with inner product $\langle P | P' \rangle = \langle 0 | P^*(\bar{A}) P'(A) | 0 \rangle$.

2.3.5 Recurrence Relations

Many useful relations between the representation functions may be derived as special cases of general relations between these functions and the WCG coefficients given in Sect. 2.7.1. The simplest of these are obtained from the Kronecker reduction

$$D^j \times D^{\frac{1}{2}} = D^{j+1/2} \oplus D^{j-1/2} .$$

Such relations are usually presented in terms of the Euler angle realization of U , leading to the following relations between the functions $d_{m',m}^j(\beta)$:

$$\begin{aligned} & (j-m+1)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d_{m'-1/2,m-1/2}^{j+1/2}(\beta) \\ & + (j+m+1)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d_{m'-1/2,m+1/2}^{j+1/2}(\beta) \\ & = (j-m'+1)^{\frac{1}{2}} d_{m',m}^j(\beta) , \\ & - (j-m+1)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d_{m'+1/2,m-1/2}^{j+1/2}(\beta) \\ & + (j+m+1)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d_{m'+1/2,m+1/2}^{j+1/2}(\beta) \\ & = (j+m'+1)^{\frac{1}{2}} d_{m',m}^j(\beta) , \\ & (j+m)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d_{m'-1/2,m-1/2}^{j-1/2}(\beta) \\ & - (j-m)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d_{m'-1/2,m+1/2}^{j-1/2}(\beta) \\ & = (j+m')^{\frac{1}{2}} d_{m',m}^j(\beta) , \end{aligned}$$

$$\begin{aligned} & (j+m)^{\frac{1}{2}} \sin\left(\frac{1}{2}\beta\right) d_{m'+1/2,m-1/2}^{j-1/2}(\beta) \\ & + (j-m)^{\frac{1}{2}} \cos\left(\frac{1}{2}\beta\right) d_{m'+1/2,m+1/2}^{j-1/2}(\beta) \\ & = (j-m')^{\frac{1}{2}} d_{m',m}^j(\beta) . \end{aligned}$$

Two useful relations implied by the above are:

$$\begin{aligned} & [(j-m)(j+m+1)]^{\frac{1}{2}} \sin\beta d_{m',m+1}^j(\beta) \\ & + [(j+m)(j-m+1)]^{\frac{1}{2}} \sin\beta d_{m',m-1}^j(\beta) \\ & = 2(m \cos\beta - m') d_{m',m}^j(\beta) , \\ & [(j+m)(j-m+1)]^{\frac{1}{2}} d_{m',m-1}^j(\beta) \\ & + [(j+m')(j-m'+1)]^{\frac{1}{2}} d_{m'-1,m}^j(\beta) \\ & = (m-m') \cot\left(\frac{1}{2}\beta\right) d_{m',m}^j(\beta) . \end{aligned}$$

By considering

$$D^j \times D^1 = D^{j+1} \oplus D^j \oplus D^{j-1} ,$$

one can also readily derive the matrix elements of the direction cosines specifying the orientation of the body-fixed frame $(\hat{f}_1, \hat{f}_2, \hat{f}_3)$ of a symmetric rotor relative to the inertial frame $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$:

$$\lambda_{\mu,\nu} \Psi_{m,m'}^j = \sum_{j'} \left(\frac{2j+1}{2j'+1} \right)^{\frac{1}{2}} C_{m\mu m+\mu}^{j1j'} C_{m'\nu m'+\nu}^{j1j'} \Psi_{m+\mu, m'+\nu}^{j'} ,$$

where the wave functions are those defined for integral j by Eq. (2.37), for half-integral j by Eq. (2.36), and

$$\begin{aligned} \lambda_{\mu,\nu} & = \hat{e}_\mu \cdot \hat{f}_\nu^* = (D_{\mu,\nu}^1)^* , \quad \mu, \nu = -1, 0, +1 ; \\ \hat{e}_{+1} & = -(\hat{e}_1 + i\hat{e}_2)/\sqrt{2} , \quad \hat{e}_0 = \hat{e}_3 , \\ \hat{e}_{-1} & = (\hat{e}_1 - i\hat{e}_2)/\sqrt{2} , \\ \hat{f}_{+1} & = -(\hat{f}_1 + i\hat{f}_2)/\sqrt{2} , \quad \hat{f}_0 = \hat{f}_3 , \\ \hat{f}_{-1} & = (\hat{f}_1 - i\hat{f}_2)/\sqrt{2} . \end{aligned}$$

2.3.6 Symmetry Relations

Symmetry relations for the representation functions $D_{m'm}^j(Z)$ defined by Eq. (2.24) are associated with the action of a finite group G on the set $M(2, 2)$ of complex 2×2 matrices: $g : M(2, 2) \rightarrow M(2, 2)$, $g \in G$. Equivalently, if $Z \in M(2, 2)$ is parametrized by a set Ω of parameters $\omega \in \Omega$ (parameter space), then g may be taken to act directly in the parameter space $g : \Omega \rightarrow \Omega$. The action, denoted

\square , of a group $G = \{e, g, g', \dots\}$ ($e = \text{identity}$) on a set $X = \{x, x', \dots\}$ must satisfy the rules

$$\begin{aligned} g : X &\rightarrow X & e \square x &= x, \text{ all } x \in X, \\ g' \square (g \square x) &= (g'g) \square x, \text{ all } g', g \in G, \text{ all } x \in X. \end{aligned} \quad (2.28)$$

Using \cdot to denote the action of G on $M(2, 2)$ and \square to denote the action of G on Ω , one has the relation:

$$(g \cdot Z)(\omega) = Z(g^{-1} \square \omega).$$

Only finite subgroups G of the unitary group $U(2)$ (group of 2×2 unitary matrices) are considered here: $G \subset U(2)$.

Generally, when G acts on $M(2, 2)$, it effects a unitary linear transformation of the set of functions $\{D_{m'm}^j\}$ (j fixed) defined over $Z \in M(2, 2)$. For certain groups G , or for some elements of G , a single function $D_{\mu'\mu}^j \in \{D_{m'm}^j\}$ occurs in the transformation, so that

$$\begin{aligned} (g \cdot D_{m'm}^j)(Z) &= D_{m'm}^j(g^{-1} \square Z) \\ &= g_{m'm} D_{\mu'\mu}^j(Z), \end{aligned} \quad (2.29)$$

$$(\mu' \mu) \in \{(\lambda' m', \lambda m), (\lambda m, \lambda' m') | \lambda' = \pm 1, \lambda = \pm 1\},$$

where $g_{m'm}$ is a complex number of unit modulus. Relation Eq. (2.29) is called a symmetry relation of $D_{m'm}^j$ with respect to g . Usually, not all elements in G correspond to symmetry relations. In a symmetry relation, the action of the group is effectively transferred to the discrete quantum labels themselves:

$$\begin{aligned} g : m' &\rightarrow \mu' = m'(g), \\ m &\rightarrow \mu = m(g). \end{aligned} \quad (2.30)$$

In terms of a parametrization Ω of $M(2, 2)$, relation Eq. (2.29) is written

$$\begin{aligned} (g D_{m'm}^j)(\omega) &= D_{m'm}^j(g^{-1} \square \omega) \\ &= g_{m'm} D_{\mu'\mu}^j(\omega). \end{aligned} \quad (2.31)$$

In practice, action symbols such as \cdot and \square are often dropped in favor of juxtaposition, when the context is clear. Moreover, the set of complex matrices $M(2, 2)$ may be replaced by $U(2)$ or $SU(2)$ whenever the action conditions Eq. (2.28) are satisfied. Relations (Eqs. (2.29)–(2.31)) are illustrated below by examples.

There are several finite subgroups of interest with various group–subgroup relations between them:

1. Pauli group:

$$\begin{aligned} P &= \{\sigma_\mu, -\sigma_\mu, i\sigma_\mu, -i\sigma_\mu | \mu = 0, 1, 2, 3\}, \\ |P| &= 16. \end{aligned}$$

Each element of this group is an element of $U(2)$. The action of the group P may, therefore, be defined on the group $U(2)$ by left and right actions, as discussed in Sect. 2.4.1.

2. Symmetric group S_4 :

$S_4 = \{p | p \text{ is a permutation of the four Euler–Rodrigues parameters } (\alpha_0, \alpha_1, \alpha_2, \alpha_3)\}$, $|S_4| = 24$. Points in S^3 are mapped to distinct points in S^3 ; hence, one can take $Z \in SU(2)$ and define the group action directly from $U(\alpha_0, \alpha)$ in Eq. (2.20). It is simpler, however, to define the action of the group directly on the representation functions Eq. (2.22). Not all elements of this group define a symmetry in the sense defined by Eq. (2.29) (see below).

3. Abelian group T :

$$\begin{aligned} T &= \{(t_0, t_1, t_2, t_3) | \text{each } t_\mu = \pm 1\}, \\ |T| &= 16. \end{aligned}$$

Group multiplication is component-wise multiplication, and the identity is $(1, 1, 1, 1)$. The action of an element of T is defined directly on the Euler–Rodrigues parameters by component-wise multiplication, thus mapping points in S^3 to points in S^3 ; hence, one can take $Z \in SU(2)$. This group is isomorphic to the direct product group $S_2 \times S_2 \times S_2 \times S_2$, $S_2 = \text{symmetric group on two distinct objects}$.

4. Group G :

$$G = \langle \mathcal{R}, \mathcal{C}, \mathcal{T}, \mathcal{K} \rangle, \quad |G| = 32,$$

where $\mathcal{R}, \mathcal{C}, \mathcal{T}, \mathcal{K}$ denote the operations of row interchange, column interchange, transposition, and conjugation (see below) of an arbitrary matrix.

$$Z = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

The notation $\langle \rangle$ designates that the enclosed elements generate G .

It is impossible to give here all the interrelationships among the groups defined in (1)–(4). Instead, some relations are listed as obtained directly from either $D_{m'm}^j(Z)$ defined by Eq. (2.24) or $D_{m'm}^j(\alpha_0, \alpha)$ defined by Eq. (2.22). The actions of the groups T and G defined in (3) and (4) are fully given.

Abelian group T of order 16.

Generators:

$$\begin{aligned} T &= \langle t_0, t_1, t_2, t_3 \rangle, \quad t_0 = (-1, 1, 1, 1), \\ t_1 &= (1, -1, 1, 1), \quad t_2 = (1, 1, -1, 1), \\ t_3 &= (1, 1, 1, -1). \end{aligned}$$

Group action:

$$\begin{aligned} t \cdot a &= (t_0\alpha_0, t_1\alpha_1, t_2\alpha_2, t_3\alpha_3), \\ \text{each } t &= (t_0, t_1, t_2, t_3) \in T, \\ \text{each } a &= (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \in \mathcal{S}^3, \\ (tF)(a) &= F(t \cdot a), \\ t_0 D_{m'm}^j &= (-1)^{m'-m} D_{-m-m'}^j, \\ t_1 D_{m'm}^j &= (-1)^{m'-m} D_{mm'}^j, \\ t_2 D_{m'm}^j &= D_{mm'}^j, \\ t_3 D_{m'm}^j &= D_{-m-m'}^j. \end{aligned}$$

Group G of order 32.

Generators:

$$G = \langle \mathcal{R}, C, \mathcal{T}, \mathcal{K} \rangle.$$

Generator actions:

$$\begin{aligned} (\mathcal{R}F) \begin{pmatrix} a & b \\ c & d \end{pmatrix} &= F \begin{pmatrix} c & d \\ a & b \end{pmatrix}, & \text{row interchange} \\ (\mathcal{C}F) \begin{pmatrix} a & b \\ c & d \end{pmatrix} &= F \begin{pmatrix} b & a \\ d & c \end{pmatrix}, & \text{column interchange} \\ (\mathcal{T}F) \begin{pmatrix} a & b \\ c & d \end{pmatrix} &= F \begin{pmatrix} a & c \\ b & d \end{pmatrix}, & \text{transposition} \\ (\mathcal{K}F) \begin{pmatrix} a & b \\ c & d \end{pmatrix} &= F \begin{pmatrix} d & -c \\ -b & a \end{pmatrix}, & \text{conjugation} \end{aligned}$$

Subgroup H :

$$\begin{aligned} H &= \langle \mathcal{R}, C, \mathcal{T} \rangle \\ &= \{1, \mathcal{R}, C, \mathcal{T}, \mathcal{R}C = \mathcal{C}\mathcal{R}, \mathcal{T}\mathcal{R} = \mathcal{C}\mathcal{T}, \mathcal{T}C \\ &= \mathcal{R}\mathcal{T}, \mathcal{R}\mathcal{C}\mathcal{T}\}, \end{aligned}$$

with relations in H given by

$$\begin{aligned} \mathcal{R}^2 &= \mathcal{C}^2 = \mathcal{T}^2 = 1, \\ \mathcal{T}\mathcal{R}C &= \mathcal{T}C\mathcal{R} = \mathcal{R}\mathcal{C}\mathcal{T} = \mathcal{C}\mathcal{R}\mathcal{T}, \\ \mathcal{R}\mathcal{T}C &= \mathcal{C}\mathcal{T}\mathcal{R} = \mathcal{T}. \end{aligned}$$

Adjoining the idempotent element \mathcal{K} to H gives the group G of order 32:

$$G = \{H, H\mathcal{K}, H\mathcal{K}\mathcal{R}, H\mathcal{K}\mathcal{R}\mathcal{K}\}.$$

Symmetry relations:

$$\begin{aligned} \mathcal{R}D_{m'm}^j &= D_{-m'm}^j, \\ \mathcal{C}D_{m'm}^j &= D_{m'-m}^j, \\ \mathcal{T}D_{m'm}^j &= D_{mm'}^j, \\ \mathcal{K}D_{m'm}^j &= (-1)^{m'-m} D_{-m'-m}^j. \end{aligned} \quad (2.32)$$

These function relations are valid for $D_{m'm}^j$ defined over the arbitrary matrix Z defined by Eq. (2.24). They are also true for $Z = U \in SU(2)$, but now the operations \mathcal{R} and \mathcal{C} change the sign of the determinant of the matrix Z , so that the transformed matrix no longer belongs to $SU(2)$. It does, however, belong to $U(2)$, the group of all 2×2 unitary matrices. The special irreducible representation functions of $U(2)$ defined by Eq. (2.24),

$$D_{m'm}^j(U), \quad U \in U(2),$$

possess each of the 32 symmetries corresponding to the operations in the group G . (There exist other irreducible representations of $U(2)$, involving $\det U$.) The operation \mathcal{K} is closely related to complex conjugation, since for each $U \in U(2)$, $U = (u_{ij})$, one can write

$$\begin{aligned} U^* &= (\det U)^{-1} \begin{pmatrix} u_{22} & -u_{21} \\ -u_{12} & u_{11} \end{pmatrix}, \\ (\mathcal{K}D_{m'm}^j)(U) &= (\det U)^{2j} D_{m'm}^j(U^*) \\ &= (\det U)^{2j} D_{m'm}^{j*}(U) \\ &= (-1)^{m'-m} D_{-m'-m}^j(U). \end{aligned} \quad (2.33)$$

Relations Eqs. (2.32) and (2.33) are valid in an arbitrary parametrization of $U \in U(2)$. In terms of the parametrization

$$U(\chi, \alpha_0, \boldsymbol{\alpha}) = e^{i\chi/2} U(\alpha_0, \boldsymbol{\alpha}), \quad 0 \leq \chi \leq 2\pi,$$

where $U(\alpha_0, \boldsymbol{\alpha}) \in SU(2)$ is the Euler–Rodrigues parametrization, the actions of \mathcal{R} , \mathcal{C} , \mathcal{T} , and \mathcal{K} correspond to the following transformations in parameter space:

$$\begin{aligned} \mathcal{R} : \quad & \chi \rightarrow \chi + \pi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \\ & \rightarrow (-\alpha_1, \alpha_0, -\alpha_3, \alpha_2), \\ \mathcal{C} : \quad & \chi \rightarrow \chi + \pi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \\ & \rightarrow (-\alpha_1, \alpha_0, \alpha_3, -\alpha_2), \\ \mathcal{T} : \quad & \chi \rightarrow \chi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \rightarrow (\alpha_0, \alpha_1, -\alpha_2, \alpha_3), \\ \mathcal{K} : \quad & \chi \rightarrow \chi, (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \\ & \rightarrow (\alpha_0, -\alpha_1, \alpha_2, -\alpha_3). \end{aligned}$$

The new angle $\chi' = \chi + \pi$ is to be identified with the corresponding point on the unit circle so that these mappings are always in the parameter space, which is the sphere \mathcal{S}^3 together with the unit circle for χ . Observe that the following identities hold for functions over $SU(2)$; hence, over $U(2)$:

$$C = T_1 T_3, \quad \mathcal{T} = T_2.$$

Abelian subgroup of S_4 .

Generators:

$K = \langle (0, 3), (1, 2) \rangle$, where $(0, 3)$ and $(1, 2)$ denote transpositions in S_4 , $|K| = 4$.

Group action in parameter space:

$$(0, 3)(\alpha_0, \alpha_1, \alpha_2, \alpha_3) = (\alpha_3, \alpha_1, \alpha_2, \alpha_0) ,$$

$$(1, 2)(\alpha_0, \alpha_1, \alpha_2, \alpha_3) = (\alpha_0, \alpha_2, \alpha_1, \alpha_3) .$$

Symmetry relations:

$$(0, 3)D_{m'm}^j = (-i)^{m'+m} D_{-m-m'}^j ,$$

$$(1, 2)D_{m'm}^j = (-i)^{m'-m} D_{mm'}^j .$$

Diagonal subgroup Σ of the direct product group $P \times P$ ($P = \text{Pauli group}$).

Group elements:

$$\Sigma = \{(\sigma, \sigma) | \sigma \in P\} , \quad |\Sigma| = 16 .$$

Group action:

$$(\sigma, \sigma) : U \rightarrow \sigma U \sigma^T , \quad \text{each } \sigma \in P ,$$

$$[(\sigma, \sigma)F](U) = F(\sigma^T U \sigma) .$$

Example: $\sigma = i\sigma_2$:

$$(\sigma, \sigma) : (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \rightarrow (\alpha_0, -\alpha_1, \alpha_2, -\alpha_3) ,$$

$$[(\sigma, \sigma)F](\alpha_0, \alpha_1, \alpha_2, \alpha_3) = F(\alpha_0, -\alpha_1, \alpha_2, -\alpha_3) ,$$

$$(\sigma, \sigma) = t_1 t_2 \text{ on functions over } U(2) .$$

The relations presented above barely touch on the interrelations among the finite groups introduced in (1)–(4). Symmetry relations Eqs. (2.32) and (2.33), however, give the symmetries of the $d_{m'm}^j(\beta)$ given in Sect. 2.3.3 in the Euler angle parametrization. In general, it is quite tedious to present the above symmetries in terms of Euler angles, with χ adjoined when necessary, because the Euler angles are not uniquely determined by the points of S^3 .

2.4 Group and Lie Algebra Actions

The concept of a group acting on a set is fundamental to applications of group theory to physical problems. Because of the unity that this notion brings to angular momentum theory, it is well worth a brief review in a setting in which a matrix group acts on the set of complex matrices. Thus, let $G \subseteq GL(n, \mathbb{C})$ and $H \subseteq GL(m, \mathbb{C})$ denote arbitrary subgroups, respectively, of the general linear groups of $n \times n$ and $m \times m$ nonsingular complex matrices, and let $M(n, m)$ denote the set of $n \times m$ complex matrices. A matrix $Z \in M(n, m)$ has row and column entries $(z_i^\alpha), i = 1, 2, \dots, n; \alpha = 1, 2, \dots, m$.

2.4.1 Matrix Group Actions

Left and right translations of $Z \in M(n, m)$:

$$L_g Z = g Z , \quad \text{each } g \in G , \quad \text{each } Z \in M(n, m) ,$$

$$R_h Z = Z h^T , \quad \text{each } h \in H , \quad \text{each } Z \in M(n, m) .$$

(T denotes matrix transposition.)

Left and right translations commute:

$$Z' = L_g(R_h Z) = R_h(L_g Z) , \quad \text{each } g \in G, h \in H ,$$

$$Z \in M(n, m) .$$

Equivalent form as a transformation on $\mathbf{z} \in \mathbb{C}^{nm}$:

$$\mathbf{z}' = (g \times h)\mathbf{z} ,$$

where \times denotes the direct product of g and h ; the column matrix \mathbf{z} (respectively, \mathbf{z}') is obtained from the columns of Z (respectively, Z'), $z^\alpha, \alpha = 1, 2, \dots, m$, of the $n \times m$ matrix Z as successive entries in a single column vector $\mathbf{z} \in \mathbb{C}^{nm}$.

Left and right translations in function space:

$$(\mathcal{L}_g f)(Z) = f(g^T Z) , \quad \text{each } g \in G ,$$

$$(\mathcal{R}_h f)(Z) = f(Z h) , \quad \text{each } h \in H ,$$

where $f(Z) = f(z_i^\alpha)$, and the commuting property holds for all well-defined functions f :

$$\mathcal{L}_g(\mathcal{R}_h f) = \mathcal{R}_h(\mathcal{L}_g f) .$$

2.4.2 Lie Algebra Actions

Lie algebra of left and right translations:

$$(D_X f)(Z) = i \frac{d}{dt} f(e^{-itX^T} Z) |_{t=0} ,$$

$$(D^Y f)(Z) = i \frac{d}{dt} f(Z e^{-itY}) |_{t=0} ;$$

$$D_X = \text{Tr}(Z^T X \partial / \partial Z) , \quad \text{each } X \in L(G) ,$$

$$D^Y = \text{Tr}(Y^T Z^T \partial / \partial Z) , \quad \text{each } Y \in L(H) ,$$

$$L(G) = \text{Lie algebra of } G ,$$

$$L(H) = \text{Lie algebra of } H .$$

Linear derivations:

$$D_{\alpha X + \beta X'} = \alpha D_X + \beta D_{X'} , \quad \alpha, \beta \in \mathbb{C} ,$$

$$[D_X, D_{X'}] = D_{[X, X']} ,$$

D^Y obeys these same rules.

Commuting property of left and right derivations:

$$[D_X, D^Y] = 0, \quad X \in L(G), \quad Y \in L(H).$$

Basis set:

$$D_X = \sum_{i,j=1}^n x_{ij} D_{ij}, \quad X = (x_{ij}),$$

$$D^Y = \sum_{\alpha,\beta=1}^m y^{\alpha\beta} D^{\alpha\beta}, \quad Y = (y^{\alpha\beta}),$$

$$D_{ij} = \sum_{\alpha=1}^m z_i^\alpha \frac{\partial}{\partial z_j^\alpha},$$

$$D^{\alpha\beta} = \sum_{i=1}^n z_i^\alpha \frac{\partial}{\partial z_i^\beta}.$$

Commutation rules:

$$[D_{ij}, D_{kl}] = \delta_{jk} D_{il} - \delta_{il} D_{kj},$$

$$[D^{\alpha\beta}, D^{\gamma\epsilon}] = \delta^{\beta\gamma} D^{\alpha\epsilon} - \delta^{\alpha\epsilon} D^{\gamma\beta},$$

$$[D_{ij}, D^{\alpha\beta}] = 0,$$

where $i, j, k, l = 1, 2, \dots, n$, and $\alpha, \beta, \gamma, \epsilon = 1, 2, \dots, m$. The operator sets $\{D_{ij}\}$ and $\{D^{\alpha\beta}\}$ are realizations of the Weyl generators of $GL(n, C)$ and $GL(m, C)$, respectively.

2.4.3 Hilbert Spaces

Space of polynomials with inner product:

$$(P, P') = P^*(\partial/\partial Z)P'(Z)|_{Z=0}.$$

Bargmann space of entire functions with inner product:

$$\langle F, F' \rangle = \int F^*(Z)F'(Z)d\mu(Z),$$

$$d\mu(Z) = \pi^{-nm} \exp\left(-\sum_{i,\alpha} z_i^{\alpha*} z_i^\alpha\right) \prod_{i,\alpha} dx_i^\alpha dy_i^\alpha,$$

$$z_i^\alpha = x_i^\alpha + iy_i^\alpha, i = 1, 2, \dots, n; \alpha = 1, 2, \dots, m.$$

Numerical equality of inner products:

$$(P, P') = \langle P, P' \rangle.$$

2.4.4 Relation to Angular Momentum Theory

Spinorial realization of Sects. 2.4.2 and 2.4.3:

$$G = SU(2), \quad H = (1), \quad Z \in M(2, 1),$$

$$z = \text{col}(z_1, z_2),$$

$$X = \text{set of } 2 \times 2 \text{ traceless, Hermitian matrices,}$$

$$(\mathcal{R}_U f)(z) = f(U^T z),$$

$$D_{\sigma_1/2} = (z^T \sigma_1 \partial/\partial z)/2,$$

$$J_\pm = D_{\sigma_1/2} \pm iD_{\sigma_2/2}, \quad J_3 = D_{\sigma_3/2},$$

$$J_+ = z_1 \partial/\partial z_2, \quad J_- = z_2 \partial/\partial z_1,$$

$$J_3 = (1/2)(z_1 \partial/\partial z_1 - z_2 \partial/\partial z_2),$$

$$(P, P') = P^*(\partial/\partial z_1, \partial/\partial z_2)P(z_1, z_2)|_{z_1=z_2=0}.$$

Orthonormal basis:

$$P_{jm}(z_1, z_2) = z_1^{j+m} z_2^{j-m} / [(j+m)!(j-m)!]^{1/2},$$

$$j = 0, 1/2, 1, 3/2, \dots; \quad m = j, j-1, \dots, -j.$$

Standard action:

$$J^2 P_{jm}(z) = j(j+1)P_{jm}(z),$$

$$J_3 P_{jm}(z) = mP_{jm}(z),$$

$$J_\pm P_{jm}(z) = [(j \mp m)(j \pm m + 1)]^{1/2} P_{j, m \pm 1}(z).$$

Group transformation:

$$(\mathcal{R}_U P_{jm})(z) = \sum_{m'} D_{m'm}^j(U) P_{jm'}(z),$$

where the representation functions are given by Eq. (2.17).

The 2-Spinorial Realization of Sects. 2.4.2 and 2.4.3:

$$G = H = SU(2), \quad Z \in M(2, 2),$$

$$Z = [z^1 z^2], \quad z^\alpha = \text{col}(z_1^\alpha z_2^\alpha),$$

$$X = Y = \text{set of } 2 \times 2 \text{ traceless, Hermitian matrices,}$$

$$(\mathcal{R}_U f)(Z) = f(U^T Z), \quad (\mathcal{L}_V f)(Z) = f(ZV),$$

$$U, V \in SU(2),$$

$$D_{\sigma_1/2} = \text{Tr}(Z^T \sigma_1 \partial/\partial Z)/2,$$

$$D^{\sigma_1/2} = \text{Tr}(\sigma_1 Z^T \partial/\partial Z)/2.$$

$$M_\pm = D_{\sigma_1/2} \pm iD_{\sigma_2/2}, \quad M_3 = D_{\sigma_3/2},$$

$$K_\pm = D^{\sigma_1/2} \pm iD^{\sigma_2/2}, \quad K_3 = D^{\sigma_3/2},$$

$$M_+ = \sum_{\alpha=1}^2 z_1^\alpha \partial/\partial z_2^\alpha, \quad M_- = \sum_{\alpha=1}^2 z_2^\alpha \partial/\partial z_1^\alpha,$$

$$M_3 = \frac{1}{2} \sum_{\alpha=1}^2 (z_1^\alpha \partial/\partial z_1^\alpha - z_2^\alpha \partial/\partial z_2^\alpha),$$

$$K_+ = \sum_{i=1}^2 z_i^1 \partial/\partial z_i^2, \quad K_- = \sum_{i=1}^2 z_i^2 \partial/\partial z_i^1,$$

$$K_3 = \frac{1}{2} \sum_{i=1}^2 (z_i^1 \partial/\partial z_i^1 - z_i^2 \partial/\partial z_i^2).$$

Mutual commutativity of Lie algebras:

$$[M_i, K_j] = 0, \quad i, j = 1, 2, 3.$$

Inner product:

$$(P, P') = P^*(Z)P'(\partial/\partial Z)|_{Z=0},$$

Orthogonal basis Eq. (2.24):

$$\begin{aligned} D_{mm'}^j(Z), \quad j = 0, 1/2, 1, 3/2, \dots, \\ m = j, j-1, \dots, -j; \\ m' = j, j-1, \dots, -j; \\ (D_{mm'}^j, D_{\mu\mu'}^{j'}) = (2j)! \delta_{jj'} \delta_{m\mu} \delta_{m'\mu'} . \end{aligned}$$

Equality of Casimir operators:

$$\mathbf{M}^2 = \mathbf{K}^2 = M_1^2 + M_2^2 + M_3^2 = K_1^2 + K_2^2 + K_3^2.$$

Standard actions:

$$\begin{aligned} M^2 D_{mm'}^j(Z) &= \mathbf{K}^2 D_{mm'}^j(Z) = j(j+1) D_{mm'}^j(Z), \\ M_3 D_{mm'}^j(Z) &= m D_{mm'}^j(Z), \\ K_3 D_{mm'}^j(Z) &= m' D_{mm'}^j(Z), \\ M_{\pm} D_{mm'}^j(Z) &= [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}} D_{m\pm 1, m'}^j(Z), \\ K_{\pm} D_{mm'}^j(Z) &= [(j \mp m')(j \pm m' + 1)]^{\frac{1}{2}} \\ &\quad \times D_{m, m'\pm 1}^j(Z). \end{aligned}$$

Special values:

$$\begin{aligned} D^j \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} &= I_{2j+1} = \text{unit matrix}, \\ D_{mm'}^j \begin{pmatrix} z_1 & 0 \\ z_2 & 0 \end{pmatrix} &= \delta_{jm'} P_{jm}(z_1, z_2), \\ D_{mm'}^j \begin{pmatrix} 0 & z_1 \\ 0 & z_2 \end{pmatrix} &= \delta_{jm} P_{jm'}(z_1, z_2), \\ D_{mm'}^j \begin{pmatrix} z_1 & 0 \\ 0 & z_2 \end{pmatrix} &= \delta_{mm'} z_1^{j+m} z_2^{j-m}, \\ D_{jj}^j(Z) &= (z_1^j)^{2j}. \end{aligned}$$

Symmetry relation:

$$[D^j(Z)]^T = D^j(Z^T).$$

Generation from highest weight:

$$\begin{aligned} D_{mm'}^j(Z) &= \left(\frac{(j+m)!}{(2j)!(j-m)!} \times \frac{(j+m')!}{(2j)!(j-m')!} \right)^{\frac{1}{2}} \\ &\quad \times M_-^{j-m} K_-^{j-m'} D_{jj}^j(Z). \end{aligned}$$

Generating functions:

$$\begin{aligned} (\mathbf{x}^T Z \mathbf{y})^{2j} / (2j)! &= \sum_{mm'} P_{jm}(\mathbf{x}) D_{mm'}^j(Z) P_{jm'}(\mathbf{y}), \\ \exp(t \mathbf{x}^T Z \mathbf{y}) &= \sum_j t^{2j} \sum_{mm'} P_{jm}(\mathbf{x}) D_{mm'}^j(Z) P_{jm'}(\mathbf{y}), \\ \mathbf{x} &= \text{col}(x_1 x_2), \quad \mathbf{y} = \text{col}(y_1 y_2), \\ Z &= (z_i^\alpha), \quad i, \alpha = 1, 2; \quad \text{all indeterminates.} \end{aligned}$$

2.5 Differential Operator Realizations of Angular Momentum

Differential operators realizing the standard commutation relations Eqs. (2.7) and (2.8) can be obtained from the 2-spinorial realizations given in Sect. 2.4.4 by specializing the matrix Z to the appropriate unitary unimodular matrix $U \in SU(2)$ and using the chain rule of elementary calculus. Similarly, one obtains the explicit functions $D_{mm'}^j$ simply by substituting for Z the parametrized U in Eq. (2.24). This procedure is used in this section to obtain all the realizations listed. The notations $\mathbf{M} = (M_1, M_2, M_3)$ and $\mathbf{K} = (K_1, K_2, K_3)$ and the associated M_{\pm} and K_{\pm} refer to the differential operators given by the 2-spinorial realization now transformed to the parameters in question.

Euler angles with $Z = U(\alpha\beta\gamma)$ (Sect. 2.3.1):

$$\begin{aligned} M_3 &= i\partial/\partial\alpha, \quad K_3 = i\partial/\partial\gamma, \\ \frac{1}{2}(e^{i\alpha} M_+ - e^{-i\alpha} M_-) &= \frac{1}{2}(e^{-i\gamma} K_- - e^{i\gamma} K_+) = \frac{\partial}{\partial\beta}, \\ \frac{1}{2}(e^{i\alpha} M_+ + e^{-i\alpha} M_-) &= -(\cot\beta) M_3 + (\sin\beta)^{-1} K_3, \\ \frac{1}{2}(e^{-i\gamma} K_- + e^{i\gamma} K_+) &= (\cot\beta) K_3 - (\sin\beta)^{-1} M_3, \\ M_+ &= e^{-i\alpha} [\partial/\partial\beta - (\cot\beta) M_3 + (\sin\beta)^{-1} K_3], \\ M_- &= e^{i\alpha} [-\partial/\partial\beta - (\cot\beta) M_3 + (\sin\beta)^{-1} K_3], \\ K_+ &= e^{-i\gamma} [-\partial/\partial\beta + (\cot\beta) K_3 - (\sin\beta)^{-1} M_3], \\ K_- &= e^{i\gamma} [\partial/\partial\beta + (\cot\beta) K_3 - (\sin\beta)^{-1} M_3]. \end{aligned}$$

Euler angles with $Z = U^*(\alpha\beta\gamma)$ (replace i by $-i$ in the above relations):

$$\begin{aligned} M_3 &= -i\partial/\partial\alpha, \quad K_3 = -i\partial/\partial\gamma, \\ M_{\pm} &= e^{\pm i\alpha} [\pm\partial/\partial\beta - (\cot\beta) M_3 + (\sin\beta)^{-1} K_3], \\ K_{\pm} &= e^{\pm i\gamma} [\mp\partial/\partial\beta + (\cot\beta) K_3 - (\sin\beta)^{-1} M_3]. \end{aligned} \tag{2.34}$$

Since $D^j(U^*) = (D^j(U))^*$, which is denoted $D^{j*}(U)$, these operators have the standard action on the complex conjugate functions $D_{mm'}^{j*}(U)$.

Quaternionic variables. $(x_0, \mathbf{x}) \in \mathbf{R}^4$:

$$(x'_0, \mathbf{x}') (x_0, \mathbf{x}) = (x'_0 x_0 - \mathbf{x}' \cdot \mathbf{x}, x'_0 \mathbf{x} + x_0 \mathbf{x}' + \mathbf{x}' \times \mathbf{x});$$

$$Z = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} = \begin{pmatrix} x_0 - ix_3 & -ix_1 - x_2 \\ -ix_1 + x_2 & x_0 + ix_3 \end{pmatrix};$$

$$\frac{\partial}{\partial Z} = \begin{pmatrix} \partial/\partial z_{11} & \partial/\partial z_{12} \\ \partial/\partial z_{21} & \partial/\partial z_{22} \end{pmatrix}$$

$$= \frac{1}{2} \begin{pmatrix} \partial/\partial x_0 + i\partial/\partial x_3 & i\partial/\partial x_1 - \partial/\partial x_2 \\ i\partial/\partial x_1 + \partial/\partial x_2 & \partial/\partial x_0 - i\partial/\partial x_3 \end{pmatrix};$$

$$M_i = \frac{1}{2} \text{Tr}(Z^T \sigma_i \partial/\partial Z), \quad K_i = \frac{1}{2} \text{Tr}(\sigma_i Z^T \partial/\partial Z).$$

(The form of $\partial/\partial Z$ is determined by the requirement $(\partial/\partial z_{ij})z_{lk} = \delta_{il}\delta_{jk}$; for example, $\frac{1}{2}(\partial/\partial x_0 + i\partial/\partial x_3)(x_0 - ix_3) = 1$).

Define the six orbital angular momentum operators in \mathbf{R}^4 by

$$L_{jk} = -i(x_j \partial/\partial x_k - x_k \partial/\partial x_j), \quad j < k = 0, 1, 2, 3,$$

which may be written as the orbital angular momentum \mathbf{L} in \mathbf{R}^3 together with the three operators \mathbf{A} given by

$$\mathbf{L} = -i\mathbf{x} \times \nabla, \quad L_1 = L_{23},$$

$$L_2 = L_{31}, \quad L_3 = L_{12},$$

$$\mathbf{A} = (A_1, A_2, A_3) = (L_{01}, L_{02}, L_{03}).$$

Then, we have the following relations:

$$K_1 = (L_1 - A_1)/2, \quad K_2 = (L_2 - A_2)/2,$$

$$K_3 = (L_3 - A_3)/2;$$

$$M_1 = -(L_1 + A_1)/2, \quad M_2 = (L_2 + A_2)/2,$$

$$M_3 = -(L_3 + A_3)/2.$$

Commutation rules:

$$[M_j, K_k] = 0, \quad j, k = 1, 2, 3,$$

$$\mathbf{M} \times \mathbf{M} = i\mathbf{M}, \quad \mathbf{K} \times \mathbf{K} = i\mathbf{K},$$

$$\mathbf{L} \times \mathbf{L} = i\mathbf{L}, \quad \mathbf{A} \times \mathbf{A} = i\mathbf{L},$$

$$[L_j, A_k] = ie_{jkl} A_l,$$

where $e_{jkl} = 1$ for j, k, l an even permutation of 1, 2, 3; $e_{jkl} = -1$ for an odd permutation of 1, 2, 3; $e_{jkl} = 0$, otherwise.

The $\mathbf{M} = (M_1, M_2, M_3)$ and $\mathbf{K} = (K_1, K_2, K_3)$ operators have the standard action given in Sect. 2.2 on the functions

$D_{mm'}^j(x_0, \mathbf{x})$ defined by Eq. (2.22) (Replace α_0 by x_0 and α by \mathbf{x} .) Additional relations:

$$\mathbf{K}^2 = \mathbf{M}^2 = -\frac{1}{4} R^2 \nabla_4^2 + K_0^2 + K_0,$$

$$R^2 = x_0^2 + \mathbf{x} \cdot \mathbf{x},$$

$$\nabla_4^2 = \frac{\partial^2}{\partial x_0^2} + \nabla^2 = \sum_{\mu} \frac{\partial^2}{\partial x_{\mu}^2},$$

$$K_0 = \frac{1}{2} \text{Tr} \left(Z^T \frac{\partial}{\partial Z} \right) = \frac{1}{2} \sum_{\mu=0}^3 x_{\mu} \frac{\partial}{\partial x_{\mu}};$$

$$K_0 D_{mm'}^j(x_0, \mathbf{x}) = j D_{mm'}^j(x_0, \mathbf{x}),$$

$$\nabla_4^2 D_{mm'}^j(x_0, \mathbf{x}) = 0;$$

$$(M_1, -M_2, M_3) = \left(\sum_i R_{i1} K_i, \sum_i R_{i2} K_i, \sum_i R_{i3} K_i \right),$$

$$R_{ij} = \frac{(x_0^2 - \mathbf{x} \cdot \mathbf{x}) \delta_{ij} - 2e_{ijk} x_0 x_k + 2x_i x_j}{x_0^2 + \mathbf{x} \cdot \mathbf{x}},$$

$$\text{each } (x_0, \mathbf{x}) \in \mathbf{R}^4.$$

The relation $R_{ij} = R_{ij}(x_0, \mathbf{x})$ is a mapping of all points of four-space \mathbf{R}^4 (except the origin) onto the group of proper, orthogonal matrices; for $x_0^2 + \mathbf{x} \cdot \mathbf{x} = 1$, it is just the Euler-Rodrigues parametrization, Eq. (2.21).

The operators $\mathbf{R} = (-M_1, M_2, -M_3)$ and $\mathbf{K} = (K_1, K_2, K_3)$ have the standard action on $(-1)^{j+m} D_{-m, m'}^j(x_0, \mathbf{x})$, so that the orbital angular momentum in \mathbf{R}^3 is given by the addition $\mathbf{L} = \mathbf{R} + \mathbf{K}$. Thus, one finds:

$$\sum_{mm'} C_{mm'M}^{jjL} (-1)^{j+m} D_{-mm'}^j(x_0, \mathbf{x})$$

$$= A_{2j, L} R^{2j-L} \mathcal{Y}_{LM}(\mathbf{x}) C_{2j-L}^{(L+1)}(x_0/R),$$

$$A_{2j, L} = (2i)^L (-1)^{2j} L! \left(\frac{4\pi(2j-L)!}{(2j+L+1)!} \right)^{\frac{1}{2}}.$$

2.6 The Symmetric Rotor and Representation Functions

The rigid rotor is an important physical object, and its quantum description enters into many physical theories. This description is an application of angular momentum theory with subtleties that need to be made explicit. It is customary to describe the classical rotor in terms of a right-handed triad of unit vectors $(\hat{f}_1, \hat{f}_2, \hat{f}_3)$ fixed in the rotor and constituting a principal axes system located at the center of mass. The instantaneous orientation of this body-fixed frame relative to a right-handed triad of unit vector $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$ specifying an inertial frame, also located at the center of mass, is then given, say, in terms of Euler angles (for this purpose, one

could use any parametrization of a proper, orthogonal matrix). For Euler angles, the relationship is

$$\hat{\mathbf{f}}_j = \sum_i R_{ij}(\alpha\beta\gamma)\hat{\mathbf{e}}_i . \quad (2.35)$$

The Hamiltonian for the rigid rotor is then of the form

$$H = AP_1^2 + BP_2^2 + CP_3^2 ,$$

\mathbf{J} where $A, B,$ and C are physical constants related to the reciprocals of the principal moments of inertia, and the angular momenta \mathcal{P}_j ($j = 1, 2, 3$) are the components of the total angular momentum \mathbf{J} referred to the body-fixed frame:

$$\mathcal{P}_j = \hat{\mathbf{f}}_j \cdot \mathbf{J} = \sum_i R_{ij}(\alpha\beta\gamma)J_i ,$$

$$\mathbf{J} = \hat{\mathbf{e}}_1 J_1 + \hat{\mathbf{e}}_2 J_2 + \hat{\mathbf{e}}_3 J_3 .$$

For the symmetric rotor (taking $A = B$), the Hamiltonian can be written in the form

$$H = a\mathcal{P}^2 + b\mathcal{P}_3^2 .$$

It is in the interpretation of this Hamiltonian for quantum mechanics that the subtleties already enter, since the nature of angular momentum components referred to a moving reference system must be treated correctly. Relation Eq. (2.35) shows that the body-fixed axes cannot commute with the components of the total angular momentum \mathbf{J} referred to the frame ($\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3$). A position vector \mathbf{x} and the orbital angular momentum \mathbf{L} , with components both referred to an inertial frame, satisfy the commutation relations $[L_j, x_k] = ie_{jkl}x_l$, and for a rigid body thought of as a collection of point particles rotating together, the same conditions are to be enforced. Relative to the body-fixed frame, the vector \mathbf{x} is expressed as

$$\sum_k x_k \hat{\mathbf{e}}_k = \sum_h a_h \hat{\mathbf{f}}_h , \quad \text{each } a_h = \text{constant} ,$$

$$x_k = \sum_h a_h R_{kh}(\alpha\beta\gamma) .$$

The direction cosines $R_{kh} = R_{kh}(\alpha\beta\gamma) = \hat{\mathbf{e}}_k \cdot \hat{\mathbf{f}}_h$ and the physical total angular momentum components referred to an inertial frame must satisfy

$$[J_j, R_{kh}] = ie_{jkl}R_{lh} , \quad \text{each } h = 1, 2, 3 ,$$

in complete analogy to $[L_j, x_k] = ie_{jkl}x_l$.

The description of the angular momentum associated with a symmetric rigid rotor and the angular momentum states is summarized as follows [Eq. (2.35)]:

Physical total angular momentum \mathbf{J} with components referred to ($\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3$):

$$J_1 = i \cos \alpha \cot \beta \frac{\partial}{\partial \alpha} + i \sin \alpha \frac{\partial}{\partial \beta} - i \frac{\cos \alpha}{\sin \beta} \frac{\partial}{\partial \gamma} ,$$

$$J_2 = i \sin \alpha \cot \beta \frac{\partial}{\partial \alpha} - i \cos \alpha \frac{\partial}{\partial \beta} - i \frac{\sin \alpha}{\sin \beta} \frac{\partial}{\partial \gamma} ,$$

$$J_3 = -i \frac{\partial}{\partial \alpha} .$$

Physical angular momentum \mathbf{J} with components referred to ($\hat{\mathbf{f}}_1, \hat{\mathbf{f}}_2, \hat{\mathbf{f}}_3$):

$$P_1 = -i \cos \gamma \cot \beta \frac{\partial}{\partial \gamma} - i \sin \gamma \frac{\partial}{\partial \beta} + i \frac{\cos \gamma}{\sin \beta} \frac{\partial}{\partial \alpha} ,$$

$$P_2 = i \sin \gamma \cot \beta \frac{\partial}{\partial \gamma} - i \cos \gamma \frac{\partial}{\partial \beta} - i \frac{\sin \gamma}{\sin \beta} \frac{\partial}{\partial \alpha} ,$$

$$P_3 = -i \frac{\partial}{\partial \gamma} .$$

Standard commutation of the J_i :

$$[J_i, J_j] = iJ_k , \quad i, j, k \text{ cyclic} .$$

J_i can stand on either side:

$$P_j = \sum_i R_{ij}(\alpha\beta\gamma)J_i , \quad J_i = \sum_j J_i R_{ij}(\alpha\beta\gamma) .$$

The famous Van Vleck factor of $-i$ in the commutation of the \mathcal{P}_i :

$$[P_i, P_j] = -iP_k , \quad i, j, k \text{ cyclic} .$$

Mutual commutativity of the J_j and \mathcal{P}_i :

$$[P_i, J_j] = 0 , \quad i, j = 1, 2, 3 .$$

Same invariant (squared) total angular momentum:

$$\mathcal{P}_1^2 + \mathcal{P}_2^2 + \mathcal{P}_3^2 = J_1^2 + J_2^2 + J_3^2 = \mathcal{J}^2$$

$$= -\csc^2 \beta \left(\frac{\partial^2}{\partial \alpha^2} + \frac{\partial^2}{\partial \gamma^2} - 2 \cos \beta \frac{\partial^2}{\partial \alpha \partial \gamma} \right)$$

$$- \frac{\partial^2}{\partial \beta^2} - \cot \beta \frac{\partial}{\partial \beta} .$$

Standard actions:

$$\mathcal{J}^2 D_{mm'}^{j*}(\alpha\beta\gamma) = j(j+1)D_{mm'}^{j*}(\alpha\beta\gamma) ,$$

$$J_3 D_{mm'}^{j*}(\alpha\beta\gamma) = m D_{mm'}^{j*}(\alpha\beta\gamma) ,$$

$$P_3 D_{mm'}^{j*}(\alpha\beta\gamma) = m' D_{mm'}^{j*}(\alpha\beta\gamma) ;$$

$$J_{\pm} D_{mm'}^{j*}(\alpha\beta\gamma) = [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}}$$

$$\times D_{m \pm 1, m'}^{j*}(\alpha\beta\gamma) ,$$

$$(P_1 - iP_2) D_{mm'}^{j*}(\alpha\beta\gamma) = [(j - m')(j + m' + 1)]^{\frac{1}{2}}$$

$$\times D_{m, m'+1}^{j*}(\alpha\beta\gamma) ,$$

$$(P_1 + iP_2) D_{mm'}^{j*}(\alpha\beta\gamma) = [(j + m')(j - m' + 1)]^{\frac{1}{2}}$$

$$\times D_{m, m'-1}^{j*}(\alpha\beta\gamma) .$$

Normalized wave functions.

Integral or half-integral j ($SU(2)$ solid body):

$$\left\langle \alpha\beta\gamma \left| \begin{matrix} j \\ m m' \end{matrix} \right. \right\rangle = \sqrt{\frac{2j+1}{2\pi^2}} D_{mm'}^{j*}(\alpha\beta\gamma), \quad (2.36)$$

with inner product

$$\langle F|F' \rangle = \int d\Omega \langle \alpha\beta\gamma|F \rangle^* \langle \alpha\beta\gamma|F' \rangle,$$

where $d\Omega$ is defined by Eq. (2.25), and the integration extends over all α, β, γ given by Eq. (2.26).

Integral j (collection of rigid point particles):

$$\Psi_{mm'}^j(\alpha\beta\gamma) = \sqrt{\frac{2j+1}{8\pi^2}} D_{mm'}^{j*}(\alpha\beta\gamma), \quad (2.37)$$

with inner product

$$\langle \Psi, \Psi' \rangle = \int_0^{2\pi} d\alpha \int_0^\pi d\beta \sin \beta \int_0^{2\pi} d\gamma F^*(\alpha\beta\gamma) F'(\alpha\beta\gamma).$$

The concept of a solid (impenetrable) body is conceptually distinct from that of a collection of point particles moving collectively together in translation and rotation.

2.7 Wigner–Clebsch–Gordan and 3- j Coefficients

Wigner–Clebsch–Gordan (WCG) coefficients (also called vector coupling coefficients) enter the theory of angular momentum in several ways: (1) as the coefficients in the real, orthogonal matrix that reduces the Kronecker product of two irreducible representations of the quantal rotation group into a direct sum of irreducibles; (2) as the coupling coefficients for constructing basis states of sharp angular momentum in the tensor product space from basis states of sharp angular momentum spanning the two constituent spaces; (3) as purely combinatoric objects in the expansion of a power of a 3×3 determinant; and (4) as coupling coefficients in the algebra of tensor operators. These perspectives are intimately connected but have a different focus. The first considers the group itself to be primary and views the Lie algebra as the secondary or derived concept; the second considers the Lie algebra and the construction of the vector spaces that carry irreducible representations as primary and views the representations carried by these spaces as derived quantities; the third is a mathematical construction, at first seeming almost empty of angular momentum concepts, yet the most revealing in showing the symmetry and other properties of the WCG coefficients; and the fourth is the natural extension

of (2) to operators, recognizing that the set of mappings of a vector space into itself is also a vector space. The subject of tensor operator algebra is considered in the next section because of its special importance for physical applications. This section summarizes formulas relating to the first three viewpoints, also giving the explicit mathematical expression of the coefficients in their several forms.

Either viewpoint, (1) or (2), may be taken as an interpretation of the Clebsch–Gordan series, which abstractly expresses the reduction of a Kronecker product of matrices (denoted \times) into a direct sum (denoted \oplus) of matrices:

$$\begin{aligned} [j_1] \times [j_2] &= \sum_{j=|j_1-j_2|}^{j_1+j_2} \oplus [j] \\ &= [|j_1 - j_2|] \oplus [|j_1 - j_2| + 1] \oplus \cdots \oplus [j_1 + j_2]. \end{aligned} \quad (2.38)$$

Given two angular momenta $j_1 \in \{0, \frac{1}{2}, 1, \dots\}$ and $j_2 \in \{0, \frac{1}{2}, 1, \dots\}$, the Clebsch–Gordan (CG) series also expresses the rule of addition of two angular momenta:

$$j = j_1 + j_2, j_1 + j_2 - 1, \dots, |j_1 - j_2|.$$

The integers $\epsilon_{j_1 j_2 j}$ defined by

$$\epsilon_{j_1 j_2 j} = \begin{cases} 1, & \text{for } j_1, j_2, j \text{ satisfying} \\ & \text{the CG-series rule} \\ 0, & \text{otherwise} \end{cases} \quad (2.39)$$

are useful in many relations between angular momentum quantities. The notation $(j_1 j_2 j)$ is used to symbolize the CG-series relation between three angular momentum quantum numbers.

The representation function and Lie algebra interpretations of the CG-series Eq. (2.38) are, respectively:

$$\begin{aligned} C(D^{j_1} \times D^{j_2}) C^T &= \sum_j \oplus \epsilon_{j_1 j_2 j} D^j, \\ C(J_i^{(j_1)} \times J_i^{(j_2)}) C^T &= \sum_j \oplus \epsilon_{j_1 j_2 j} J_i^{(j)}, \\ & i = 1, 2, 3. \end{aligned}$$

The notation $J_i^{(j)}$ denotes the $(2j+1) \times (2j+1)$ matrix with elements

$$\begin{aligned} J_{m',m}^{(j)} &= \langle j m' | J_i | j m \rangle, \\ m', m &= j, j-1, \dots, -j. \end{aligned}$$

The elements of the real, orthogonal matrix C of dimension $(2j_1+1)(2j_2+1)$ that effects these reductions are the WCG coefficients:

$$(C)_{j m_1 m_2} = C_{m_1 m_2}^{j_1 j_2 j}.$$

The pairs, (jm) and (m_1m_2) , index rows and columns, respectively, of the matrix C :

$$\begin{aligned} (jm) : j &= j_1 + j_2, \dots, |j_1 - j_2|, \\ m &= j, \dots, -j; \\ (m_1m_2) : m_1 &= j_1, \dots, -j_1; \\ m_2 &= j_2, \dots, -j_2. \end{aligned}$$

Sum rule on projection quantum numbers:

$$C_{m_1m_2m}^{j_1j_2j} = 0, \quad \text{for } m_1 + m_2 \neq m. \quad (2.40)$$

Clebsch–Gordan series rule on angular momentum quantum numbers:

$$C_{m_1m_2m}^{j_1j_2j} = 0, \quad \text{for } \epsilon_{j_1j_2j} = 0. \quad (2.41)$$

In presenting formulas that express relations relating to the conceptual framework described above, it is best to use a notation for a WCG coefficient giving it as an element of an orthogonal matrix. For the expression of symmetry relations, the $3-j$ coefficient, or $3-j$ symbol notation, is the most convenient. The following notations are used here:

WCG coefficient notation:

$$\begin{aligned} |(j_1j_2)jm\rangle &= \sum_{m_1m_2} C_{m_1m_2m}^{j_1j_2j} |j_1m_1\rangle \otimes |j_2m_2\rangle, \\ |j_1m_1; j_2m_2\rangle &= |j_1m_1\rangle \otimes |j_2m_2\rangle, \\ C_{m_1m_2m}^{j_1j_2j} &= \langle j_1m_1; j_2m_2 | (j_1j_2)jm \rangle, \\ \langle (j_1j_2)j'm' | (j_1j_2)jm \rangle &= \delta_{j'j} \delta_{m'm}. \end{aligned}$$

The $3-j$ coefficient notation:

$$\begin{pmatrix} j_1 & j_2 & j \\ m_1 & m_2 & -m \end{pmatrix} = (-1)^{j_1-j_2+m} (2j+1)^{-1/2} C_{m_1m_2m}^{j_1j_2j}. \quad (2.42)$$

Orthogonality of WCG coefficients:

Orthogonality of rows:

$$\sum_{m_1m_2} C_{m_1m_2m}^{j_1j_2j} C_{m_1m_2m'}^{j_1j_2j'} = \delta_{jj'} \delta_{mm'}. \quad (2.43)$$

Orthogonality of columns (three forms):

$$\begin{aligned} \sum_{jm} C_{m_1m_2m}^{j_1j_2j} C_{m'_1m'_2m}^{j_1j_2j} &= \delta_{m_1m'_1} \delta_{m_2m'_2}, \\ \sum_j C_{m_1m-m_1,m}^{j_1j_2j} C_{m'_1,m-m'_1,m}^{j_1j_2j} &= \delta_{m_1m'_1}, \\ \sum_j C_{m-m_2,m_2,m}^{j_1j_2j} C_{m-m'_2,m'_2,m}^{j_1j_2j} &= \delta_{m_2m'_2}. \end{aligned} \quad (2.44)$$

Orthogonality of $3-j$ coefficients (symbols):

$$\begin{aligned} \sum_{m_1m_2} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & j_2 & j'_3 \\ m_1 & m_2 & m'_3 \end{pmatrix} \\ = \delta_{j_3j'_3} \delta_{m_3m'_3} / (2j_3 + 1), \end{aligned} \quad (2.45)$$

$$\begin{aligned} \sum_{j_3m_3} (2j_3 + 1) \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & j_2 & j_3 \\ m'_1 & m'_2 & m_3 \end{pmatrix} \\ = \delta_{m_1m'_1} \delta_{m_2m'_2}. \end{aligned} \quad (2.46)$$

The integers $\epsilon_{j_1j_2j}$ ($j_3 = j$) are sometimes included in the orthogonality relations Eqs. (2.43) and (2.45) to incorporate the extended definition Eq. (2.41) of the WCG coefficients.

2.7.1 Kronecker Product Reduction

Product form:

$$\begin{aligned} D_{m'_1m_1}^{j_1}(U) D_{m'_2m_2}^{j_2}(U) \\ = \sum_j C_{m'_1m'_2,m'_1+m'_2}^{j_1j_2j} C_{m_1m_2,m_1+m_2}^{j_1j_2j} D_{m'_1+m'_2,m_1+m_2}^j(U). \end{aligned}$$

Singly coupled form:

$$\begin{aligned} \sum_{m_1+m_2=m} C_{m_1m_2m}^{j_1j_2j} D_{m'_1m_1}^{j_1}(U) D_{m'_2m_2}^{j_2}(U) \\ = C_{m'_1,m'_2,m'_1+m'_2}^{j_1j_2j} D_{m'_1+m'_2,m}^j(U). \end{aligned}$$

Doubly coupled (reduction) form:

$$\begin{aligned} \sum_{\substack{m'_1+m'_2=m' \\ m_1+m_2=m}} C_{m'_1m'_2m'}^{j_1j_2j} C_{m_1m_2m}^{j_1j_2j} D_{m'_1m_1}^{j_1}(U) D_{m'_2m_2}^{j_2}(U) \\ = \delta_{j'j} D_{m'm}^j(U). \end{aligned}$$

Integral relation:

$$\begin{aligned} \int d\Omega D_{m'_1m_1}^{j_1}(U) D_{m'_2m_2}^{j_2}(U) D_{m'm_1}^{j_3}(U) \\ = \frac{2\pi^2}{2j+1} C_{m'_1m'_2m'}^{j_1j_2j} C_{m_1m_2m}^{j_1j_2j}, \end{aligned}$$

in any parametrization of $U \in SU(2)$ that covers \mathcal{S}^3 exactly once.

Gaunt's integral:

$$\begin{aligned} \int_0^{2\pi} d\alpha \int_0^\pi \sin \beta d\beta Y_{l_1m_1}^*(\beta\alpha) Y_{l_1m_1}(\beta\alpha) Y_{l_2m_2}(\beta\alpha) \\ = \left(\frac{(2l_1+1)(2l_2+1)}{4\pi(2l+1)} \right)^{1/2} C_{000}^{l_1l_2l} C_{m_1m_2m'}. \end{aligned}$$

Integral over three Legendre functions:

$$\begin{aligned} & \int_0^\pi \sin \beta d\beta P_l(\cos \beta) P_{l_1}(\cos \beta) P_{l_2}(\cos \beta) \\ &= \frac{2 \left(C_{000}^{l_1 l_2 l} \right)^2}{2l+1} \\ & C_{000}^{l_1 l_2 l} \\ &= \left(\frac{(2l+1)(l_1+l_2-l)!(l_1-l_2+l)!(-l_1+l_2+l)!}{(l_1+l_2+l+1)!} \right)^{\frac{1}{2}} \\ & \times \frac{(-1)^{L-1} L!}{(L-l_1)!(L-l_2)!(L-l)!}, \\ & L = \frac{1}{2}(l_1+l_2+l), \\ & \text{for } l_1+l_2+l \text{ even} \\ & C_{000}^{l_1 l_2 l} = 0, \quad \text{for } l_1+l_2+l \text{ odd}. \end{aligned}$$

2.7.2 Tensor Product Space Construction

Orthonormal basis of H_{j_1} :

$$\{|j_1 m_1\rangle \mid m_1 = j_1, j_1 - 1, \dots, -j_1\}.$$

Orthonormal basis of H_{j_2} :

$$\{|j_2 m_2\rangle \mid m_2 = j_2, j_2 - 1, \dots, -j_2\}.$$

Uncoupled basis of $H_{j_1} \otimes H_{j_2}$:

$$\{|j_1 m_1\rangle \otimes |j_2 m_2\rangle \mid m_1 = j_1, j_1 - 1, \dots, -j_1; \\ m_2 = j_2, j_2 - 1, \dots, -j_2\}.$$

Coupled basis of $H_{j_1} \otimes H_{j_2}$:

$$\begin{aligned} & \{|(j_1 j_2) j m\rangle \mid j = j_1 + j_2, j_1 + j_2 - 1, \dots, |j_1 - j_2|; \\ & \quad m = j, j - 1, \dots, -j\}, \\ & |(j_1 j_2) j m\rangle = \sum_{m_1 m_2} C_{m_1 m_2}^{j_1 j_2 j} |j_1 m_1\rangle \otimes |j_2 m_2\rangle. \end{aligned}$$

Unitary transformations of spaces:

$$\begin{aligned} T_U |j_1 m_1\rangle &= \sum_{m'_1} D_{m'_1 m_1}^{j_1}(U) |j_1 m'_1\rangle, \\ m_1 &= j_1, j_1 - 1, \dots, -j_1, \quad \text{each } U \in SU(2); \\ T_V |j_2 m_2\rangle &= \sum_{m'_2} D_{m'_2 m_2}^{j_2}(V) |j_2 m'_2\rangle, \\ m_2 &= j_2, j_2 - 1, \dots, -j_2, \quad \text{each } V \in SU(2); \end{aligned}$$

$$\begin{aligned} T_{(U,V)} |j_1 m_1\rangle \otimes |j_2 m_2\rangle &= T_U |j_1 m_1\rangle \otimes T_V |j_2 m_2\rangle \\ &= \sum_{m'_1 m'_2} D_{m'_1 m_1}^{j_1}(U) D_{m'_2 m_2}^{j_2}(V) |j_1 m'_1\rangle \otimes |j_2 m'_2\rangle, \\ & \text{each } U \in SU(2), \quad \text{each } V \in SU(2); \\ T_{(U,U)} |(j_1 j_2) j m\rangle &= \sum_{m'} D_{m' m}^j(U) |(j_1 j_2) j m'\rangle, \\ m &= j, j - 1, \dots, -j; \text{ each } U \in SU(2). \end{aligned}$$

Representation of direct product group $SU(2) \times SU(2)$:

$$T_{(U,V)} T_{(U',V')} = T_{(UU',VV')}.$$

Representation of $SU(2)$ as diagonal subgroup of $SU(2) \times SU(2)$:

$$\begin{aligned} T_{(U,U)} T_{(U',U')} &= T_{(UU',UU')}, \\ T_U &= T_{(U,U)}. \end{aligned}$$

2.7.3 Explicit Forms of WCG Coefficients

Wigner's form:

$$\begin{aligned} & C_{m_1 m_2 m}^{j_1 j_2 j} \\ &= \delta(m_1 + m_2, m) (2j + 1)^{\frac{1}{2}} \\ & \times \left(\frac{(j + j_1 - j_2)!(j - j_1 + j_2)!(j_1 + j_2 - j)!}{(j + j_1 + j_2 + 1)!} \right)^{\frac{1}{2}} \\ & \times \left(\frac{(j + m)!(j - m)!}{(j_1 + m_1)!(j_1 - m_1)!(j_2 + m_2)!(j_2 - m_2)!} \right)^{\frac{1}{2}} \\ & \times \sum_s \frac{(-1)^{j_2 + m_2 + s} (j_2 + j + m_1 - s)!(j_1 - m_1 + s)!}{s!(j - j_1 + j_2 - s)!(j + m - s)!(j_1 - j_2 - m + s)!}. \end{aligned}$$

Racah's form:

$$\begin{aligned} & C_{m_1 m_2 m}^{j_1 j_2 j} \\ &= \delta(m_1 + m_2, m) \\ & \times \left(\frac{(2j + 1)(j_1 + j_2 - j)!}{(j_1 + j_2 + j + 1)!(j + j_1 - j_2)!(j + j_2 - j_1)!} \right)^{\frac{1}{2}} \\ & \times \left(\frac{(j_1 - m_1)!(j_2 - m_2)!(j - m)!(j + m)!}{(j_1 + m_1)!(j_2 + m_2)!} \right)^{\frac{1}{2}} \\ & \times \sum_t \frac{(-1)^{j_1 - m_1 + t} (j_1 + m_1 + t)!(j + j_2 - m_1 - t)!}{t!(j - m - t)!(j_1 - m_1 - t)!(j_2 - j + m_1 + t)!}. \end{aligned}$$

Van der Waerden's form:

$$\begin{aligned} & C_{m_1 m_2 m}^{j_1 j_2 j} \\ &= \delta(m_1 + m_2, m) \\ & \times \left(\frac{(2j + 1)(j_1 + j_2 - j)!(j + j_1 - j_2)!(j + j_2 - j_1)!}{(j_1 + j_2 + j + 1)!} \right)^{\frac{1}{2}} \end{aligned}$$

$$\begin{aligned}
& \times [(j_1 + m_1)!(j_1 - m_1)!(j_2 + m_2)!(j_2 - m_2)!]^{\frac{1}{2}} \\
& \times [(j + m)!(j - m)!]^{\frac{1}{2}} \\
& \times \sum_k (-1)^k [k!(j_1 + j_2 - j - k)!(j_1 - m_1 - k)! \\
& \times (j_2 + m_2 - k)!(j - j_2 + m_1 + k)! \\
& \times (j - j_1 - m_2 + k)!]^{-1}.
\end{aligned}$$

Regge's formula and its combinatoric structure:

$$(\det A)^k = \sum_{\boxed{\alpha}} A(\alpha) \prod_{i,j=1}^3 (a_{ij})^{\alpha_{ij}}, \quad A = (a_{ij}), \quad (2.47)$$

where the summation is over all nonnegative integers α_{ij} that satisfy the row and column sum constraints Eq. (2.17) given by

$$\alpha = \begin{array}{|ccc|} \hline \alpha_{11} & \alpha_{12} & \alpha_{13} \\ \alpha_{21} & \alpha_{22} & \alpha_{23} \\ \alpha_{31} & \alpha_{32} & \alpha_{33} \\ \hline \end{array} \begin{array}{l} k \\ k \\ k \\ k \\ k \\ k \end{array} \quad (2.48)$$

The coefficients $A(\alpha)$ are constrained sums over multinomial coefficients:

$$A(\alpha) = \sum (-1)^{\phi(K)} \binom{k}{k_{123}, k_{132}, k_{231}, k_{213}, k_{312}, k_{321}},$$

where the summation is carried out over all nonnegative integers $k_{i_1 i_2 i_3}$ such that

$$\begin{aligned}
\alpha_{11} &= k_{123} + k_{132}, & \alpha_{12} &= k_{231} + k_{213}, \\
\alpha_{13} &= k_{312} + k_{321}, \\
\alpha_{21} &= k_{312} + k_{213}, & \alpha_{22} &= k_{123} + k_{321}, \\
\alpha_{23} &= k_{231} + k_{132}, \\
\alpha_{31} &= k_{231} + k_{321}, & \alpha_{32} &= k_{312} + k_{132}, \\
\alpha_{33} &= k_{123} + k_{213}, \\
\phi(K) &= \sum_{\pi \in A_3} k_{\pi} = k_{132} + k_{213} + k_{321}.
\end{aligned}$$

The general multinomial coefficient is the integer defined by

$$\binom{k}{k_1, k_2, \dots, k_s} = k! / k_1! k_2! \dots k_s!, \quad k = \sum_i k_i.$$

Relation Eq. (2.47) generalizes in the obvious way to an $n \times n$ determinant, using the symmetric group S_n and its S_{n-1} subgroups $S_{n-1}^{(j)}$, where j denotes that this is the permutation group on the integers $1, 2, \dots, n$ with j deleted [2].

Regge's formula for the $3-j$ coefficient is:

$$\begin{aligned}
& \binom{j_1 \quad j_2 \quad j_3}{m_1 \quad m_2 \quad m_3} \\
& = \delta(m_1 + m_2 + m_3, 0) \left[\prod_{i,j=1}^3 (\alpha_{ij})! \right]^{\frac{1}{2}} \frac{A(\alpha)}{k! [(k+1)!]^{\frac{1}{2}}}, \\
& k = j_1 + j_2 + j_3, \quad (2.49)
\end{aligned}$$

$$\begin{aligned}
\alpha_{11} &= j_1 + m_1, & \alpha_{12} &= j_2 + m_2, & \alpha_{13} &= j_3 + m_3, \\
\alpha_{21} &= j_1 - m_1, & \alpha_{22} &= j_2 - m_2, & \alpha_{23} &= j_3 - m_3, \\
\alpha_{31} &= j_2 + j_3 - j_1, & \alpha_{32} &= j_3 + j_1 - j_2, \\
\alpha_{33} &= j_1 + j_2 - j_3.
\end{aligned}$$

Equation (2.49) shows that WCG coefficients and $3-j$ coefficients are sums over integers, except for a multiplicative normalization factor.

Schwinger's generating function:

$$\exp(t \det A) = \sum_k \frac{t^k}{k!} \sum_{\boxed{\alpha}} A(\alpha) \prod_{i,j} (a_{ij})^{\alpha_{ij}}.$$

The general definition of the ${}_p F_q$ hypergeometric function depending on p numerator parameters, q denominator parameters, and a single variable z is:

$$\begin{aligned}
{}_p F_q \left(\begin{matrix} a_1, \dots, a_p \\ b_1, \dots, b_q \end{matrix}; z \right) &= \sum_{n=0}^{\infty} \frac{(a_1)_n \dots (a_p)_n}{(b_1)_n \dots (b_q)_n} \frac{z^n}{n!}, \\
(a)_n &= a(a+1) \dots (a+n-1), \quad (a)_0 = 1.
\end{aligned}$$

Such a series is terminating if at least one of the numerator parameters is a negative integer (and all other factors are well defined). Both WCG coefficients and Racah $6-j$ coefficients relate to special series of this type, evaluated at $z = 1$. For WCG coefficients, we have for $\alpha + \beta = \gamma$:

$$\begin{aligned}
C_{\alpha\beta\gamma}^{abc} &= [(2c+1)(a+\alpha)!(a-\alpha)!(b+\beta)!(b-\beta)!(c+\gamma)! \\
& \times (c-\gamma)!]^{\frac{1}{2}} (-1)^{a+b+\gamma+\delta_1} \Delta(abc) \\
& \times \frac{{}_3 F_2 \left(\begin{matrix} \epsilon_1 - \delta_1, \epsilon_2 - \delta_1, \epsilon_3 - \delta_1 \\ \delta_2 - \delta_1 + 1, \delta_3 - \delta_1 + 1 \end{matrix}; 1 \right)}{(\delta_2 - \delta_1)!(\delta_3 - \delta_1)!(\delta_1 - \epsilon_1)!(\delta_1 - \epsilon_2)!(\delta_1 - \epsilon_3)!},
\end{aligned}$$

$\delta_1 = \min(a + \alpha + b + \beta, b - \beta + c + \gamma, a + \alpha + c + \gamma)$, $(\delta_1, \delta_2, \delta_3) =$ any permutation of $(a + \alpha + b + \beta, b - \beta + c + \gamma, a + \alpha + c + \gamma)$, after δ_1 is fixed, $(\epsilon_1, \epsilon_2, \epsilon_3) =$ any permutation of $(a + \alpha, b + \alpha + \gamma, c + \gamma)$. A somewhat better form can be found in [2].

The quantity

$$\Delta(abc) = \left(\frac{(a+b-c)!(a-b+c)!(-a+b+c)!}{(a+b+c+1)!} \right)^{\frac{1}{2}}$$

is called a triangle coefficient.

All 72 Regge symmetries are consequences of known properties of the ${}_3F_2$ hypergeometric series.

2.7.4 Symmetries of WCG Coefficients in 3- j Symbol Form

There are 72 known symmetries (up to sign changes) of the 3- j coefficient. There are at least four ways of verifying these symmetries: (1) directly from the van der Waerden form of the coefficients; (2) directly from Regge's generating function; (3) from the known symmetries of the ${}_3F_2$ hypergeometric series; and (4) directly from the symmetries of the representation functions $D_{mm'}^j(U)$. The set of 72 symmetries is succinctly expressed in terms of the coefficient $A(\alpha)$ defined in Sect. 2.8.3 with α_{ij} entries given by Eqs. (2.48) and (2.49) in which $m_1 + m_2 + m_3 = 0$:

$$A \begin{pmatrix} j_1 + m_1 & j_2 + m_2 & j_3 + m_3 \\ j_1 - m_1 & j_2 - m_2 & j_3 - m_3 \\ j_2 + j_3 - j_1 & j_3 + j_1 - j_2 & j_1 + j_2 - j_3 \end{pmatrix}.$$

This coefficient has determinantal symmetry; that is, it is invariant under even permutations of its rows or columns and under transposition, and is multiplied by the factor $(-1)^{j_1+j_2+j_3}$ under odd permutations of its rows or columns. These 72 determinantal operations may be generated from the three operations C_{12}, C_{13}, T consisting of interchange of columns 1 and 2, interchange of columns 1 and 3, and transposition, since the first two operations generate the symmetric group S_3 of permutations of columns, and the symmetric group S'_3 of permutations of rows is then given by TS_3T . The transposition T itself generates a group $\{e, T\}$ isomorphic to the symmetric group S_2 . Thus, the 72 element determinantal group is the direct product group $S_3 \times S'_3 \times \{e, T\}$. The three relations between 3- j coefficients corresponding to the generators C_{12}, C_{13}, T are

$$\begin{aligned} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} &= (-1)^{j_1+j_2+j_3} \begin{pmatrix} j_2 & j_1 & j_3 \\ m_2 & m_1 & m_3 \end{pmatrix}, \\ \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} &= (-1)^{j_1+j_2+j_3} \begin{pmatrix} j_3 & j_2 & j_1 \\ m_3 & m_2 & m_1 \end{pmatrix}, \\ \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} &= \begin{pmatrix} \frac{j_1+j_2+m_1+m_2}{2} & \frac{j_1+j_2-m_1-m_2}{2} & j_3 \\ \frac{j_1-j_2+m_1-m_2}{2} & \frac{j_1-j_2-m_1+m_2}{2} & j_2-j_1 \end{pmatrix}. \end{aligned}$$

All 72 relations among 3- j coefficients can be obtained from these 3. The 12 classical symmetries of the 3- j symbol

$$\begin{pmatrix} a & b & c \\ \alpha & \beta & \gamma \end{pmatrix}$$

are expressed by:

1. Even permutations of the columns leave the coefficient invariant.
2. Odd permutations of the columns change the sign by the factor $(-1)^{a+b+c}$.
3. Simultaneous sign reversal of the projection quantum numbers changes the sign by $(-1)^{a+b+c}$.

The 72 corresponding symmetries of the WCG coefficients (up to sign changes and dimensional factors) are best obtained from those of the 3- j coefficients by using Eq. (2.42).

2.7.5 Recurrence Relations

Three-term:

$$\begin{aligned} & [(J+1)(J-2j_1)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \\ &= [(j_2+m_2)(j_3-m_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3+\frac{1}{2} \end{pmatrix} \\ &\quad - [(j_2-m_2)(j_3+m_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ m_1 & m_2+\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix}; \\ & [(J-2j_2)(J+1-2j_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \\ &\quad + [(j_2+m_2+1)(j_3+m_3)]^{\frac{1}{2}} \\ &\quad \times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3+\frac{1}{2} \end{pmatrix} \\ &\quad + [(j_2-m_2+1)(j_3-m_3)]^{\frac{1}{2}} \\ &\quad \times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ m_1 & m_2+\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix} = 0; \\ & (j_2+m_2)^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m & m_3 \end{pmatrix} \\ &= [(j_3-j_1+j_2)(J+1)(j_3-m_3)]^{\frac{1}{2}} \\ &\quad \times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3-\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3-\frac{1}{2} \end{pmatrix} \\ &\quad - [(j_1-j_3+j_2)(J-2j_2+1)(j_3+m_3+1)]^{\frac{1}{2}} \\ &\quad \times \begin{pmatrix} j_1 & j_2-\frac{1}{2} & j_3+\frac{1}{2} \\ m_1 & m_2-\frac{1}{2} & m_3+\frac{1}{2} \end{pmatrix}; \end{aligned}$$

$$\begin{aligned} & \begin{pmatrix} j_1 & j_2 & j_3 \\ j_2 - m_3 & -j_2 & m_3 \end{pmatrix} \\ &= - \left(\frac{2j_2(j_3 + m_3)}{(j_3 - j_1 + j_2)(J + 1)} \right)^{\frac{1}{2}} \\ & \quad \times \begin{pmatrix} j_1 & j_2 - \frac{1}{2} & j_3 - \frac{1}{2} \\ j_2 - m_3 & -j_2 + \frac{1}{2} & m_3 - \frac{1}{2} \end{pmatrix}, \\ & j_3 = j_1 + j_2, j_1 + j_2 - 1, \dots, j_1 - j_2 + 1 \quad \text{for } j_1 \geq j_2; \end{aligned}$$

$$\begin{aligned} & \begin{pmatrix} j_1 & j_2 & j_3 \\ j_2 - m_3 & -j_2 & m_3 \end{pmatrix} \\ &= - \left(\frac{2j_2(j_3 - m_3 + 1)}{(j_1 - j_3 + j_2)(J - 2j_2 + 1)} \right)^{\frac{1}{2}} \\ & \quad \times \begin{pmatrix} j_1 & j_2 - \frac{1}{2} & j_3 + \frac{1}{2} \\ j_2 - m_3 & -j_2 + \frac{1}{2} & m_3 - \frac{1}{2} \end{pmatrix}, \\ & j_3 = j_1 + j_2 - 1, j_1 + j_2 - 2, \dots, j_1 - j_2 \quad \text{for } j_1 \geq j_2. \end{aligned}$$

Four-term:

$$\begin{aligned} & [(J + 1)(J - 2j_1)(J - 2j_2)(J - 2j_3 + 1)]^{\frac{1}{2}} \\ & \quad \times \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = [(j_2 - m_2)(j_2 + m_2 + 1) \\ & \quad \times (j_3 + m_3)(j_3 + m_3 - 1)]^{\frac{1}{2}} \\ & \quad \times \begin{pmatrix} j_1 & j_2 & j_3 - 1 \\ m_1 & m_2 + 1 & m_3 - 1 \end{pmatrix} \\ & \quad - 2m_2[(j_3 + m_3)(j_3 - m_3)]^{\frac{1}{2}} \begin{pmatrix} j_1 & j_2 & j_3 - 1 \\ m_1 & m_2 & m_3 \end{pmatrix} \\ & \quad - [(j_2 + m_2)(j_2 - m_2 + 1)(j_3 - m_3)(j_3 - m_3 - 1)]^{\frac{1}{2}} \\ & \quad \times \begin{pmatrix} j_1 & j_2 & j_3 - 1 \\ m_1 & m_2 - 1 & m_3 + 1 \end{pmatrix}. \end{aligned}$$

Five-term:

$$\begin{aligned} & C_{\beta, \delta, \beta + \delta}^{bdf} \\ &= \left(\frac{(b + d - f)(b + f - d + 1)(d - \delta)(f + \beta + \delta + 1)}{(2d)(2f + 1)(2d)(2f + 2)} \right)^{\frac{1}{2}} \\ & \quad \times C_{\beta, \delta + 1/2, \beta + \delta + 1/2}^{bd-1/2f+1/2} \\ & \quad - \left(\frac{(b + d - f)(b + f - d + 1)(d + \delta)(f - \beta - \delta + 1)}{(2d)(2f + 1)(2d)(2f + 2)} \right)^{\frac{1}{2}} \\ & \quad \times C_{\beta, \delta - 1/2, \beta + \delta - 1/2}^{bd-1/2f+1/2} \\ & \quad + \left(\frac{(d + f - b)(b + d + f + 1)(d + \delta)(f + \beta + \delta)}{(2d)(2f + 1)(2d)(2f)} \right)^{\frac{1}{2}} \\ & \quad \times C_{\beta, \delta - 1/2, \beta + \delta - 1/2}^{bd-1/2f-1/2} \end{aligned}$$

$$\begin{aligned} & + \left(\frac{(d + f - b)(b + d + f + 1)(d - \delta)(f - \beta - \delta)}{(2d)(2f + 1)(2d)(2f)} \right)^{\frac{1}{2}} \\ & \quad \times C_{\beta, \delta + 1/2, \beta + \delta + 1/2}^{bd-1/2f-1/2}. \end{aligned}$$

This relation may be used to prove the limit relation Eq. (2.50) from the similar recurrence relation Eq. (2.84c) for the Racah coefficients.

2.7.6 Limiting Properties and Asymptotic Forms

$$\begin{aligned} & \lim_{a \rightarrow \infty} C_{a-\alpha, \beta, a-\alpha+\beta}^{aba+\rho} = \delta_{\rho\beta}, \\ & \lim_{j \rightarrow \infty} (-1)^{a+b+2j-\tau} [(2c + 1)(2j - 2\sigma + 1)]^{\frac{1}{2}} \\ & \quad \times \left\{ \begin{matrix} j - \tau & a & j - \sigma \\ b & j & c \end{matrix} \right\} = C_{\rho\sigma\tau}^{abc}, \end{aligned} \quad (2.50)$$

where the brace symbol is a 6- j coefficient (Sect. 2.9).

$$\begin{aligned} & C_{m, \mu, m+\mu}^{jkj+\Delta} \approx (-1)^{\Delta-\mu} D_{\mu\Delta}^k \begin{pmatrix} \cos \frac{1}{2}\beta & \sin \frac{1}{2}\beta \\ -\sin \frac{1}{2}\beta & \cos \frac{1}{2}\beta \end{pmatrix} \\ & \quad = d_{\mu\Delta}^k(\beta), \quad \text{for large } j; \\ & \cos \frac{1}{2}\beta = \sqrt{\frac{j+m}{2j}}, \quad \sin \frac{1}{2}\beta = \sqrt{\frac{j-m}{2j}}, \\ & C_{m0m}^{jkj} \approx P_k(\cos \beta), \quad \text{for large } j; \end{aligned}$$

$(-1)^k [(2j + 1)(2J + 1)]^{\frac{1}{2}} W(j, k, J + m, J; j, J) \sim P_k(\cos \beta)$,
first for large J , then large j (Sect. 2.9).

2.7.7 WCG Coefficients as Discretized Representation Functions

$$\begin{aligned} & C_{m_1 m_2 m}^{j_1 j_2 j} \\ &= \delta_{m_1 + m_2, m} (-1)^{j_1 - m_1} \\ & \quad \times \left(\frac{(2j + 1)(j_1 + j_2 - j)!}{(j_1 + j_2 + j + 1)!} \right)^{\frac{1}{2}} \\ & \quad \times D_{m, j_1 - j_2}^j \begin{pmatrix} \sqrt{j_1 + m_1} & \sqrt{j_2 + m_2} \\ -\sqrt{j_1 - m_1} & \sqrt{j_2 - m_2} \end{pmatrix} \text{symbolic powers}, \end{aligned} \quad (2.51)$$

where in evaluating this result one first substitutes

$$\begin{aligned} & u_{11} = \sqrt{j_1 + m_1}, \\ & u_{12} = \sqrt{j_2 + m_2}, \\ & u_{21} = -\sqrt{j_1 - m_1}, \\ & u_{22} = \sqrt{j_2 - m_2} \end{aligned}$$

into the form Eq. (2.17), followed by the replacement of ordinary powers by generalized powers:

$$(\pm\sqrt{k})^s \rightarrow (\pm 1)^s \left(\frac{k!}{(k-s)!} \right)^{\frac{1}{2}}.$$

2.8 Tensor Operator Algebra

2.8.1 Conceptual Framework

A tensor operator can be characterized in terms of its algebraic properties with respect to the angular momentum \mathbf{J} or in terms of its transformation properties under unitary transformations generated by \mathbf{J} . Both viewpoints are essential.

A tensor operator \mathbf{T} with respect to the group $SU(2)$ is a set of linear operators

$$\mathbf{T} = \{T_1, T_2, \dots, T_n\},$$

where each operator in the set acts in the space \mathcal{H} defined by Eq. (2.10) and maps this space into itself $T_i : \mathcal{H} \rightarrow \mathcal{H}$, $i = 1, 2, \dots, n$, and where this set of operators has the following properties with respect to the angular momentum \mathbf{J} , which acts in the same space \mathcal{H} in the standard way:

1. Commutation relations with respect to the angular momentum \mathbf{J} :

$$[J_i, T_j] = \sum_{k=1}^n t_{kj}^{(i)} T_k,$$

where the $t_{kj}^{(i)}$ are scalars (invariants) with respect to \mathbf{J} .

2. Unitary transformation with respect to $SU(2)$ rotations:

$$e^{-i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} T_i e^{i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} = \sum_{j=1}^n D_{ji}(U) T_j,$$

$$U = U(\psi, \hat{\mathbf{n}}),$$

where the matrix $D(U)$ is an $n \times n$ unitary matrix representation of $SU(2)$. Reduction of this representation into its irreducible constituents gives the notion of an irreducible tensor operator \mathbf{T}^J of rank J . An irreducible tensor operator \mathbf{T}^J of rank J is a set of $2J + 1$ operators

$$\mathbf{T}^J = \{T_M^J \mid M = J, J-1, \dots, -J\},$$

with the following properties with respect to $SU(2)$.

1. Commutation relations with respect to the angular momentum \mathbf{J} :

$$\begin{aligned} [J_+, T_M^J] &= [(J-M)(J+M+1)]^{\frac{1}{2}} T_{M+1}^J, \\ [J_-, T_M^J] &= [(J+M)(J-M+1)]^{\frac{1}{2}} T_{M-1}^J, \\ [J_3, T_M^J] &= M T_M^J, \\ \sum_i [J_i, [J_i, T_M^J]] &= J(J+1) T_M^J. \end{aligned} \quad (2.52)$$

2. Generation from highest *weight*:

$$T_M^J = \left(\frac{(J+M)!}{(2J)!(J-M)!} \right)^{\frac{1}{2}} [J_-, T_J^J]_{(J-M)},$$

where $[A, B]_{(k)} = [A, [A, B]_{(k-1)}]$, $k = 1, 2, \dots$, with $[A, B]_{(0)} = B$, denotes the k -fold commutator of A with B .

3. Unitary transformation with respect to $SU(2)$ rotations:

$$\begin{aligned} e^{-i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} T_M^J e^{i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} \\ = \sum_{M'} D_{M'M}^J(U) T_{M'}^J, \quad U = U(\psi, \hat{\mathbf{n}}). \end{aligned} \quad (2.53)$$

Angular momentum operators act in Hilbert spaces by acting linearly on the vectors in such spaces. The concept of a tensor operator generalizes this by replacing the irreducible space H_J by the irreducible tensor \mathbf{T}^J , and angular momentum operator action on H_J by commutator action on \mathbf{T}^J , as symbolized, respectively, by

$$\begin{aligned} \mathbf{J} : \{ \text{states} \} &\rightarrow \{ \text{states} \}, \\ \{ \text{commutator action of } \mathbf{J} \} &: \{ \text{tensor operators} \} \\ &\rightarrow \{ \text{tensor operators} \}. \end{aligned}$$

Just as exponentiation of the standard generator action Eqs. (2.13) and (2.14) gives relation Eq. (2.16), so does the exponentiation of the commutator action Eq. (2.52) give relation Eq. (2.53), when one uses the Baker–Campbell–Hausdorff identity:

$$e^{tA} B e^{-tA} = \sum_k \frac{t^k}{k!} [A, B]_{(k)}.$$

Thus, the linear vector space of states is replaced by the linear vector space of operators. Abstractly, relations Eqs. (2.13) and (2.52) are identical: only the rule of action and the object of that action has changed.

An example of an irreducible tensor of rank 1 is the angular momentum \mathbf{J} itself, which has the special property $\mathbf{J} : \mathcal{H}_j \rightarrow \mathcal{H}_j$. Thus, relations Eqs. (2.52) and (2.53) are realized as:

$$\begin{aligned} T_1^1 &= J_{+1} = -(J_1 + iJ_2)/\sqrt{2}, \\ T_0^1 &= J_0 = J_3, \\ T_{-1}^1 &= J_{-1} = (J_1 - iJ_2)/\sqrt{2}; \\ [J_+, T_\mu^1] &= [(1-\mu)(2+\mu)]^{\frac{1}{2}} T_{\mu+1}^1, \\ [J_-, T_\mu^1] &= [(1+\mu)(2-\mu)]^{\frac{1}{2}} T_{\mu-1}^1, \\ [J_3, T_\mu^1] &= \mu T_\mu^1, \quad \mu = 1, 0, -1; \end{aligned}$$

$$\begin{aligned}
e^{-i\psi\hat{\mathbf{n}}\cdot\mathbf{J}}\mathbf{J}e^{i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} &= \mathbf{J}\cos\psi + \hat{\mathbf{n}}(\hat{\mathbf{n}}\cdot\mathbf{J})(1 - \cos\psi) \\
&\quad - (\hat{\mathbf{n}}\times\mathbf{J})\sin\psi, \\
e^{-i\psi\hat{\mathbf{n}}\cdot\mathbf{J}}T_{\mu}^1e^{i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} &= \sum_{\nu} D_{\nu\mu}^1(\psi, \hat{\mathbf{n}})T_{\nu}^1.
\end{aligned}$$

2.8.2 Universal Enveloping Algebra of \mathbf{J}

The universal enveloping algebra $A(\mathbf{J})$ of \mathbf{J} is the set of all complex polynomial operators in the components J_i of \mathbf{J} , or equivalently in (J_+, J_3, J_-) . The irreducible tensor operators spanning this algebra are the analogues of the solid harmonics $\mathcal{Y}_{lm}(\mathbf{x})$ and are characterized by the following properties: Basis set:

$$\begin{aligned}
\mathcal{T}_k^k &= a_k J_+^k, \quad a_k \text{ arbitrary constant}, \\
\mathcal{T}_{\mu}^k &= a_k \left(\frac{(k+\mu)!}{(2k)!(k-\mu)!} \right) [J_-, J_+^k]_{(k-\mu)}, \\
\mu &= k, k-1, \dots, -k; \quad k = 0, 1, 2, \dots
\end{aligned}$$

Standard action with respect to \mathbf{J} :

$$\begin{aligned}
[J_{\pm}, \mathcal{T}_{\mu}^k] &= [(k \mp \mu)(k \pm \mu + 1)]^{\frac{1}{2}} \mathcal{T}_{\mu \pm 1}^k, \\
[J_3, \mathcal{T}_{\mu}^k] &= \mu \mathcal{T}_{\mu}^k, \\
\sum_{i=1}^3 [J_i, [J_i, \mathcal{T}_{\mu}^k]] &= k(k+1) \mathcal{T}_{\mu}^k.
\end{aligned}$$

Unitary transformation:

$$e^{-i\psi\hat{\mathbf{n}}\cdot\mathbf{J}}\mathcal{T}_{\mu}^k e^{i\psi\hat{\mathbf{n}}\cdot\mathbf{J}} = \sum_{\nu} D_{\nu\mu}^k(\psi, \hat{\mathbf{n}})\mathcal{T}_{\nu}^k.$$

2.8.3 Algebra of Irreducible Tensor Operators

Irreducible tensor operators possess, as linear operators acting in the same space, properties 1, 2, and 3 below, and an additional multiplication property 4, which constructs new irreducible tensor operators out of two given ones and is called coupling of irreducible tensor operators. Property 4 extends also to tensor operators acting in the tensor product space associated with kinematically independent systems. It is important that associativity extends to the product Eq. (2.54), as well as to the product Eq. (2.55). Commutativity in these products is generally invalid. The coupling properties given in 4 and 5 are analogous to the coupling of basis state vectors. The operation of Hermitian conjugation of operators, which is the analogue of complex conjugation of states, is also important, and has the properties presented under 5

1. Multiplication of an irreducible tensor operator of rank k by a complex number or an invariant with respect to angular momentum \mathbf{J} gives an irreducible tensor operator of the same rank.
2. Addition of two irreducible tensor operator of the same rank gives an irreducible tensor of that rank.
3. Ordinary multiplication (juxtaposition) of three irreducible tensor operators is associative, but the multiplication of two is noncommutative, in general.
4. Two irreducible tensor operators \mathcal{S}^{k_1} and \mathcal{T}^{k_2} of different or the same ranks acting in the same space may be multiplied to obtain new irreducible tensor operators of ranks given by the angular momentum addition rule (Clebsch-Gordan series):

$$[\mathcal{S}^{k_1} \times \mathcal{T}^{k_2}]_{\mu}^k = \sum_{\mu_1, \mu_2} C_{\mu_1 \mu_2 \mu}^{k_1 k_2 k} \mathcal{S}_{\mu_1}^{k_1} \mathcal{T}_{\mu_2}^{k_2}, \quad (2.54)$$

$$\mu = k, k-1, \dots, -k;$$

$$\text{rank} = k \in \{k_1 + k_2, k_1 + k_2 - 1, \dots, |k_1 - k_2|\}.$$

The following symbol denotes the irreducible tensor operator with the μ -components Eq. (2.54):

$$[\mathcal{S}^{k_1} \times \mathcal{T}^{k_2}]^k.$$

5. Two irreducible tensor operators \mathcal{S}^{k_1} and \mathcal{T}^{k_2} of different or the same ranks acting in different Hilbert spaces, say \mathcal{H} and \mathcal{K} , may first be multiplied by the tensor product rule so as to act in the tensor product space $\mathcal{H} \otimes \mathcal{K}$, that is,

$$S_{\mu_1}^{k_1} \otimes T_{\mu_2}^{k_2} : \mathcal{H} \otimes \mathcal{K} \rightarrow \mathcal{H} \otimes \mathcal{K},$$

and then coupled to obtain new irreducible tensor operators, acting in the same tensor product space $\mathcal{H} \otimes \mathcal{K}$:

$$\begin{aligned}
[\mathcal{S}^{k_1} \otimes \mathcal{T}^{k_2}]_{\mu}^k &= \sum_{\mu_1, \mu_2} C_{\mu_1 \mu_2 \mu}^{k_1 k_2 k} \mathcal{S}_{\mu_1}^{k_1} \otimes \mathcal{T}_{\mu_2}^{k_2}, \\
\mu &= k, k-1, \dots, -k. \quad (2.55)
\end{aligned}$$

The following symbol denotes the tensor operator with the μ -components Eq. (2.55):

$$\begin{aligned}
[\mathcal{S}^{k_1} \otimes \mathcal{T}^{k_2}]^k, \\
k \in \{k_1 + k_2, k_1 + k_2 - 1, \dots, |k_1 - k_2|\}.
\end{aligned}$$

6. The conjugate tensor operator to \mathcal{T}^J , denoted by $\mathcal{T}^{J\dagger}$, is the set of operators with components $T_M^{J\dagger}$ defined by

$$\langle j'm' | T_M^{J\dagger} | jm \rangle = \langle jm | T_M^J | j'm' \rangle^*.$$

These components satisfy the following relations:

$$\begin{aligned}
[J_{\pm}, T_M^{J\dagger}] &= -[(J \pm M)(J \mp M + 1)]^{\frac{1}{2}} T_{M \mp 1}^{J\dagger} \\
[J_3, T_M^{J\dagger}] &= -M T_M^{J\dagger},
\end{aligned}$$

$$\begin{aligned} \sum_i [J_i, [J_i, T_M^{J\dagger}]] &= J(J+1)T_M^{J\dagger}; \\ e^{-i\psi\hat{n}\cdot\mathbf{J}} T_M^{J\dagger} e^{i\psi\hat{n}\cdot\mathbf{J}} &= \sum_{M'} D_{M'M}^{J*}(\psi, \hat{n}) T_{M'}^{J\dagger}; \\ I^J &= \sum_M T_M^J T_M^{J\dagger} = \left(\begin{array}{c} \text{invariant operator to} \\ SU(2) \text{ rotations} \end{array} \right), \\ e^{-i\psi\hat{n}\cdot\mathbf{J}} I^J e^{i\psi\hat{n}\cdot\mathbf{J}} &= I^J. \end{aligned}$$

An important invariant operator is

$$I^{k_1 k_2 k} = \sum_{\mu_1 \mu_2 \mu} C_{\mu_1 \mu_2 \mu}^{k_1 k_2 k} T_{\mu_1}^{k_1} T_{\mu_2}^{k_2} T_{\mu}^{k\dagger}.$$

7. Other definitions of conjugation:

$$T_M^T \rightarrow (-1)^{J-M} T_{-M}^J, \quad T_M^J \rightarrow (-1)^{J+M} T_{-M}^J.$$

2.8.4 Wigner–Eckart Theorem

The Wigner–Eckart theorem establishes the form of the matrix elements of an arbitrary irreducible tensor operator:

$$\begin{aligned} \langle j'm' | T_M^J | jm \rangle &= \langle j' \| \mathbf{T}^J \| j \rangle C_{mMm'}^{jJj'} \\ &= (j' \| \mathbf{T}^J \| j) (-1)^{j+J+m'} \begin{pmatrix} j & J & j' \\ m & M & -m' \end{pmatrix}. \end{aligned}$$

Reduced matrix elements with respect to WCG coefficients:

$$\langle j' \| \mathbf{T}^J \| j \rangle = \sum_{\mu M} C_{\mu M \mu'}^{jJj'} \langle j' \mu' | T_M^J | j \mu \rangle,$$

each $\mu' = j', j' - 1, \dots, -j'$ (the reduced matrix element is independent of μ').

Reduced matrix elements with respect to 3- j coefficients:

$$(j' \| \mathbf{T}^J \| j) = (-1)^{2J} \sqrt{2j'+1} (j' \| \mathbf{T}^J \| j).$$

Examples of irreducible tensor operators include:

1. The solid harmonics with respect to the orbital angular momentum L :

$$\begin{aligned} \mathbf{y}^k(\mathbf{x}) &= \{y_{k\mu}(\mathbf{x}) : \mu = k, \dots, -k\}, \\ y_{k\mu} |lm\rangle &= \sum_{l'} \langle l' \| \mathbf{y}^k \| l \rangle C_{m,\mu,m+\mu}^{l'kl'} |l', m+\mu\rangle, \end{aligned}$$

where

$$\begin{aligned} \langle \mathbf{x} | lm \rangle &= y_{lm}(\mathbf{x}), \\ \langle l' \| \mathbf{y}^k \| l \rangle &= r^{l+k-l'} \left(\frac{(2l+1)(2k+1)}{4\pi(2l'+1)} \right)^{\frac{1}{2}} C_{000}^{l'kl'}, \end{aligned}$$

$$\begin{aligned} y_{k\mu}(\mathbf{x}) y_{lm}(\mathbf{x}) &= \sum_{l'} \langle l' \| \mathbf{y}^k \| l \rangle C_{m,\mu,m+\mu}^{l'kl'} y_{l',m+\mu}(\mathbf{x}), \\ [\mathbf{y}^{k_1}(\mathbf{x}) \otimes \mathbf{y}^{k_2}(\mathbf{x})]_{\mu}^k &= \sum_{\mu_1 \mu_2} C_{\mu_1 \mu_2 \mu}^{k_1 k_2 k} y_{k_1 \mu_1}(\mathbf{x}) y_{k_2 \mu_2}(\mathbf{x}), \\ [\mathbf{y}^{k_1}(\mathbf{x}) \otimes \mathbf{y}^{k_2}(\mathbf{x})]_{\mu}^k &= \langle k \| \mathbf{y}^{k_1} \| k_2 \rangle y_{k\mu}(\mathbf{x}). \end{aligned}$$

2. The polynomial operator \mathcal{T}^k in the components of \mathbf{J} (Sect. 2.8.2):

$$\begin{aligned} \langle j'm' | \mathcal{T}_{\mu}^k | jm \rangle &= \delta_{j'j} \langle j \| \mathcal{T}^k \| j \rangle C_{m\mu m'}^{j k j}, \\ \langle j \| \mathcal{T}^k \| j \rangle &= a_k (-1)^k \left(\frac{(2j+k+1)! k!}{(2j+1)(2j-k)!(2k)!} \right)^{\frac{1}{2}}. \end{aligned}$$

3. Polynomials in the components of an arbitrary vector operator \mathbf{V} , which has the defining relations:

$$\begin{aligned} [J_i, V_j] &= i e_{ijk} V_k, \\ [J_{\pm}, V_{\mu}] &= [(1 \mp \mu)(2 \pm \mu)]^{\frac{1}{2}} V_{\mu \pm 1}, \\ [J_3, V_{\mu}] &= \mu V_{\mu}, \\ V_{+1} &= -(V_1 + iV_2)/\sqrt{2}, \quad V_0 = V_3, \\ V_{-1} &= (V_1 - iV_2)/\sqrt{2}. \end{aligned}$$

This construction parallels exactly that given in Sect. 2.8.2 upon replacing \mathbf{J} by \mathbf{V} . The explicit form of the resulting polynomials may be quite different since no assumptions are made concerning commutation relations between the components V_i of \mathbf{V} . The solid harmonics in the gradient operator ∇ constitute an irreducible tensor operator with respect to the orbital angular momentum L .

2.8.5 Unit Tensor Operators or Wigner Operators

A unit tensor operator is an irreducible tensor operator $\hat{\mathbf{T}}^{J,\Delta}$, indexed not only by the angular momentum quantum number J but also by an additional label Δ , which specifies that this irreducible tensor operator has reduced matrix elements given by

$$\langle j' \| \hat{\mathbf{T}}^{J,\Delta} \| j \rangle = \delta_{j',j+\Delta}.$$

This condition is to be true for all $j = 0, 1/2, 1, \dots$. There is a unit tensor operator defined for each

$$\Delta = J, J-1, \dots, -J.$$

The special symbol

$$\left\langle \begin{array}{ccc} 2J & J+\Delta & \\ & \bullet & \\ & & 0 \end{array} \right\rangle$$

denotes a unit tensor operator, replacing the boldface symbol $\hat{\mathbf{T}}^{J,\Delta}$, while the symbol

$$\left\langle \begin{array}{c} 2J \quad J + \Delta \\ \quad \quad J + M \end{array} \right\rangle, \quad M = J, J - 1, \dots, -J$$

denotes the components. In the same way that abstract angular momentum \mathbf{J} and state vectors $\{|jm\rangle\}$ extract the intrinsic structure of all realizations of angular momentum theory, as given in Sect. 2.2, so does the notion of a unit tensor operator extract the intrinsic structure of the concept of irreducible tensor operator by disregarding the physical content of the theory, which is carried in the structure of the reduced matrix elements. Physical theory is regained from the fact that the unit tensor operators are the basis for arbitrary tensor operators, which is the structural content of the Wigner–Eckart theorem. The concept of a unit tensor operator was introduced by Racah, but it was Biedenharn who recognized the full significance of this concept not only for $SU(2)$, but for all the unitary groups.

All of the content of physical tensor operator theory can be regained from the properties of unit tensor operators or Wigner operators as summarized below.

Notation (double Gel'fand patterns):

$$\left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle, \quad M, \Delta = J, J - 1, \dots, -J \\ 2J = 0, 1, 2, \dots$$

Definition (shift action):

$$\left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle |jm\rangle = C_{m,M,m+M}^{jJj+\Delta} |j + \Delta, m + M\rangle, \quad (2.56)$$

for all $j = 0, \frac{1}{2}, \dots$; $m = j, j - 1, \dots, -j$.

Conjugation:

$$\left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle^\dagger |jm\rangle = C_{m-M,M,m}^{j-\Delta Jj} |j - \Delta, m - M\rangle. \quad (2.57)$$

Orthogonality:

$$\sum_M \left\langle \begin{array}{c} J + \Delta' \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle = \delta_{\Delta'\Delta} \mathbf{I}_\Delta^J, \quad (2.58)$$

$$\sum_\Delta \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M' \end{array} \right\rangle \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle = \delta_{M'M}, \quad (2.59)$$

$$\sum_m \langle jm | \left\langle \begin{array}{c} J' + \Delta' \\ 2J' \quad \quad 0 \\ \quad \quad J' + M' \end{array} \right\rangle \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle^\dagger |jm\rangle \\ = \frac{2j+1}{2J+1} \delta_{J'J} \delta_{M'M} \delta_{\Delta'\Delta}. \quad (2.60)$$

The invariant operator \mathbf{I}_Δ^J is defined by its action on an arbitrary vector $\psi_j \in \mathcal{H}_j$:

$$\mathbf{I}_\Delta^J \psi_j = \epsilon_{j-\Delta, J, j} \psi_j.$$

Tensor operator property:

$$e^{-i\psi \hat{\mathbf{n}} \cdot \mathbf{J}} \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle e^{i\psi \hat{\mathbf{n}} \cdot \mathbf{J}} \\ = \sum_{M'} D_{M'M}^J(\psi, \hat{\mathbf{n}}) \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M' \end{array} \right\rangle. \quad (2.61)$$

Basis property (Wigner–Eckart theorem):

$$T_M^J |jm\rangle \\ = \left(\sum_\Delta \langle j + \Delta \| \mathbf{T}^J \| j \rangle \left\langle \begin{array}{c} J + \Delta \\ 2J \quad \quad 0 \\ \quad \quad J + M \end{array} \right\rangle \right) |jm\rangle. \quad (2.62)$$

Characteristic null space.

The characteristic null space of the Wigner operator defined by Eq. (2.56) is the set of irreducible subspaces $\mathcal{H}_j \subset \mathcal{H}$ given by

$$\{\mathcal{H}_j : 2j = 0, 1, \dots, J - \Delta - 1\}.$$

Coupling law:

$$\sum_{\alpha\beta} C_{\alpha\beta\gamma}^{abc} \left\langle \begin{array}{c} b + \sigma \\ 2b \quad \quad 0 \\ \quad \quad b + \beta \end{array} \right\rangle \left\langle \begin{array}{c} a + \rho \\ 2a \quad \quad 0 \\ \quad \quad a + \alpha \end{array} \right\rangle \\ = \mathbf{W}_{\rho,\sigma,\rho+\sigma}^{abc} \left\langle \begin{array}{c} c + \rho + \sigma \\ 2c \quad \quad 0 \\ \quad \quad c + \gamma \end{array} \right\rangle, \quad (2.63)$$

where $\mathbf{W}_{\rho\sigma\tau}^{abc}$ is an invariant operator (commutes with \mathbf{J}) and is called a Racah invariant. Its relationship to Racah coefficients and 6- j coefficients is given in Sect. 2.9.

Product law:

$$\left\langle \begin{array}{c} b + \sigma \\ 2b \quad \quad 0 \\ \quad \quad b + \beta \end{array} \right\rangle \left\langle \begin{array}{c} a + \rho \\ 2a \quad \quad 0 \\ \quad \quad a + \alpha \end{array} \right\rangle \\ = \sum_c \mathbf{W}_{\rho,\sigma,\rho+\sigma}^{abc} C_{\alpha,\beta,\alpha+\beta}^{abc} \left\langle \begin{array}{c} c + \rho + \sigma \\ 2c \quad \quad 0 \\ \quad \quad c + \alpha + \beta \end{array} \right\rangle. \quad (2.64)$$

Racah invariant:

$$W_{\rho\sigma\tau}^{abc} = \sum_{\alpha\beta\gamma} C_{\alpha\beta\gamma}^{abc} \times \left\langle \begin{array}{c} b + \sigma \\ 2b \\ b + \beta \end{array} 0 \middle| \begin{array}{c} a + \rho \\ 2a \\ a + \alpha \end{array} 0 \middle| \begin{array}{c} c + \tau \\ 2c \\ c + \gamma \end{array} 0 \right\rangle^\dagger. \quad (2.65)$$

The notation $W_{\rho\sigma\tau}^{abc}$ for a Racah invariant is designed to *match* that of the WCG coefficient on the left, the latter being associated with the lower group theoretical labels, for example,

$$\left(\begin{array}{c} 2a \\ a + \alpha \\ 0 \end{array} \right) \rightarrow |a\alpha\rangle,$$

the state vector having a group transformation law under the action of $SU(2)$, and the former with the shift labels of a unit tensor operator,

$$\left(\begin{array}{c} \alpha + \rho \\ 2\alpha \\ 0 \end{array} \right),$$

and having no associated group transformation law. The invariant operator defined by Eq. (2.65) has real eigenvalues, hence, is a Hermitian operator,

$$W_{\rho\sigma\tau}^{abc\dagger} = W_{\rho\sigma\tau}^{abc}, \quad (2.66)$$

which is diagonal on an arbitrary state vector in \mathcal{H}_j (Sect. 2.9).

The Racah invariant operator does not commute with a unit tensor operator, and it makes a difference whether it is written to the left or to the right of such a unit tensor operator. The convention here writes it to the left.

Relation Eq. (2.65) is taken as the definition of $W_{\rho\sigma\tau}^{abc}$, and the following properties all follow from this expression.

Domain of definition:

$$\begin{aligned} W_{\rho\sigma\tau}^{abc} &: a, b, c \in \{0, 1/2, 1, 3/2, \dots\}; \\ \rho &= a, a - 1, \dots, -a \\ \sigma &= b, b - 1, \dots, -b \\ \tau &= c, c - 1, \dots, -c; \\ W_{\rho\sigma\tau}^{abc} &= \mathbf{0}, \text{ if } \rho + \sigma \neq \tau; \text{ if } \epsilon_{abc} = 0. \end{aligned}$$

Orthogonality relations:

$$\sum_{\rho\sigma} W_{\rho\sigma\tau}^{abc} W_{\rho\sigma\tau'}^{abd} = \delta_{cd} \delta_{\tau\tau'} \epsilon_{abc} \mathbf{I}_\tau^c, \quad (2.67)$$

$$\sum_{c\tau} W_{\rho\sigma\tau}^{abc} W_{\rho'\sigma'\tau}^{abc} = \delta_{\rho\rho'} \delta_{\sigma\sigma'} \mathbf{I}_{\rho\sigma}^{ab}, \quad (2.68)$$

where the \mathbf{I} invariant operators in these expressions have the following eigenvalues on an arbitrary vector $\psi_j \in \mathcal{H}_j$:

$$\begin{aligned} \mathbf{I}_\tau^c \psi_j &= \epsilon_{j-\tau,c,j} \psi_j, \\ \mathbf{I}_{\rho\sigma}^{ab} \psi_j &= \epsilon_{j-\sigma-\rho,a,j-\sigma} \epsilon_{j-\sigma,b,j} \psi_j. \end{aligned}$$

The orthogonality relations for Racah invariants parallel exactly those of WCG coefficients.

Using the orthogonality relations Eq. (2.67) for Racah invariants, the following two relations now follow from Eqs. (2.63) and (2.64), respectively:

WCG and Racah operator coupling:

$$\begin{aligned} &\sum_{\rho\sigma} \sum_{\alpha\beta} W_{\rho,\sigma,\rho+\sigma}^{abd} C_{\alpha,\beta,\alpha+\beta}^{abc} \\ &\times \left\langle \begin{array}{c} b + \sigma \\ 2b \\ b + \beta \end{array} 0 \middle| \begin{array}{c} a + \rho \\ 2a \\ a + \alpha \end{array} 0 \right\rangle \\ &= \delta_{cd} \epsilon_{abc} \mathbf{I}_\tau^d \left\langle \begin{array}{c} c + \tau \\ 2c \\ c + \gamma \end{array} 0 \right\rangle. \end{aligned} \quad (2.69)$$

Racah operator coupling of shift patterns:

$$\begin{aligned} &\sum_{\rho\sigma} W_{\rho\sigma\tau}^{abc} \left\langle \begin{array}{c} b + \sigma \\ 2b \\ b + \beta \end{array} 0 \middle| \begin{array}{c} a + \rho \\ 2a \\ a + \alpha \end{array} 0 \right\rangle \\ &= C_{\alpha,\beta,\alpha+\beta}^{abc} \left\langle \begin{array}{c} c + \tau \\ 2c \\ c + \alpha + \beta \end{array} 0 \right\rangle. \end{aligned} \quad (2.70)$$

Relations (Eqs. (2.56)–(2.70)) capture the full content of irreducible tensor operator algebra through the concept of unit tensor operators that have only 0 or 1 for their reduced matrix elements. Using the Wigner–Eckart theorem Eq. (2.62), the relations between general tensor operators can be reconstructed. Unit tensor operators were invented to exhibit in the most elementary way possible the abstract and intrinsic structure of the irreducible tensor operator algebra, stripping away the details of particular physical applications, thus giving the theory universal application. It accomplishes the same goal for tensor operator theory that the abstract multiplet theory in Sect. 2.2 accomplishes for representation theory.

Physical theory is regained through the concept of reduced matrix element. The coupling rule Eq. (2.54) is now transformed to a rule empty of WCG coefficient content and becomes a rule for coupling of reduced matrix elements using the invariant Racah operators:

$$\begin{aligned} &\langle (\alpha') j' \| [\mathbf{S}^{k_1} \times \mathbf{T}^{k_2}]^k \| (\alpha) j \rangle \\ &= (-1)^{k_1+k_2-k} \sum_{(\alpha'') j''} W_{j''-j, j'-j'', j-j}^{k_2 k_1 k} (j') \\ &\times \langle (\alpha') j' \| \mathbf{S}^{k_1} \| (\alpha'') j'' \rangle \langle (\alpha'') j'' \| \mathbf{T}^{k_2} \| (\alpha) j \rangle. \end{aligned} \quad (2.71)$$

This coupling rule is invariant to all $SU(2)$ rotations and reveals the true role of the Racah coefficients and reduced matrix elements in physical theory as invariant objects under $SU(2)$ rotations. It now becomes imperative to understand Racah coefficients as objects free of their original definition in terms of WCG coefficients.

2.9 Racah Coefficients

Relation Eq. (2.65) is taken, initially, as the definition of the Racah coefficient with appropriate adjustments of notations to conform to Racah's W notation and to Wigner's $6-j$ notation. Corresponding to each of Eqs. (2.63)–(2.65), (2.69), and (2.70), there is a corresponding numerical relationship between WCG coefficients and Racah coefficients. Despite the present day popularity of expressing all such relations in terms of the $3-j$ and $6-j$ notation, this temptation is resisted here for this particular set of relations because of their fundamental origins. The relation between the Racah invariant notation and Racah's original W notation is

$$\begin{aligned} W_{\rho\sigma\tau}^{abc} | jm \rangle &= W_{\rho\sigma\tau}^{abc}(j) | jm \rangle, \\ W_{\rho\sigma\tau}^{abc}(j) &= 0 \quad \text{if } \tau \neq \rho + \sigma, \quad \text{or } \epsilon_{abc} = 0, \\ W_{\rho\sigma\tau}^{abc}(j) &= [(2c+1)(2j-2\sigma+1)]^{1/2} \\ &\quad \times W(j-\tau, a, j, b; j-\sigma, c), \\ [(2e+1)(2f+1)]^{1/2} W(abcd; ef) & \\ &= W_{e-a, c-e, c-a}^{bdf}(c), \end{aligned}$$

$W(abcd; ef) = 0$ unless the triples of nonnegative integers and half-integers (abe) , (cde) , (acf) , and (bdf) satisfy the triangle conditions.

2.9.1 Basic Relations Between WCG and Racah Coefficients

$$\begin{aligned} &\sum_{\beta\delta} C_{\beta\delta\gamma}^{bdf} C_{\alpha+\beta, \delta, \alpha+\gamma}^{edc} C_{\alpha, \beta, \alpha+\beta}^{abe} \\ &= [(2e+1)(2f+1)]^{1/2} W(abcd; ef) C_{\alpha, \gamma, \alpha+\gamma}^{afc}, \\ &\sum_f [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\ &\quad \times C_{\beta, \delta, \beta+\delta}^{bdf} C_{\alpha, \beta+\delta, \alpha+\beta+\delta}^{afc} \\ &= C_{\alpha+\beta, \delta, \alpha+\beta+\delta}^{edc} C_{\alpha, \beta, \alpha+\beta}^{abe}, \\ \delta_{cc'} [(2e+1)(2f+1)]^{1/2} W(abcd; ef) & \\ &= \sum_{\beta\delta} C_{\beta, \delta, \beta+\delta}^{bdf} C_{\gamma-\delta, \delta, \gamma}^{edc} C_{\gamma-\beta-\delta, \beta, \gamma-\delta}^{abe} \\ &\quad \times C_{\gamma-\beta-\delta, \beta+\delta, \gamma}^{abc'}, \end{aligned}$$

$$\begin{aligned} &\sum_{\beta\delta e} [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\ &\quad \times C_{\beta\delta\gamma}^{bdf'} C_{\alpha+\beta, \delta, \alpha+\gamma}^{edc} C_{\alpha, \beta, \alpha+\beta}^{abe} \\ &= \delta_{ff'} C_{\alpha, \gamma, \alpha+\gamma}^{afc}, \\ &\sum_e [(2e+1)(2f+1)]^{1/2} W(abcd; ef) \\ &\quad \times C_{\alpha+\beta, \delta, \alpha+\beta+\delta}^{edc} C_{\alpha, \beta, \alpha+\beta}^{abe} \\ &= C_{\beta, \delta, \beta+\delta}^{bdf} C_{\alpha, \beta+\delta, \alpha+\beta+\delta}^{afc}. \end{aligned}$$

2.9.2 Orthogonality and Explicit Form

Orthogonality relations for Racah coefficients:

$$\begin{aligned} &\sum_e (2e+1)(2f+1) W(abcd; ef) W(abcd; ef') \\ &= \delta_{ff'} \epsilon_{acf} \epsilon_{bdf}, \end{aligned} \quad (2.72)$$

$$\begin{aligned} &\sum_f (2e+1)(2f+1) W(abcd; ef) W(abcd; e'f) \\ &= \delta_{ee'} \epsilon_{abe} \epsilon_{cde}. \end{aligned} \quad (2.73)$$

Definition of $6-j$ coefficients:

$$\left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} = (-1)^{a+b+c+d} W(abcd; ef). \quad (2.74)$$

Orthogonality of $6-j$ coefficients:

$$\begin{aligned} &\sum_e (2e+1)(2f+1) \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} \left\{ \begin{matrix} a & b & e \\ d & c & f' \end{matrix} \right\} \\ &= \delta_{ff'} \epsilon_{acf} \epsilon_{bdf}, \end{aligned} \quad (2.75)$$

$$\begin{aligned} &\sum_f [(2e+1)(2f+1)] \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} \left\{ \begin{matrix} a & b & e' \\ d & c & f \end{matrix} \right\} \\ &= \delta_{ee'} \epsilon_{abe} \epsilon_{cde}. \end{aligned} \quad (2.76)$$

Explicit form of Racah coefficients:

$$\begin{aligned} W(abcd; ef) &= \Delta(abe) \Delta(cde) \Delta(acf) \Delta(bdf) \\ &\quad \times \sum_k \frac{(-1)^{a+b+c+d+k} (k+1)!}{(k-a-b-e)!(k-c-d-e)!} \\ &\quad \times \frac{1}{(k-a-c-f)!(k-b-d-f)!} \\ &\quad \times \frac{1}{(a+b+c+d-k)!} \\ &\quad \times \frac{1}{(a+d+e+f-k)!(b+c+e+f-k)!}, \end{aligned} \quad (2.77)$$

where $\Delta(abc)$ denotes the triangle coefficient, defined for every triple a, b, c of integers and half-odd integers satisfying the triangle conditions by:

$$\Delta(abc) = \left(\frac{(a+b-c)!(a-b+c)!(-a+b+c)!}{(a+b+c+1)!} \right)^{\frac{1}{2}}. \quad (2.78)$$

2.9.3 The Fundamental Identities Between Racah Coefficients

Each of the three relations given in this section is between Racah coefficients alone. Each expresses a fundamental mathematical property. The Biedenharn–Elliott identity is a consequence of the associativity rule for the open product of three irreducible tensor operators; the Racah sum rule is a consequence of the commutativity of a mapping diagram associated with the coupling of three angular momenta; and the triangle coupling rule is a consequence of the associativity of the open product of three symplection polynomials [1]. As such, these three relations between Racah coefficients, together with the orthogonality relations, are the building blocks on which is constructed a theory of these coefficients that stands on its own, independent of the WCG coefficient origins. Indeed, the latter is recovered through the limit relation Eq. (2.50).

Biedenharn–Elliott identity:

$$W(a'ab'b; c'e)W(a'ed'd; b'c) = \sum_f (2f+1)W(abcd; ef)W(c'bd'd; b'f) \times W(a'ad'f; c'c), \quad (2.79a)$$

$$\begin{aligned} & \begin{Bmatrix} a' & a & c' \\ b & b' & e \end{Bmatrix} \begin{Bmatrix} a' & e & b' \\ d & d' & c \end{Bmatrix} \\ &= \sum_f (-1)^\phi (2f+1) \begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \begin{Bmatrix} c' & b & b' \\ d & d' & f \end{Bmatrix} \\ & \times \begin{Bmatrix} a' & a & c' \\ f & d' & c \end{Bmatrix}, \\ & \phi = f - e + a' + a + b' + b + c' - c + d' - d. \end{aligned} \quad (2.79b)$$

Racah sum rule:

$$\begin{aligned} & \sum_f (-1)^{b+d-f} (2f+1)W(abcd; ef)W(adcb; gf) \\ &= (-1)^{e+g-a-c} W(bacd; eg), \end{aligned} \quad (2.80a)$$

$$\begin{aligned} & \sum_f (-1)^{e+g+f} (2f+1) \begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \begin{Bmatrix} a & d & g \\ b & c & f \end{Bmatrix} \\ &= \begin{Bmatrix} b & a & e \\ d & c & g \end{Bmatrix}. \end{aligned} \quad (2.80b)$$

Triangle sum rule:

$$\begin{aligned} & [\Delta(acf)\Delta(bdf)]^{-1} \\ &= (2f+1) \sum_e [\Delta(abe)\Delta(cde)]^{-1} W(abcd; ef), \end{aligned} \quad (2.81a)$$

$$\begin{aligned} & (-1)^{a+b+c+d} [\Delta(acf)\Delta(bdf)]^{-1} \\ &= (2f+1) \sum_e [\Delta(abe)\Delta(cde)]^{-1} \begin{Bmatrix} a b e \\ d c f \end{Bmatrix}. \end{aligned} \quad (2.81b)$$

2.9.4 Schwinger–Bargmann Generating Function and Its Combinatorics

Triangles associated with the 6- j symbol $\begin{Bmatrix} j_1 & j_2 & j_3 \\ j_4 & j_5 & j_6 \end{Bmatrix}$:

$$(j_1 j_2 j_3), \quad (j_3 j_4 j_5), \quad (j_1 j_5 j_6), \quad (j_2 j_4 j_6).$$

Points in \mathbf{R}^3 associated with the triangles:

$$\begin{aligned} & (j_1 j_2 j_3) \rightarrow (x_1, x_2, x_3), \quad (j_3 j_4 j_5) \rightarrow (y_3, x_4, x_5), \\ & (j_1 j_5 j_6) \rightarrow (y_1, y_5, x_6), \quad (j_2 j_4 j_6) \rightarrow (y_2, y_4, y_6). \end{aligned}$$

Tetrahedron associated with the points:

The points define the vertices of a general tetrahedron with lines joining each pair of points that share a common subscript, and the lines are labeled by the product of the common coordinates (Fig. 2.2).

Monomial term:

Define the triangle monomial associated with a triangle $(j_a j_b j_c)$ and its associated point (z_a, z_b, z_c) in \mathbf{R}^3 by

$$(z_a, z_b, z_c)^{(j_a j_b j_c)} = z_a^{j_b+j_c-j_a} z_b^{j_c+j_a-j_b} z_c^{j_a+j_b-j_c}. \quad (2.82)$$

Cubic graph (tetrahedral T_4) functions.

Interchange the symbols x and y in the coordinates of the vertices of the tetrahedron and define the following polynomials on the vertices and edges of the tetrahedron with this modified labeling.

Vertex function: multiply together the coordinates of each vertex and sum over all such vertices to obtain

$$V_3 = y_1 y_2 y_3 + x_3 y_4 y_5 + x_1 x_5 y_6 + x_2 x_4 x_6;$$

Fig. 2.2 Labeled cubic graph (tetrahedron) associated with $6-j$ coefficients

Edge function: multiply together the coordinates of a given edge and the opposite edge and sum over all such pairs to obtain

$$E_4 = x_1 y_1 x_4 y_4 + x_2 y_2 x_5 y_5 + x_3 y_3 x_6 y_6 .$$

Generating function:

$$(1 + V_3 + E_4)^{-2} = \sum_{\Delta} T(\Delta) Z^{\Delta} , \quad (2.83a)$$

$$Z^{\Delta} = (x_1, x_2, x_3)^{(j_1 j_2 j_3)} (y_3, x_4, x_5)^{(j_3 j_4 j_5)} \\ \times (y_1, y_5, x_6)^{(j_1 j_5 j_6)} (y_2, y_4, y_6)^{(j_2 j_4 j_6)} , \quad (2.83b)$$

$$\Delta = \begin{bmatrix} (j_1 j_2 j_3) \\ (j_3 j_4 j_5) \\ (j_1 j_5 j_6) \\ (j_2 j_4 j_6) \end{bmatrix} ;$$

$$T(\Delta) = \sum_k (-1)^k (k+1) \\ \times \binom{k}{k_1, k_2, k_3, k_4, k_5, k_6, k_7} , \quad (2.83c)$$

$$k_i = k - t_i , \quad i = 1, 2, 3, 4 , \\ k_j = e_j - k , \quad j = 5, 6, 7 ; \\ t_i = \text{triangle sum} = \text{vertex sum}, \\ e_j = \text{opposite edge sum, in pairs}, \\ t_1 = j_1 + j_2 + j_3 , \quad t_2 = j_3 + j_4 + j_5 , \\ t_3 = j_1 + j_5 + j_6 , \quad t_4 = j_2 + j_4 + j_6 ,$$

$$e_1 = (j_2 + j_5) + (j_3 + j_6) , \\ e_2 = (j_1 + j_4) + (j_3 + j_6) , \\ e_3 = (j_1 + j_4) + (j_2 + j_5) .$$

The summation in Eq. (2.83b) is over the infinite set of all tetrahedra, that is, over the infinite set of arrays Δ having nonnegative integral entries. The $6-j$ coefficient is then given by

$$\begin{Bmatrix} j_1 & j_2 & j_3 \\ j_4 & j_5 & j_6 \end{Bmatrix} = \frac{T(\Delta)}{\Delta(j_1 j_2 j_3) \Delta(j_1 j_5 j_6) \Delta(j_2 j_4 j_6) \Delta(j_3 j_4 j_5)} .$$

Since the factor $T(\Delta)$ is an integer in the expansion Eq. (2.83a), this result shows that the $6-j$ coefficient is an integer, up to the multiplicative triangle coefficient factors.

2.9.5 Symmetries of $6-j$ Coefficients

There are 144 symmetry relations among the Racah $6-j$ coefficients. The 24 classical ones, given already by Racah and corresponding to the tetrahedral point group T_d of rotations-inversions (isomorphic to the symmetric group S_4) mapping the regular tetrahedron onto itself, are realized in the $6-j$ symbol

$$\begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix}$$

as permutations of its columns and the exchange of any pair of letters in the top row with the corresponding pair in the bottom row. *Regge* discovered the sixfold increase in symmetry by noting that each term in the summation in Eq. (2.77) is invariant not only to the classical 24 symmetries but also under certain linear transformations of the quantum labels. These symmetries are also implicit in Schwinger's generating function.

The full set, including the original 24 substitutions, of linear transformations of the letters a, b, c, d, e, f thus yields a group of linear transformations isomorphic to $S_4 \times S_3$. The column permutations and row-pair interchanges described above applied to each of the 6 symbols in the equalities below yield the set of 144 relationships:

$$\begin{Bmatrix} a & b & e \\ d & c & f \end{Bmatrix} \\ = \begin{Bmatrix} a & \frac{b+c+e-f}{2} & \frac{b+e+f-c}{2} \\ d & \frac{b+c+f-e}{2} & \frac{c+e+f-b}{2} \end{Bmatrix} \\ = \begin{Bmatrix} \frac{a+d+e-f}{2} & b & \frac{a+e+f-d}{2} \\ \frac{a+d+f-e}{2} & c & \frac{d+e+f-a}{2} \end{Bmatrix}$$

$$\begin{aligned}
&= \left\{ \frac{a+b+d-c}{2} \quad \frac{a+b+c-d}{2} \quad e \right\} \\
&= \left\{ \frac{a+b+d-c}{2} \quad \frac{b+c+e-f}{2} \quad \frac{a+e+f-d}{2} \right\} \\
&= \left\{ \frac{a+d+e-f}{2} \quad \frac{a+b+c-d}{2} \quad \frac{b+e+f-c}{2} \right\} \\
&= \left\{ \frac{a+d+f-e}{2} \quad \frac{b+c+d-a}{2} \quad \frac{c+e+f-b}{2} \right\}.
\end{aligned}$$

2.9.6 Further Properties

Recurrence relations:

Three-term:

$$\begin{aligned}
&[(a+b+e+1)(b+e-a) \\
&\quad \times (c+d+e+1)(d+e-c)]^{1/2} \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} \\
&= -2e[(b+d+f+1)(b+d-f)]^{1/2} \\
&\quad \times \left\{ \begin{matrix} a & b-\frac{1}{2} & e-\frac{1}{2} \\ d-\frac{1}{2} & c & f \end{matrix} \right\} \\
&\quad + [(a+b-e+1)(a+e-b)(c+d-e+1) \\
&\quad \times (c+e-d)]^{1/2} \left\{ \begin{matrix} a & b & e-1 \\ d & c & f \end{matrix} \right\}, \quad (2.84a)
\end{aligned}$$

$$\begin{aligned}
&[(a+c+f+1)(c+e-d) \\
&\quad \times (d+e-c+1)(b+d-f+1)]^{1/2} \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} \\
&= [(a+c-f)(a+e-b) \\
&\quad \times (b+f+d+2)(b+e-a+1)]^{1/2} \\
&\quad \times \left\{ \begin{matrix} a+\frac{1}{2} & b+\frac{1}{2} & e \\ d+\frac{1}{2} & c-\frac{1}{2} & f \end{matrix} \right\} \\
&\quad + [(c+f-a)(c+e-d)(b-a-c+d+1)]^{1/2} \\
&\quad \times \left\{ \begin{matrix} a & b & e \\ d+\frac{1}{2} & c-\frac{1}{2} & f-\frac{1}{2} \end{matrix} \right\}. \quad (2.84b)
\end{aligned}$$

Five-term:

$$\begin{aligned}
&(2c+1)(2d)(2f+1) \left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} \\
&= [(b+d-f)(b+f-d+1)(d+e-c) \\
&\quad \times (c+e-d+1)(c+f-a+1)(a+c+f+2)]^{1/2}
\end{aligned}$$

$$\begin{aligned}
&\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c+\frac{1}{2} & f+\frac{1}{2} \end{matrix} \right\} + [(b+d-f) \\
&\quad \times (b+f-d+1)(c+d-e)(c+d+e+1) \\
&\quad \times (a+c-f)(a+f-c+1)]^{1/2} \\
&\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c-\frac{1}{2} & f+\frac{1}{2} \end{matrix} \right\} - [(d+f-b) \\
&\quad \times (b+d+f+1)(c+d-e)(c+d+e+1) \\
&\quad \times (c+f-a)(a+c+f+1)]^{1/2} \\
&\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c-\frac{1}{2} & f-\frac{1}{2} \end{matrix} \right\} + [(d+f-b) \\
&\quad \times (b+d+f+1)(d+e-c)(c+e-d+1) \\
&\quad \times (a+f-c)(a+c-f+1)]^{1/2} \\
&\times \left\{ \begin{matrix} a & b & e \\ d-\frac{1}{2} & c+\frac{1}{2} & f-\frac{1}{2} \end{matrix} \right\}. \quad (2.84c)
\end{aligned}$$

Relation to hypergeometric series:

$$\begin{aligned}
\left\{ \begin{matrix} a & b & e \\ d & c & f \end{matrix} \right\} &= (-1)^{a+b+c+d} W(abcd; ef) \\
&= \Delta(abe)\Delta(cde)\Delta(acf)\Delta(bdf) \\
&\quad \times \frac{(-1)^{\beta_1}(\beta_1+1)!}{(\beta_2-\beta_1)!(\beta_3-\beta_1)!} \\
&\quad \times \frac{{}_4F_3\left(\begin{matrix} \alpha_1-\beta_1, & \alpha_2-\beta_1, & \alpha_3-\beta_1, & \alpha_4-\beta_1 \\ -\beta_1-1, & \beta_2-\beta_1+1, & \beta_3-\beta_1+1, & \end{matrix}; 1\right)}{(\beta_1-\alpha_1)!(\beta_1-\alpha_2)!(\beta_1-\alpha_3)!(\beta_1-\alpha_4)!}, \\
\beta_1 &= \min(a+b+c+d, a+d+e+f, b+c+e+f).
\end{aligned}$$

The parameters β_2 and β_3 are identified in either way with the pair remaining in the 3-tuple

$$(a+b+c+d, a+d+e+f, b+c+e+f)$$

after deleting β_1 . The $(\alpha_1, \alpha_2, \alpha_3, \alpha_4)$ may be identified with any permutation of the 4-tuple

$$(a+b+e, c+d+e, a+c+f, b+d+f).$$

The ${}_4F_3$ series is Saalschützian:

$$\begin{aligned}
&1 + \sum (\text{numerator parameters}) \\
&= \sum (\text{denominator parameters}).
\end{aligned}$$

2.10 The 9- j Coefficients

2.10.1 Hilbert Space and Tensor Operator Actions

Let $T^a(1)$ and $T^b(2)$ denote irreducible tensor operators of ranks a and b with respect to kinematically independent angular momentum operators $\mathbf{J}(1)$ and $\mathbf{J}(2)$ that act, respectively, in separable Hilbert spaces $\mathcal{H}(1)$ and $\mathcal{H}(2)$. Let $\mathcal{H}(1)$ and $\mathcal{H}(2)$ be reduced, respectively, into a direct sum of spaces $\mathcal{H}_{j_1}(1)$ and $\mathcal{H}_{j_2}(2)$. The angular momentum $\mathbf{J}(1)$ has the standard action on the orthonormal basis $\{|j_1 m_1\rangle \mid m_1 = j_1, j_1 - 1, \dots, -j_1\}$ of $\mathcal{H}_{j_1}(1)$, and $\mathbf{J}(2)$ has the standard action on the orthonormal basis $\{|j_2 m_2\rangle \mid m_2 = j_2, j_2 - 1, \dots, -j_2\}$ of $\mathcal{H}_{j_2}(2)$. The irreducible tensor operators $T^a(1)$ and $T^b(2)$ also have the standard actions in their respective Hilbert spaces $\mathcal{H}(1)$ and $\mathcal{H}(2)$, as given by the Wigner–Eckart theorem. The total angular momentum \mathbf{J} has the standard action on the coupled orthonormal basis of the tensor product space $\mathcal{H}_{j_1} \otimes \mathcal{H}_{j_2}$:

$$|(j_1 j_2) j m\rangle = \sum_{m_1 m_2} C_{m_1 m_2 m}^{j_1 j_2 j} |j_1 m_1\rangle \otimes |j_2 m_2\rangle. \quad (2.85)$$

The tensor product operator $T^a(1) \otimes T^b(2)$ acts in the tensor product space $\mathcal{H}(1) \otimes \mathcal{H}(2)$ according to the rule:

$$\begin{aligned} (T^a(1) \otimes T^b(2))(|j_1 m_1\rangle \otimes |j_2 m_2\rangle) \\ = T^a(1)|j_1 m_1\rangle \otimes T^b(2)|j_2 m_2\rangle, \end{aligned}$$

so that

$$\begin{aligned} (T^a(1) \otimes T^b(2))|(j_1 j_2) j m\rangle \\ = \sum_{m_1 m_2} C_{m_1 m_2 m}^{j_1 j_2 j} T^a(1)|j_1 m_1\rangle \otimes T^b(2)|j_2 m_2\rangle. \end{aligned} \quad (2.86a)$$

The angular momentum quantities called 9- j coefficients arise when the coupled tensor operators $T^{(ab)c}$ with components γ defined by

$$\begin{aligned} T_{\gamma}^{(ab)c} &= \sum_{\alpha\beta} C_{\alpha\beta\gamma}^{abc} T_{\alpha}^a(1) \otimes T_{\beta}^b(2), \\ \gamma &= c, c-1, \dots, -c, \end{aligned} \quad (2.86b)$$

are considered. The quantity $T^{(ab)c}$ is an irreducible tensor operator of rank c with respect to the total angular momentum \mathbf{J} for all a, b that yield c under the rule of addition of angular momentum.

2.10.2 9- j Invariant Operators

The entire angular momentum content of relation Eq. (2.86b) is captured by taking the irreducible tensor operators $T^a(1)$

and $T^b(2)$ to be unit tensor operators acting in the respective spaces $\mathcal{H}(1)$ and $\mathcal{H}(2)$:

$$\begin{aligned} T_{(\rho\sigma)\gamma}^{(ab)c} \\ = \sum_{\alpha\beta} C_{\alpha\beta\gamma}^{abc} \left\langle \begin{array}{ccc} 2a & \alpha + \rho & 0 \\ & a + \alpha & \end{array} \right\rangle_1 \otimes \left\langle \begin{array}{ccc} 2b & b + \sigma & 0 \\ & b + \beta & \end{array} \right\rangle_2. \end{aligned} \quad (2.87)$$

The placement of the unit tensor operators shows in which space they act, so that the additional identification by indices 1 and 2 could be eliminated. For each given $c \in \{0, 1/2, 1, 3/2, 2, \dots\}$ and all a, b such that the triangle relation (abc) is satisfied, and, for each such pair a, b , all ρ, σ with $\rho \in \{a, a-1, \dots, -a\}$, $\sigma \in \{b, b-1, \dots, -b\}$, an irreducible tensor operator of rank c with respect to the total angular momentum \mathbf{J} with components γ is defined by Eq. (2.87). By the Wigner–Eckart theorem, it must be possible to write

$$\begin{aligned} \sum_{\alpha\beta} C_{\alpha\beta\gamma}^{abc} \left\langle \begin{array}{ccc} 2a & \alpha + \rho & 0 \\ & a + \alpha & \end{array} \right\rangle_1 \otimes \left\langle \begin{array}{ccc} 2b & b + \sigma & 0 \\ & b + \beta & \end{array} \right\rangle_2 \\ = \sum_{\tau} \left[\begin{array}{ccc} abc \\ \rho\sigma\tau \end{array} \right] \left\langle \begin{array}{ccc} c + \tau & & \\ 2c & & 0 \\ c + \gamma & & \end{array} \right\rangle. \end{aligned} \quad (2.88)$$

Where (i) the unit tensor operator on the right-hand side is a irreducible tensor operator with respect to \mathbf{J} ; that is, it has the action on the coupled states given by

$$\begin{aligned} \left\langle \begin{array}{ccc} c + \tau & & \\ 2c & & 0 \\ c + \gamma & & \end{array} \right\rangle |(j_1 j_2) j m\rangle \\ = C_{m, \gamma, m+\gamma}^{j, c, j+\tau} |(j_1 j_2) j + \tau, m + \gamma\rangle; \end{aligned} \quad (2.89)$$

and (ii) the symbol $\left[\begin{array}{ccc} abc \\ \rho\sigma\tau \end{array} \right]$ denotes an invariant operator with respect to the total angular momentum \mathbf{J} . Using the orthogonality of unit tensor operators, we can also write relation Eq. (2.88) in the form:

$$\begin{aligned} \left[\begin{array}{ccc} abc \\ \rho\sigma\tau \end{array} \right] &= \sum_{\alpha\beta\gamma} C_{\alpha\beta\gamma}^{abc} \left\langle \begin{array}{ccc} a + \rho & & \\ 2a & & 0 \\ a + \alpha & & \end{array} \right\rangle_1 \\ &\otimes \left\langle \begin{array}{ccc} b + \sigma & & \\ 2b & & 0 \\ b + \beta & & \end{array} \right\rangle_2 \left\langle \begin{array}{ccc} c + \tau & & \\ 2c & & 0 \\ c + \gamma & & \end{array} \right\rangle^{\dagger}. \end{aligned} \quad (2.90)$$

This form is taken as the definition of the 9- j invariant operator. Its eigenvalues in the coupled basis define the 9- j

coefficient:

$$\begin{aligned}
 & \begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix} |(j_1 j_2) j m\rangle \\
 &= \langle (j_1 + \rho, j_2 + \sigma) j + \tau | \begin{bmatrix} abc \\ \rho\sigma\tau \end{bmatrix} |(j_1 j_2) j\rangle \\
 & \quad \times |(j_1 j_2) j m\rangle \\
 &= [(2j + 1)(2c + 1)(2j_1 + 2\rho + 1)(2j_2 + 2\sigma + 1)]^{\frac{1}{2}} \\
 & \quad \times \begin{Bmatrix} j_1 & j_2 & j \\ a & b & c \\ j_1 + \rho & j_2 + \sigma & j + \tau \end{Bmatrix} |(j_1 j_2) j m\rangle. \quad (2.91)
 \end{aligned}$$

The 9- j invariant operators play exactly the same role in the tensor product space of two irreducible angular momentum spaces as do the Racah invariants in one such irreducible angular momentum space.

The full content of the coupling law Eq. (2.86b) for physical irreducible tensor operators is regained in the coupling law for reduced matrix elements:

$$\begin{aligned}
 & \langle (\alpha'_1 \alpha'_2 j'_1 j'_2) j' | [T^a(1) \times T^b(2)]^c | (\alpha_1 \alpha_2 j_1 j_2) j \rangle \\
 &= \begin{bmatrix} j_1 & j_2 & j \\ a & b & c \\ j'_1 & j'_2 & j' \end{bmatrix} \langle (\alpha'_1) j'_1 | T^a(1) | (\alpha_1) j_1 \rangle \\
 & \quad \times \langle (\alpha'_2) j'_2 | T^b(2) | (\alpha_2) j_2 \rangle; \quad (2.92a)
 \end{aligned}$$

$$\begin{aligned}
 & \begin{bmatrix} j_1 & j_2 & j \\ a & b & c \\ j'_1 & j'_2 & j' \end{bmatrix} \\
 &= [(2j'_1 + 1)(2j'_2 + 1)(2j + 1)(2c + 1)]^{\frac{1}{2}} \\
 & \quad \times \begin{Bmatrix} j_1 & j_2 & j \\ a & b & c \\ j'_1 & j'_2 & j' \end{Bmatrix}. \quad (2.92b)
 \end{aligned}$$

2.10.3 Basic Relations Between 9- j Coefficients and 6- j Coefficients

Orthogonality of 9- j coefficients:

$$\begin{aligned}
 & \sum_{hi} (2c + 1)(2f + 1)(2h + 1)(2i + 1) \\
 & \quad \times \begin{Bmatrix} a & b & c \\ d & e & f \\ h & i & j \end{Bmatrix} \begin{Bmatrix} a & b & c' \\ d & e & f' \\ h & i & j \end{Bmatrix} = \delta_{cc'} \delta_{ff'},
 \end{aligned}$$

where this relation is to be applied only to triples (abc) , (def) , (cfj) , (abc') , (def') , $(c'f'j)$ for which the triangle conditions hold.

9- j coefficients in terms of 3- j coefficients:

$$\begin{aligned}
 & \delta_{j_3 j'_3} (2j_3 + 1)^{-1} \begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ j_{21} & j_{22} & j_{23} \\ j_{31} & j_{32} & j_{33} \end{Bmatrix} \\
 &= \sum_{\substack{\text{all } m_{ij} \\ \text{except } m_{33}}} \begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ m_{11} & m_{12} & m_{13} \end{Bmatrix} \begin{Bmatrix} j_{21} & j_{22} & j_{23} \\ m_{21} & m_{22} & m_{23} \end{Bmatrix} \\
 & \quad \times \begin{Bmatrix} j_{31} & j_{32} & j_{33} \\ m_{31} & m_{32} & m_{33} \end{Bmatrix} \begin{Bmatrix} j_{11} & j_{21} & j_{31} \\ m_{11} & m_{21} & m_{31} \end{Bmatrix} \\
 & \quad \times \begin{Bmatrix} j_{12} & j_{22} & j_{32} \\ m_{12} & m_{22} & m_{32} \end{Bmatrix} \begin{Bmatrix} j_{13} & j_{23} & j'_{33} \\ m_{13} & m_{23} & m_{33} \end{Bmatrix}. \quad (2.93)
 \end{aligned}$$

9- j coefficients in terms of 6- j coefficients:

$$\begin{aligned}
 & \begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ j_{21} & j_{22} & j_{23} \\ j_{31} & j_{32} & j_{33} \end{Bmatrix} = \sum_k (-1)^{2k} (2k + 1) \\
 & \quad \times \begin{Bmatrix} j_{11} & j_{21} & j_{31} \\ j_{32} & j_{33} & k \end{Bmatrix} \begin{Bmatrix} j_{12} & j_{22} & j_{32} \\ j_{21} & k & j_{23} \end{Bmatrix} \\
 & \quad \times \begin{Bmatrix} j_{13} & j_{23} & j_{33} \\ k & j_{11} & j_{12} \end{Bmatrix}. \quad (2.94)
 \end{aligned}$$

Basic defining relation for 9- j coefficient from Eq. (2.88):

$$\begin{aligned}
 & (-1)^\phi \begin{Bmatrix} j_{12} & j_{22} & j_{32} \\ j_{11} & j_{21} & j_{31} \\ j_{13} & j_{23} & j_{33} \end{Bmatrix} \begin{Bmatrix} j_{31} & j_{32} & j_{33} \\ m_{31} & m_{32} & m_{33} \end{Bmatrix} \\
 &= \sum_{\text{all } m_{(1i)m_{(2i)}}} \begin{Bmatrix} j_{11} & j_{21} & j_{31} \\ m_{11} & m_{21} & m_{31} \end{Bmatrix} \\
 & \quad \times \begin{Bmatrix} j_{12} & j_{22} & j_{32} \\ m_{12} & m_{22} & m_{32} \end{Bmatrix} \begin{Bmatrix} j_{13} & j_{23} & j_{33} \\ m_{13} & m_{23} & m_{33} \end{Bmatrix} \\
 & \quad \times \begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ m_{11} & m_{12} & m_{13} \end{Bmatrix} \begin{Bmatrix} j_{21} & j_{22} & j_{23} \\ m_{21} & m_{22} & m_{23} \end{Bmatrix}, \\
 & \phi = \sum_{kl} j_{kl}. \quad (2.95)
 \end{aligned}$$

Additional relations:

$$\begin{aligned}
 & \sum_{kl} (-1)^{2b+l+h-f} (2k + 1)(2l + 1) \\
 & \quad \times \begin{Bmatrix} a & b & c \\ e & d & f \\ k & l & i \end{Bmatrix} \begin{Bmatrix} a & e & k \\ d & b & l \\ g & h & i \end{Bmatrix} = \begin{Bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{Bmatrix},
 \end{aligned}$$

$$\begin{aligned}
& \sum_c (2c+1) \begin{Bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{Bmatrix} \begin{Bmatrix} a & b & c \\ f & i & j \end{Bmatrix} \\
&= (-1)^{2j} \begin{Bmatrix} d & e & f \\ b & j & h \end{Bmatrix} \begin{Bmatrix} g & h & i \\ j & a & d \end{Bmatrix}, \\
& \sum_{klm} (2k+1)(2l+1)(2m+1) \\
& \quad \times \begin{Bmatrix} a & b & c \\ d & e & f \\ k & l & m \end{Bmatrix} \begin{Bmatrix} k & l & m \\ a' & b' & c' \\ d' & e' & f' \end{Bmatrix} \\
& \quad \times \begin{Bmatrix} a & d & k \\ a' & d' & k' \end{Bmatrix} \begin{Bmatrix} b & e & l \\ b' & e' & l' \end{Bmatrix} \begin{Bmatrix} c & f & m \\ c' & f' & m' \end{Bmatrix} \\
&= \begin{Bmatrix} a & b & c \\ d' & e' & f' \\ k' & l' & m' \end{Bmatrix} \begin{Bmatrix} k' & l' & m' \\ a' & b' & c' \\ d & e & f \end{Bmatrix}.
\end{aligned}$$

2.10.4 Symmetry Relations for 9- j Coefficients and Reduction to 6- j Coefficients

The 9- j coefficient

$$\begin{Bmatrix} j_{11} & j_{12} & j_{13} \\ j_{21} & j_{22} & j_{23} \\ j_{31} & j_{32} & j_{33} \end{Bmatrix}$$

is invariant under even permutation of its rows, even permutation of its columns, and under the interchange of rows and columns (matrix transposition). It is multiplied by the factor $(-1)^\phi$ Eq. (2.95) under odd permutations of its rows or columns. These 72 symmetries are all consequences of the 72 symmetries of the 3- j coefficient in relation Eq. (2.93).

Reduction to 6- j coefficients:

$$\begin{aligned}
\begin{Bmatrix} a & b & e \\ c & d & e \\ f & f & 0 \end{Bmatrix} &= \begin{Bmatrix} 0 & e & e \\ f & d & b \\ f & c & a \end{Bmatrix} = \begin{Bmatrix} e & 0 & e \\ c & f & a \\ d & f & b \end{Bmatrix} \\
&= \begin{Bmatrix} f & f & 0 \\ d & c & e \\ b & a & e \end{Bmatrix} = \begin{Bmatrix} f & b & d \\ 0 & e & e \\ f & a & c \end{Bmatrix} = \begin{Bmatrix} a & f & c \\ e & 0 & e \\ b & f & d \end{Bmatrix} \\
&= \begin{Bmatrix} b & a & e \\ f & f & 0 \\ d & c & e \end{Bmatrix} = \begin{Bmatrix} e & d & c \\ e & b & a \\ 0 & f & f \end{Bmatrix} = \begin{Bmatrix} c & e & d \\ a & e & b \\ f & 0 & f \end{Bmatrix} \\
&= \frac{(-1)^{b+c+e+f}}{[(2e+1)(2f+1)]^{\frac{1}{2}}} \begin{Bmatrix} a b e \\ d c f \end{Bmatrix}.
\end{aligned}$$

2.10.5 Explicit Algebraic Form of 9- j Coefficients

$$\begin{aligned}
\begin{Bmatrix} a & b & c \\ d & e & f \\ h & i & j \end{Bmatrix} &= (1)^{c+f-j} \frac{(dah)(bei)(jhi)}{(def)(bac)(jcf)} \\
&\times \sum_{xyz} \frac{(-1)^{x+y+z}}{x!y!z!} \\
&\times \frac{(2f-x)!(2a-z)!}{(2i+1+y)!(a+d+h+1-z)!} \\
&\times \frac{(d+e-f+x)!(c+j-f+x)!}{(e+f-d-x)!(c+f-j-x)!} \\
&\times \frac{(e+i-b+y)!(h+i-j+y)!}{(b+e-i-y)!(h+j-i-y)!} \\
&\times \frac{(b+c-a+z)!}{(a+d-h-z)!(a+c-b-z)!} \\
&\times \frac{(a+d+j-i-y-z)!}{(d+i-b-f+x+y)!(b+j-a-f+x+z)!}, \\
(abc) &= \left(\frac{(a-b+c)!(a+b-c)!(a+b+c+1)!}{(b+c-a)!} \right)^{\frac{1}{2}}.
\end{aligned}$$

2.10.6 Racah Operators

A Racah operator is denoted

$$\begin{Bmatrix} a + \rho & & \\ 2a & & 0 \\ & a + \sigma & \end{Bmatrix} \quad \rho, \sigma = a, a-1, \dots, -a, \\
2a = 0, 1, 2, \dots$$

and is a special case of the operator defined by Eq. (2.87):

$$\begin{aligned}
& \begin{Bmatrix} a + \rho & & \\ 2a & & 0 \\ & a + \sigma & \end{Bmatrix} |(j_1 j_2) j m\rangle \\
&= \left(\frac{(2a+1)(2j_2+1)}{(2j_2+2\sigma+1)} \right)^{\frac{1}{2}} \mathbf{T}_{(\rho\sigma)0}^{(aa)0} |(j_1 j_2) j m\rangle. \quad (2.96)
\end{aligned}$$

Thus, a Racah operator is an invariant operator with respect to the total angular momentum \mathbf{J} . Alternative definitions are:

$$\begin{aligned}
& \begin{Bmatrix} a + \rho & & \\ 2a & & 0 \\ & a + \sigma & \end{Bmatrix} \\
&= (-1)^{a+\sigma} \sum_a \begin{Bmatrix} a + \rho & & \\ 2a & & 0 \\ & a + \alpha & \end{Bmatrix} \otimes \begin{Bmatrix} a - \sigma & & \\ 2a & & 0 \\ & a + \alpha & \end{Bmatrix}^\dagger,
\end{aligned}$$

$$\left\{ \begin{array}{ccc} a + \rho & & \\ 2a & & 0 \\ & a + \sigma & \end{array} \right\} |(j_1 j_2) j m\rangle$$

$$= [(2j_1 + 2\rho + 1)(2j_2 + 1)]^{\frac{1}{2}}$$

$$\times W(j, j_1, j_2 + \sigma, a; j_2, j_1 + \rho)$$

$$\times |(j_1 + \rho, j_2 + \sigma) j m\rangle,$$

with conjugate

$$\left\{ \begin{array}{ccc} a + \rho & & \\ 2a & & 0 \\ & a + \sigma & \end{array} \right\}^\dagger |(j_1 j_2) j m\rangle$$

$$= [(2j_1 + 1)(2j_2 - 2\sigma + 1)]^{\frac{1}{2}}$$

$$\times W(j, j_1 - \rho, j_2, a; j_2 - \sigma, j_1)$$

$$\times |(j_1 - \rho, j_2 - \sigma) j m\rangle.$$

Racah operators satisfy orthogonality relations similar in form to Wigner operators. The open product rule is:

$$\left\{ \begin{array}{ccc} b + \sigma & & \\ 2b & & 0 \\ & b + \beta & \end{array} \right\} \left\{ \begin{array}{ccc} a + \rho & & \\ 2a & & 0 \\ & a + \alpha & \end{array} \right\}$$

$$= \sum_c \overline{W}_{\rho, \sigma, \rho + \sigma}^{abc} W_{\alpha, \beta, \alpha + \beta}^{abc} \left\{ \begin{array}{ccc} c + \rho + \sigma & & \\ 2c & & 0 \\ & c + \alpha + \beta & \end{array} \right\}. \quad (2.97)$$

In this result, $\overline{W}_{\rho\sigma\tau}^{abc}$ and $W_{\alpha, \beta, \alpha + \beta}^{abc}$ denote Racah invariants with respect to the angular momenta $\mathbf{J}(1)$ and $\mathbf{J}(2)$, respectively, so that

$$\overline{W}_{\rho\sigma\tau}^{abc} |(j_1 j_2) j m\rangle = W_{\rho\sigma\tau}^{abc}(j_1) |(j_1 j_2) j m\rangle,$$

$$\underline{W}_{\alpha\beta\gamma}^{abc} |(j_1 j_2) j m\rangle = W_{\alpha\beta\gamma}^{abc}(j_2) |(j_1 j_2) j m\rangle.$$

The matrix elements of relation Eq. (2.97) lead to the Biedenharn–Elliott identity. There are five versions of this relationship in complete analogy to relations Eqs. (2.63)–(2.65) and (2.69)–(2.70) for Wigner operators.

Racah operators are a basis for all invariant operators acting in the tensor product space spanned by the coupled basis vectors Eq. (2.85) and are the natural way of formulating interactions in that space. Their algebra is a fascinating study, initiated already in a different guise in the work of Schwinger [3]. Little use has been made of this concept in physical applications.

Additional relations between Racah coefficients or 6– j coefficients may be derived from the various versions of the rule Eq. (2.97) or directly from relation Eq. (2.79b) by using

the orthogonality relations Eq. (2.75). Two of these are:

$$\sum_e (-1)^{a+b+e} (2e + 1)$$

$$\times \left\{ \begin{array}{ccc} a & b & e \\ d & c & g \end{array} \right\} \left\{ \begin{array}{ccc} a' & a & c' \\ b & b' & e \end{array} \right\} \left\{ \begin{array}{ccc} a' & e & b' \\ d & d' & c \end{array} \right\}$$

$$= (-1)^{\phi_1} \left\{ \begin{array}{ccc} c' & b & b' \\ d & d' & g \end{array} \right\} \left\{ \begin{array}{ccc} a' & a & c' \\ g & d' & c \end{array} \right\},$$

$$\phi_1 = g + a' + b' + c' + c + d' + d;$$

$$\sum_{e, e'} (-1)^{a-c'+e-e'} (2e + 1)(2e' + 1)(2f + 1)$$

$$\times \left\{ \begin{array}{ccc} c' & b & e' \\ d & d' & f \end{array} \right\} \left\{ \begin{array}{ccc} a & b & e \\ d & c & g \end{array} \right\} \left\{ \begin{array}{ccc} a' & a & c' \\ b & e' & e \end{array} \right\} \left\{ \begin{array}{ccc} a' & e & e' \\ d & d' & c \end{array} \right\}$$

$$= \delta_{fg} (-1)^{\phi_2} \left\{ \begin{array}{ccc} a' & a & c' \\ g & d' & c \end{array} \right\},$$

$$\phi_2 = g + a' - b + c + d' + d.$$

The W coefficient form of these relations is obtained by deleting all phase factors and making the substitution Eq. (2.74), ignoring the phase factor. There are no phase factors in the corresponding W coefficient relations.

2.10.7 Schwinger–Wu Generating Function and Its Combinatorics

Triangles associated with the 9– j coefficient $\left\{ \begin{array}{ccc} j_1 j_2 j_3 \\ j_4 j_5 j_6 \\ j_7 j_8 j_9 \end{array} \right\}$:

$$(j_1 j_2 j_3), (j_4 j_5 j_6), (j_7 j_8 j_9), (j_1 j_4 j_7),$$

$$(j_2 j_5 j_8), (j_3 j_6 j_9).$$

Points in \mathbf{R}^3 associated with the triangles:

$$(j_1 j_2 j_3) \rightarrow (x_1, x_2, x_3), (j_4 j_5 j_6) \rightarrow (x_4, x_5, x_6),$$

$$(j_7 j_8 j_9) \rightarrow (x_7, x_8, x_9), (j_1 j_4 j_7) \rightarrow (y_1, y_4, y_7),$$

$$(j_2 j_5 j_8) \rightarrow (y_2, y_5, y_8), (j_3 j_6 j_9) \rightarrow (y_3, y_6, y_9).$$

Cubic graph \mathbf{C}_6 in \mathbf{R}^3 associated with the points:

The points define the vertices of a cubic graph \mathbf{C}_6 on six points with lines joining each pair of points that share a common subscript, and the lines are labeled by the products $x_i y_i$, where i is the common subscript (Fig. 2.3).

Cubic graph \mathbf{C}_6 functions:

Interchange the symbols x and y in the coordinates of the vertices of the cubic graph \mathbf{C}_6 and define the following polynomials on the vertices and edges of the \mathbf{C}_6 with this modified labeling.

Fig. 2.3 Labeled cubic graph associated with the $9-j$ coefficient

Vertex function: multiply together the coordinates of each pair of adjacent vertices, divide out the coordinates with a common subscript, and sum over all pairs of vertices to obtain

$$V_4 = y_1 y_2 x_6 x_9 + y_1 y_3 x_5 x_8 + y_2 y_3 x_4 x_7 \\ + y_4 y_5 x_3 x_9 + y_4 y_6 x_2 x_8 + y_5 y_6 x_1 x_7 \\ + y_7 y_8 x_3 x_6 + y_7 y_9 x_2 x_5 + y_8 y_9 x_1 x_4 .$$

Edge function:

$$E_6 = \det \begin{bmatrix} x_1 y_1 & x_2 y_2 & x_3 y_3 \\ x_4 y_4 & x_5 y_5 & x_6 y_6 \\ x_7 y_7 & x_8 y_8 & x_9 y_9 \end{bmatrix} .$$

Generating function [4–6]:

$$(1 - V_4 + E_6)^{-2} = \sum_{\Delta} C(\Delta) Z^{\Delta} ,$$

$$Z^{\Delta} = \prod_{\text{all vertices}} (z_a, z_b, z_c)^{(j_a j_b j_c)} \quad (\text{see Eq. (2.82)}) ,$$

$$\Delta = \begin{bmatrix} (j_1 j_2 j_3) \\ (j_4 j_5 j_6) \\ (j_7 j_8 j_9) \\ (j_1 j_4 j_7) \\ (j_2 j_5 j_8) \\ (j_3 j_6 j_9) \end{bmatrix} ,$$

$$C(\Delta) = \sum_k \sum_{\square} \sum_a (-1)^{k_{10} + k_{11} + k_{12}} (k+1) \\ \times \binom{k}{k_1, \dots, k_9, k_{10}, \dots, k_{15}} ,$$

where summation \sum_{\square} is over all 3×3 square arrays of nonnegative integers k_j ($j = 1, 2, \dots, 9$) with fixed row and column sums given by

$$\begin{bmatrix} k_1 & k_2 & k_3 \\ k_4 & k_5 & k_6 \\ k_7 & k_8 & k_9 \end{bmatrix} \quad \begin{matrix} k - t_1 \\ k - t_2 \\ k - t_3 \\ k - t_4 & k - t_5 & k - t_6 \end{matrix}$$

and for each such array the summation \sum_a is over all nonnegative integers a such that the following quantities are nonnegative integers:

$$k_{10} = -a + k_1 - k + j_2 + j_3 + j_4 + j_7 , \\ k_{11} = -a + k_6 - k + j_3 + j_4 + j_5 + j_9 , \\ k_{12} = -a + k_8 - k + j_2 + j_5 + j_7 + j_9 , \\ k_{13} = a + k_5 - k_1 - j_3 + j_6 - j_7 + j_8 , \\ k_{14} = a + k_2 - k_6 + j_1 - j_4 + j_8 - j_9 , \\ k_{15} = a .$$

Note that

$$\sum_{i=10}^{15} k_i = -2k + \sum_{i=1}^9 j_i .$$

The t_i are the following triangle sums:

$$t_1 = j_1 + j_2 + j_3, \quad t_2 = j_4 + j_5 + j_6 , \\ t_3 = j_7 + j_8 + j_9 , \\ t_4 = j_1 + j_4 + j_7, \quad t_5 = j_2 + j_5 + j_8 , \\ t_6 = j_3 + j_6 + j_9 .$$

The $9-j$ coefficient is given by

$$\begin{Bmatrix} j_1 j_2 j_3 \\ j_4 j_5 j_6 \\ j_7 j_8 j_9 \end{Bmatrix} = \Delta(j_1 j_2 j_3) \Delta(j_4 j_5 j_6) \Delta(j_7 j_8 j_9) \\ \times \Delta(j_1 j_4 j_7) \Delta(j_2 j_5 j_8) \Delta(j_3 j_6 j_9) C(\Delta) .$$

The coefficient $C(\Delta)$ is an integer associated with each cubic graph C_6 that counts the number of occurrences of the monomial term Z^{Δ} in the expansion of $(1 - V_4 + E_6)^{-2}$.

2.11 Tensor Spherical Harmonics

Tensor spherical or tensor solid harmonics are special cases of the coupling of two irreducible tensor operators in the tensor product space given in Sect. 2.7.2. They are defined by

$$\mathbf{y}^{(ls)jm} = \sum_v C_{m-v, v, m}^{l s j} \mathbf{y}_{l, m-v} \otimes \xi_v$$

and belong to the tensor product space $\mathcal{H}_l \otimes \mathcal{H}'_s$, where the orthonormal bases of the spaces \mathcal{H}_l and \mathcal{H}'_s are:

$$\{\mathbf{y}_{l\mu} : \mu = l, l-1, \dots, -l\} , \\ \{\xi_v : v = s, s-1, \dots, -s\} .$$

The orbital angular momentum \mathbf{L} has the standard action on the solid harmonics, and a second set of kinematically independent angular momentum operators \mathbf{S} has the standard action on the basis set of \mathcal{H}'_s .

The total angular momentum is:

$$\mathbf{J} = \mathbf{L} \otimes \mathbf{1}' + \mathbf{1} \otimes \mathbf{S},$$

The set of vectors

$$\{ \mathbf{y}^{(ls)jm} : m = j, j-1, \dots, -j; (lsj) \text{ obey the triangle conditions} \}$$

has the following properties:

Orthogonality:

$$\begin{aligned} & \langle \mathbf{y}^{(l's)j'm'}, \mathbf{y}^{(ls)jm} \rangle \\ &= \sum_{vv'} C_{m'-v',v',m'}^{l's j'} C_{m-v,v,m}^{lsj} (\mathbf{y}_{l',m'-v'}, \mathbf{y}_{l,m-v}) \\ & \times (\xi_{v'}, \xi_v)' = \delta_{j'l'} \delta_{l'l} \delta_{m'm}, \end{aligned}$$

where \langle , \rangle denotes the inner product in the space $\mathcal{H}_l \otimes \mathcal{H}_s'$, $(,)$ the inner product in \mathcal{H}_l , and $(,)'$ the inner product in \mathcal{H}_s' .

Operator actions:

$$\begin{aligned} \mathbf{J}^2 \mathbf{y}^{(ls)jm} &= j(j+1) \mathbf{y}^{(ls)jm}, \\ J_3 \mathbf{y}^{(ls)jm} &= m \mathbf{y}^{(ls)jm}, \\ (\mathbf{L}^2 \otimes \mathbf{1}') \mathbf{y}^{(ls)jm} &= l(l+1) \mathbf{y}^{(ls)jm}, \\ (\mathbf{1} \otimes \mathbf{S}^2) \mathbf{y}^{(ls)jm} &= s(s+1) \mathbf{y}^{(ls)jm}, \\ \mathbf{J}^2 &= \mathbf{L}^2 \otimes \mathbf{1}' + \mathbf{1} \otimes \mathbf{S}^2 + 2 \sum_i L_i \otimes S_i, \\ J_{\pm} \mathbf{y}^{(ls)jm} &= [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}} \mathbf{y}^{(ls)j,m \pm 1}. \end{aligned}$$

Transformation property under unitary rotations:

$$\exp(-i \psi \hat{\mathbf{n}} \cdot \mathbf{J}) \mathbf{y}^{(ls)jm} = \sum_{m'} D_{m'm}^j(\psi, \hat{\mathbf{n}}) \mathbf{y}^{(ls)jm'}.$$

Special realization:

The eigenvectors ξ_v are often replaced by column matrices:

$$\begin{aligned} \xi_v &= \text{col}(0 \cdots 0 1 0 \cdots 0), \\ & \text{1 in position } s - v + 1, \quad v = s, s-1, \dots, -s. \end{aligned}$$

The operators $\mathbf{S} = (S_1, S_2, S_3)$ are correspondingly replaced by their standard $(2s+1) \times (2s+1)$ matrix representations $S_i^{(s)}$. The tensor product of operators becomes a $(2s+1) \times (2s+1)$ matrix containing both operators and numerical matrix elements, e.g.,

$$J_i = L_i I_{2s+1} + S_i^{(s)},$$

in which L_i is a differential operator multiplying the unit matrix, that is, L_i is repeated $2s+1$ times along the diagonal.

2.11.1 Spinor Spherical Harmonics as Matrix Functions

Choose $\xi_{+1/2} = \text{col}(1, 0)$, $\xi_{-1/2} = \text{col}(0, 1)$, and $\mathbf{S} = \boldsymbol{\sigma}/2$. The spinor spherical harmonics or Pauli central field spinors are the following, where $j \in \{1/2, 3/2, \dots\}$:

$$\begin{aligned} \mathbf{y}^{(j-\frac{1}{2}, \frac{1}{2})jm} &= \begin{pmatrix} \sqrt{\frac{j+m}{2j}} \mathbf{y}_{j-\frac{1}{2}, m-\frac{1}{2}} \\ \sqrt{\frac{j-m}{2j}} \mathbf{y}_{j-\frac{1}{2}, m+\frac{1}{2}} \end{pmatrix}, \\ \mathbf{y}^{(j+\frac{1}{2}, \frac{1}{2})jm} &= \begin{pmatrix} -\sqrt{\frac{j-m+1}{2j+2}} \mathbf{y}_{j+\frac{1}{2}, m-\frac{1}{2}} \\ \sqrt{\frac{j+m+1}{2j+2}} \mathbf{y}_{j+\frac{1}{2}, m+\frac{1}{2}} \end{pmatrix}. \end{aligned}$$

2.11.2 Vector Spherical Harmonics as Matrix Functions

Choose $\xi_{+1} = \text{col}(1, 0, 0)$, $\xi_0 = \text{col}(0, 1, 0)$, $\xi_{-1} = \text{col}(0, 0, 1)$, and \mathbf{S} the 3×3 angular momentum matrices given by

$$\begin{aligned} S_+ &= \begin{pmatrix} 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \\ 0 & 0 & 0 \end{pmatrix}, \quad S_- = \begin{pmatrix} 0 & 0 & 0 \\ \sqrt{2} & 0 & 0 \\ 0 & \sqrt{2} & 0 \end{pmatrix}, \\ S_3 &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}. \end{aligned}$$

The vector spherical harmonics are the following, where $j \in \{0, 1, 2, \dots\}$:

$$\begin{aligned} \mathbf{y}^{(j-1,1)jm} &= \begin{pmatrix} \sqrt{\frac{(j+m-1)(j+m)}{2j(2j-1)}} \mathbf{y}_{j-1, m-1} \\ \sqrt{\frac{(j-m)(j+m)}{j(2j-1)}} \mathbf{y}_{j-1, m} \\ \sqrt{\frac{(j-m-1)(j-m)}{2j(2j-1)}} \mathbf{y}_{j-1, m+1} \end{pmatrix}, \\ \mathbf{y}^{(j,1)jm} &= \begin{pmatrix} -\sqrt{\frac{(j+m)(j-m+1)}{2j(j+1)}} \mathbf{y}_{j, m-1} \\ \frac{m}{\sqrt{j(j+1)}} \mathbf{y}_{j, m} \\ \sqrt{\frac{(j-m)(j+m+1)}{2j(j+1)}} \mathbf{y}_{j, m+1} \end{pmatrix}, \\ \mathbf{y}^{(j+1,1)jm} &= \begin{pmatrix} \sqrt{\frac{(j-m+1)(j-m+2)}{2(j+1)(2j+3)}} \mathbf{y}_{j+1, m-1} \\ -\sqrt{\frac{(j-m+1)(j+m+1)}{(j+1)(2j+3)}} \mathbf{y}_{j+1, m} \\ \sqrt{\frac{(j+m+2)(j+m+1)}{2(j+1)(2j+3)}} \mathbf{y}_{j+1, m+1} \end{pmatrix}. \end{aligned}$$

Eigenvalue properties:

$$\begin{aligned}\nabla^2 \mathbf{y}^{(l)jm} &= 0, \\ \mathbf{J}^2 \mathbf{y}^{(l)jm} &= j(j+1) \mathbf{y}^{(l)jm}, \\ \mathbf{J}_3 \mathbf{y}^{(l)jm} &= m \mathbf{y}^{(l)jm}, \\ \mathbf{L}^2 \mathbf{y}^{(l)jm} &= l(l+1) \mathbf{y}^{(l)jm}, \\ \mathbf{S}^2 \mathbf{y}^{(l)jm} &= 2 \mathbf{y}^{(l)jm}.\end{aligned}$$

2.11.3 Vector Solid Harmonics as Vector Functions

Vector spherical and solid harmonics can also be defined and their properties presented in terms of the ordinary solid harmonics, using the vectors \mathbf{x} , ∇ , and \mathbf{L} , and the operations of divergence and curl.

Defining equations:

$$\begin{aligned}\mathbf{y}^{(l+1,1)lm} &= -[(l+1)(2l+1)]^{-\frac{1}{2}} [(l+1)\mathbf{x} \\ &\quad + \mathbf{i}\mathbf{x} \times \mathbf{L}] \mathbf{y}_{lm}, \\ \mathbf{y}^{(l,1)lm} &= [l(l+1)]^{-1/2} \mathbf{L} \mathbf{y}_{lm}, \\ r^2 \mathbf{y}^{(l-1,1)lm} &= -[l(2l+1)]^{-\frac{1}{2}} \times (-l\mathbf{x} + \mathbf{i}\mathbf{x} \\ &\quad \times \mathbf{L}) \mathbf{y}_{lm}.\end{aligned}$$

Eigenvalue properties:

$$\begin{aligned}\mathbf{J}^2 \mathbf{y}^{(l)jm} &= j(j+1) \mathbf{y}^{(l)jm}, \\ \mathbf{L}^2 \mathbf{y}^{(l)jm} &= l(l+1) \mathbf{y}^{(l)jm}, \\ \mathbf{S}^2 \mathbf{y}^{(l)jm} &= 2 \mathbf{y}^{(l)jm}, \\ \mathbf{J}_3 \mathbf{y}^{(l)jm} &= m \mathbf{y}^{(l)jm}, \\ \nabla^2 \mathbf{y}^{(l)jm} &= \mathbf{0}, \\ 2i\mathbf{L} \times \mathbf{y}^{(l)jm} &= [j(j+1) - l(l+1) - 2] \mathbf{y}^{(l)jm}.\end{aligned}$$

Orthogonality:

$$\int dS_{\hat{x}} \mathbf{y}^{(l')j'm'*}(\mathbf{x}) \cdot \mathbf{y}^{(l)jm}(\mathbf{x}) = \delta_{l'l} \delta_{j'j} \delta_{m'm} r^{l'+l},$$

where the integration is over the unit sphere in \mathbf{R}^3 .

Complex conjugation:

$$\mathbf{y}^{(l)jm*} = (-1)^{l+1-j} (-1)^m \mathbf{y}^{(l)j,-m}.$$

Vector and gradient formulas:

$$\begin{aligned}\mathbf{x} \mathbf{y}_{lm} &= -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \mathbf{y}^{(l+1,1)lm} \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} r^2 \mathbf{y}^{(l-1,1)lm}, \\ [(l+1)\nabla + \mathbf{i}\nabla \times \mathbf{L}](F \mathbf{y}_{lm}) \\ &= -[(l+1)(2l+1)]^{\frac{1}{2}} \left(\frac{1}{r} \frac{dF}{dr}\right) \mathbf{y}^{(l+1,1)lm},\end{aligned}$$

$$\begin{aligned}[-l\nabla + \mathbf{i}\nabla \times \mathbf{L}](F \mathbf{y}_{lm}) \\ &= -[l(2l+1)]^{\frac{1}{2}} \left[r \frac{dF}{dr} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm}, \\ \nabla(F \mathbf{y}_{lm}) &= -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r} \frac{dF}{dr}\right) \mathbf{y}^{(l+1,1)lm} \\ &\quad + \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \left[r \frac{dF}{dr} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm}, \\ \mathbf{i}\nabla \times \mathbf{L}(F \mathbf{y}_{lm}) &= -l \left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r} \frac{dF}{dr}\right) \mathbf{y}^{(l+1,1)lm} \\ &\quad - (l+1) \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \left[r \frac{dF}{dr} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm}.\end{aligned}$$

Curl equations:

$$\begin{aligned}\mathbf{i}\nabla \times (F \mathbf{y}^{(l+1,1)lm}) &= -\left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \\ &\quad \times \left[r \frac{dF}{dr} + (2l+3)F\right] \mathbf{y}^{(l,1)lm}, \\ \mathbf{i}\nabla \times (F \mathbf{y}^{(l,1)lm}) &= -\left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \\ &\quad \times \left(\frac{1}{r} \frac{dF}{dr}\right) \mathbf{y}^{(l+1,1)lm} - \left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \\ &\quad \times \left[r \frac{dF}{dr} + (2l+1)F\right] \mathbf{y}^{(l-1,1)lm}, \\ \mathbf{i}\nabla \times (F \mathbf{y}^{(l-1,1)lm}) &= -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r} \frac{dF}{dr}\right) \mathbf{y}^{(l,1)lm}.\end{aligned}$$

Divergence equations:

$$\begin{aligned}\nabla \cdot (F \mathbf{y}^{(l+1,1)lm}) &= -\left(\frac{l+1}{2l+1}\right)^{\frac{1}{2}} \left[r \frac{dF}{dr} + (2l+3)F\right] \mathbf{y}_{lm}, \\ \nabla \cdot (F \mathbf{y}^{(l,1)lm}) &= 0, \\ \nabla \cdot (F \mathbf{y}^{(l-1,1)lm}) &= \left(\frac{l}{2l+1}\right)^{\frac{1}{2}} \left(\frac{1}{r} \frac{dF}{dr}\right) \mathbf{y}_{lm}.\end{aligned}$$

Parity property:

$$\mathbf{y}^{(l+\delta,1)lm}(-\mathbf{x}) = (-1)^{l+\delta} \mathbf{y}^{(l+\delta,1)lm}(\mathbf{x}).$$

Scalar product:

$$\begin{aligned}\mathbf{y}^{(l')j'm'} \cdot \mathbf{y}^{(l)jm} \\ &= \sum_{l''} r^{l+l'-l''} \left(\frac{(2j+1)(2j'+1)(2l+1)(2l'+1)}{4\pi(2l''+1)}\right)^{\frac{1}{2}} \\ &\quad \times (-1)^{l+j'+l''} C_{000}^{l'l''} C_{m,m',m+m'}^{j j' l''} \\ &\quad \times \begin{Bmatrix} l' & j' & 1 \\ j & l & l'' \end{Bmatrix} \mathbf{y}_{l'',m+m'}.\end{aligned}$$

Cross product:

$$\begin{aligned} \mathbf{y}^{(l'1)j'm'} \times \mathbf{y}^{(l1)jm} &= (-i\sqrt{2}) \sum_{l''j''} r^{l+l'-l''} \\ &\times \left(\frac{(2j+1)(2j'+1)(3)(2l+1)(2l'+1)}{4\pi} \right)^{\frac{1}{2}} \\ &\times C_{000}^{l'l''} C_{m,m',m+m'}^{j'j''} \begin{Bmatrix} l & 1 & j \\ l' & 1 & j' \\ l'' & 1 & j'' \end{Bmatrix} \mathbf{y}^{(l''1)j''m+m'}. \end{aligned}$$

Conversion to spherical harmonic form:

$$\mathbf{y}^{(l+\delta,1)lm}(\mathbf{x}) = r^{l+\delta} \mathbf{y}^{(l+\delta,1)lm}(\hat{\mathbf{x}}),$$

with appropriate modification of F to account for the factor $r^{l+\delta}$.

2.12 Coupling and Recoupling Theory and 3n-j Coefficients

2.12.1 Composite Angular Momentum Systems

An *elementary* angular momentum system is one whose state space can be written as a direct sum of vector spaces \mathcal{H}_j with orthonormal basis

$$\{|jm\rangle | m = j, j-1, \dots, -j\},$$

on which the angular momentum \mathbf{J} has the standard action, and which under unitary transformation by $\exp(-i\psi\hat{\mathbf{n}} \cdot \mathbf{J})$ undergoes the standard unitary transformation. A composite angular momentum system is one whose state space is a direct sum of the tensor product spaces $\mathcal{H}_{j_1 j_2 \dots j_n}$ of dimension $\prod_{\alpha=1}^n (2j_\alpha + 1)$ with orthonormal basis in the tensor product space of the elementary systems given by

$$|j_1 m_1\rangle \otimes |j_2 m_2\rangle \otimes \dots \otimes |j_n m_n\rangle, \quad (2.98)$$

each $m_\alpha = j_\alpha, j_\alpha - 1, \dots, -j_\alpha$.

The following properties then hold for the composite system.

Independent rotations of the elementary parts:

$$\begin{aligned} &\left\{ \exp[-i\psi_1 \hat{\mathbf{n}}_1 \cdot \mathbf{J}(1)] \otimes \dots \otimes \exp[-i\psi_n \hat{\mathbf{n}}_n \cdot \mathbf{J}(n)] \right\} \\ &\times |j_1 m_1\rangle \otimes \dots \otimes |j_n m_n\rangle \\ &= \exp[-i\psi_1 \hat{\mathbf{n}}_1 \cdot \mathbf{J}(1)] |j_1 m_1\rangle \otimes \dots \\ &\otimes \exp[-i\psi_n \hat{\mathbf{n}}_n \cdot \mathbf{J}(n)] |j_n m_n\rangle \end{aligned}$$

$$\begin{aligned} &= \sum_{m'_1 \dots m'_n} [D^{j_1}(U_1) \times \dots \times D^{j_n}(U_n)]_{m'_1 \dots m'_n; m_1 \dots m_n} \\ &\times |j_1 m'_1\rangle \otimes \dots \otimes |j_n m'_n\rangle, \end{aligned} \quad (2.99)$$

$$\begin{aligned} &[D^{j_1}(U_1) \times \dots \times D^{j_n}(U_n)]_{m'_1 \dots m'_n; m_1 \dots m_n} \\ &= D_{m'_1 m_1}^{j_1}(U_1) \dots D_{m'_n m_n}^{j_n}(U_n), \end{aligned}$$

$$U_\alpha = U(\psi_\alpha, \hat{\mathbf{n}}_\alpha) \in SU(2), \quad \alpha = 1, 2, \dots, n.$$

Multiple Kronecker (direct) product group $SU(2) \times \dots \times SU(2)$.

Group elements:

$$(U_1, \dots, U_n), \quad \text{each } U_\alpha \in SU(2).$$

Multiplication rule:

$$(U'_1, \dots, U'_n)(U_1, \dots, U_n) = (U'_1 U_1, \dots, U'_n U_n).$$

Irreducible representations:

$$D^{j_1}(U_1) \times \dots \times D^{j_n}(U_n). \quad (2.100)$$

Rotation of the composite system as a unit.

Common rotation:

$$U_1 = U_2 = \dots = U_n = U \in SU(2).$$

Diagonal subgroup $SU(2) \subset SU(2) \times \dots \times SU(2)$:

$$(U, U, \dots, U), \quad \text{each } U \in SU(2).$$

Reducible representation of $SU(2)$:

$$D^{j_1}(U) \times \dots \times D^{j_n}(U). \quad (2.101)$$

Total angular momentum of the composite system:

$$\mathbf{J} = \mathbf{J}(1) + \mathbf{J}(2) + \dots + \mathbf{J}(n),$$

in which the k -th term in the sum is to be interpreted as the tensor product operator:

$$\mathbf{I}_1 \otimes \dots \otimes \mathbf{J}(k) \otimes \dots \otimes \mathbf{I}_n, \quad \mathbf{I}_\alpha = \text{unit operator in } \mathcal{H}_{j_\alpha}.$$

The basic problem for composite systems:

The basic problem is to reduce the n -fold direct product representation Eq. (2.101) of $SU(2)$ into a direct sum of irreducible representations, or equivalently, to find all subspaces $\mathcal{H}_j \subset \mathcal{H}_{j_1 j_2 \dots j_n}$, $j \in \{0, 1/2, 1, \dots\}$, with orthonormal bases sets $\{|jm\rangle | m = j, j-1, \dots, -j\}$ on which the total angular momentum \mathbf{J} has the standard action.

Form of the solution:

$$| (j_1 j_2 \cdots j_n)(k) j m \rangle = \sum_{\substack{\text{all } m_\alpha \\ \sum m_\alpha = m}} C_{m_1 m_2 \cdots m_n m}^{j_1 j_2 \cdots j_n j}(k) \\ \times | j_1 m_1 \rangle \otimes | j_2 m_2 \rangle \otimes \cdots \otimes | j_n m_n \rangle, \quad (2.102)$$

$m = j, j-1, \dots, -j$; index set (k) unspecified.

Diagonal operators:

$$\mathbf{J}^2(\alpha) = J_1^2(\alpha) + J_2^2(\alpha) + J_3^2(\alpha), \\ \mathbf{J}^2(\alpha) | (j_1 j_2 \cdots j_n)(k) j m \rangle \\ = j_\alpha(j_\alpha + 1) | (j_1 j_2 \cdots j_n)(k) j m \rangle, \\ \alpha = 1, 2, \dots, n. \quad (2.103)$$

Total angular momentum properties imposed:

$$\mathbf{J}^2 | (j_1 j_2 \cdots j_n)(k) j m \rangle \\ = j(j+1) | (j_1 j_2 \cdots j_n)(k) j m \rangle, \\ J_3 | (j_1 j_2 \cdots j_n)(k) j m \rangle \\ = m | (j_1 j_2 \cdots j_n)(k) j m \rangle, \\ J_\pm | (j_1 j_2 \cdots j_n)(k) j m \rangle \\ = [(j \mp m)(j \pm m + 1)]^{\frac{1}{2}} \\ \times | (j_1 j_2 \cdots j_n)(k) j m \pm 1 \rangle. \quad (2.104)$$

Properties of the index set (k) .

Reduction of Kronecker product Eq. (2.101):

$$D^{j_1} \times D^{j_2} \times \cdots \times D^{j_n} = \sum_j \oplus n_j D^j, \\ \prod_\alpha (2j_\alpha + 1) = \sum_j n_j (2j + 1). \quad (2.105)$$

For fixed j_1, j_2, \dots, j_n , and j , the index set (k) must enumerate exactly n_j perpendicular spaces \mathcal{H}_j .

Incompleteness of set of operators:

There are $2n$ commuting Hermitian operators diagonal on the basis Eq. (2.98):

$$\{ \mathbf{J}^2(\alpha), J_3(\alpha) \mid \alpha = 1, 2, \dots, n \}. \quad (2.106a)$$

There are $n+2$ commuting Hermitian operators diagonal on the basis Eq. (2.102):

$$\{ \mathbf{J}^2, J_3; \mathbf{J}^2(\alpha) \mid \alpha = 1, 2, \dots, n \}. \quad (2.106b)$$

There are $n-2$ additional commuting Hermitian operators, or other rules, required to complete set Eq. (2.106b) and determine the indexing set (k) .

Basic content of coupling and recoupling theory:

Coupling theory is the study of completing the operator set Eq. (2.106b), or the specification of other rules, that

uniquely determine the irreducible representation spaces \mathcal{H}_j occurring in the Kronecker product reduction Eq. (2.105). Recoupling theory is the study of the interrelations between different methods of effecting this reduction; it is a study of relations between the different ways of spanning the multiplicity space

$$\mathcal{H}_j \oplus \mathcal{H}_j \oplus \cdots \oplus \mathcal{H}_j \quad (n_j \text{ terms}).$$

2.12.2 Binary Coupling Theory: Combinatorics

Binary coupling of angular momenta refers to selecting any pair of angular momentum operators from the set of individual system angular momenta

$$\{ \mathbf{J}(1), \mathbf{J}(2), \dots, \mathbf{J}(n) \}$$

and carrying out the *addition of angular momenta* for that pair by coupling the corresponding states in the tensor product space by the standard use of $SU(2)$ WCG coefficients; this is followed by addition of a new pair, which may be a pair distinct from the first pair, or the addition of one new angular momentum to the sum of the first pair, etc. If the order $1, 2, \dots, n$ of the angular momenta is kept fixed in

$$\mathbf{J}_1 + \mathbf{J}_2 + \cdots + \mathbf{J}_n, \quad (2.107)$$

one is led to the problem of parentheses. (To avoid misleading parentheses, the notation $\mathbf{J}_\alpha = \mathbf{J}(\alpha)$ is used in this section.) This is the problem of introducing pairs of parentheses into expression Eq. (2.107) that specify the coupling procedure to be implemented. The procedure is clear from the following cases for $n = 2, 3$, and 4:

$$n = 2: \quad \mathbf{J}_1 + \mathbf{J}_2; \\ n = 3: \quad (\mathbf{J}_1 + \mathbf{J}_2) + \mathbf{J}_3, \\ \mathbf{J}_1 + (\mathbf{J}_2 + \mathbf{J}_3); \\ n = 4: \quad (\mathbf{J}_1 + \mathbf{J}_2) + (\mathbf{J}_3 + \mathbf{J}_4), \\ [(\mathbf{J}_1 + \mathbf{J}_2) + \mathbf{J}_3] + \mathbf{J}_4, \\ [\mathbf{J}_1 + (\mathbf{J}_2 + \mathbf{J}_3)] + \mathbf{J}_4, \\ \mathbf{J}_1 + [(\mathbf{J}_2 + \mathbf{J}_3) + \mathbf{J}_4], \\ \mathbf{J}_1 + [\mathbf{J}_2 + (\mathbf{J}_3 + \mathbf{J}_4)].$$

It is customary to use the ordered sequence

$$j_1 j_2 \cdots j_n \quad (2.108)$$

of angular momentum quantum numbers in place of the angular momentum operators in Eq. (2.107). Thus, the five placement of parentheses for $n = 4$ becomes:

$$(j_1 j_2)(j_3 j_4), [(j_1 j_2) j_3] j_4, [j_1 (j_2 j_3)] j_4, \\ j_1 [(j_2 j_3) j_4], j_1 [j_2 (j_3 j_4)].$$

(It is also customary to omit the last parentheses pair, which encloses the whole sequence.) A sequence Eq. (2.108) into which pairwise insertions of parentheses has been completed is called a binary bracketing of the sequence and is denoted by $(j_1 j_2 \cdots j_n)^B$. This symbol may also be called a coupling symbol. The total number of coupling symbols, that is, the total number of elements a_n in the set

$$\{(j_1 j_2 \cdots j_n)^B | B \text{ is a binary bracketing}\}$$

is given by the Catalan numbers:

$$a_n = \frac{1}{n} \binom{2n-2}{n-1}, \quad n = 2, 3, \dots$$

Effect of permuting the angular momenta:

Since the position of an individual vector space in the tensor product $\mathcal{H}_{j_1} \otimes \cdots \otimes \mathcal{H}_{j_n}$ is kept fixed, the meaning of a permutation of the j_α in the sequence Eq. (2.108) corresponding to a given binary bracketing is to permute the positions of the terms in the summation for the total angular momentum, e.g., $(j_1 j_2) j_3 \rightarrow (j_3 j_1) j_2$ corresponds to

$$\begin{aligned} & (\mathbf{J}_1 \otimes \mathbf{I}_2 \otimes \mathbf{I}_3 + \mathbf{I}_1 \otimes \mathbf{J}_2 \otimes \mathbf{I}_3) + \mathbf{I}_1 \otimes \mathbf{I}_2 \otimes \mathbf{J}_3 \\ &= (\mathbf{I}_1 \otimes \mathbf{I}_2 \otimes \mathbf{J}_3 + \mathbf{J}_1 \otimes \mathbf{I}_2 \otimes \mathbf{I}_3) + \mathbf{I}_1 \otimes \mathbf{J}_2 \otimes \mathbf{I}_3. \end{aligned}$$

Total number of binary bracketing schemes including permutations:

The number of symbols in the set

$$\left\{ (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B \left| \begin{array}{l} B \text{ is a binary bracketing and} \\ \alpha_1 \alpha_2 \cdots \alpha_n \text{ is a permutation} \\ \text{of } 1, 2, \dots, n \end{array} \right. \right\} \quad (2.109)$$

is $c_n = n! a_n = (n)_{n-1} = n(n+1) \cdots (2n-2)$.

Caution: one should not assign numbers to the symbols j_α , since these symbols serve as noncommuting, nonassociative distinct objects in a counting process.

Binary subproducts:

A binary subproduct in the coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ is the subset of symbols between a given parentheses pair, say, $\{xy\}$. The symbols x and y may themselves contain binary subproducts. Commutation of a binary subproduct is the operation $\{xy\} \rightarrow \{yx\}$. For example, the coupling symbol $\{(j_1 j_2) j_3\} j_4$ contains three binary subproducts, $\{xy\}$, $[xy]$, (xy) .

Equivalence relation:

Two coupling symbols are defined to be equivalent

$$(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B \sim (j_{\alpha'_1} j_{\alpha'_2} \cdots j_{\alpha'_n})^B,$$

if one can be obtained from the other by commutation of the symbols in the binary subproducts. Such commutations

change the overall phase of the state vector Eq. (2.102) corresponding to a particular coupling symbol, and such states are counted as being the same (equivalent).

Number of inequivalent coupling schemes:

The equivalence relation under commutation of binary subproducts partitions the set Eq. (2.109) into equivalence classes, each containing 2^{n-1} elements. There are $d_n = c_n / 2^{n-1} = (2n-3)!!$ inequivalent coupling schemes in binary coupling theory. Thus, for $n = 4$, there are $5!! = 5 \times 3 \times 1 = 15$ inequivalent binary coupling schemes.

Type of a coupling symbol:

The type of the coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ is defined to be the symbol obtained by setting all the j_α equal to a common symbol, say, x . Thus, the type of the coupling symbol $\{(j_1 j_2) j_3\} j_4$ is $\{(x^2)x\}x$.

The Wedderburn–Etherington number b_n gives the number of coupling symbols of distinct types, counting two symbols as equivalent if they are related by commutation of binary subproducts. A closed form of these numbers is not known, although generating functions exist. The first few numbers are:

n	1	2	3	4	5	6	7	8	9	10
b_n	1	1	1	2	3	6	11	23	46	98

There are 15 nontrivial coupling schemes for 4 angular momenta, and they are classified into 2 types, allowing commutation of binary subproducts:

$$\begin{aligned} & \text{Type } [(x^2)x]x \\ & [(j_1 j_2) j_3] j_4, [(j_2 j_3) j_1] j_4, [(j_3 j_1) j_2] j_4 \\ & [(j_1 j_2) j_4] j_3, [(j_2 j_4) j_1] j_3, [(j_4 j_1) j_2] j_3 \\ & [(j_1 j_3) j_4] j_2, [(j_3 j_4) j_1] j_2, [(j_4 j_1) j_3] j_2 \\ & [(j_2 j_3) j_4] j_1, [(j_3 j_4) j_2] j_1, [(j_4 j_2) j_3] j_1 \\ & \text{Type } (x^2)(x^2) \\ & (j_1 j_2)(j_3 j_4), (j_1 j_3)(j_2 j_4), (j_2 j_3)(j_1 j_4) \end{aligned}$$

2.12.3 Implementation of Binary Couplings

Each binary coupling scheme specifies uniquely a set of intermediate angular momentum operators. For example, the intermediate angular momenta associated with the coupling symbol $[(j_1 j_2) j_3] j_4$ are

$$\begin{aligned} \mathbf{J}(1) + \mathbf{J}(2) &= \mathbf{J}(12), \quad \mathbf{J}(12) + \mathbf{J}(3) = \mathbf{J}(123), \\ \mathbf{J}(123) + \mathbf{J}(4) &= \mathbf{J}, \end{aligned}$$

where \mathbf{J} is the total angular momentum. Each coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ defines exactly $n-2$ intermediate angular momentum operators $\mathbf{K}(\lambda)$, $\lambda = 1, 2, \dots, n-2$. The

squares of these operators completes the set of operators Eq. (2.106b) for each coupling symbol; that is, the states' vectors satisfying Eqs. (2.103)–(2.104) and the following equations are unique, up to an overall choice of phase factor:

$$\begin{aligned} & \mathbf{K}^2(\lambda) | (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) j m \rangle \\ &= k_\lambda (k_\lambda + 1) | (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) j m \rangle, \\ & \lambda = 1, 2, \dots, n-2, \quad n > 2. \end{aligned} \quad (2.110)$$

The intermediate angular momentum operators $\mathbf{K}^2(\lambda)$ depend, of course, on the choice of binary couplings implicit in the symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$. The vectors have the following properties.

Orthonormal basis of $\mathcal{H}_{j_1}(1) \otimes \cdots \otimes \mathcal{H}_{j_n}(n)$:

$$\begin{aligned} \langle (j_\alpha)^B (k') j m | (j_\alpha)^B (k) j m \rangle &= \prod_\lambda \delta_{k'_\lambda k_\lambda}, \\ (j_\alpha) &= (j_{\alpha_1}, j_{\alpha_2}, \dots, j_{\alpha_n}), \\ (k) &= (k_1, k_2, \dots, k_{n-2}), \\ (k') &= (k'_1, k'_2, \dots, k'_{n-2}). \end{aligned}$$

The range of each k_λ is uniquely determined by the Clebsch–Gordan series and the binary couplings in the coupling symbol. Together these ranges enumerate exactly the multiplicity n_j of \mathcal{H}_j occurring in the reduction of the multiple Kronecker product.

Uniqueness of state vectors:

$$\begin{aligned} & | (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) j m \rangle \\ &= \sum_{\sum m_\alpha = m} C \left[\begin{array}{c} j_{\alpha_1} \cdots j_{\alpha_n} \\ m_{\alpha_1} \cdots m_{\alpha_n} \end{array} \right]^B \begin{array}{c} j \\ m \end{array} (k_1, \dots, k_{n-2}) \\ & \times | j_1 m_1 \rangle \otimes \cdots \otimes | j_n m_n \rangle. \end{aligned}$$

In the C coefficient, the $\left(\begin{array}{c} j_\alpha \\ m_\alpha \end{array} \right)$ are paired in the binary bracketing. Each such C coefficient is a summation over a unique product of $n-1$ $SU(2)$ WCG coefficients.

Equivalent basis vectors:

$$\begin{aligned} & | (j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B (k_1 k_2 \cdots k_{n-2}) j m \rangle \\ &= \pm | (j_{\alpha'_1} j_{\alpha'_2} \cdots j_{\alpha'_n})^B (k_1 k_2 \cdots k_{n-2}) j m \rangle, \end{aligned}$$

if and only if $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B \sim (j_{\alpha'_1} j_{\alpha'_2} \cdots j_{\alpha'_n})^B$. Inequivalent basis vector are orthonormal in all quantum numbers labeling the state vector.

Recoupling coefficients:

A recoupling coefficient is a transformation coefficient

$$\langle (j_\beta)^{B'} | (l) j m | (j_\alpha)^B (k) j m \rangle$$

relating any two orthonormal bases of the space $\mathcal{H}_{j_1} \otimes \cdots \otimes \mathcal{H}_{j_n}$, say, the one defined by Eqs. (2.103), (2.104), and (2.110) for a prescribed coupling scheme corresponding to a bracketing B , and a second one, again defined by these relations but for a different coupling scheme corresponding to a bracketing B' . For example, for $n=3$, there are three inequivalent coupling symbols and $\binom{3}{2} = 3$ recoupling coefficients; for $n=4$, there are 15 inequivalent coupling symbols and $\binom{15}{2} = 105$ recoupling coefficients. Each coefficient is, of course, expressible as a sum over products of $2(n-1)$ WCG coefficients, obtained simply by taking the inner product:

$$\begin{aligned} & \langle (j_\beta)^{B'} (l) j m | (j_\alpha)^B (k) j m \rangle \\ &= \sum_{\sum m_\alpha = m} C \left[\begin{array}{c} j_{\beta_1} \cdots j_{\beta_n} \\ m_{\beta_1} \cdots m_{\beta_n} \end{array} \right]^{B'} \begin{array}{c} j \\ m \end{array} (l) \\ & \times C \left[\begin{array}{c} j_{\alpha_1} \cdots j_{\alpha_n} \\ m_{\alpha_1} \cdots m_{\alpha_n} \end{array} \right]^B \begin{array}{c} j \\ m \end{array} (k). \end{aligned} \quad (2.111)$$

The fundamental theorem of binary coupling theory states for inequivalent coupling schemes:

Each recoupling coefficient is expressible as a sum over products of Racah coefficients, the only other quantities occurring in the summation being phase and dimension factors.

In every instance, the summation over projection quantum numbers in the right-hand side of Eq. (2.111) is expressible as a sum over Racah coefficients.

2.12.4 Construction of All Transformation Coefficients in Binary Coupling Theory

Augmented notation:

The coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$ contains all information as to how n angular momenta are to be coupled but is not specific in how the intermediate angular momentum quantum numbers $(k_1 k_2 \cdots k_{n-2})$, are to be matched with the binary couplings implicit in the coupling symbol. For explicit calculations, it is necessary to remedy this deficiency in notation. This may be done by attaching the $n-2$ intermediate angular momentum quantum numbers and the total angular momentum j as subscripts to the $n-1$ parentheses pairs in the coupling symbol. For example, for $(j_1 j_2 j_3 j_4 j_5)^B = \{[(j_1 j_2)(j_3 j_4)]j_5\}$, this results in the replacement

$$\begin{aligned} & \{[(j_1 j_2)(j_3 j_4)]j_5\} (k_1 k_2 k_3) \\ & \rightarrow \{[(j_1 j_2)_{k_1} (j_3 j_4)_{k_2}]_{k_3} j_5\}_j. \end{aligned}$$

The basic coupling symbol structure is regained simply by ignoring all inferior letters.

Basic rules for commutation and association:

Let x, y, z denote arbitrary disjoint contiguous subcoupling symbols $\{[(x)(y)](z)\}$ contained in the coupling symbol $(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B$. Let a, b, c denote the intermediate angular momenta associated with addition of the angular momenta represented in x, y, z , respectively, d the angular momentum representing the sum of a and b , and k the sum of d and c . Symbolically, this subcoupling may be presented as

$$\begin{aligned} \sum \mathbf{J}(x) &= \mathbf{J}(a), & \sum \mathbf{J}(y) &= \mathbf{J}(b), \\ \sum \mathbf{J}(z) &= \mathbf{J}(c), \\ \mathbf{J} &= \cdots \{[\mathbf{J}(a) + \mathbf{J}(b)] + \mathbf{J}(c)\} \cdots; \\ \mathbf{J}(a) + \mathbf{J}(b) &= \mathbf{J}(d); & \mathbf{J}(d) + \mathbf{J}(c) &= \mathbf{J}(k), \end{aligned}$$

with augmented coupling symbol

$$(j_{\alpha_1} j_{\alpha_2} \cdots j_{\alpha_n})^B = \cdots \{[(x)_a(y)_b]_d(z)_c\}_k \cdots.$$

There are only two basic operations in constructing the recoupling coefficient between any two coupling schemes.

Commutation of symbols:

$$(x)_a(y)_b \rightarrow (y)_b(x)_a,$$

with the transformation of state vector given by

$$\begin{aligned} |\cdots [(x)_a(y)_b]_d \cdots\rangle \\ \rightarrow (-1)^{a+b-d} |\cdots [(y)_b(x)_a]_d \cdots\rangle \\ = |\cdots [(x)_a(y)_b]_d \cdots\rangle. \end{aligned}$$

Association of symbols:

$$[(x)_a(y)_b]_d(z)_c \rightarrow (x)_a[(y)_b(z)_c],$$

with the transformation of state vector given by

$$\begin{aligned} |\cdots \{[(x)_a(y)_b]_d(z)_c\}_k \cdots\rangle \\ \rightarrow \sum_e [(2d+1)(2e+1)]^{1/2} W(abkc; de) \\ \times |\cdots \{(x)_a[(y)_b(z)_c]_e\}_k \cdots\rangle \\ = |\cdots \{[(x)_a(y)_b]_d(z)_c\}_k \cdots\rangle. \end{aligned}$$

The basic result for the calculation of all recoupling coefficients:

Each pair of coupling schemes for n angular momenta can be brought into coincidence by a series of commutations and associations performed on either of the set of coupling symbols defining the coupling scheme.

In principle, this result gives a method for the construction of all recoupling transformation coefficients and sets

the stage for the formulation of still deeper questions arising in recoupling theory, as summarized in Sect. 2.12.5. The following examples illustrate the content of the preceding abstract constructions.

Examples:

WCG coefficient form:

$$\begin{aligned} \{[(ab)_e c]_f d\}_g \mid [(ac)_h (bd)_k]_g \\ = \sum_{\alpha+\beta+\gamma+\delta=m} C_{\alpha,\beta,\alpha+\beta}^{abe} C_{\alpha+\beta,\gamma,\alpha+\beta+\gamma}^{ecf} C_{\alpha+\beta+\gamma,\delta,m}^{fdg} \\ \times C_{\alpha,\gamma,\alpha+\gamma}^{ach} C_{\beta,\delta,\beta+\delta}^{bdk} C_{\alpha+\gamma,\beta+\delta,m}^{hkg}. \end{aligned}$$

6- j coefficient as recoupling coefficient:

$$\begin{aligned} (ac)(bd) \xrightarrow{R} [(ac)b]d \xrightarrow{\phi} [b(ac)]d \xrightarrow{R} [(ba)c]d \\ \xrightarrow{\phi} [(ab)c]d, \end{aligned}$$

where ϕ denotes that the communication of symbols effects a phase factor transformation, and R denotes that the associative of symbol effects a Racah coefficient transformation:

$$\begin{aligned} \{[(ab)_e c]_f d\}_g \mid [(ac)_h (bd)_k]_g \\ = (-1)^{e+h-a-f} [(2f+1)(2k+1)]^{1/2} W(hbgd; fk) \\ \times [(2e+1)(2h+1)]^{1/2} W(bafc; eh). \end{aligned}$$

9- j coefficient as recoupling coefficient:

$$\begin{aligned} (ac)(bd) \xrightarrow{R} [(ac)b]d \xrightarrow{\phi} [b(ac)]d \xrightarrow{R} [(ba)c]d \\ \xrightarrow{\phi} [(ab)c]d \xrightarrow{R} (ab)(cd), \\ \{[(ab)_e (cd)_f]_g \mid [(ac)_h (bd)_k]_g\} \\ = [(2e+1)(2f+1)(2h+1)(2k+1)]^{1/2} \\ \times \sum_l (-1)^{2l} (2l+1) \begin{Bmatrix} ach \\ lbe \end{Bmatrix} \begin{Bmatrix} bdk \\ ghl \end{Bmatrix} \begin{Bmatrix} efg \\ dlc \end{Bmatrix} \\ = [(2e+1)(2f+1)(2h+1)(2k+1)]^{1/2} \begin{Bmatrix} abe \\ cdf \\ hkg \end{Bmatrix}. \end{aligned}$$

2.12.5 Unsolved Problems in Recoupling Theory

1. Define a route between two coupling symbols for n angular momenta to be any sequence of transpositions and associations that carries one symbol into the other. Each such route then gives rise to a unique expression for the corresponding recoupling coefficient in terms of 6- j coefficients. In general, there are several routes between the same pair of coupling symbols, leading, therefore, to

identities between $6-j$ coefficients. How many nontrivial routes are there between two given coupling symbols, leading to nontrivial relations between $6-j$ coefficients (trivial means related by a phase factor)?

2. Only $6-j$ coefficients arise in all possible couplings of three angular momenta; only $6-j$ and $9-j$ coefficients arise in all possible couplings of four angular momenta; in addition to $6-j$ and $9-j$ coefficients, two new *classes* of coefficients, called $12-j$ coefficients of the first and second kind, arise in the coupling of five angular momenta; in addition to $6-j$, $9-j$, and the two classes of $12-j$ coefficients, five new classes of $15-j$ coefficients arise in the coupling of six angular momenta, \dots . What are the classes of $3n-j$ coefficients? The nonconstructive answer is that a summation over $6-j$ coefficients arising in the coupling of n angular momenta is of a new class if it cannot be expressed in terms of previously defined coefficients occurring in the recoupling of $n-1$ or fewer angular momenta.
3. Toward answering the question of classes of $3n-j$ coefficients, one is led into the classification problem of planar cubic graphs. It is known that every $3n-j$ coefficient corresponds to a planar cubic graph, but the converse is not true. For small n , the relation between the coupling of n angular momenta, the number of new classes of $3(n-1)-j$ coefficients, and the number of nonisomorphic planar cubic graphs on $2(n-1)$ points is:

n	Classes of $3(n-1)-j$ coefficients	Cubic graphs on $2(n-1)$ points
3	1	1
4	1	2
5	2	5
6	5	19
7	18	87
8	84	?
9	576	?

The geometrical object for $n=3$ is a planar graph isomorphic to the tetrahedron in 3-space. The classification of all nonisomorphic cubic graphs on $2(n-1)$ points is an unsolved problem in mathematics, as is the classification of classes for $3(n-1)-j$ coefficients.

4. There are (at least) two methods of realizing the basic triangles of angular momentum theory in terms of graphs. The fundamental structural element $[(ab)c]$ is represented either in terms of its points or in terms of its lines (Fig. 2.4). The right representation leads to the interpretation of recoupling coefficients as functions defined on pairs of labeled binary trees [1]; the left corresponds to the diagrams of the *Jucys* school [7, 8]. Either method leads to the relationship of recoupling coefficients to cubic graphs.
5. The approach of classifying $3n-j$ coefficients through the use of unit tensor operator couplings, Racah operators,

Fig. 2.4 The fundamental triangle $[(ab)c]$ can be realized by lines or points

$9-j$ -invariant operators, and general invariant operators is undeveloped.

2.13 Supplement on Combinatorial Foundations

The quantum theory of angular momentum can be worked out using the abstract postulates of the properties of angular momenta operators and the abstract Hilbert space in which they act. The underlying mathematical apparatus is the Lie algebra of the group $SU(2)$ and multiple copies thereof. An alternative approach is to use special Hilbert spaces that realize all the properties of the abstract postulates and perform calculations within that framework. The framework must be sufficiently rich in structure so as to apply to a manifold of physical situations. This approach has often been used in our treatment; it is an approach that is particularly useful for revealing the combinatorial foundations of quantum angular momentum theory. We illustrate this concretely in this supplementary section. The basic objects are the polynomials defined by Eq. (2.24), which we now call $SU(2)$ solid harmonics, where we change the notation slightly by interchanging the role of m and m' .

2.13.1 $SU(2)$ Solid Harmonics

The $SU(2)$ solid harmonics are defined to be the homogeneous polynomials of degree $2j$ in four commuting indeterminates given by

$$D_{mm'}^j(Z) = \sqrt{\alpha! \beta!} \sum_{(\alpha:A;\beta)} \frac{Z^A}{A!}, \quad (2.112)$$

in which the indeterminates Z and the nonnegative exponents A are encoded in the matrix arrays

$$Z = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix}, \quad A = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix},$$

$$X^A = \prod_{i,j=1}^2 z_{ij}^{a_{ij}}, \quad A! = \prod_{i,j=1}^2 (a_{ij})!,$$

$$\alpha! = \alpha_1! \alpha_2!, \quad \beta! = \beta_1! \beta_2!.$$

The symbol $(\alpha : A : \beta)$ in Eq. (2.112) denotes that the matrix array A of nonnegative integer entries has row and column sums of its a_{ij} entries given in terms of the quantum numbers j, m, m' by

$$a_{11} + a_{12} = \alpha_1 = j + m, \quad a_{21} + a_{22} = \alpha_2 = j - m,$$

$$a_{11} + a_{21} = \beta_1 = j + m', \quad a_{12} + a_{22} = \beta_2 = j - m'.$$

These $SU(2)$ solid harmonics are among the most important functions in angular momentum theory. Not only do they unify the irreducible representations of $SU(2)$ in any parametrization by the appropriate definition of the indeterminates in terms of generalized coordinates, they also include the popular boson calculus realization of state vectors for quantum mechanical systems, as well as the state vectors for the symmetric rigid rotator.

The realization of the inner product is essential. Physical theory demands an inner product that is given in terms of integrations of wave functions over the variables of the theory, as required by the probabilistic interpretation of wave functions. It is the requirement that realizations of angular momentum operators be Hermitian with respect to the inner product for the spaces being used that assures the orthogonality of functions, so that one is able to take results from one realization of the inner product to another with compatibility of relations. Often, in combinatorial arguments, the inner product plays no direct role.

The nomenclature for $SU(2)$ solid harmonics for the polynomials defined by Eq. (2.112) is by analogy with the term $SO(3, \mathbf{R})$ solid harmonics for the polynomials described in Sect. 2.1.

The polynomials $\mathcal{Y}_{lm}(\mathbf{x})$, $\mathbf{x} = (x_1, x_2, x_3) \in \mathbf{R}^3$ are homogeneous of degree l . The angular momentum operator \mathbf{L}^2 is given by

$$\mathbf{L}^2 = -r^2 \nabla^2 + (\mathbf{x} \cdot \nabla)^2 + (\mathbf{x} \cdot \nabla),$$

which is a sum of two commuting operators $-r^2 \nabla^2$ and $(\mathbf{x} \cdot \nabla)^2 + \mathbf{x} \cdot \nabla$, each of which is invariant under orthogonal transformations. The $SO(3, \mathbf{R})$ solid harmonics are homogeneous polynomials of degree l that solve $\nabla^2 \mathcal{Y}_{lm}(\mathbf{x}) = 0$, so that $\mathbf{L}^2 \mathcal{Y}_{lm}(\mathbf{x}) = l(l+1) \mathcal{Y}_{lm}(\mathbf{x})$. The component angular momentum operators L_i then have the standard action on these polynomials, and under real, proper, orthogonal transformations give the irreducible representations of the group $SO(3, \mathbf{R})$.

The polynomials $D_{mm'}^j(\mathbf{Z})$, $\mathbf{z} = (z_{11}, z_{21}, z_{12}, z_{22}) \in \mathbf{C}^4$ are homogeneous of degree $2j$. The angular momentum op-

erator \mathbf{J}^2 , with $\mathbf{J} = (J_1, J_2, J_3)$, is given by

$$\mathbf{J}^2 = -(\det Z) \left(\det \frac{\partial}{\partial Z} \right) + J_0(J_0 + 1),$$

$$J_0 = \frac{1}{2} \mathbf{z} \cdot \boldsymbol{\partial},$$

$$\boldsymbol{\partial} = \left(\frac{\partial}{\partial z_{11}}, \frac{\partial}{\partial z_{21}}, \frac{\partial}{\partial z_{12}}, \frac{\partial}{\partial z_{22}} \right), \quad (2.113)$$

which is a sum of two commuting operators $-(\det Z) \left(\det \frac{\partial}{\partial Z} \right)$ and $J_0(J_0 + 1)$, each of which is invariant under $SU(2)$ transformations. The $SU(2)$ solid harmonics are homogeneous polynomials of degree $2j$ such that

$$\det \frac{\partial}{\partial Z} D_{mm'}^j(\mathbf{Z}) = 0,$$

$$\mathbf{J}^2 D_{mm'}^j(\mathbf{Z}) = j(j+1) D_{mm'}^j(\mathbf{Z}).$$

The components of the angular momentum operators $\mathbf{J} = (J_1, J_2, J_3) = (M_1, M_2, M_3)$ and $\mathbf{K} = (K_1, K_2, K_3)$ then have the standard action on these polynomials as given in Sect. 2.4.4, and under either left or right $SU(2)$ transformations, these polynomials give the irreducible representations of the group $SU(2)$.

2.13.2 Combinatorial Definition of Wigner–Clebsch–Gordan Coefficients

The $SU(2)$ solid harmonics have a basic role in the interpretation of WCG coefficients in combinatorial terms. We recall from Sect. 2.7.2 that the basic abstract Hilbert space coupling rule for compounding two kinematically independent angular momenta with components $\mathbf{J}_1 = (J_1(1), J_2(1), J_3(1))$ and $\mathbf{J}_2 = (J_1(2), J_2(2), J_3(2))$ to a total angular momentum $\mathbf{J} = (J_1, J_2, J_3) = \mathbf{J}_1 + \mathbf{J}_2$ is

$$|(j_1 j_2) j m\rangle$$

$$= \sum_{m_1+m_2=m} C \begin{matrix} j_1 & j_2 & j \\ m_1 & m_2 & m \end{matrix} |j_1 m_1\rangle \otimes |j_2 m_2\rangle. \quad (2.114)$$

This relation in abstract Hilbert space is realized explicitly by spinorial polynomials as follows:

$$\psi_{(j_1 j_2) j m}(\mathbf{Z}) = \sum_{m_1+m_2=m} C \begin{matrix} j_1 & j_2 & j \\ m_1 & m_2 & m \end{matrix}$$

$$\times \psi_{j_1 m_1}(z_{11}, z_{21}) \psi_{j_2 m_2}(z_{12}, z_{22}), \quad (2.115)$$

$$\psi_{(j_1 j_2) j m}(\mathbf{Z}) = \sqrt{\frac{2j+1}{(j_1+j_2-j)!(j_1+j_2+j+1)!}}$$

$$\times (\det Z)^{j_1+j_2-j} D_{m, j_1-j_2}^j(\mathbf{Z}), \quad (2.116)$$

$$\psi_{jm}(x, y) = \frac{x^{j+m} y^{j-m}}{\sqrt{(j+m)!(j-m)!}}. \quad (2.117)$$

Explicit knowledge of the WCG coefficients is not needed to prove these relationships. The angular momentum operators

$$\begin{aligned} J_+(1) &= z_{11} \frac{\partial}{\partial z_{21}}, & J_-(1) &= z_{21} \frac{\partial}{\partial z_{11}}, \\ J_3(1) &= \frac{1}{2} \left(z_{11} \frac{\partial}{\partial z_{11}} - z_{21} \frac{\partial}{\partial z_{21}} \right); \\ J_+(2) &= z_{12} \frac{\partial}{\partial z_{22}}, & J_-(2) &= z_{22} \frac{\partial}{\partial z_{12}}, \\ J_3(2) &= \frac{1}{2} \left(z_{12} \frac{\partial}{\partial z_{12}} - z_{22} \frac{\partial}{\partial z_{22}} \right) \end{aligned}$$

are Hermitian in the polynomial inner product defined in Sect. 2.4.3 and have the standard action on the polynomials $\psi_{j_1 m_1}(z_{11}, z_{21})$ and $\psi_{j_2 m_2}(z_{12}, z_{22})$, respectively, which are normalized in the inner product (\cdot, \cdot) . The components of total angular momentum operator $\mathbf{J} = \mathbf{M} = \mathbf{J}_1 + \mathbf{J}_2$ have the standard action on the polynomials $\psi_{(j_1 j_2) j m}(Z)$ since they have the standard action on the factor $D_m^{j_1 j_2}(Z)$, as given in Sect. 2.4.4, and $[\mathbf{J}, \det X] = [\mathbf{J}, \det \frac{\partial}{\partial Z}] = 0$. Thus, we have

$$\begin{aligned} \mathbf{J}^2 \psi_{(j_1 j_2) j m}(Z) &= j(j+1) \psi_{(j_1 j_2) j m}(Z), \\ J_{\pm} \psi_{(j_1 j_2) j m}(Z) &= \sqrt{(j \mp m)(j \pm m + 1)} \\ &\quad \times \psi_{(j_1 j_2) j m \pm 1}(Z). \end{aligned}$$

We also note that the two commuting parts of \mathbf{J}^2 are diagonal on these functions:

$$\begin{aligned} J_0(J_0 + 1) \psi_{(j_1 j_2) j m}(Z) &= (j_1 + j_2)(j_1 + j_2 + 1) \psi_{(j_1 j_2) j m}(Z), \\ (\det Z) \left(\det \frac{\partial}{\partial X} \right) \psi_{(j_1 j_2) j m}(Z) &= (j_1 + j_2 - j)(j_1 + j_2 + j_1 + 1) \psi_{(j_1 j_2) j m}(Z). \end{aligned}$$

It is necessary only to verify these properties for the highest weight function $D_j^j(Z) = z_{11}^j / \sqrt{(2j)!}$, for which they are seen to hold.

The angular momentum operators $\mathbf{K} = (K_1, K_2, K_3)$ defined in Sect. 2.4.4 with components that commute with those of $\mathbf{J} = (M_1, M_2, M_3)$ and having $\mathbf{K}^2 = \mathbf{J}^2$ also have a well-defined action on the functions $\psi_{(j_1 j_2) j m}(Z)$. The action of K_+ , K_- , and K_3 on the quantum numbers (j_1, j_2) is to effect the shifts to $(j_1 + \frac{1}{2}, j_2 - \frac{1}{2})$, $(j_1 - \frac{1}{2}, j_2 + \frac{1}{2})$, and (j_1, j_2) , respectively. These actions of Hermitian angular momentum operators satisfying the standard commutation relations $\mathbf{K} \times \mathbf{K} = i\mathbf{K}$ are quite unusual in that they depend only on the angular momentum quantum numbers j_1, j_2, j themselves, which satisfy the triangle rule and give further interesting properties of the modified $SU(2)$ solid harmon-

ics $\psi_{(j_1 j_2) j m}(Z)$. We note these properties in full:

$$\begin{aligned} \mathbf{K}^2 \psi_{(j_1 j_2) j m}(Z) &= j(j+1) \psi_{(j_1 j_2) j m}(Z), \\ K_3 \psi_{(j_1 j_2) j m}(Z) &= (j_1 - j_2) \psi_{(j_1 j_2) j m}(Z), \\ K_+ \psi_{(j_1 j_2) j m}(Z) &= \sqrt{(j - j_1 + j_2)(j + j_1 - j_2 + 1)} \psi_{(j_1 + \frac{1}{2} j_2 - \frac{1}{2}) j m}(Z), \\ K_- \psi_{(j_1 j_2) j m}(Z) &= \sqrt{(j + j_1 - j_2)(j - j_1 + j_2 + 1)} \psi_{(j_1 - \frac{1}{2} j_2 + \frac{1}{2}) j m}(Z). \end{aligned}$$

These relations play no direct role in our continuing considerations of Eq. (2.116) and the determination of the WCG coefficients, and we do not interpret them further.

The explicit WCG coefficients are obtained by expanding the 2×2 determinant in Eq. (2.116), multiplying this expansion into the D -polynomial, and changing the order of the summation. These operations are most succinctly expressed in terms of the umbral calculus of *Roman* and *Rota* [6], using their method of evaluation. The evaluation at y of a divided power $x^k/k!$ of a single indeterminate x to a nonnegative integral power k is defined by

$$\text{eval}_y \frac{x^k}{k!} = \frac{(y)_k}{k!} = \frac{y(y-1) \cdots (y-k+1)}{k!} = \binom{y}{k},$$

where $(y)_k$ is the falling factorial. This definition is extended to products by

$$\text{eval}_{(y_1, y_2, \dots, y_n)} \prod_{i=1}^n \frac{x^{k_i}}{k_i!} = \prod_{i=1}^n \text{eval}_{y_i} \frac{x^{k_i}}{k_i!} = \prod_{i=1}^n \binom{y_i}{k_i}.$$

It is also extended by linearity to sums of such divided powers, multiplied by arbitrary numbers.

The application of these rules to our problem involving four indeterminates gives

$$\begin{aligned} &\frac{(\det X)^n}{n!} \sum_{(\alpha: A: \alpha')} \frac{X^A}{A!} \\ &= \sum_{(\beta: B: \beta')} \text{eval}_B \left(\frac{(\det X)^n}{n!} \right) \frac{X^B}{B!}, \quad (2.118) \\ &\beta = (\alpha_1 + n, \alpha_2 + n), \quad \beta' = (\alpha'_1 + n, \alpha'_2 + n), \\ &\text{eval}_B \frac{(\det X)^n}{n!} \\ &= \sum_{k_1 + k_2 = n} (-1)^{k_2} k_1! k_2! \binom{b_{11}}{k_1} \binom{b_{12}}{k_2} \binom{b_{21}}{k_2} \binom{b_{22}}{k_1}. \quad (2.119) \end{aligned}$$

In this result, we do not identify the labels with angular momentum quantum numbers. Relation Eq. (2.119) is a purely

combinatorial, algebraic identity for arbitrary indeterminates and arbitrary row and column sum constraints on the array A as specified by $\alpha = (\alpha_1, \alpha_2)$ and $\alpha' = (\alpha'_1, \alpha'_2)$. There are no square roots involved.

We now apply relations (Eqs. (2.118)–(2.119)) to the case at hand: $n = j_1 + j_2 - j$, $\alpha = (j + m, j - m)$, $\alpha' = (j + j_1 - j_2, j - j_1 + j_2)$, $\beta = (j_1 + j_2 + m, j_1 + j_2 - m)$, $\beta' = (2j_1, 2j_2)$. This gives the following result for the WCG coefficients:

$$\begin{aligned} & C_{m_1 m_2 m}^{j_1 j_2 j} \\ &= \sqrt{\frac{(j_1 + j_2 - j)!(j_1 - j_2 + j)!(-j_1 + j_2 + j)!}{(j_1 + j_2 + j + 1)!}} \\ & \times \sqrt{\frac{(2j + 1)(j + m)!(j - m)!}{(j_1 + m_1)!(j_1 - m_1)!(j_2 + m_2)!(j_2 - m_2)!}} \\ & \times \text{eval}_A \frac{(\det X)^{j_1 + j_2 - j}}{(j_1 + j_2 - j)!}, \quad (2.120) \\ & \text{eval}_A \frac{(\det X)^{j_1 + j_2 - j}}{(j_1 + j_2 - j)!} \\ &= \sum_{k_1 + k_2 = j_1 + j_2 - j} (-1)^{k_2} k_1! k_2! \binom{j_1 + m_1}{k_1} \binom{j_2 + m_2}{k_2} \\ & \times \binom{j_1 - m_1}{k_2} \binom{j_2 - m_2}{k_1}. \quad (2.121) \end{aligned}$$

In summary, we have the following. Up to multiplicative square-root factors, the WCG coefficient is the evaluation at the point

$$B = \begin{pmatrix} j_1 + m_1 & j_2 + m_2 \\ j_1 - m_1 & j_2 - m_2 \end{pmatrix}$$

of the divided power

$$\frac{(\det X)^{j_1 + j_2 - j}}{(j_1 + j_2 - j)!}$$

of a determinant, which is an integer.

The abstract umbral calculus of Rota thus finds its way, at a basic level, into angular momentum theory. Relation Eq. (2.120) is but a rewriting in terms of evaluations of the well-known Van der Waerden form of the WCG coefficients.

2.13.3 Magic Square Realization of the Addition of Two Angular Momenta

The origin of Eq. (2.114), giving the states of total angular momentum by compounding two angular momenta, is usually attributed to properties of the direct sum of two copies of the Lie algebra of the unitary unimodular group $SU(2)$ and

to the use of differential operators to realize the Lie algebras and state vectors, as was done above. It is an interesting combinatorial result that this structure for adding angular momentum is fully encoded within the properties of magic squares of order 3, and no operators whatsoever are needed, only the condition of being a magic square. We have already noted in Sect. 2.7.4 that Regge observed that the restrictions on the domains of the quantum numbers j_1, m_1, j_2, m_2, j, m are encoded in terms of a magic square A with line sum $J = j_1 + j_2 + j$:

$$A = \begin{pmatrix} j_1 + m_1 & j_2 + m_2 & j - m \\ j_1 - m_1 & j_2 - m_2 & j + m \\ j_2 - j_1 + j & j_1 - j_2 + j & j_1 + j_2 - j \end{pmatrix}. \quad (2.122)$$

The angular momentum quantum numbers are given in terms of the elements of $A = (a_{ij})_{1 \leq i, j \leq 3}$ by the invertible relations

$$\begin{aligned} j_1 &= \frac{1}{2}(a_{11} + a_{21}), & j_2 &= \frac{1}{2}(a_{12} + a_{22}), \\ j &= \frac{1}{2}(a_{13} + a_{23}), \\ m_1 &= \frac{1}{2}(a_{11} - a_{21}), & m_2 &= \frac{1}{2}(a_{12} - a_{22}), \\ m &= \frac{1}{2}(a_{23} - a_{13}). \end{aligned}$$

It follows from these definitions and the fact that A is a magic square of line sum J that the sum rule $m_1 + m_2 = m$ and the triangle condition are fulfilled.

We use the symbol $\langle j_1, j_2, j \rangle$ to denote any triple j_1, j_2, j of angular momentum quantum numbers that satisfy the triangle conditions, where we note that, if a given triple satisfies the triangle conditions, then all permutations of the triple also satisfy the triangle conditions. The number of magic squares for fixed line sum J is obtained as follows. Define $\Delta_J = \{\text{all triangles } \langle j_1, j_2, j \rangle \mid j_1 + j_2 + j = J\}$ and $M(j_1, j_2, j) = \{(m_1, m_2) \mid -j_1 \leq m_1 \leq j_1; -j_2 \leq m_2 \leq j_2; -j \leq m_1 + m_2 \leq j\}$. Then we have the following identity, which gives the number of angular momentum magic squares with line sum J :

$$\sum_{(j_1, j_2, j) \in \Delta_J} |M(j_1, j_2, j)| = \binom{J+5}{5} - \binom{J+2}{5}. \quad (2.123)$$

It is nontrivial to effect the summation on the left-hand side of this relation to obtain the right-hand side, but this expression is known from the theory of magic squares of Stanley [9, 10].

Not only can the addition of two angular momenta in quantum theory, with its triangle rule for three angular momentum quantum numbers and its sum rule on the corresponding projection quantum numbers, be codified in magic

squares of order 3 and arbitrary line sum, but also the content of the abstract state vector of Eq. (2.114) itself can be thus expressed:

$$\begin{aligned} & \left| \frac{1}{2}(a_{11} + a_{21}), \frac{1}{2}(a_{12} + a_{22}); \frac{1}{2}(a_{13} + a_{23}), \frac{1}{2}(a_{23} - a_{13}) \right\rangle \\ &= \sum_{\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}} C(A) \left| \frac{1}{2}(a_{11} + a_{21}), \frac{1}{2}(a_{11} - a_{21}) \right\rangle \\ & \quad \otimes \left| \frac{1}{2}(a_{12} + a_{22}), \frac{1}{2}(a_{12} - a_{22}) \right\rangle, \end{aligned}$$

where the summation is over all subsets

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}$$

of the magic square of order 3, such that row 3 and column 3 are held fixed. The coefficients $C(A)$ themselves are the WCG coefficients, which may be regarded as a function whose domain of definition is the set of all magic squares of order 3. The triangle rule $\langle j_1, j_2, j \rangle$ and the sum rule on (m_1, m_2, m) are implied by the structure of magic squares of order 3. These rich combinatorial footings of angular momentum theory are completed by the observation that the Clebsch–Gordan coefficients themselves are obtained by the Schwinger–Regge generating function given in Sect. 2.7.3 (see [2] for the relation to ${}_3F_2$ hypergeometric functions).

2.13.4 MacMahon’s and Schwinger’s Master Theorems

Generating functions codify the content of many mathematical entities in a unifying, comprehensive way. These functions are very popular in combinatorics, and Schwinger used them extensively in his treatment of angular momentum theory. In this section, we present a natural generalization of the $SU(2)$ solid harmonics to a class of polynomials that are homogeneous in n^2 indeterminates. While these polynomials are of interest in their own right, it is their fundamental role in the addition of n kinematically independent angular momenta that motivates their introduction here. They bring an unexpected unity and coherence to angular momentum coupling and recoupling theory [11].

We list in compendium format some of the principal results.

Special $U(n)$ solid harmonics:

$$D_{\alpha,\beta}^k(Z) = \sqrt{\alpha!\beta!} \sum_{A \in M(\alpha,\beta)} \frac{Z^A}{A!}, \quad (2.124)$$

$A = (a_{ij})_{1 \leq i, j \leq n}$: matrix of order n in nonnegative integers;

$$A! = \prod_{i,j=1}^n a_{ij}!, \quad Z^A = \prod_{i,j=1}^n z_{ij}^{a_{ij}};$$

where we employ the notations:

$\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)$: sequence (composition) of nonnegative integers having the sum k , denoted $\alpha \vdash k$;
 $x^\alpha = x_1^{\alpha_1} x_2^{\alpha_2} \dots x_n^{\alpha_n}$, $\alpha! = \alpha_1! \alpha_2! \dots \alpha_n!$;
 $\beta = (\beta_1, \beta_2, \dots, \beta_n)$: second composition $\beta \vdash k$;
 $M(\alpha, \beta)$, the set of all matrices A such that the entries in row i sums to α_i and those in column j to β_j .

The significance of the row-sum vector α is that α_i is the degree of the polynomial in the variables $(z_{i1}, z_{i2}, \dots, z_{in})$ in row i of Z , with a similar interpretation for β in terms of columns.

Matrix of the $D_{\alpha,\beta}^k(Z)$ polynomials:

The number of compositions of the integer k into n nonnegative parts is given by $\binom{n+k-1}{k}$. The compositions in this set may be linearly ordered by the lexicographical rule $\alpha > \beta$, if the first nonzero part of $\alpha - \beta$ is positive. The polynomial $D_{\alpha,\beta}^k(Z)$ is then the entry in row α and column β in the matrix $D^k(Z)$ of dimension $\dim D^k(Z) = \binom{n+k-1}{k}$, where, following the convention for $SU(2)$, the rows are labeled from top to bottom by the greatest to the least sequence, and the columns are labeled in the same manner as read from left to right. There is a combinatorial proof by Chen and Louck [12] that these polynomials satisfy the following multiplication rule for arbitrary matrices X and Y :

$$D^k(XY) = D^k(X)D^k(Y). \quad (2.125)$$

Orthogonality in the inner product $(,)$ defined in Sect. 2.4.3:

$$\langle D_{\alpha,\beta}^k, D_{\alpha',\beta'}^k \rangle = \delta_{\alpha,\alpha'} \delta_{\beta,\beta'} k!.$$

Value on $Z = \text{diag}(z_1, z_2, \dots, z_n)$:

$$\begin{aligned} D_{\alpha,\beta}^k[\text{diag}(z_1, z_2, \dots, z_n)] &= \delta_{\alpha,\beta} z^\alpha, \\ D^k(I_n) &= I_{\binom{n+k-1}{k}}. \end{aligned} \quad (2.126)$$

Transposition property:

$$D^k(Z^T) = [D^k(Z)]^T.$$

Special irreducible unitary representations of $U(n)$:

$$D^k(U)D^k(V) = D^k(UV), \quad \text{all } U, V \in U(n).$$

Schwinger’s Master Theorem: for any two matrices X and Y of order n , the following identities hold:

$$\begin{aligned} e^{(\partial_x: X: \partial_y)} e^{(x: Y: y)} \Big|_{x=y=0} &= \sum_{k=0}^{\infty} \sum_{\alpha, \beta \vdash k} D_{\alpha,\beta}^k(X) D_{\beta,\alpha}^k(Y) \\ &= \frac{1}{\det(I - XY)}, \end{aligned} \quad (2.127)$$

$$(x : Z : y) = xZy^T = \sum_{i,j=1}^n z_{ij}x_iy_j .$$

MacMahon's Master Theorem: let X be the diagonal matrix $X = \text{diag}(x_1, x_2, \dots, x_n)$ and Y a matrix of order n . Then the coefficient of x^α in the expansion of $\frac{1}{\det(I - XY)}$ equals the coefficient of x^α in the product y^α , $y_i = \sum_{j=1}^n y_{ij}x_j$, that is,

$$\frac{1}{\det(I - XY)} = \sum_{k=0}^{\infty} \sum_{\alpha \vdash k} D_{\alpha, \alpha}^k(Y) x^\alpha . \quad (2.128)$$

Basic Master Theorem: let Z be a matrix of order n . Then

$$\frac{1}{\det(I - tZ)} = \sum_{k=0}^{\infty} t^k \sum_{\alpha \vdash k} D_{\alpha, \alpha}^k(Z) . \quad (2.129)$$

Schwinger's relation Eq. (2.127) follows from the basic relation Eq. (2.129) by setting $Z = XY$ and using the multiplication property Eq. (2.125); MacMahon's relation then follows from Schwinger's result by setting $X = \text{diag}(x_1, x_2, \dots, x_n)$ and using property Eq. (2.126). Of course, MacMahon's Master Theorem preceded Schwinger's result by many years [13]. The unification into the single form by using properties of the $D_{\alpha, \beta}^k(Z)$ polynomials was pointed out in [14]. More surprisingly, relation Eq. (2.129) was already discovered for the general linear group in 1897 by *Molien* [15]; its properties are developed extensively in *Michel* and *Zhilinski* [16] in the context of group theory.

For many purposes, it is better in combinatorics to avoid all square roots by using the polynomials

$$L_{\alpha, \beta}(Z) = \sum_{A \in M(\alpha, \beta)} \frac{Z^A}{A!}$$

in place of the $D_{\alpha, \beta}^k(Z)$ defined in Eq. (2.124).

2.13.5 The Pfaffian and Double Pfaffian

Schwinger observed that the calculation of $3n - j$ coefficients involves taking the square root $\sqrt{\det(I - AB)}$, where A and B are skew symmetric (antisymmetric) matrices of order n , but the procedure is rather obscure. The appropriate concepts for taking the square root is that of a Pfaffian and a double Pfaffian, denoted, respectively, by $\text{Pf}(A)$ and $\text{Pf}(A, B)$. The definitions require the concept of a matching of the set of integers $\{1, 2, \dots, n\}$. A matching of $\{1, 2, \dots, n\}$ is an unordered set of disjoint subsets $\{i, j\}$ containing two elements. For example, the matchings of $1, 2, 3$ are $\{1, 2\}$, $\{1, 3\}$, and $\{2, 3\}$. We then have the following constructs.

The Pfaffian and double Pfaffian of skew symmetric matrices $A = (a_{ij})$ and $B = (b_{ij})$ of order n :

$$\text{Pf}(A) = \sum_{\{i_1, i_2\}, \{i_3, i_4\}, \dots, \{i_{n-1}, i_n\}} \varepsilon(i_1 i_2 \cdots i_n) \times a_{i_1, i_2} a_{i_3, i_4} \cdots a_{i_{n-1}, i_n} , \quad (2.130)$$

$$\text{Pf}(A, B) = 1 + \sum_{k \geq 1} \sum_{\substack{\{i_1, i_2\}, \{i_3, i_4\}, \dots, \{i_{2k-1}, i_{2k}\} \\ \{j_1, j_2\}, \{j_3, j_4\}, \dots, \{j_{2k-1}, j_{2k}\}}} \varepsilon(i_1 i_2 \cdots i_{2k}) \varepsilon(j_1 j_2 \cdots j_{2k}) \times a_{i_1, i_2} a_{i_3, i_4} \cdots a_{i_{2k-1}, i_{2k}} \times b_{j_1, j_2} b_{j_3, j_4} \cdots b_{j_{2k-1}, j_{2k}} , \quad (2.131)$$

where $\{i_1, i_2\}, \{i_3, i_4\}, \dots, \{i_{n-1}, i_n\}$ is a matching of $\{1, 2, \dots, n\}$, and $\varepsilon(i_1 i_2 \cdots i_n)$ is the sign of the permutation (number of inversions). Similarly, in the double Pfaffian, the 2-subsets are matchings of a subset of $\{1, 2, \dots, n\}$ of even length.

Relations of skew symmetric matrices A, B to Pfaffians:

$$\sqrt{\det A} = \text{Pf}(A) ; \quad \sqrt{\det(I - AB)} = \text{Pf}(A, B) . \quad (2.132)$$

2.13.6 Generating Functions for Coupled Wave Functions and Recoupling Coefficients

This section is a reformulation, nontrivial extension, and interpretation of results found in *Schwinger* [3]. We first refine the notation used in Sect. 2.12.3.

Set of triangles in the coupling scheme:

Each coupling scheme, as determined by the bracketing B , has associated with it a unique ordered set of $n - 1$ triangles

$$\begin{aligned} T_B(j, k, j) &= \{ \langle a_i, b_i, k_i \rangle \mid i = 1, 2, \dots, n - 1 \} , \\ j &= (j_1, j_2, \dots, j_n) , \\ k &= (k_1, k_2, \dots, k_{n-2}) , \\ k_{n-1} &= j . \end{aligned}$$

The third part k_i of $\langle a_i, b_i, k_i \rangle$ can always be chosen, without loss of generality, as an intermediate angular momentum ($k_{n-1} = j$), and the triangles in the set can be ordered by $\langle a_i, b_i, k_i \rangle < \langle a_{i+1}, b_{i+1}, k_{i+1} \rangle$. The remaining pair of angular momentum labels in the triangle $\langle a_i, b_i, k_i \rangle$ then fall, in general, into four classes: $\langle a_i, b_i, k_i \rangle$ in which a_i can be either a j_r or a k_s , and b_i can be either a $j_{r'}$ or $k_{s'}$. The distribution of the j 's and k 's among the a_i and b_i is uniquely determined by the bracketing B that defines the coupling scheme.

Clebsch–Gordan coefficients for a given coupling scheme:

$$\begin{pmatrix} \mathbf{j} & \mathbf{k} & \mathbf{j} \\ \mathbf{m} & \mathbf{q} & \mathbf{m} \end{pmatrix}^B = \prod_{(a_i, b_i, k_i) \in \mathbf{T}_B(\mathbf{j}, \mathbf{k}, \mathbf{j})} C_{\alpha_i \beta_i q_i}^{a_i b_i k_i}, \quad (2.133)$$

in which the projection quantum numbers α_i and β_i are m 's and q 's that match the a_i and b_i . In the given coupling scheme determined by the bracketing B , only (j_i, m_i) , $i = 1, 2, \dots, n$; (k_i, q_i) , $i = 1, 2, \dots, n-2$, and (j, m) appear in the Clebsch–Gordan coefficients. In fact, if one explicitly implements the sum rule on the projection quantum numbers, it is always possible to express the q_i as sums over the m_i and m .

Coupled angular momentum function for n angular momenta:

$$\Psi_{(\mathbf{j}, \mathbf{k}) \mathbf{j} \mathbf{m}}^B(\mathbf{x}, \mathbf{y}) = \sum_{\mathbf{m}} \begin{pmatrix} \mathbf{j} & \mathbf{k} & \mathbf{j} \\ \mathbf{m} & \mathbf{q} & \mathbf{m} \end{pmatrix}^B \prod_{i=1}^n \psi_{j_i m_i}(x_i, y_i). \quad (2.134)$$

$$\begin{pmatrix} \mathbf{j} \\ \mathbf{m} \end{pmatrix} = \begin{pmatrix} j_1 & j_2 & \cdots & j_n \\ m_1 & m_2 & \cdots & m_n \end{pmatrix},$$

$$\begin{pmatrix} \mathbf{k} \\ \mathbf{q} \end{pmatrix} = \begin{pmatrix} k_1 & k_2 & \cdots & k_{n-2} \\ q_1 & q_2 & \cdots & q_{n-2} \end{pmatrix}. \quad (2.135)$$

$$Z = (z_1 z_2 \dots z_{n+1}) = \begin{pmatrix} x_1 & x_2 & \cdots & x_{n+1} \\ y_1 & y_2 & \cdots & y_{n+1} \end{pmatrix}. \quad (2.136)$$

Only the first n columns of Z enter into Eq. (2.136), but the last column occurs below.

The skew symmetric matrix of a coupling scheme:

The set of triangles $\mathbf{T}_B(\mathbf{j}, \mathbf{k}, \mathbf{j}) = \{(a_i, b_i, k_i) | i = 1, 2, \dots, n-1\}$, which is uniquely defined by the bracketing B , can be mapped to a unique skew symmetric matrix of order $n+1$. This mapping is one of the most important results for obtaining generating functions for the coupled wave functions Eq. (2.134) and the recoupling coefficients given below. The skew symmetric matrix depends on the bracketing B and the detailed manner in which the j 's and k 's are distributed among the triangles in $\mathbf{T}_B(\mathbf{j}, \mathbf{k}, \mathbf{j})$. The rule for constructing the skew symmetric matrix is quite intricate. First, we define a $3 \times (n-1)$ matrix T of indeterminates by

$$T = \begin{pmatrix} t_{11} & t_{12} & \cdots & t_{1,n-1} \\ t_{21} & t_{22} & \cdots & t_{2,n-1} \\ t_{31} & t_{32} & \cdots & t_{3,n-1} \end{pmatrix}. \quad (2.137)$$

Second, we associate with each $(a_i, b_i, k_i) \in \mathbf{T}_B(\mathbf{j}, \mathbf{k}, \mathbf{j})$, a triple of indeterminates (u_i, v_i, w_i) as given by

$$\begin{aligned} (a_1, b_1, k_1) &\mapsto (u_1, v_1, w_1), & \text{with } w_1 &= t_{21}u_1 + t_{11}v_1, \\ (a_2, b_2, k_2) &\mapsto (u_2, v_2, w_2), & \text{with } w_2 &= t_{22}u_2 + t_{12}v_2, \\ &\vdots & & \vdots \end{aligned}$$

$$\begin{aligned} (a_{n-1}, b_{n-1}, k_{n-1}) &\mapsto (u_{n-1}, v_{n-1}, w_{n-1}), \\ \text{with } w_{n-1} &= t_{2,n-1}u_{n-2} + t_{1,n-1}v_{n-1}. \end{aligned} \quad (2.138)$$

The indeterminates u_i and v_i are identified as a column $z_i = (x_i, y_i)$ of the $2 \times (n+1)$ matrix Z defined by Eq. (2.136), or as one of the w 's occurring higher in the display Eq. (2.138). The distribution rule is in one-to-one correspondence with the distribution of j 's and k 's in the corresponding triangle. Thus, we have

$$\begin{aligned} u_i &= z_r, & \text{if } a_i &= j_r; & v_i &= z_s, & \text{if } b_i &= j_s; \\ u_i &= z_r, & \text{if } a_i &= j_r; & v_i &= w_s, & \text{if } b_i &= k_s; \\ u_i &= w_r, & \text{if } a_i &= k_r; & v_i &= z_s, & \text{if } b_i &= j_s; \\ u_i &= w_r, & \text{if } a_i &= k_r; & v_i &= w_s, & \text{if } b_i &= k_s. \end{aligned}$$

The explicit identification of all j 's and k 's is uniquely determined by the bracketing B . Once this identification has been made, the elements a_{ij} , $i < j$ of the skew symmetric matrix A of order $n+1$ are uniquely determined in terms of the elements of T by equating coefficients of $\det(z_i, z_j) = x_i y_j - x_j y_i$ on the two sides of the form

$$\begin{aligned} \sum_{1 \leq i < j \leq n+1} a_{ij} \det(z_i, z_j) \\ = \sum_{i=1}^{n-1} t_{3i} \det(u_i, v_i) + \det(w_{n-1}, z_{n+1}), \end{aligned} \quad (2.139)$$

where (t_{1i}, t_{2i}, t_{3i}) is the i -th column of the $3 \times (n-1)$ matrix T of indeterminates. This relation can be inferred from results given by Schwinger. Since the elements of A are determined as monomials in the elements of T , we sometimes denote A by $A(T)$. It is useful to illustrate the rule for determining A for $n = 2, 3, 4$.

$n = 2$: triangle: $\langle j_1, j_2, k_1 \rangle$:

$$w_1 = t_{21}z_1 + t_{11}z_2$$

$$\begin{aligned} a_{12} \det(z_1, z_2) + a_{13} \det(z_1, z_3) + a_{23} \det(z_2, z_3) \\ = t_{31} \det(u_1, v_1) + \det(w_1, z_3) \\ = t_{31} \det(z_1, z_2) + t_{21} \det(z_1, z_3) \\ + t_{11} \det(z_2, z_3); \end{aligned}$$

$$a_{12} = t_{31}, \quad a_{13} = t_{21}, \quad a_{23} = t_{11}.$$

$n = 3$: ordered triangles: $\langle j_1, j_2, k_1 \rangle, \langle k_1, j_3, k_2 \rangle$:

$$w_1 = t_{21}u_1 + t_{11}v_1, \quad u_1 = z_1, v_1 = z_2;$$

$$w_2 = t_{22}u_2 + t_{12}v_2, \quad u_2 = w_1, v_2 = z_3.$$

$$\begin{aligned} \sum_{1 \leq i < j \leq 4} a_{ij} \det(z_i, z_j) \\ = t_{31} \det(u_1, v_1) + t_{32} \det(u_2, v_2) + \det(w_2, z_4); \end{aligned}$$

$$\begin{aligned} a_{12} &= t_{31}, & a_{13} &= t_{21}t_{32}, & a_{14} &= t_{21}t_{22} \\ a_{23} &= t_{11}t_{32}, & a_{24} &= t_{11}t_{22} \\ a_{34} &= t_{12} \end{aligned}$$

$n = 4$: ordered triangles: $\langle j_3, j_1, k_1 \rangle, \langle j_4, j_2, k_2 \rangle, \langle k_1, k_2, k_3 \rangle$:

$$\begin{aligned} w_1 &= t_{21}u_1 + t_{11}v_1, & u_1 &= z_3, & v_1 &= z_1, \\ w_2 &= t_{22}u_2 + t_{12}v_2, & u_2 &= z_4, & v_2 &= z_2, \\ w_3 &= t_{23}u_3 + t_{13}v_3, & u_3 &= w_1, & v_3 &= w_2; \\ w_3 &= t_{11}t_{23}z_1 + t_{12}t_{13}z_2 + t_{21}t_{23}z_3 + t_{22}t_{13}z_4, \\ \sum_{1 \leq i < j \leq 5} a_{ij} \det(z_i, z_j) &= t_{31} \det(u_1, v_1) + t_{32} \\ &\times \det(u_2, v_2) + t_{33} \det(u_3, v_3) + \det(w_3, z_5); \\ a_{12} &= t_{11}t_{12}t_{33}, & a_{13} &= -t_{31}, & a_{14} &= t_{11}t_{22}t_{33}, \\ a_{23} &= -t_{12}t_{21}t_{33}, & a_{24} &= -t_{32}, \\ a_{34} &= t_{21}t_{22}t_{33}, \end{aligned}$$

$$\begin{aligned} a_{15} &= t_{11}t_{23} \\ a_{25} &= t_{12}t_{13} \\ a_{35} &= t_{21}t_{23} \\ a_{45} &= t_{22}t_{13} \end{aligned}$$

Triangle monomials.

Let $\langle a, b, c \rangle$ be a triangle of quantum numbers (a, b, c) , let (x, y, z) be three indeterminates, and let B denote a binary coupling scheme with the set of triangles $T_B(\mathbf{j}, \mathbf{k}, j)$.

Elementary triangle monomial:

$$\begin{aligned} \Phi_{\langle a, b, c \rangle}(x, y, z) &= \{abc\}^{-1} x^{b+c-a} y^{a+c-b} z^{a+b-c}, \\ \{abc\} &= \frac{(2c+1)(b+c-a)(a+c-b)!(a+b-c)!}{(a+b+c+1)!}^{\frac{1}{2}}. \end{aligned} \quad (2.140)$$

Triangle monomial associated with a given coupling scheme B :

$$\Phi_{\mathbf{j}, \mathbf{k}, j}^B(T) = \prod_{\langle a_i, b_i, k_i \rangle \in T_B(\mathbf{j}, \mathbf{k}, j)} \Phi_{\langle a_i, b_i, k_i \rangle}(t_{1i}, t_{2i}, t_{3i}). \quad (2.141)$$

Using the definitions introduced above, we can now give the generating functions for the coupled wave functions and the recoupling coefficients for each coupling scheme as determined by the bracketing B .

Generating function for coupled wave functions:

$$\begin{aligned} e^{xA(T)y^T} &= e^{\sum_{1 \leq i < j \leq n+1} a_{ij} \det(z_i, z_j)} \\ &= \sum_{\mathbf{j}, \mathbf{k}} \Phi_{\mathbf{j}, \mathbf{k}, j}^B(T) \sum_m (-1)^{j-m} \psi_{j, -m}(x_{n+1}, y_{n+1}) \\ &\quad \times \Psi_{(\mathbf{j}, \mathbf{k})_{jm}}^B(\mathbf{x}, \mathbf{y}), \\ x &= (x_1, x_2, \dots, x_{n+1}), \quad y = (y_1, y_2, \dots, y_{n+1}). \end{aligned} \quad (2.142)$$

Relation to $U(n+1)$ solid harmonics:

$$e^{xA(T)y^T} = \sum_{k=0}^{\infty} \sum_{\alpha, \beta \vdash k} \frac{x^\alpha}{\sqrt{\alpha!}} D_{\alpha, \beta}^k(A(T)) \frac{y^\beta}{\sqrt{\beta!}}. \quad (2.143)$$

Relation of $U(n+1)$ solid harmonics to triangle monomials:

$$D_{\alpha, \beta}^k[A(T)] = (-1)^{j-m} \sum_k \begin{pmatrix} \mathbf{j} & \mathbf{k} & j \\ \mathbf{m} & \mathbf{q} & m \end{pmatrix}^B \Phi_{\mathbf{j}, \mathbf{k}, j}^B(T) \quad (2.144)$$

$$\begin{aligned} \alpha_i &= j_i + m_i, & \beta_i &= j_i - m_i \quad i = 1, 2, \dots, n; \\ \alpha_{n+1} &= j - m, & \beta_{n+1} &= j + m; \\ \sum_i \alpha_i &= \sum_i \beta_i = j_1 + j_2 + \dots + j_n + j. \end{aligned}$$

The relation between the skew symmetric matrix $A(T)$ of order $n+1$ and the elements of the $3 \times (n-1)$ matrix T is that described in relations Eq. (2.138).

Generating function for all recoupling coefficients:

$$\begin{aligned} \frac{1}{[\text{Pf}(A(T), A'(T'))]^2} &= \frac{1}{[\text{Pf}(A(T), A'(T'))]^2} \\ &= \sum_{\mathbf{j}, \mathbf{k}, \mathbf{k}', j} \Phi_{\mathbf{j}, \mathbf{k}, j}^B(T) \Phi_{\mathbf{j}', \mathbf{k}', j}^{B'}(T') \langle \mathbf{j}, \mathbf{k}, j \parallel \mathbf{j}', \mathbf{k}', j \rangle, \end{aligned} \quad (2.145)$$

where $\langle \mathbf{j}, \mathbf{k}, j \parallel \mathbf{j}', \mathbf{k}', j \rangle$ denotes the recoupling coefficient that effects the transformation between the coupling schemes corresponding to the bracketing B and the bracketing B' , and where the sequence \mathbf{j}' is a permutation of \mathbf{j} in accordance with the bracketing B' . We also note that

$$\begin{aligned} \frac{1}{\text{Pf}(A, A')} &= \frac{1}{\sqrt{\det(I - AA')}} \\ &= \left[1 + \sum_{k \geq 1} \sum_{\alpha, \beta \vdash k} D_{\alpha, \beta}^k(A) D_{\beta, \alpha}^k(A') \right]^{\frac{1}{2}}, \end{aligned} \quad (2.146)$$

for arbitrary skew symmetric matrices of order n .

Relation Eq. (2.145) generates all recoupling coefficients, the trivial ones (those differing by signs) and all the complicated ones, that is, those corresponding to $3n-j$ coefficients. It will also be observed that the expansion of the reciprocal of the double Pfaffian effects an infinite sum in which no radicals occur, which in turn implies that the every recoupling coefficient has the form

$$\begin{aligned} \langle \mathbf{j}, \mathbf{k}, j \parallel \mathbf{j}', \mathbf{k}', j \rangle &= \prod_{\langle a_i, b_i, k_i \rangle \in T_B(\mathbf{j}, \mathbf{k}, j)} \{a_i, b_i, k_i\} \\ &\quad \times \prod_{\langle a'_i, b'_i, k'_i \rangle \in T_{B'}(\mathbf{j}', \mathbf{k}', j)} \{a'_i, b'_i, k'_i\} \\ &\quad \times I(\mathbf{j}, \mathbf{k}, j \parallel \mathbf{j}', \mathbf{k}', j), \end{aligned}$$

where $I(j, k, j || j', k', j)$ is an integer. Each recoupling coefficient is an integer multiplied by square-root factors that depend on the triangles associated with the coupling scheme.

Such features can be very useful in the development of algorithms for the calculation of $3n-j$ coefficients, including WCG coefficients [17]. Relation Eq. (2.145) should be useful for the classification of $3n-j$ coefficients.

2.14 Author's Comments

The relationship between the group $SU(2)$ of 2×2 unitary unimodular (determinant 1) matrices under the usual rule of matrix multiplication for multiplying pairs and the group of 3×3 rotation group $SO(3, R)$ of proper (determinant 1) orthogonal matrices under matrix multiplication of pairs most often uses the known fact that $SU(2)$ is the minimal covering group of $SO(3, R)$. This is the method used in the first version of the *Springer Handbook* and the *Revised Springer Handbook* presented here. However, there is another way of viewing the relationship between the two groups as a sort of nonlinear isomorphism. This is the 3×3 Cartan Hermitian matrix representation, which gives a one-to-one correspondence with the fundamental 3×3 representation of the rotation group. This was already initiated in Sect. 2.1 of this chapter. It will not be carried further here. However, it is appropriate to point out that entering into the development will be the domain of definition, which may be taken to be the unit sphere for the rotation group, and to which is adjoined the Euler angle χ for the unitary unimodular group $SU(2)$ (Chap. 2 and, in particular, Sect. 5, of [1]). It is this Cartan representation by Hermitian matrices that is to be compared to the 3×3 representation of the rotation group $SO(3, R)$ by the active rotation of a physical system onto itself. All of this must be woven together in a coherent fashion.

Then, there is always the question of whether or not the electron is a composite object: electron plus spin? (All reasonable questions should be allowed in any reasonable theory.) Can the electron contain within itself a hidden massless object of spin-1/2 that it can cast-off only in a special environment? Surely this is nonsense. Nonetheless, the invisible partner can be there in the above viewpoint.

Quite aside from the above possibilities of structure, there is another feature of angular momentum theory as presented in this article—the use of the covering group $SU(2)$ of $SO(3, R)$. Racah calculated the coefficients in the form given by Eq. (2.77) by summing over four Clebsch–Gordan coefficients as given by the third formula in the collection at the beginning of Sect. 2.9.1. The details of this calculation can be found in Vol. 8 of [1]. What is important about this form is its expression in terms of triangle coefficients. The question is: since the Racah form of angular momentum theory is applicable to both angular momenta with integer and half-odd

integers, and this feature carries forward to the full family of $3n-j$ coefficients constructed from the Clebsch–Gordan and Racah coefficients, how does it happen that only factorials appear in Eq. (2.77), and the occurrence of the gamma function is never an issue? It must be the case that the set of triangle coefficients that occur in the Racah coefficient somehow block out the occurrence of the gamma function. This places the role of triangle coefficients at the basis of the quantum mechanics of physics. *In the development of angular momentum theory, it is triangle coefficients that have a built-in structure that assures that only factorials occur in the expression of its family of $3n-j$ coefficients.*

The author has carried the properties of triangle coefficients forward by showing how to include all triangles into a single comprehensive symbol for every $3n-j$ coefficient. This leads directly to the classification of $3n-j$ coefficients in terms of binary trees and gives many new insights into the tenets of angular momentum theory. The reference to the two books is given here for the benefit of the reader wishing to pursue this subject: James D. Louck, *Unitary Symmetry and Combinatorics*, World Scientific, Singapore, 2008; *Applications of Unitary Symmetry and Combinatorics*, World Scientific, Singapore, 2011.

In pointing out these references, the author is also obligated to mention an error that occurs throughout. The statement that the smallest angular momentum that occurs in implementing the Clebsch–Gordan series into the addition of n angular momenta is the least of all positive angular momenta in the multiset $pmj_1, pmj_2, \dots, pmj_n$ of 2^n angular momenta is wrong. This was pointed out to the author by Dr. Wade Smith about 4 years ago by giving the counterexample $j_1 = 1, j_2 = 1, j_3 = 1, j_4 = 4$. The correct answer is $j(\min) =$ greatest angular momentum in the set j_1, j_2, \dots, j_n of original angular momenta being coupled.

The author expresses his gratitude to Debi Erpenbeck, whose artful mastery of \TeX and scrupulous attention to detail allowed the numerous complex relations to be displayed in two-column format.

Author's note. It is quite impossible to attribute credits fairly in this subject because of its diverse origins across all areas of physics, chemistry, and mathematics. Any attempt to do so would likely be as misleading as it is informative. Most of the material is rooted in the very foundations of quantum theory itself, and the physical problems it addresses, making it still more difficult to assess unambiguous credit of ideas. Pragmatically, there is also the problem of confidence in the detailed correctness of complicated relationships, which prejudices one to cite those relationships personally checked. This accounts for the heavy use of formulas from [1], which is, by far, the most often used source. But most of that material itself is derived from other primary sources, and an inadequate attempt was made there to indicate the broad base of origins. While one might expect to find in a reference book a comprehensive list of credits for most of the formulas, it has been necessary to weigh the relative merits of presenting a mature subject from a viewpoint of conceptual unity versus credits for individual contributions. The first position was adopted. Nonetheless, there is an obligation to indicate the origins of a subject, noting those works that have been most influential in its developments. The list of textbooks and seminal articles given in the references is intended to serve this purpose, however inadequately.

Abstract

The basic elements of the theory of Lie groups and their irreducible representations (IRs) are described. The IRs are used to label the states of an atomic shell and also the components of operators of physical interest. Applications of the generalized Wigner–Eckart theorem lead to relations between matrix elements appearing in different electronic configurations. This is particularly useful in the *f* shell, where transformations among the seven orbital states of an *f* electron can be described by the unitary group $U(7)$ and its sequential subgroups $SO(7)$, G_2 , and $SO(3)$ with respective IRs $[\lambda]$, W , U , and L . Extensions to groups that involve electron spin S (like $Sp(14)$) are described, as are groups that do not conserve electron number. The most useful of the latter is the quasispin group whose generators Q connect states of identical W , U , L and seniority v in the *f* shell. The symmetries of products of objects (states or operators) that themselves possess symmetries are described by the technique of plethysms.

Keywords

group theory · atomic shells · Lie groups · irreducible representations · Wigner–Eckart theorem · quasispin

3.1 Generators

3.1.1 Group Elements

An element S_a of a Lie group \mathcal{G} corresponding to an infinitesimal transformation can be written in the form

$$S_a = 1 + \delta a^\sigma X_\sigma, \quad (3.1)$$

where the δa^σ are the infinitesimal parameters and the X_σ are the generators [1]. Summation over the repeated Greek

B. R. Judd (✉)
Dept. of Physics & Astronomy, The Johns Hopkins University
Baltimore, MD, USA
e-mail: juddbr@pha.jhu.edu

index is implied. Transformations corresponding to finite parameters can be found by exponentiation

$$S_a \rightarrow \exp(a^1 X_1) \exp(a^2 X_2) \cdots \exp(a^r X_r). \quad (3.2)$$

The generators necessarily form a Lie algebra, that is, they close under commutation

$$[X_\rho, X_\sigma] = c_{\rho\sigma}^\tau X_\tau. \quad (3.3)$$

In terms of the structure constants $c_{\rho\sigma}^\tau$, the metric tensor is defined as

$$g_{\rho\sigma} = c_{\rho\lambda}^\mu c_{\sigma\mu}^\lambda. \quad (3.4)$$

3.1.2 Conditions on the Structure Constants

For an Abelian group, all the generators commute with one another

$$c_{\rho\sigma}^\tau = 0. \quad (3.5)$$

The operators X_σ ($\sigma = 1, 2, \dots, p < r$) form the generators of a subgroup if [2]

$$c_{\rho\sigma}^\tau = 0, \quad (\rho, \sigma \leq p, \tau > p). \quad (3.6)$$

The subgroup is invariant if the stronger condition

$$c_{\rho\sigma}^\tau = 0, \quad (\rho \leq p, \tau > p) \quad (3.7)$$

is satisfied. A group is *simple* if it contains no invariant subgroup (besides the unit element). A group is *semisimple* if it contains no Abelian invariant subgroup (besides the unit element). A necessary and sufficient condition that a group be semisimple is that

$$\det |g_{\rho\tau}| \neq 0. \quad (3.8)$$

All simple groups are semisimple. For semisimple groups, the inverse tensor $g^{\mu\nu}$ can be formed, thus permitting suffixes to be raised. The quadratic operator

$$C = g^{\rho\sigma} X_\rho X_\sigma \quad (3.9)$$

commutes with all generators of the group and is called Casimir's operator [1]. If the generators of a group \mathcal{G} can be broken up into two sets such that each member of one set commutes with all the members of the other, that is, if

$$c_{\rho\sigma}^\tau = 0, \quad (\rho \leq p, \sigma > p), \quad (3.10)$$

then the two sets form the generators of two invariant subgroups, \mathcal{H} and \mathcal{K} . The group \mathcal{G} is the direct product of \mathcal{H} and \mathcal{K} and is written as $\mathcal{H} \times \mathcal{K}$.

3.1.3 Cartan–Weyl Form

By taking suitable linear combinations H_i and E_α of the generators X_σ , the basic commutation relations Eq. (3.3) can be thrown into the so-called Cartan–Weyl form [1]

$$[H_i, H_j] = 0, \quad (3.11)$$

$$[H_i, E_\alpha] = \alpha_i E_\alpha, \quad (3.12)$$

$$[E_\alpha, E_{-\alpha}] = \alpha^i H_i, \quad (3.13)$$

$$[E_\alpha, E_\beta] = N_{\alpha\beta} E_{\alpha+\beta}. \quad (3.14)$$

The Roman symbols i, j, \dots run over an l -dimensional space (the *weight* space of *rank* l) in which the numbers α_i can be visualized as the components of the vectors (called *roots*). The E_α are shift operators, the displacements being specified by the components of α . The operator $E_{\alpha+\beta}$ in Eq. (3.17) is to be interpreted as 0 if $\alpha + \beta$ is not a root. The coefficient $N_{\alpha\beta}$ depends on the choice of normalization.

3.1.4 Atomic Operators as Generators

The pairs $a_\xi^\dagger a_\eta$ of creation and annihilation operators for either bosons or fermions, as defined in Sect. 6.1.1 close under commutation and form a Lie algebra. The coupled forms $W^{(\kappa k)}$, defined in Sect. 6.2.2, are often used to play the role of the generators for electrons in an atomic shell.

3.2 Classification of Lie Algebras

3.2.1 Introduction

The semisimple Lie algebras have been classified by *Cartan* [3]. They consist of four main classes A_l, B_l, C_l, D_l , and five exceptions G_2, F_4, E_6, E_7, E_8 . Each algebra is characterized by an array of roots in the l -dimensional weight space; they are conveniently specified by a set of mutually orthogonal unit vectors e_i . The total number of generators (those of type E_α plus the l generators of type H_i) gives the *order* of the algebra.

3.2.2 The Semisimple Lie Algebras

A_l . The roots are conveniently represented by the vectors $e_i - e_j$ ($i, j = 1, 2, \dots, l + 1$). They are all perpendicular to Σe_k and do not extend beyond the l -dimensional weight space. The order of the algebra is $l(l + 2)$. The group for which this algebra can serve as a basis is the special unitary group $SU(l + 1)$.

Table 3.1 Generators of the Lie groups for the atomic l shell. The subscripts i and j run over all $4l + 2$ states of a single electron

Group	Generators
$SO(8l + 5)^a$	$a_i^\dagger a_j^\dagger, a_i^\dagger a_j, a_i a_j, a_i^\dagger, a_j$
$SO(8l + 4)^a$	$a_i^\dagger a_j^\dagger, a_i^\dagger a_j, a_i a_j$
$U(4l + 2)^b$	$W^{(\kappa k)}$ ($\kappa = 0, 1; k = 0, 1, \dots, 2l$)
$SU(4l + 2)^b$	$W^{(\kappa k)}$ (as above, with $\kappa = k = 0$ excluded)
$Sp(4l + 2)^c$	$W^{(\kappa k)}$ (as above, with $\kappa + k$ odd)
$U(2l + 1)^d$	$W^{(0k)}$ ($k = 0, 1, \dots, 2l$)
$SU(2l + 1)^d$	$W^{(0k)}$ ($k = 1, 2, \dots, 2l$)
$SO(2l + 1)^d$	$W^{(0k)}$ ($k = 1, 3, 5, \dots, 2l - 1$)
G_2^d	$W^{(01)}, W^{(05)}$ (for $l = 3$)
$SO_L(3)^e$	$W^{(01)}$ (or L)
$SO_S(3)^e$	$W^{(10)}$ (or S)
$U_A(2l + 1) \times U_B(2l + 1)^f$	$W_{0q}^{(0k)} + W_{0q}^{(1k)}, W_{0q}^{(0k)} - W_{0q}^{(1k)}$ ($k = 0, 1, \dots, 2l$)
$SO_\lambda(2l + 1) \times SO_\mu(2l + 1) \times SO_\nu(2l + 1) \times SO_\xi(2l + 1)^g$	$(\theta^\dagger \theta)^{(k)}$ (k odd, $\theta \equiv \lambda, \mu, \nu, \xi$)
$U_\lambda(2^l) \times U_\mu(2^l) \times U_\nu(2^l) \times U_\xi(2^l)^h$	$q_\theta^\dagger q_\theta$ (all components, $\theta \equiv \lambda, \mu, \nu, \xi$)

^a [4, 5]; ^b [1, 6]; ^c [6, 7]; ^d [6]; ^e [8]; ^f [9]; ^g [10, 11] and Eqs. (6.69)–(6.72); ^h [12]

B_l . The roots are $\pm e_i$ and $\pm e_i \pm e_j$ ($i, j = 1, 2, \dots, l; i \neq j$). The order of the algebra is $l(2l + 1)$. A corresponding group is the special orthogonal (or rotation) group in $2l + 1$ dimensions, $SO(2l + 1)$.

C_l . The roots are $\pm 2e_i$ and $\pm e_i \pm e_j$ ($i, j = 1, 2, \dots, l; i \neq j$). The order of the algebra is $l(2l + 1)$. A corresponding group is the symplectic group in $2l$ dimensions, $Sp(2l)$. A rotation of the roots yields $C_2 = B_2$.

D_l . The roots are $\pm e_i \pm e_j$ ($i, j = 1, 2, \dots, l; i \neq j$). The order of the algebra is $l(2l - 1)$. A corresponding group is the special orthogonal (or rotation) group $SO(2l)$. A rotation of the roots yields $D_3 = A_3$. Also, $D_2 = A_1 \times A_1$.

E_6, E_7, E_8 . The roots are given by *Racah* [1]. The respective orders are 78, 133, and 248.

F_4 . The roots consist of the roots of B_4 together with the 16 vectors $\frac{1}{2}(\pm e_1 \pm e_2 \pm e_3 \pm e_4)$. The order of the algebra is 52.

G_2 . The roots consist of the roots of A_2 together with the six vectors $\pm(2e_i - e_j - e_k)$ ($i \neq j \neq k = 1, 2, 3$). The order of the algebra is 14.

Examples of Lie groups used in atomic shell theory, together with their generators, are given in Table 3.1.

3.3 Irreducible Representations

3.3.1 Labels

If n atomic states of a collection transform among themselves under an arbitrary action of the generators of a group \mathcal{G} , then the states form a *representation* of \mathcal{G} . The representation is *irreducible* if n' linear combinations of the states cannot be found that also exhibit that property, where $n' < n$. The commuting generators H_i of \mathcal{G} can be simultaneously diagonalized within the n states: their eigenvalues (m_1, m_2, \dots, m_l) for an eigenstate ψ specify the *weight* of the eigenstate. The weight above is said to be *higher* than $(m'_1, m'_2, \dots, m'_l)$ if the first non-vanishing term in the sequence $m_1 - m'_1, m_2 - m'_2, \dots$ is positive. An irreducible representation (IR) of a semisimple group is uniquely specified (to within an equivalence) by its highest weight [1], which can therefore be used as a defining label.

3.3.2 Dimensions

The dimensions of the IRs of various groups are expressed in terms of the highest weights and set out in Table 3.2. General algebraic expressions have been given by *Wybourne* [13, pp. 137]. Numerical tabulations have been made by Butler in the appendix to another book by *Wybourne* [14], and also by *McKay* and *Patera* [15]. The latter defines the IRs by specifying the coordinates of the weights with respect to the simple roots of *Dynkin* [16].

Table 3.2 Dimensions D of the irreducible representations (IR's) of various Lie groups

Group	IR	D
SO(2)	M	1
SO(3)	D_J	$2J + 1$
SO(4) = SO _A (3) × SO _B (3)	$D_J \times D_K$	$(2J + 1)(2K + 1)$
SO(5)	$(w_1 w_2)$	$(w_1 + w_2 + 2)(w_1 - w_2 + 1)(2w_1 + 3)(2w_2 + 1)/6$
SO(6)	$(w_1 w_2 w_3)$	$(w_1 - w_2 + 1)(w_1 - w_3 + 2)(w_2 - w_3 + 1) \times (w_1 + w_2 + 3)(w_1 + w_3 + 2)(w_2 + w_3 + 1)/12$
SO(7)	$(w_1 w_2 w_3)$	$(w_1 + w_2 + 4)(w_1 + w_3 + 3)(w_2 + w_3 + 2)(w_1 - w_2 + 1)(w_1 - w_3 + 2)(w_2 - w_3 + 1) \times (2w_1 + 5)(2w_2 + 3)(2w_3 + 1)/720$
G ₂	$(u_1 u_2)$	$(u_1 + u_2 + 3)(u_1 + 2)(2u_1 + u_2 + 5)(u_1 + 2u_2 + 4)(u_1 - u_2 + 1)(u_2 + 1)/120$
SU(3) or U(3)	$[\lambda_1 \lambda_2 \lambda_3]$	$(\lambda_1 - \lambda_2 + 1)(\lambda_1 - \lambda_3 + 2)(\lambda_2 - \lambda_3 + 1)/2$
SU(4) or U(4)	$[\lambda_1 \lambda_2 \lambda_3 \lambda_4]$	As for $(w_1 w_2 w_3)$ of SO(6) ^a
Sp(4)	$\langle \sigma_1 \sigma_2 \rangle$	As for $(w_1 w_2)$ of SO(5) ^b
Sp(6)	$\langle \sigma_1 \sigma_2 \sigma_3 \rangle$	$(\sigma_1 - \sigma_2 + 1)(\sigma_1 - \sigma_3 + 2)(\sigma_1 + \sigma_2 + 5)(\sigma_1 + \sigma_3 + 4)(\sigma_2 + \sigma_3 + 3)(\sigma_2 - \sigma_3 + 1) \times (\sigma_1 + 3)(\sigma_2 + 2)(\sigma_3 + 1)/720$

^a Subject to the conditions $w_1 = (\lambda_1 + \lambda_2 - \lambda_3 - \lambda_4)/2$, $w_2 = (\lambda_1 - \lambda_2 + \lambda_3 - \lambda_4)/2$, $w_3 = (\lambda_1 - \lambda_2 - \lambda_3 + \lambda_4)/2$

^b Subject to the conditions $w_1 = (\sigma_1 + \sigma_2)/2$, $w_2 = (\sigma_1 - \sigma_2)/2$

Table 3.3 Eigenvalues of Casimir's operator C for groups used in the atomic l shell

Group	IR	Operator	Eigenvalue
SU($2l + 1$)	$[\lambda]^a$	$\sum_{k>0} (\mathbf{V}^{(k)})^2$	$3N + 2Nl - \frac{1}{2}N^2 - 2S(S + 1) - N^2/(2l + 1)$
SO($2l + 1$)	\mathcal{W}^b	$\sum_{k\text{ odd}} (\mathbf{V}^{(k)})^2$	$\frac{1}{2} \sum_{i=1}^l w_i(w_i + 1 + 2l - 2i)$
G ₂	$(u_1 u_2)$	$\frac{1}{4} [(\mathbf{V}^{(1)})^2 + (\mathbf{V}^{(5)})^2]$	$(u_1^2 + u_2^2 + u_1 u_2 + 5u_1 + 4u_2)/12$

^a Appropriate for terms of l^N with total spin S [7, p. 125]

^b Defined by the l weights $(w_1 w_2 \dots w_l)$

3.3.3 Casimir's Operator

The eigenvalues of Casimir's operator C , defined in Eq. (3.9), can be expressed in terms of the highest weights of an IR [1]. A complete algebraic listing for all the semisimple Lie groups has been given by *Wybourne* [13, p. 140]. Sometimes Casimir's operator is given in terms of the spherical tensors $\mathcal{W}^{(k)}$, or of their special cases $\mathbf{V}^{(k)}$ ($= 2^{\frac{1}{2}} \mathcal{W}^{(0k)}$) for which the single-electron reduced matrix element satisfies

$$(nl \| v^{(k)} \| nl) = (2k + 1)^{\frac{1}{2}}. \quad (3.15)$$

The eigenvalues of several operators of that form are given in Table 3.3.

3.4 Branching Rules

3.4.1 Introduction

If a group \mathcal{H} shares some of its generators with a group \mathcal{G} , the first can be considered a subgroup of the second. That is, $\mathcal{G} \supset \mathcal{H}$. Many of the groups in Table 3.1 can be put in extended group–subgroup sequences. The IRs of a subgroup that together span an IR of the group constitute a *branching* rule.

3.4.2 $U(n) \supset SU(n)$

The group $U(n)$ differs from $SU(n)$ in that the former contains among its generators a scalar such as $(W^{(00)})$ that, by itself, forms an invariant subgroup. Thus $U(n)$ is not semisimple. The scalar in question commutes with all the generators of the group and so is of type H_i . Its presence enlarges the dimension, l , of the weight space by 1, an extension that can be accommodated by the unit vectors \mathbf{e}_i of A_l given in Sect. 3.2.2. The reduction $U(n) \supset SU(n)$ leads to the branching rule

$$[\lambda_1 \lambda_2 \dots \lambda_n] \rightarrow [\lambda_1 - a, \lambda_2 - a, \dots, \lambda_n - a], \quad (3.16)$$

where, in the IR of $SU(n)$ on the right,

$$a = (\lambda_1 + \lambda_2 + \dots + \lambda_n)/n. \quad (3.17)$$

To avoid fractional weights, the IRs of $SU(n)$ are frequently replaced by those of $U(n)$ for which the λ_i are integers. The weights $\lambda_1, \lambda_2, \dots$ can be interpreted as the number of cells in successive rows of a *Young Tableau*. When the n states of a single particle are taken as a basis for the IR $[10 \dots 0]$ of $U(n)$, thus corresponding to a tableau comprising a single cell, the tableaux comprising N cells can be interpreted in two ways, namely, (1) as an IR of $U(n)$ for a system of

N particles, and (2) as an IR of S_N , the finite group of permutations on N objects. A given tableau corresponds to as many permutations as there are ways of entering the numbers $1, 2, \dots, N$ in the cells such that the numbers increase going from left to right along the rows, and from top to bottom down the columns. A tableau possessing cells numbered in this way is called *standard*; it defines a permutation corresponding to a symmetrization with respect to the numbers in the rows, followed by an antisymmetrization with respect to the numbers in the columns [17].

3.4.3 Canonical Reductions

A group–subgroup sequence of the type

$$U(n) \supset U(n-1) \supset U(n-2) \supset \dots \supset U(1) \quad (3.18)$$

is called *canonical* [18]. The branching rules for those IRs $[\lambda'_1 \lambda'_2 \dots \lambda'_{n-1}]$ of $U(n-1)$ contained in $[\lambda_1 \lambda_2 \dots \lambda_n]$ of $U(n)$ have been given by Weyl [19] in terms of the *betweenness* conditions

$$\lambda_1 \geq \lambda'_1 \geq \lambda_2 \geq \lambda'_2 \geq \dots \geq \lambda'_{n-1} \geq \lambda_n. \quad (3.19)$$

The possibility of using the scheme of Eq. (3.18) in the theory of complex atomic spectra has been explored by Harter [20, 21], Harter and Patterson [22], and by Drake and Schlesinger [23, 24] (see also Sect. 4.3.1).

3.4.4 Other Reductions

The algebraic formulae for $U(n) \supset SO(n)$ and $U(n) \supset Sp(n)$ have been given by Littlewood [25] and in a rather more accessible form by Wybourne [14]. Special cases have been tabulated by Butler (in Tables C-1 through C-15 in [14]). Another set of tables, in which Dynkin's labeling scheme is used, has been given by McKay and Patera [15]. Descriptions of how to apply the mechanics of the mathematics to the Young tableaux that describe the IRs of $U(n)$ can be found in the articles of Jahn [26] [with particular reference to $SO(5)$] and Flowers [27] [for $Sp(2j+1)$]. For the atomic l shell, the reductions $SO(2l+1) \supset SO(3)$ and (for f electrons) $SO(7) \supset G_2$ and $G_2 \supset SO(3)$ are important. The sources cited in the previous Section are useful here. It is important to recognize that the embedding of one group in another can often be performed in inequivalent ways, depending on which generators are discarded in the reduction process. Thus the use of $SO(5) \supset SO(3)$ in the atomic d shell involves a different $SO(3)$ group from that derived from the canonical sequence $SO(5) \supset SO(4) \supset SO(3)$.

3.5 Kronecker Products

3.5.1 Outer Products of Tableaux

Consider the tableau $[\lambda_1 \lambda_2 \dots \lambda_n]$, where the total number of cells is N . A preliminary definition is required. If among the first r terms of any permutation of the N factors of the product, $x_1^{\lambda_1} x_2^{\lambda_2} \dots x_n^{\lambda_n}$, the number of times x_1 occurs is \geq the number of times x_2 occurs \geq the number of times x_3 occurs, etc. for all values of r , this permutation is called a *lattice* permutation. The prescription of Littlewood [25] for finding the tableaux appearing in the Kronecker product of $[\lambda_1 \lambda_2 \dots \lambda_n]$ with $[\mu_1 \mu_2 \dots \mu_m]$ is as follows. The acceptable tableaux are those that can be built by adding to the tableau $[\lambda_1 \lambda_2 \dots \lambda_n]$, μ_1 cells containing the same symbol α , then μ_2 cells containing the same symbol β , etc., subject to two conditions:

1. After the addition of each set of cells labeled by a common symbol we must have a permissible tableau with no two identical symbols in the same column;
2. If the total set of added symbols is read from right to left in the consecutive rows of the final tableau, we obtain a lattice permutation of $\alpha^{\mu_1} \beta^{\mu_2} \gamma^{\mu_3} \dots$

Examples of this procedure have been given [25, p. 96; 7, p. 136; 14, p. 24]. An extensive tabulation involving tableaux with $N < 8$ has been calculated by Butler and given by Wybourne [14, Table B-1].

3.5.2 Other Outer Products

The rules for constructing the Kronecker products for $U(n)$ follow by interpreting the Young tableaux of the previous section as IRs of $U(n)$. The known branching rules for reductions to subgroups enable the Kronecker products for the subgroups to be found. Many examples for $SO(n)$, $Sp(n)$, and G_2 can be found in the book by Wybourne [14, Tables D-1–D-15, and E-4].

3.5.3 Plethysms

Sometimes a particle can be thought of as being composite (as when the six orbital states $s+d$ of a single electron are taken to span the IR [200] of $SU(3)$). When the n' component states of a particle form a basis for an IR $[\lambda']$ of $U(n)$ other than $[10 \dots 0]$, the process of finding which IRs of $U(n)$ occur for N -particle states whose permutation symmetries are determined by a given Young tableau $[\lambda]$ with N cells is called a *plethysm* [25, p. 289] and written as $[\lambda'] \otimes [\lambda]$.

The special techniques for doing this have been described by *Wybourne* [14]. An elementary method, which is often adequate in many cases, runs as follows:

1. Expand $[\lambda']^N$ by repeated use of Table B-1 from [14]. The resulting tableaux $[\lambda'']$ are independent of n .
2. Choose a small value of n , and strike out all tableaux from the set $[\lambda'']$ that possess more than n rows (since they are unacceptable as IRs of $U(n)$).
3. Interpret the remaining tableaux $[\lambda'']$ as IRs of $U(n)$ and find their dimensions from Tables A-2 through A-17 of [14]. Check that the sum of the dimensions is $(\dim[\lambda'])^N$.
4. Interpret the various tableaux $[\lambda]$ possessing the same number N of cells as IRs of $U(\dim[\lambda'])$, and find their dimensions from [14].
5. Match the dimensions of parts (3) and (4), remembering that each tableau $[\lambda]$ occurs as often as the number of its standard forms. This determines the possible ways of assigning the IRs $[\lambda'']$ of $U(n)$ to each $[\lambda]$.
6. Proceed to higher n to remove ambiguities and to include the tableaux struck out in step 2.

This procedure can be extended to calculate the plethysms for other groups. Examples of the type $W \otimes [\lambda]$ and $U \otimes [\lambda]$, where W and U are IRs of $SO(7)$ and G_2 , have been given for $[\lambda] \equiv [2]$ and $[11]$ corresponding to the separation of W^2 and U^2 into their symmetric and antisymmetric parts [28]. The technique of plethysm is also useful for mixed atomic configurations (Sect. 3.6.1).

3.6 Atomic States

3.6.1 Shell Structure

The 2^{4l+2} states of the l shell span the elementary spinor IR $(\frac{1}{2}\frac{1}{2}\cdots\frac{1}{2})$ of $SO(8l+5)$, which decomposes into the two IRs $(\frac{1}{2}\frac{1}{2}\cdots\pm\frac{1}{2})$ of $SO(8l+4)$, corresponding to an even and an odd number N of electrons [4]. The states of l^N span the IR $[1^N 0^{4l+2-N}]$ of $U(4l+2)$, corresponding to the antisymmetric Young tableau comprising a single column of N cells. The separation of spin and orbit through the subgroup $U(2) \times U(2l+1)$ yields the tableau products $[\lambda] \times [\tilde{\lambda}]$, where $[\tilde{\lambda}]$ is the tableau obtained by reflecting $[\lambda]$ in a diagonal line [1]. The IRs of the subgroup $U(2) \times SO(2l+1)$ are denoted by S and W [6]. An alternative way of reaching this subgroup from $U(4l+2)$ involves the intermediary $Sp(4l+2)$, whose IRs $\langle 1^v 0^{2l+1-v} \rangle$ possess as a basis the states with seniority v [7]. A subgroup of $SO(2l+1)$ is the $SO(3)$ group whose IRs specify L , the total orbital angular momentum.

Table 3.4 The states of the d shell

d^N	M_Q	$^{2S+1}[\lambda]$	v	W	L	
d^0	$-\frac{5}{2}$	$^1[0]$	0	(00)	S	
d^1	-2	$^2[1]$	1	(10)	D	
d^2	$-\frac{3}{2}$	$^1[2]$	0	(00)	S	
			2	(20)	DG	
d^3	-1	$^3[11]$	2	(11)	PF	
			$^2[21]$	1	(10)	D
				3	(21)	PDFGH
d^4	$-\frac{1}{2}$	$^4[111]$	3	(11)	PF	
			$^1[22]$	0	(00)	S
				2	(20)	DG
		4		(22)	SDFGI	
		$^3[211]$	2	(11)	PF	
			4	(21)	PDFGH	
d^5	0	$^5[1111]$	4	(10)	D	
			$^2[221]$	1	(10)	D
				3	(21)	PDFGH
		5		(22)	SDFGI	
		$^4[2111]$	3	(11)	PF	
			5	(20)	DG	
$^6[11111]$	5	(00)	S			

Alternatives to this classic sequence are provided by the last three groups listed in Table 3.1, together with their respective subgroups. For $U_A(2l+1) \times U_B(2l+1)$, the shell is factored by considering spin-up and spin-down electrons as distinct (and statistically independent) particles [29]. A further factorization by means of the quasiparticles, θ , leads to four independent spaces. The 2^l states in each space span the elementary spinor $(\frac{1}{2}^l)$ of $SO_\theta(2l+1)$, which can be regarded as a fictitious particle (or quark), q_θ [30].

The standard classification of the states of the d-shell is given in Table 3.4. The component M_Q of the quasispin Q (defined in Eqs. (6.33)–(6.35)) is listed, as well as the seniority, $v = 2l + 1 - 2Q$, the IRs W of $SO(5)$, and the value of L (as a spectroscopic symbol). Only states in the first half of the shell appear; the classification for the second half is the same as the first except that the signs of M_Q are reversed. A general rule for arbitrary l is exemplified by noting that every W (the IR of $SO(2l+1)$) occurs with two spins (S_1 and S_2) and two quasispins (Q_1 and Q_2) such that $S_1 = Q_2$ and $S_2 = Q_1$. No duplicated spectroscopic terms appear in Table 3.4. The generators of $SO(5)$ do not commute with the inter-electronic Coulomb interaction; thus the separations effected by $SO(5)$ merely define (to within a phase) a basis. The analog of Table 3.4 has been given by *Wybourne* [31] for the f shell. As *Racah* [6] showed, the group G_2 can be used to help distinguish repeated terms, but a few duplications remain. They are distinguished by *Nielson* and *Koster* [32] in their tables of spectroscopic coefficients by the letters A and B . The scope for applications of group theory becomes enlarged when the states of a single electron embrace more

than one l value. Extensions of the standard model have been made by *Feneuille* [33–36] with particular reference to the configurations $(d + s)^N$, for which quasiparticles have also been considered [37]. The group $SU(3)$ has been used for $(d + s)^N p^M$ [38]. The mixed configurations $(s + f)^4$ have found a use in the quark model of the atomic f shell [30]. A brief description of this model has been given by *Fano* and *Rao* [39].

3.6.2 Automorphisms of $SO(8)$

The quark structure $s + f$ derives from the $SO(3)$ structure of the elementary spinor $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$ of $SO(7)$. Its eight components span the IR (1000) of $SO(8)$, a group that admits automorphisms [40]. This property is exhibited by the existence of the three distinct subgroups $SO(7)$ (Racah's group), $SO(7)'$, and $SO(7)''$, all of which possess the same G_2 and $SO(3)$ as subgroups. A reversal of the relative phase of the s and f quarks takes $SO(7)$ into $SO(7)''$ and vice versa [41]. The generators of $SO(7)'$ are the sums of the corresponding generators of $SO(7)$ and $SO(7)''$. The phase reversal between the s and f quarks, when interpreted in terms of electronic states, explains the unexpected simplifications found by *Racah* [6] in his equation (87) [42], which goes beyond what the Wigner–Eckart theorem for G_2 would predict. Similarly, explanations can be found for some (but not all) proportionalities between blocks of matrix elements of components of the spin–other-orbit interaction for f electrons [43]. *Hansen* and *Ven* have given some examples of still unexplained proportionalities [44]. The group $SO(7)'$ has proved useful in analyses of the effective three-electron operators used to represent weak configuration interaction in the f shell [41].

3.6.3 Hydrogen and Hydrogen-Like Atoms

The nonrelativistic hydrogen atom possesses an $SO(4)$ symmetry associated with the invariance of the Runge–Lenz vector, which indicates the direction of the major axis of the classical elliptic orbit [5]. The quantum-mechanical form of this vector can be written in dimensionless units as

$$\mathbf{a} = \frac{(\mathbf{l} \times \mathbf{p}) - (\mathbf{p} \times \mathbf{l}) + 2Zr\hbar^2/ra_0}{2p_0}, \quad (3.20)$$

where $a_0 = \hbar^2/me^2$ is the Bohr radius, Ze is the nuclear charge, p_0 is related to the principal quantum number n by $p_0 = Z/na_0$, and where the momentum \mathbf{p} and angular momentum \mathbf{l} of the electron in its orbit are measured in units of \hbar . The analysis is best carried out in momentum space [45]. The four coordinates to which $SO(4)$ refers can

be taken from Eqs. (9.43)–(9.46) or directly as kp_x, kp_y, kp_z , and $kp_0(1 - p^2/p_0^2)/2$, where $k = 2p_0/(p^2 + p_0^2)$. The generators of $SO(4)$ are provided by the 6 components of the two mutually commuting vectors $(\mathbf{l} + \mathbf{a})/2$ and $(\mathbf{l} - \mathbf{a})/2$, each of which behaves as an angular momentum vector. The equivalence $SO(4) = SO(3) \times SO(3)$ corresponds to the isomorphism $D_2 = A_1 \times A_1$ of Sect. 3.2.2.

Hydrogenic eigenfunctions belonging to various energies can be selected to form bases for a number of groups. The inclusion of all the levels up to a given n yields the IR $(n - 1, 0)$ of $SO(5)$. Levels of a given l and all n form an infinite basis for an IR of the noncompact group $SO(2, 1)$ [46]. All the bound hydrogenic states span an IR of $SO(4, 2)$, as do the states in the continuum [47]. Subgroups of $SO(4, 2)$ and their generators have been listed by *Wybourne* [13] in his Table 21.2.

To the extent that the central potential of a complex atom resembles the r^{-1} dependence for a bare nucleus, the group $SO(4)$ can be used to label the states [48].

3.7 The Generalized Wigner–Eckart Theorem

3.7.1 Operators

All atomic operators involving only the electrons can be built from their creation and annihilation operators. The appropriate group labels for an atomic operator acting on N electrons, each with n relevant component states, reduces to working out the various parts of the Kronecker products $[10 \dots 0]^N \times [0 \dots 0 - 1]^N$ of $U(n)$. Subgroups of $U(n)$ can further define these parts, which may be limited by Hermiticity constraints. The group labels for the Coulomb interaction for f electrons were first given by *Racah* [6]. Interactions involving electron spin were classified later [49–51]. Operators that represent the effects of configuration interaction on the d and f shells have also been studied [28, 52–56].

3.7.2 The Theorem

Let the ket, operator T , and bra of a matrix element be labeled by an IR (R_a, R_c, R_b) of a group \mathcal{G} , each with a component (i_a, i_c, i_b) . Suppose the supplementary labels γ_k are also required to complete the definitions. The generalized Wigner–Eckart theorem is

$$\begin{aligned} & \langle \gamma_a R_a i_a | T(\gamma_c R_c i_c) | \gamma_b R_b i_b \rangle \\ &= \sum_{\beta} A_{\beta}(\beta R_a i_a | R_b i_b, R_c i_c), \end{aligned} \quad (3.21)$$

where β distinguishes the IRs R_a should they appear more than once in the reduction of the Kronecker product $R_b \times R_c$.

The *reduced* matrix element A_β is independent of the i_k [6, 8]. The second factor on the right-hand side of Eq. (3.21) is a Clebsch–Gordan (CG) coefficient for the group \mathcal{G} .

If the specification Ri can be replaced by $R\tau r_i$, where r denotes an IR of a subgroup \mathcal{H} of \mathcal{G} , and τ is an additional symbol that may be necessary to make the classification unambiguous, the CG coefficient for \mathcal{G} factorizes according to the Racah lemma [6]

$$\begin{aligned} & (\beta R_a \tau_a r_a i_a | R_b \tau_b r_b i_b, R_c \tau_c r_c i_c) \\ &= \sum_{\alpha} (\alpha r_a i_a | r_b i_b, r_c i_c) (\beta R_a \tau_a r_a | R_b \tau_b r_b + R_c \tau_c r_c)_{\alpha}. \end{aligned} \quad (3.22)$$

The first factor on the right is a CG coefficient for the group \mathcal{H} ; the second factor is an *isoscalar* factor [57].

3.7.3 Calculation of the Isoscalar Factors

The group \mathcal{H} above is often $\text{SO}(3)$, whose Clebsch–Gordan coefficients (and their related $3-j$ symbols) are well-known (Chap. 2). The principal difficulty in establishing comparable formulae for the isoscalar factors lies in giving algebraic meaning to β . Several methods are available for obtaining numerical results as follows.

Extraction from Tabulated Quantities

If R_b or R_c correspond to the IRs labeling a single electron, the factorization of the known [32] coefficients of fractional parentage (cfp) according to formulae of the type [6]

$$\begin{aligned} & (d^N SLv \{d^{N-1} S' L' v'\}) \\ &= (d^N S v \{d^{N-1} S' v'\}) (W' L' + (10) d | W L) \end{aligned} \quad (3.23)$$

yields some isoscalar factors. In this example, W and W' are the IRs of $\text{SO}(5)$ defined by the triples NSv and $N'S'v'$ (with $N' = N - 1$) as in Table 3.4. This approach can be applied to the f shell to give isoscalar factors for $\text{SO}(7)$ and G_2 . The many-electron cfp of *Donlan* [58] and the multielectron cfp of *Velkov* [59] further extend the range to IRs R_b and R_c describing many-electron systems. Isoscalar factors found in this way have the advantage that their relative phases as well as the significance of the indices β and τ coincide with current usage.

Evaluation Using Casimir's Operator

Two commuting copies (b and c) are made of the generators of the group \mathcal{G} to form the generators of the direct product $\mathcal{G}_b \times \mathcal{G}_c$ [60]. Corresponding generators of \mathcal{G}_b and \mathcal{G}_c are added to give the generators of \mathcal{G}_a . Each quadratic operator $(T_a)^2$ appearing in the expression for Casimir's operator C_a for \mathcal{G}_a (as listed in Table 3.3) is written as $(T_b + T_c)^2$. On expanding the expressions of this type, the terms $(T_b)^2$ and

$(T_c)^2$ yield Casimir's operators C_b and C_c for \mathcal{G}_b and \mathcal{G}_c . Their eigenvalues can be written down in terms of the highest weights of the IRs appearing in the isoscalar factor of Eq. (3.22). If the cross products of the type $(T_b \cdot T_c)$ can be evaluated within the uncoupled states $|R_b \tau_b r_b, R_c \tau_c r_c\rangle$, then our knowledge of the eigenvalues of C_a for the coupled states $|\beta R_a \tau_a r_a\rangle$ provides the equations for determining (to within the freedom implied by β) the isoscalar factors relating the uncoupled to the coupled states. The evaluation of the cross products is straightforward when $\mathcal{H} = \text{SO}(3)$, since the relevant $6-j$ symbols are readily available [61]. Examples of this method can be found in the literature [52].

3.7.4 Generalizations of Angular Momentum Theory

CG coefficients, $n-j$ symbols, reduced matrix elements, and the entire apparatus of angular momentum theory all have their generalizations to groups other than $\text{SO}(3)$. An interchange of two columns of a $3-j$ symbol has its analog in the interchange of two parts of an isoscalar factor. For IRs W and L of $\text{SO}(2l + 1)$ and $\text{SO}(3)$, there are two possibilities:

1. The interchange of the two parts separated by the plus sign, namely,

$$\begin{aligned} & (W_a \tau_a L_a | W_b \tau_b L_b + W_c \tau_c L_c) \\ &= (-1)^t (W_a \tau_a L_a | W_c \tau_c L_c + W_b \tau_b L_b), \end{aligned} \quad (3.24)$$

where $t = L_a - L_b - L_c + x$, with x dependent on the IRs W only; or,

2. The *reciprocity* relation of *Racah* [6]

$$\begin{aligned} & (W_a \tau_a L_a | W_b \tau_b L_b + W_c \tau_c L_c) \\ &= (-1)^{t'} [(2L_b + 1) \dim W_a / (2L_a + 1) \dim W_b]^{\frac{1}{2}} \\ &\quad \times (W_b \tau_b L_b | W_a \tau_a L_a + W_c \tau_c L_c), \end{aligned} \quad (3.25)$$

where $t' = L_a - L_b - L_c + x'$, with x' dependent on the IRs W , but taken to be l by *Racah* for $W_c = (10 \dots 0)$.

Reduced matrix elements in $\text{SO}(3)$ can be further reduced by the extraction of isoscalar factors. When W_a occurs once in the decomposition of $W \times W_b$ we have

$$\begin{aligned} & (\gamma_a W_a \tau_a L_a || T^{(WL)} || \gamma_b W_b \tau_b L_b) \\ &= [(2L_a + 1) / \dim W_a]^{\frac{1}{2}} (\gamma_a W_a || T^{(W)} || \gamma_b W_b) \\ &\quad \times (W_b \tau_b L_b + W L | W_a \tau_a L_a). \end{aligned} \quad (3.26)$$

Analogous of the $n-j$ symbols are discussed by *Butler* [62].

3.8 Checks

The existence of numerical checks is useful when using group theory in atomic physics. The CG coefficients, isoscalar factors, and the various generalizations of the $n-j$ symbols are often calculated in ways that conceal the simplicity and structure of the answer. Practitioners are familiar with several empirical rules:

1. Numbers with different irrationalities, such as $\sqrt{2}$ and $\sqrt{3}$, are never added to one another.
2. The denominators of fractions seldom involve high primes.
3. High primes are uncommon, but when they appear, it is usually in diagonal matrix elements rather than off-diagonal ones.
4. A sum of a number of terms frequently factors in what appears to be an unexpected way, and similar sums often exhibit similar factors.

Guided by these rules, one will find that such errors as do arise occur with phases rather than with magnitudes.

Abstract

The well-known *symmetry (invariance, degeneracy) groups* or *algebras* of quantum mechanical Hamiltonians provide quantum numbers (conservation laws, integrals of motion) for state labeling and the associated selection rules. In addition, it is often advantageous to employ much larger groups, referred to as the *dynamical groups (noninvariance groups, dynamical algebras, spectrum generating algebras)*, which may or may not be the invariance groups of the studied system [1–7]. In all known cases, they are Lie groups (LGs), or rather corresponding Lie algebras (LAs), and one usually requires that all states of interest of a system be contained

in a single irreducible representation (irrep). Likewise, one may require that the Hamiltonian be expressible in terms of the Casimir operators of the corresponding universal enveloping algebra [8, 9]. In a weaker sense, one regards any group (or corresponding algebra) as a dynamical group if the Hamiltonian can be expressed in terms of its generators [10–12]. In nuclear physics, one sometimes distinguishes *exact* (baryon number preserving), *almost exact* (e.g., total isospin), *approximate* (e.g., $SU(3)$ of the “eightfold way”) and *model* (e.g., nuclear shell model) *dynamical symmetries* [13]. The dynamical groups of interest in atomic and molecular physics can be conveniently classified by their topological characteristic of compactness. Noncompact LGs (LAs) generally arise in simple problems involving an infinite number of bound states, while those involving a finite number of bound states (e.g., molecular vibrations or abinitio models of electronic structure) exploit compact LG’s.

We follow the convention of designating Lie groups by capital letters and Lie algebras by lower case letters, e.g., the Lie algebra of the rotation group $SO(3)$ is designated as $so(3)$.

4.1 Noncompact Dynamical Groups

As an illustration we present basic facts concerning LAs that are useful for centrosymmetric Kepler-type problems, their realizations and typical applications. Recall that a *realization* of a LA is a homomorphism associating a concrete set of physically relevant operators with each abstract basis of the given LA. The physical operators we will use are general (intrinsic) position vectors $\mathbf{R} = (X_1, X_2, \dots, X_N)$ in \mathbb{R}^N and their corresponding momenta $\mathbf{P} = (P_1, P_2, \dots, P_N)$, satisfying the basic commutation relations ($\hbar = 1$)

$$[X_j, X_k] = [P_j, P_k] = 0, \quad [X_j, P_k] = i\delta_{jk}I. \quad (4.1)$$

4.1.1 Realizations of so(2,1)

This important LA is a simple noncompact analogue of the well-known rotation group LA so(3), (Sect. 2.1 and Sect. 3.2). Designating its three generators by T_j ($j = 1, 2, 3$), its structure constants (Sect. 2.1.1 and Sect. 3.1.1) are defined by

$$\begin{aligned} [T_1, T_2] &= i\gamma T_3, \\ [T_2, T_3] &= iT_1, \\ [T_3, T_1] &= iT_2, \end{aligned} \quad (4.2)$$

with $\gamma = -1$, while $\gamma = 1$ gives so(3). Defining the so-called ladder (raising and lowering) operators

$$T_{\pm} = T_1 \pm iT_2, \quad (4.3)$$

we also have that

$$[T_+, T_-] = 2\gamma T_3, \quad [T_3, T_{\pm}] = \pm T_3. \quad (4.4)$$

The Casimir operator then has the form

$$T^2 = \gamma(T_1^2 + T_2^2) + T_3^2 = \gamma T_+ T_- + T_3^2 - T_3. \quad (4.5)$$

With a Hermitian scalar product satisfying $T_j^\dagger = T_j$ ($j = 1, 2, 3$), so that $T_{\pm}^\dagger = T_{\mp}$, the unitary irreps (unirreps) carried by the simultaneous eigenstates of T^2 and T_3 have the form (Sect. 2.1.1 and Sect. 2.2)

$$\begin{aligned} T^2|kq\rangle &= k(k+1)|kq\rangle, \\ T_3|kq\rangle &= q|kq\rangle, \\ T_{\pm}|kq\rangle &= \sqrt{\gamma(k \mp q)(k \pm q + 1)}|k, q \pm 1\rangle. \end{aligned} \quad (4.6)$$

For so(3), ($\gamma = 1$), only finite dimensional irreps $\mathcal{D}^{(k)}$, $k = 0, 1, 2, \dots$ with $|q| \leq k$ are possible (Sect. 2.2 and Sect. 2.3). In contrast, there are no nontrivial finite dimensional unirreps of so(2,1); (for classification, see e.g., [2, 14, 15]). The

relevant class $\mathcal{D}^+(k)$ of so(2,1) unirreps for bound state problems has a T_3 eigenspectrum bounded from below and is given by $q = -k + \mu$; $\mu = 0, 1, 2, \dots$, and $k < 0$ or, equivalently, $\mathcal{D}^+(-k-1)$ with $q = k+1 + \mu$; $\mu = 0, 1, 2, \dots$; $k > -1$, since $k_1 = -k-1$ defines an equivalent unirrep and $k_1(k_1+1) = k(k+1)$. There exists a similar class of irreps with the T_3 spectrum bounded from above and two classes (principal and supplementary) with unbounded T_3 spectra (which may be exploited in scattering problems).

For problems involving only central potentials, a useful realization is given in terms of the radial distance $R = |\mathbf{R}|$ and the radial momentum

$$\begin{aligned} P_R &= -\frac{i}{R} \frac{\partial}{\partial R} R = -i \left(\frac{\partial}{\partial R} + \frac{1}{R} \right) \\ &= \frac{1}{R} (\mathbf{R} \cdot \mathbf{P} - iI), \end{aligned} \quad (4.7)$$

so that $[R, P_R] = iI$. Recall that

$$P^2 = P_R^2 + \frac{L^2}{R^2}, \quad \mathbf{L} = \mathbf{R} \wedge \mathbf{P}. \quad (4.8)$$

The general form of the desired so(2,1) realization is [2, 14–17]

$$\begin{aligned} \left. \begin{aligned} T_1 \\ T_3 \end{aligned} \right\} &= \frac{1}{2} R^{-\nu} (\nu^{-2} R^2 P_R^2 + \xi \mp R^{2\nu}), \\ T_2 &= \frac{1}{2} [2\nu^{-1} R P_R - i(1 - \nu^{-1})I], \end{aligned} \quad (4.9)$$

where ξ is either a c -number (scalar operator) or an operator that commutes with both R and P_R , and ν is an arbitrary real number.

To interrelate this realization with so(2,1) unirreps $\mathcal{D}^+(k)$ or $\mathcal{D}^+(-k-1)$, we have to establish the connection between the quantum numbers k, q and the parameters ξ and ν . Considering the Casimir operator T^2 in Eq. (4.5), we find that in our realization Eq. (4.9)

$$T^2 = \xi + (1 - \nu^2)/4\nu^2, \quad (4.10)$$

so that

$$k = \frac{1}{2} \left(-1 \pm \sqrt{4\xi + \nu^{-2}} \right), \quad (4.11)$$

and

$$q = q_0 + \mu, \quad \mu = 0, 1, 2, \dots, \quad (4.12)$$

where

$$q_0 = k + 1 = \frac{1}{2} \left(1 \pm \sqrt{4\xi + \nu^{-2}} \right), \quad k > -1. \quad (4.13)$$

4.1.2 Hydrogenic Realization of so(4,2)

To obtain suitable hydrogenic realizations of so(4,2) it is best to proceed from so(4) (the dynamical symmetry group for

the bound states of the nonrelativistic Kepler problem) and merge it with $\text{so}(2,1)$ [2, 14, 15].

The $\text{so}(4)$ LA can be realized either as a direct sum $\text{so}(4) = \text{so}(3) \oplus \text{so}(3)$ or by supplementing $\text{so}(3)$ with an appropriately scaled quantum mechanical analogue of the Laplace–Runge–Lenz (LRL) vector (Sect. 3.6.2). In the first case, we use two commuting angular momentum vectors \mathbf{M} and \mathbf{N} (Sect. 2.5),

$$\begin{aligned} [M_j, M_k] &= i\varepsilon_{jkl}M_\ell, & [N_j, N_k] &= i\varepsilon_{jkl}N_\ell, \\ [M_j, N_k] &= 0, & (j, k, \ell &= 1, 2, 3), \end{aligned} \quad (4.14)$$

while in the second case, we use the components of the total angular momentum vector \mathbf{J} and LRL-like vector \mathbf{V} with commutation relations

$$\begin{aligned} [J_j, J_k] &= i\varepsilon_{jkl}J_\ell, \\ [V_j, V_k] &= i\sigma\varepsilon_{jkl}J_\ell, \\ [J_j, V_k] &= i\varepsilon_{jkl}V_\ell, & (j, k, \ell &= 1, 2, 3), \end{aligned} \quad (4.15)$$

with $\sigma = 1$. For $\sigma = -1$, we obtain $\text{so}(3,1)$ (the LA of the homogeneous Lorentz group), which is relevant to the scattering problem of a particle in the Coulomb (or Kepler) potential (see the text following Eqs. (4.25) and (4.31)). For $\sigma = 0$, we get $\text{e}(3)$ (the LA of the three-dimensional Euclidean group) [18–20]. Note that Eqs. (4.14) and (4.15) are interrelated by

$$\mathbf{M} = \frac{1}{2}(\mathbf{J} + \mathbf{V}), \quad \mathbf{N} = \frac{1}{2}(\mathbf{J} - \mathbf{V}), \quad (4.16)$$

so that $\mathbf{J} = \mathbf{M} \oplus \mathbf{N}$ and $\mathbf{V} = 2\mathbf{M} - \mathbf{J}$. The two Casimir operators C_1 and C_2 are

$$\begin{aligned} C_1 &= \sigma J^2 + V^2 \\ &= \sigma J_+ J_- + V_+ V_- + V_3^2 + \sigma J_3(J_3 - 2), \\ C_2 &= (\mathbf{V} \cdot \mathbf{J}) = (\mathbf{J} \cdot \mathbf{V}) \\ &= \frac{1}{2}(V_+ J_- + V_- J_+) + V_3 J_3, \end{aligned} \quad (4.17)$$

where, again,

$$X_\pm = X_1 \pm iX_2, \quad X = J \text{ or } V. \quad (4.18)$$

For $\text{so}(3,1)$ and $\text{e}(3)$, only infinite dimensional nontrivial irreps are possible, while for $\text{so}(4)$, only finite dimensional ones arise. To get unirreps, we require \mathbf{J} and \mathbf{V} to be Hermitian. Using $\{J^2, J_3, C_1, C_2\}$ as a complete set of commuting operators for $\text{so}(4)$, we label the basis vectors by the four quantum numbers as $|\gamma jm\rangle \equiv |(j_0, \eta) jm\rangle$, so that

$$\begin{aligned} J^2|\gamma jm\rangle &= j(j+1)|\gamma jm\rangle, \\ J_3|\gamma jm\rangle &= m|\gamma jm\rangle, \\ C_1|\gamma jm\rangle &= (j_0^2 - \eta^2 - 1)|\gamma jm\rangle, \\ C_2|\gamma jm\rangle &= j_0\eta|\gamma jm\rangle, \end{aligned} \quad (4.19)$$

with $2|j_0|$ being a nonnegative integer and

$$\begin{aligned} j &= |j_0|, |j_0| + 1, \dots, \eta - 1; \\ \eta &= |j_0| + k, \quad k = 1, 2, \dots \end{aligned} \quad (4.20)$$

(see, e.g., [17] for the action of J_\pm, V_3 and V_\pm).

To obtain the hydrogenic (or Kepler) realization of $\text{so}(4)$, we consider the quantum mechanical analogue of the classical LRL vector

$$\begin{aligned} \tilde{\mathbf{V}} &= \frac{1}{2}(\mathbf{p} \wedge \mathbf{L} - \mathbf{L} \wedge \mathbf{p}) - Zr^{-1}\mathbf{r} \\ &= \frac{1}{2}\mathbf{r}p^2 - \mathbf{p}(\mathbf{r} \cdot \mathbf{p}) + \mathbf{r}H, \\ \mathbf{L} &= \mathbf{r} \wedge \mathbf{p}, \end{aligned} \quad (4.21)$$

which commutes with the hydrogenic Hamiltonian

$$H = \frac{1}{2}p^2 - Zr^{-1}. \quad (4.22)$$

Note that

$$\begin{aligned} [\mathbf{L}, H] &= [\tilde{\mathbf{V}}, H] = 0, \\ (\mathbf{L} \cdot \tilde{\mathbf{V}}) &= (\tilde{\mathbf{V}} \cdot \mathbf{L}) = 0, \\ \tilde{\mathbf{V}}^2 &= 2H(L^2 + 1) + Z^2, \end{aligned} \quad (4.23)$$

while the components of \mathbf{L} and $\tilde{\mathbf{V}}$ satisfy the commutation relations

$$\begin{aligned} [L_j, L_k] &= i\varepsilon_{jkl}L_\ell, \\ [L_j, \tilde{V}_k] &= i\varepsilon_{jkl}\tilde{V}_\ell, \\ [\tilde{V}_j, \tilde{V}_k] &= (-2H)\varepsilon_{jkl}L_\ell. \end{aligned} \quad (4.24)$$

Thus, restricting ourselves to a specific bound state energy level E_n , we can replace H by E_n and define

$$V_j = (-2E_n)^{-1/2}\tilde{V}_j \quad (j = 1, 2, 3), \quad (4.25)$$

obtaining the $\text{so}(4)$ commutation relations Eq. (4.15) (with \mathbf{J} replaced by \mathbf{L}). This is Pauli's hydrogenic realization of $\text{so}(4)$ [21–23]. [In a similar way we can consider continuum states $E > 0$ and define $\mathbf{V} = (2E)^{-1/2}\tilde{\mathbf{V}}$, obtaining an $\text{so}(3,1)$ realization.] The last identity of Eq. (4.23) now becomes

$$V^2 = -(L^2 + 1) - Z^2/2E_n, \quad (4.26)$$

which immediately implies Bohr's formula, since $V^2 + L^2 = 4M^2 = -1 - Z^2/2E_n$, so that

$$E_n = -Z^2/2(2j_1 + 1)^2 = -Z^2/2n^2, \quad (4.27)$$

where $n = 2j_1 + 1$ and j_1 is the angular momentum quantum number for \mathbf{M} , Eq. (4.16). In terms of the irrep labels Eq. (4.20), we have that $j_0 = 0$, $\eta = n$, so that $|\gamma \ell m\rangle = |(0, n)\ell m\rangle \equiv |n\ell m\rangle$, $\ell = 0, 1, \dots, n - 1$.

Using the stepwise merging of $\text{so}(4)$ and $\text{so}(2,1)$ [adding first T_2 , which leads to $\text{so}(4,1)$, and subsequently T_1 and T_3],

we arrive at the hydrogenic realization of $\text{so}(4,2)$ having 15 generators $\mathbf{L}, \mathbf{A}, \mathbf{B}, \mathbf{\Gamma}, T_1, T_2, T_3$, namely ([2, 14, 15, 17])

$$\begin{aligned} \mathbf{L} &= \mathbf{R} \wedge \mathbf{P}, \\ \left. \begin{array}{l} \mathbf{A} \\ \mathbf{B} \end{array} \right\} &= \frac{1}{2} \mathbf{R} \mathbf{P}^2 - \mathbf{P}(\mathbf{R} \cdot \mathbf{P}) \mp \mathbf{R}, \\ \mathbf{\Gamma} &= \mathbf{R} \mathbf{P}, \\ \left. \begin{array}{l} T_1 \\ T_3 \end{array} \right\} &= \frac{1}{2} (\mathbf{R} \mathbf{P}^2 \mp \mathbf{R}) = \frac{1}{2} (\mathbf{R} \mathbf{P}_R^2 + L^2 \mathbf{R}^{-1} \mp \mathbf{R}), \\ T_2 &= \mathbf{R} \cdot \mathbf{P} - iI = \mathbf{R} \mathbf{P}_R. \end{aligned} \quad (4.28)$$

Relabeling these generators by the elements of an antisymmetric 6×6 matrix according to the scheme

$$L_{jk} \leftrightarrow \begin{pmatrix} 0 & L_3 & -L_2 & A_1 & B_1 & \Gamma_1 \\ & 0 & L_1 & A_2 & B_2 & \Gamma_2 \\ & & 0 & A_3 & B_3 & \Gamma_3 \\ & & & 0 & T_2 & T_1 \\ & & & & 0 & T_3 \\ & & & & & 0 \end{pmatrix} \quad (4.29)$$

we can write the commutation relations in the following standard form

$$[L_{jk}, L_{\ell m}] = i(g_{j\ell} L_{km} + g_{km} L_{j\ell} - g_{k\ell} L_{jm} - g_{jm} L_{k\ell}), \quad (4.30)$$

with the diagonal metric tensor g_{jk} defined by the matrix $G = \text{diag}[1, 1, 1, 1, -1, -1]$. The matrix form Eq. (4.29) also implies the subalgebra structure

$$\text{so}(4,2) \supset \text{so}(4,1) \supset \text{so}(4) \supset \text{so}(3), \quad (4.31)$$

with $\text{so}(4,1)$ generated by $\mathbf{L}, \mathbf{A}, \mathbf{B}$ and T_2 , and $\text{so}(4)$ by \mathbf{L}, \mathbf{A} . [\mathbf{L}, \mathbf{B} also generate $\text{so}(3,1)$.]

The three independent Casimir operators (quadratic, cubic, and quartic) are [24] (summation over all indices is implied)

$$\begin{aligned} Q_2 &= \frac{1}{2} L_{jk} L^{jk} \\ &= L^2 + A^2 - B^2 - \Gamma^2 + T_3^2 - T_1^2 - T_2^2, \\ Q_3 &= \frac{1}{48} \varepsilon_{ijklmn} L^{ij} L^{kl} L^{mn} \\ &= T_1(\mathbf{B} \cdot \mathbf{L}) + T_2(\mathbf{\Gamma} \cdot \mathbf{L}) + T_3(\mathbf{A} \cdot \mathbf{L}) \\ &\quad + \mathbf{A} \cdot (\mathbf{B} \wedge \mathbf{\Gamma}), \\ Q_4 &= L_{jk} L^{k\ell} L_{\ell m} L^{mj}. \end{aligned} \quad (4.32)$$

For our hydrogenic realization $Q_2 = -3$, $Q_3 = Q_4 = 0$. Thus, our hydrogenic realization implies a single unirrep of $\text{so}(4,2)$ adapted to the chain Eq. (4.31).

4.2 Hamiltonian Transformation and Simple Applications

The basic idea is to transform the relevant Schrödinger equation into an eigenvalue problem for one of the operators from the complete set of commuting operators in our realizations, e.g., T_3 for $\text{so}(2,1)$. Instead of using a rather involved ‘‘tilting’’ transformation ([1, p. 20], and [2, 14, 15]), we can rely on a simple scaling transformation [16, 25]

$$\mathbf{r} = \lambda \mathbf{R}, \quad \mathbf{p} = \lambda^{-1} \mathbf{P}, \quad r = \lambda R, \quad p_r = \lambda^{-1} P_R, \quad (4.33)$$

where

$$r = \left(\sum_{j=1}^N x_j^2 \right)^{1/2}, \quad (4.34)$$

and

$$p^2 = p_r^2 + r^{-2} \left[\frac{1}{4} (N-1)(N-3) + L^2 \right], \quad (4.35)$$

with p_r defined analogously to P_R in Eq. (4.7); r and p are the physical operators in terms of which the Hamiltonian of the studied system is expressed. Recall that L^2 has eigenvalues [26]

$$\ell(\ell + N - 2), \quad \ell = 0, 1, 2, \dots \quad \text{for } N \geq 2, \quad (4.36)$$

and we can set $\ell = 0$ for $N = 1$ (the angular momentum term vanishes in the one-dimensional case). The units in which $m = e = \hbar = 1$, $c \approx 137$ are used throughout.

4.2.1 N-Dimensional Isotropic Harmonic Oscillator

Considering the Hamiltonian

$$H = \frac{1}{2} p^2 + \frac{1}{2} \omega^2 r^2, \quad (4.37)$$

with p^2 in the form Eq. (4.35), transforming the corresponding Schrödinger equation using the scaling transformation Eq. (4.33) and multiplying by $\frac{1}{4} \lambda^2$, we get for the radial component

$$\frac{1}{2} \left(\frac{1}{4} P_R^2 + R^{-2} \xi + \frac{1}{4} \omega^2 \lambda^4 R^2 - \frac{1}{2} \lambda^2 E \right) \psi_R(\lambda R) = 0, \quad (4.38)$$

with

$$\xi = \frac{1}{16} (N-1)(N-3) + \frac{1}{4} \ell(\ell + N - 2). \quad (4.39)$$

Choosing λ such that $(\omega/2)^2 \lambda^4 = 1$, we can rewrite Eq. (4.38) using the $\text{so}(2,1)$ realization Eq. (4.9) with $\nu = 2$ as

$$\left(T_3 - \frac{1}{4} \lambda^2 E \right) \psi_R(\lambda R) = 0. \quad (4.40)$$

Thus, using the second equation of Eq. (4.6) we can interchange $\psi_{\mathbf{R}}(\lambda R)$ with $|kq\rangle$ and set $\frac{1}{4}\lambda^2 E = q$, so that

$$E = 4q/\lambda^2 = 2q\omega, \quad (4.41)$$

with q given by Eqs. (4.12) and (4.13), i.e.,

$$q = q_0 + \mu, \quad \mu = 0, 1, 2, \dots, \quad (4.42)$$

and

$$q_0 = k + 1 = \frac{1}{2} \left[1 \pm \left(\ell + \frac{1}{2}N - 1 \right) \right]. \quad (4.43)$$

Now, for $N = 1$, we set $\ell = 0$ so that $q_0 = \frac{1}{4}$ and $q_0 = \frac{3}{4}$, yielding for $E = 2q\omega$ the values $(\frac{1}{2} + 2\mu)\omega$ and $(\frac{1}{2} + 2\mu + 1)\omega$, $\mu = 0, 1, 2, \dots$. Combining both sets we thus get for $N = 1$ the well-known result

$$E \equiv E_n = \left(n + \frac{1}{2} \right) \omega, \quad n = 0, 1, 2, \dots \quad (4.44)$$

Similarly, for the general case $N \geq 2$, we choose the upper sign in Eq. (4.43) [so that $k > -1$] and get

$$E \equiv E_n = \left(n + \frac{1}{2}N \right) \omega, \quad n = 0, 1, 2, \dots, \quad (4.45)$$

where we identified $(\ell + 2\mu)$ with the principal quantum number n .

4.2.2 N -Dimensional Hydrogenic Atom

Applying the scaling transformation Eq. (4.33) to the hydrogenic Hamiltonian Eq. (4.22) in N -dimensions, we get for the radial component (after multiplying from the left by $\lambda^2 R$)

$$\left[\frac{1}{2} (R P_{\mathbf{R}}^2 + R^{-1} \xi - 2\lambda^2 E R) - \lambda Z \right] \psi_{\mathbf{R}}(\lambda R) = 0, \quad (4.46)$$

where now

$$\xi = \frac{1}{4} (N-1)(N-3) + \ell(\ell + N - 2). \quad (4.47)$$

In this case, we must set $2\lambda^2 E = -1$ and use realization Eq. (4.9) with $\nu = 1$ to obtain

$$(T_3 - \lambda Z) \psi_{\mathbf{R}}(\lambda R) = 0. \quad (4.48)$$

This immediately implies that

$$\lambda Z = q, \quad (4.49)$$

and

$$q_0 = k + 1 = \frac{1}{2} [1 \pm (2\ell + N - 2)]. \quad (4.50)$$

Choosing the upper sign [since $\ell \geq 0$ and $k > -1$], so that $q_0 = \ell + \frac{1}{2}(N-1)$, and identifying q with the principal quantum number n , we finally have that

$$E \equiv E_n = -\frac{1}{2\lambda^2} = -\frac{Z^2}{2n^2}. \quad (4.51)$$

The N -dimensional relativistic hydrogenic atom can be treated in the same way, using either the Klein–Gordon or Dirac–Coulomb equations [2, 14–17].

4.2.3 Perturbed Hydrogenic Systems

The $\text{so}(4,2)$ based Lie algebraic formalism can be conveniently exploited to carry out large-order perturbation theory ([27–29] and Chap. 5) for hydrogenic systems described by the Schrödinger equation

$$[H_0 + \varepsilon V(\mathbf{r})] \psi(\mathbf{r}) = (E_0 + \Delta E) \psi(\mathbf{r}), \quad (4.52)$$

with H_0 given by Eq. (4.22) and E_0 by E of Eq. (4.51). Applying transformation Eq. (4.33), using Eqs. (4.49), (4.51), and multiplying on the left-hand side by $\lambda^2 R$, we get

$$\left[\frac{1}{2} R P^2 - q + \frac{1}{2} R + \varepsilon \lambda^2 R V(\lambda \mathbf{R}) - \lambda^2 R \Delta E \right] \Psi(\mathbf{R}) = 0, \quad (4.53)$$

where we set $\psi(\lambda \mathbf{R}) \equiv \Psi(\mathbf{R})$. For the important case of a three-dimensional hydrogenic atom [$N = 3$, $\xi = \ell(\ell + 1)$, $q \equiv n$], using the $\text{so}(4,2)$ realization Eq. (4.28) [or $\text{so}(2,1)$ realization Eq. (4.9) with $\nu = 1$] we get

$$(K + \varepsilon W - S \Delta E) \Psi(\mathbf{R}) = 0, \quad (4.54)$$

with

$$\begin{aligned} K &= T_3 - n, \\ W &= \lambda^2 R V(\lambda \mathbf{R}), \\ S &= \lambda^2 R. \end{aligned} \quad (4.55)$$

We also have that $\lambda = n/Z$ and for the ground state case $n = q = 1$. Although Eq. (4.54) has the form of a generalized eigenvalue problem requiring perturbation theory formalism with a nonorthogonal basis (where S represents an overlap), T_3 is Hermitian with respect to a $(1/R)$ scalar product, and the required matrix elements can, therefore, be evaluated easily [2, 14, 15, 17, 27–29].

For central field perturbations, $V(\mathbf{r}) = V(r)$, the problem reduces to one dimension, and since $R = T_3 - T_1$, the $\text{so}(2,1)$ hydrogenic realization ($\nu = 1$) can be employed. For problems of a hydrogenic atom in a magnetic field (Zeeman effect) [27–30] or a one-electron diatomic ion [31], the $\text{so}(4,2)$ formalism is required (note, however, that the LoSurdo–Stark effect can also be treated as a one-dimensional problem using parabolic coordinates [32]).

The main advantage of the LA approach stems from the fact that the spectrum of T_3 is discrete, so that no integration over continuum states is required. Moreover, the relevant perturbations are closely packed around the diagonal in this representation, so that infinite sums are replaced by small finite sums.

For example, for the LoSurdo–Stark problem, when $V(\mathbf{r}) = \mathcal{F}z$, where \mathcal{F} designates electric field strength in the z -direction, we get Eq. (4.54) with $\varepsilon = \mathcal{F}$ and $W = (n/Z)^3 RZ$, $S = (n/Z)^2 R$. Since both R and Z are readily expressed in terms of $\text{so}(4,2)$ generators,

$$Z = B_3 - A_3, \quad R = T_3 - T_1, \quad (4.56)$$

we can easily compute all the required matrix elements [2, 14, 15, 17].

Similarly, considering the Zeeman effect with

$$V(\mathbf{r}) = \frac{1}{2}BL_3 + \frac{1}{8}B^2(r^2 - z^2), \quad (4.57)$$

where B designates magnetic field strength in the z -direction, we have for the ground state when $n = 1$, $\ell = m = 0$ that $\varepsilon = \frac{1}{8}B^2$, $K = T_3 - 1$, $W = Z^{-4}R(R^2 - Z^2)$ and $S = Z^{-2}R$. Again, the matrix elements of W and S are obtained from those of Z and R , Eq. (4.56), by matrix multiplication (for tables and programs, see [17]).

One can treat one-electron diatomic ions [2, 14, 15, 31] and screened Coulomb potentials, including charmonium and harmonium [10–12, 17, 33, 34], in a similar way.

Note, finally, that we can also formulate the perturbed problem Eq. (4.54) in a standard form not involving the “overlap” by defining the scaling factor as $\lambda = (-2E)^{-1/2}$, where E is now the exact energy $E = E_0 + \Delta E$; Eq. (4.54) then becomes

$$(T_3 + \varepsilon W - \lambda Z)\Psi(\mathbf{R}) = 0, \quad (4.58)$$

with the eigenvalue λZ . In this case, any conventional perturbation formalism applies, but the desired energy has to be found from λZ [35].

4.3 Compact Dynamical Groups

Unitary groups $U(n)$ and their LAs often play the role of (compact) dynamical groups since

1. Quantum mechanical observables are Hermitian, and the LA of $U(n)$ is comprised of Hermitian operators [under the $\exp(iA)$ mapping].
2. Any compact Lie group is isomorphic to a subgroup of some $U(n)$.

3. “Nothing of algebraic import is lost by the unitary restriction” [36].

All $U(n)$ irreps have finite dimension and are, thus, relevant to problems involving a finite number of bound states [3–6, 10–12, 36–45].

4.3.1 Unitary Group and Its Representations

The unitary group $U(n)$ has n^2 generators E_{ij} spanning its LA and satisfying the commutation relations

$$[E_{ij}, E_{k\ell}] = \delta_{jk} E_{i\ell} - \delta_{i\ell} E_{kj} \quad (4.59)$$

and the Hermitian property

$$E_{ij}^\dagger = E_{ji}. \quad (4.60)$$

They are classified as *raising* ($i < j$), *lowering* ($i > j$), and *weight* ($i = j$) generators according to whether they raise, lower, and preserve the weight, respectively. The *weight vector* is a vector of the carrier space of an irrep that is a simultaneous eigenvector of all weight generators E_{ii} of $U(n)$ (comprising its Cartan subalgebra), and the vector $\mathbf{m} = (m_1, m_2, \dots, m_n)$ with integer components, consisting of corresponding eigenvalues, is called a *weight*. The *highest weight* \mathbf{m}_n (in lexical ordering),

$$\mathbf{m}_n = (m_{1n}, m_{2n}, \dots, m_{nn}), \quad (4.61)$$

with

$$m_{1n} \geq m_{2n} \geq \dots \geq m_{nn}, \quad (4.62)$$

uniquely labels $U(n)$ irreps, $\Gamma(\mathbf{m}_n)$, and may be represented by a Young pattern. Subducing $\Gamma(\mathbf{m}_r)$ of $U(r)$ to $U(r-1)$, embedded as $U(r-1) \oplus 1$ in $U(r)$, gives [41]

$$\Gamma(\mathbf{m}_r) \downarrow U(r-1) = \bigoplus \Gamma(\mathbf{m}_{r-1}), \quad (4.63)$$

where the sum extends over all $U(r-1)$ weights $\mathbf{m}_{r-1} = (m_{1,r-1}, m_{2,r-1}, \dots, m_{r-1,r-1})$ satisfying the so-called “betweenness conditions” [38]

$$m_{ir} \geq m_{i,r-1} \geq m_{i+1,r} \quad (i = 1, \dots, r-1). \quad (4.64)$$

Two irreps $\Gamma(\mathbf{m}_n)$ and $\Gamma(\mathbf{m}'_n)$ of $U(n)$ yield the same irrep when restricted to $SU(n)$ if $m_i = m'_i + h$, $i = 1, \dots, n$. The $SU(n)$ irreps are thus labeled with highest weights with $m_{nn} = 0$. The dimension of $\Gamma(\mathbf{m}_n)$ of $U(n)$ is given by the Weyl dimension formula [36]

$$\dim \Gamma(\mathbf{m}_n) = \prod_{i < j} (m_{in} - m_{jn} + j - i) / 1!2! \dots (n-1)!. \quad (4.65)$$

The $U(n)$ Casimir operators have the form

$$C_k^{U(n)} = \sum_{i_1, i_2, \dots, i_k=1}^n E_{i_1 i_2} E_{i_2 i_3} \cdots E_{i_{k-1} i_k} E_{i_k i_1}. \quad (4.66)$$

The first-order Casimir operator is given by the sum of weight generators and equals the sum of the highest weight components.

Since $U(1)$ is Abelian, the *Gel'fand-Tsetlin* [42] canonical chain (Sect. 3.4.3)

$$U(n) \supset U(n-1) \supset \cdots \supset U(1) \quad (4.67)$$

can be used to label uniquely the basis vectors of the carrier space of $\Gamma(\mathbf{m}_n)$ by triangular Gel'fand tableaux $[m]$ defined by

$$[m] = \begin{bmatrix} \mathbf{m}_n \\ \mathbf{m}_{n-1} \\ \cdots \\ \mathbf{m}_2 \\ \mathbf{m}_1 \end{bmatrix} = \begin{bmatrix} m_{1n} & m_{2n} & \cdots & m_{nn} \\ m_{1,n-1} & \cdots & m_{n-1,n-1} & \\ & \cdots & & \\ & & \cdots & \\ & & & m_{12} & m_{22} \\ & & & & m_{11} \end{bmatrix}, \quad (4.68)$$

with entries satisfying betweenness conditions Eq. (4.64). Matrix representatives of weight generators are diagonal

$$\langle [m'] | E_{ii} | [m] \rangle = \delta_{[m],[m']} \left(\sum_{j=1}^i m_{ji} - \sum_{j=1}^{i-1} m_{j,i-1} \right), \quad (4.69)$$

while those for other generators are rather involved [42–45]. Note that only elementary ($E_{i,i+1}$) raising generators are required since

$$\langle [m'] | E_{ij} | [m] \rangle = \langle [m] | E_{ji} | [m'] \rangle, \quad (4.70)$$

and

$$E_{ij} = [E_{i,i+1}, E_{i+1,j}]. \quad (4.71)$$

In special cases required in applications ([39, 40] and Sect. 4.3.4) efficient algorithms exist for the computation of explicit representations.

4.3.2 Orthogonal Group $O(n)$ and Its Representations

Since $O(n)$ is a proper subgroup of $U(n)$, its representation theory has a similar structure. The suitable generators are

$$\begin{aligned} F_{ij} &= E_{ij} - E_{ji}, & F_{ji} &= -F_{ij}, \\ F_{ii} &= 0, & F_{ij}^\dagger &= -F_{ji} \end{aligned} \quad (4.72)$$

and satisfy the commutation relations

$$[F_{ij}, F_{k\ell}] = \delta_{jk} F_{i\ell} + \delta_{i\ell} F_{jk} - \delta_{ik} F_{j\ell} - \delta_{j\ell} F_{ik}. \quad (4.73)$$

The canonical chain has the form

$$O(n) \supset O(n-1) \supset \cdots \supset O(2). \quad (4.74)$$

The components of the highest weight \mathbf{m}_n ,

$$\mathbf{m}_n = (m_{1n}, m_{2n}, \dots, m_{kn}), \quad (4.75)$$

satisfy the conditions

$$m_{1n} \geq m_{2n} \geq \cdots \geq m_{kn} \geq 0 \quad \text{for } n = 2k + 1, \quad (4.76)$$

and

$$m_{1n} \geq m_{2n} \geq \cdots \geq |m_{kn}| \quad \text{for } n = 2k, \quad (4.77)$$

where m_{in} are simultaneously integers or half-odd integers. The former are referred to as *tensor representations* (since they arise as tensor products of fundamental irreps), while those with half-odd integer components are called *spinor representations*. Note that for $n = 2k$, we have two lowest (mirror-conjugated) spinor representations, namely $\mathbf{m}^{(+)} = (\frac{1}{2}, \frac{1}{2}, \dots, \frac{1}{2})$ and $\mathbf{m}^{(-)} = (\frac{1}{2}, \dots, \frac{1}{2}, -\frac{1}{2})$. Only tensor representations can be labeled by Young tableaux.

Subducing $O(n)$ to $O(n-1)$, the betweenness conditions (branching rules) have the form

$$m_{in} \geq m_{i,n-1} \geq m_{i+1,n} \quad (i = 1, \dots, k-1) \quad (4.78)$$

together with

$$m_{k,2k+1} \geq |m_{k,2k}|, \quad (4.79)$$

when $n = 2k + 1$. The $m_{i,n-1}$ components are integral (half-odd integral) if the m_{in} are integral (half-odd integral). The $U(n) \supset O(n)$ [or $SU(n) \supset SO(n)$] subduction rules are more involved [46].

4.3.3 Clifford Algebras and Spinor Representations

While all reps of $U(n)$ or $SL(n)$ arise as tensor powers of the standard rep, only half of the reps of $SO(m)$ or $O(m)$ arise this way, since $SO(m)$ is not simply connected when $m > 2$. A double covering of $SO(m)$ leads to *spin groups* $\text{Spin}(m)$. The best way to proceed is, however, to construct the so-called *Clifford algebras* C_m , whose multiplicative group (consisting of invertible elements) contains a subgroup that provides a double cover of $SO(m)$. The key fact is that C_{2k} is

isomorphic with $\mathfrak{gl}(2^k)$ and C_{2k+1} with $\mathfrak{gl}(2^k) \oplus \mathfrak{gl}(2^k)$. The reps of C_m thus provide the required *spinor reps*.

A Clifford algebra C_m is an associative algebra generated by *Clifford numbers* α_i satisfying the anticommutation relations

$$\{\alpha_i, \alpha_j\} = 2\delta_{ij} \quad (i, j = 1, \dots, m). \quad (4.80)$$

Since $\alpha_i^2 = 1$, $\dim C_m = 2^m$, and a general element of C_m is a product of Clifford numbers $\alpha_1^{v_1} \alpha_2^{v_2} \dots \alpha_m^{v_m}$ with $v_i = 0$ or 1.

To see the relation with $\mathfrak{so}(m+1)$ note that

$$F_{0k} = -\frac{1}{2}i\alpha_k, \quad F_{jk} = \frac{1}{4}[\alpha_j, \alpha_k] = \frac{1}{2}\alpha_j\alpha_k, \quad (j \neq k) \quad (4.81)$$

satisfy the commutation relations Eq. (4.73).

As an example, C_2 can be realized by Pauli matrices by setting

$$\alpha_1 = \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \alpha_2 = \sigma_2 = \begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix}. \quad (4.82)$$

Clearly, the four matrices $\mathbf{1}_2, \alpha_1, \alpha_2$, and $\alpha_1\alpha_2$ are linearly independent (note that $\sigma_3 = i\sigma_1\sigma_2$), so that C_2 is isomorphic to $\mathfrak{gl}(2, \mathbb{C})$.

Similarly, considering Dirac–Pauli matrices

$$\gamma_0 = \begin{pmatrix} -i\mathbf{1}_2 & \mathbf{0} \\ \mathbf{0} & -i\mathbf{1}_2 \end{pmatrix} = i\gamma_4, \quad \gamma_k = \begin{pmatrix} \mathbf{0} & i\sigma_k \\ -i\sigma_k & \mathbf{0} \end{pmatrix}, \quad (k = 1, 2, 3), \quad (4.83)$$

we have that

$$\{\gamma_i, \gamma_j\} = 2\delta_{ij}, \quad (i, j = 1, \dots, 4), \quad (4.84)$$

so that γ_i ($i = 1, \dots, 4$) or ($i = 0, \dots, 3$) represent Clifford numbers for C_4 and $\mathbf{1}_4, \gamma_i, \gamma_i\gamma_j$ ($i < j$), $\gamma_i\gamma_j\gamma_k$ ($i < j < k$) and $\gamma_5 \equiv \gamma_1\gamma_2\gamma_3\gamma_4 = i\gamma_0\gamma_1\gamma_2\gamma_3$ form an additive basis for $\mathfrak{gl}(4, \mathbb{C})$ (the γ_i themselves are said to form a multiplicative basis). For general construction of C_m Clifford numbers in terms of direct products of Pauli matrices see [47, 48].

4.3.4 Bosonic and Fermionic Realizations of $U(n)$

Designating by b_i^\dagger (b_i) the boson creation (annihilation) operators (Sect. 6.1.1) satisfying the commutation relations $[b_i, b_j] = [b_i^\dagger, b_j^\dagger] = 0$, $[b_i, b_j^\dagger] = \delta_{ij}$, we obtain a possible $U(n)$ realization by defining its n^2 generators as follows

$$G_{ij} = b_i^\dagger b_j. \quad (4.85)$$

The first-order Casimir operator, Eq. (4.66) with $k = 1$, then represents the total number operator

$$\hat{N} \equiv C_1^{U(n)} = \sum_{i=1}^n G_{ii} = \sum_{i=1}^n b_i^\dagger b_i, \quad (4.86)$$

and the physically relevant states, being totally symmetric, carry single row irreps $\Gamma(N\dot{0}) \equiv \Gamma(N0\dots 0)$.

Similarly, for fermion creation (annihilation) operators X_I^\dagger (X_I) that are associated with some orthonormal spin-orbital set $\{|I\rangle\}$, $I = 1, 2, \dots, 2n$, and satisfy the anticommutation relations $\{X_I, X_J\} = \{X_I^\dagger, X_J^\dagger\} = 0$, $\{X_I, X_J^\dagger\} = \delta_{IJ}$, the operators

$$e_{IJ} = X_I^\dagger X_J \quad (4.87)$$

again represent the $U(2n)$ generators satisfying Eqs. (4.59) and (4.60). The first-order Casimir then represents the total number operator $\hat{N} = \sum_I X_I^\dagger X_I$, while the possible physical states are characterized by totally antisymmetric single column irreps $\Gamma(1^N\dot{0}) \equiv \Gamma(11\dots 10\dots 0)$.

4.3.5 The Vibron Model

Similar to the unified description of nuclear collective rovibrational states using the interacting boson model [49–51], one can build an analogous model for molecular rotation-vibration spectra [8]. For diatomics, an appropriate dynamical group is $U(4)$ [8, 52–54] and, generally, for rotation-vibration spectra in r -dimensions, one requires $U(r+1)$. For triatomics, the $U(4)$ generating algebra is generalized to $U(4) \otimes U(4)$, and for the $(k+1)$ atomic molecule to $U^{(1)}(4) \otimes \dots \otimes U^{(k)}(4)$ [8, 52–54].

For the bosonic realization of $U(4)$, we need four creation (b_i^\dagger , $i = 1, \dots, 4$) and four annihilation (b_i) operators (Sect. 4.3.4). The Hamiltonian may be generally expressed as a multilinear form in terms of boson number preserving products ($b_i^\dagger b_j$), so that using Eq. (4.85) we can write

$$H = h^{(0)} + \sum_{ij} h_{ij}^{(1)} G_{ij} + \frac{1}{2} \sum_{ijkl} h_{ijkl}^{(2)} G_{ij} G_{kl} + \dots \quad (4.88)$$

The energy levels (as a function of 0, 1, 2, \dots -body matrix elements $h^0, h_{ij}^{(1)}, h_{ijkl}^{(2)}$, etc.) are then determined by diagonalizing H in an appropriate space, which is conveniently provided by the carrier space of the totally symmetric irrep $\Gamma(N000) \equiv \Gamma(N\dot{0})$ of $U(4)$.

The requirement that the resulting states be characterized by angular momentum J and parity P quantum numbers necessitates that the boson operators involved have definite transformation properties under rotations and reflections [8]. The boson operators are thus subdivided into

the scalar operators (σ^\dagger, σ) , $J = 0$, and vector operators $(\pi_\mu^\dagger, \pi_\mu; \mu = 0, \pm 1)$, $J = 1$ with parity $P = (-)^J$. All commutators vanish except for

$$[\sigma, \sigma^\dagger] = 1, \quad [\pi_\mu, \pi_{\mu'}^\dagger] = \delta_{\mu\mu'}. \quad (4.89)$$

Since H preserves the total number of vibrons $N = n_\sigma + n_\pi$, the second-order Hamiltonian Eq. (4.88) within the irrep $\Gamma(N\dot{0})$ can be expressed in terms of four independent parameters (apart from an overall constant) as

$$\begin{aligned} H = & e^{(0)} + e^{(1)}[\pi^\dagger \times \tilde{\pi}]_0^{(0)} \\ & + e_1^{(2)}\left[[\pi^\dagger \times \pi^\dagger]^{(0)} \times [\tilde{\pi} \times \tilde{\pi}]^{(0)}\right]_0^{(0)} \\ & + e_2^{(2)}\left[[\pi^\dagger \times \pi^\dagger]^{(2)} \times [\tilde{\pi} \times \tilde{\pi}]^{(2)}\right]_0^{(0)} \\ & + e_3^{(2)}\left[[\pi^\dagger \times \pi^\dagger]^{(0)} \times [\tilde{\sigma} \times \tilde{\sigma}]\right]^{(0)} \\ & + [\sigma^\dagger \times \sigma^\dagger]^{(0)} \times [\tilde{\pi} \times \tilde{\pi}]_0^{(0)} + \dots, \quad (4.90) \end{aligned}$$

where $\tilde{\sigma} = \sigma$, $\tilde{\pi}_\mu = (-)^{1-\mu}\pi_{-\mu}$ and square brackets indicate the SU(2) couplings.

In special cases, the eigenvalue problem for H can be solved analytically, assuming that H can be expressed in terms of Casimir operators of a complete chain of subgroups of U(4) (referred to as dynamical symmetries). Requiring that the chain contains the physical rotation group O(3), one has two possibilities

$$\begin{aligned} \text{(I)} \quad & \text{U}(4) \supset \text{O}(4) \supset \text{O}(3) \supset \text{O}(2), \\ \text{(II)} \quad & \text{U}(4) \supset \text{U}(3) \supset \text{O}(3) \supset \text{O}(2). \quad (4.91) \end{aligned}$$

These imply labels (quantum numbers): N [total vibron number defining a totally symmetric irrep of U(4)], $\omega = N, N-2, N-4, \dots, 1$ or 0 [defining a totally symmetric irrep of O(4)] and $n_\pi = N, N-1, \dots, 0$ [defining the U(3) irrep], in addition to the O(3) \supset O(2) labels $J, M; |M| \leq J$. In terms of these labels one finds for the respective Hamiltonians

$$\begin{aligned} H^{(\text{I})} &= F + A C_2^{\text{O}(4)} + B C_2^{\text{O}(3)}, \\ H^{(\text{II})} &= F + \varepsilon C_1^{\text{U}(3)} + \alpha C_2^{\text{U}(3)} + \beta C_2^{\text{O}(3)}, \quad (4.92) \end{aligned}$$

where $F, A, B, \varepsilon, \alpha, \beta$ are free parameters, and $C_i^{\text{U}(k)}, C_i^{\text{O}(k)}$ are relevant Casimir operators, the following expressions [8, 52–54] for their eigenvalues

$$\begin{aligned} E^{(\text{I})}(N, \omega, J, M) &= F + A\omega(\omega + 2) + BJ(J + 1), \\ E^{(\text{II})}(N, n_\pi, J, M) &= F + \varepsilon n_\pi + \alpha n_\pi(n_\pi + 3) \\ &+ \beta J(J + 1). \quad (4.93) \end{aligned}$$

The limit (I) is appropriate for rigid diatomics and limit (II) for nonrigid ones [8, 52–54].

In addition to handling diatomic and triatomic systems, the vibron model was also applied to the overtone spectrum of acetylene [55], intramolecular relaxation in benzene and its dimers [56, 57], octahedral molecules of the XF₆ type (X = S, W, and U) [58], and to linear polyatomics [59]. Most recently, the experimental (dispersed fluorescence and stimulated emission pumping) vibrational spectra of H₂O and SO₂ in their ground states, representing typical local-mode and normal-mode molecules, respectively, have been analyzed, including highly excited levels, by relying on the U(2) algebraic effective Hamiltonian approach [60–62]. The U(2) algebraic scheme [63] also enabled the treatment of Franck–Condon transition intensities [64, 65] in rovibronic spectra. The attempts at a similar heuristic phenomenological description of electronic spectra have so far met with only limited success [66].

4.3.6 Many-Electron Correlation Problem

In atomic and molecular electronic structure calculations one employs a spin-independent model Hamiltonian

$$\begin{aligned} H = & \sum_{i,j} h_{ij} \sum_{\sigma=1}^2 X_{i\sigma}^\dagger X_{j\sigma} \\ & + \frac{1}{2} \sum_{i,j,k,\ell} v_{ij,k\ell} \sum_{\sigma,\tau=1}^2 X_{i\sigma}^\dagger X_{j\tau}^\dagger X_{\ell\tau} X_{k\sigma}, \quad (4.94) \end{aligned}$$

where $X_I^\dagger \equiv X_{i\sigma}^\dagger$ (X_I) designate the creation (annihilation) operators associated with the orthonormal spin orbitals $|I\rangle \equiv |i\sigma\rangle = |i\rangle \otimes |\sigma\rangle; i = 1, \dots, n; \sigma = 1, 2$ [$\sigma = 1, 2$ labeling the spin-up and spin-down eigenstates of S_z], and $h_{ij} = \langle i|\hat{h}|j\rangle$, $v_{ij,k\ell} = \langle i(1)j(2)|\hat{v}|k(1)\ell(2)\rangle$ are the one and two-electron integrals in the orbital basis $\{|i\rangle\}$. As stated in Sect. 4.3.4, $e_{IJ} \equiv e_{i\sigma,j\tau} = X_{i\sigma}^\dagger X_{j\tau}$ may then be regarded as U(2n) generators, and the appropriate U(2n) irrep for N -electron states is $\Gamma(1^N\dot{0})$.

Similar to the nuclear many-body problem [67], one defines mutually commuting partial traces of spin-orbital generators e_{IJ} , Eq. (4.87),

$$\begin{aligned} E_{ij} &= \sum_{\sigma=1}^2 e_{i\sigma,j\sigma} = \sum_{\sigma=1}^2 X_{i\sigma}^\dagger X_{j\sigma}, \\ \mathcal{E}_{\sigma\tau} &= \sum_{i=1}^n e_{i\sigma,i\tau} = \sum_{i=1}^n X_{i\sigma}^\dagger X_{i\tau}, \quad (4.95) \end{aligned}$$

which again satisfy the unitary group commutation relations Eq. (4.59) and property Eq. (4.60), and may thus be considered as the generators of the orbital group U(n) and the spin group U(2). The Hamiltonian Eq. (4.94) is thus expressible

in terms of orbital $U(n)$ generators

$$H = \sum_{i,j} h_{ij} E_{ij} + \frac{1}{2} \sum_{i,j,k,\ell} v_{ij,k\ell} (E_{ik} E_{j\ell} - \delta_{jk} E_{i\ell}) . \quad (4.96)$$

We can thus achieve an automatic spin adaptation by exploiting the chain

$$U(2n) \supset U(n) \otimes U(2) \quad (4.97)$$

and diagonalize H within the carrier space of two-column $U(n)$ irreps $\Gamma(2^a 1^b 0^c) \equiv \Gamma(a, b, c)$ with [39, 68]

$$\begin{aligned} a &= \frac{1}{2}N - S , & b &= 2S , \\ c &= n - a - b = n - \frac{1}{2}N - S , \end{aligned} \quad (4.98)$$

considering the states of multiplicity $(2S + 1)$ involving n orbitals and N electrons. The dimension of each spin-adapted subproblem equals [39, 68]

$$\dim \Gamma(2^a 1^b 0^c) = \frac{b+1}{n+1} \binom{n+1}{a} \binom{n+1}{c} , \quad (4.99)$$

where $\binom{m}{n}$ designate binomial coefficients.

Exploiting simplified irrep labeling by triples of integers (a, b, c) , Eq. (4.98), at each level of the canonical chain Eq. (4.67), one achieves more efficient state labeling by replacing Gel'fand tableaux Eq. (4.68) by $n \times 3$ ABC [68] or Paldus or Gel'fand–Paldus tableaux [40, 69–77]

$$[P] = [a_i b_i c_i] , \quad (4.100)$$

where $a_i + b_i + c_i = i$. Another convenient labeling uses the ternary *step numbers* d_i , $0 \leq d_i \leq 3$ [68–70, 78, 79]

$$d_i = 1 + 2(a_i - a_{i-1}) - (c_i - c_{i-1}) . \quad (4.101)$$

A compact representation of a spin-adapted basis of *configuration state functions* (CSFs) spanning a given $U(n)$ irrep $\Gamma(2^a 1^b 0^c)$ is given by a *distinct row table* (DRT) ([69, 70], cf. also [10–12, 39, 71]). The entire basis is then conveniently described by a *Shavitt graph* [11, 69, 70], providing a compact and transparent representation of the entire basis of CSFs, and the corresponding formalism is referred to as the graphical UGA (GUGA). This facilitates the design of computer codes not only for the full configuration interaction (FCI) calculations ([80]) but mainly for a limited or truncated CI.

The Shavitt graph is a two-rooted graph whose vertices represent distinct rows of the ABC tableaux for each subgroup $U(i)$ ($i = 1, \dots, n$) with the top root representing the highest weight $(a, b, c) \equiv (a_n, b_n, c_n)$ for $U(n)$ and the bottom root the trivial row $(0, 0, 0) \equiv (a_0, b_0, c_0)$. The entire graph is placed on a grid so that the slope of its edges im-

plies the relevant step numbers. Each basis vector or CSF is thus represented by a path interconnecting both roots.

Considering the generator matrix elements, we note that the bra and ket state paths coincide outside the range given by the generator indices, thus forming a loop within this range that can be split into the *segment values* for each elementary step. The explicit form of segment values has been derived in several different ways [10–12, 68–71, 75–77, 79, 81–85] (but not within GUGA per se [82]). However, this factorization into a product of segment values is not unique and can be done in several ways ([79, 84, 85]).

The most efficient way for a derivation of explicit expressions for segment values exploits the *graphical methods of spin algebras* employing Jucys-type angular-momentum diagrams ([86]) while relying on the fact that the $U(n)$ electronic CSFs correspond to the Yamanouchi–Kotani coupling scheme [67]. This approach is particularly efficient for matrix elements involving generator products [79, 87, 88]. Yet another useful approach [84, 85, 89] introduced spin-adapted creation and annihilation operators that in a certain way mimic those of the standard second-quantization formalism ([82]), which also proved to be very useful for spin-dependent formalism (Sect. 4.3.8).

A recent development that exploits GUGA representation of the electronic CSF $U(n)$ basis is the so-called *graphically contracted function* (GCF) method [90, 91], which is based on the graph density concept. This approach enables a comparison of CSFs in terms of nodes and arcs (edges) of the Shavitt graph, thus opening a possibility of handling extremely large CIs exceeding traditional ones by many orders of magnitude. For the most recent development that also introduced a multifacet GCF (MFGCF), see [92].

Finally, we note that the unitary group formalism that is based either on $U(n)$ or on the universal enveloping algebra of $U(n)$ proved to be of great usefulness in various post-Hartree–Fock approaches to molecular electronic structure [93], especially in large-scale CI calculations (cf., the COLUMBUS Program System [94–97]; see also [24–31] in [12]), in MC-SCF approaches [98–101], propagator methods [102], and coupled cluster (CC) methods of both single-reference [103–118] and multi-reference [119–122] type, as well as in various other investigations, such as quantum dots [123], in handling of composite systems [89, 124–126], valence-bond (VB) approaches [127–132], reduced density matrices (RDMs) [105, 133], nuclear magnetic resonance (NMR) [134], or charge migration in fragmentation of peptide ions [135, 136]; see also [10–12] for other references. We should also mention numerous other developments and extensions, such as Clifford algebra UGA (CAUGA) (Sect. 4.3.7), bonded tableau UGA [137], parafermi algebras [138], and related developments ([139]).

Very recently there have been a new, very promising, exploitation of UGA (see recent critical reviews [140–

142]) and GUGA in the FCI-QMC (Quantum Monte Carlo) method [143–145], enabling a very efficient handling of relatively large, complex systems [146–151], as well as an exploitation [152] of eCCSD (*externally corrected* Coupled Cluster methods with Singles and Doubles) ([153] and Sect. 5.3.8).

4.3.7 Clifford Algebra Unitary Group Approach

The Clifford algebra unitary group approach (CAUGA) exploits a realization of the spinor algebra of the rotation group $SO(2n + 1)$ in the covering algebra of $U(2^n)$ to obtain explicit representation matrices for the $U(n)$ [or $SO(2n + 1)$ or $SO(2n)$] generators in the basis adapted to the chain [125, 154–157]

$$U(2^n) \supset \text{Spin}(m) \supset SO(m) \supset U(n) , \\ (m = 2n + 1 \quad \text{or} \quad m = 2n) \quad (4.102)$$

supplemented, if desired, by the canonical chain Eq. (4.67) for $U(n)$.

To realize the connection with the fermionic Grassmann algebra generated by the creation (X_I^\dagger) and annihilation (X_I) operators, $I = 1, \dots, 2n$, note that it is isomorphic with the Clifford algebra C_{4n} when we define [12, 25]

$$\alpha_I = X_I + X_I^\dagger , \quad \alpha_{I+2n} = i(X_I - X_I^\dagger) , \\ (I = 1, \dots, 2n) . \quad (4.103)$$

For practical applications, the most important is the finite imbedding $U(2^n) \supset U(n)$ (for the role of intermediate groups, see [154–156]). All states of an n -orbital model, regardless the electron number N and the total spin S , are contained in a single two-box totally symmetric irrep $\langle 20 \rangle$ of $U(2^n)$ [125, 157]. To simplify the notation, one employs the one-to-one correspondence between the Clifford algebra monomials, labeled by the occupation numbers $m_i = 0$ or $m_i = 1$ ($i = 1, \dots, n$), and “multiparticle” single-column $U(n)$ states labeled by

$$p \equiv p\{m_i\} = 2^n - (m_1 m_2 \cdots m_n)_2 , \quad (4.104)$$

where the occupation number array $(m_1 \cdots m_n)$ is interpreted as a binary integer, which we then regard as one-box states $|p\rangle$ of $U(2^n)$. The orbital $U(n)$ generators A_{ij} may then be expressed as simple linear combinations of $U(2^n)$ generators $E_{pq} = |p\rangle\langle q|$ with coefficients equal to ± 1 [125, 157].

Generally, any p -column $U(n)$ irrep is contained at least once in the totally symmetric p -box irrep of $U(2^n)$. For many-electron problems, one thus requires a two-box irrep $\langle 20 \rangle$. Any state arising in the $U(n)$ irrep $\Gamma(a, b, c)$

can then be represented as a linear combination of two-box states, labeled by the Weyl tableaux $[i|j] \equiv \boxed{i|j}$. In particular, the highest weight state of $\Gamma(a, b, c)$ is represented by $[2^c|2^{b+c}]$. Once this representation is available, it is straightforward to compute explicit representations of $U(n)$ generators, since E_{pq} act trivially on $[i|j]$ [125]. Defining unnormalized states $(i|j)$ as

$$(i|j) = \sqrt{1 + \delta_{ij}} \quad [i|j] , \quad (4.105)$$

we have

$$E_{pq}(i|j) = \delta_{qi}(p|j) + \delta_{qj}(i|p) . \quad (4.106)$$

The main features of CAUGA may, thus, be summarized as follows: CAUGA

1. Effectively reduces an N -electron problem to a number of two-boson problems
2. Enables an exploitation of an arbitrary coupling scheme (being particularly suited for the valence bond method)
3. Can be applied to particle-number nonconserving operators
4. Easily extends to fermions with an arbitrary spin
5. Drastically simplifies evaluation of explicit representations of $U(n)$ generators and of their products
6. Can be exploited in other than shell-model approaches [127–129, 131, 158–160].

4.3.8 Spin-Dependent Operators

The spin-adapted $U(n)$ -based UGA is entirely satisfactory in most investigations of molecular electronic structure. However, when exploring the fine structure in high-resolution spectra, the intersystem crossings, phosphorescent lifetimes, molecular predissociation, spin–orbit interactions in transition metals, and like phenomena, the *explicitly* spin-dependent terms must be included in the Hamiltonian. Since in most cases the total spin S represents a good approximate quantum number, it is advantageous to employ $U(n)$ spin-adapted N -electron states as a point of departure and consider the matrix elements of general spin-orbital $U(2n)$ generators in terms of the $U(2n) \supset U(n) \otimes SU(2)$ basis. Such an approach is generally referred to as a spin-dependent UGA and was first considered in the context of the symmetric group and Racah algebra by Drake and Schlesinger [83] and later on in terms of the *Gel'fand–Paldus tableaux* [82, 161–165].

Now, the segmentation of the matrix elements of spin-dependent one-body operators may be shown to be very similar to that for the two-body operators, which makes it possible to exploit the existing UGA or GUGA codes. However, this necessitates that we employ a larger group, say

$U(n + 1)$, or even $U(n + 2)$ [82, 165], since $U(n + 1)$ generators can change the spin at the $U(n)$ level, as is the case for spin-dependent one-body operators. In fact, the advantage of a large $U(n + 1)$ group follows immediately when we employ the graphical methods of spin algebras ([79]), as was done by Drake and Schlesinger [83]. This fact was also exploited by Yabushita *et al.* [166] and implemented in GUGA codes. However, since this approach [166] relies on Racah–Wigner calculus, it requires six additional steps in order to conform with the standard UGA-based formalism, including the introduction of an additional phase factor and a transformation to a “real spherical” spin function in order to ascertain a real-valued form of the relevant matrix elements. These steps may be avoided using an approach that is based on the spin-free analogues of creation and annihilation operators [84, 85]. Indeed, this approach leads to a simple formalism [82] that enables the evaluation of the required one-electron spin-dependent terms in much the same way as the standard spin-independent two-electron (i.e., Coulomb) matrix elements. Only a few additional expressions had to be derived and all the required segment values are given in [82].

In general, the $U(2n)$ generators $e_{i\sigma,j\tau} \equiv e_{IJ}$ may be resolved into the spin-shift components $e(\pm)_{IJ}$ that increase (+) or decrease (–) the total spin S by one unit and the zero-spin component $e(0)_{IJ}$ that preserves S . The relevant matrix elements can then be expressed in terms of the matrix elements of a single $U(n)$ adjoint tensor operator Δ , which is given by the following second-degree polynomial in $U(n)$ generators,

$$\Delta = \mathbf{E}(\mathbf{E} + N/2 - n - 2), \quad \mathbf{E} = \|E_{ij}\|, \quad (4.107)$$

and by the well-known matrix elements of $U(2)$ or $SU(2)$ generators in terms of the pure spin states [161, 162] ([167, 168]). The operator Eq. (4.107), referred to as the Gould–Paldus operator [169], also plays a key role in the determination of reduced density matrices [105, 133] and has recently been exploited in the multireference spin-adapted variant of the density functional theory [169]. Very recently Robb *et al.* used spin dependent UGA to evaluate spin densities for CI in a basis of S^2 -adapted CSFs [170].

Abstract

Perturbation theory (PT) represents one of the bridges that takes us from a simpler, exactly solvable (unperturbed) problem to a corresponding real (perturbed) problem by expressing its solutions as a series expansion in a suitably chosen “small” parameter ε in such a way that the problem reduces to the unperturbed problem when $\varepsilon = 0$. It originated in classical mechanics and eventually developed into an important branch of applied mathematics

 e-mail: paldus@uwaterloo.ca

enabling physicists and engineers to obtain approximate solutions of various systems of differential equations [1–5]. For the problems of atomic and molecular structure and dynamics, the perturbed problem is usually given by the time-independent or time-dependent Schrödinger equation [6–10].

5.1 Matrix Perturbation Theory (PT)

A prototype of a time-independent PT considers an eigenvalue problem for the Hamiltonian H of the form

$$H = H_0 + V, \quad V = \sum_{i=1}^{\infty} \varepsilon^i V_i, \quad (5.1)$$

acting in a (finite-dimensional) Hilbert space \mathcal{V}_n , assuming that the spectral resolution of the unperturbed operator H_0 is known; i.e.,

$$H_0 = \sum_i \omega_i P_i, \quad P_i P_j = \delta_{ij} P_j, \quad \sum_i P_i = I, \quad (5.2)$$

where ω_i are distinct eigenvalues of H_0 , the P_i form a complete orthonormal set of Hermitian idempotents, and I is the identity operator on \mathcal{V}_n . The PT problem for H can then be

formulated within the Lie algebra \mathcal{A} (Sect. 3.2) generated by H_0 and V [11, 12].

5.1.1 Basic Concepts

Define the diagonal part $\langle X \rangle$ of a general operator $X \in \mathcal{A}$ by

$$\langle X \rangle = \sum_i P_i X P_i \quad (5.3)$$

and recall that the adjoint action of $X \in \mathcal{A}$, $\text{ad } X: \mathcal{A} \rightarrow \mathcal{A}$ is defined by

$$\text{ad } X(Y) = [X, Y], \quad (\forall Y \in \mathcal{A}), \quad (5.4)$$

where the square bracket denotes the commutator. The key problem of PT is the ‘‘inversion’’ of this operation, i.e., the solution of the equation [11–13]

$$\text{ad } H_0(X) \equiv [H_0, X] = Y. \quad (5.5)$$

Assuming that $\langle Y \rangle = 0$, then

$$X = R(Y) + \langle A \rangle, \quad (5.6)$$

where $A \in \mathcal{A}$ is arbitrary, and

$$R(Y) = \sum_{i \neq j} \Delta_{ij}^{-1} P_i Y P_j, \quad (5.7)$$

with $\Delta_{ij} = \omega_i - \omega_j$, represents the solution of Eq. (5.5) with the vanishing diagonal part $\langle R(Y) \rangle = 0$.

5.1.2 Level-Shift Operators

To solve the PT problem for H , Eq. (5.1) we search for a unitary level-shift transformation U [11, 12], $U^\dagger U = U U^\dagger = I$,

$$U H U^\dagger = U(H_0 + V)U^\dagger = H_0 + E, \quad (5.8)$$

where the level-shift operator E satisfies the condition

$$E = \langle E \rangle. \quad (5.9)$$

To guarantee the unitarity of U we express it in the form

$$U = e^G, \quad G^\dagger = -G, \quad \langle G \rangle = 0. \quad (5.10)$$

Using the Hausdorff formula

$$e^A B e^{-A} = \sum_{k=0}^{\infty} (k!)^{-1} (\text{ad } A)^k B \quad (5.11)$$

and defining the operator

$$F = [H_0, G], \quad (5.12)$$

we find from Eq. (5.8) that

$$E + F = V + \frac{1}{2}[G, V + E] + \sum_{k=2}^{\infty} (k!)^{-1} B_k (\text{ad } G)^k (V - E), \quad (5.13)$$

where we used the identity [14]

$$\left(\sum_{k=0}^{\infty} \frac{B_k}{k!} X^k \right) \left(\sum_{k=0}^{\infty} \frac{1}{(k+1)!} X^k \right) = I, \quad (5.14)$$

and B_k designates the Bernoulli numbers [15]

$$\begin{aligned} B_0 &= 1, & B_1 &= -\frac{1}{2}, & B_2 &= \frac{1}{6}, \\ B_{2k+1} &= 0 \quad (k \geq 1), \\ B_4 &= \frac{1}{30}, & B_6 &= \frac{1}{42}, & \text{etc.} \end{aligned} \quad (5.15)$$

5.1.3 General Formalism

Introducing the PT expansion for relevant operators,

$$X = \sum_{i=1}^{\infty} \varepsilon^i X_i, \quad X = E, F, G; \quad F_i = [H_0, G_i], \quad (5.16)$$

Eq. (5.13) leads to the following system of equations

$$\begin{aligned} E_1 + F_1 &= V_1, \\ E_2 + F_2 &= V_2 + \frac{1}{2}[G_1, V_1 + E_1], \\ E_3 + F_3 &= V_3 + \frac{1}{2}[G_1, V_2 + E_2] \\ &\quad + \frac{1}{2}[G_2, V_1 + E_1] \\ &\quad + \frac{1}{12}[G_1, [G_1, V_1 - E_1]], \quad \text{etc.}, \end{aligned} \quad (5.17)$$

which can be solved recursively for E_i and G_i by taking their diagonal part and applying operator R , Eq. (5.7), since

$$\begin{aligned} \langle E_i \rangle &= E_i, & \langle G_i \rangle &= \langle F_i \rangle = 0, \\ R F_i &= G_i, & R E_i &= 0. \end{aligned} \quad (5.18)$$

We thus get

$$\begin{aligned} E_1 &= \langle V_1 \rangle, \\ E_2 &= \langle V_2 \rangle + \frac{1}{2} \langle [R V_1, V_1] \rangle, \\ E_3 &= \langle V_3 \rangle + \langle [R V_1, V_2] \rangle \\ &\quad + \frac{1}{6} \langle [R V_1, [R V_1, 2V_1 + E_1]] \rangle, \quad \text{etc.}, \end{aligned} \quad (5.19)$$

and

$$\begin{aligned} G_1 &= RV_1, \\ G_2 &= RV_2 + \frac{1}{2}R[RV_1, V_1 + E_1], \quad \text{etc.} \end{aligned} \quad (5.20)$$

Since

$$\begin{aligned} \langle R(X) \rangle &= R\langle X \rangle = 0, \quad \langle R(X)Y \rangle = -\langle XR(Y) \rangle, \\ R\langle X \rangle &= R(X)\langle Y \rangle, \quad R(\langle X \rangle Y) = \langle X \rangle R(Y), \end{aligned} \quad (5.21)$$

these relationships can be transformed to a more conventional form

$$\begin{aligned} E_2 &= \langle V_2 \rangle - \langle V_1 RV_1 \rangle, \\ E_3 &= \langle V_3 \rangle - \langle V_1 RV_2 \rangle - \langle V_2 RV_1 \rangle \\ &\quad + \frac{1}{6} \langle R(V_1)R(V_1)[2V_1 + \langle V_1 \rangle] \rangle \\ &\quad - \frac{1}{3} \langle R(V_1)[2V_1 + \langle V_1 \rangle]R(V_1) \rangle \\ &\quad + \frac{1}{6} \langle [2V_1 + \langle V_1 \rangle]R(V_1)R(V_1) \rangle, \quad \text{etc.} \end{aligned} \quad (5.22)$$

However, in this way certain nonphysical terms arise that exactly cancel when the commutator form is employed (Sect. 5.3.7).

5.1.4 Nondegenerate Case

In the nondegenerate case, when $P_i = |i\rangle\langle i|$, with $|i\rangle$ representing the eigenvector of H_0 associated with the eigenvalue ω_i , the level-shift operator is diagonal, and its explicit PT expansion (as well as that for the corresponding eigenvectors) is readily obtained from Eqs. (5.19) and (5.20). Writing x_{ij} for the matrix element $\langle i|X|j\rangle$, we get

$$\begin{aligned} (e_1)_{ii} &= (v_1)_{ii}, \\ (e_2)_{ii} &= (v_2)_{ii} - \sum'_j \frac{(v_1)_{ij}(v_1)_{ji}}{\Delta_{ji}}, \\ (e_3)_{ii} &= (v_3)_{ii} - \sum'_j \frac{(v_1)_{ij}(v_2)_{ji} + (v_2)_{ij}(v_1)_{ji}}{\Delta_{ji}} \\ &\quad + \sum'_{j,k} \frac{(v_1)_{ij}(v_1)_{jk}(v_1)_{ki}}{\Delta_{ji}\Delta_{ki}} \\ &\quad - (v_1)_{ii} \sum'_j \frac{(v_1)_{ij}(v_1)_{ji}}{\Delta_{ji}^2}, \quad \text{etc.}, \end{aligned} \quad (5.23)$$

the prime on the summation symbols indicating that the terms with the vanishing denominator are to be deleted.

Note that in contrast to PT expansions, which directly expand the level-shift transformation U , $U = 1 + \varepsilon U_1 + \varepsilon^2 U_2 + \dots$, the above Lie algebraic formulation has the advantage that U stays unitary in every order of PT. This is particularly useful in spectroscopic applications, such as line broadening.

5.2 Time-Independent Perturbation Theory

For stationary problems, particularly those arising in atomic and molecular electronic structure studies relying on ab initio model Hamiltonians, the PT of Sect. 5.1 can be given a more explicit form that avoids a priori the nonphysical, size inextensive terms [7–10, 16–18].

5.2.1 General Formulation

We wish to find the eigenvalues and eigenvectors of the full (perturbed) problem

$$K|\Psi_i\rangle \equiv (K_0 + W)|\Psi_i\rangle = k_i|\Psi_i\rangle, \quad (5.24)$$

assuming we know those of the unperturbed problem

$$K_0|\Phi_i\rangle = \kappa_i|\Phi_i\rangle, \quad \langle \Phi_i|\Phi_j\rangle = \delta_{ij}. \quad (5.25)$$

For simplicity, we restrict ourselves to the nondegenerate case ($\kappa_i \neq \kappa_j$ if $i \neq j$) and consider only the first-order perturbation (Eq. (5.1), $\varepsilon V_1 \equiv W$, $V_i = 0$ for $i \geq 2$). Of course, K and K_0 are Hermitian operators acting in a Hilbert space, which, in ab initio applications, is finite-dimensional.

Using the intermediate normalization for $|\Psi_i\rangle$,

$$\langle \Psi_i|\Phi_i\rangle = 1, \quad (5.26)$$

the asymmetric energy formula gives

$$k_i = \kappa_i + \langle \Phi_i|W|\Psi_i\rangle. \quad (5.27)$$

The idempotent Hermitian projectors

$$P_i = |\Phi_i\rangle\langle \Phi_i|, \quad Q_i = P_i^\perp = 1 - P_i = \sum_{j(\neq i)} |\Phi_j\rangle\langle \Phi_j| \quad (5.28)$$

commute with K_0 , so that

$$(\lambda - K_0)Q_i|\Psi_i\rangle = Q_i(\lambda - k_i + W)|\Psi_i\rangle, \quad (5.29)$$

λ being an arbitrary scalar (note that we write λI simply as λ). Since the resolvent $(\lambda - K_0)^{-1}$ of K_0 is nonsingular on the orthogonal complement of the i -th eigenspace, we get

$$Q_i|\Psi_i\rangle = |\Psi_i\rangle - |\Phi_i\rangle = R_i(\lambda)(\lambda - k_i + W)|\Psi_i\rangle, \quad (5.30)$$

where

$$\begin{aligned} R_i &\equiv R_i(\lambda) = (\lambda - K_0)^{-1}Q_i \\ &= Q_i(\lambda - K_0)^{-1} = \sum_{j(\neq i)} \frac{|\Phi_j\rangle\langle \Phi_j|}{\lambda - \kappa_j}, \end{aligned} \quad (5.31)$$

assuming $(\lambda \neq \kappa_j)$. Iterating this relationship, we get prototypes of the desired PT expansion for $|\Psi_i\rangle$,

$$|\Psi_i\rangle = \sum_{n=0}^{\infty} [R_i(\lambda - k_i + W)]^n |\Phi_i\rangle, \quad (5.32)$$

and, from Eq. (5.27), for k_i ,

$$k_i = \kappa_i + \sum_{n=0}^{\infty} \langle \Phi_i | W [R_i(\lambda - k_i + W)]^n | \Phi_i \rangle. \quad (5.33)$$

5.2.2 Brillouin–Wigner and Rayleigh–Schrödinger PT (RSPT)

So far, the parameter λ was arbitrary as long as $\lambda \neq \kappa_j$ ($j \neq i$). The following two choices lead to the two basic types of many-body perturbation theory (MBPT):

Brillouin–Wigner (BW) PT Setting $\lambda = k_i$ gives

$$k_i = \kappa_i + \sum_{n=0}^{\infty} \langle \Phi_i | W (R_i^{(\text{BW})} W)^n | \Phi_i \rangle, \quad (5.34)$$

$$|\Psi_i\rangle = \sum_{n=0}^{\infty} (R_i^{(\text{BW})} W)^n |\Phi_i\rangle, \quad (5.35)$$

where

$$R_i^{(\text{BW})} = \sum_{j(\neq i)} \frac{|\Phi_j\rangle\langle\Phi_j|}{k_i - \kappa_j}. \quad (5.36)$$

Rayleigh–Schrödinger (RS) PT Setting $\lambda = \kappa_i$ gives

$$k_i = \kappa_i + \sum_{n=0}^{\infty} \langle \Phi_i | W [R_i^{(\text{RS})}(\kappa_i - k_i + W)]^n | \Phi_i \rangle, \quad (5.37)$$

$$|\Psi_i\rangle = \sum_{n=0}^{\infty} [R_i^{(\text{RS})}(\kappa_i - k_i + W)]^n |\Phi_i\rangle, \quad (5.38)$$

where now

$$R_i \equiv R_i^{(\text{RS})} = \sum_{j(\neq i)} \frac{|\Phi_j\rangle\langle\Phi_j|}{\kappa_i - \kappa_j}. \quad (5.39)$$

The main distinction between these two PTs lies in the fact that the BW form has the exact eigenvalues appearing in the denominators and, thus, leads to polynomial expressions for k_i . Although these are not difficult to solve numerically, since the eigenvalues are separated, the resulting energies are never size extensive and, thus, unusable for extended systems. They are also unsuitable for finite systems when the particle number changes, as in various dissociation processes. From now on, we thus investigate only the RSPT, which yields a fully size-extensive theory.

5.2.3 Bracketing Theorem and RSPT

Expressions Eqs. (5.37) and (5.38) are not explicit, since they involve the exact eigenvalues k_i on the right-hand side. To achieve an order-by-order separation, set

$$k_i \equiv k = \sum_{j=0}^{\infty} k^{(j)}, \quad |\Psi_i\rangle \equiv |\Psi\rangle = \sum_{j=0}^{\infty} |\Psi^{(j)}\rangle, \quad (5.40)$$

where the superscript (j) indicates the j -th-order in the perturbation W . We only consider the eigenvalue expressions, since the corresponding eigenvectors are readily recovered from them by removing the bra state and the first interaction W (Eqs. (5.37) and (5.38)). We also simplify the mean value notation writing for a general operator X ,

$$\langle X \rangle \equiv \langle \Phi_i | X | \Phi_i \rangle. \quad (5.41)$$

Substituting the first expansion Eq. (5.40) into Eq. (5.37) and collecting the terms of the same order in W , we get

$$\begin{aligned} k^{(0)} &= \kappa_i, \\ k^{(1)} &= \langle W \rangle, \\ k^{(2)} &= \langle WRW \rangle, \\ k^{(3)} &= \langle W(RW)^2 \rangle - \langle W \rangle \langle WR^2W \rangle, \\ k^{(4)} &= \langle W(RW)^3 \rangle \\ &\quad - \langle W \rangle (\langle WR(RW)^2 \rangle + \langle (WR)^2 RW \rangle) \\ &\quad + \langle W \rangle^2 \langle WR^3W \rangle - \langle WRW \rangle \langle WR^2W \rangle, \quad \text{etc.} \end{aligned} \quad (5.42)$$

The general expression has the form

$$k^{(n)} = \langle W(RW)^{n-1} \rangle + \mathcal{R}^{(n)}, \quad (5.43)$$

the first term on the right-hand side being referred to as the *principal* n -th-order term, while $\mathcal{R}^{(n)}$ designates the so-called *renormalization* terms that are obtained by the *bracketing theorem* [16, 19] as follows:

1. Insert the bracketings $\langle \dots \rangle$ around the $W, WRW, \dots, WR \dots RW$ operator strings of the principal term in all possible ways.
2. Bracketings involving the rightmost and/or the leftmost interaction vanish.
3. The sign of each bracketed term is given by $(-1)^{n_B}$, where n_B is the number of bracketings.
4. Bracketings within bracketings are allowed, e.g., $\langle WR \langle WR \langle W \rangle RW \rangle RW \rangle = \langle W \rangle \langle WR^2W \rangle^2$.
5. The total number of bracketings (including the principal term) is $(2n - 2)! / [n!(n - 1)!]$.

5.3 Fermionic Many-Body Perturbation Theory (MBPT)

5.3.1 Time-Independent Wick's Theorem

The development of an explicit MBPT formalism is greatly facilitated by the exploitation of the time-independent version of Wick's theorem. This version of the theorem expresses an arbitrary product of creation (a_μ^\dagger) and annihilation (a_μ) operators (Chap. 6) as a normal product (relative to $|\Phi_0\rangle$) and as normal products with all possible contractions of these operators [16–18],

$$\begin{aligned} x_1 x_2 \cdots x_k &= N[x_1 x_2 \cdots x_k] + \Sigma N[x_1 \overline{x_2 \cdots x_k}], \\ (x_i &= a_{\mu_i}^\dagger \text{ or } x_i = a_{\mu_i}), \end{aligned} \quad (5.44)$$

where

$$\begin{aligned} \overline{a_\mu^\dagger a_\nu^\dagger} &= \overline{a_\mu a_\nu} = 0, \\ \overline{a_\mu^\dagger a_\nu} &= h(\mu)\delta_{\mu\nu}, \quad \overline{a_\mu a_\nu^\dagger} = p(\mu)\delta_{\mu\nu}, \end{aligned} \quad (5.45)$$

and

$$\begin{aligned} h(\mu) &= 1, \quad p(\mu) = 0 \text{ if } |\mu\rangle \text{ is occupied in } |\Phi_0\rangle \\ &\text{(hole states),} \\ h(\mu) &= 0, \quad p(\mu) = 1 \text{ if } |\mu\rangle \text{ is unoccupied in } |\Phi_0\rangle \\ &\text{(particle states).} \end{aligned} \quad (5.46)$$

The N -product with contractions is defined as a product of individual contractions times the N -product of uncontracted operators (defining $N[\emptyset] \equiv 1$ for an empty set) with the sign given by the parity of the permutation reordering the operators into their final order.

Note that the Fermi vacuum mean value of an N -product vanishes unless all operators are contracted. Thus, $\langle x_1 x_2 \cdots x_k \rangle$ is given by the sum over all possible fully contracted terms (vacuum terms). Similar rules follow for the expressions of the type $\langle x_1 x_2 \cdots x_k \rangle |\Phi\rangle$. Moreover, if some operators on the left-hand side of Eq. (5.44) are already in the N -product form, all the terms involving contractions between these operators vanish.

5.3.2 Normal Product Form of PT

Consider the eigenvalue problem for a general ab initio or semiempirical electronic Hamiltonian H with one and two-body components Z and V , namely,

$$\begin{aligned} H|\Psi_i\rangle &= E_i|\Psi_i\rangle, \\ H &= Z + V = \sum_i z(i) + \sum_{i<j} v(i, j), \end{aligned} \quad (5.47)$$

and a corresponding unperturbed problem

$$\begin{aligned} H_0|\Phi_i\rangle &= \varepsilon_i|\Phi_i\rangle, \\ H_0 &= Z + U, \quad \langle\Phi_i|\Phi_j\rangle = \delta_{ij}, \end{aligned} \quad (5.48)$$

with U representing some approximation to V . In the case that U is also a one-electron operator, $U = \Sigma_i u(i)$, the unperturbed problem Eq. (5.48) is separable and reduces to a one-electron problem,

$$(z + u)|\mu\rangle = \omega_\mu|\mu\rangle, \quad (5.49)$$

which is assumed to be solved. Choosing the orthonormal spin orbitals $\{|\mu\rangle\}$ as a basis of the second quantization representation Sect. 6.1, the N -electron solutions of Eq. (5.48) can be represented as

$$|\Phi_i\rangle = a_{\mu_1}^\dagger a_{\mu_2}^\dagger \cdots a_{\mu_N}^\dagger |0\rangle, \quad (5.50)$$

$$\varepsilon_i = \sum_{j=1}^N \omega_{\mu_j}, \quad (5.51)$$

the state label i representing the occupied spin orbital set $\{\mu_1, \mu_2, \dots, \mu_N\}$, while the one and two-body operators take the form

$$X = \sum_{\mu, \nu} \langle \mu|x|\nu \rangle a_\mu^\dagger a_\nu, \quad X = Z, U; \quad x = z, u, \quad (5.52)$$

$$V = \frac{1}{2} \sum_{\mu, \nu, \sigma, \tau} \langle \mu\nu|v|\sigma\tau \rangle a_\mu^\dagger a_\nu^\dagger a_\tau a_\sigma. \quad (5.53)$$

Considering, for simplicity, a nondegenerate ground state $|\Phi\rangle \equiv |\Phi_0\rangle = a_1^\dagger a_2^\dagger \cdots a_N^\dagger |0\rangle$, referred to as a Fermi vacuum, we define the *normal product form* of these operators relative to $|\Phi\rangle$

$$\begin{aligned} X_N &\equiv X - \langle X \rangle = \sum_{\mu, \nu} \langle \mu|x|\nu \rangle N[a_\mu^\dagger a_\nu], \\ (X &= Z, U, G; \quad x = z, u, g) \end{aligned} \quad (5.54a)$$

$$\begin{aligned} V_N &\equiv V - \langle V \rangle - G_N \\ &= \frac{1}{2} \sum_{\mu, \nu, \sigma, \tau} \langle \mu\nu|v|\sigma\tau \rangle N[a_\mu^\dagger a_\nu^\dagger a_\tau a_\sigma] \\ &= \frac{1}{4} \sum_{\mu, \nu, \sigma, \tau} \langle \mu\nu|v|\sigma\tau \rangle_A N[a_\mu^\dagger a_\nu^\dagger a_\tau a_\sigma], \end{aligned} \quad (5.54b)$$

where

$$\langle \mu|g|\nu \rangle = \sum_{\sigma=1}^N \langle \mu\sigma|v|\nu\sigma \rangle_A, \quad (5.55)$$

$$\langle \mu\nu|v|\sigma\tau \rangle_A = \langle \mu\nu|v|\sigma\tau \rangle - \langle \mu\nu|v|\tau\sigma \rangle, \quad (5.56)$$

$\langle X \rangle = \langle \Phi | X | \Phi \rangle$, and $N[\dots]$ designates the normal product relative to $|\Phi\rangle$ [16–18]. (Recall that $N[x_1 x_2 \dots x_k] = \pm b_{\mu_1}^\dagger \dots b_{\mu_i}^\dagger b_{\mu_{i+1}} \dots b_{\mu_k}$, where $x_i = b_{\mu_i}$ or $b_{\mu_i}^\dagger$ are the annihilation and creation operators of the particle-hole formalism relative to $|\Phi\rangle$, i.e., $b_\mu = a_\mu^\dagger$ for $\mu \leq N$ and $b_\mu = a_\mu$ for $\mu > N$, the sign being determined by the parity of the permutation $p : j \mapsto \mu_j$.)

Defining

$$K = H - \langle H \rangle, \quad K_0 = H_0 - \langle H_0 \rangle = H_0 - \varepsilon_0, \quad (5.57)$$

we can return to Eqs. (5.24) and (5.25), where now

$$\begin{aligned} k_i &= E_i - \langle H \rangle, \quad \kappa_i = \varepsilon_i - \varepsilon_0, \\ \varepsilon_0 &= \sum_{\mu=1}^N \omega_\mu, \end{aligned} \quad (5.58)$$

and

$$W = K - K_0 = V - U - \langle V - U \rangle. \quad (5.59)$$

With this choice, $\langle W \rangle = 0$, so that for the reference state $|\Phi\rangle$, Eq. (5.42) simplify to (we drop the subscript 0 for simplicity)

$$\begin{aligned} k^{(0)} &= 0, \quad k^{(1)} = 0, \\ k^{(2)} &= \langle WRW \rangle, \\ k^{(3)} &= \langle WRWRW \rangle, \\ k^{(4)} &= \langle W(RW)^3 \rangle - \langle WRW \rangle \langle WR^2W \rangle, \quad \text{etc.} \end{aligned} \quad (5.60)$$

Note that W is also in the N -product form,

$$W = W_1 + W_2, \quad W_1 = G_N - U_N, \quad W_2 = V_N. \quad (5.61)$$

5.3.3 Møller–Plesset and Epstein–Nesbet PT

Choosing $U = G$ we have

$$H_0 = Z + G \equiv F, \quad (5.62)$$

so that Eq. (5.49) represent Hartree–Fock (HF) equations, and ω_μ and $|\mu\rangle$ the canonical HF orbital energies and spin orbitals, respectively. Since $\langle H \rangle = \sum_{\mu=1}^N (\langle \mu | z | \mu \rangle + \frac{1}{2} \langle \mu | g | \mu \rangle)$ is the HF energy, $k = k_0$ gives directly the ground state correlation energy. (Note, however, that the N -product form of PT eliminates the first-order contribution $k^{(1)} = \langle W \rangle$ in any basis, even when F is not diagonal.) With this choice, $W_1 = 0$, $W = V_N$, and the denominators in Eq. (5.39) are given by the differences of HF orbital energies

$$\kappa_0 - \kappa_j = \sum_{i=1}^{\lambda} (\omega_{\mu_i} - \omega_{\nu_i}) \equiv \Delta\{\{\mu_i\}; \{\nu_j\}\}, \quad (5.63)$$

assuming that $|\Phi_j\rangle$ is a λ -times excited configuration relative to $|\Phi\rangle$ obtained through excitations $\mu_i \rightarrow \nu_i$, $i = 1, \dots, \lambda$. Using the Slater rules (or the second quantization algebra), we can express the second-order contribution in terms of the two-electron integrals and HF orbital energies as

$$k^{(2)} = \frac{1}{2} \sum_{a,b,r,s} \frac{\langle ab | v | rs \rangle (\langle rs | v | ab \rangle - \langle rs | v | ba \rangle)}{\omega_a + \omega_b - \omega_r - \omega_s}, \quad (5.64)$$

where the summations over $a, b (r, s)$ extend over all occupied (unoccupied) spin orbitals in $|\Phi\rangle$. Obtaining the corresponding higher-order corrections becomes more and more laborious and, beginning with the fourth-order, important cancellations arise between the principal and renormalization terms, even when the N -product form is employed. These will be addressed in Sect. 5.3.7.

The above outlined PT with H_0 given by the HF operator is often referred to as the *Møller–Plesset* PT [20] and, when truncated to the n -th order, is designated by the acronym *MPn*, $n = 2, 3, \dots$. In this version, the two-electron integrals enter the denominators only through the HF orbital energies. In an alternative, less often employed variant, referred to as the *Epstein–Nesbet* PT [21, 22], the whole diagonal part of H is used as the unperturbed Hamiltonian, i.e.,

$$H_0 = \sum_i \langle \Phi_i | H | \Phi_i \rangle P_i. \quad (5.65)$$

With this choice, the denominators are given as differences of the diagonal elements of the configuration interaction matrix.

5.3.4 Diagrammatic MBPT

To facilitate the evaluation of higher-order terms and, especially, to derive the general properties and characteristics of the MBPT, it is useful to employ a diagrammatic representation [7–10, 16–18]. Representing all the operators in Eqs. (5.42) and (5.43) or (5.60) in the second quantized form, we have to deal with the reference state (i.e., the Fermi vacuum) mean values of the strings of annihilation and creation operators (or with these strings acting on the reference in the case of a wave function). This is efficiently done using Wick’s theorem and its diagrammatic representation via a special form of Feynman diagrams. In this representation, we associate with various operators suitable vertices with incident oriented lines representing the creation (outgoing lines) and annihilation (ingoing lines) operators that are involved in their second quantization form. A few typical diagrams representing operators ($-U$), W_1 and V are shown in Fig. 5.1a, Fig. 5.1b and Fig. 5.1c, Fig. 5.1d, respectively. Using the N -product form of PT with HF orbitals (Sect. 5.3.3), we only need the two-electron operator V or V_N , which

Fig. 5.1 Diagrammatic representation of one and two-electron operators

can be represented using either nonantisymmetrized vertices (Fig. 5.1c), leading to the *Goldstone diagrams* [23], or antisymmetrized vertices (Fig. 5.1d), associated with antisymmetrized two-electron integrals Eq. (5.56) and yielding the *Hugenholtz diagrams* [24].

5.3.5 Vacuum and Wave Function Diagrams

Applying Wick's theorem to the strings of operators involved, we represent the individual contractions, Eq. (5.45), by joining corresponding oriented lines. To obtain a nonvanishing contribution, only contractions preserving the orientation need be considered (Eq. (5.45)). The resulting *internal* lines have either the left–right orientation (*hole* lines) or the right–left one (*particle* lines). Only fully contracted terms, represented by the so-called *vacuum diagrams* (having only internal lines), can contribute to the energy, while those representing wave function contributions have uncontracted or *free* lines extending to the left. When the operators involved are in the N -product form, no contractions of oriented lines issuing from the same vertex are allowed. The projection-like operators R , Eq. (5.39), or their powers, lead to the denominators, Eq. (5.63), given by the difference of hole and particle orbital energies associated with, respectively, hole and particle lines passing through the interval separating the corresponding two neighboring vertices. Clearly, there must always be at least one pair of such lines lest the denominator vanish. Thus, for example, the second-order contribution $\langle WRW \rangle$ is represented either by the two Goldstone diagrams [23] (Fig. 5.2a,b) or by the single Hugenholtz diagram [24] (Fig. 5.2c). The rules for the energy (vacuum) diagram evaluation are as follows:

1. Associate appropriate matrix elements with all vertices and form their product. The outgoing (ingoing) lines

Fig. 5.2 The second-order Goldstone (a), (b) and Hugenholtz (c) diagrams

Fig. 5.3 Hugenholtz diagrams for the third-order energy contribution

on each vertex define the bra (ket) states of a given matrix element, and for the Goldstone diagrams, the oriented lines attached to the same node are associated with the same electron number, (e.g., for the leftmost vertex in diagram (a) of Fig. 5.2, we have $\langle ab|v|rs \rangle \equiv \langle a(1)b(2)|v|r(1)s(2) \rangle$).

2. Associate a denominator, Eq. (5.63), or its appropriate power, with every neighboring pair of vertices (and, for the wave function diagrams, also with the free lines extending to the left of the leftmost vertex; with each pair of such free lines associate also the corresponding pair of particle creation and hole annihilation operators).
3. Sum over all hole and particle labels.
4. Multiply each diagram contribution by the weight factor given by the reciprocal value of the order of the group of automorphisms of the diagram (stripped of summation labels) and by the sign $(-1)^{h+\ell}$, where h designates the number of internal hole lines, and ℓ gives the number of closed loops of oriented lines (for Hugenholtz diagrams, use any of its Goldstone representatives to determine the correct phase).

Applying these rules to diagrams (a) and (b) of Fig. 5.2 we clearly recover Eq. (5.64) or, using the Hugenholtz diagram of Fig. 5.2, the equivalent expression

$$k^{(2)} = \frac{1}{4} \sum_{a,b,r,s} \langle ab|v|rs \rangle_A \langle rs|v|ab \rangle_A \Delta^{-1}(a,b;r,s). \quad (5.66)$$

The possible third-order Hugenholtz diagrams are shown in Fig. 5.3 with the central vertex involving particle–particle, hole–hole, and particle–hole interaction [16–18].

5.3.6 Hartree–Fock Diagrams

In the general case (non-HF orbitals and/or not normal product form of PT), the one-electron terms, as well as the contractions between operators associated with the same vertex, can occur (the latter are always the hole lines). Representing the W_1 and $(-U)$ operators as shown in Fig. 5.1, the one-body perturbation W_1 represents in fact the three diagrams as shown in Fig. 5.4. The second-order contribution of this type is then represented by the diagrams in Fig. 5.5, which in fact represents nine diagrams that result when each W_1 vertex is replaced by three vertices as shown in Fig. 5.4.

Fig. 5.4 Schematic representation of $W_1 = G_N - U_N$

Fig. 5.5 The second-order, one-particle contribution

Using HF orbitals, all these terms mutually cancel out, as can be seen above. For this reason, the diagrams involving contractions of lines issuing from the same vertex are referred to as *Hartree–Fock diagrams*. Note, however, that even when not employing the canonical HF orbitals, it is convenient to introduce W_1 vertices of the normal product form PT and replace all nine HF-type diagrams by a single diagram of Fig. 5.5. Clearly, this feature provides even greater efficiency in higher orders of PT.

5.3.7 Linked and Connected Cluster Theorems

Using the N -product form of PT, the first nonvanishing renormalization term occurs in the fourth-order (Eq. (5.60)). For a system consisting of N noninteracting species, the energy given by this nonphysical term is proportional to N^2 and, thus, violates the size extensivity of the theory. It was first shown by *Brueckner* [25] that in the fourth order, these terms are in fact exactly canceled by the corresponding contributions originating in the principal term. A general proof of this cancellation in an arbitrary order was then given by *Goldstone* [23] and *Hubbard* [26] using a time-dependent PT based on Gell-Mann and Low adiabatic theorem and evolution operator (Sect. 5.4) and by *Hugenholtz* [24] employing a time-independent PT, relying on Green’s function or the resolvent operator.

To comprehend this cancellation, consider the fourth-order energy contribution arising from the so-called unlinked diagrams (no such contribution can arise in the second or third order) shown in Fig. 5.6. An *unlinked diagram* is defined as a diagram containing a disconnected vacuum diagram (for the energy diagrams, the terms unlinked and disconnected are synonymous). The numerators associated with both diagrams being identical, we only consider the denominators. Designating the denominator associated with the

Fig. 5.6 The fourth-order unlinked diagrams

top and the bottom part by A and B , respectively, we find for the overall contribution

$$\frac{1}{B} \cdot \frac{1}{A+B} \cdot \frac{1}{B} + \frac{1}{A} \cdot \frac{1}{A+B} \cdot \frac{1}{B} = \left(\frac{1}{B} + \frac{1}{A} \right) \frac{1}{(A+B)B} = \frac{1}{AB^2}. \quad (5.67)$$

Thus, the contribution from these terms exactly cancels that from the renormalization term $\langle WRW \rangle \langle WR^2W \rangle$.

Generalizing Eq. (5.67) we obtain the *factorization lemma* of *Frantz and Mills* [27], which implies the cancellation of renormalization terms by the unlinked terms originating from the principal term. This result holds for the energy as well as for the wave function contributions in every order of PT, as ascertained by the *linked cluster theorem*, which states that

$$\Delta E = k = \sum_{n=0}^{\infty} \langle \Phi | W | \Psi^{(n)} \rangle = \sum_{n=0}^{\infty} \langle W(RW)^n \rangle_L, \quad (5.68)$$

$$|\Psi\rangle = \sum_{n=0}^{\infty} |\Psi^{(n)}\rangle = \sum_{n=0}^{\infty} \{ (RW)^n |\Phi\rangle \}_L, \quad (5.69)$$

where the subscript L indicates that only linked diagrams (or terms) are to be considered. This enables us to obtain general, explicit expressions for the n -th-order PT contributions by first constructing all possible linked diagrams involving n vertices and by converting them into the explicit algebraic expressions using the rules of Sect. 5.3.5. Note that linked energy diagrams are always connected, but the linked wave function diagrams are either connected or disconnected, each disconnected component possessing at least one pair of particle–hole free lines extending to the left.

To reveal a deeper structure of the result Eq. (5.69) define the *cluster operator* T that generates all connected wave function diagrams,

$$T|\Phi\rangle = \sum_{n=1}^{\infty} \{ (RW)^n |\Phi\rangle \}_C, \quad (5.70)$$

the subscript C indicating that only contributions from *connected* diagrams are to be included. Since the general component with r disconnected parts can be shown to be

represented by the term $(r!)^{-1}T^r|\Phi\rangle$, the general structure of the exact wave function $|\Psi\rangle$ is given by the *connected cluster theorem* [24, 26], which states that

$$|\Psi\rangle = e^T |\Phi\rangle, \quad (5.71)$$

assuming an *intermediate normalization* $\langle\Phi|\Psi\rangle = 1$. In other words, the wave operator \mathcal{W} that transforms the unperturbed independent particle model wave function $|\Phi\rangle$ into the exact one according to

$$|\Psi\rangle = \mathcal{W}|\Phi\rangle \quad (5.72)$$

is given by the exponential of the cluster operator T ,

$$\mathcal{W} = e^T, \quad (5.73)$$

which, in turn, is given by the connected wave function diagrams. This is in fact the basis of the coupled cluster methods [28–33] (Sect. 5.3.8). For recent reviews, see, e.g., [10, 17, 18, 34–41]; for a historical perspective, see [42, 43].

The contributions to T may be further classified by their excitation rank i ,

$$T = \sum_{i=1}^N T_i, \quad (5.74)$$

where T_i designates connected diagrams with i pairs of free particle–hole lines, producing i -times excited components of $|\Psi\rangle$ when acting on $|\Phi\rangle$.

5.3.8 Coupled Cluster Theory

To motivate coupled cluster (CC) approaches we recall that summing all HF diagrams (Sect. 5.3.6) is equivalent to solving the HF equations. Likewise, depending on the average electron density of the system, it may be essential to sum certain types of PT diagrams to infinite order at the post-HF level, namely the ring diagrams (*random phase approximation*) in the case of high-density electron gas and ladder diagrams for low-density systems. An ideal approach that can sum different kinds of diagrams and their combinations, and is thus capable of recovering a large part of the electronic correlation energy, is based on the connected cluster theorem (Sect. 5.3.7), referred to in this context as the *exponential cluster ansatz* Eq. (5.71) for the wave operator. Using this ansatz, one derives a system of energy-independent non-linear coupled cluster (CC) equations [10, 17, 18, 30–33] determining the cluster amplitudes of T . These CC equations can be regarded as recurrence relations generating the MBPT series [17, 18], so that by solving these equations one, in fact, implicitly generates all the relevant MBPT diagrams and sums them to infinite order. Since the solution

of the full CC equations is equivalent to the exact solution of the Schrödinger equation, we must—in all practical applications—introduce a suitable truncation scheme, which implies that only diagrams of certain types are summed. (For different possible truncation schemes, see [44, Sect. 2].)

Generally, using the cluster expansion Eq. (5.71) in the N -product form of the Schrödinger equation,

$$\begin{aligned} H_N|\Psi\rangle &\equiv (H - \langle H \rangle)|\Psi\rangle = \Delta E|\Psi\rangle, \\ \Delta E &= E - E_0, \end{aligned} \quad (5.75)$$

premultiplying with the inverse of the wave operator, and using the Hausdorff formula Eq. (5.11) yields

$$e^{-T} H_N e^T |\Phi\rangle = \sum_{n=0}^{\infty} \frac{[\text{ad}(-T)]^n H_N}{n!} = \Delta E|\Phi\rangle. \quad (5.76)$$

In fact, this expansion terminates, so that using Eq. (5.74) and projecting onto $|\Phi\rangle$ we obtain the energy expression

$$\Delta E = \langle H_N T_2 \rangle + \frac{1}{2} \langle H_N T_1^2 \rangle, \quad (5.77)$$

while the projection onto the manifold of excited states $\{|\Phi_i\rangle\}$ relative to $|\Phi\rangle \equiv |\Phi_0\rangle$ gives the system of CC equations

$$\langle\Phi_i|H_N + [H_N, T] + \frac{1}{2}[[H_N, T], T] + \dots|\Phi\rangle = 0. \quad (5.78)$$

Approximating, e.g., T by the most important pair cluster component $T \approx T_2$ gives the so-called CCD (coupled clusters with doubles) approximation

$$\langle\Phi_i^{(2)}|H_N + [H_N, T_2] + \frac{1}{2}[[H_N, T_2], T_2]|\Phi\rangle = 0, \quad (5.79)$$

the superscript (2) indicating pair excitations relative to $|\Phi\rangle$.

Equivalently, Eqs. (5.77) and (5.78) can be written in the form

$$\Delta E = \langle H_N e^T \rangle_C, \quad (5.80)$$

$$\langle\Phi_i|(H_N e^T)_C|\Phi\rangle = 0, \quad (5.81)$$

the subscript C again indicating that only connected diagrams are to be considered. The general explicit form of CC equations is

$$a_i + \sum_j b_{ij} t_j + \sum_{j \leq k} c_{ijk} t_j t_k + \dots = 0, \quad (5.82)$$

where $a_i = \langle\Phi_i|H_N|\Phi_0\rangle$, $b_{ij} = \langle\Phi_i|H_N|\Phi_j\rangle_C$, $c_{ijk} = \langle\Phi_i|H_N|\Phi_j \otimes \Phi_k\rangle_C$, etc. Writing the diagonal linear term b_{ii} in the form

$$b_{ii} = \Delta_i + b'_{ii}, \quad (5.83)$$

this system can be solved iteratively by rewriting it in the form

$$t_i^{(n+1)} = \Delta_i^{-1} \left(a_i + b'_{ii} t_i^{(n)} + \sum_j b'_{ij} t_j^{(n)} + \sum_{j \leq k} c_{ijk} t_j^{(n)} t_k^{(n)} + \dots \right). \quad (5.84)$$

Starting with the zeroth approximation $t_i^{(0)} = 0$, the first iteration is

$$t_i^{(1)} = \Delta_i^{-1} a_i, \quad (5.85)$$

which yields the second-order PT energy when used in Eq. (5.77). Clearly, the successive iterations generate higher and higher orders of the PT. At any truncation level, a size extensive result is obtained.

The single reference (SR) CC methods continue to be remarkably efficient in handling the dynamic correlation effects and are, thus, widely exploited in computations of molecular electronic structure. Several general-purpose codes are available for this purpose (for reviews: [10, 18, 34–36, 38]). The basic workhorse that provides the required T_1 and T_2 cluster amplitudes results by setting $T_i = 0$ for $i > 2$ in Eq. (5.74) (the CC with singles and doubles (CCSD) method [45]). A small, but often important, T_3 component is usually accounted for perturbatively via the CCSD(T) method [46, 47], which is often referred to as the “gold standard” of quantum chemistry, since it provides very accurate and reliable results. Unfortunately, this is no longer the case in the presence of quasidegeneracy when handling strongly-correlated systems or when breaking chemical bonds as in generating potential energy curves or surfaces. This can to some extent be avoided by employing one of the renormalized versions of CCSD(T) [48] but, in general, requires multireference-type approaches (see below).

In order to compute the excitation, ionization, or electron attachment energies one employs the *equation-of-motion* (EOM) and the *linear-response* formalisms relying on the generalized cluster ansatz [49] $|\Psi\rangle = R e^T |\Phi\rangle$, where R yields an appropriate zero (or first)-order wave function of the open-shell system considered when acting on $|\Phi\rangle$. In general, this leads to a non-Hermitian eigenvalue problem, which requires a computation of the right and left eigenvectors [10]. These developments also enabled calculation of other properties than the energy (dipole and quadrupole moments, polarizabilities, etc.), [10, 18, 34–36]. Here, we should also mention a possibility of using the cluster ansatz based on the *unitary group approach* (UGA) [50, 51] (Sect. 4.3.6).

At this stage it is important to recall that the standard SR MBPT and CC approaches pertain to nondegenerate, lowest-lying closed-shell states of a given symmetry species. Although the CC methods are often used even for open-shell states by relying on the unrestricted HF (UHF) reference (of the different-orbitals-for-different-spins (DODS) type),

a proper description of such states requires a multireference (MR) generalization based on the *effective Hamiltonian* formalism [7, 18, 36, 52–54]. Unfortunately, such a generalization is not unambiguous. The two viable formulations, the so-called *valence universal* (VU) [7, 53] and *state universal* (SU) [54] MR CC methods have enjoyed continued following (see [55] for recent developments), yet are computationally demanding and often plagued with the intruder state and other problems [17, 52]. For these reasons, no general-purpose codes have yet been developed, and only a few actual applications have been carried out [18, 36] (see, however, the recently formulated SU CC approach for *general model spaces* [56–59]).

In view of the ambiguity, complexity, and computational demands of genuine MR CC approaches it is tempting to design SR CC-type methods that are capable of accommodating both the nondynamic and dynamic correlation effects. This may be achieved by exploiting the complementarity of perturbative (i.e., CC) and variational (CI, CAS SCF, etc.)-type approaches, leading to the so-called *externally corrected* (ec) ecCCSD or ecCCSD(T) methods (for an overview, see [44]; see also [60, 61] and the so-called *state selective* or *state specific* (SS) approaches [62]). The basic idea here is to extract a suitable approximation $T_3^{(0)}$ and $T_4^{(0)}$ of, respectively, the T_3 and T_4 clusters from some independent source and account for them in the CCD or CCSD equations, i.e.,

$$\langle \Phi_i | H_N \left(T_2 + \frac{1}{2} T_2^2 + T_3^{(0)} + T_4^{(0)} \right) | \Phi \rangle_C = 0, \quad (5.86)$$

thus achieving a more meaningful decoupling of the CC chain by simply evaluating the $T_3^{(0)}$ and $T_4^{(0)}$ -dependent terms and adding them to the absolute term. Note that using the exact (i.e., *full configuration interaction* (FCI)) T_3 and T_4 amplitudes the ecCCSD equations will recover the exact FCI energy. The most promising version of such an ecCCSD approach employs the three- and four-body amplitudes obtained by a cluster analysis of a small MR CI wave function and is referred to as the reduced MR CCSD (RMR CCSD) method [63–65] (see [44] for a list of numerous applications). Very recently, the required approximate three and four-body clusters were extracted by relying on the (G)UGA based ((graphical) UGA) (see [66–68] for recent reviews) FCI quantum Monte Carlo (FCI-QMC) or *i*-FCI-QMC codes [69–71] yielding encouraging results [61, 72–74]. Very recently, Chan et al. [75] exploited for the same purpose the density matrix renormalization group (DMRG) approach [76–78] in the ecCCSD formalism [44].

The same goal, which simultaneously leads to more efficient SR CC formalisms, may also be achieved via an effective implicit account of higher-order clusters by relying on the role of the EPV (exclusion principle violating) diagrams that are separable over the hole lines, leading to the so-called *internally corrected* (ic) methods, such as approx-

imate coupled pair (ACP-D45) approach, approximate CC with doubles (ACCD) or with approximate quads (ACPQ) methods (see [44] for relevant references). Very recently, similar ideas to the icCCSD approaches [44] were exploited by Kats et al. [79–81] in the so-called *distinguished cluster* (DC) approximations, such as DC with doubles (DCD), DC with singles and doubles (DCSD) and DCSD corrected for triples (DCSD(T)) methods, leading to numerous exploitations in actual systems [82–85], including transcorrelated CC methods [86].

A very recent development [87] exploits the quantum Monte Carlo (MC) formalism in solving the CC equations, resulting in a stochastic CCMC method [87, 88], which was also extended to the *equation of motion* CC (EOMCC) type approaches [89] enabling handling the excited states energetics. This way of solving the CC equations should allow applications to larger systems than do the currently available standard codes.

Finally, note that the CC approach has also been used to handle bosonic-type problems of the vibrational structure in molecular spectra and, generally, multimode dynamics [90].

5.4 Time-Dependent Perturbation Theory

5.4.1 Evolution Operator PT Expansion

By introducing the *evolution operator* $U(t, t_0)$

$$|\Psi(t)\rangle = U(t, t_0)|\Psi(t_0)\rangle, \quad (5.87)$$

the time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} |\Psi(t)\rangle = H |\Psi(t)\rangle \quad (5.88)$$

becomes

$$i\hbar \frac{\partial}{\partial t} U(t, t_0) = H U(t, t_0). \quad (5.89)$$

Clearly,

$$\begin{aligned} U(t_0, t_0) &= 1, \\ U(t, t_0) &= U(t, t')U(t', t_0), \\ U(t, t_0)^{-1} &= U(t_0, t) = U^\dagger(t, t_0). \end{aligned} \quad (5.90)$$

If the Hamiltonian is time-independent, then

$$U(t, t_0) = \exp\left[-\frac{i}{\hbar} H(t - t_0)\right]. \quad (5.91)$$

In the *interaction picture* (subscript I),

$$|\Psi(t)\rangle_I = \exp\left(\frac{i}{\hbar} H_0 t\right) |\Psi(t)\rangle, \quad (5.92)$$

where now

$$H = H_0 + V, \quad (5.93)$$

the Schrödinger equation becomes

$$i\hbar \frac{\partial}{\partial t} |\Psi(t)\rangle_I = V(t)_I |\Psi(t)\rangle_I. \quad (5.94)$$

This is known as the *Tomonaga–Schwinger equation* [91]. Analogously, the evolution operator in this picture (we drop the subscript I from now on) satisfies

$$i\hbar \frac{\partial}{\partial t} U(t, t_0) = V(t)U(t, t_0), \quad (5.95)$$

with the initial condition $U(t_0, t_0) = 1$. This differential equation is equivalent to an integral equation

$$U(t, t_0) = 1 - \frac{i}{\hbar} \int_{t_0}^t V(t_1)U(t_1, t_0) dt_1. \quad (5.96)$$

Iterating we get [92, 93]

$$\begin{aligned} U(t, t_0) &= \sum_{n=0}^{\infty} \left(-\frac{i}{\hbar}\right)^n \\ &\quad \times \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \int_{t_0}^{t_{n-1}} dt_n V(t_1)V(t_2) \cdots V(t_n) \\ &= \sum_{n=0}^{\infty} \frac{(-i/\hbar)^n}{n!} \\ &\quad \times \int_{t_0}^t dt_1 \cdots \int_{t_0}^t dt_n T[V(t_1) \cdots V(t_n)], \end{aligned} \quad (5.97)$$

where $T[\cdots]$ designates the time-ordering or chronological operator.

5.4.2 Gell-Mann and Low Formula

For a time-independent perturbation, one introduces the so-called *adiabatic switching* by writing

$$H_\alpha(t) = H_0 + \lambda e^{-\alpha|t|} V, \quad \alpha > 0, \quad (5.98)$$

so that $H_\alpha(t \rightarrow \pm\infty) = H_0$ and $H_\alpha(t \rightarrow 0) = H = H_0 + \lambda V$. Then

$$|\Psi(t)\rangle_I = U_\alpha(t, -\infty|\lambda)|\Phi_0\rangle, \quad (5.99)$$

with $U_\alpha(t, -\infty|\lambda)$ obtained with $V_\alpha(t) = \lambda e^{-\alpha|t|} V$ (all in the interaction picture). The desired energy is then given by the Gell-Mann and Low formula [94]

$$\Delta E = \lim_{\alpha \rightarrow 0^+} i\hbar \alpha \lambda \frac{\partial}{\partial \lambda} \ln \langle \Phi_0 | U_\alpha(0, -\infty|\lambda) | \Phi_0 \rangle, \quad (5.100a)$$

or

$$\Delta E = \frac{1}{2} \lim_{\alpha \rightarrow 0^+} i\hbar \alpha \lambda \frac{\partial}{\partial \lambda} \ln \langle \Phi_0 | U_\alpha(\infty, -\infty|\lambda) | \Phi_0 \rangle, \quad (5.100b)$$

which result from the asymmetric energy formula Eq. (5.27). One can similarly obtain the perturbation expansion for the one or two-particle Green's functions, e.g.,

$$G_{\mu\nu}(t, t') = \lim_{\alpha \rightarrow 0^+} \frac{\langle T \{ a_\mu(t) a_\nu^\dagger(t') U_\alpha(\infty, -\infty | \lambda) \} \rangle}{\langle U_\alpha(\infty, -\infty | \lambda) \rangle}, \quad (5.101)$$

with the operators in the interaction representation and the expectation values in the noninteracting ground state $|\Phi_0\rangle$. Analogous expressions result for $G(\mathbf{r}t, \mathbf{r}'t')$, etc., when the creation and annihilation operators are replaced by the corresponding field operators.

5.4.3 Potential Scattering and Quantum Dynamics

The Schrödinger equation for a free particle of energy $E = \hbar^2 k^2 / 2m$, moving in the potential $V(\mathbf{r})$,

$$\begin{aligned} (\nabla^2 + k^2)\psi(k, \mathbf{r}) &= v(\mathbf{r})\psi(k, \mathbf{r}), \\ v(\mathbf{r}) &= (2m/\hbar^2)V(\mathbf{r}), \end{aligned} \quad (5.102)$$

has the formal solution

$$\psi(k, \mathbf{r}) = \Phi(k, \mathbf{r}) + \int G_0(k, \mathbf{r}, \mathbf{r}') v(\mathbf{r}') \psi(k, \mathbf{r}') d\mathbf{r}', \quad (5.103)$$

where $\Phi(k, \mathbf{r})$ is a solution of the homogeneous equation [$v(\mathbf{r}) \equiv 0$], and $G_0(k, \mathbf{r}, \mathbf{r}')$ is a classical Green's function

$$(\nabla^2 + k^2)G_0(k, \mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'). \quad (5.104)$$

For an in-going plane wave $\Phi(k, \mathbf{r}) \equiv \Phi_{\mathbf{k}_i}(\mathbf{r}) = (2\pi)^{3/2} \exp(i\mathbf{k}_i \cdot \mathbf{r})$ with the initial wave vector \mathbf{k}_i and appropriate asymptotic boundary conditions (outgoing spherical wave with positive phase velocity), when $G_0(k, \mathbf{r}, \mathbf{r}') \equiv G_0^{(+)}(|\mathbf{r} - \mathbf{r}'|) = -(4\pi|\mathbf{r} - \mathbf{r}'|)^{-1} e^{ik|\mathbf{r} - \mathbf{r}'|}$, Eq. (5.103) is referred to as the *Lippmann–Schwinger equation* [95]. It can be equivalently transformed into the integral equation for Green's function

$$\begin{aligned} G^{(+)}(\mathbf{r}, \mathbf{r}') &= G_0^{(+)}(\mathbf{r}, \mathbf{r}') + \int G_0^{(+)}(\mathbf{r}, \mathbf{r}'') v(\mathbf{r}'') \\ &\times G^{(+)}(\mathbf{r}'', \mathbf{r}') d\mathbf{r}'', \end{aligned} \quad (5.105)$$

representing a special case of the Dyson equation.

In the time-dependent case, considering the scattering of a spinless massive particle by a time-dependent potential $V(\mathbf{r}, t)$, we get similarly

$$\begin{aligned} \psi(\mathbf{r}, t) &= \Phi(\mathbf{r}, t) \\ &+ \int G_0(\mathbf{r}, \mathbf{r}'; t, t') V(\mathbf{r}', t') \psi(\mathbf{r}', t') d\mathbf{r}' dt', \end{aligned} \quad (5.106)$$

where the zero-order time-dependent Green's function now satisfies the equation

$$\left(i\hbar \frac{\partial}{\partial t} - H_0 \right) G_0(\mathbf{r}, \mathbf{r}'; t, t') = \delta(\mathbf{r} - \mathbf{r}') \delta(t - t'). \quad (5.107)$$

Again, for causal propagation one chooses the *time-retarded* or *causal* Green's function or propagator $G_0^{(+)}(\mathbf{r}, \mathbf{r}'; t, t')$.

5.4.4 Born Series

Iteration of Eq. (5.106) gives the *Born sequence*

$$\begin{aligned} \psi_0(\mathbf{r}, t) &= \Phi(\mathbf{r}, t), \\ \psi_1(\mathbf{r}, t) &= \Phi(\mathbf{r}, t) + \int G_0^{(+)}(\mathbf{r}, \mathbf{r}'; t, t') \\ &\times V(\mathbf{r}', t') \Phi(\mathbf{r}', t') d\mathbf{r}' dt', \end{aligned} \quad (5.108a)$$

$$\begin{aligned} \psi_2(\mathbf{r}, t) &= \Phi(\mathbf{r}, t) + \int G_0^{(+)}(\mathbf{r}, \mathbf{r}'; t, t') \\ &\times V(\mathbf{r}', t') \psi_1(\mathbf{r}', t') d\mathbf{r}' dt', \end{aligned} \quad (5.108b)$$

and, generally

$$\begin{aligned} \psi_n(\mathbf{r}, t) &= \Phi(\mathbf{r}, t) + \int G_0^{(+)}(\mathbf{r}, \mathbf{r}'; t, t') \\ &\times V(\mathbf{r}', t') \psi_{n-1}(\mathbf{r}', t') d\mathbf{r}' dt'. \end{aligned} \quad (5.109)$$

Summing individual contributions gives the *Born series* for $\psi(\mathbf{r}, t) \equiv \psi^{(+)}(\mathbf{r}, t)$,

$$\psi(\mathbf{r}, t) = \sum_{n=0}^{\infty} \chi_n(\mathbf{r}, t), \quad (5.110)$$

where

$$\begin{aligned} \chi_0(\mathbf{r}, t) &= \Phi(\mathbf{r}, t), \\ \chi_n(\mathbf{r}, t) &= \int \mathcal{G}_n(\mathbf{r}, \mathbf{r}'; t, t') \Phi(\mathbf{r}', t') d\mathbf{r}' dt', \end{aligned} \quad (5.111)$$

with

$$\begin{aligned} \mathcal{G}_n(\mathbf{r}, \mathbf{r}'; t, t') &= \int \mathcal{G}_1(\mathbf{r}, \mathbf{r}''; t, t'') \\ &\times \mathcal{G}_{n-1}(\mathbf{r}'', \mathbf{r}'; t'', t') d\mathbf{r}'' dt'', \quad (n > 1) \\ \mathcal{G}_1(\mathbf{r}, \mathbf{r}'; t, t') &= G_0^{(+)}(\mathbf{r}, \mathbf{r}'; t, t') V(\mathbf{r}', t'). \end{aligned} \quad (5.112)$$

In a similar way we obtain the Born series for the scattering amplitudes or transition matrix elements.

5.4.5 Variation of Constants Method

An alternative way of formulating the time-dependent PT is the method of variation of the constants [96, 97]. Start again with the time-dependent Schrödinger equation (5.88) with $H = H_0 + V$ and assume that H_0 is time-independent, while V is a time-dependent perturbation. Designating the eigenvalues and eigenstates of H_0 by ε_i and $|\Phi_i\rangle$, respectively (Eq. (5.48)), the general solution of the unperturbed time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} |\Psi_0\rangle = H_0 |\Psi_0\rangle \quad (5.113)$$

has the form

$$|\Psi_0\rangle = \sum_j c_j |\Phi_j\rangle \exp\left(-\frac{i}{\hbar} \varepsilon_j t\right), \quad (5.114)$$

with c_j representing arbitrary constants, and the sum indicating both the summation over the discrete part and the integration over the continuum part of the spectrum of H_0 .

In the spirit of the general variation of constants procedure, write the unknown perturbed wave function $|\Psi(t)\rangle$, Eq. (5.88), in the form

$$|\Psi(t)\rangle = \sum_j C_j(t) |\Phi_j\rangle \exp\left(-\frac{i}{\hbar} \varepsilon_j t\right), \quad (5.115)$$

where the $C_j(t)$ are now functions of time. Substituting this ansatz into the time-dependent Schrödinger equation (5.88) gives

$$\dot{C}_j(t) = (i\hbar)^{-1} \sum_k C_k(t) V_{jk} \exp[(i/\hbar) \Delta_{jk} t], \quad (5.116)$$

where

$$\Delta_{jk} = \varepsilon_j - \varepsilon_k, \quad V_{jk} = \langle \Phi_j | V | \Phi_k \rangle. \quad (5.117)$$

Introducing again the “small” parameter λ by writing the Hamiltonian H in the form

$$H = H_0 + \lambda V(t) \quad (5.118)$$

and expanding the “coefficients” $C_j(t)$ in powers of λ ,

$$C_j \equiv C_j(t) = \sum_{k=0}^{\infty} C_j^{(k)}(t) \lambda^k, \quad (5.119)$$

gives the system of first-order differential equations

$$\begin{aligned} \dot{C}_j^{(n+1)} &= (i\hbar)^{-1} \sum_k C_k^{(n)} V_{jk} \exp[(i/\hbar) \Delta_{jk} t], \\ n &= 0, 1, 2, \dots, \end{aligned} \quad (5.120)$$

with the initial condition $\dot{C}_j^{(0)} = 0$, which implies that $C_j^{(0)}$ are time independent, so that $C_j^{(0)} = c_j$, obtaining Eq. (5.114) in the zeroth order. The system Eq. (5.120) can be integrated to any prescribed order. For example, if the system is initially in a stationary state $|\Phi_i\rangle$, then set

$$C_j^{(0)} = \begin{cases} \delta_{ji} & \text{for discrete states,} \\ \delta(j-i) & \text{for continuous states,} \end{cases} \quad (5.121)$$

so that

$$C_{j(i)}^{(1)}(t) = (i\hbar)^{-1} \int_{-\infty}^t V_{ji} \exp[(i/\hbar) \Delta_{ji} t'] dt', \quad (5.122)$$

assuming $C_{j(i)}^{(1)}(-\infty) = 0$. Clearly, $|C_{j(i)}^{(1)}(t)|^2$ gives the first-order transition probability for the transition from the initial state $|\Phi_i\rangle$ to a particular state $|\Phi_j\rangle$. These in turn will yield the first-order differential cross sections [98].

Abstract

In second quantization, the characteristic properties of eigenfunctions are transferred to operators. This approach has the advantage of treating the atomic shell as the basic unit, as opposed to the electron configuration. The creation and annihilation operators allow one to move from configuration to configuration, exposing an intrinsic shell structure. The introduction of coefficients of fractional parentage (cfp) then allows the calculation of the matrix elements of an operator in one configuration to be expressed in terms of those of the same operator in another configuration; hence the matrix elements of an operator

in all configurations may be determined from the knowledge of its matrix elements in but one. This can be viewed as an extension of the usual Wigner-Eckart theorem. The basic concepts of quasispin and quasiparticle are also introduced within this context.

Keywords

second quantization · intrinsic shell structure · coefficients of fractional parentage · Wigner–Eckart theorem · quasispin

6.1 Basic Properties

6.1.1 Definitions

The creation operator a_{ξ}^{\dagger} creates the quantum state ξ . The annihilation (or destruction) operator a_{η} annihilates the quantum state η . The vacuum (or reference) state $|0\rangle$ satisfies the equation

$$a_{\eta}|0\rangle = 0. \quad (6.1)$$

Bosons satisfy the commutation relations

$$[a_{\xi}^{\dagger}, a_{\eta}^{\dagger}] = 0, \quad (6.2)$$

$$[a_{\xi}, a_{\eta}] = 0, \quad (6.3)$$

$$[a_{\xi}, a_{\eta}^{\dagger}] = \delta(\xi, \eta), \quad (6.4)$$

where $[A, B] \equiv AB - BA$. Fermions satisfy the anticommutation relations

$$[a_{\xi}^{\dagger}, a_{\eta}^{\dagger}]_{+} = 0, \quad (6.5)$$

$$[a_{\xi}, a_{\eta}]_{+} = 0, \quad (6.6)$$

$$[a_{\xi}, a_{\eta}^{\dagger}]_{+} = \delta(\xi, \eta), \quad (6.7)$$

where $[A, B]_{+} \equiv AB + BA$.

6.1.2 Representation of States

For an electron in an atom, characterized by the quantum number quartet $(n \ell m_s m_\ell)$, the identification $\xi \equiv (n \ell m_s m_\ell)$ for fermions is made. For normalized Slater determinants $\{\alpha\beta \dots v\}$ characterized by the electron states α, β, \dots, v , the equivalences

$$a_\alpha^\dagger a_\beta^\dagger \dots a_v^\dagger |0\rangle \equiv \{\alpha\beta \dots v\}, \quad (6.8)$$

$$\langle 0|a_v \dots a_\beta a_\alpha \equiv \{\alpha\beta \dots v\}^* \quad (6.9)$$

are valid, where the asterisk denotes the complex conjugate.

For a normalized boson state $\{\dots\}$ in which the label ξ appears N_ξ times, the additional factor

$$[N_\alpha! N_\beta! \dots N_v!]^{-\frac{1}{2}} \quad (6.10)$$

must be included on the left-hand sides of the equivalences Eqs. (6.8) and (6.9).

6.1.3 Representation of Operators

For an operator F , consisting of the sum of operators f_i acting on the single electron i ,

$$F \equiv \sum_{\xi, \eta} a_\xi^\dagger \langle \xi | f | \eta \rangle a_\eta. \quad (6.11)$$

For an operator G , consisting of the sum of operators g_{ij} acting on the pair of electrons i and j ,

$$G \equiv \frac{1}{2} \sum_{\xi, \eta, \zeta, \lambda} a_\xi^\dagger a_\eta^\dagger \langle \xi_1 \eta_2 | g_{12} | \zeta_1 \lambda_2 \rangle a_\lambda a_\zeta. \quad (6.12)$$

For an N -particle system $|\Psi\rangle$,

$$\sum_{\xi} a_\xi^\dagger a_\xi |\Psi\rangle = N |\Psi\rangle. \quad (6.13)$$

The representations of single-particle and two-particle operators for bosons are identical to those given above for fermions [1].

6.2 Tensors

6.2.1 Construction

If the description ξ for a single fermion or boson state includes an angular momentum quantum number t and the corresponding magnetic quantum number m_t , then the $2t + 1$ components of a creation operator a_σ^\dagger , where $\sigma \equiv (t, m_t)$ and

$-t \leq m_t \leq t$, satisfy the commutation relations of *Racah* [2] for an irreducible spherical tensor of rank t with respect to the total angular momentum \mathbf{T} , given by

$$\mathbf{T} = \sum_{\xi} a_\xi^\dagger \langle \xi | \mathbf{T} | \eta \rangle a_\eta. \quad (6.14)$$

That is, with the phase conventions of *Condon and Shortley* [3],

$$[T_z, a_\sigma^\dagger] = m_t a_\sigma^\dagger, \quad (6.15)$$

$$[T_x \pm iT_y, a_\sigma^\dagger] = [t(t+1) - m_t(m_t \pm 1)]^{\frac{1}{2}} a_\tau^\dagger, \quad (6.16)$$

where $\tau \equiv (t, m_t \pm 1)$.

A spherical tensor \mathbf{a} constructed from annihilation operators possesses the components \tilde{a}_σ , which satisfy

$$\tilde{a}_\sigma = (-1)^p a_\zeta, \quad (6.17)$$

with $p = t - m_t$ and $\zeta \equiv (t, -m_t)$.

The $4\ell + 2$ components of the creation operator for an electron in the atomic ℓ shell form a double tensor of rank $\frac{1}{2}$ with respect to the total spin \mathbf{S} , and rank ℓ with respect to the total angular momentum \mathbf{L} .

6.2.2 Coupled Forms

Tensors formed from annihilation and creation operators can be coupled by means of the usual rules of angular momentum theory [4]. The double tensor defined for electrons in the ℓ shell by

$$\mathbf{W}^{(\kappa k)} = -(\mathbf{a}^\dagger \mathbf{a})^{(\kappa k)}, \quad (6.18)$$

possesses a rank κ with respect to \mathbf{S} , and rank k with respect to \mathbf{L} . Its reduced matrix element, defined here as in (5.4.1) of *Edmonds* [4], for a single electron in both the spin and orbital spaces, is given by

$$(s \ell || \mathbf{W}^{(\kappa k)} || s \ell) = [(2\kappa + 1)(2k + 1)]^{\frac{1}{2}}. \quad (6.19)$$

The connections to tensors whose matrix elements have been tabulated [5, 6] are

$$\mathbf{W}^{(0k)} = [(2k + 1)/2]^{\frac{1}{2}} \mathbf{U}^{(k)}, \quad (6.20)$$

$$\mathbf{W}^{(1k)} = [2(2k + 1)]^{\frac{1}{2}} \mathbf{V}^{(k1)}. \quad (6.21)$$

For terms with common spin S , say ψ and ψ' ,

$$\begin{aligned} & (\psi || \mathbf{W}^{(0k)} || \psi') \\ &= [(2S + 1)(2k + 1)/2]^{\frac{1}{2}} (\psi || \mathbf{U}^{(k)} || \psi'). \end{aligned} \quad (6.22)$$

This result is obtained because the ranks assigned to the tensors imply that $\mathbf{W}^{(0k)}$ is to be reduced with respect to both

the spin \mathbf{S} and the orbit \mathbf{L} , while $U^{(k)}$ is to be reduced only with respect to \mathbf{L} .

The following relations hold for electrons with azimuthal quantum numbers ℓ [7]:

$$\mathbf{S} = [(2\ell + 1)/2]^{\frac{1}{2}} \mathbf{W}^{(10)}, \quad (6.23)$$

$$\mathbf{L} = [2\ell(\ell + 1)(2\ell + 1)/3]^{\frac{1}{2}} \mathbf{W}^{(01)}, \quad (6.24)$$

$$\sum_i (s_i \mathbf{C}_i^{(2)})^{(1)} = - \left(\frac{\ell(\ell + 1)(2\ell + 1)}{10(2\ell - 1)(2\ell + 3)} \right)^{\frac{1}{2}} \mathbf{W}^{(12)1}, \quad (6.25)$$

$$\sum_i (s_i \cdot \ell_i) = -[\ell(\ell + 1)(2\ell + 1)/2] \mathbf{W}^{(11)0}, \quad (6.26)$$

where the tensor \mathbf{C}^k of Racah [2] is related to the spherical harmonics by

$$\mathbf{C}_q^{(k)} = [4\pi/(2k + 1)]^{\frac{1}{2}} Y_{kq}, \quad (6.27)$$

and where the tensors of the type $\mathbf{W}^{(\kappa k)K}$ indicate that the spin and orbital ranks are coupled to a resultant K .

6.2.3 Coefficients of Fractional Parentage

Let ψ and $\bar{\psi}$ denote terms of ℓ^N and ℓ^{N-1} characterized by (S, L) and (\bar{S}, \bar{L}) . The coefficients of fractional parentage (cfp) $(\psi \{ \bar{\psi})$ of Racah [8] allow one to calculate an antisymmetrized function ψ by vector-coupling $\bar{\psi}$ to the spin and orbit of the N th electron:

$$|\psi\rangle = \sum_{\bar{\psi}} |\bar{\psi}, {}^2\ell, SL\rangle (\bar{\psi} \{ \psi), \quad (6.28)$$

where the sum over $\bar{\psi}$ includes \bar{S}, \bar{L} , and any other quantum numbers necessary to define the spectroscopic terms of ℓ^{N-1} . The cfp's are given by

$$(\psi || a^\dagger || \bar{\psi}) = (-1)^N [N(2S + 1)(2L + 1)]^{\frac{1}{2}} (\psi \{ \bar{\psi}), \quad (6.29)$$

$$(\bar{\psi} || a || \psi) = (-1)^g [N(2S + 1)(2L + 1)]^{\frac{1}{2}} (\bar{\psi} \{ \psi), \quad (6.30)$$

where $g = N + \bar{S} + \bar{L} - s - S - \ell - L$. A tabulation for the p, d, and f shells has been given by Nielson and Koster [5].

Two-electron cfp are given by

$$(\psi || (a^\dagger a^\dagger)^{(\kappa k)} || \bar{\psi}) = [N(N - 1)(2S + 1)(2L + 1)]^{\frac{1}{2}} \times (\psi \{ \bar{\psi}, \ell^2(\kappa k)), \quad (6.31)$$

where $\bar{\psi}$ denotes a term of ℓ^{N-2} , and the symbols κ and k stand for the S and the L of a term of ℓ^2 . A tabulation for the p, d, and f shells has been given by Donlan [9]. An extension to all multielectron cfp has been carried out by Velkov [10].

If, through successive applications of the two-particle operators $(\mathbf{a}\mathbf{a})^{(00)}$, a state of ℓ^N can be reduced to ℓ^v , but no further, then v is the seniority number of Racah [8].

If the ranks s and ℓ of \mathbf{a}^\dagger are coupled to \bar{S} and \bar{L} of $\bar{\psi}$, the term

$$(\mathbf{a}^\dagger | \bar{\psi})^{(SL)} \quad (6.32)$$

either vanishes, or is a term of ℓ^N characterized by S and L . Such a term is said to possess the godparent $\bar{\psi}$. Redmond [11] has used the notion of godparents to generate an explicit formula for the single particle cfp [7].

6.3 Quasispin

6.3.1 Fermions

For electrons, the components $Q_\pm (\equiv Q_x \pm iQ_y)$ and Q_z of the quasispin \mathbf{Q} are defined by [7, 12]

$$Q_+ = [(2\ell + 1)/2]^{\frac{1}{2}} (\mathbf{a}^\dagger \mathbf{a}^\dagger)^{(00)}, \quad (6.33)$$

$$Q_- = -[(2\ell + 1)/2]^{\frac{1}{2}} (\mathbf{a}\mathbf{a})^{(00)}, \quad (6.34)$$

$$Q_z = -[(2\ell + 1)/8]^{\frac{1}{2}} [(\mathbf{a}^\dagger \mathbf{a})^{(00)} + (\mathbf{a}\mathbf{a}^\dagger)^{(00)}]. \quad (6.35)$$

The term quasispin comes from the fact that the components of \mathbf{Q} satisfy the commutation relations of an angular momentum vector. The eigenvalues M_Q of Q_z , for a state of ℓ^N , are given by

$$M_Q = -(2\ell + 1 - N)/2. \quad (6.36)$$

The shift operators Q_+ and Q_- connect states of the ℓ shell possessing the same value of the seniority v of Racah [8]. A string of such connected states defines the extrema of M_Q , from which it follows that

$$Q = (2\ell + 1 - v)/2. \quad (6.37)$$

Rudzikas has placed special emphasis on quasispin in his reworking of atomic shell theory, and he has also introduced isospin to embrace electrons differing in their principal quantum numbers n [13]. Concise tables of one-electron cfp with their quasispin dependence factored out have been given [14], as have the algebraic dependences on v and S of two-electron cfp [15].

6.3.2 Bosons

For real vibrational modes created by $a_v^\dagger (v = 1, 2, \dots, d)$, the analogs of Eqs. (6.33)–(6.35) are

$$P_+ = -\frac{1}{2} \sum_v a_v^\dagger a_v^\dagger, \quad (6.38)$$

$$P_- = \frac{1}{2} \sum_v a_v a_v, \quad (6.39)$$

$$P_z = \frac{1}{4} \sum_v (a_v^\dagger a_v + a_v a_v^\dagger), \quad (6.40)$$

and \mathbf{P} is an angular momentum vector [16]. The eigenvalues M_P for an n -boson state are given by

$$M_P = (2n + d)/4, \quad (6.41)$$

and can therefore be quarter-integral. Successive application of the operator P_+ to a state $|n_0\rangle$, for which $P_-|n_0\rangle = 0$, generates an infinite ladder of states characterized by

$$P = (2n + d - 4)/4. \quad (6.42)$$

6.3.3 Triple Tensors

The creation and annihilation operators a_ξ^\dagger and a_ξ for a given state ξ can be regarded as the two components of a tensor of rank $\frac{1}{2}$ with respect to quasispin (either \mathbf{Q} or \mathbf{P}). For electrons, this leads to triple tensors $\mathbf{a}^{(qs\ell)}$ (for which $q = s = \frac{1}{2}$) satisfying

$$\begin{aligned} a_\lambda^{(qs\ell)} a_\mu^{(qs\ell)} + a_\mu^{(qs\ell)} a_\lambda^{(qs\ell)} \\ = (-1)^{x+1} \delta(m_q, -m'_q) \delta(m_s, -m'_s) \delta(m_\ell, -m'_\ell), \end{aligned} \quad (6.43)$$

where $\lambda \equiv (m_q m_s m_\ell)$, $\mu \equiv (m'_q m'_s m'_\ell)$, and $x = q + s + \ell + m_q + m_s + m_\ell$. In terms of the coupled tensor

$$\mathbf{X}^{(K\kappa k)} = (\mathbf{a}^{(qs\ell)} \mathbf{a}^{(qs\ell)})^{(K\kappa k)}, \quad (6.44)$$

the angular momenta \mathbf{Q} , \mathbf{S} , and \mathbf{L} are given by

$$\mathbf{Q} = -[(2\ell + 1)/4]^{\frac{1}{2}} \mathbf{X}^{(100)}, \quad (6.45)$$

$$\mathbf{S} = -[(2\ell + 1)/4]^{\frac{1}{2}} \mathbf{X}^{(010)}, \quad (6.46)$$

$$\mathbf{L} = -[\ell(\ell + 1)(2\ell + 1)/3]^{\frac{1}{2}} \mathbf{X}^{(001)}. \quad (6.47)$$

Furthermore, the components of $\mathbf{X}^{(K\kappa k)}$ for which $M_K = 0$ are identical to the corresponding components of $2^{\frac{1}{2}} (\mathbf{a}^\dagger \mathbf{a})^{(\kappa k)}$ when $K + \kappa + k$ is odd; and

$$\mathbf{X}^{(K\kappa k)} = -(2\ell + 1)^{\frac{1}{2}} \delta(K, 0) \delta(\kappa, 0) \delta(k, 0) \quad (6.48)$$

when $K + \kappa + k$ is even.

6.3.4 Conjugation

Creation and annihilation operators can be interchanged by the operation of the conjugation operator C [7, 17]. For electrons in the atomic ℓ shell,

$$C a_\xi^{(qs\ell)} C^{-1} = (-1)^{q-m_q} a_\eta^{(qs\ell)}, \quad (6.49)$$

where $\xi \equiv (m_q m_s m_\ell)$ and $\eta \equiv ((-m_q) m_s m_\ell)$. In terms of the tensors \mathbf{a}^\dagger and \mathbf{a} ,

$$C \mathbf{a}^\dagger C^{-1} = \mathbf{a}, \quad C \mathbf{a} C^{-1} = -\mathbf{a}^\dagger. \quad (6.50)$$

Furthermore,

$$C X_\lambda^{(K\kappa k)} C^{-1} = (-1)^{K-M_K} X_\mu^{(K\kappa k)}, \quad (6.51)$$

where $\lambda \equiv (M_K M_\kappa M_k)$ and $\mu \equiv [(-M_K) M_\kappa M_k]$, and

$$C |QM_Q\rangle = (-1)^{Q-M_Q} |Q - M_Q\rangle. \quad (6.52)$$

Thus, from Eq. (6.36), the action of C takes N into $4\ell + 2 - N$; that is, C interchanges electrons and holes. When the case $\kappa = k = 0$ is excluded, application of Eqs. (6.51) and (6.52) yields

$$\begin{aligned} (\ell^N \psi || W^{(\kappa k)} || \ell^N \psi') \\ = (-1)^y (\ell^{4\ell+2-N} \psi || W^{(\kappa k)} || \ell^{4\ell+2-N} \psi'), \end{aligned} \quad (6.53)$$

where $y = \kappa + k + \frac{1}{2}(v' - v) + 1$, and where the seniorities v and v' are implied by ψ and ψ' . A similar application to reduced matrix elements of \mathbf{a}^\dagger and \mathbf{a} gives the following relation between cfp:

$$\begin{aligned} (\ell^{N+1} \psi \{ | \ell^N \psi') \\ = (-1)^z (\ell^{4\ell+1-N} \psi \{ | \ell^{4\ell+2-N} \psi') \\ \times \left(\frac{(4\ell + 2 - N)(2S' + 1)(2L' + 1)}{(N + 1)(2S + 1)(2L + 1)} \right)^{\frac{1}{2}}, \end{aligned} \quad (6.54)$$

where $z = S + S' - s + L + L' - \ell + \frac{1}{2}(v + v' - 1)$. The phases y and z stem from the conventions of angular momentum theory, which enter via quasispin. *Racah* [2, 8] did not use this concept, and his phase choices are slightly different from the ones above.

For a Cartesian component Q_u of the quasispin \mathbf{Q} ,

$$C Q_u C^{-1} = -Q_u. \quad (6.55)$$

Thus, C is the analog of the time-reversal operator T , for which

$$T L_u T^{-1} = -L_u, \quad (6.56)$$

$$T S_u T^{-1} = -S_u. \quad (6.57)$$

Both C and T are antiunitary; thus,

$$C i C^{-1} = -i. \quad (6.58)$$

6.3.5 Dependence on Electron Number

Application of the Wigner–Eckart theorem to matrix elements whose component parts have well-defined quasispin

ranks yields the dependence of the matrix elements on the electron number N [18, 19]. For $\kappa + k$ even and nonzero, the quasispin rank of $W^{(\kappa k)}$ is 1, and

$$\begin{aligned} & (\ell^N \psi || W^{(\kappa k)} || \ell^N \psi') \\ &= \frac{(2\ell + 1 - N)}{(2\ell + 1 - v)} (\ell^v \psi || W^{(\kappa k)} || \ell^v \psi'). \end{aligned} \quad (6.59)$$

For $\kappa + k$ odd, $W^{(\kappa k)}$ is necessarily a quasispin scalar, and the matrix elements are diagonal with respect to the seniority and independent of N . These properties were first stated in Eqs. (69) and (70) of [8].

Application of these ideas to single-electron cfp yields, for states ψ and $\bar{\psi}$ with seniorities v and $v + 1$, respectively,

$$\begin{aligned} & (\ell^N \psi || \ell^{N-1} \bar{\psi}) \\ &= [(N - v)(v + 2)/2N]^{\frac{1}{2}} (\ell^{v+2} \psi || \ell^{v+1} \bar{\psi}). \end{aligned} \quad (6.60)$$

6.3.6 The Half-Filled Shell

Selection rules for operators of good quasispin rank K , taken between states of the half-filled shell (for which $M_Q = 0$), can be found by inspecting the $3-j$ symbol

$$\begin{pmatrix} Q & K & Q' \\ 0 & 0 & 0 \end{pmatrix},$$

which appears when the Wigner-Eckart theorem is applied in quasispin space. This $3-j$ symbol vanishes unless $Q + K + Q'$ is even. An equivalent result can be obtained for $W^{(\kappa k)}$ by referring to Eq. (6.53) and insisting that y be even.

6.4 Complementarity

6.4.1 Spin-Quasispin Interchange

The operator R formally interchanges spin and quasispin. The result for the creation and annihilation operators for electrons can be expressed in terms of triple tensors:

$$Ra_{\xi}^{(qs\ell)} R^{-1} = a_{\eta}^{(qs\ell)}, \quad (6.61)$$

where $\xi \equiv (m_q m_s m_\ell)$ and $\eta \equiv (m_s m_q m_\ell)$. For the tensors $X^{(K\kappa k)}$ defined in Eq. (6.44), we get

$$RX_{\lambda}^{(K\kappa k)} R^{-1} = X_{\mu}^{(\kappa K k)}, \quad (6.62)$$

where $\lambda \equiv (M_K M_{\kappa} M_k)$ and $\mu \equiv (M_{\kappa} M_K M_k)$. For states of the ℓ shell,

$$R|\gamma Q M_Q S M_S\rangle = (-1)^t |\gamma S M_S Q M_Q\rangle, \quad (6.63)$$

where the quasispin of the ket on the right is S and the spin is Q . The phase factor t depends on S and Q and on phase choices made for the coefficients of fractional parentage. The symbol γ denotes the additional labels necessary to completely define the state in question, including L and M_L .

For every γ , Racah [20] observed that there are two possible pairs (v_1, S_1) and (v_2, S_2) satisfying

$$v_1 + 2S_2 = v_2 + 2S_1 = 2\ell + 1. \quad (6.64)$$

From Eq. (6.37) it follows that

$$S_1 = Q_2, \quad S_2 = Q_1. \quad (6.65)$$

6.4.2 Matrix Elements

Application of the complementarity operator R to the component parts of a matrix element leads to the equation

$$\begin{aligned} & \langle \gamma Q M_Q S M_S | X_{\lambda}^{(K\kappa k)} | \gamma' Q' M'_Q S' M'_S \rangle \\ &= (-1)^y \langle \gamma S M_S Q M_Q | X_{\mu}^{(\kappa K k)} | \gamma' S' M'_S Q' M'_Q \rangle, \end{aligned} \quad (6.66)$$

where λ and μ have the same significance as in Eq. (6.62), and where y , like t of Eq. (6.63), depends on the spins and quasispins but not on the associated magnetic quantum numbers. Equation (6.66) leads to a useful special case when $M_K = M_{\kappa} = 0$ and the tensors X are converted to those of type W , defined in Eq. (6.18). The sum $K + \kappa + k$ is taken to be odd, with the scalars $\kappa = k = 0$ and $K = k = 0$ excluded. Application of the Wigner-Eckart theorem to the spin and orbital spaces yields

$$\begin{aligned} & \frac{\langle \gamma Q M_Q S || W^{(\kappa k)} || \gamma' Q' M'_Q S' \rangle}{\langle \gamma S M_S Q || W^{(K k)} || \gamma' S' M'_S Q' \rangle} \\ &= (-1)^z \frac{\begin{pmatrix} Q & K & Q' \\ -M_Q & 0 & M_Q \end{pmatrix}}{\begin{pmatrix} S & \kappa & S' \\ -M_S & 0 & M_S \end{pmatrix}}, \end{aligned} \quad (6.67)$$

where $z = y + Q - M_Q - S + M_S$. An equivalent form is

$$\begin{aligned} & \frac{(\ell^N \gamma v_1 S_1 || W^{(\kappa k)} || \ell^N \gamma' v'_1 S'_1)}{(\ell^{N'} \gamma' v_2 S_2 || W^{(K k)} || \ell^{N'} \gamma' v'_2 S'_2)} \\ &= (-1)^z \frac{\begin{pmatrix} \frac{1}{2}(2\ell + 1 - v_1) & K & \frac{1}{2}(2\ell + 1 - v'_1) \\ \frac{1}{2}(2\ell + 1 - N) & 0 & \frac{1}{2}(N - 2\ell - 1) \end{pmatrix}}{\begin{pmatrix} \frac{1}{2}(2\ell + 1 - v_2) & \kappa & \frac{1}{2}(2\ell + 1 - v'_2) \\ \frac{1}{2}(2\ell + 1 - N') & 0 & \frac{1}{2}(N' - 2\ell - 1) \end{pmatrix}}, \end{aligned} \quad (6.68)$$

where Eq. (6.64) is satisfied both for the unprimed and primed quantities.

6.5 Quasiparticles

Sets of linear combinations of the creation and annihilation operators for electrons in the ℓ shell can be constructed such that every member of one set anticommutes with a member of a different set. To preserve the tensorial character of these quasiparticle operators with respect to \mathbf{L} , it is convenient to define [21, 22]

$$\lambda_q^\dagger = 2^{-\frac{1}{2}} \left[a_{\frac{1}{2},q}^\dagger + (-1)^{\ell-q} a_{\frac{1}{2},-q} \right], \quad (6.69)$$

$$\mu_q^\dagger = 2^{-\frac{1}{2}} \left[a_{\frac{1}{2},q}^\dagger - (-1)^{\ell-q} a_{\frac{1}{2},-q} \right], \quad (6.70)$$

$$\nu_q^\dagger = 2^{-\frac{1}{2}} \left[a_{-\frac{1}{2},q}^\dagger + (-1)^{\ell-q} a_{-\frac{1}{2},-q} \right], \quad (6.71)$$

$$\xi_q^\dagger = 2^{-\frac{1}{2}} \left[a_{-\frac{1}{2},q}^\dagger - (-1)^{\ell-q} a_{-\frac{1}{2},-q} \right]. \quad (6.72)$$

The four tensors θ^\dagger ($\equiv \lambda^\dagger, \mu^\dagger, \nu^\dagger$, or ξ^\dagger) anticommute with each other; the first two act in the spin-up space, the second two in the spin-down space. The tensors θ , whose components $\tilde{\theta}_q$ are defined as in Eq. (6.17) with $t = \ell$ and $m_t = q$, are related to their adjoints by the equations

$$\lambda^\dagger = \lambda, \quad \mu^\dagger = -\mu, \quad (6.73)$$

$$\nu^\dagger = \nu, \quad \xi^\dagger = -\xi. \quad (6.74)$$

Under the action of the complementarity operator R (see Eq. (6.61)) [23],

$$R \lambda R^{-1} = \lambda, \quad R \mu R^{-1} = \mu, \quad (6.75)$$

$$R \nu R^{-1} = \nu, \quad R \xi R^{-1} = -\xi. \quad (6.76)$$

The tensors λ , μ , and ν , for a given component q , form a vector with respect to $\mathbf{S} + \mathbf{Q}$. Every component of ξ is scalar with respect to $\mathbf{S} + \mathbf{Q}$ [24].

The compound quasiparticle operators defined by [21, 22]

$$\Theta_q^\dagger = 2^{-\frac{1}{2}} [\theta_q^\dagger, \theta_0^\dagger], \quad (6.77)$$

where $q > 0$ and $\theta \equiv \lambda, \mu, \nu$, or ξ satisfy the anticommutation relations

$$[\Theta_q^\dagger, \Theta_{q'}^\dagger]_+ = 0, \quad (6.78)$$

$$[\Theta_q, \Theta_{q'}]_+ = 0, \quad (6.79)$$

$$[\Theta_q^\dagger, \Theta_{q'}]_+ = \delta(q, q'), \quad (6.80)$$

for $q, q' > 0$. The Θ_q^\dagger with $q > 0$ can thus be regarded as the creation operators for a fermion quasiparticle with ℓ components.

The connection between the creation and annihilation operators for quasiparticles and for quarks (appearing in the last two rows of Table 3.1) is

$$\theta \rightarrow 2^{(\ell-1)/2} \epsilon_\theta \gamma_\theta (\mathbf{q}_\theta^\dagger \mathbf{q}_\theta)^{(10\dots 0)}, \quad (6.81)$$

where the γ_θ are Dirac matrices satisfying

$$\gamma_\theta \gamma_\phi + \gamma_\phi \gamma_\theta = 2\delta(\theta, \phi), \quad (6.82)$$

and the ϵ_θ are phases, to some extent dependent on the definitions Eqs. (6.69)–(6.72) [25]. The superscript $(10\dots 0)$ indicates that $\mathbf{q}_\theta^\dagger$ and \mathbf{q}_θ each of which belongs to the elementary spinor $(\frac{1}{2}\frac{1}{2}\dots\frac{1}{2})$ of $\text{SO}_\theta(2\ell + 1)$, are to be coupled to the resultant $(10\dots 0)$, which matches the group label for θ . In the quark model, the $2^{4\ell+2}$ states of the atomic ℓ shell are given by

$$\mathbf{q}_\lambda^\dagger \mathbf{q}_\mu^\dagger \mathbf{q}_\nu^\dagger \mathbf{q}_\xi^\dagger |0\rangle_{pp'}, \quad (6.83)$$

where p and p' are parity labels that distinguish the four reference states $|0\rangle$ corresponding to the evenness and oddness of the number of spin-up and spin-down electrons. The scalar nature of ξ (and hence of \mathbf{q}_ξ) with respect to $\mathbf{S} + \mathbf{Q}$ can be used to derive relations between spin-orbit matrix elements that go beyond those expected from an application of the Wigner–Eckart theorem [26].

Abstract

The density operator was first introduced by *J. von Neumann* [1] in 1927 and has since been widely used in quantum statistics. Over the past decades, however, the application of density matrices has spread to many other fields of physics. Density matrices have been used to describe, for example, coherence and correlation phenomena, alignment and orientation and their effect on the polarization of emitted radiation, quantum beat spectroscopy, optical pumping, and scattering processes, particularly when spin-polarized projectiles and/or targets are involved. A thorough introduction to the theory of density matrices and their applications, with an emphasis on atomic physics, can be found in the book by *Blum* [2], from which many equations have been extracted for use in this chapter.

Keywords

density matrix · density operator · reduce density matrix · Stokes parameter · tensor operator

The main advantage of the density matrix formalism is its ability to deal with pure and mixed states in the same consistent manner. The preparation of the initial state as well as the details regarding the observation of the final state can be treated in a systematic way. In particular, averages over quantum numbers of unpolarized beams in the initial state and incoherent sums over nonobserved quantum numbers in the final state can be accounted for via the reduced density matrix. Furthermore, expansion of the density matrix in terms of irreducible tensor operators and the corresponding state multipoles allows for the use of advanced angular momentum techniques, as outlined in Chaps. 2, 3 and 13. More details can be found in textbooks such as [3, 4].

7.1 Basic Formulae

7.1.1 Pure States

Consider a system in a quantum state that is represented by a single wave function $|\Psi\rangle$. The density operator for this situation is defined as

$$\rho = |\Psi\rangle\langle\Psi|. \quad (7.1)$$

If $|\Psi\rangle$ is normalized to unity, i.e., if

$$\langle\Psi|\Psi\rangle = 1, \quad (7.2)$$

then

$$\rho^2 = \rho. \quad (7.3)$$

Equation (7.3) is the basic equation for identifying *pure* quantum mechanical states represented by a density operator.

Next, consider the expansion of $|\Psi\rangle$ in terms of a complete orthonormal set of basis functions $\{|\Phi_n\rangle\}$, i.e.,

$$|\Psi\rangle = \sum_n c_n |\Phi_n\rangle. \quad (7.4)$$

The density operator then becomes

$$\rho = \sum_{n,m} c_n c_m^* |\Phi_n\rangle\langle\Phi_m| = \rho_{nm} |\Phi_n\rangle\langle\Phi_m|, \quad (7.5)$$

where the star denotes the complex conjugate quantity. Note that the density matrix elements $\rho_{nm} = \langle\Phi_n|\rho|\Phi_m\rangle$ depend on the choice of the basis and that the density matrix is Hermitian, i.e.,

$$\rho_{mn}^* = \rho_{nm}. \quad (7.6)$$

Finally, if $|\Psi\rangle = |\Phi_i\rangle$ is one of the basis functions, then

$$\rho_{mn} = \delta_{ni}\delta_{mi}, \quad (7.7)$$

where δ_{ni} is the Kronecker δ . Hence, the density matrix is diagonal in this representation with only one nonvanishing element.

7.1.2 Mixed States

The above concepts can be extended to treat statistical ensembles of pure quantum states. In the simplest case, such *mixed* states can be represented by a diagonal density matrix of the form

$$\rho = \sum_n w_n |\Psi_n\rangle\langle\Psi_n|, \quad (7.8)$$

where the weight w_n is the fraction of systems in the pure quantum state $|\Psi_n\rangle$. The standard normalization for the trace

of ρ is

$$\text{Tr}\{\rho\} = \sum_n w_n = 1. \quad (7.9)$$

Since the trace is invariant under unitary transformations of the basis functions, Eq. (7.9) also holds if the $|\Psi_n\rangle$ states themselves are expanded in terms of basis functions as in Eq. (7.4). For a pure state and the normalization Eq. (7.9), one finds in an arbitrary basis

$$\text{Tr}\{\rho\} = \text{Tr}\{\rho^2\} = 1. \quad (7.10)$$

7.1.3 Expectation Values

The density operator contains the maximum available information about a physical system. Consequently, it can be used to calculate expectation values for any operator A that represents a physical observable. In general,

$$\langle A \rangle = \text{Tr}\{A\rho\}/\text{Tr}\{\rho\}, \quad (7.11)$$

where $\text{Tr}\{\rho\}$ in the denominator of Eq. (7.11) ensures the correct result even for a normalization that is different from Eq. (7.9). The invariance of the trace operation ensures the same result—independently of the particular choice of the basis representation.

7.1.4 The Liouville Equation

Suppose Eq. (7.8) is valid for a time $t = 0$. If the functions $|\Psi_n(\mathbf{r}, t)\rangle$ obey the Schrödinger equation, i.e.,

$$i\frac{\partial}{\partial t}|\Psi_n(\mathbf{r}, t)\rangle = H(t)|\Psi_n(\mathbf{r}, t)\rangle, \quad (7.12)$$

the density operator at the time t can be written as

$$\rho(t) = U(t)\rho(0)U^\dagger(t). \quad (7.13)$$

In Eq. (7.13), $U(t)$ is the time evolution operator that relates the wave functions at times $t = 0$ and t according to

$$|\Psi_n(\mathbf{r}, t)\rangle = U(t)|\Psi_n(\mathbf{r}, 0)\rangle, \quad (7.14)$$

and $U^\dagger(t)$ denotes its adjoint. Note that

$$U(t) = e^{-iHt}, \quad (7.15)$$

if the Hamiltonian H is time independent.

Differentiation of Eq. (7.13) with respect to time and inserting Eq. (7.14) into the Schrödinger equation (7.12) yields the equation of motion

$$i\frac{\partial}{\partial t}\rho(t) = [H(t), \rho(t)], \quad (7.16)$$

where $[A, B]$ denotes a commutator.

The Liouville equation (7.16) can be used to determine the density matrix and to treat transitions from nonequilibrium to equilibrium states in quantum mechanical systems. Especially for approximate solutions in the presence of small time-dependent perturbation terms in an otherwise time-independent Hamiltonian, i.e., for

$$H(t) = H_0 + V(t), \quad (7.17)$$

the interaction picture is preferably used. The Liouville equation then becomes

$$i\frac{\partial}{\partial t}\rho_I(t) = [V_I(t), \rho_I(t)], \quad (7.18)$$

where the subscript I denotes the operator in the interaction picture. In first-order perturbation theory, Eq. (7.18) can be integrated to yield

$$\rho_I(t) = \rho_I(0) - i \int_0^t [V_I(\tau), \rho_I(0)] d\tau, \quad (7.19)$$

and higher-order terms can be obtained through subsequent iterations.

7.1.5 Systems in Thermal Equilibrium

According to quantum statistics, the density operator for a system that is in thermal equilibrium with a surrounding reservoir \mathcal{R} at a temperature T (canonical ensemble) can be expressed as

$$\rho = \frac{\exp(-\beta H)}{Z}, \quad (7.20)$$

where H is the Hamiltonian, and $\beta = 1/k_B T$ with k_B being the Boltzmann constant. The partition sum

$$Z = \text{Tr}\{\exp(-\beta H)\} \quad (7.21)$$

ensures the normalization condition Eq. (7.9). Expectation values are calculated according to Eq. (7.11), and extensions to other types of ensembles are straightforward.

7.1.6 Relaxation Processes

Transitions from nonequilibrium to equilibrium states can also be described within the density matrix formalism. One of the basic problems is to account for irreversibility in the energy (and sometimes particle) exchange between the system of interest, S , and the reservoir, \mathcal{R} . This is usually achieved by assuming that the interaction of the system with the reservoir is negligible and, therefore, the density matrix

representation for the reservoir at any time t is the same as the representation for $t = 0$.

Another frequently made assumption is the Markov approximation. In this approximation, one assumes that the system *forgets* all knowledge of the past, so that the density matrix elements at the time $t + \Delta t$ depend only on the values of these elements, and their first derivatives, at the time t . When Eq. (7.19) is put back into Eq. (7.18), the result in the Markov approximation can be rewritten as

$$\frac{\partial}{\partial t}\rho_{SI}(t) = -i \text{Tr}_{\mathcal{R}}[V_I(t), \rho_{SI}(0)\rho_{\mathcal{R}}(0)] - \int_0^t d\tau \text{Tr}_{\mathcal{R}}[V_I(t), [V_I(\tau), \rho_{SI}(t)\rho_{\mathcal{R}}(0)]] , \quad (7.22)$$

where $\text{Tr}_{\mathcal{R}}$ denotes the trace with regard to all variables of the reservoir. Note that the integral over $d\tau$ contains the system density matrix in the interaction picture, ρ_{SI} , at the time t , rather than at all times τ that are integrated over (the Markov approximation), and that the density matrix for the reservoir is taken as $\rho_{\mathcal{R}}(0)$ at all times. For more details, see Chap. 7 of *Blum* [2] and references therein.

Equations such as Eq. (7.22) are the basis for the master or rate equation approach used, for example, in quantum optics for the theory of lasers and the coupling of atoms to cavity modes. For more details, see Chaps. 72, 74, 77 and 82.

7.2 Spin and Light Polarizations

Density matrices are frequently used to describe the polarization state of spin-polarized particle beams as well as light. The latter can either be emitted from excited atomic or molecular ensembles or can be used, for example, for laser pumping purposes.

7.2.1 Spin-Polarized Electrons

The spin polarization of an electron beam with respect to a given quantization axis \hat{n} is defined as [5]

$$P_{\hat{n}} = \frac{N_{\uparrow} - N_{\downarrow}}{N_{\uparrow} + N_{\downarrow}}, \quad (7.23)$$

where $N_{\uparrow}(N_{\downarrow})$ is the number of electrons with spin up (down) with regard to this axis. An arbitrary polarization state is described by the density matrix

$$\rho = \frac{1}{2} \begin{pmatrix} 1 + P_z & P_x - iP_y \\ P_x + iP_y & 1 - P_z \end{pmatrix}, \quad (7.24)$$

where $P_{x,y,x}$ are the Cartesian components of the spin polarization vector. The individual components can be obtained

from the density matrix as

$$P_i = \text{Tr}\{\sigma_i \rho\}, \quad (7.25)$$

where σ_i ($i = x, y, z$) are the standard Pauli spin matrices.

7.2.2 Light Polarization

Another important use of the density matrix formalism is the description of light polarization in terms of the so-called Stokes parameters [6]. For a given direction of observation, the general polarization state of light can be fully determined by the measurement of one circular and two independent linear polarizations. Using the notation of *Born and Wolf* [7], the density matrix is given by

$$\rho = \frac{I_{\text{tot}}}{2} \begin{pmatrix} 1 - P_3 & P_1 - iP_2 \\ P_1 + iP_2 & 1 + P_3 \end{pmatrix}, \quad (7.26)$$

where P_1 and P_2 are linear light polarizations, while P_3 is the circular polarization (also Sect. 7.6). In Eq. (7.26), the density matrix is normalized in such a way that

$$\text{Tr}\{\rho\} = I_{\text{tot}}, \quad (7.27)$$

where I_{tot} is the total light intensity. Other frequently used names for the various Stokes parameters are

$$P_1 = \eta_3 = M, \quad (7.28)$$

$$P_2 = \eta_1 = C, \quad (7.29)$$

$$P_3 = -\eta_2 = S. \quad (7.30)$$

The Stokes parameters of electric dipole radiation can be related directly to the charge distribution of the emitting atomic ensemble. As discussed in detail in Chap. 48, one finds, for example,

$$L_{\perp} = -P_3 \quad (7.31)$$

for the angular momentum transfer perpendicular to the scattering plane in collisional (de)excitation, and

$$\gamma = \frac{1}{2} \arg\{P_1 + iP_2\} \quad (7.32)$$

for the alignment angle.

7.3 Atomic Collisions

7.3.1 Scattering Amplitudes

Transitions from an initial state $|J_0 M_0; \mathbf{k}_0 m_0\rangle$ to a final state $|J_1 M_1; \mathbf{k}_1 m_1\rangle$ are described by scattering amplitudes

$$f(M_1 m_1; M_0 m_0) = \langle J_1 M_1; \mathbf{k}_1 m_1 | \mathcal{T} | J_0 M_0; \mathbf{k}_0 m_0 \rangle, \quad (7.33)$$

where \mathcal{T} is the transition operator. Furthermore, J_0 (J_1) is the total electronic angular momentum in the initial (final) state of the target and M_0 (M_1) its corresponding z -component, while \mathbf{k}_0 (\mathbf{k}_1) is the initial (final) momentum of the projectile and m_0 (m_1) its spin component.

7.3.2 Reduced Density Matrices

While the scattering amplitudes are the central elements in a theoretical description, some restrictions usually need to be taken into account in a practical experiment. The most important ones are: (i) there is no *pure* initial state, and (ii) not all possible quantum numbers are simultaneously determined in the final state. The solution to this problem can be found by using the density matrix formalism. First, the complete density operator after the collision process is given by [2]

$$\rho_{\text{out}} = \mathcal{T} \rho_{\text{in}} \mathcal{T}^\dagger, \quad (7.34)$$

where ρ_{in} is the density operator before the collision. The corresponding matrix elements are given by

$$\begin{aligned} (\rho_{\text{out}})_{m'_1 m_1}^{k_1, M'_1 M_1} &= \sum_{m'_0 m_0 M'_0 M_0} \rho_{m'_0 m_0} \rho_{M'_0 M_0} \\ &\times f(M'_1 m'_1; M'_0 m'_0) \\ &\times f^*(M_1 m_1; M_0 m_0), \end{aligned} \quad (7.35)$$

where the term $\rho_{m'_0 m_0} \rho_{M'_0 M_0}$ describes the preparation of the initial state (i). Secondly, *reduced* density matrices account for (ii). For example, if only the scattered projectiles are observed, the corresponding elements of the reduced density matrix are obtained by summing over the atomic quantum numbers as follows:

$$(\rho_{\text{out}})_{m'_1 m_1}^{k_1} = \sum_{M_1} (\rho_{\text{out}})_{m'_1 m_1}^{k_1, M_1 M_1}. \quad (7.36)$$

The differential cross section for unpolarized projectile and target beams is given by

$$\frac{d\sigma}{d\Omega} = C \sum_{m_1} (\rho_{\text{out}})_{m_1 m_1}^{k_1}, \quad (7.37)$$

where C is a constant that depends on the normalization of the continuum waves in a numerical calculation.

On the other hand, if only the atoms are observed (for example, by analyzing the light emitted in optical transitions), the elements

$$(\rho_{\text{out}})_{M'_1 M_1} = \int d^3 \mathbf{k}_1 \sum_{m_1} (\rho_{\text{out}})_{m_1 m_1}^{k_1, M'_1 M_1} \quad (7.38)$$

determine the integrated Stokes parameters [8, 9], i.e., the polarization of the emitted light. They contain information about the angular momentum distribution in the excited target ensemble.

Finally, for electron–photon coincidence experiments without spin analysis in the final state, the elements

$$(\rho_{\text{out}})_{M'_1 M_1}^{k_1} = \sum_{m_1} (\rho_{\text{out}})_{m_1 m_1}^{k_1, M'_1 M_1} \quad (7.39)$$

simultaneously contain information about the projectiles and the target. This information can be extracted by measuring the angle-differential Stokes parameters. In particular, for unpolarized electrons and atoms, the *natural coordinate system*, where the quantization axis coincides with the normal to the scattering plane, allows for a simple physical interpretation of the various parameters [10] (Chap. 48).

The density matrix formalism outlined above is very useful for obtaining a qualitative description of the geometrical and sometimes also of the dynamical symmetries of the collision process [11]. Two explicit examples are discussed in Sect. 7.6.

7.4 Irreducible Tensor Operators

The general density matrix theory can be formulated in a very elegant fashion by decomposing the density operator in terms of irreducible components whose matrix elements then become the state multipoles. In such a formulation, full advantage can be taken of the most sophisticated techniques developed in angular momentum algebra (Chap. 2). Many explicit examples can be found in [3, 4].

7.4.1 Definition

The density operator for an ensemble of particles in quantum states labeled as $|JM\rangle$, where J and M are the total angular momentum and its magnetic component, respectively, can be written as

$$\rho = \sum_{J'JM'M} \rho_{M'M}^{J'J} |J'M'\rangle \langle JM|, \quad (7.40)$$

where

$$\rho_{M'M}^{J'J} = \langle J'M' | \rho | JM \rangle \quad (7.41)$$

are the matrix elements. (For simplicity, interactions outside the single manifold of momentum states $|JM\rangle$ are neglected.) Alternatively, one may write

$$+ \rho = \sum_{J'JKQ} \langle T(J'J)_{KQ}^\dagger \rangle T(J'J)_{KQ}, \quad (7.42)$$

where the irreducible tensor operators are defined in terms of 3- j -symbols as

$$T(J'J)_{KQ} = \sum_{M'M} (-1)^{J'-M'} \sqrt{2K+1} \times \begin{pmatrix} J' & J & K \\ M' & -M & -Q \end{pmatrix} |J'M'\rangle \langle JM|, \quad (7.43)$$

and the state multipoles or statistical tensors are given by

$$\langle T(J'J)_{KQ}^\dagger \rangle = \sum_{M'M} (-1)^{J'-M'} \sqrt{2K+1} \times \begin{pmatrix} J' & J & K \\ M' & -M & -Q \end{pmatrix} \langle J'M' | \rho | JM \rangle. \quad (7.44)$$

Hence, the selection rules for the 3- j -symbols imply that

$$|J - J'| \leq K \leq J + J', \quad (7.45)$$

$$M' - M = Q. \quad (7.46)$$

Equation (7.44) can be inverted through the orthogonality condition of the 3- j -symbols to give

$$\langle J'M' | \rho | JM \rangle = \sum_{KQ} (-1)^{J'-M'} \sqrt{2K+1} \times \begin{pmatrix} J' & J & K \\ M' & -M & -Q \end{pmatrix} \langle T(J'J)_{KQ}^\dagger \rangle. \quad (7.47)$$

7.4.2 Transformation Properties

Suppose a coordinate system (X_2, Y_2, Z_2) is obtained from another coordinate system (X_1, Y_1, Z_1) through a rotation by a set of three Euler angles (γ, β, α) as defined in *Edmonds* [12]. The irreducible tensor operators Eq. (7.43) defined in the (X_1, Y_1, Z_1) system are then related to the operators $\langle T(J'J)_{KQ}^\dagger \rangle$ in the (X_2, Y_2, Z_2) system by

$$T(J'J)_{KQ} = \sum_q T(J'J)_{Kq} D(\gamma, \beta, \alpha)_{qQ}^K, \quad (7.48)$$

where

$$D(\gamma, \beta, \alpha)_{M'M}^J = e^{iM'\gamma} d(\beta)_{M'M}^J e^{iM\alpha} \quad (7.49)$$

is a rotation matrix (Chap. 2). Note that the rank K of the tensor operator is invariant under such rotations. Similarly,

$$\langle T(J'J)_{KQ}^\dagger \rangle = \sum_q \langle T(J'J)_{Kq}^\dagger \rangle D(\gamma, \beta, \alpha)_{qQ}^{K*} \quad (7.50)$$

holds for the state multipoles.

The irreducible tensor operators fulfill the orthogonality condition

$$\text{Tr}\left\{T(J'J)_{KQ} T(J'J)_{K'Q'}^\dagger\right\} = \delta_{K'K} \delta_{Q'Q}. \quad (7.51)$$

With

$$T(J'J)_{00} = \frac{1}{\sqrt{2J+1}} \delta_{J'J} \mathbf{1} \quad (7.52)$$

being proportional to the unit operator $\mathbf{1}$, it follows that all tensor operators have vanishing trace, except for the monopole $T(J'J)_{00}$.

Reduced tensor operators fulfill the Wigner–Eckart theorem (Sect. 2.8.4)

$$\begin{aligned} & \langle J'M' | T(J'J)_{KQ} | JM \rangle \\ &= (-1)^{J'-M'} \begin{pmatrix} J' & K & J \\ -M' & Q & M \end{pmatrix} \langle J' || T_K || J \rangle, \end{aligned} \quad (7.53)$$

where the reduced matrix element is simply given by

$$\langle J' || T_K || J \rangle = \frac{1}{\sqrt{2K+1}}. \quad (7.54)$$

7.4.3 Symmetry Properties of State Multipoles

The Hermiticity condition for the density matrix implies

$$\langle T(J'J)_{KQ}^\dagger \rangle^* = (-1)^{J'-J+Q} \langle T(JJ')_{K-Q}^\dagger \rangle, \quad (7.55)$$

which, for sharp angular momentum $J' = J$, yields

$$\langle T(J)_{KQ}^\dagger \rangle^* = (-1)^Q \langle T(J)_{K-Q}^\dagger \rangle. \quad (7.56)$$

Hence, the state multipoles $\langle T(J)_{K0}^\dagger \rangle$ are real numbers.

Furthermore, the transformation property Eq. (7.50) of the state multipoles imposes restrictions on nonvanishing state multipoles to describe systems with given symmetry properties. In detail, one finds:

1. For spherically symmetric systems,

$$\langle T(J'J)_{KQ}^\dagger \rangle = \langle T(J'J)_{KQ}^\dagger \rangle_{\text{rot}} \quad (7.57)$$

for *all* sets of Euler angles. This implies that only the monopole term $\langle T(J)_{00}^\dagger \rangle$ can be different from zero.

2. For axially symmetric systems,

$$\langle T(J'J)_{KQ}^\dagger \rangle = \langle T(J'J)_{KQ}^\dagger \rangle_{\text{rot}} \quad (7.58)$$

for *all* Euler angles ϕ that describe a rotation around the z -axis. Since this angle enters via a factor $\exp(-iQ\phi)$ into the general transformation formula Eq. (7.50), it follows

that only state multipoles with $Q = 0$, i.e., $\langle T(J'J)_{K0}^\dagger \rangle$, can be different from zero in such a situation.

3. For planar symmetric systems with fixed $J' = J$,

$$\langle T(J)_{KQ}^\dagger \rangle = (-1)^K \langle T(J)_{KQ}^\dagger \rangle^* \quad (7.59)$$

if the system properties are invariant under reflection in the xz -plane. Hence, state multipoles with even rank K are real numbers, while those with odd rank are purely imaginary in this case.

The above results can be applied immediately to the description of atomic collisions where the incident beam axis is the quantization axis (the so-called *collision system*). For example, impact excitation of unpolarized targets by unpolarized projectiles without observation of the scattered projectiles is symmetric both with regard to rotation around the incident beam axis and with regard to reflection in any plane containing this axis. Consequently, the state multipoles $\langle T(J)_{00}^\dagger \rangle$, $\langle T(J)_{20}^\dagger \rangle$, $\langle T(J)_{40}^\dagger \rangle$, ... fully characterize the atomic ensemble of interest. Using Eq. (7.50), similar relationships can be derived for state multipoles defined with regard to other coordinate systems, such as the *natural system* where the quantization axis coincides with the normal vector to the scattering plane (Chap. 48).

7.4.4 Orientation and Alignment

From the above discussion, it is apparent that the description of systems that do not exhibit spherical symmetry requires the knowledge of state multipoles with rank $K \neq 0$. Frequently, the multipoles with $K = 1$ and $K = 2$ are determined via the angular correlation and the polarization of radiation emitted from an ensemble of collisionally excited targets. The state multipoles with $K = 1$ are proportional to the spherical components of the angular momentum expectation value and, therefore, give rise to a nonvanishing circular light polarization (Sect. 7.6). This corresponds to a sense of rotation or an orientation in the ensemble, which is, therefore, called oriented (Sect. 48.1).

On the other hand, nonvanishing multipoles with rank $K = 2$ describe the alignment of the system. Some authors, however, use the terms *alignment* or *orientation* synonymously for all nonvanishing state multipoles with rank $K \neq 0$, thereby describing any system with anisotropic occupation of magnetic sublevels as *aligned* or *oriented*. For details on alignment and orientation, see Chap. 48 and [3, 4].

7.4.5 Coupled Systems

Tensor operators and state multipoles for coupled systems are constructed as direct products (\otimes) of the operators for

the individual systems. For example, the density operator for two subsystems in basis states $|L, M_L\rangle$ and $|S, M_S\rangle$ is constructed as [2]

$$\rho = \sum_{KQkq} \langle T(L)_{KQ}^\dagger \otimes T(S)_{kq}^\dagger \rangle [T(L)_{KQ} \otimes T(S)_{kq}]. \quad (7.60)$$

If the two systems are uncorrelated, the state multipoles factor as

$$\langle T(L)_{KQ}^\dagger \otimes T(S)_{kq}^\dagger \rangle = \langle T(L)_{KQ}^\dagger \rangle \langle T(S)_{kq}^\dagger \rangle. \quad (7.61)$$

More generally, irreducible representations of coupled operators can be defined in terms of a 9- j -symbol as

$$T(J', J)_{K'Q'} = \sum_{KQkq} \hat{K} \hat{k} \hat{J} \hat{J}' (KQ, kq | K'Q') \times \begin{Bmatrix} K & k & K' \\ L & S & J' \\ L & S & J \end{Bmatrix} T(L)_{KQ} \otimes T(S)_{kq}, \quad (7.62)$$

where $\hat{x} \equiv \sqrt{2x+1}$ and $(j_1 m_1, j_2 m_2 | j_3 m_3)$ is a standard Clebsch–Gordan coefficient.

7.5 Time Evolution of State Multipoles

7.5.1 Perturbation Coefficients

From the general expansions

$$\rho(t) = \sum_{j'jkq} \langle T(j'j; t)_{kq}^\dagger \rangle T(j'j)_{kq} \quad (7.63)$$

in terms of irreducible components, together with Eq. (7.42) for time $t = 0$ and Eq. (7.13) for the time development of the density operator, it follows that

$$\langle T(j'j; t)_{kq}^\dagger \rangle = \sum_{J'JKQ} \langle T(J'J; 0)_{KQ}^\dagger \rangle G(J'J, j'j; t)_{Kk}^{Qq}, \quad (7.64)$$

where the perturbation coefficients are defined as

$$G(J'J, j'j; t)_{Kk}^{Qq} = \text{Tr} \left\{ U(t) T(J'J)_{KQ} U(t)^\dagger T(j'j)_{kq}^\dagger \right\}. \quad (7.65)$$

Hence, these coefficients relate the state multipoles at time t to those at $t = 0$.

7.5.2 Quantum Beats

An important application of the perturbation coefficients is the coherent excitation of several quantum states, which sub-

sequently decay by optical transitions. Such an excitation may be performed, for example, in beam-foil experiments or electron–atom collisions where the energy width of the electron beam is too large to resolve the fine structure (or hyperfine structure) of the target states.

Suppose, for instance, that explicitly relativistic effects, such as the spin–orbit interaction between the projectile and the target, can be neglected *during* a collision process between an incident electron and a target atom. In that case, the orbital angular momentum (L) system of the collisionally excited target states may be oriented, depending on the scattering angle of the projectile. On the other hand, the spin (S) system remains unaffected (unpolarized), provided that both the target and the projectile beams are unpolarized. During the lifetime of the excited target states, however, the spin–orbit interaction *within* the target produces an exchange of orientation between the L and the S systems, which results in a net loss of orientation in the L system.

This effect can be observed directly through the intensity and the polarization of the light emitted from the excited target ensemble. The perturbation coefficients for the fine-structure interaction are found to be [2, 13]

$$G(L; t)_K = \frac{\exp(-\gamma t)}{2S+1} \sum_{J'J} (2J'+1)(2J+1) \times \begin{Bmatrix} L & J' & S \\ J & L & K \end{Bmatrix}^2 \cos(\omega_{J'} - \omega_J)t, \quad (7.66)$$

where $\omega_{J'} - \omega_J$ corresponds to the (angular) frequency difference between the various multiplet states with total electronic angular momenta J' and J , respectively. Also, γ is the natural width of the spectral line; for simplicity, the same lifetime was assumed in Eq. (7.66) for all states of the multiplet.

Note that the perturbation coefficients are independent of the multipole component Q in this case, and that there is no mixing between different multipole ranks K . Similar results can be derived [2, 13] for the hyperfine interaction and also to account for the combined effect of fine and hyperfine structure. The cosine terms represent correlation between the signal from different fine-structure states, and they lead to oscillations in the intensity as well as the measured Stokes parameters in a time-resolved experiment.

Finally, generalized perturbation coefficients have been derived for the case where both the L and the S systems may be oriented and/or aligned during the collision process [14]. This can happen when spin-polarized projectiles and/or target beams are prepared.

7.5.3 Time Integration over Quantum Beats

If the excitation and decay times cannot be resolved in a given experimental setup, the perturbation coefficients need

to be integrated over time. As a result, the quantum beats disappear, but a net effect may still be visible through a depolarization of the emitted radiation. For the case of atomic fine structure interaction discussed above, one finds [2, 13]

$$\begin{aligned}\bar{G}(L)_K &= \int_0^\infty G(L; t)_K dt \\ &= \frac{1}{2S+1} \sum_{J'J} (2J'+1)(2J+1) \\ &\quad \times \begin{Bmatrix} L & J' & S \\ J & L & K \end{Bmatrix}^2 \frac{\gamma}{\gamma^2 + \omega_{J'J}^2},\end{aligned}\quad (7.67)$$

where $\omega_{J'J} = \omega_{J'} - \omega_J$. Note that the amount of depolarization depends on the relationship between the fine structure splitting and the natural line width. For $|\omega_{J'J}| \gg \gamma$ (if $J' \neq J$), the terms with $J' = J$ dominate and cause the maximum depolarization; for the opposite case $|\omega_{J'J}| \ll \gamma$, the sum rule for the 6- j -symbols can be applied and no depolarization is observed.

Similar depolarizations can be caused through hyperfine structure effects, as well as through external fields. An important example of the latter case is the Hanle effect (Sect. 18.2.1).

7.6 Examples

In this section, two examples of the reduced density formalism are discussed explicitly. These are: (i) the change of the spin polarization of initially polarized spin- $\frac{1}{2}$ projectiles after scattering from unpolarized targets, and (ii) the Stokes parameters describing the angular distribution and the polarization of light as detected in projectile-photon coincidence experiments after collisional excitation. The recent book by *Andersen and Bartschat* [4] provides a detailed introduction to these topics, together with a thorough discussion of benchmark studies in the field of electronic and atomic collisions, including extensions to ionization processes, as well as applications in plasma, surface, and nuclear physics. Even more extensive compilations of such studies can be found in a review series dealing with unpolarized electrons colliding with unpolarized targets [10], heavy-particle collisions [15], and the special role of projectile and target spins in such collisions [16].

7.6.1 Generalized *STU*-Parameters

For spin-polarized projectile scattering from unpolarized targets, the generalized *STU*-parameters [11] contain information about the projectile spin polarization after the collision.

These parameters can be expressed in terms of the elements Eq. (7.36).

To analyze this problem explicitly, one defines the quantities

$$\begin{aligned}\langle m'_1 m'_0; m_1 m_0 \rangle &= \frac{1}{2J_0+1} \sum_{M_1 M_0} f(M_1 m'_1; M_0 m'_0) \\ &\quad \times f^*(M_1 m_1; M_0 m_0),\end{aligned}\quad (7.68)$$

which contain the *maximum information* that can be obtained from the scattering process, if only the polarization of the projectiles is prepared before the collision and measured thereafter.

Next, the number of independent parameters that can be determined in such an experiment needs to be examined. For spin- $\frac{1}{2}$ particles, there are $2 \times 2 \times 2 \times 2 = 16$ possible combinations of $\{m'_1 m'_0; m_1 m_0\}$ and, therefore, 16 complex or 32 real parameters (in the most general case of spin- S particles, there would be $(2S+1)^4$ combinations). However, from the definition Eq. (7.68) and the Hermiticity of the reduced density matrix contained therein, it follows that

$$\langle m'_1 m'_0; m_1 m_0 \rangle = \langle m_1 m_0; m'_1 m'_0 \rangle^*.\quad (7.69)$$

Furthermore, parity conservation of the interaction or the equivalent reflection invariance with regard to the scattering plane yields the additional relationship [11]

$$\begin{aligned}f(M_1 m_1; M_0 m_0) &= (-1)^{J_1 - M_1 + \frac{1}{2} - m_1 + J_0 - M_0 + \frac{1}{2} - m_0} \\ &\quad \times \Pi_1 \Pi_0 f(-M_1 - m_1; -M_0 - m_0),\end{aligned}\quad (7.70)$$

where Π_1 and Π_0 are ± 1 , depending on the parities of the atomic states involved. Hence,

$$\begin{aligned}\langle m'_1 m'_0; m_1 m_0 \rangle &= (-1)^{m'_1 - m_1 + m'_0 - m_0} \\ &\quad \times \langle -m'_1 - m'_0; -m_1 - m_0 \rangle.\end{aligned}\quad (7.71)$$

Note that Eqs. (7.70) and (7.71) hold for the collision frame, where the quantization axis (\hat{z}) is taken as the incident beam axis and the scattering plane is the xz -plane. Similar formulas can be derived for the natural frame (Sect. 7.3.2).

Consequently, *eight* independent parameters are sufficient to characterize the reduced spin density matrix of the scattered projectiles. These can be chosen as the *absolute* differential cross section

$$\sigma_u = \frac{1}{2} \sum_{m_1, m_0} \langle m_1 m_0; m_1 m_0 \rangle,\quad (7.72)$$

for the scattering of unpolarized projectiles from unpolarized targets and the seven *relative* parameters

$$S_A = -\frac{2}{\sigma_u} \text{Im} \left\{ \left\langle \frac{1}{2} - \frac{1}{2}; \frac{11}{22} \right\rangle \right\}, \quad (7.73)$$

$$S_P = -\frac{2}{\sigma_u} \text{Im} \left\{ \left\langle \frac{11}{22}; -\frac{11}{22} \right\rangle \right\}, \quad (7.74)$$

$$T_y = \frac{1}{\sigma_u} \left[\left\langle -\frac{1}{2} - \frac{1}{2}; \frac{11}{22} \right\rangle - \left\langle -\frac{11}{22}; \frac{1}{2} - \frac{1}{2} \right\rangle \right], \quad (7.75)$$

$$T_x = \frac{1}{\sigma_u} \left[\left\langle -\frac{1}{2} - \frac{1}{2}; \frac{11}{22} \right\rangle + \left\langle -\frac{11}{22}; \frac{1}{2} - \frac{1}{2} \right\rangle \right], \quad (7.76)$$

$$T_z = \frac{1}{\sigma_u} \left[\left\langle \frac{11}{22}; \frac{11}{22} \right\rangle - \left\langle \frac{11}{22}; -\frac{11}{22} \right\rangle \right], \quad (7.77)$$

$$U_{xz} = \frac{2}{\sigma_u} \text{Re} \left\{ \left\langle \frac{11}{22}; -\frac{11}{22} \right\rangle \right\}, \quad (7.78)$$

$$U_{zx} = -\frac{2}{\sigma_u} \text{Re} \left\{ \left\langle \frac{1}{2} - \frac{1}{2}; \frac{11}{22} \right\rangle \right\}, \quad (7.79)$$

where $\text{Re}\{x\}$ and $\text{Im}\{x\}$ denote the real and imaginary parts of the complex quantity x , respectively. Note that normalization constants have been omitted in Eq. (7.72) to simplify the notation.

Therefore, the most general form for the polarization vector after scattering, \mathbf{P}' , for an initial polarization vector $\mathbf{P} = (P_x, P_y, P_z)$ is given by

$$\frac{(S_P + T_y P_y) \hat{y} + (T_x P_x + U_{xz} P_z) \hat{x} + (T_z P_z - U_{zx} P_x) \hat{z}}{1 + S_A P_y}. \quad (7.80)$$

The physical meaning of the above relation is illustrated in Fig. 7.1.

Fig. 7.1 Physical meaning of the generalized *STU*-parameters: the polarization function S_P gives the polarization of an initially unpolarized projectile beam after the collision, while the asymmetry function S_A determines a left–right asymmetry in the differential cross section for the scattering of a spin-polarized beam. Furthermore, the contraction parameters (T_x, T_y, T_z) describe the change of an initial polarization component along the three Cartesian axes, while the parameters U_{xz} and U_{zx} determine the rotation of a polarization component in the scattering plane

The following geometries are particularly suitable for the experimental determination of the individual parameters; σ_u and S_P can be measured with unpolarized incident projectiles. A transverse polarization component perpendicular to the scattering plane ($\mathbf{P} = P_y \hat{y}$) is needed to obtain S_A and T_y . Finally, the measurement of T_x , U_{zx} , T_z , and U_{xz} requires both transverse ($P_x \hat{x}$) and longitudinal ($P_z \hat{z}$) projectile polarization components in the scattering plane.

7.6.2 Radiation from Excited States: Stokes Parameters

The state-multipole description is also widely used for the parametrization of the Stokes parameters that describe the polarization of light emitted in optical decays of excited atomic ensembles. The general case of excitation by spin-polarized projectiles has been treated by *Bartschat* and collaborators [8]. The basic experimental setup for electron–photon coincidence experiments and the definition of the Stokes parameters are illustrated in Figs. 7.2 and 7.3.

For impact excitation of an atomic state with total electronic angular momentum J and an electric dipole transition to a state with J_f , the photon intensity in a direction $\hat{n} = (\Theta_\gamma, \Phi_\gamma)$ is given by

$$I(\Theta_\gamma, \Phi_\gamma) = C \left[\frac{2(-1)^{J-J_f}}{3\sqrt{2J+1}} \langle T(J)_{00}^\dagger \rangle - \begin{Bmatrix} 1 & 1 & 2 \\ J & J & J_f \end{Bmatrix} \times \left(\text{Re} \left\{ \langle T(J)_{22}^\dagger \rangle \right\} \sin^2 \Theta_\gamma \cos 2\Phi_\gamma - \text{Re} \left\{ \langle T(J)_{21}^\dagger \rangle \right\} \sin 2\Theta_\gamma \cos \Phi_\gamma + \sqrt{\frac{1}{6}} \langle T(J)_{20}^\dagger \rangle (3 \cos^2 \Theta_\gamma - 1) - \text{Im} \left\{ \langle T(J)_{22}^\dagger \rangle \right\} \sin^2 \Theta_\gamma \sin 2\Phi_\gamma + \text{Im} \left\{ \langle T(J)_{21}^\dagger \rangle \right\} \sin 2\Theta_\gamma \sin \Phi_\gamma \right) \right], \quad (7.81)$$

Fig. 7.2 Geometry of electron–photon coincidence experiments

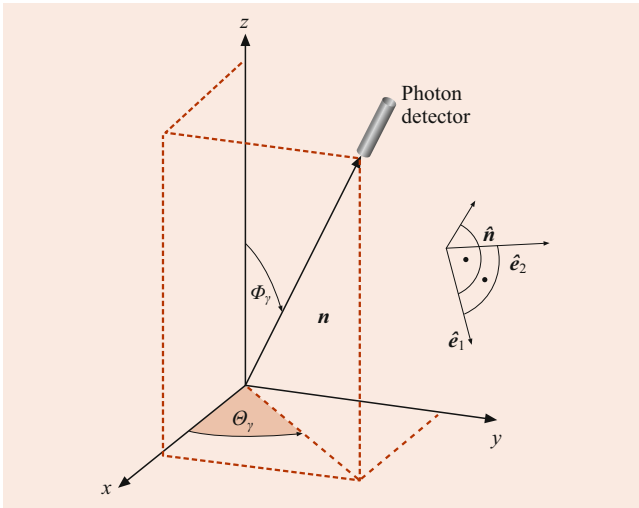

Fig. 7.3 Definition of the Stokes parameters: photons are observed in a direction \hat{n} with polar angles $(\Theta_\gamma, \Phi_\gamma)$ in the collision system. The three unit vectors $(\hat{n}, \hat{e}_1, \hat{e}_2)$ define the helicity system of the photons, $\hat{e}_1 = (\Theta_\gamma + 90^\circ, \Phi_\gamma)$ lies in the plane spanned by \hat{n} and \hat{z} and is perpendicular to \hat{n} , while $\hat{e}_2 = (\Theta_\gamma, \Phi_\gamma + 90^\circ)$ is perpendicular to both \hat{n} and \hat{e}_1 . In addition to the circular polarization P_3 , the linear polarizations P_1 and P_2 are defined with respect to axes in the plane spanned by \hat{e}_1 and \hat{e}_2 . Counting from the direction of \hat{e}_1 , the axes are located at $(0^\circ, 90^\circ)$ for P_1 and at $(45^\circ, 135^\circ)$ for P_2 , respectively

where

$$C = \frac{e^2 \omega^4}{2\pi c^3} |\langle J_f \| \mathbf{r} \| J \rangle|^2 (-1)^{J-J_f} \quad (7.82)$$

is a constant containing the frequency ω of the transition as well as the reduced radial dipole matrix element.

Similarly, the product of the intensity I and the circular light polarization P_3 can be written in terms of state multipoles as

$$\begin{aligned} (I \cdot P_3)(\Theta_\gamma, \Phi_\gamma) = & -C \begin{Bmatrix} 1 & 1 & 1 \\ J & J & J_f \end{Bmatrix} \\ & \times \left(\text{Im} \left\{ \left\langle T(J)_{11}^\dagger \right\rangle \right\} 2 \sin \Theta_\gamma \sin \Phi_\gamma \right. \\ & - \text{Re} \left\{ \left\langle T(J)_{11}^\dagger \right\rangle \right\} 2 \sin \Theta_\gamma \cos \Phi_\gamma \\ & \left. + \sqrt{2} \left\langle T(J)_{10}^\dagger \right\rangle \cos \Theta_\gamma \right), \quad (7.83) \end{aligned}$$

so that P_3 can be calculated as

$$P_3(\Theta_\gamma, \Phi_\gamma) = (I \cdot P_3)(\Theta_\gamma, \Phi_\gamma) / I(\Theta_\gamma, \Phi_\gamma). \quad (7.84)$$

Note that each state multipole gives rise to a characteristic angular dependence in the formulas for the Stokes parameters, and that perturbation coefficients may need to be applied

to deal, for example, with depolarization effects due to internal or external fields. General formulas for $P_1 = \eta_3$ and $P_2 = \eta_1$ can be found in [8] and, for both the natural and the collision systems, in [4].

As was pointed out before, some of the state multipoles may vanish, depending on the experimental arrangement. A detailed analysis of the information contained in the state multipoles and the generalized Stokes parameters (which are defined for specific values of the projectile spin polarization) has been given by *Andersen* and *Bartschat* [4, 17, 18]. They reanalyzed the experiment performed by *Sohn* and *Hanne* [19] and showed how the density matrix of the excited atomic ensemble can be determined by a measurement of the generalized Stokes parameters. In some cases, this will allow for the extraction of a complete set of scattering amplitudes for the collision process. Such a *perfect scattering experiment* was called for by *Bederson* many years ago [20] and is within reach even for fairly complex excitation processes. The most promising cases were discussed by *Andersen* and *Bartschat* [4, 17, 21].

7.7 Summary

The basic formulas dealing with density matrices in quantum mechanics, with particular emphasis on reduced matrix theory and its applications in atomic physics, have been summarized. More details are given in the introductory textbooks by *Blum* [2], *Balashov* et al. [3], *Andersen* and *Bartschat* [4], and the references listed below.

Abstract

Essential to atomic, molecular, and optical physics is the ability to perform numerical computations accurately and efficiently. Whether the specific approach involves perturbation theory, close coupling expansion, solution of classical equations of motion, or fitting and smoothing of data, basic computational techniques such as integration, differentiation, interpolation, matrix and eigenvalue manipulation, Monte Carlo sampling, and solution of differential equations must be among the standard tool kit.

This chapter outlines a portion of this tool kit with the aim of giving guidance and organization to a wide array

of computational techniques. After having digested the present overview, the reader is then referred to detailed treatments given in many of the large number of texts existing on numerical analysis and computational techniques [1–6], mathematical functions [7–9], and mathematical physics [10–18].

In addition to these excellent general references, in the age of the internet, many resources are also available through free publishing projects or research laboratory resources made public. Many of these resources seek to provide techniques and computer codes of high accuracy, portability, robustness, and efficiency, and often take advantage of modern structured programming and computational parallelism, going beyond the highly accessible, broadly applicable, but simple numerical recipes and codes described in the classic texts. A list of such numerical analysis software is given on the Wikipedia, providing very brief descriptions of the packages available [19], and the journal *Computer Physics Communications* (CPC) publishes computational physics research and applications software with many codes applicable to atomic, molecular, and optical physics (see the CPC program library maintained at Queen’s University Belfast [20]). Especially in the sections that follow on differential equations and computational linear algebra, mention is made of the role of software packages readily available to aid in implementing practical solutions.

Finally, in this brief introduction to computational techniques, we note the existence of commercial packages for mathematics, including those for computer algebra, performing numerical calculations and visualizing results through proprietary programming languages, and even performing simulations through such tools as finite-element analysis, including Mathematica, Maple, MATLAB, Mathcad, and COMSOL, for example.

8.1 Representation of Functions

The ability to represent functions in terms of polynomials or other basic functions is the key to interpolating or fitting data, and to approximating numerically the operations of integration and differentiation. In addition, using methods such as Fourier analysis, knowledge of the properties of functions beyond even their intermediate values, derivatives, and antiderivatives may be determined (e.g., the *spectral* properties).

8.1.1 Interpolation

Given the value of a function $f(x)$ at a set of points x_1, x_2, \dots, x_n , the function is often required at some other values between these abscissas. The process known as *interpolation* seeks to estimate these unknown values by adjusting the parameters of a known function to approximate the local or global behavior of $f(x)$. One of the most useful representations of a function for these purposes utilizes the *algebraic polynomials*, $P_n(x) = a_0 + a_1x + \dots + a_nx^n$, where the coefficients are real constants, and the exponents are nonnegative integers. The utility stems from the fact that given any continuous function defined on a closed interval, there exists an algebraic polynomial that is as close to that function as desired (Weierstrass theorem).

One simple application of these polynomials is the power series expansion of the function $f(x)$ about some point, x_0 , i.e.,

$$f(x) = \sum_{k=0}^{\infty} a_k (x - x_0)^k. \quad (8.1)$$

A familiar example is the *Taylor expansion*, in which the coefficients are given by

$$a_k = \frac{f^{(k)}(x_0)}{k!}, \quad (8.2)$$

where $f^{(k)}$ indicates the k -th derivative of the function. This form, although quite useful in the derivation of formal techniques, is not very useful for interpolation, since it assumes the function and its derivatives are known and since it is guaranteed to be a good approximation only very near the point x_0 about which the expansion has been made.

Lagrange Interpolation

The polynomial of degree $n - 1$ that passes through all n points $[x_1, f(x_1)], [x_2, f(x_2)], \dots, [x_n, f(x_n)]$ is given by

$$P(x) = \sum_{k=1}^n f(x_k) \prod_{i=1, i \neq k}^n \frac{x - x_i}{x_k - x_i} \quad (8.3)$$

$$= \sum_{k=1}^n f(x_k) L_{nk}(x), \quad (8.4)$$

where $L_{nk}(x)$ are the *Lagrange interpolating polynomials*. Perhaps the most familiar example is that of linear interpolation between the points $[x_1, y_1 \equiv f(x_1)]$ and $[x_2, y_2 \equiv f(x_2)]$, namely,

$$P(x) = \frac{x - x_2}{x_1 - x_2} y_1 + \frac{x - x_1}{x_2 - x_1} y_2. \quad (8.5)$$

In practice, it is difficult to estimate the formal error bound for this method, since it depends on knowledge of the $(n + 1)$ -th derivative. Alternatively, one uses *iterated interpolation*, in which successively higher-order approximations are tried until appropriate agreement is obtained. *Neville's algorithm* defines a recursive procedure to yield an arbitrary order interpolant from polynomials of lower order. This method and subtle refinements of it form the basis for most recommended polynomial interpolation schemes [3–5].

One important word of caution to bear in mind is that the more points used in constructing the interpolant, and therefore the higher the polynomial order, the greater will be the oscillation in the interpolating function. This highly oscillating polynomial most likely will not correspond more closely to the desired function than polynomials of lower order. As a general rule of thumb, fewer than six points should be used.

Cubic Splines

By dividing the interval of interest into a number of subintervals and in each using a polynomial of only modest order, one may avoid the oscillatory nature of high-order (many-point) interpolants. This approach utilizes *piecewise polynomial functions*, the simplest of which is just a linear segment. However, such a straight line approximation has a discontinuous derivative at the data points – a property that one may wish to avoid, especially if the derivative of the function is also desired – and which clearly does not provide a smooth interpolant. The solution, therefore, is to choose the polynomial of lowest order that has enough free parameters (the constants a_0, a_1, \dots) to satisfy the constraints that the function and its derivative are continuous across the subintervals, as well as specifying the derivative at the endpoints x_0 and x_n .

Piecewise cubic polynomials satisfy these constraints and have a continuous second derivative as well. *Cubic spline interpolation* does not, however, guarantee that the derivatives of the interpolant agree with those of the function at the data

points, much less globally. The cubic polynomial in each interval has four undetermined coefficients,

$$P_i(x) = a_i + b_i(x - x_i) + c_i(x - x_i)^2 + d_i(x - x_i)^3, \quad (8.6)$$

for $i = 0, 1, \dots, n - 1$. Applying the constraints, a system of equations is found that may be solved once the endpoint derivatives are specified. If the second derivatives at the endpoints are set to zero, then the result is termed a *natural spline*, and its shape is like that which a long flexible rod would take if forced to pass through all the data points. A *clamped spline* results if the first derivatives are specified at the endpoints, and is usually a better approximation since it incorporates more information about the function (if one has a reasonable way to determine or approximate these first derivatives).

The set of equations in the unknowns, along with the boundary conditions, constitute a *tridiagonal system or matrix*, and is therefore amenable to solution by algorithms designed for speed and efficiency for such systems (Sect. 8.3; [1–5]). Other alternatives of potentially significant utility are schemes based on the use of rational functions and orthogonal polynomials.

Rational Function Interpolation

If the function that one seeks to interpolate has one or more poles for real x , then polynomial approximations are not good, and a better method is to use quotients of polynomials, so-called *rational functions*. This occurs since the inverse powers of the dependent variable will fit the region near the pole better if the order is large enough. In fact, if the function is free of poles on the real axis but its analytic continuation in the complex plane has poles, the polynomial approximation may also be poor. It is this property that slows or prevents the convergence of power series. Numerical algorithms very similar to those used to generate iterated polynomial interpolants exist [1, 3–5] and can be useful for functions that are not amenable to polynomial interpolation. Rational function interpolation is related to the method of *Padé approximation* used to improve convergence of power series. This is a rational function analog of Taylor expansion.

Orthogonal Function Interpolation

Interpolation using functions other than the algebraic polynomials can be defined and are often useful. Particularly worthy of mention are schemes based on *orthogonal polynomials* since they play a central role in numerical quadrature. A set of functions $\phi_1(x), \phi_2(x), \dots, \phi_n(x)$ defined on the interval $[a, b]$ is said to be orthogonal with respect to a weight function $\mathcal{W}(x)$, if the inner product defined by

$$\langle \phi_i | \phi_j \rangle = \int_a^b \phi_i(x) \phi_j(x) \mathcal{W}(x) dx \quad (8.7)$$

is zero for $i \neq j$ and positive for $i = j$. In this case, for any polynomial $P(x)$ of degree at most n , there exists unique constants α_k such that

$$P(x) = \sum_{k=0}^n \alpha_k \phi_k(x). \quad (8.8)$$

Among the more commonly used orthogonal polynomials are *Legendre*, *Laguerre*, and *Chebyshev* polynomials.

Chebyshev Interpolation

The significant advantages of employing a representation of a function in terms of Chebyshev polynomials, $T_k(x)$, i.e.,

$$f(x) = \sum_{k=0}^{\infty} a_k T_k(x), \quad (8.9)$$

stems from the fact that (i) the expansion rapidly converges, (ii) the polynomials have a simple form, and (iii) the polynomial approximates the solution of the *minimax* problem very closely. This latter property refers to the requirement that the expansion *minimizes* the *maximum* magnitude of the error of the approximation. In particular, the Chebyshev series expansion can be truncated, so that for a given n it yields the most accurate approximation to the function. Thus, Chebyshev polynomial interpolation is essentially as good as one can hope to do. Since these polynomials are defined on the interval $[-1, 1]$, if the endpoints of the interval in question are a and b , the change of variable

$$y = \frac{x - \frac{1}{2}(b + a)}{\frac{1}{2}(b - a)} \quad (8.10)$$

will affect the proper transformation. *Press et al.* [3–5], for example, give convenient and efficient routines for computing the Chebyshev expansion of a function. See [7, 10] for tabulations, recurrence formulas, orthogonality properties, etc., of these polynomials.

8.1.2 Fitting

Fitting of data stands in distinction from interpolation in that the data may have some uncertainty. Therefore, simply determining a polynomial that passes through the points may not yield the best approximation of the underlying function. In fitting, one is concerned with minimizing the deviations of some model function from the data points in an optimal or best-fit manner. For example, given a set of data points, even a low-order interpolating polynomial might have significant oscillation. In fact, if one accounts for the statistical uncertainties in the data, the best fit may be obtained simply by considering the points to lie on a line.

In addition, most of the traditional methods of assigning this quality of best fit to a particular set of parameters of the model function rely on the assumption that the random deviations are described by a Gaussian (normal) distribution. Results of physical measurements, for example the counting of events, is often closer to a Poisson distribution, which tends (not necessarily uniformly) to a Gaussian in the limit of a large number of events, or may even contain *outliers* that lie far outside a Gaussian distribution. In these cases, fitting methods might significantly distort the parameters of the model function in trying to force these different distributions to the Gaussian form. Thus, the *least-squares* and *chi-square* fitting procedures discussed below should be used with this caveat in mind. Other techniques, often termed *robust fitting* [3–5, 21], should be used when the distribution is not Gaussian or replete with outliers.

Least Squares

In this common approach to fitting, we wish to determine the m parameters a_l of some function $f(x; a_1, a_2, \dots, a_m)$, in this example depending on one variable, x . In particular, we seek to minimize the sum of the squares of the deviations

$$\sum_{k=1}^n [y(x_k) - f(x_k; a_1, a_2, \dots, a_m)]^2 \quad (8.11)$$

by adjusting the parameters, where the $y(x_k)$ are the n data points. In the simplest case, the model function is just a straight line, $f(x; a_1, a_2) = a_1x + a_2$. Elementary multivariate calculus implies that a minimum occurs if

$$a_1 \sum_{k=1}^n x_k^2 + a_2 \sum_{k=1}^n x_k = \sum_{k=1}^n x_k y_k, \quad (8.12)$$

$$a_1 \sum_{k=1}^n x_k + a_2 n = \sum_{k=1}^n y_k, \quad (8.13)$$

which are called the *normal equations*. Solution of these equations is straightforward, and an error estimate of the fit can be found [3–5]. In particular, variances may be computed for each parameter, as well as measures of the correlation between uncertainties and an overall estimate of the *goodness of fit* of the data.

Chi-Square Fitting

If the data points each have associated with them a different standard deviation, σ_k , the least-squares principle is modified by minimizing the *chi-square*, defined as

$$\chi^2 \equiv \sum_{k=1}^n \left[\frac{y_k - f(x_k; a_1, a_2, \dots, a_m)}{\sigma_k} \right]^2. \quad (8.14)$$

Assuming that the uncertainties in the data points are normally distributed, the chi-square value gives a measure of the

goodness of fit. If there are n data points and m adjustable parameters, then the probability that χ^2 should exceed a particular value purely by chance is

$$Q = Q\left(\frac{n-m}{2}, \frac{\chi^2}{2}\right), \quad (8.15)$$

where $Q(a, x) = \Gamma(a, x)/\Gamma(a)$ is the incomplete gamma function. For small values of Q , the deviations of the fit from the data are unlikely to be by chance, and values close to one are indications of better fits. In terms of the chi-square, reasonable fits often have $\chi^2 \approx n - m$.

Other important applications of the chi-square method include simulation and estimating standard deviations. For example, if one has some idea of the actual (i.e., non-Gaussian) distribution of uncertainties of the data points, Monte Carlo simulation can be used to generate a set of test data points subject to this presumed distribution, and then the fitting procedure may be performed on the simulated data set. This allows one to test the accuracy or applicability of the model function chosen. In other situations, if the uncertainties of the data points are unknown, one can assume that they are all equal to some value, say σ , fit using the chi-square procedure, and solve for the value of σ . Thus, some measure of the uncertainty from this statistical point of view can be provided.

General Least Squares

The least-squares procedure can be generalized, usually by allowing any linear combination of basis functions to determine the model function

$$f(x; a_1, a_2, \dots, a_m) = \sum_{l=1}^m a_l \psi_l(x). \quad (8.16)$$

The basis functions need not be polynomials. Similarly, the formula for chi-square can be generalized and normal equations determined through minimization. The equations may be written in compact form by defining a matrix \mathbf{A} with elements

$$A_{i,j} = \frac{\psi_j(x_i)}{\sigma_i}, \quad (8.17)$$

and a column vector \mathbf{B} with elements

$$B_i = \frac{y_i}{\sigma_i}. \quad (8.18)$$

Then the normal equations are [3–5]

$$\sum_{j=1}^m \alpha_{kj} a_j = \beta_k, \quad (8.19)$$

where

$$[\alpha] = \mathbf{A}^T \mathbf{A}, \quad [\beta] = \mathbf{A}^T \mathbf{B}, \quad (8.20)$$

and a_j are the adjustable parameters. These equations may be solved using standard methods of computational linear algebra such as Gauss–Jordan elimination. Difficulties involving sensitivity to round-off errors can be avoided by using carefully developed codes to perform this solution [3–5]. We note that elements of the inverse of the matrix α are related to the variances associated with the free parameters and to the covariances relating them.

Statistical Analysis of Data

Data generated by an experiment, or from a Monte Carlo simulation, have uncertainties due to the statistical, or random, character of the processes by which they are acquired. Therefore, one must be able to describe certain features of the data statistically, such as their mean, variance and skewness, and the degree to which correlations exist, either between one portion of the data and another, or between the data and some other standard or model distribution. A very readable introduction to this type of analysis was given by *Young* [22], while more comprehensive treatments are also available [23].

8.1.3 Fourier Analysis

The *Fourier transform* takes, for example, a function of time into a function of frequency, or vice versa, namely

$$\tilde{\varphi}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \varphi(t) e^{i\omega t} dt, \quad (8.21)$$

$$\varphi(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{\varphi}(\omega) e^{-i\omega t} d\omega. \quad (8.22)$$

In this case, the time history of the function $\varphi(t)$ may be termed the *signal* and $\tilde{\varphi}(\omega)$ the *frequency spectrum*. Also, if the frequency is related to the energy by $E = \hbar\omega$, one obtains an *energy spectrum* from a signal, and thus the name *spectral methods* for techniques based on the Fourier analysis of signals.

The Fourier transform also defines the relationship between the spatial and momentum representations of wave functions, i.e.,

$$\psi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{\psi}(p) e^{ipx} dp, \quad (8.23)$$

$$\tilde{\psi}(p) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \psi(x) e^{-ipx} dx. \quad (8.24)$$

Along with the closely related *sine*, *cosine*, and *Laplace transforms*, the Fourier transform is an extraordinarily powerful tool in the representation of functions, spectral analysis,

convolution of functions, filtering, and analysis of correlation. Good introductions to these techniques with particular attention to applications in physics can be found in [10, 16, 24]. To implement the Fourier transform numerically, the integral transform pair can be converted to sums

$$\tilde{\varphi}(\omega_j) = \frac{1}{\sqrt{2N2\pi}} \sum_{k=0}^{2N-1} \varphi(t_k) e^{i\omega_j t_k}, \quad (8.25)$$

$$\varphi(t_k) = \frac{1}{\sqrt{2N2\pi}} \sum_{j=0}^{2N-1} \tilde{\varphi}(\omega_j) e^{-i\omega_j t_k}, \quad (8.26)$$

where the functions are *sampled* at $2N$ points. These equations define the *discrete Fourier transform* (DFT). Two cautions in using the DFT are as follows.

First, if a continuous function of time is sampled at, for simplicity, uniformly spaced intervals, (i.e., $t_{i+1} = t_i + \Delta$), then there is a critical frequency $\omega_c = \pi/\Delta$, known as the *Nyquist frequency*, which limits the fidelity of the DFT of this function in that it is *aliased*. That is, components outside the frequency range $-\omega_c$ to ω_c are falsely transformed into this range due to the finite sampling. This effect can be remediated by filtering or windowing techniques. If, however, the function is *bandwidth limited* to frequencies smaller than ω_c , then the DFT does not suffer from this effect, and the signal is completely determined by its samples.

Second, implementing the DFT directly from the equations above would require approximately N^2 multiplications to perform the Fourier transform of a function sampled at N points. A variety of *fast Fourier transform* (FFT) algorithms have been developed (e.g., the Danielson–Lanczos and Cooley–Tukey methods) that require only on the order of $(N/2) \log_2 N$ multiplications. Thus, for even moderately large sets of points, the FFT methods are, indeed, much faster than the direct implementation of the DFT. Issues involved in sampling, aliasing, and selection of algorithms for the FFT are discussed in great detail, for example, in [3–5, 15, 25]. In addition to basic computer codes with which to implement the FFT and related tasks, given, for example, in *Numerical Recipes* [3–5], codes for real and complex valued FFTs that have been implemented and benchmarked on a variety of platforms including parallel computer systems are available, for example, the Fastest Fourier Transform in the West (FFTW) [26].

8.1.4 Approximating Integrals

Polynomial Quadrature

Definite integrals may be approximated through a procedure known as numerical quadrature by replacing the integral by

an appropriate sum, i.e.,

$$\int_a^b f(x)dx \approx \sum_{k=0}^n a_k f(x_k) . \quad (8.27)$$

Most formulas for such approximations are based on the interpolating polynomials described in Sect. 8.1.1, especially the Lagrange polynomials, in which case the coefficients a_k are given by

$$a_k = \int_a^b L_{nk}(x_k)dx . \quad (8.28)$$

If first or second degree Lagrange polynomials are used with a uniform spacing between the data points, one obtains the *trapezoidal* and *Simpson's rules*, i.e.,

$$\int_a^b f(x)dx \approx \frac{\delta}{2} [f(a) + f(b)] + \mathcal{O}[\delta^3 f^{(2)}(\zeta)] , \quad (8.29)$$

$$\int_a^b f(x)dx \approx \frac{\delta}{3} \left[f(a) + 4f\left(\frac{\delta}{2}\right) + f(b) \right] + \mathcal{O}[\delta^5 f^{(4)}(\zeta)] , \quad (8.30)$$

respectively, with $\delta = b - a$, and for some ζ in $[a, b]$.

Other commonly used formulas based on low-order polynomials, generally referred to as *Newton-Cotes* formulas, are described and discussed in detail in numerical analysis texts [1, 2]. Since potentially unwanted rapid oscillations in interpolants may arise, it is generally the case that increasing the order of the quadrature scheme too greatly does not generally improve the accuracy of the approximation. Dividing the interval $[a, b]$ into a number of subintervals and summing the result of application of a low-order formula in each subinterval is usually a much better approach. This procedure, referred to as *composite quadrature*, may be combined with choosing the data points at a nonuniform spacing, decreasing the spacing where the function varies rapidly, and increasing the spacing for economy where the function is smooth to construct an *adaptive quadrature*.

Gaussian Quadrature

If the function whose definite integral is to be approximated can be evaluated explicitly, then the data points (abscissas) can be chosen in a manner in which significantly greater accuracy may be obtained than using Newton-Cotes formulas of equal order. *Gaussian quadrature* is a procedure in which the error in the approximation is minimized owing to this freedom to choose both data points (abscissas) and coefficients. By utilizing orthogonal polynomials and choosing the abscissas at the roots of the polynomials in the interval under

consideration, it can be shown that the coefficients may be optimally chosen by solving a simple set of linear equations.

Thus, a Gaussian quadrature scheme approximates the definite integral of a function multiplied by the weight function appropriate to the orthogonal polynomial being used as

$$\int_a^b \mathcal{W}(x)f(x)dx \approx \sum_{k=1}^n a_k f(x_k) , \quad (8.31)$$

where the function is to be evaluated at the abscissas given by the roots of the orthogonal polynomial, x_k . In this case, the coefficients a_k are often referred to as *weights* but should not be confused with the weight function $\mathcal{W}(x)$ (Sect. 8.1.1). Since the Legendre polynomials are orthogonal over the interval $[-1, 1]$ with respect to the weight function $\mathcal{W}(x) \equiv 1$, this equation has a particularly simple form, leading immediately to the *Gauss-Legendre quadrature*. If $f(x)$ contains the weight function of another of the orthogonal polynomials as a factor, the corresponding *Gauss-Laguerre* or *Gauss-Chebyshev* quadrature should be used.

The roots and coefficients have been tabulated [7] for many common choices of the orthogonal polynomials (e.g., Legendre, Laguerre, Chebyshev) and for various orders. Simple computer subroutines are also available that conveniently compute them [3–5]. Since the various orthogonal polynomials are defined over different intervals, use of the change of variables such as that given in Eq. (8.10) may be required. So, for Gauss-Legendre quadrature we make use of the transformation

$$\int_a^b f(x) dx \approx \frac{(b-a)}{2} \int_{-1}^1 f\left(\frac{(b-a)y + b + a}{2}\right) dy . \quad (8.32)$$

Other Methods

Especially for multidimensional integrals that cannot be reduced analytically to separable or iterated integrals of lower dimension, *Monte Carlo* integration may provide the only means of finding a good approximation. This method is described in Sect. 8.4.3. Also, a convenient quadrature scheme can be devised based on the cubic spline interpolation described in Sect. 8.1.1, since in each subinterval, the definite integral of a cubic polynomial of known coefficients is evident.

8.15 Approximating Derivatives

Numerical Differentiation

The calculation of derivatives from a numerical representation of a function is generally less stable than the calculation of integrals, because differentiation tends to enhance fluctuations and worsen the convergence properties of power series.

For example, if $f(x)$ is twice continuously differentiable on $[a, b]$, then differentiation of the linear Lagrange interpolation formula Eq. (8.5) yields

$$f^{(1)}(x_0) = \frac{f(x_0 + \delta) - f(x_0)}{\delta} + \mathcal{O}[\delta f^{(2)}(\zeta)], \quad (8.33)$$

for some x_0 and ζ in $[a, b]$, where $\delta = b - a$. In the limit $\delta \rightarrow 0$, Eq. (8.33) coincides with the definition of the derivative. However, in practical calculations with finite precision arithmetic, δ cannot be taken too small because of numerical cancellation in the calculation of $f(a + \delta) - f(a)$.

In practice, increasing the order of the polynomial used decreases the truncation error, but at the expense of increasing round-off error, the upshot being that three and five-point approximations are usually the most useful. Various three and five-point formulas are given in standard texts [2, 7, 9]. Two common five-point formulas (centered and forward/backward) are

$$f^{(1)}(x_0) = \frac{1}{12\delta} [f(x_0 - 2\delta) - 8f(x_0 - \delta) + 8f(x_0 + \delta) - f(x_0 + 2\delta)] + \mathcal{O}[\delta^4 f^{(5)}(\zeta)] \quad (8.34)$$

$$f^{(1)}(x_0) = \frac{1}{12\delta} [-25f(x_0) + 48f(x_0 + \delta) - 36f(x_0 + 2\delta) + 16f(x_0 + 3\delta) - 3f(x_0 + 4\delta)] + \mathcal{O}[\delta^4 f^{(5)}(\zeta)]. \quad (8.35)$$

The second formula is useful for evaluating the derivative at the left or right endpoint of the interval, depending on whether δ is positive or negative, respectively.

Derivatives of Interpolated Functions

An interpolating function can be directly differentiated to obtain the derivative at any desired point. For example, if $f(x) \approx a_0 + a_1x + a_2x^2$, then $f^{(1)}(x) = a_1 + 2a_2x$. However, this approach may fail to give the best approximation to $f^{(1)}(x)$ if the original interpolation was optimized to give the best possible representation of $f(x)$.

8.2 Differential and Integral Equations

The subject of differential and integral equations is immense in both richness and scope. The discussion here focuses on techniques and algorithms, rather than the formal aspect of the theory. Further information can be found elsewhere under the broad categories of finite-element and finite-difference methods. The *Numerov method*, which is particularly useful in integrating the Schrödinger equation, is described in great detail in [18].

8.2.1 Ordinary Differential Equations

An *ordinary differential equation* is an equation involving an unknown function and one or more of its derivatives that depend on only one independent variable [27]. The *order* of a differential equation is the order of the highest derivative appearing in the equation. A solution of a general differential equation of order n ,

$$f(t, y, \dot{y}, \dots, y^{(n)}) = 0, \quad (8.36)$$

is a real-valued function $y(t)$ having the following properties: (1) $y(t)$ and its first n derivatives exist, so $y(t)$ and its first $n - 1$ derivatives must be continuous, and (2) $y(t)$ satisfies the differential equation for all t . A unique solution requires the specification of n conditions on $y(t)$ and its derivatives. The conditions may be specified as n initial conditions at a single t to give an *initial-value problem*, or at the end points of an interval to give a *boundary value problem*.

First consider solutions to the simple equation

$$\dot{y} = f(t, y), \quad y(a) = A. \quad (8.37)$$

The methods discussed below can be extended to systems of first-order differential equations and to higher-order differential equations. The methods are referred to as *discrete-variable methods* and generate a sequence of approximate values for $y(t)$, y_1, y_2, y_3, \dots at points t_1, t_2, t_3, \dots . For simplicity, the discussion here assumes a constant spacing h between t points. We shall first describe a class of methods known as *one-step methods* [28]. They have no memory of the solutions at past times; given y_i , there is a recipe for y_{i+1} that depends only on information at t_i . Errors enter into numerical solutions from two sources. The first is the *discretization error* and depends on the method being used. The second is the *computational error* that includes such things as round-off error.

For a solution on the interval $[a, b]$, let the t points be equally spaced; so for some positive integer n and $h = (b - a)/n$, $t_i = a + ih$, $i = 0, 1, \dots, n$. If $a < b$, h is positive, and the integration is forward; if $a > b$, h is negative, and the integration is backward. The latter case could occur in solving for the initial point of a solution curve given the terminal point. A general one-step method can then be written in the form

$$y_{i+1} = y_i + h\Delta(t_i, y_i), \quad y_0 = y(t_0), \quad (8.38)$$

where Δ is a function that characterizes the method. Different Δ functions are displayed next, giving rise to the Taylor-series methods and the Runge–Kutta methods.

Taylor-Series Algorithm

To obtain an approximate solution of order p on $[a, b]$, generate the sequence

$$\begin{aligned} y_{i+1} &= y_i + h \left[f(t_i, y_i) + \cdots + f^{(p-1)}(t_i, y_i) \frac{h^{p-1}}{p!} \right], \\ t_{i+1} &= t_i + h, \quad i = 0, 1, \dots, n-1, \end{aligned} \quad (8.39)$$

where $t_0 = a$, and $y_0 = A$. The Taylor method of order $p = 1$ is known as *Euler's method*:

$$\begin{aligned} y_{i+1} &= y_i + hf(t_i, y_i), \\ t_{i+1} &= t_i + h. \end{aligned} \quad (8.40)$$

Taylor-series methods can be quite effective if the total derivatives of f are not too difficult to evaluate. Software packages are available that perform exact differentiation (ADIFOR, Maple, Mathematica, etc.), facilitating the use of this approach.

Runge–Kutta Methods

Runge–Kutta methods are designed to approximate Taylor-series methods [29] but have the advantage of not requiring explicit evaluations of the derivatives of $f(t, y)$. The basic idea is to use a linear combination of values of $f(t, y)$ to approximate $y(t)$. This linear combination is matched up as closely as possible with a Taylor series for $y(t)$ to obtain methods of the highest possible order p . Euler's method is an example using one function evaluation.

To obtain an approximate solution of order $p = 2$, let $h = (b - a)/n$ and generate the sequences

$$\begin{aligned} y_{i+1} &= y_i + h \left[(1 - \gamma)f(t_i, y_i) \right. \\ &\quad \left. + \gamma f \left[t_i + \frac{h}{2\gamma}, y_i + \frac{h}{2\gamma} f(t_i, y_i) \right] \right], \\ t_{i+1} &= t_i + h, \quad i = 0, 1, \dots, n-1, \end{aligned} \quad (8.41)$$

where $\gamma \neq 0$, $t_0 = a$, $y_0 = A$.

Euler's method is the special case, $\gamma = 0$, and has order 1; the improved Euler method has $\gamma = 1/2$, and the Euler–Cauchy method has $\gamma = 1$.

The Adams–Bashforth and Adams–Moulton Formulas

These formulas furnish important and widely used examples of multistep methods [30]. On reaching a mesh point t_i with approximate solution $y_i \cong y(t_i)$, (usually) approximate solutions $y_{i+1-j} \cong y(t_{i+1-j})$ for $j = 2, 3, \dots, p$ are available. From the differential equation itself, approximations to the derivatives $\dot{y}(t_{i+1-j})$ can be obtained.

An attractive feature of the approach is the form of the underlying polynomial approximation, $P(t)$, to $\dot{y}(t)$ because it can be used to approximate $y(t)$ between mesh points

$$y(t) \cong y_i + \int_{t_i}^t P(t) dt. \quad (8.42)$$

The lowest-order Adams–Bashforth formula arises from interpolating the single value $f_i = f(t_i, y_i)$ by $P(t)$. The interpolating polynomial is constant, so its integration from t_i to t_{i+1} results in $hf(t_i, y_i)$, and the first-order Adams–Bashforth formula:

$$y_{i+1} = y_i + hf(t_i, y_i). \quad (8.43)$$

This is just the forward Euler formula. For constant step size h , the second-order Adams–Bashforth formula is

$$y_{i+1} = y_i + h \left[\left(\frac{3}{2} \right) f(t_i, y_i) - \left(\frac{1}{2} \right) f(t_{i-1}, y_{i-1}) \right]. \quad (8.44)$$

The lowest-order Adams–Moulton formula involves interpolating the single value $f_{i+1} = f(t_{i+1}, y_{i+1})$ and leads to the backward Euler formula

$$y_{i+1} = y_i + hf(t_{i+1}, y_{i+1}), \quad (8.45)$$

which defines y_{i+1} implicitly. From its definition it is clear that it has the same accuracy as the forward Euler method; its advantage is vastly superior stability. The second-order Adams–Moulton method also does not use previously computed solution values; it is called the trapezoidal rule, because it generalizes the trapezoidal rule for integrals to differential equations:

$$y_{i+1} = y_i + \frac{h}{2} [f(t_{i+1}, y_{i+1}) + f(t_i, y_i)]. \quad (8.46)$$

The Adams–Moulton formula of order p is more accurate than the Adams–Bashforth formula of the same order. Hence, it can use a larger step size; the Adams–Moulton formula is also more stable. A code based on such methods is more complex than a Runge–Kutta code, because it must cope with the difficulties of starting the integration and changing the step size. Modern Adams codes attempt to select the most efficient formula at each step, as well as to choose an optimal step size h to achieve a specified accuracy.

8.2.2 Differencing Algorithms for Partial Differential Equations

Differencing schemes, based on flux conservation methods [31], are the modern approach to solving partial differential equations describing the evolution of physical systems.

One begins by writing the balance equations for a single cell and subsequently applying quadratures and interpolation formulas. Such approaches have been successful for the full spectrum of hyperbolic, elliptic, and parabolic equations. For simplicity, we begin by discussing systems involving only one space variable.

As a prototype, consider the parabolic equation

$$c \frac{\partial}{\partial t} u(x, t) = \sigma \frac{\partial^2}{\partial x^2} u(x, t), \quad (8.47)$$

where c and σ are constants, and $u(x, t)$ is the solution. We begin by establishing a grid of points on the xt -plane with step size h in the x direction and step size k in the t -direction. Let spatial grid points be denoted by $x_n = x_0 + nh$ and time grid points by $t_j = t_0 + jk$, where n and j are integers, and (x_0, t_0) is the origin of the space–time grid. The points ξ_{n-1} and ξ_n are introduced to establish a *control interval*. We begin with a conservation statement

$$\begin{aligned} & \int_{\xi_{n-1}}^{\xi_n} dx [r(x, t_{j+1}) - r(x, t_j)] \\ &= \int_{t_j}^{t_{j+1}} dt [q(\xi_{n-1}, t) - q(\xi_n, t)]. \end{aligned} \quad (8.48)$$

This equation states that the change in the field density on the interval (ξ_{n-1}, ξ_n) from time $t = t_j$ to time $t = t_{j+1}$ is given by the flux into this interval at ξ_{n-1} minus the flux out of the interval at ξ_n from time t_j to time t_{j+1} . This expresses the conservation of material in the case that no sources or sinks are present. We relate the field variable u to the physical variables (the density r and the flux q). We consider the case in which the density is assumed to have the form

$$r(x, t) = cu(x, t) + b, \quad (8.49)$$

with c and b constants; thus

$$\begin{aligned} & c \int_{\xi_{n-1}}^{\xi_n} dx [u(x, t_{j+1}) - u(x, t_j)] \\ & \approx c [u(x_n, t_{j+1}) - u(x_n, t_j)] h. \end{aligned} \quad (8.50)$$

When developing conservation-law equations, there are two commonly used strategies for approximating the right-hand-side of Eq. (8.48): (i) left-end-point quadrature

$$\begin{aligned} & \int_{t_j}^{t_{j+1}} dt [q(\xi_{n-1}, t) - q(\xi_n, t)] \\ & \approx [q(\xi_{n-1}, t_j) - q(\xi_n, t_j)] k, \end{aligned} \quad (8.51)$$

and (ii) right-end-point quadrature

$$\begin{aligned} & \int_{t_j}^{t_{j+1}} dt [q(\xi_{n-1}, t) - q(\xi_n, t)] \\ & \approx [q(\xi_{n-1}, t_{j+1}) - q(\xi_n, t_{j+1})] k. \end{aligned} \quad (8.52)$$

Combining Eq. (8.48) with the respective approximations yields: from (i) an *explicit* method

$$\begin{aligned} & c [u(x_n, t_{j+1}) - u(x_n, t_j)] h \\ & \approx [q(\xi_{n-1}, t_j) - q(\xi_n, t_j)] k, \end{aligned} \quad (8.53)$$

and from (ii) an *implicit* method

$$\begin{aligned} & c [u(x_n, t_{j+1}) - u(x_n, t_j)] h \\ & \approx [q(\xi_{n-1}, t_{j+1}) - q(\xi_n, t_{j+1})] k. \end{aligned} \quad (8.54)$$

Using centered-finite-difference formulas to approximate the fluxes at the control points ξ_{n-1} and ξ_n yields

$$q(\xi_{n-1}, t_j) = -\sigma \frac{u(x_n, t_j) - u(x_{n-1}, t_j)}{h}, \quad (8.55)$$

and

$$q(\xi_n, t_j) = -\sigma \frac{u(x_{n+1}, t_j) - u(x_n, t_j)}{h}, \quad (8.56)$$

where σ is a constant. We also obtain similar formulas for the fluxes at time t_{j+1} .

We have used a lower case u to denote the continuous field variable, $u = u(x, t)$. Note that all of the quadrature and difference formulas involving u are stated as approximate equalities. In each of these approximate equality statements, the amount by which the right-hand side differs from the left-hand side is called the truncation error. If u is a well-behaved function (has enough smooth derivatives), then it can be shown that these truncation errors approach zero as the grid spacings, h and k , approach zero.

If U_n^j denotes the exact solution on the grid, from (i) we have the result

$$c(U_n^{j+1} - U_n^j)h^2 = \sigma k (U_{n-1}^j + U_{n+1}^j - 2U_n^j). \quad (8.57)$$

This is an *explicit* method, since it provides the solution to the difference equation at time t_{j+1} , knowing the values at time t_j .

If we use the numerical approximations (ii), we obtain the result

$$c(U_n^{j+1} - U_n^j)h^2 = \sigma k (U_{n-1}^{j+1} + U_{n+1}^{j+1} - 2U_n^{j+1}). \quad (8.58)$$

Note that this equation defines the solution at time t_{j+1} *implicitly*, since a system of algebraic equations is required to be satisfied.

8.2.3 Variational Methods

A common problem in atomic, molecular, and optical physics is to find the extrema or the stationary values of functionals. For example, one might seek the eigenvalues and eigenvectors of a Hamiltonian system, such as via the minimization of the expectation value of the energy of a trial wave function to determine the ground state of an atom or molecule, via so-called *variational methods*. We shall outline in detail the Rayleigh–Ritz method [32]. This method is limited to boundary value problems that can be formulated in terms of the minimization of a functional $J[u]$. For definiteness we consider the case of a differential operator defined by

$$Lu(x) = f(x) , \quad (8.59)$$

with $x = x_i, i = 1, 2, 3$ in R , for example, and with $u = 0$ on the boundary of R . The function $f(x)$ is the source. It is assumed that L is always nonsingular, and in addition, for the Ritz method L is Hermitian. The real-valued functions u are in the Hilbert space Ω of the operator L . We construct the functional $J[u]$ defined as

$$J[u] = \int_{\Omega} dx [u(x)Lu(x) - 2u(x)f(x)] . \quad (8.60)$$

The variational ansatz considers a subspace of Ω , Ω_n , spanned by a class of functions $\phi_n(x)$, and we construct the function $u^n \approx u$ as

$$u^n(x) = \sum_{i=1}^n c_i \phi_i(x) . \quad (8.61)$$

We solve for the coefficients c_i by minimizing $J[u^n]$:

$$\partial_{c_i} J[u^n] = 0 , \quad i = 1, \dots, n . \quad (8.62)$$

These equations are cast into a set of well-behaved algebraic equations

$$\sum_{j=1}^n A_{i,j} c_j = g_i , \quad i = 1, \dots, n , \quad (8.63)$$

with $A_{i,j} = \int_{\Omega} dx \phi_i(x)L\phi_j(x)$, and $g_i = \int_{\Omega} dx \phi_i(x)f(x)$.

Under very general conditions, the functions u^n converge uniformly to u . The main drawback of the Ritz method lies in the assumption of hermiticity of the operator L . For the *Galerkin method* we relax this assumption with no other changes. Thus, we obtain an identical set of equations as above, with the exception that the function g is no longer symmetric. The convergence of the sequence of solutions u^n to u is no longer guaranteed, unless the operator can be separated into a symmetric part L_0 , $L = L_0 + K$, so that $L_0^{-1}K$ is bounded.

8.2.4 Finite Elements

As discussed in Sect. 8.2.2, in the finite-difference method for classical partial differential equations, the solution domain is approximated by a grid of uniformly spaced nodes. At each node, the governing differential equation is approximated by an algebraic expression that references adjacent grid points. A system of equations is obtained by evaluating the previous algebraic approximations for each node in the domain. Finally, the system is solved for each value of the dependent variable at each node. The *finite-element method* evolved from computational approaches to implementation of the variational method and of potentially greater accuracy and flexibility.

In the finite-element method [33], the solution domain can be discretized into a number of uniform or nonuniform finite elements that are connected via nodes. The change of the dependent variable with regard to location is approximated within each element by an interpolation function. The interpolation function is defined relative to the values of the variable at the nodes associated with each element. The original boundary value problem is then replaced with an equivalent integral formulation. The interpolation functions are substituted into the integral equation, integrated, and combined with the results from all other elements in the solution domain.

The results of this procedure can be reformulated into a matrix equation of the form

$$\sum_{j=1}^n A_{i,j} c_j = g_i , \quad i = 1, \dots, n , \quad (8.64)$$

with $A_{i,j} = \int_{\Omega} dx \phi_i(x)L\phi_j(x)$, and $g_i = \int_{\Omega} dx \phi_i(x)f(x)$ exactly as obtained in Sect. 8.2.3. The only difference arises in the definitions of the support functions $\phi_i(x)$. In general, if these functions are piecewise polynomials on some finite domain, they are called finite elements or splines. Finite elements make it possible to deal in a systematic fashion with regions having curved boundaries of an arbitrary shape. Also, one can systematically estimate the accuracy of the solution in terms of the parameters that label the finite-element family, and the solutions are no more difficult to generate than more complex variational methods.

In one space dimension, the simplest finite-element family begins with the set of step functions defined by

$$\phi_i(x) = \begin{cases} 1 & x_{i-1} \leq x \leq x_i \\ 0 & \text{otherwise} . \end{cases} \quad (8.65)$$

The use of these simple *hat* functions as a basis does not provide any advantage over the usual finite-difference schemes. However, for certain problems in two or more dimensions, finite-element methods have distinct advantages

over other methods. Generally, the use of finite elements requires complex, sophisticated computer programs for implementation. The use of higher-order polynomials, commonly called splines, as a basis has been extensively used in atomic and molecular physics. An extensive literature is available [34, 35].

We illustrate the use of the finite-element method by applying it to the Schrödinger equation. In this case, the linear operator L is $H - E$, where, as usual, E is the energy, and the Hamiltonian H is the sum of the kinetic and potential energies, that is, $L = H - E = \mathcal{T} + V - E$ and $Lu(x) = 0$. We define the finite elements through support points, or knots, given by the sequence $\{x_1, x_2, x_3, \dots\}$, which are not necessarily spaced uniformly. Since the *hat* functions have vanishing derivatives, we employ the next more complex basis, that is, *tent* functions, which are piecewise linear functions given by

$$\phi_i(x) = \begin{cases} \frac{x - x_{i-1}}{x_i - x_{i-1}} & x_{i-1} \leq x \leq x_i \\ \frac{x_{i+1} - x}{x_{i+1} - x_i} & x_i \leq x \leq x_{i+1} \\ 0 & \text{otherwise} \end{cases} \quad (8.66)$$

and for which the derivative is given by

$$\frac{d}{dx}\phi_i(x) = \begin{cases} \frac{1}{x_i - x_{i-1}} & x_{i-1} \leq x \leq x_i \\ -\frac{1}{x_{i+1} - x_i} & x_i \leq x \leq x_{i+1} \\ 0 & \text{otherwise} \end{cases} \quad (8.67)$$

The functions have a maximum value of 1 at the midpoint of the interval $[x_{i-1}, x_{i+1}]$, with partially overlapping adjacent elements. In fact, the overlaps may be represented by a matrix \mathbf{O} with elements

$$O_{ij} = \int_{-\infty}^{\infty} dx \phi_i(x)\phi_j(x). \quad (8.68)$$

Thus, if $i = j$,

$$\begin{aligned} O_{ii} &= \int_{x_{i-1}}^{x_i} dx \frac{(x - x_{i-1})^2}{(x_i - x_{i-1})^2} + \int_{x_i}^{x_{i+1}} dx \frac{(x - x_i)^2}{(x_{i+1} - x_i)^2} \\ &= \frac{1}{3}(x_{i+1} - x_{i-1}); \end{aligned} \quad (8.69)$$

if $i = j - 1$,

$$\begin{aligned} O_{ij} &= \int_{x_i}^{x_{i+1}} dx \frac{(x - x_i)(x_{i+1} - x)}{(x_{i+1} - x_i)^2} \\ &= \frac{1}{6}(x_{i+1} - x_i); \end{aligned} \quad (8.70)$$

if $i = j + 1$,

$$\begin{aligned} O_{ij} &= \int_{x_{i-1}}^{x_i} dx \frac{(x - x_{i-1})(x_i - x)}{(x_i - x_{i-1})^2} \\ &= \frac{1}{6}(x_i - x_{i-1}); \end{aligned} \quad (8.71)$$

and $O_{ij} = 0$ otherwise.

The potential energy is represented by the matrix

$$V_{ij} = \int_{-\infty}^{\infty} dx \phi_i(x)V(x)\phi_j(x), \quad (8.72)$$

which may be well approximated by

$$\begin{aligned} V_{ij} &\approx V(x_i) \int_{-\infty}^{\infty} dx \phi_i(x)\phi_j(x) \\ &= V(x_i)O_{ij}, \end{aligned} \quad (8.73)$$

if $x_j - x_i$ is small. The kinetic energy, $\mathcal{T} = -\frac{1}{2}d^2/dx^2$, is similarly given by

$$\mathcal{T}_{ij} = -\frac{1}{2} \int_{-\infty}^{\infty} dx \phi_i(x) \frac{d^2}{dx^2} \phi_j(x), \quad (8.74)$$

which we compute by integrating by parts, since the tent functions have a singular second derivative

$$\mathcal{T}_{ij} = \frac{1}{2} \int_{-\infty}^{\infty} dx \left(\frac{d}{dx} \phi_i(x) \right) \left(\frac{d}{dx} \phi_j(x) \right), \quad (8.75)$$

which in turn is evaluated to yield

$$\mathcal{T}_{ij} = \begin{cases} \frac{x_{i+1} - x_{i-1}}{2(x_i - x_{i-1})(x_{i+1} - x_i)} & i = j \\ \frac{1}{2(x_i - x_{i+1})} & i = j - 1 \\ \frac{1}{2(x_{i-1} - x_i)} & i = j + 1 \\ 0 & \text{otherwise} \end{cases} \quad (8.76)$$

Finally, since the Hamiltonian matrix is $H_{ij} = \mathcal{T}_{ij} + V_{ij}$, the solution vector $u_i(x)$ may be found by solving the eigenvalue equation

$$[H_{ij} - EO_{ij}]u_i(x) = 0. \quad (8.77)$$

Going beyond this simple example, discrete variable representation (DVR) methods, also known as pseudospectral methods, and direct solution of the Schrödinger equation

on numeral grids via finite-difference, finite-element, and high-order interpolant methods, have been adopted broadly in atomic, molecular, and optical physics as the power of computational resources has grown in recent decades. An introduction to DVR methods applied to solving the time-dependent Schrödinger equation for quantum dynamics of molecules, as an example, has been given by *Light* [36, 37].

8.2.5 Integral Equations

Central to much of practical and formal scattering theory is the integral equation and techniques of its solution. For example, in atomic collision theory, the Schrödinger differential equation

$$[E - H_0(\mathbf{r})]\psi(\mathbf{r}) = V(\mathbf{r})\psi(\mathbf{r}), \quad (8.78)$$

where the Hamiltonian $H_0 \equiv -(\hbar^2/2m)\nabla^2 + V_0$ may be solved by exploiting the solution for a delta function source, i.e.,

$$(E - H_0)G(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'). \quad (8.79)$$

In terms of this *Green's function* $G(\mathbf{r}, \mathbf{r}')$, and any solution $\chi(\mathbf{r})$ of the homogeneous equation (i.e., with $V(\mathbf{r}) = 0$), the general solution is

$$\psi(\mathbf{r}) = \chi(\mathbf{r}) + \int d\mathbf{r}' G(\mathbf{r}, \mathbf{r}')V(\mathbf{r}')\psi(\mathbf{r}'), \quad (8.80)$$

for which, given a choice of the functions $G(\mathbf{r}, \mathbf{r}')$ and $\chi(\mathbf{r})$, particular boundary conditions are determined. This integral equation is the Lippmann–Schwinger equation of potential scattering. Further topics on scattering theory are covered in other chapters (especially Chaps. 49 to 62) and in standard texts such as those by *Joachain* [38], *Rodberg*, and *Thaler* [39], and *Goldberger* and *Watson* [40]. Owing especially to the wide variety of specialized techniques for solving integral equations, we briefly survey only a few of the most-frequently applied methods.

Integral Transforms

Certain classes of integral equations may be solved using integral transforms such as the Fourier or Laplace transforms. These integral transforms typically have the form

$$f(x) = \int dx' K(x, x')g(x'), \quad (8.81)$$

where $f(x)$ is the integral transform of $g(x')$ by the kernel $K(x, x')$. Such a pair of functions is the solution of the Schrödinger equation (spatial wave function) and its Fourier transform (momentum representation wave function). *Arfken* [10], *Morse*, and *Feshbach* [12], and *Courant*

and *Hilbert* [13] give other examples, as well as being excellent references for the application of integral equations and Green's functions in mathematical physics. In their analytic form, these transform methods provide a powerful method of solving integral equations for special cases. In addition, they may be implemented by performing the transform numerically.

Power Series Solution

For an equation of the form (in one dimension for simplicity)

$$\psi(r) = \chi(r) + \lambda \int dr' K(r, r')\psi(r'), \quad (8.82)$$

a solution may be found by iteration. That is, as a first approximation, set $\psi_0(r) = \chi(r)$ so that

$$\psi_1(r) = \chi(r) + \lambda \int dr' K(r, r')\chi(r'). \quad (8.83)$$

This may be repeated to form a power series solution, i.e.,

$$\psi_n(r) = \sum_{k=0}^n \lambda^k I_k(r), \quad (8.84)$$

where

$$I_0(r) = \chi(r), \quad (8.85)$$

$$I_1(r) = \int dr' K(r, r')\chi(r'), \quad (8.86)$$

$$I_2(r) = \int dr'' \int dr' K(r, r')K(r', r'')\chi(r''), \quad (8.87)$$

$$I_n(r) = \int dr' \dots \int dr^{(n)} K(r, r')K(r, r'') \dots K(r^{(n-1)}, r^{(n)}). \quad (8.88)$$

If the series converges, then the solution $\psi(r)$ is approached by the expansion. When the Schrödinger equation is cast as an integral equation for scattering in a potential, this iteration scheme leads to the *Born series*, the first term of which is the incident, unperturbed wave, and the second term is usually referred to simply as the *Born approximation*.

Separable Kernels

If the kernel is separable, i.e.,

$$K(r, r') = \sum_{k=1}^n f_k(r)g_k(r'), \quad (8.89)$$

where n is finite, then substitution into the prototype integral equation (8.82) yields

$$\psi(r) = \chi(r) + \lambda \sum_{k=1}^n f_k(r) \int dr' g_k(r')\psi(r'). \quad (8.90)$$

Multiplying by $f_k(r)$, integrating over r , and rearranging yields the set of algebraic equations

$$c_j = b_j + \lambda \sum_{k=1}^n a_{jk} c_k, \quad (8.91)$$

where

$$c_k = \int dr' g_k(r') \psi(r'), \quad (8.92)$$

$$b_k = \int dr f_k(r) \chi(r), \quad (8.93)$$

$$a_{jk} = \int dr g_j(r) f_k(r), \quad (8.94)$$

or, if \mathbf{c} and \mathbf{b} denote vectors, and \mathbf{A} denotes the matrix of constants a_{jk} ,

$$\mathbf{c} = (\mathbf{1} - \lambda \mathbf{A})^{-1} \mathbf{b}. \quad (8.95)$$

The eigenvalues are the roots of the determinantal equation. Substituting these into $(\mathbf{1} - \lambda \mathbf{A})\mathbf{c} = 0$ yields the constants c_k that determine the solution of the original equation. This derivation may be found in the text by *Arfken* [10], along with an explicit example. Even if the kernel is not exactly separable, if it is approximately so, then this procedure can yield a result that can be substituted into the original equation as a first step in an iterative solution.

Numerical Integration

Perhaps the most straightforward method of solving an integral equation is to apply a numerical integration formula such as Gaussian quadrature. An equation of the form

$$\psi(r) = \int dr' K(r, r') \chi(r') \quad (8.96)$$

can be approximated as

$$\psi(r_j) = \sum_{k=1}^n w_k K(r_j, r'_k) \chi(r_k), \quad (8.97)$$

where w_k are quadrature weights, if the kernel is well behaved. However, such an approach is not without pitfalls. In light of the previous section, this approach is equivalent to replacing the integral equation by a set of algebraic equations. In this example, we have

$$\psi_j = \sum_{k=1}^n M_{jk} \chi_k, \quad (8.98)$$

so that the solution of the equation is found by inverting the matrix \mathbf{M} . Since there is no guarantee that this matrix is not ill conditioned, the numerical procedure may not produce meaningful results. In particular, only certain classes of integral equations and kernels will lead to stable solutions.

8.3 Computational Linear Algebra

Previous sections of this chapter dealt with interpolation, differential equations, and related topics. Generally, discretization methodologies lead to classes of algebraic equations. In recent decades, enormous progress has been made in developing algorithms for solving linear-algebraic equations [41]. Many of the most widely adopted computational linear algebra routines are available through *Netlib* [42], a portal developed to facilitate the distribution of such software for use in scientific computation. These routines include packages such as the Basic Linear Algebra Subprograms (BLAS) [42, 43], which performs vector addition, dot products, matrix multiplications, etc., and the Linear Algebra Package (LAPACK, and ScaLAPACK its distributed memory implementation) [42, 44], which is used for solving linear systems of equations, eigenvalue problems, factorizations, and decompositions, etc.

Here, we discuss methods for solving systems of equations such as

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1, \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2, \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m. \end{aligned} \quad (8.99)$$

In these equations, a_{ij} and b_i form the set of known quantities, and x_i must be determined. The solution to these equations can be found if they are linearly independent. Numerically, problems can arise due to truncation and round-off errors that lead to an approximate linear dependence [45]. In this case, the set of equations are approximately singular, and special methods must be invoked. Much of the complexity of modern algorithms comes from minimizing the effects of such errors. For relatively small sets of nonsingular equations, direct methods in which the solution is obtained after a definite number of operations can work well. However, for very large systems iterative techniques are preferable [46].

A great many algorithms are available for solving Eq. (8.99), depending on the structure of the coefficients. For example, if the matrix of coefficients \mathbf{A} is dense, using Gaussian elimination takes $2n^3/3$ operations; if \mathbf{A} is also symmetric and positive definite, using the Cholesky algorithm takes a factor of 2 fewer operations. If \mathbf{A} is triangular, that is, either zero above the diagonal or zero below the diagonal, we can solve the above system by simple substitution in only n^2 operations. For example, if \mathbf{A} arises from solving certain elliptic partial differential equations, such as Poisson's equation, then $\mathbf{A}\mathbf{x} = \mathbf{b}$ can be solved using multigrid methods in only n operations.

We shall outline below how to solve Eq. (8.99) using elementary Gaussian elimination. More advanced methods,

such as the *conjugate gradient*, *generalized minimum residuals*, and the *Lanczos method* are treated elsewhere [47].

To solve $A\mathbf{x} = \mathbf{b}$, we first use Gaussian elimination to factor the matrix A as $PA = LU$, where L is lower triangular, U is upper triangular, and P is a matrix that permutes the rows of A . Then we solve the triangular system $L\mathbf{y} = P\mathbf{b}$ and $U\mathbf{x} = \mathbf{y}$. These last two operations are easily performed using standard linear algebra libraries. The factorization $PA = LU$ takes most of the time. Reordering the rows of A with P is called pivoting and is necessary for numerical stability. In the standard partial pivoting scheme, L has 1s on its diagonal and other entries bounded in absolute value by 1. The simplest version of Gaussian elimination involves adding multiples of one row of A to others to zero out subdiagonal entries, and overwriting A with L and U .

We first describe the decomposition of PA into a product of upper and lower triangular matrices,

$$A' = LU, \quad (8.100)$$

where the matrix A' is defined by $A' = PA$. Writing out the indices, we obtain

$$A'_{ij} = \sum_{k=1}^{\min(i,j)} L_{ik}U_{kj}. \quad (8.101)$$

We shall make the choice

$$L_{ii} = 1. \quad (8.102)$$

These equations have the remarkable property that the elements A'_{ij} of each row can be scanned in turn, writing L_{ij} and U_{ij} into the locations A'_{ij} as we go. At each position (i, j) , only the current A'_{ij} and already-calculated values of $L_{i'j'}$ and $U_{i'j'}$ are required. To see how this works, consider the first few rows. If $i = 1$,

$$A'_{1j} = U_{1j}, \quad (8.103)$$

defining the first row of L and U . The U_{1j} are written over the A'_{1j} , which are no longer needed. If $i = 2$,

$$\begin{aligned} A'_{21} &= L_{21}U_{11}, & j &= 1 \\ A'_{2j} &= L_{21}U_{1j} + U_{2j}, & j &\geq 2. \end{aligned} \quad (8.104)$$

The first line gives L_{21} and the second U_{2j} , in terms of existing elements of L and U . The U_{2j} and L_{21} are written over the A'_{2j} . (Remember that $L_{ii} = 1$ by definition.) If $i = 3$,

$$\begin{aligned} A'_{31} &= L_{31}U_{11}, & j &= 1 \\ A'_{32} &= L_{31}U_{12} + L_{32}U_{22}, & j &= 2 \\ A'_{3j} &= L_{31}U_{1j} + L_{32}U_{2j} + U_{3j}, & j &\geq 3, \end{aligned} \quad (8.105)$$

yielding in turn L_{31}, L_{32} , and U_{3j} , which are written over A'_{3j} .

The algorithm should now be clear. At the i -th row,

$$\begin{aligned} L_{ij} &= U_{jj}^{-1} \left(A'_{ij} - \sum_{k=1}^{j-1} L_{ik}U_{kj} \right), & j &\leq i-1 \\ U_{ij} &= A'_{ij} - \sum_{k=1}^{i-1} L_{ik}U_{kj}, & j &\geq i. \end{aligned} \quad (8.106)$$

We observe from the first line of these equations that the algorithm may run into numerical inaccuracies if any U_{jj} becomes very small. Now $U_{11} = A'_{11}$, while in general $U_{ii} = A'_{ii} - \dots$. Thus the absolute values of the U_{ii} are maximized if the rows are rearranged so that the absolutely largest elements of A' in each column lie on the diagonal. Note that the solutions are unchanged by permuting the rows (same equations, different order).

The *LU decomposition* can now be used to solve the system. This relies on the fact that the inversion of a triangular matrix is a simple process of back substitution. We replace Eq. (8.99) by two systems of equations. Written out in full, the equations for a typical column of \mathbf{y} look like

$$\begin{aligned} L_{11}y_1 &= b'_1, \\ L_{21}y_1 + L_{22}y_2 &= b'_2, \\ L_{31}y_1 + L_{32}y_2 + L_{33}y_3 &= b'_3, \\ &\vdots, \end{aligned} \quad (8.107)$$

where the vector \mathbf{b}' is $\mathbf{p}' = P\mathbf{b}$. Thus, from successive rows, we obtain y_1, y_2, y_3, \dots in turn

$$\begin{aligned} U_{11}x_1 &= y_1, \\ U_{12}x_1 + U_{22}x_2 &= y_2, \\ U_{13}x_1 + U_{23}x_2 + U_{33}x_3 &= y_3, \\ &\vdots, \end{aligned} \quad (8.108)$$

and from successive rows of the latter, we obtain x_1, x_2, x_3, \dots in turn.

Software libraries (*Netlib* [42], described above) also exists for evaluating all the error bounds for dense and band matrices. Gaussian elimination with pivoting is almost always numerically stable, so the error bound one expects from solving these equations is of the order of $n\epsilon$, where ϵ is related to the condition number of the matrix A . A good discussion of errors and conditioning is given in [3–5].

8.4 Monte Carlo Methods

Owing to the continuing rapid development of computational facilities and the ever-increasing desire to perform *ab initio* calculations, the use of Monte Carlo methods is becoming widespread as a means to evaluate previously intractable

multidimensional integrals and to enable complex modeling and simulation.

For example, a wide range of applications broadly classified as *quantum Monte Carlo* have been used to compute, for example, the ground-state eigenfunctions of simple molecules. Also, guided random walks have found application in the computation of Green's functions, and variables chosen randomly, subject to particular constraints, have been used to mimic the electronic distribution of atoms. The latter application, used in the *classical trajectory Monte Carlo technique* (CTMC) described in Chap. 62, allows the statistical quasiquantum representation of ion-atom collisions. CTMC is akin to another class of Monte Carlo simulations, classical molecular dynamics, which is used to describe systems ranging from molecules to solids as being composed of atoms whose movement is governed by classical mechanics subject to quantum mechanically derived potentials.

Here, we summarize the basic tools needed in these methods and how they may be used to produce specific distributions and make tractable the evaluation of multidimensional integrals with complicated boundaries. Detailed descriptions of these methods can be found in [3–5, 18, 48].

8.4.1 Random Numbers

An essential ingredient of any Monte Carlo procedure is the availability of a computer-generated sequence of random numbers that is not periodic and is free of other significant statistical correlations. Often, such numbers are termed *pseudorandom* or *quasirandom*, in distinction to truly random physical processes. While the quality of random number generators supplied with computers has greatly improved over time, it is important to be aware of the potential dangers that can be present. For example, many systems are supplied with a random number generator based on the *linear congruential method*. Typically, a sequence of integers n_1, n_2, n_3, \dots is first produced between 0 and $N - 1$ by using the recurrence relation

$$n_{i+1} = (an_i + b) \bmod N, \quad 0 \leq i < N - 1, \quad (8.109)$$

where a, b, N , and the seed value n_0 are positive integers. Real numbers between 0 and (strictly) 1 are then obtained by dividing by N . The period of this sequence is at most N and depends on the judicious choice of the constants, with N being limited by the word size of the computer. A user who is unsure whether the character of the random numbers generated on a particular computer platform is proper can perform additional randomizing shuffles or use a portable random number generator; both procedures are described in detail in the texts by Knuth [6] and Press et al. [3–5], for example. In addition, tests of random number sequences have

been developed, for example, the widely used tests published by L'Ecuyer and Simard [49].

The need for such tests has grown in the present era of parallel computing, relevant not only to use of parallel random number generators on supercomputers and clusters but also the use of personal computers and workstations employing multicore/multithread, computation. In fact, the scale of Monte Carlo calculations possible on contemporary platforms has exposed deficiencies of many commonly used methods of generating random numbers, leading to development of more robust techniques. These new methods seek to ensure the quality of random numbers, first of all for large sequences within a single stream, as well as for multiple streams (other threads on a single processing unit or across nodes within a cluster). A widely used set of parallel random number generators that pass robust tests was developed and described by Srinivasan, Mascagni, and Ceperley [50], for example.

8.4.2 Distributions of Random Numbers

Most distributions of random numbers begin with sequences generated uniformly between a lower and an upper limit, and are therefore called *uniform deviates*. However, it is often useful to draw the random numbers from other distributions, such as the Gaussian, Poisson, exponential, gamma, or binomial distributions. These are particularly useful in modeling data or supplying input for an event generator or simulator. In addition, as described below, choosing the random numbers according to some weighting function can significantly improve the efficiency of integration schemes based on Monte Carlo sampling.

Perhaps the most direct way to produce the required distribution is the *transformation method*. If we have a sequence of uniform deviates x on $(0, 1)$ and wish to find a new sequence y that is distributed with probability given by some function $f(y)$, it can be shown that the required transformation is given by

$$y(x) = \left[\int_0^y f(y) dy \right]^{-1}. \quad (8.110)$$

Evidently, the indefinite integral must be both known and invertible, either analytically or numerically. Since this is seldom the case for distributions of interest, other less direct methods are most often applied. However, even these other methods often rely on the transformation method as one stage of the procedure. The transformation method may also be generalized to more than one dimension [3–5].

A more widely applicable approach is the *rejection method*, also known as *von Neumann rejection*. In this case, if one wishes to find a sequence y distributed according to $f(y)$, one first chooses another function $\tilde{f}(y)$, called the

comparison function, which is everywhere greater than $f(y)$ on the desired interval. In addition, a way must exist to generate y according to the comparison function, such as use of the transformation method. Thus, the comparison function must be simpler or better known than the distribution to be found. One simple choice is a constant function that is larger than the maximum value of $f(y)$, but choices that are *closer* to $f(y)$ will be much more efficient.

To proceed, y is generated uniformly according to $\tilde{f}(y)$, and another deviate x is chosen uniformly on $(0, 1)$. One then rejects or accepts y , depending on whether x is greater than or less than the ratio $f(y)/\tilde{f}(y)$, respectively. The fraction of trial numbers accepted depends on the ratio of the area under the desired function to that under the comparison function. Clearly, the efficiency of this scheme depends on how few of the numbers initially generated must be rejected, and, therefore, on how closely the comparison function approximates the desired distribution. The Lorentzian distribution, for which the inverse definite integral is known (the tangent function), is a good comparison function for a variety of *bell-shaped* distributions such as the Gaussian (normal), Poisson, and gamma distributions.

Especially for distributions that are functions of more than one variable and possess complicated boundaries, the rejection method is impractical, and the transformation method simply inapplicable. In the 1950s, a method to generate distributions for such situations was developed and applied in the study of statistical mechanics, where multidimensional integrals (e.g., the partition function) must often be solved numerically. It is known as the *Metropolis algorithm*. This procedure, or its variants, has more recently been adopted to aid in the computation of eigenfunctions of complicated Hamiltonians and scattering operators. In essence, the Metropolis method generates a random walk through the space of the dependent variables, and in the limit of a large number of steps in the walk, the points visited approximate the desired distribution.

In its simplest form, the Metropolis method generates this distribution of points by stepping through this space, most frequently taking a step *downhill* but sometimes taking a step *uphill*. That is, given a set of coordinates \mathbf{q} and a desired distribution function $f(\mathbf{q})$, a trial step is taken from the i -th configuration \mathbf{q}_i to the next, depending on whether the ratio $f(\mathbf{q}_{i+1})/f(\mathbf{q}_i)$ is greater or less than 1. If the ratio is greater than 1, the step is accepted, but if it is less than 1, the step is accepted with a probability given by the ratio.

8.4.3 Monte Carlo Integration

The basic idea of Monte Carlo integration is that if a large number of points is generated uniformly randomly in some n -dimensional space, the number falling inside a given re-

gion is proportional to the volume, or definite integral, of the function defining that region. Although this idea is as true in one dimension as it is in n , unless there is a large number (*large* could be as little as three) of dimensions or the boundaries are quite complicated, the numerical quadrature schemes described previously are more accurate and efficient. However, since the Monte Carlo approach is based on just sampling the function at representative points rather than evaluating the function at a large number of finely spaced quadrature points, its advantage for very large problems is apparent.

For simplicity, consider the Monte Carlo method for integrating a function of only one variable; the generalization to n dimensions being straightforward. If we generate N random points uniformly on (a, b) , then in the limit of large N , the integral is

$$\int_a^b f(x)dx \approx \frac{1}{N} \langle f(x) \rangle \pm \sqrt{\frac{\langle f^2(x) \rangle - \langle f(x) \rangle^2}{N}}, \quad (8.111)$$

where

$$\langle f(x) \rangle \equiv \frac{1}{N} \sum_{i=1}^N f(x_i) \quad (8.112)$$

is the arithmetic mean. The probable error given is appropriately a statistical one rather than a rigorous error bound and is the one standard error limit. From this, one can see that the error decreases only as $N^{1/2}$, more slowly than the rate of decrease for the quadrature schemes based on interpolation. Also, the accuracy is greater for relatively smooth functions, since the Monte Carlo generation of points is unlikely to sample narrowly peaked features of the integrand well. To estimate the integral of a multidimensional function with complicated boundaries, find an enclosing volume and generate points uniformly randomly within it. Keeping the enclosing volume as close as possible to the volume of interest minimizes the number of points that fall outside, and therefore increases the efficiency of the procedure.

The Monte Carlo integral is related to the techniques for generating random numbers according to prescribed distributions described in Sect. 8.4.2. If we consider a normalized distribution $w(x)$, known as the *weight function*, then with the change of variables defined by

$$y(x) = \int_a^x w(x')dx', \quad (8.113)$$

the Monte Carlo estimate of the integral becomes

$$\int_a^b f(x)dx \approx \frac{1}{N} \left\langle \frac{f[x(y)]}{w[x(y)]} \right\rangle, \quad (8.114)$$

assuming that the transformation is invertible. Choosing $w(x)$ to behave approximately as $f(x)$ allows a more efficient generation of points within the boundaries of the integrand. This occurs since the uniform distribution of points y results in values of x distributed according to w and, therefore, close to f . This procedure, generally termed the *reduction of variance* of the Monte Carlo integration, improves the efficiency of the procedure to the extent that the transformed function f/w can be made smooth, and that the sampled region is as small as possible but still contains the volume to be estimated.

9.1 Schrödinger Equation

The nonrelativistic Schrödinger equation for a hydrogenic ion of nuclear charge Z in atomic units is

$$\left(-\frac{1}{2}\nabla^2 - \frac{Z}{r}\right)\psi(\mathbf{r}) = E\psi(\mathbf{r}). \quad (9.1)$$

9.1.1 Spherical Coordinates

The separable solutions of Eq. (9.1) in spherical coordinates are

$$\psi(\mathbf{r}) = Y_{\ell m}(\theta, \phi)R_{\ell}(r), \quad (9.2)$$

where $Y_{\ell m}(\theta, \phi)$ is a spherical harmonic as defined by Edmonds [13] and $R_{\ell}(r)$ is a solution of the radial equation

$$\left[-\frac{1}{2}\left(\frac{d^2}{dr^2} + \frac{2}{r}\frac{d}{dr} - \frac{\ell(\ell+1)}{r^2}\right) - \frac{Z}{r}\right]R_{\ell}(r) = ER_{\ell}(r). \quad (9.3)$$

The general solution to Eq. (9.3) is

$$R_{\ell}(r) = r^{\ell}\exp(ikr)[A_1F_1(a; c; z) + BU(a, c, z)], \quad (9.4)$$

where ${}_1F_1$ and U are the regular and irregular solutions of the confluent hypergeometric equation defined in Eqs. (9.130) and (9.131) below, and

$$k = \sqrt{2E}, \quad (9.5)$$

$$a = \ell + 1 - ik^{-1}Z, \quad (9.6)$$

$$c = 2\ell + 2, \quad (9.7)$$

$$z = -2ikr. \quad (9.8)$$

Abstract

This chapter summarizes the solutions of the one-electron nonrelativistic Schrödinger equation, and the one-electron relativistic Dirac equation, for the Coulomb potential. The standard notations and conventions used in the mathematics literature for special functions have been chosen in preference to the notations customarily used in the physics literature whenever there is a conflict. This has been done to facilitate the use of standard reference works such as Abramowitz and Stegun [1], the *Bateman* project [2, 3], *Gradshteyn and Ryzhik* [4], *Jahnke and Emde* [5], *Luke* [6, 7], *Magnus, Oberhettinger, and Soni* [8], *Olver* [9], *Szegö* [10], and the new NIST Digital Library of Mathematical Functions project, which has prepared a hardcover update [11] of *Abramowitz and Stegun* [1] and an online digital library of mathematical functions [12]. The section on special functions contains many of the formulas which are needed to check the results quoted in the previous sections, together with a number of other useful formulas. It includes a brief introduction to asymptotic methods. References to the numerical evaluation of special functions are given.

A and B are arbitrary constants. The solution given in Eq. (9.4) has an $r^{-\ell-1}$ singularity at $r = 0$ unless $B = 0$ or a is a non-positive integer. The leading term for small r is proportional to r^ℓ when $B = 0$ and/or a is a non-positive integer. The large r behavior of the solution for Eq. (9.4) follows from Eqs. (9.134), (9.135), and (9.164) below. Bound state solutions, with energy

$$E = -\frac{1}{2}Z^2n^{-2} \quad (9.9)$$

are obtained when $a = -n + \ell + 1$ where $n > \ell$ is the principal quantum number. The properly normalized bound state solutions are

$$R_{n,\ell}(r) = \frac{2Z}{n^2} \sqrt{\frac{Z(n-\ell-1)!}{(n+\ell)!}} \left(\frac{2Zr}{n}\right)^\ell \times \exp\left(-\frac{Zr}{n}\right) L_{n-\ell-1}^{(2\ell+1)}\left(\frac{2Zr}{n}\right), \quad (9.10)$$

where $L_{n-\ell-1}^{(2\ell+1)}$ is the generalized Laguerre polynomial defined in Eq. (9.187). The relation in Eq. (9.188) shows that ${}_1F_1$ and U are linearly dependent in this case, so that Eq. (9.4) is no longer the general solution of Eq. (9.3). A linearly independent solution for this case can be obtained by replacing the $L_{n-\ell-1}^{(2\ell+1)}(2Zr/n)$ in Eq. (9.10) by the second (irregular) solution $M_{n-\ell-1}^{(2\ell+1)}(2Zr/n)$ of the Laguerre equation (see Eqs. (9.194), (9.196), and (9.197)). The first three $R_{n,\ell}$ are

$$R_{1,0}(r) = 2Z^{3/2} \exp(-Zr), \quad (9.11)$$

$$R_{2,0}(r) = \left(\frac{1}{2}Z\right)^{3/2} (2 - Zr) \exp\left(-\frac{1}{2}Zr\right), \quad (9.12)$$

$$R_{2,1}(r) = \left(\frac{1}{2}Z\right)^{3/2} \left(\frac{1}{3}\right)^{1/2} Zr \exp\left(-\frac{1}{2}Zr\right). \quad (9.13)$$

Additional explicit expressions, together with graphs of some of them, can be found in *Pauling and Wilson* [14].

The $R_{n,\ell}$ can be expanded in powers of $1/n$ [15]

$$R_{n,\ell}(r) = -\left[\frac{2Z^2(n+\ell)!}{(n-\ell-1)!n^{2\ell+4}}\right]^{1/2} \times r^{-1/2} \sum_{k=0}^{\infty} g_k^{(\ell)} \left[(8Zr)^{1/2}\right] n^{-2k}, \quad (9.14)$$

where the functions $g_k^{(\ell)}(z)$ are finite linear combinations of Bessel functions

$$g_k^{(\ell)}(z) = z^{3k} \sum_{m=0}^k a_{k,m}^{(\ell)} J_{2\ell+2m+k+1}(z). \quad (9.15)$$

The coefficients $a_{k,m}^{(\ell)}$ in Eq. (9.15) are calculated recursively from

$$a_{k,m}^{(\ell)} = \frac{(2\ell+2m+k+1)}{32(2k+m)(2\ell+m+2k+1)} \times \frac{1}{(2\ell+2m+k-1)} \times \left[(2\ell+2m+k-1)a_{k-1,m}^{(\ell)} + 32(k-m+1)(2\ell+m-k)a_{k,m-1}^{(\ell)} \right], \quad (9.16)$$

starting with the initial condition

$$a_{0,0}^{(\ell)} = 1. \quad (9.17)$$

The expansion Eq. (9.14) converges uniformly in r for r in any bounded region of the complex r -plane. However, it converges fast enough so that a few terms give a good description of $R_{n,\ell}$ only if r is small. The square root in Eq. (9.14) has not been expanded in inverse powers of n because it has a branch point at $1/n = 1/\ell$ which would reduce the radius of convergence of the expansion to $1/\ell$. In some cases, large n expansions of matrix elements can be obtained by inserting Eq. (9.14) for $R_{n,\ell}$ and integrating term by term; examples can be found in *Drake and Hill* [15]. An asymptotic expansion in powers of $1/n$, which is valid from r equal to an arbitrary fixed positive number through the turning point at $r = 2n^2/Z$ out to $r = \infty$, can be assembled from Eqs. (9.133), (9.166)–(9.181), and (9.188) below.

The $R_{n,\ell}$ are not a complete set because the continuum has been left out. The *Sturmian* functions $\rho_{k,\ell}$, given by

$$\rho_{k,\ell}(\beta; r) = \sqrt{\frac{\beta^3 k!}{\Gamma(k+2\ell+3)}} (\beta r)^\ell e^{-\beta r/2} \times L_k^{(2\ell+2)}(\beta r), \quad (9.18)$$

do form a complete orthonormal set. The positive constant β , which is independent of k and ℓ , sets the length scale for the basis set Eq. (9.18).

9.1.2 Parabolic Coordinates

The Schrödinger equation (9.1) is separable in parabolic coordinates ξ, η, ϕ , which are related to spherical coordinates r, θ, ϕ via

$$\xi = r + z = r[1 + \cos(\theta)], \quad (9.19)$$

$$\eta = r - z = r[1 - \cos(\theta)], \quad (9.20)$$

$$\phi = \phi. \quad (9.21)$$

This separability in a second coordinate system is related to the existence of a *hidden* $O(4)$ symmetry, which is also responsible for the degeneracy of the bound states [16, 17].

The solutions in parabolic coordinates are particularly convenient for derivations of the Stark effect and the Rutherford scattering cross section. The separable solutions of Eq. (9.1) in parabolic coordinates are

$$\psi(\mathbf{r}) = \exp(im\phi)N(\eta)\mathcal{E}(\xi), \quad (9.22)$$

where

$$\begin{aligned} N(\eta) &= \eta^{|m|/2} \exp\left(\frac{1}{2}ik_1\eta\right) \\ &\quad \times [A_1 F_1(a_1; c; -ik_1\eta) \\ &\quad + BU(a_1, c, -ik_1\eta)], \end{aligned} \quad (9.23)$$

$$\begin{aligned} \mathcal{E}(\xi) &= \xi^{|m|/2} \exp\left(\frac{1}{2}ik_2\xi\right) \\ &\quad \times [C_1 F_1(a_2; c; -ik_2\xi) \\ &\quad + DU(a_2, c, -ik_2\xi)], \end{aligned} \quad (9.24)$$

with ${}_1F_1$ and U defined in Eqs. (9.130), (9.131) below, and

$$k_1 = \pm k_2 = \pm\sqrt{2E}, \quad (9.25)$$

$$a_1 = \frac{1}{2}(|m| + 1) - ik_1^{-1}\mu, \quad (9.26)$$

$$a_2 = \frac{1}{2}(|m| + 1) - ik_2^{-1}(Z - \mu), \quad (9.27)$$

$$c = |m| + 1. \quad (9.28)$$

A , B , C , and D are arbitrary constants; μ is the separation constant. An important special case is the well-known *Coulomb function*

$$\begin{aligned} \psi_C(\mathbf{r}) &= \Gamma(1 - ik^{-1}Z) \exp\left(\frac{1}{2}\pi k^{-1}Z + i\mathbf{k} \cdot \mathbf{r}\right) \\ &\quad \times {}_1F_1[ik^{-1}Z; 1; i(kr - \mathbf{k} \cdot \mathbf{r})], \end{aligned} \quad (9.29)$$

which is obtained by orienting the z -axis in the \mathbf{k} direction and taking $m = 0$, $-k_1 = k_2 = |\mathbf{k}|$, $\mu = Z + \frac{1}{2}i|\mathbf{k}|$. ψ_C is normalized to unit incoming flux [see Eq. (9.34) below]. In applications, Z is often replaced by $-Z_1Z_2$, so that the Coulomb potential in Eq. (9.1) becomes $+Z_1Z_2/r$. Equation (9.232), the addition theorem for the spherical harmonics [13, p. 63 Eq. 4.6.6], and the $\lambda = c = 1$ special case of Eq. (9.163) below can be used to expand ψ_C into an infinite sum of solutions of the form Eq. (9.2)

$$\begin{aligned} \psi_C(\mathbf{r}) &= 4\pi \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \frac{\Gamma(\ell + 1 - ik^{-1}Z)}{(2\ell + 1)!} \\ &\quad \times (-2ik)^\ell e^{\pi k^{-1}Z/2} Y_{\ell m}^*(\theta_k, \phi_k) Y_{\ell m}(\theta, \phi) \\ &\quad \times r^\ell e^{ikr} {}_1F_1(\ell + 1 - ik^{-1}Z; 2\ell + 2; -2ikr), \end{aligned} \quad (9.30)$$

where k , θ_k , and ϕ_k are the spherical coordinates of \mathbf{k} . ψ_C can be split into an incoming plane wave and an outgoing spherical wave with the aid of Eq. (9.134) below

$$\psi_C(\mathbf{r}) = \psi_{\text{in}}(\mathbf{r}) + \psi_{\text{out}}(\mathbf{r}), \quad (9.31)$$

where

$$\begin{aligned} \psi_{\text{in}}(\mathbf{r}) &= \exp\left(i\mathbf{k} \cdot \mathbf{r} - \frac{1}{2}\pi k^{-1}Z\right) \\ &\quad \times U[ik^{-1}Z; 1; i(kr - \mathbf{k} \cdot \mathbf{r})], \end{aligned} \quad (9.32)$$

$$\begin{aligned} \psi_{\text{out}}(\mathbf{r}) &= -\frac{\Gamma(1 - ik^{-1}Z)}{\Gamma(ik^{-1}Z)} \exp\left(ikr - \frac{1}{2}\pi k^{-1}Z\right) \\ &\quad \times U[1 - ik^{-1}Z; 1; -i(kr - \mathbf{k} \cdot \mathbf{r})]. \end{aligned} \quad (9.33)$$

The functions ψ_{in} and ψ_{out} can be expanded for $kr - \mathbf{k} \cdot \mathbf{r}$ large with the aid of Eq. (9.164). The result is

$$\begin{aligned} \psi_{\text{in}}(\mathbf{r}) &\approx \exp[i\mathbf{k} \cdot \mathbf{r} - ik^{-1}Z \ln(kr - \mathbf{k} \cdot \mathbf{r})] \\ &\quad \times \sum_{n=0}^{\infty} \frac{(-i)^n}{n!} \left[\frac{\Gamma(ik^{-1}Z + n)}{\Gamma(ik^{-1}Z)} \right]^2 \\ &\quad \times (kr - \mathbf{k} \cdot \mathbf{r})^{-n}, \end{aligned} \quad (9.34)$$

$$\begin{aligned} \psi_{\text{out}}(\mathbf{r}) &\approx -\frac{i\Gamma(1 - ik^{-1}Z)}{\Gamma(ik^{-1}Z)(kr - \mathbf{k} \cdot \mathbf{r})} \\ &\quad \times \exp[ikr - ik^{-1}Z \ln(kr - \mathbf{k} \cdot \mathbf{r})] \\ &\quad \times \sum_{n=0}^{\infty} \frac{i^n}{n!} \left[\frac{\Gamma(1 - ik^{-1}Z + n)}{\Gamma(1 - ik^{-1}Z)} \right]^2 \\ &\quad \times (kr - \mathbf{k} \cdot \mathbf{r})^{-n}. \end{aligned} \quad (9.35)$$

Because Eq. (9.1) is an elliptic partial differential equation, its solutions must be analytic functions of the Cartesian coordinates (except at $r = 0$, where the solutions have cusps). The $n = 0$ special case of Eq. (9.138) shows that ψ_{in} and ψ_{out} are logarithmically singular at $\mathbf{k} \cdot \mathbf{r} = kr$. Thus ψ_{in} and ψ_{out} are not solutions to Eq. (9.1) at $\mathbf{k} \cdot \mathbf{r} = kr$. The logarithmic singularity cancels when ψ_{in} and ψ_{out} are added to form ψ_C , which is a solution to Eq. (9.1).

Bound state solutions, with energy

$$E = -\frac{1}{2}Z^2(n_1 + n_2 + |m| + 1)^{-2}, \quad (9.36)$$

are obtained when $a_1 = -n_1$ and $a_2 = -n_2$ where n_1 and n_2 are non-negative integers. The properly normalized bound state solutions, which can be put into one-one correspondence with the bound state solutions in spherical coordinates,

are

$$\begin{aligned} \psi_{n_1, n_2, m}(\eta, \xi, \phi) &= \sqrt{\frac{\beta^{2|m|+4} n_1! n_2!}{2\pi Z(n_1 + |m|)! (n_2 + |m|)!}} \\ &\times \exp\left[im\phi - \frac{1}{2}\beta(\eta + \xi)\right] \\ &\times (\eta\xi)^{|m|/2} L_{n_1}^{(|m|)}(\beta\eta) L_{n_2}^{(|m|)}(\beta\xi), \end{aligned} \quad (9.37)$$

where

$$\beta = Z(n_1 + n_2 + |m| + 1)^{-1}. \quad (9.38)$$

9.1.3 Momentum Space

The nonrelativistic Schrödinger equation (9.1) becomes the integral equation

$$\frac{1}{2}p^2\phi(\mathbf{p}) - \frac{Z}{2\pi^2} \int \frac{\phi(\mathbf{p}')}{(\mathbf{p} - \mathbf{p}')^2} d^3\mathbf{p}' = E\phi(\mathbf{p}) \quad (9.39)$$

in momentum space. Its solutions are related to the solutions in coordinate space via the Fourier transforms

$$\psi(\mathbf{r}) = (2\pi)^{-3/2} \int \exp(i\mathbf{p} \cdot \mathbf{r}) \phi(\mathbf{p}) d^3\mathbf{p}, \quad (9.40)$$

$$\phi(\mathbf{p}) = (2\pi)^{-3/2} \int \exp(-i\mathbf{p} \cdot \mathbf{r}) \psi(\mathbf{r}) d^3\mathbf{r}. \quad (9.41)$$

A trick of *Fock's* [16, 18] can be used to expose the *hidden* $O(4)$ symmetry of hydrogen and construct the bound state solutions to Eq. (9.39). Let p, θ_p, ϕ_p and p', θ'_p, ϕ'_p be the spherical coordinates of \mathbf{p} and \mathbf{p}' . Change variables from p, p' to χ, χ' via $p = \sqrt{-2E} \tan(\chi/2)$ and $p' = \sqrt{-2E} \tan(\chi'/2)$. This brings Eq. (9.39) to the form

$$\begin{aligned} 2\pi^2 Z^{-1} \sqrt{-2E} [\sec^4[\chi/2] \phi(\mathbf{p})] \\ = \int \frac{[\sec^4(\chi'/2) \phi(\mathbf{p}')] \sin^2(\chi') d\chi' \sin(\theta_p) d\theta_p d\phi_p}{2 - 2[\cos(\chi) \cos(\chi') + \sin(\chi) \sin(\chi') \cos(\gamma')]}, \end{aligned} \quad (9.42)$$

where γ' is the angle between \mathbf{p} and \mathbf{p}' . Equation (9.42) is solved by introducing spherical coordinates and spherical harmonics in four dimensions via a natural extension of the procedure used in three dimensions. Going to polar coordinates on x and y yields the cylindrical coordinates r_2, ϕ, z ; the further step of going to polar coordinates on r_2 and z yields spherical coordinates r_3, θ, ϕ . If there is a fourth coordinate w , spherical coordinates in four dimensions are obtained via the additional step of going to polar coordinates on r_3 and w . The result is

$$x = r_4 \sin(\chi) \sin(\theta) \cos(\phi), \quad (9.43)$$

$$y = r_4 \sin(\chi) \sin(\theta) \sin(\phi), \quad (9.44)$$

$$z = r_4 \sin(\chi) \cos(\theta), \quad (9.45)$$

$$w = r_4 \cos(\chi). \quad (9.46)$$

The volume element, which is easily obtained via the same series of transformations, is

$$dV = r_4^3 dr_4 d\Omega_4, \quad (9.47)$$

$$d\Omega_4 = \sin^2(\chi) d\chi \sin(\theta) d\theta d\phi. \quad (9.48)$$

The four-dimensional spherical harmonics [2, Vol. 2, Chap. XI] are

$$\begin{aligned} Y_{n, \ell, m}(\chi, \theta, \phi) &= 2^{\ell+1} \ell! \sqrt{\frac{n(n-\ell-1)!}{2\pi(n+\ell)!}} \sin^\ell(\chi) \\ &\times C_{n-\ell-1}^{\ell+1}[\cos(\chi)] Y_{\ell m}(\theta, \phi), \end{aligned} \quad (9.49)$$

where $C_{n-\ell-1}^{\ell+1}$ is a Gegenbauer polynomial and $n \geq \ell + 1$ is an integer. They have the orthonormality property

$$\begin{aligned} \int Y_{n, \ell, m}^*(\chi, \theta, \phi) Y_{n', \ell', m'}(\chi, \theta, \phi) d\Omega_4 \\ = \delta_{n, n'} \delta_{\ell, \ell'} \delta_{m, m'}. \end{aligned} \quad (9.50)$$

Equations (9.229) and (9.230) with $\lambda = 1$, (9.231), and the addition theorem for the three dimensional spherical harmonics $Y_{\ell m}$ can be used to show that

$$\begin{aligned} \{1 - 2[\cos(\chi) \cos(\chi') \sin(\chi) \sin(\chi') \cos(\gamma')]\} t + t^2\}^{-1} \\ = \sum_{n=1}^{\infty} \sum_{\ell=0}^{n-1} \sum_{m=-\ell}^{\ell} \frac{2\pi^2}{n} t^{n-1} Y_{n, \ell, m}(\chi, \theta, \phi) \\ \times Y_{n, \ell, m}^*(\chi', \theta', \phi') \end{aligned} \quad (9.51)$$

holds for $|t| < 1$, where γ' is the angle between \mathbf{p} and \mathbf{p}' . Multiply both sides of Eq. (9.51) by $Y_{n, \ell, m}(\chi', \theta', \phi') d\Omega'_4$ (where $d\Omega'_4$ is $d\Omega_4$ with χ, θ, ϕ replaced by χ', θ', ϕ') and use the orthogonality relation Eq. (9.50). The result can be rearranged to the form

$$\begin{aligned} 2\pi^2 n^{-1} t^{n-1} Y_{n, \ell, m}(\chi, \theta, \phi) \\ = \int \frac{Y_{n, \ell, m}(\chi', \theta', \phi') \sin^2(\chi') d\chi' \sin(\theta) d\theta d\phi}{1 - 2[\cos(\chi) \cos(\chi') + \sin(\chi) \sin(\chi') \cos(\gamma')]\} t + t^2}. \end{aligned} \quad (9.52)$$

Analytic continuation can be used to show that Eq. (9.52) is valid for all complex t despite the fact that Eq. (9.51) is restricted to $|t| < 1$. Comparing the $t = 1$ case of Eq. (9.52) with Eq. (9.42) shows that $E = -\frac{1}{2}Z^2 n^{-2}$ in agreement with Eq. (9.9), and that

$$\begin{aligned} \phi(\mathbf{p}) &= \left\{ \begin{array}{l} \text{normalizing} \\ \text{factor} \end{array} \right\} \cos^4(\chi/2) \\ &\times Y_{n, \ell, m}(\chi, \theta, \phi). \end{aligned} \quad (9.53)$$

Transforming from χ back to p brings these to the form

$$\phi(\mathbf{p}) = Y_{\ell m}(\theta_p, \phi_p) F_{n, \ell}(p), \quad (9.54)$$

where the properly normalized radial functions are

$$F_{n,\ell}(p) = 2^{2\ell+2} n^2 \ell! \sqrt{\frac{2(n-\ell-1)!}{\pi Z^3 (n+\ell)!}} \left(\frac{np}{Z}\right)^\ell \times \frac{Z^{2\ell+4}}{(n^2 p^2 + Z^2)^{\ell+2}} \times C_{n-\ell-1}^{\ell+1} \left(\frac{n^2 p^2 - Z^2}{n^2 p^2 + Z^2}\right). \quad (9.55)$$

The first three $F_{n,\ell}$ are

$$F_{1,0}(p) = 4 \sqrt{\frac{2}{\pi Z^3}} \frac{Z^4}{(p^2 + Z^2)^2}, \quad (9.56)$$

$$F_{2,0}(p) = \frac{32}{\sqrt{\pi Z^3}} \frac{Z^4 (4p^2 - Z^2)}{(4p^2 + Z^2)^3}, \quad (9.57)$$

$$F_{2,1}(p) = \frac{128}{\sqrt{3\pi Z^3}} \frac{Z^5 p}{(4p^2 + Z^2)^3}. \quad (9.58)$$

The $F_{n,\ell}$ satisfy the integral equation

$$\frac{1}{2} p^2 F_{n,\ell}(p) - \frac{Z}{\pi p} \int_0^\infty Q_\ell \left(\frac{p^2 + p'^2}{2pp'}\right) F_{n,\ell}(p') p' dp' = E F_{n,\ell}(p), \quad (9.59)$$

which can be obtained by inserting Eq. (9.54) in Eq. (9.39). Here Q_ℓ is the Legendre function of the second kind, which is defined in Eq. (9.233) below.

9.2 Dirac Equation

The relativistic Dirac equation for a hydrogenic ion of nuclear charge Z can be reduced to dimensionless form by using the Compton wavelength $\hbar/(mc)$ for the length scale and the rest mass energy mc^2 for the energy scale. The result is

$$\left(-i\boldsymbol{\alpha} \cdot \nabla + \beta - \frac{Z\alpha}{r}\right) \psi(\mathbf{r}) = E \psi(\mathbf{r}), \quad (9.60)$$

where $\alpha = e^2/(\hbar c)$ is the fine structure constant, and $\boldsymbol{\alpha}$, β are the usual Dirac matrices

$$\boldsymbol{\alpha} = \begin{pmatrix} 0 & \boldsymbol{\sigma} \\ \boldsymbol{\sigma} & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}. \quad (9.61)$$

Here $\boldsymbol{\sigma}$ is a vector whose components are the two by two Pauli matrices, and I is the two by two identity matrix given by

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \\ \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (9.62)$$

The solutions to Eq. (9.60) in spherical coordinates have the form

$$\psi(\mathbf{r}) = \begin{pmatrix} G(r) \chi_\kappa^m(\theta, \phi) \\ iF(r) \chi_{-\kappa}^m(\theta, \phi) \end{pmatrix}, \quad (9.63)$$

where, for positive energy states, $G(r)$ is the radial part of the large component and $iF(r)$ is the radial part of the small component. For negative energy states, $G(r)$ is the radial part of the small component and $iF(r)$ is the radial part of the large component. χ is the two component spinor

$$\chi_\kappa^m = \begin{pmatrix} -\frac{\kappa}{|\kappa|} \left(\frac{\kappa + \frac{1}{2} - m}{2\kappa + 1}\right)^{1/2} Y_{|\kappa + \frac{1}{2}| - \frac{1}{2}, m - \frac{1}{2}} \\ \left(\frac{\kappa + \frac{1}{2} + m}{2\kappa + 1}\right)^{1/2} Y_{|\kappa + \frac{1}{2}| - \frac{1}{2}, m + \frac{1}{2}} \end{pmatrix}. \quad (9.64)$$

The relativistic quantum number κ is related to the total angular momentum quantum number j by

$$\kappa = \pm \left(j + \frac{1}{2}\right). \quad (9.65)$$

Because j takes on the values $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$, κ is restricted to the values $\pm 1, \pm 2, \pm 3, \dots$. The spinor χ_κ^m obeys the useful relations

$$\boldsymbol{\sigma} \cdot \hat{\mathbf{r}} \chi_\kappa^m = -\chi_{-\kappa}^m, \quad (9.66)$$

$$\boldsymbol{\sigma} \cdot \mathbf{L} \chi_\kappa^m = -(\kappa + 1) \chi_\kappa^m, \quad (9.67)$$

where $\hat{\mathbf{r}} = \mathbf{r}/r$ and $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ with $\mathbf{p} = -i\nabla$. Equations (9.66), (9.67), and the identity

$$\boldsymbol{\sigma} \cdot \mathbf{p} = (\boldsymbol{\sigma} \cdot \hat{\mathbf{r}}) \left(\hat{\mathbf{r}} \cdot \mathbf{p} + \frac{i\boldsymbol{\sigma} \cdot \mathbf{L}}{r}\right) \quad (9.68)$$

can be used to derive the radial equations, which are

$$\left(\frac{d}{dr} + \frac{1+\kappa}{r}\right) G(r) - \left(1 + E + \frac{Z\alpha}{r}\right) F(r) = 0, \quad (9.69)$$

$$\left(\frac{d}{dr} + \frac{1-\kappa}{r}\right) F(r) - \left(1 - E - \frac{Z\alpha}{r}\right) G(r) = 0. \quad (9.70)$$

Equations (9.158), (9.159), (9.161), and (9.162) below can be used to show that the general solution to Eqs. (9.69) and (9.70) is

$$G(r) = r^\nu \exp(-\lambda r) (1 + E)^{1/2} \{A[f_2(r) + f_1(r)] + B[f_4(r) + f_3(r)]\}, \quad (9.71)$$

$$F(r) = r^\nu \exp(-\lambda r) (1 - E)^{1/2} \{A[f_2(r) - f_1(r)] + B[f_4(r) - f_3(r)]\}, \quad (9.72)$$

where

$$f_1(r) = (Z\alpha\lambda^{-1} - \kappa)_1 F_1(a; c; 2\lambda r), \quad (9.73)$$

$$f_2(r) = a_1 F_1(a + 1; c; 2\lambda r), \quad (9.74)$$

$$f_3(r) = U(a, c, 2\lambda r), \quad (9.75)$$

$$f_4(r) = (Z\alpha\lambda^{-1} + \kappa) U(a + 1, c, 2\lambda r), \quad (9.76)$$

$$\lambda = (1 + E)^{1/2}(1 - E)^{1/2}, \quad (9.77)$$

$$\gamma = -1 + (\kappa^2 - Z^2\alpha^2)^{1/2}, \quad (9.78)$$

$$a = 1 + \gamma - \lambda^{-1}EZ\alpha, \quad (9.79)$$

$$c = 3 + 2\gamma. \quad (9.80)$$

A and B are arbitrary constants. Because γ is in general not an integer, the solutions have a branch point at $r = 0$, and become infinite at $r = 0$ when $\kappa = \pm 1$, which makes γ negative. The solutions for $E < -1$ and $E > +1$ are in the continuum, which implies that one of the factors $(1 + E)^{1/2}$, $(1 - E)^{1/2}$ is real with the other imaginary. Square integrable solutions, with energy

$$E_{n,\kappa} = \frac{Z}{|Z|} \left[1 + \frac{Z^2\alpha^2}{(n+1+\gamma)^2} \right]^{-1/2}, \quad (9.81)$$

are obtained when $a = -n$ where n is a non-negative integer. The properly normalized square integrable solutions are

$$G_{n,\kappa}(r) = C_{n,\kappa}(2\lambda r)^\gamma \exp(-\lambda r)(1 + E_{n,\kappa})^{1/2} \times [g_{n,\kappa}^{(2)}(r) + g_{n,\kappa}^{(1)}(r)], \quad (9.82)$$

$$F_{n,\kappa}(r) = C_{n,\kappa}(2\lambda r)^\gamma \exp(-\lambda r)(1 - E_{n,\kappa})^{1/2} \times [g_{n,\kappa}^{(2)}(r) - g_{n,\kappa}^{(1)}(r)], \quad (9.83)$$

$$g_{n,\kappa}^{(1)}(r) = (Z\alpha\lambda^{-1} - \kappa)^{1/2} L_n^{(2+2\gamma)}(2\lambda r), \quad (9.84)$$

$$g_{n,\kappa}^{(2)}(r) = -(n+2+2\gamma)(Z\alpha\lambda^{-1} - \kappa)^{-1/2} \times L_{n-1}^{(2+2\gamma)}(2\lambda r), \quad (9.85)$$

$$C_{n,\kappa} = \sqrt{\frac{2\lambda^4 n!}{Z\alpha\Gamma(n+3+2\gamma)}}. \quad (9.86)$$

When $n = 0$, $|Z\alpha\lambda^{-1}| = |\kappa|$, and the value of κ whose sign is the same as the sign of $Z\alpha\lambda^{-1}$ is not permitted. Also, $L_{-1}^{(2+2\gamma)}(2\lambda r)$ is counted as zero, so that $g_{0,\kappa}^{(2)}(r) = 0$.

The eigenvalues and eigenfunctions for the first four states for $Z > 0$ will now be written out explicitly in terms of the variable $\rho = Z\alpha r$. For the $1S_{1/2}$ ground state, with $n = 0$, $j = \frac{1}{2}$, $\kappa = -1$, the formulae are

$$E_{0,-1} = \sqrt{1 - Z^2\alpha^2}, \quad (9.87)$$

$$G_{0,-1}(r) = \sqrt{\frac{4Z^3\alpha^3(1 + E_{0,-1})}{\Gamma(1 + 2E_{0,-1})}} (2\rho)^{E_{0,-1}-1} e^{-\rho}, \quad (9.88)$$

$$F_{0,-1}(r) = -\sqrt{\frac{4Z^3\alpha^3(1 - E_{0,-1})}{\Gamma(1 + 2E_{0,-1})}} (2\rho)^{E_{0,-1}-1} e^{-\rho}. \quad (9.89)$$

The formulae for the $2S_{1/2}$ excited state, with $n = 1$, $j = \frac{1}{2}$, $\kappa = -1$, and for the $2P_{1/2}$ excited state, with $n = 1$, $j = \frac{1}{2}$, $\kappa = 1$, can be written together. They are

$$E_{1,\kappa} = \left(\frac{1}{2} + \frac{1}{2} \sqrt{1 - Z^2\alpha^2} \right)^{1/2}, \quad (9.90)$$

$$G_{1,\kappa}(r) = \sqrt{\frac{Z^3\alpha^3(2E_{1,\kappa} - \kappa)(1 + E_{1,\kappa})}{2E_{1,\kappa}^2 \Gamma(4E_{1,\kappa}^2 + 1)}} \times \rho_1^{2E_{1,\kappa}^2 - 2} e^{-\rho_1/2} \times [(2E_{1,\kappa} - \kappa - 1)(2E_{1,\kappa} + \kappa) - \rho_1], \quad (9.91)$$

$$F_{1,\kappa}(r) = -\sqrt{\frac{Z^3\alpha^3(2E_{1,\kappa} - \kappa)(1 - E_{1,\kappa})}{2E_{1,\kappa}^2 \Gamma(4E_{1,\kappa}^2 + 1)}} \times \rho_1^{2E_{1,\kappa}^2 - 2} e^{-\rho_1/2} \times [(2E_{1,\kappa} - \kappa + 1)(2E_{1,\kappa} + \kappa) - \rho_1], \quad (9.92)$$

where $\rho_1 = \rho/E_{1,\kappa}$. For the $2P_{3/2}$ excited state, with $n = 0$, $j = \frac{3}{2}$, $\kappa = -2$, the formulae are

$$E_{0,-2} = \sqrt{1 - \frac{1}{4}Z^2\alpha^2}, \quad (9.93)$$

$$G_{0,-2}(r) = \sqrt{\frac{Z^3\alpha^3(1 + E_{0,-2})}{2\Gamma(1 + 4E_{0,-2})}} \rho^{2E_{0,-2}-1} e^{-\rho/2}, \quad (9.94)$$

$$F_{0,-2}(r) = -\sqrt{\frac{Z^3\alpha^3(1 - E_{0,-2})}{2\Gamma(1 + 4E_{0,-2})}} \rho^{2E_{0,-2}-1} e^{-\rho/2}. \quad (9.95)$$

9.3 The Coulomb Green's Function

The abstract Green's operator for a Hamiltonian H is the inverse $G(E) = (H - E)^{-1}$. It is used to write the solution to $(H - E)|\xi\rangle = |\eta\rangle$ in the form $|\xi\rangle = G|\eta\rangle$. It has the spectral representation

$$G(E) = \sum_j \frac{1}{E_j - E} |e_j\rangle \langle e_j|. \quad (9.96)$$

The sum over j in Eq. (9.96) runs over *all* of the spectrum of H , including the continuum. For the bound state part of the spectrum, the numbers E_j and vectors $|e_j\rangle$ are the eigenvalues and eigenvectors of H . For the continuous spectrum, $|e_j\rangle \langle e_j|$ is a projection valued measure [19]. The representation Eq. (9.96) shows that $G(E)$ has first order poles at the eigenvalues. The reduced Green's operator (also known as the generalized Green's operator), which is the ordinary Green's operator with the singular terms subtracted out, remains finite when E is at an eigenvalue. It can be calculated from

$$G^{(\text{red})}(E_k) = \lim_{E \rightarrow E_k} \left\{ \frac{\partial}{\partial E} [(E - E_k)G(E)] \right\}. \quad (9.97)$$

The coordinate and momentum space representatives of the abstract Green's operator are the Green's functions. The non-relativistic Coulomb Green's function has been discussed by *Hostler and Schwinger* [20–22]. A unified treatment of the Coulomb Green's functions for the Schrödinger and Dirac equations has been given by *Swainson and Drake* [23–25]. Reduced Green's functions are discussed in the third of the Swainson–Drake papers, and in the paper of *Hill and Huxtable* [26].

9.3.1 The Green's Function for the Schrödinger Equation

The Green's function $G^{(S)}$ for the Schrödinger equation (9.98) is a solution of

$$\left(-\frac{1}{2}\nabla^2 - \frac{Z}{r} - E\right)G^{(S)}(\mathbf{r}, \mathbf{r}'; E) = \delta(\mathbf{r} - \mathbf{r}'). \quad (9.98)$$

An explicit closed form expression for $G^{(S)}$ is

$$G^{(S)}(\mathbf{r}, \mathbf{r}'; E) = \frac{\Gamma(1-\nu)}{2\pi|\mathbf{r} - \mathbf{r}'|} \times \left[W_{\nu, \frac{1}{2}}(z_2) \frac{\partial}{\partial z_1} M_{\nu, \frac{1}{2}}(z_1) - M_{\nu, \frac{1}{2}}(z_1) \frac{\partial}{\partial z_2} W_{\nu, \frac{1}{2}}(z_2) \right], \quad (9.99)$$

where $M_{\nu, 1/2}$ and $W_{\nu, 1/2}$ are the Whittaker functions defined in Eqs. (9.132) and (9.133) below, and

$$\nu = Z(-2E)^{-1/2}, \quad (9.100)$$

$$z_1 = (-2E)^{1/2}(r + r' - |\mathbf{r} - \mathbf{r}'|), \quad (9.101)$$

$$z_2 = (-2E)^{1/2}(r + r' + |\mathbf{r} - \mathbf{r}'|). \quad (9.102)$$

The branch on which $(-2E)^{1/2}$ is positive should be taken when $E < 0$. When $E > 0$, the branch which corresponds to incoming (or outgoing) waves at infinity can be selected with the aid of the asymptotic approximation

$$G^{(S)}(\mathbf{r}, \mathbf{r}'; E) \approx \frac{\Gamma(1-\nu)}{2\pi|\mathbf{r} - \mathbf{r}'|} z_2^\nu \exp(-\frac{1}{2}z_2), \quad (9.103)$$

which holds when $z_2 \gg z_1$. This approximation is obtained by using Eqs. (9.130), (9.132), (9.133), and (9.164) in Eq. (9.99). A number of useful expansions for $G^{(S)}$ can be obtained from the integral representation

$$G^{(S)}(\mathbf{r}, \mathbf{r}'; E) = \frac{2Z}{\nu} \int_0^\infty \left[\coth\left(\frac{1}{2}\rho\right) \right]^{2\nu} \sinh(\rho) \times I_0 \left\{ \nu^{-1} Z \sinh(\rho) (2rr')^{1/2} [1 + \cos(\Theta)] \right\} \times \exp[-\nu^{-1} Z (r + r') \cosh(\rho)] d\rho, \quad (9.104)$$

where Θ is the angle between \mathbf{r} and \mathbf{r}' . These expansions, and other integral representations, can be found in [20–25]. The partial wave expansion of $G^{(S)}$ is

$$G^{(S)}(\mathbf{r}, \mathbf{r}'; E) = \sum_{\ell, m} g_\ell^{(S)}(r, r'; \nu) Y_{\ell m}(\theta, \phi) Y_{\ell m}^*(\theta', \phi'). \quad (9.105)$$

The radial Green's function $g_\ell^{(S)}$ is a solution of the radial equation

$$\left[-\frac{1}{2} \left(\frac{d^2}{dr^2} + \frac{2}{r} \frac{d}{dr} - \frac{\ell(\ell+1)}{r^2} \right) - \frac{Z}{r} - E \right] g_\ell^{(S)}(r, r'; \nu) = \frac{\delta(r - r')}{rr'}. \quad (9.106)$$

The standard method for calculating the Green's function of a second order ordinary differential equation [27, pp. 354–355] yields

$$g_\ell^{(S)}(r, r'; \nu) = \frac{(2Z)^{2\ell+2} \Gamma(\ell+1-\nu)}{(2\ell+1)! \nu^{2\ell+1}} \exp[-\nu^{-1} Z (r + r')] \times (rr')^\ell {}_1F_1(\ell+1-\nu; 2\ell+2; 2\nu^{-1} Z r_<) \times U(\ell+1-\nu, 2\ell+2, 2\nu^{-1} Z r_>), \quad (9.107)$$

where $r_<$ is the smaller of the pair r, r' and $r_>$ is the larger of the pair r, r' . Matrix elements of $g_\ell^{(S)}$ can be calculated with the aid of the formula for the double Laplace transform, which is

$$\int_0^\infty dr \int_0^\infty dr' (rr')^{\ell+1} \exp(-\lambda r - \lambda' r') g_\ell^{(S)}(r, r'; \nu) = \frac{2(2\ell+1)!}{\ell-\nu+1} \left(\frac{\nu}{2Z} \right)^{2\ell+3} \left(\frac{4Z^2}{(\nu\lambda+Z)(\nu\lambda'+Z)} \right)^{2\ell+2} \times {}_2F_1(2\ell+2, \ell-\nu+1; \ell-\nu+2; 1-\zeta), \quad (9.108)$$

where

$$\zeta = \frac{2\nu Z(\lambda + \lambda')}{(\nu\lambda + Z)(\nu\lambda' + Z)}, \quad (9.109)$$

Matrix elements with respect to Slater orbitals can be calculated from Eq. (9.108) by taking derivatives with respect to λ and/or λ' to bring down powers of r and r' . Matrix elements with respect to Laguerre polynomials can be calculated by using Eq. (9.108) to evaluate integrals over the generating function Eq. (9.199) for the Laguerre polynomial [26]. Other methods of calculating matrix elements are discussed in *Swainson and Drake* [23–25]. The Green's function $\tilde{G}^{(S)}$ in momentum space is related to the coordinate space Green's function $G^{(S)}$ via the Fourier transforms

$$G^{(S)}(\mathbf{r}, \mathbf{r}'; E) = (2\pi)^{-3} \int \exp[i(\mathbf{p} \cdot \mathbf{r} - \mathbf{p}' \cdot \mathbf{r}')] \times \tilde{G}^{(S)}(\mathbf{p}, \mathbf{p}'; E) d^3 p d^3 p', \quad (9.110)$$

$$\begin{aligned} \tilde{G}^{(S)}(\mathbf{p}, \mathbf{p}'; E) &= (2\pi)^{-3} \int \exp[-i(\mathbf{p} \cdot \mathbf{r} - \mathbf{p}' \cdot \mathbf{r}')] \\ &\quad \times G^{(S)}(\mathbf{r}, \mathbf{r}'; E) d^3\mathbf{r} d^3\mathbf{r}'. \end{aligned} \quad (9.111)$$

The Green's function $\tilde{G}^{(S)}$ is a solution of

$$\begin{aligned} \left(\frac{1}{2}p^2 - E\right) \tilde{G}^{(S)}(\mathbf{p}, \mathbf{p}'; E) - \frac{Z}{2\pi^2} \int \frac{1}{(\mathbf{p} - \mathbf{p}'')^2} \\ \times \tilde{G}^{(S)}(\mathbf{p}'', \mathbf{p}'; E) d^3\mathbf{p}'' = \delta(\mathbf{p} - \mathbf{p}'). \end{aligned} \quad (9.112)$$

An explicit closed form expression for $\tilde{G}^{(S)}$ is

$$\begin{aligned} \tilde{G}^{(S)}(\mathbf{p}, \mathbf{p}'; E) &= \frac{\delta(\mathbf{p} - \mathbf{p}')}{\frac{1}{2}p^2 - E} + \frac{Z}{2\pi^2 |\mathbf{p} - \mathbf{p}'|^2 \left(\frac{1}{2}p^2 - E\right) \left[\frac{1}{2}(p')^2 - E\right]} \\ &\quad \times \left\{ 1 + \frac{\nu q}{1 - \nu} \left[\left(\frac{1 - q}{1 + q}\right) {}_2F_1\left(1, 1 - \nu; 2 - \nu; \frac{1 - q}{1 + q}\right) \right. \right. \\ &\quad \left. \left. - \left(\frac{1 + q}{1 - q}\right) {}_2F_1\left(1, 1 - \nu; 2 - \nu; \frac{1 + q}{1 - q}\right) \right] \right\}, \end{aligned} \quad (9.113)$$

where

$$q = \sqrt{\frac{2E |\mathbf{p} - \mathbf{p}'|^2}{4E^2 - 4E \mathbf{p} \cdot \mathbf{p}' + (pp')^2}}. \quad (9.114)$$

9.3.2 The Green's Function for the Dirac Equation

The Green's function G_D for the Dirac equation (9.60) is a 4×4 matrix valued solution of

$$\begin{aligned} \left(-i\boldsymbol{\alpha} \cdot \nabla + \beta - \frac{Z\boldsymbol{\alpha}}{r} - E\right) G_D(\mathbf{r}, \mathbf{r}'; E) \\ = \delta(\mathbf{r} - \mathbf{r}') I_4, \end{aligned} \quad (9.115)$$

where I_4 is the 4×4 identity matrix. The partial wave expansion of G_D is

$$G_D(\mathbf{r}, \mathbf{r}'; E) = \sum_{\kappa, m} \begin{pmatrix} G_{11}^{\kappa, m} & -iG_{12}^{\kappa, m} \\ iG_{21}^{\kappa, m} & G_{22}^{\kappa, m} \end{pmatrix}, \quad (9.116)$$

where

$$G_{11}^{\kappa, m} = \chi_{\kappa}^m(\theta, \phi) \chi_{\kappa}^{m\dagger}(\theta', \phi') g_{11}(r, r'; E), \quad (9.117)$$

$$G_{12}^{\kappa, m} = \chi_{\kappa}^m(\theta, \phi) \chi_{-\kappa}^{m\dagger}(\theta', \phi') g_{12}(r, r'; E), \quad (9.118)$$

$$G_{21}^{\kappa, m} = \chi_{-\kappa}^m(\theta, \phi) \chi_{\kappa}^{m\dagger}(\theta', \phi') g_{21}(r, r'; E), \quad (9.119)$$

$$G_{22}^{\kappa, m} = \chi_{-\kappa}^m(\theta, \phi) \chi_{-\kappa}^{m\dagger}(\theta', \phi') g_{22}(r, r'; E). \quad (9.120)$$

The identity

$$\begin{aligned} \delta(\mathbf{r} - \mathbf{r}') I_4 &= \frac{\delta(r - r')}{r r'} \\ &\quad \times \sum_{\kappa, m} \begin{pmatrix} \chi_{\kappa}^m(\theta, \phi) \chi_{\kappa}^{m\dagger}(\theta', \phi') & 0 \\ 0 & \chi_{-\kappa}^m(\theta, \phi) \chi_{-\kappa}^{m\dagger}(\theta', \phi') \end{pmatrix} \end{aligned} \quad (9.121)$$

can be used to show that the radial functions $g_{jk}(r, r'; E)$ satisfy the equation

$$\begin{aligned} \begin{pmatrix} \left(1 - E - \frac{Z\alpha}{r}\right) & -\left(\frac{d}{dr} + \frac{1 - \kappa}{r}\right) \\ \left(\frac{d}{dr} + \frac{1 + \kappa}{r}\right) & -\left(1 + E + \frac{Z\alpha}{r}\right) \end{pmatrix} \\ \times \begin{pmatrix} g_{11}(r, r'; E) & g_{12}(r, r'; E) \\ g_{21}(r, r'; E) & g_{22}(r, r'; E) \end{pmatrix} = \frac{\delta(r - r')}{r r'} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \end{aligned} \quad (9.122)$$

The solution to Eq. (9.122) is

$$\begin{aligned} \begin{pmatrix} g_{11}(r, r'; E) & g_{12}(r, r'; E) \\ g_{21}(r, r'; E) & g_{22}(r, r'; E) \end{pmatrix} &= \frac{(2\lambda)^{1+2\gamma} \Gamma(a)}{\Gamma(3 + 2\gamma)} \\ &\quad \times \left[\Theta(r' - r) \begin{pmatrix} G_{<}(r) \\ F_{<}(r) \end{pmatrix} \begin{pmatrix} G_{>}(r') & F_{>}(r') \end{pmatrix} \right. \\ &\quad \left. + \Theta(r - r') \begin{pmatrix} G_{>}(r) \\ F_{>}(r) \end{pmatrix} \begin{pmatrix} G_{<}(r') & F_{<}(r') \end{pmatrix} \right], \end{aligned} \quad (9.123)$$

where a is defined by Eq. (9.79), Θ is the Heaviside unit function, defined by

$$\Theta(x) = \begin{cases} 1, & x > 0, \\ \frac{1}{2}, & x = 0, \\ 0, & x < 0, \end{cases} \quad (9.124)$$

and the functions $G_{<}$, $F_{<}$, $G_{>}$, and $F_{>}$ are special cases of the homogeneous solutions Eq. (9.71)–(9.80)

$$G_{<}(r) = r^\gamma \exp(-\lambda r) (1 + E)^{1/2} [f_2(r) + f_1(r)], \quad (9.125)$$

$$F_{<}(r) = r^\gamma \exp(-\lambda r) (1 - E)^{1/2} [f_2(r) - f_1(r)], \quad (9.126)$$

$$G_{>}(r) = r^\gamma \exp(-\lambda r) (1 + E)^{1/2} [f_4(r) + f_3(r)], \quad (9.127)$$

$$F_{>}(r) = r^\gamma \exp(-\lambda r) (1 - E)^{1/2} [f_4(r) - f_3(r)]. \quad (9.128)$$

The functions $G_{<}(r)$ and $F_{<}(r)$ obey the boundary conditions at $r = 0$. The functions $G_{>}(r)$ and $F_{>}(r)$ obey the boundary conditions at $r = \infty$. Integral representations and expansions for the Dirac Green's function can be found in [23–25, 28]. Matrix element evaluation is discussed in [23–25].

9.4 Special Functions

This section contains a brief list of formulae for the special functions which appear in the solutions discussed above. Derivations, and many additional formulae, can be found in

the standard reference works listed in the bibliography. For numerically useful approximations and available software packages, see *Olver et al.* [12], and *Lozier and Olver* [29].

9.4.1 Confluent Hypergeometric Functions

The confluent hypergeometric differential equation is

$$\left[z \frac{d^2}{dz^2} + (c - z) \frac{d}{dz} - a \right] w(z) = 0. \quad (9.129)$$

Equation (9.129) has a regular singular point at $r = 0$ with indices 0 and $1 - c$ and an irregular singular point at ∞ . The regular solution to Eq. (9.129) is the confluent hypergeometric function, denoted by ${}_1F_1$ in generalized hypergeometric series notation. It can be defined by the series

$${}_1F_1(a; c; z) = \frac{\Gamma(c)}{\Gamma(a)} \sum_{n=0}^{\infty} \frac{\Gamma(a+n)}{\Gamma(c+n)} \frac{z^n}{n!}. \quad (9.130)$$

The series Eq. (9.130) for ${}_1F_1$ converges for all finite z if c is not a negative integer or zero. It reduces to a polynomial of degree n in z if $a = -n$ where n is a positive integer and c is not a negative integer or zero. The function ${}_1F_1(a; c; z)$ is denoted by the symbol $M(a, c, z)$ in *Abramowitz and Stegun* [1], in *Jahnke and Emde* [5], and in *Olver* [9], by ${}_1F_1(a; c; z)$ in both of *Luke's* books [6, 7] and in *Magnus, Oberhettinger, and Soni* [8], and by $\Phi(a, c; z)$ in the *Bateman* project [2, 3] and *Gradshteyn and Ryzhik* [4]. The irregular solution to Eq. (9.129) is

$$\begin{aligned} U(a, c, z) &= \frac{\Gamma(1-c)}{\Gamma(1+a-c)} {}_1F_1(a; c; z) \\ &+ \frac{\Gamma(c-1)}{\Gamma(a)} z^{1-c} \\ &\times {}_1F_1(1+a-c; 2-c; z). \end{aligned} \quad (9.131)$$

The function $U(a, c, z)$ is multiple-valued, with principal branch $-\pi < \arg z \leq \pi$. It is denoted by the symbol $U(a, c, z)$ in *Abramowitz and Stegun* [1], in *Magnus, Oberhettinger, and Soni* [8], and in *Olver* [9], by $\psi(a; c; z)$ in the first of *Luke's* books [6], by $U(a; c; z)$ in the second of *Luke's* books [7], and by $\Psi(a, c; z)$ in the *Bateman* project [2, 3] and *Gradshteyn and Ryzhik* [4].

The Whittaker functions $M_{\kappa, \mu}$ and $W_{\kappa, \mu}$, which are related to ${}_1F_1$ and U via

$$\begin{aligned} M_{\kappa, \mu}(z) &= \exp\left(-\frac{1}{2}z\right) z^{\mu+\frac{1}{2}} \\ &\times {}_1F_1\left(\mu + \frac{1}{2} - \kappa; 2\mu + 1; z\right), \end{aligned} \quad (9.132)$$

$$\begin{aligned} W_{\kappa, \mu}(z) &= \exp\left(-\frac{1}{2}z\right) z^{\mu+\frac{1}{2}} \\ &\times U\left(\mu + \frac{1}{2} - \kappa, 2\mu + 1, z\right), \end{aligned} \quad (9.133)$$

are sometimes used instead of ${}_1F_1$ and U . For numerical evaluation and a program, see [30, 31].

The regular solution can be written as a linear combination of irregular solutions via

$$\begin{aligned} {}_1F_1(a; c; z) &= \frac{\Gamma(c)}{\Gamma(c-a)} e^{i\pi\epsilon a} U(a, c, z) + \frac{\Gamma(c)}{\Gamma(a)} \\ &\times e^{z+i\pi\epsilon(a-c)} U(c-a, c, -z), \end{aligned} \quad (9.134)$$

$$\epsilon = \begin{cases} +1, & \text{Im } z > 0, \\ -1, & \text{Im } z < 0. \end{cases} \quad (9.135)$$

${}_1F_1$ can also be obtained from U as the discontinuity across a branch cut

$$\begin{aligned} &z^{c-1} \exp(-z) {}_1F_1(a; c; z) \\ &= \frac{\Gamma(1-a)\Gamma(c)}{2\pi i} \\ &\times \left[(ze^{-i\pi})^{c-1} U(c-a, c, ze^{-i\pi}) \right. \\ &\quad \left. - (ze^{i\pi})^{c-1} U(c-a, c, ze^{i\pi}) \right]. \end{aligned} \quad (9.136)$$

The Wronskian of the two solutions is

$$\begin{aligned} &{}_1F_1(a; c; z) \frac{d}{dz} U(a, c, z) - U(a, c, z) \frac{d}{dz} {}_1F_1(a; c; z) \\ &= -\Gamma(c) z^{-c} \frac{\exp(z)}{\Gamma(a)}. \end{aligned} \quad (9.137)$$

A formula for $U(a, c, z)$ when c is the integer $n+1$ can be obtained by taking the $c \rightarrow n+1$ limit of the right-hand side of Eq. (9.131) to obtain

$$\begin{aligned} U(a, n+1, z) &= \frac{(-1)^{n+1}}{\Gamma(a-n)} \\ &\times \left[\frac{1}{n!} \ln(z) {}_1F_1(a; n+1; z) \right. \\ &\quad \left. + \sum_{k=-n}^{\infty} \frac{\Gamma(a+k) a_k z^k}{\Gamma(a)(k+n)!} \right], \end{aligned} \quad (9.138)$$

where

$$a_k = \begin{cases} (-1)^{k+1} (-k-1)!, & -n \leq k \leq -1, \\ [\Psi(k+a) - \Psi(k+1) \\ - \Psi(k+n+1)]/k!, & k \geq 0. \end{cases} \quad (9.139)$$

Here Ψ is the logarithmic derivative of the gamma function

$$\Psi(z) = \Gamma'(z)/\Gamma(z). \quad (9.140)$$

n is a non-negative integer. When $n = 0$, the sum from $k = -n$ to -1 is omitted.

The basic integral representations for ${}_1F_1$ and U are

$${}_1F_1(a; c; z) = \frac{\Gamma(c)}{\Gamma(a)\Gamma(c-a)} \times \int_0^1 e^{zt} t^{a-1} (1-t)^{c-a-1} dt, \quad (9.141)$$

$$U(a, c, z) = \frac{1}{\Gamma(a)} \int_0^\infty e^{-zt} t^{a-1} (1+t)^{c-a-1} dt. \quad (9.142)$$

The basic transformation formulae for ${}_1F_1$ and U are

$${}_1F_1(a; c; z) = e^z {}_1F_1(c-a; c; -z), \quad (9.143)$$

$$U(a, c, z) = z^{1-c} U(a-c+1, 2-c, z). \quad (9.144)$$

The recurrence relations among contiguous functions are

$$(z+2a-c) {}_1F_1(a; c; z) = (a-c) {}_1F_1(a-1; c; z) + a {}_1F_1(a+1; c; z), \quad (9.145)$$

$$(z+a-1) {}_1F_1(a; c; z) = (a-c) {}_1F_1(a-1; c; z) + (c-1) {}_1F_1(a; c-1; z), \quad (9.146)$$

$$c {}_1F_1(a; c; z) = c {}_1F_1(a-1; c; z) + z {}_1F_1(a; c+1; z), \quad (9.147)$$

$$(a+1-c) {}_1F_1(a; c; z) = a {}_1F_1(a+1; c; z) + (1-c) {}_1F_1(a; c-1; z), \quad (9.148)$$

$$c(z+a) {}_1F_1(a; c; z) = a c {}_1F_1(a+1; c; z) + (c-a) z {}_1F_1(a; c+1; z), \quad (9.149)$$

$$c(z+c-1) {}_1F_1(a; c; z) = c(c-1) {}_1F_1(a; c-1; z) + (c-a) {}_1F_1(a; c+1; z), \quad (9.150)$$

$$(z+2a-c)U(a; c; z) = U(a-1; c; z) + a(a-c+1)U(a+1; c; z), \quad (9.151)$$

$$(z+a-1)U(a; c; z) = U(a-1; c; z) + (c-a-1)U(a; c-1; z), \quad (9.152)$$

$$(c-a)U(a; c; z) = -U(a-1; c; z) + zU(a; c+1; z), \quad (9.153)$$

$$(a+1-c)U(a; c; z) = aU(a+1; c; z) + U(a; c-1; z), \quad (9.154)$$

$$(z+a)U(a; c; z) = a(a-c+1)U(a+1; c; z) + zU(a; c+1; z), \quad (9.155)$$

$$(z+c-1)U(a; c; z) = (c-a-1)(c-1)U(a; c-1; z) + zU(a; c+1; z). \quad (9.156)$$

Useful differentiation formulae include

$$\frac{d}{dz} {}_1F_1(a; c; z) = a c^{-1} {}_1F_1(a+1; c+1; z), \quad (9.157)$$

$$\frac{d}{dz} [z^a {}_1F_1(a; c; z)] = a z^{a-1} {}_1F_1(a+1; c; z), \quad (9.158)$$

$$\frac{d}{dz} [e^{-z} z^{c-a-1} {}_1F_1(a+1; c; z)] = (c-a-1) e^{-z} z^{c-a-2} {}_1F_1(a; c; z), \quad (9.159)$$

$$\frac{d}{dz} U(a, c, z) = -a U(a+1, c+1, z), \quad (9.160)$$

$$\frac{d}{dz} [z^a U(a, c, z)] = a(a-c+1) z^{a-1} U(a+1, c, z), \quad (9.161)$$

$$\frac{d}{dz} [e^{-z} z^{c-a-1} U(a+1, c, z)] = -e^{-z} z^{c-a-2} U(a, c, z). \quad (9.162)$$

An important multiplication theorem is

$${}_1F_1(a; c; z_1 z_2) = \sum_{k=0}^\infty \frac{\Gamma(a+k)\Gamma(\lambda+2k)}{k!\Gamma(a)\Gamma(\lambda+k)} (-z_1)^k \times {}_2F_1(-k, \lambda+k; c; z_1) \times {}_1F_1(a+k; \lambda+2k+1; z_2). \quad (9.163)$$

The fundamental asymptotic expansion for large z is

$$U(a, c, z) \approx z^{-a} \sum_{n=0}^\infty \frac{\Gamma(a+n)\Gamma(1+a-c+n)}{n!\Gamma(a)\Gamma(1+a-c)} (-z)^{-n}, \quad -\frac{3}{2}\pi < \arg z < \frac{3}{2}\pi. \quad (9.164)$$

The asymptotic expansion of ${}_1F_1$ for large z is obtained by using Eq. (9.164) and

$$\exp[z + i\pi\epsilon(a-c)]U(c-a, c, -z) \approx e^z z^{a-c} \sum_{n=0}^\infty \frac{\Gamma(c-a+n)\Gamma(1-a+n)}{n!\Gamma(c-a)\Gamma(1-a)} z^{-n}, \quad -\frac{5}{2}\pi < \arg z < \frac{5}{2}\pi, \quad (9.165)$$

which is a consequence of Eq. (9.164), on the right-hand side of Eq. (9.134). In the asymptotic expansion Eq. (9.165), and

in the asymptotic expansion for ${}_1F_1$, the change in the factor $\exp[i\pi\epsilon(a-c)]$ as $\arg z$ passes through zero is compensated by the phase change which comes from a factor $(-z)^{a-c}$ in the asymptotic expansion of $U(c-a, c, -z)$. The change in the factor $\exp(i\pi\epsilon a)$ in the first term of Eq. (9.134) as $\arg z$ passes through zero is not compensated by any other phase change. However, this discontinuity occurs in a region in which this first term is negligible compared to the second term. This is an example of the Stokes phenomenon [32], which occurs because the single-valued function ${}_1F_1$ is being approximated by multiple-valued functions. The large z asymptotic expansion of ${}_1F_1$ is valid for $-\frac{3}{2}\pi < \arg z < \frac{3}{2}\pi$, which is the overlap of the domain of validity of the expansions Eqs. (9.164) and (9.165).

Uniform asymptotic expansions for the Whittaker functions $M_{\kappa,\mu}$ and $W_{\kappa,\mu}$ introduced in Eqs. (9.132), (9.133) have been constructed via Olver's method. The following result [9, p. 412, Ex. 7.3], which holds for x positive, κ large and positive, and μ unrestricted, gives the flavor of these approximations

$$W_{\kappa,\mu}(4\kappa x) = \frac{2^{4/3}\pi^{1/2}\kappa^{\kappa+(1/6)}}{\phi_n(\kappa, \mu)\exp(\kappa)} \left(\frac{x\zeta}{x-1}\right)^{1/4} \times \left\{ \text{Ai}\left[(4\kappa)^{2/3}\zeta\right] \sum_{s=0}^n \frac{A_s(\zeta)}{(4\kappa)^{2s}} + \frac{\text{Ai}'\left[(4\kappa)^{2/3}\zeta\right]}{(4\kappa)^{2/3}} + \sum_{s=0}^n \frac{B_s(\zeta)}{(4\kappa)^{2s}} + \epsilon_{2n+1,2}(4\kappa, \zeta) \right\}. \quad (9.166)$$

Here Ai is the Airy function, and $\epsilon_{2n+1,2}$ is an error term which tends to zero faster than the last term kept when $\kappa \rightarrow \infty$ with n fixed. ζ is related to x by

$$\frac{4}{3}\zeta^{3/2} = (x^2 - x)^{1/2} - \ln\left[x^{1/2} + (x-1)^{1/2}\right], \quad x \geq 1, \quad (9.167)$$

$$\frac{4}{3}(-\zeta)^{3/2} = \cos^{-1}(x^{1/2}) - (x - x^2)^{1/2}, \quad 0 < x \leq 1. \quad (9.168)$$

ζ is an analytic function of x in the neighborhood of $x = 1$; conversely, x is an analytic function of ζ in the neighborhood of $\zeta = 0$. The differential form of the relations Eqs. (9.167) and (9.168) is

$$2\zeta^{1/2}d\zeta = x^{-1/2}(x-1)^{1/2}dx \quad x \geq 1, \quad (9.169)$$

$$2(-\zeta)^{1/2}d\zeta = x^{-1/2}(1-x)^{1/2}dx \quad 0 < x \leq 1. \quad (9.170)$$

A Taylor series expansion of ζ about $x = 1$ is most easily constructed by expanding the $x^{-1/2}$ in Eq. (9.169) or (9.170)

about $x = 1$ and integrating term by term. The opening terms of such an expansion are

$$\zeta = 2^{-2/3} \left[(x-1) - \frac{1}{5}(x-1)^2 + \frac{17}{175}(x-1)^3 \right] + O[(x-1)^4]. \quad (9.171)$$

The coefficient functions A_s and B_s are calculated recursively from

$$B_s(\zeta) = \frac{1}{2\zeta^{1/2}} \int_0^\zeta [\psi(\eta)A_s(\eta) - A_s''(\eta)] \frac{d\eta}{\eta^{1/2}}, \quad x \geq 1, \quad (9.172)$$

$$B_s(\zeta) = \frac{1}{2(-\zeta)^{1/2}} \int_\zeta^0 [\psi(\eta)A_s(\eta) - A_s''(\eta)] \frac{d\eta}{(-\eta)^{1/2}}, \quad 0 < x \leq 1, \quad (9.173)$$

$$A_{s+1}(\zeta) = -\frac{1}{2}B_s'(\zeta) + \frac{1}{2} \int \psi(\zeta)B_s(\zeta)d\zeta, \quad (9.174)$$

$$\psi(\zeta) = \frac{(4\mu^2 - 1)\zeta}{x(x-1)} + \frac{(3-8x)\zeta}{4x(x-1)^3} + \frac{5}{16\zeta^2}. \quad (9.175)$$

The functions $A_s(\zeta)$, $B_s(\zeta)$, and $\psi(\zeta)$, which appear to be singular at $\zeta = 0$, are actually analytic functions of ζ at $\zeta = 0$. The first few coefficient functions are

$$A_0(\zeta) = 1, \quad (9.176)$$

$$B_0(\zeta) = \frac{1}{4}\zeta^{-1/2} \left(\frac{x}{x-1}\right)^{3/2} \left[\left(8\mu^2 - \frac{1}{2}\right) \left(\frac{x}{x-1}\right)^2 - \left(\frac{x}{x-1}\right) + \frac{5}{6} \right] - \frac{5}{48}\zeta^{-2}, \quad (9.177)$$

$$A_1(\zeta) = \frac{1}{4}\zeta^{-1} [B_0(\zeta) - \psi(\zeta)] + \zeta [B_0(\zeta)]^2. \quad (9.178)$$

The function ϕ_n is calculated from

$$\phi_n(\kappa, \mu) = \sum_{s=0}^n \frac{A_s(\infty)}{(4\kappa)^{2s}} - \sum_{s=0}^{n-1} \lim_{\zeta \rightarrow \infty} \frac{\zeta^{1/2}B_s(\zeta)}{(4\kappa)^{2s+1}}. \quad (9.179)$$

The first two ϕ_n are

$$\phi_0(\kappa, \mu) = 1, \quad (9.180)$$

$$\phi_1(\kappa, \mu) = 1 - \left(\frac{12\mu^2 - 1}{24\kappa}\right) + \left(\frac{12\mu^2 - 1}{24\kappa}\right)^2. \quad (9.181)$$

A bound for the error term $\epsilon_{2n+1,2}$ has been given by Olver [9, p. 410, Eq. 7.13]. The extension to the complex case can be found in Skovgaard [33]. Skovgaard's expansions are in powers of $(4\kappa)^{-1}$ instead of $(4\kappa)^{-2}$, because the factor $1/\phi_n(\kappa, \mu)$ has been expanded out in inverse powers of 4κ

in his results; as a consequence, his coefficient functions A_s and B_s differ from Olver's. The corresponding asymptotic expansions for $U(\mu + \frac{1}{2} - \kappa, 2\mu + 1, 4\kappa z)$ and for the Laguerre polynomial

$$L_{\kappa-\mu-1/2}^{(2\mu)}(4\kappa z)$$

can be constructed with the aid of Eqs. (9.133) and (9.188).

Formulae for matrix element integrals can be obtained by inserting the integral representation Eq. (9.141) and interchanging the orders of integration. An example is

$$\int_0^\infty z^\mu {}_1F_1(a_1; c_1; \lambda_1 z) {}_1F_1(a_2; c_2; \lambda_2 z) dz = F_2(\mu + 1, a_1, a_2, c_1, c_2; -\lambda_1, -\lambda_2). \quad (9.182)$$

Here F_2 is one of the hypergeometric functions of two variables introduced by Appell, which can be defined either by the integral representation [2, Vol. 1, p. 230, Eq. 2]

$$F_2(\alpha, \beta, \beta', \gamma, \gamma'; x, y) = \frac{\Gamma(\gamma)\Gamma(\gamma')}{\Gamma(\beta)\Gamma(\beta')\Gamma(\gamma-\beta)\Gamma(\gamma'-\beta')} \times \int_0^1 du \int_0^1 dv u^{\beta-1} v^{\beta'-1} (1-u)^{\gamma-\beta-1} \times (1-v)^{\gamma'-\beta'-1} (1-ux-vy)^{-\alpha}, \quad (9.183)$$

or by the series expansion [2, Vol. 1, p. 224, Eq. 7]

$$F_2(\alpha, \beta, \beta', \gamma, \gamma'; x, y) = \sum_{m=0}^\infty \sum_{n=0}^\infty \frac{\Gamma(\alpha+m+n)}{m!n!\Gamma(\alpha)} \times \frac{\Gamma(\beta+m)\Gamma(\beta'+n)\Gamma(\gamma)\Gamma(\gamma')}{\Gamma(\beta)\Gamma(\beta')\Gamma(\gamma+m)\Gamma(\gamma'+n)} x^m y^n, \quad (9.184)$$

which converges for $|x| + |y| < 1$. Numerical evaluation of F_2 is particularly convenient in the special cases where it can be expressed in terms of ordinary hypergeometric functions ${}_2F_1$ [2, Vol. 1, Chap. 2], which are easy to calculate, or in terms of elementary functions. The key is the formula [2, Vol. 1, p. 238, Eq. 3]

$$F_2(\alpha, \beta, \beta', \alpha, \alpha; x, y) = (1-x)^{-\beta} (1-y)^{-\beta'} \times {}_2F_1\left[\beta, \beta'; \alpha; \frac{xy}{(1-x)(1-y)}\right], \quad (9.185)$$

which shows that it is necessary to get Appell functions F_2 in which the first, fourth, and fifth parameters are equal.

This can be achieved by exploiting whatever freedom in the choice of $a_1, a_2, c_1,$ and c_2 is available, and by using identities such as

$$F_2(\alpha + 2, \beta, \beta', \alpha + 1, \alpha + 1; x, y) = (\alpha + 1)^{-1} \beta' y \times F_2(\alpha + 1, \beta, \beta' + 1, \alpha + 1, \alpha + 1; x, y) + [F_2(\alpha + 1, \beta, \beta', \alpha + 1, \alpha + 1; x, y) + 2(\alpha + 1)^{-2} \beta \beta' x y \times F_2(\alpha + 2, \beta + 1, \beta' + 1, \alpha + 2, \alpha + 2; x, y)] + (\alpha + 1)^{-1} \beta x \times F_2(\alpha + 1, \beta + 1, \beta', \alpha + 1, \alpha + 1; x, y), \quad (9.186)$$

to obtain Appell functions F_2 for which the reduction Eq. (9.185) can be used.

9.4.2 Laguerre Polynomials

The Laguerre polynomials $L_n^{(\alpha)}$ are the polynomial solutions of the differential equation

$$\left[z \frac{d^2}{dz^2} + (\alpha + 1 - z) \frac{d}{dz} + n \right] L_n^{(\alpha)}(z) = 0. \quad (9.187)$$

They are a special case of the confluent hypergeometric function

$$L_n^{(\alpha)}(z) = \frac{\Gamma(n + \alpha + 1)}{n! \Gamma(\alpha + 1)} {}_1F_1(-n; \alpha + 1; z) = \frac{(-1)^n}{n!} U(-n, \alpha + 1, z), \quad (9.188)$$

and are given explicitly by

$$L_n^{(\alpha)}(z) = \sum_{k=0}^n \frac{\Gamma(\alpha + n + 1)}{k!(n-k)! \Gamma(\alpha + k + 1)} (-z)^k. \quad (9.189)$$

The $L_n^{(\alpha)}$ are sometimes called generalized Laguerre polynomials, because $L_n^{(0)}$, which is often denoted by L_n , is the polynomial introduced by Laguerre. This Laguerre polynomial differs from the *associated Laguerre function* for which the symbol L_q^p (with p and q both integers) is often used in the physics literature. The relation between the two is

$$\left[L_q^p(z) \right]_{\text{physics}} = (-1)^{p+q} q! L_{q-p}^{(p)}(z). \quad (9.190)$$

The first three $L_n^{(\alpha)}$ are

$$L_0^{(\alpha)}(z) = 1, \quad (9.191)$$

$$L_1^{(\alpha)}(z) = \alpha + 1 - z, \quad (9.192)$$

$$L_2^{(\alpha)}(z) = \frac{1}{2}(\alpha + 1)(\alpha + 2) - (\alpha + 2)z + \frac{1}{2}z^2. \quad (9.193)$$

Equation (9.188) shows that the irregular solution U does not supply a linearly independent second solution. A second solution which remains linearly independent and finite when α is a positive integer is

$$M_n^{(\alpha)}(z) = -\Gamma(\alpha) \left[z^{-\alpha} {}_1F_1(-n-\alpha; 1-\alpha; z) - \cos(\pi\alpha) \Gamma(1-\alpha) L_n^{(\alpha)}(z) \right]. \quad (9.194)$$

The Wronskian of the two solutions is

$$\begin{aligned} L_n^{(\alpha)}(z) \frac{d}{dz} M_n^{(\alpha)}(z) - M_n^{(\alpha)}(z) \frac{d}{dz} L_n^{(\alpha)}(z) \\ = \Gamma(n+\alpha+1) z^{-\alpha-1} \exp(z) / n!. \end{aligned} \quad (9.195)$$

A formula for $M_n^{(\alpha)}(z)$ when α is a positive integer m can be obtained by taking the $\alpha \rightarrow m$ limit of the right-hand side of Eq. (9.194) to obtain

$$M_n^{(m)}(z) = \ln(z) L_n^{(m)}(z) + \sum_{k=-m}^{\infty} \frac{(n+m)!}{(k+m)!} b_k z^k, \quad (9.196)$$

where

$$b_k = \begin{cases} -(-k-1)/(n-k)!, & -m \leq k \leq -1, \\ (-1)^k [\Psi(n+1-k) - \Psi(k+1) \\ - \Psi(k+m+1)] / [k!(n-k)!], & 0 \leq k \leq n, \\ (-1)^n (k-n-1)! / k!, & k \geq n+1. \end{cases} \quad (9.197)$$

The Rodrigues formula is

$$L_n^{(\alpha)}(z) = \frac{1}{n!} z^{-\alpha} \exp(z) \frac{d^n}{dz^n} [z^{n+\alpha} \exp(-z)]. \quad (9.198)$$

The generating function is

$$(1-w)^{-\alpha-1} \exp\left(-\frac{wz}{1-w}\right) = \sum_{n=0}^{\infty} L_n^{(\alpha)}(z) w^n. \quad (9.199)$$

The Christoffel–Darboux formula is

$$\begin{aligned} \sum_{k=0}^n \frac{k!}{\Gamma(k+\alpha+1)} L_k^{(\alpha)}(w) L_k^{(\alpha)}(z) \\ = \frac{(n+1)! \left[L_n^{(\alpha)}(w) L_{n+1}^{(\alpha)}(z) - L_{n+1}^{(\alpha)}(w) L_n^{(\alpha)}(z) \right]}{\Gamma(n+\alpha+1)(w-z)}. \end{aligned} \quad (9.200)$$

The orthonormality relation is

$$\begin{aligned} \int_0^{\infty} x^{\alpha} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) dx \\ = (n!)^{-1} \Gamma(n+\alpha+1) \delta_{n,n'}. \end{aligned} \quad (9.201)$$

Other useful integration formulae include

$$\begin{aligned} \int_0^{\infty} x^{\alpha+1} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) dx \\ = \frac{\Gamma(n+\alpha+1)}{n!} [-n \delta_{n,n'+1} + (2n+\alpha+1) \delta_{n,n'} \\ - (n+\alpha+1) \delta_{n,n'-1}], \end{aligned} \quad (9.202)$$

$$\begin{aligned} \int_0^{\infty} x^{\alpha-1} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) dx \\ = \frac{\Gamma(n_{<}+\alpha+1)}{n_{<}! \alpha}, \quad n_{<} = \min(n, n'), \end{aligned} \quad (9.203)$$

$$\begin{aligned} \int_0^{\infty} x^{\alpha-2} \exp(-x) L_n^{(\alpha)}(x) L_{n'}^{(\alpha)}(x) dx \\ = \frac{\Gamma(n_{<}+\alpha+1)}{n_{<}! \alpha(\alpha+2)} \left\{ \alpha [(\alpha+1)(n+n') + 4\alpha + 5] \right. \\ \left. \times (1-n_{<}) + 2(n+1)(n'+1) + 2\alpha(n+n') \right\}, \\ n_{<} = \min(n, n'). \end{aligned} \quad (9.204)$$

The differentiation and recursion relations are

$$z \frac{d}{dz} L_n^{(\alpha)}(z) = n L_n^{(\alpha)}(z) - (n+\alpha) L_{n-1}^{(\alpha)}(z), \quad (9.205)$$

$$L_{n+1}^{(\alpha)}(z) = (n+1)^{-1} \left[(2n+\alpha+1-z) L_n^{(\alpha)}(z) - (n+\alpha) L_{n-1}^{(\alpha)}(z) \right]. \quad (9.206)$$

Additional relations can be obtained as special cases of the relations listed above for the confluent hypergeometric function by using the relation Eq. (9.188).

The coefficients c_k in a Laguerre polynomial expansion such as

$$\begin{aligned} F(x) = \sum_{k=0}^{\infty} \frac{k!}{\Gamma(k+\alpha+1)} c_k \\ \times (\beta x)^{\alpha/2} \exp\left(-\frac{1}{2}\beta x\right) L_k^{(\alpha)}(\beta x) \end{aligned} \quad (9.207)$$

are given by the integral

$$c_k = \beta \int_0^{\infty} F(x) (\beta x)^{\alpha/2} \exp\left(-\frac{1}{2}\beta x\right) L_k^{(\alpha)}(\beta x) dx. \quad (9.208)$$

The rate of convergence of the expansion Eq. (9.207) is determined by the asymptotic behavior of the integral Eq. (9.208) for large k . A convenient way of extracting this asymptotic behavior will be described with the special case

$$\alpha = 0, \quad (9.209)$$

$$F(x) = (x+c)^{\nu} \exp(-\gamma x), \quad (9.210)$$

as an example. Since the discussion is intended to be illustrative rather than exhaustive, only the case $\gamma < \frac{1}{2}\beta$ will be considered. The method is based on the generating function Eq. (9.199). The generating function $g(z)$ for the coefficients c_k is given in general by

$$g(z) = \sum_{k=0}^{\infty} c_k z^k = \beta^{(2+\alpha)/2} (1-z)^{-\alpha-1} G\left[\frac{\beta(1+z)}{2(1-z)}\right], \quad (9.211)$$

where G is the Laplace transform

$$G(\lambda) = \int_0^{\infty} x^{\alpha/2} F(x) \exp(-\lambda x) dx. \quad (9.212)$$

The asymptotic analysis of the expansion coefficient c_k begins with the Cauchy integral for c_k , which is

$$c_k = \frac{1}{2\pi i} \int_C z^{-k-1} g(z) dz, \quad (9.213)$$

where the contour C is a small circle which runs counter-clockwise around the origin. The contour C is deformed to give integrals which can be evaluated via standard methods for the asymptotic evaluation of integrals [34, 35]. For the example Eqs. (9.209), (9.210),

$$g(z) = \beta c^{\nu+1} (1-z)^{-1} U[1, \nu+2, t(z)], \quad (9.214)$$

$$t(z) = \frac{(\beta+2\gamma)c + (\beta-2\gamma)cz}{2(1-z)}. \quad (9.215)$$

This $g(z)$ has a branch point on the negative real axis at $z = -(\beta+2\gamma)/(\beta-2\gamma)$, and a combination of a branch point and an essential singularity on the positive real axis at $z = 1$. It is convenient to take the associated branch cuts to run from $-\infty$ to $-(\beta+2\gamma)/(\beta-2\gamma)$ on the negative real axis, and from $+1$ to $+\infty$ on the positive real axis. The contour C can be deformed into the sum of two contours which run clockwise around the branch cuts. Then

$$c_k = c_k^{(1)} + c_k^{(2)}, \quad (9.216)$$

where $c_k^{(1)}$ is the contribution from a contour which runs clockwise around the branch cut from $-\infty$ to $-(\beta+2\gamma)/(\beta-2\gamma)$ on the negative real axis, and $c_k^{(2)}$ is the contribution from a contour which runs clockwise around the branch cut from $+1$ to $+\infty$ on the positive real axis. The asymptotic behavior of $c_k^{(1)}$ can be extracted in straightfor-

ward fashion via the method of Darboux [9, pp. 309–315, 321; 35, pp. 116–122]. The result is

$$c_k^{(1)} = \left(\frac{2\beta}{\beta+2\gamma}\right) \left[\frac{4\beta}{(\beta+2\gamma)(\beta-2\gamma)}\right]^{\nu} (-1)^k \times k^{\nu} \left(\frac{\beta-2\gamma}{\beta+2\gamma}\right)^k [1 + O(k^{-1})]. \quad (9.217)$$

The contribution $c_k^{(2)}$ requires a somewhat different strategy. The first step writes it as an integral along the real axis from $+1$ to $+\infty$ of the jump across the branch cut. Evaluating the jump yields

$$c_k^{(2)} = \frac{\beta}{\Gamma(-\nu)} \int_0^{\infty} dx x^{\nu} \left[\beta + \left(\frac{1}{2}\beta - \gamma\right)x\right]^{-\nu-1} \times \exp\left[-\left(\frac{1}{2}\beta - \gamma\right)c - (k+1)\ln(1+x) - \beta c x^{-1}\right]. \quad (9.218)$$

The integrand in Eq. (9.218) has a saddle point at $x \approx [\beta c / (k+1)]^{1/2}$. The asymptotics for $(k+1)c$ large can be extracted via the method of steepest descent (also known as the saddle point method) [9, pp. 136–138; 35, pp. 85–103; 34], (see Chap. 8). However, if $k+1$ is large with $(k+1)c$ small or moderate, the steepest descent approximation breaks down because the saddle point is too close to the branch point of the integrand at $x = 0$. The breakdown can be cured by using the small x approximations $[\beta + (1/2\beta - \gamma)x]^{-\nu-1} \approx \beta^{-\nu-1}$ and $\ln(1+x) \approx x - 1/2(k+1)^{-1}\beta c$ to obtain

$$c_k^{(2)} = \frac{2\beta}{\Gamma(-\nu)} \left(\frac{c}{(k+1)\beta}\right)^{(\nu+1)/2} \exp(\beta c) \times K_{\nu+1}\left[2\sqrt{(k+1)\beta c}\right] [1 + O(k^{-1/2})]. \quad (9.219)$$

The function $K_{\nu+1}$ which appears in Eq. (9.219) is a modified Bessel function of the third kind in standard notation. The large z approximation $K_{\nu+1}(z) \approx \pi^{1/2} (2z)^{-1/2} \exp(-z)$ can be used to recover the result of a steepest descent approximation to Eq. (9.218), which is

$$c_k^{(2)} = \frac{\pi^{1/2} \beta c^{\nu+1}}{\Gamma(-\nu)} [\beta c (k + \frac{1}{2})]^{-(2\nu+3)/4} \times \exp\left\{\gamma c - 2[\beta c (k + \frac{1}{2})]^{1/2}\right\} \times [1 + O(k^{-1})]. \quad (9.220)$$

The approximation Eq. (9.219) remains valid as $c \rightarrow 0$. The approximation Eq. (9.220) does not.

The generating function method outlined above has one very nice feature: if the singularity in the complex z -plane

which dominates the asymptotics is known, the analysis can be inverted to obtain a *convergence acceleration function* which builds in this singularity, and has no other singularities in the finite complex z -plane. The difference between the original $F(x)$ and this convergence acceleration function will have an expansion of the form Eq. (9.207) which converges faster than the expansion of $F(x)$. Examples can be found in [36–39].

The contributions $c_k^{(1)}$ and $c_k^{(2)}$ exhibit two typical features. The most rapidly varying part, which is

$$[(\beta - 2\gamma)/(\beta + 2\gamma)]^k \quad (9.221)$$

for $c_k^{(1)}$, and

$$\exp\left\{-2\left[\beta c\left(k + \frac{1}{2}\right)\right]^{1/2}\right\} \quad (9.222)$$

for the steepest descent approximation to $c_k^{(2)}$, is determined by the location of the associated singularity. The next most important part, which is k^ν for $c_k^{(1)}$, and $(k + 1/2)^{-(2\nu+3)/4}$ for the steepest descent approximation to $c_k^{(2)}$, is determined by the nature of the singularity (i.e., by the value of ν).

9.4.3 Gegenbauer Polynomials

The Gegenbauer polynomials are a special case of the Jacobi polynomial, and of the hypergeometric function

$$\begin{aligned} C_n^\lambda(z) &= \frac{\Gamma(\lambda + \frac{1}{2})\Gamma(2\lambda + n)}{\Gamma(2\lambda)\Gamma(\lambda + n + \frac{1}{2})} P_n^{(\lambda - \frac{1}{2}, \lambda - \frac{1}{2})}(z) \\ &= \frac{\Gamma(2\lambda + n)}{n!\Gamma(2\lambda)} \\ &\quad \times {}_2F_1\left(-n, n + 2\lambda; \lambda + \frac{1}{2}; \frac{1}{2} - \frac{1}{2}z\right), \end{aligned} \quad (9.223)$$

and are given explicitly by

$$C_n^\lambda(z) = \sum_{k=0}^{[n/2]} \frac{(-1)^k \Gamma(\lambda + n - k)}{k!(n - 2k)!\Gamma(\lambda)} (2z)^{n-2k}. \quad (9.224)$$

The first three C_n^λ are

$$C_0^\lambda(z) = 1, \quad (9.225)$$

$$C_1^\lambda(z) = 2\lambda z, \quad (9.226)$$

$$C_2^\lambda(z) = 2\lambda(\lambda + 1)z^2 - \lambda. \quad (9.227)$$

Additional C_n^λ can be obtained with the aid of the recursion relation

$$\begin{aligned} C_{n+1}^\lambda(z) &= (n + 1)^{-1} [2(n + \lambda)z C_n^\lambda(z) \\ &\quad - (n + 2\lambda - 1)C_{n-1}^\lambda(z)], \end{aligned} \quad (9.228)$$

which is valid for $n \geq 1$. A generating function is

$$(1 - 2zt + t^2)^{-\lambda} = \sum_{n=0}^{\infty} C_n^\lambda(z) t^n. \quad (9.229)$$

An important addition theorem, which can be used to derive addition theorems for spherical harmonics in any number of dimensions, is

$$\begin{aligned} C_n^\lambda[\cos(\gamma)] &= \frac{\Gamma(2\lambda - 1)}{[\Gamma(\lambda)]^2} \sum_{\ell=0}^n \frac{2^{2\ell}(2\lambda + 2\ell - 1)}{\Gamma(n + 2\lambda + \ell)} \\ &\quad \times \Gamma(n - \ell + 1) [\Gamma(\lambda + \ell)]^2 \\ &\quad \times \sin^\ell(\chi) \sin^\ell(\chi') \\ &\quad \times C_{n-\ell}^{\lambda+\ell}[\cos(\chi)] C_{n-\ell}^{\lambda+\ell}[\cos(\chi')] \\ &\quad \times C_\ell^{\lambda-\frac{1}{2}}[\cos(\gamma')], \end{aligned} \quad (9.230)$$

$$\begin{aligned} \cos(\gamma) &= \cos(\chi) \cos(\chi') \\ &\quad + \sin(\chi) \sin(\chi') \cos(\gamma'). \end{aligned} \quad (9.231)$$

9.4.4 Legendre Functions

The Legendre polynomials $P_\ell(z)$ are a special case of the Gegenbauer polynomial, and of the hypergeometric function

$$\begin{aligned} P_\ell(z) &= C_n^{1/2}(z) \\ &= {}_2F_1\left(-n, n + 1; 1; \frac{1}{2} - \frac{1}{2}z\right). \end{aligned} \quad (9.232)$$

The second (irregular) solution to the Legendre equation, which appears in Eq. (9.43) above, can be defined by the integral representation

$$Q_\ell(z) = 2^{-\ell-1} \int_{-1}^1 (1 - t^2)^\ell (z - t)^{-\ell-1} dt. \quad (9.233)$$

The first two Q_ℓ are

$$Q_0(z) = \frac{1}{2} \ln\left(\frac{z+1}{z-1}\right), \quad (9.234)$$

$$Q_1(z) = \frac{1}{2} z \ln\left(\frac{z+1}{z-1}\right) - 1, \quad (9.235)$$

Additional Q_ℓ can be obtained with the aid of the recursion relation

$$\begin{aligned} Q_{\ell+1}(z) &= [(2\ell + 1)z Q_\ell(z) \\ &\quad - \ell Q_{\ell-1}(z)] / (\ell + 1), \end{aligned} \quad (9.236)$$

which is valid for $\ell \geq 1$.

Abstract

When the first edition of the Handbook was published, the Internet was just beginning to become commonly used in scientific computing, outside the original Advanced Research Projects Agency Network (ARPANET) community. The landscape of scientific computing today has become much more complex and with many more options. It is timely, therefore, to include a brief discussion of the software currently used in atomic and molecular physics. Collected together in this chapter are a list of essential computer programs in atomic and molecular physics in tables designed for ease of use. Also included

is a guide to the various software libraries and repositories that can serve the atomic and molecular physics communities. Finally, some topics that generally get little explicit discussion in the literature, but are central to setting up and running a computational research group, are discussed.

Keywords

atomic scattering codes · atomic structure codes · molecular scattering codes · molecular structure codes · R-matrix codes · Perl · Python · FORTRAN compilers

10.1 Introduction

In both theoretical and experimental atomic and molecular physics, computers and software are central to the analysis and processing of data. Since the first edition of this Handbook was published in 1996, the growth of Web programming and the Internet has allowed a vast amount of software to be easily downloaded, shared, and used. Many excellent textbooks and monographs on computational physics [1–4], and programming in a large number of computer languages [5–14], are readily available. See, for example, Chap. 8 for additional details on computational techniques. Many excellent books and websites already exist that cover different pieces of information needed by working researchers in atomic and molecular physics who need to find a particular program in a given field, say atomic structure or scattering, or to help in setting up a computational standalone machine, or cluster. None provide an overall guide to finding computer programs in atomic and molecular physics for specific problems, nor a guide to software repositories and the core software most commonly used in scientific computing. This chapter begins to fill that gap by providing to the active researcher, and the new graduate student, a helpful resource that points to key atomic and molecular software and the underlying tools needed to effectively setup a computational machine.

10.2 Software for Atomic Physics

The types of programs for atomic structure calculations range from empirical and semiempirical techniques to a wide variety of *ab initio* techniques. Programs for atomic scattering have similarly ranged from simple potential models to solving coupled sets of differential or integral equations involving thousands of quantal states. The complexity of the physics included in both structure and scattering codes has tracked closely advances in both computer hardware and physical theories.

10.2.1 Atomic Structure Programs

The core list of types of atomic structure programs includes Hartree–Fock, multiconfiguration Hartree–Fock and configuration interaction programs. Also necessarily included are many-body perturbation theory programs and newer tech-

niques using B-splines. We also include a reference to two suites of programs, CHIANTI and ADAS, used widely in the astrophysics and plasma physics communities, respectively. Details on atomic structure theories can be found in Chaps. 5 and 22–24.

Table 10.1 shows a list of atomic structure programs that are available.

10.2.2 Electron-Atom/Ion Scattering Programs

The core list of electron-atom/ion scattering codes necessarily includes multiple versions of the R-matrix suite of codes, the AUTOSTRUCTURE program that employs distorted-waves, and several other distorted-wave and polarized orbital programs. Also included is the NIEM program and some additional codes that compute scattering amplitudes and observables. See Chaps. 7, 47–57 and 60 for details on atomic scattering theories and observables.

10.3 Software for Molecular Physics

The rapid advances in computer hardware (CPU design and speed, multicores, multi-GPUs, etc.) has profoundly influenced the size and complexity of the molecules that can now be tackled computationally. Molecular structure programs now routinely include basis sets of many thousands of states and incorporate complex techniques for electron exchange and configuration interaction in a full multicenter setting. Similarly, the molecular and heavy-particle scattering programs, in many cases, incorporate the results of these large-scale molecular structure programs in their scattering calculations. Computational chemistry is a vast field today, and due to space limitations we have selected a subset of the programs that are available based on their utility and widespread usage in molecular physics. In addition to the Computer Physics Communications (CPC) Program Library (discussed in Sect. 10.4.1), additional resources for molec-

ular programs can be found in [15–20]. For those readers interested in further details of computer hardware, see [21].

10.3.1 Molecular Structure Programs

The core list of types of molecular structure programs include the GAUSSIAN and GAMESS suite of programs, as well as HONDO, MOLCAS and others. Also included as an example of a non-FORTRAN program is PySCF, which is a SCF program written in Python. See Chaps. 33–34 for further details on molecular structure theories.

Table 10.3 shows a list of molecular structure programs that are available.

10.3.2 Molecular and Heavy Particle Scattering Programs

The core list of types of molecular and heavy-particle scattering programs includes the POLYRATE suite, inelastic and vibrational collisions, as well as the calculation of quantum

Table 10.4 shows a list of molecular structure codes that are available.

10.4 Software Libraries and Repositories

The number and quality of libraries and repositories of scientific and other software has increased greatly over the past 30 years. Originally, only a few scientific journals archived programs and sent to them to users who requested them for distribution. Such distributions from scientific journals, such as *Computer Physics Communications*, were not free due to the cost of producing and shipping magnetic tapes to users. Today, many websites contain high-quality scientific software and other software that complement and extend the functionality of scientific programs. In the following sections some of the core libraries and repositories that are currently available are listed.

10.4.1 The CPC Journal and Library

The journal *Computer Physics Communications* is one of the oldest scientific journals that has been archiving computer programs in all areas of physics since 1969. Currently, the vast majority of programs are in FORTRAN, with a smaller number in C, C++, Python, and Julia [22]. Since 2015, all programs archived at CPC are freely available via the Mendeley Data interface [23] and via their website at Queen's University, Belfast.

The CPC Program Library can be found at <http://www.cpc.cs.qub.ac.uk/>. Currently, over 1800 refereed programs are deposited with the CPC Program Library. The column labeled *CPC Program Name* in Tables 10.1–10.4 is referred to at the CPC website as the *Catalogue ID*. Entering the ID into the search box at the CPC website will allow easy access to the specified program.

10.4.2 Perl and CPAN

Perl is a scripting language [5–9] that comes installed on most new computers and has an extensive library of freely available modules covering the entire field of numerical computing as well as encompassing most topics in software generally.

The main website for Perl is The Comprehensive Perl Archive Network, or CPAN, and is located at <https://www.cpan.org> and currently has over 200 000+ modules, all freely available.

Noteworthy for atomic and molecular computational physics are the Perl Data Language module, the math mod-

ules `Math::BLAS`, `Math::GSL`, which provide the ability to call into the BLAS library or the GNU Scientific Library, respectively; and the `Inline` family of modules that provide the ability to embed calls to other languages into Perl modules. See Sect. 10.5.5 for more details on software bridges and the mixing of languages generally.

10.4.3 Python and PyPI

Python is another popular scripting language [11, 12] and is also generally installed on all new computers. Python is object-oriented in its basic design and has a simpler syntax than that of Perl, and is therefore quite popular. Python also has an extensive library of freely available modules, located at the Python Package Index website <https://pypi.org>, which currently has over 139 000 projects.

Especially noteworthy for computational work are the Python modules `NumPy`, `SciPy` [24], `Pandas` [25, 26], `AstroPy`, `SunPy`, and `Dedalus`. The modules `NumPy`, `SciPy` and `Pandas` are part of the SciPy Stack, which includes methods for basic N-dimensional array manipulation (`NumPy`), data analysis and structure (`Pandas`), and scientific computing (`SciPy`). See <https://scipy.org> for further details on the SciPy stack. The modules `AstroPy` and `SunPy` contain a large number of basic functions and tools used in astronomy and heliophysics, respectively. `Dedalus` is a framework (library) for solving partial differential equations using spectral methods.

Python modules that allow embedding calls to other languages from Python also exist, including `PyInline`, `inline`, and `np_inline`, among others. See Sect. 10.5.5 for more discussion on software bridges and the mixing of languages.

10.4.4 C++ and Boost

C++ is an extension of the C language to include classes [27, 28] and is a widely used language in all areas of scientific computing [29]. Most new computers come with a compiler that can compile C++ code. See Sect. 10.5.2 for more on compilers.

C++ has an extensive list of libraries that are available [30]. The Boost library, located at <https://www.boost.org>, has a large number of modules on linear algebra, multi-precision arithmetic, and numerical analysis [31].

10.4.5 GitHub

GitHub is a website, <https://www.github.com>, where one can freely create a repository (repo) for a software project and upload and share the files in it with others. Private repos can

also be created for a monthly fee. Free repos can be searched by tags or keywords to find ones dealing with specific subject areas. Free repos can be downloaded at no cost. The code uploaded to GitHub is not a refereed code deposited at (for example) the CPC library, yet many high-quality software packages are available at GitHub, in a wide variety of languages. Currently, the total number of repos at GitHub is on the order of 85 million.

10.5 General Tools

We describe here some general tools and topics that have proven essential in configuring and setting up a computational group. Much of the material in this section is generally passed along by word-of-mouth within a research group. Coverage of the topics considered here depends upon the type of computational work a given group is doing, as well as the range of computer skills within the group. By bringing together in one place a discussion of topics such as the configuration of open-source software, compilers, libraries, and the mixing of languages, we hope to bring some coherence and background to help answer common questions such as *Why doesn't X build on my machine?*, *What is gcc?*, or *Where is FORTRAN?*, among others.

10.5.1 Configuration: GNU Autotools

Configuring and installing open-source software has become much more standardized and simplified over the past 20 years. Most open-source software makes use of the GNU autotools (our shorthand) suite of scripts: `aclocal`, `autoconf`, `autoheader`, and `automake`. The purpose of these scripts is to generate the `configure` script and the `Makefile.am` automake Makefile for the machine it is running on. To complete the configuration of a given software project, one then executes `configure config options...`, and then `make` to begin the final compilation of the software. The reason for the complexity of the autotools suite is due to their overall design to be executable on as many different computer systems as possible.

The `configure` script checks for the existence of all system-supplied programs that the given open-source project requires. As `configure` checks the existence of each required component, it will create and execute a small program

to test the required program for correct output. If the output is incorrect, an error is printed in the `config.log` file, and processing continues. Once the set of existence checks are completed, `configure` will then generate the Makefiles in each subfolder of the project. If `configure` exits with an error from the existence check process, the error may be resolved simply by adding a missing header file or library, or adding additional directories to the colon-delimited shell environment variables such as `INC`, `LD_LIBRARY_PATH`, or `PKG_CONFIG_PATH`, so that already installed required programs can be found upon a rerun of `configure`.

In most cases, an open-source software project will already include a `configure` script, and hence there may be no need to run the autotool scripts in full. It is essential to run the autotools in three cases: (a) where no `configure` script is provided; (b) where the `configure` script is badly broken, or out of date, and will not run; or (c) to extend the functionality of an open-source project to include the creation of shared dynamic libraries (for example). For cases (a) and (b), the GNU programs `autoscan` (part of `autoconf` project) and `libtoolize` (part of the `libtool` project) provide a mechanism to generate a `configure.ac` script, or add `libtool` functionality to a project, respectively. Table 10.5 summarizes the execution sequence of the autotool scripts.

Each autotool script has their own GNU project webpage, which can be found at <https://www.gnu.org>. In the case where one is using an older machine, and/or an older operating system, the autotool scripts and the M4 version of the macro processor may need updating *first* to a newer version before running the autotool scripts.

The autotool scripts are designed to be used in conjunction with several other GNU project software: `libtool` and `pkg-config`. Both programs will also usually be installed on new computers, or included in a given Linux distribution, for example. `libtool` provides a very general mechanism to link object modules into a library in a multiplatform manner. `pkg-config` is a program that keeps track of the management of multiple packages installed on a machine, including the location of the libraries that support a given package. Therefore, for open-source projects that are designed to be configured and built using the GNU autotools suite, it is important that *prior* to building a given project, the program `pkg-config` is installed into the folder tree where the target projects will be installed. Hence, as open-source projects are installed into `/usr/local` (say), the

Table 10.5 GNU autotools table

Script name ~>	Input macro/autoconf required ~>	Produces output
<code>aclocal</code>	<code>acinclude.m4</code> and <code>configure.ac</code>	<code>aclocal.m4</code>
<code>autoconf</code>	<code>aclocal.m4</code> , <code>configure.ac</code> and <code>acsite.m4</code>	<code>configure</code>
<code>autoheader</code>	<code>aclocal.m4</code> , <code>configure.ac</code> and <code>acsite.m4</code>	<code>config.h.in</code>
<code>automake</code>	<code>configure.ac</code> and <code>Makefile.am</code>	<code>Makefile.in</code>

program `pkg-config` in that folder tree will keep track of each install, thereby allowing later installs of projects to find earlier dependencies.

As a general rule, when updating such important scripts as the autotools scripts, or compilers, it is safest to install the updated code in `/usr/local`, `/opt`, or some other directory outside of the system directory tree. By installing core scripts and codes in `/usr/local` one avoids breaking any operating system code. Another key point to know about `configure` is that the full set of options `configure` supports for a given open-source project can be found by executing `configure --help`. Examining the full set of options for `configure` is useful to see whether any other open-source project or library should be installed *prior* to running `configure` for the project at hand. In many cases, such project dependencies are not always covered in the README or INSTALL files, but only obtained from `configure --help`.

10.5.2 C compilers: gcc

Central to the development of new scientific software is the compiler. The scope and functionality of compilers has also grown enormously over the past 20 years or so. Many new language concepts have been developed and incorporated into C and C++ compilers, and advances in CPU architecture (massive multicore systems, GPUs, etc.) have resulted in a concomitant increase in compiler options to take advantage of the hardware advances.

Among the most widely used C/C++ compilers used today is gcc from the GNU Foundation. The gcc project has its own website, <https://gcc.gnu.org>, where an extensive amount of documentation can be found for all versions of gcc, as well as details on where one can freely download it. See [32] for further details.

Much depends on the version of gcc on a given computer. If the version of gcc is too old, many open-source packages cannot be built. Generally, one would want gcc with a version 4.2 or greater. Depending upon the manufacturer of the computer one is using, the gcc suite already installed may not be complete. For Linux users this may mean that additional gcc packages will need to be installed, using the appropriate package manager program (e.g., `yum`, `apt`, `rpm`), to get a fully functioning gcc suite. For nonscientific users these omissions are usually never encountered. Scientific soft-

ware using complex library options, or advanced features of optimization may well encounter difficulties with their system-installed gcc if the suite is not complete (missing header files or libraries being the most common omissions). In that case, it is entirely feasible to build and install a complete gcc suite separate from the system supplied one. It is beyond the scope of this chapter to describe how one goes about building gcc in such a case. We point out that the step-by-step building of newer versions of gcc from older ones is routinely done as part of the release testing performed at compiler farms by the gcc as part of their testing prior to a new release of gcc. See the archived email list for gcc for details [33].

LLVM and Clang

Another popular C/C++ compiler suite is the Low-Level Virtual Machine (LLVM) Project with its front-end package Clang. The motivation for creation of the LLVM compiler was a desire for better diagnostics and a license that would allow for commercial development (LLVM underlies much of the development of iPhone apps). Details about LLVM and documentation can be found at their website: <https://llvm.org> and in a number of books [34, 35], for example.

10.5.3 FORTRAN Compilers

Most scientific software is still written in FORTRAN [13, 14]. The FORTRAN compiler that is part of the gcc suite is called `gfortran`. Most computers unfortunately still do not come supplied with a FORTRAN compiler as part of the operating system. One either pays for the installation of FORTRAN from a vendor, or one may install `gfortran` for free from the gcc suite. See the `gfortran` website for further details: <https://gcc.gnu.org/fortran>.

Table 10.6 summarizes some of the most popular FORTRAN compilers currently being used in scientific software.

10.5.4 Shell Scripting Languages

Shell scripting languages such as Perl and Python have advanced far from their roots in `ksh`, `bash`, and `csh`, both in functionality and performance [10]. In many respects, Perl and Python compare quite well in overall performance and optimization to compiled languages such as FORTRAN

Table 10.6 Types of FORTRAN compilers

Name	Type	Description	Link
<code>gfortran</code>	GNU (free)	GCC FORTRAN compiler	https://gcc.gnu.org/fortran
<code>g95</code>	Free	Fortran 95 and later	https://www.g95.org
ProFORTRAN	Commercial	Fortran 95 and later	https://www.absoft.com
PGFORTRAN	Free/commercial (depends on edition)	Fortran 95 and later	https://www.pgroup.com

and C/C++. In fact, depending upon the requirements of the scientific software being used, an efficient partition of problems to Perl/Python for some portion of a problem (say pattern matching of regular expressions or file IO), while the rest can be handled by the compiled program in C/FORTRAN, is entirely feasible by using the many modules available in Perl/Python.

It should be noted that for many years, Perl and Python scripts have been used internally by gcc during its build for precisely the problems described above.

10.5.5 Mixing Languages

Frequently in developing software in a group with backgrounds in various computer languages, the question of rewriting existing code in a different, or newer, language arises. While in many cases there are good reasons for undertaking a rewrite, there are alternatives available that may obviate the need for a complete rewrite.

It is actually a quite commonly used technique to mix the use of two languages to solve a given problem. Software written in one language, which has high performance in tasks such as string manipulation, can be completely integrated with software written in a different language with high performance in numerical processing. In the case just described, we are referring to the mixing of C and FORTRAN, each of which worked on data *shared* between the two languages in the same compiled code. The data is shared in core when the COMMON block in FORTRAN and a C structure have the same name. The two data structures having the same name act then as a bridge between the two languages.

In the second common case, one wants to reuse some existing programs by having the ability to call them from a program written in a different language than the first program. In this latter case, one is sharing or mixing the *code* in various modules. By mixing the code one avoids the need to rewrite an existing library or program.

The two types of mixing, involving the sharing of data or code, are summarized in Table 10.7.

Another technique to facilitate the use of one language from another is through the use of “glue” or hybrid languages. The use of the XS extension to Perl [36] allows computationally intensive calls to be executed in C from Perl and is commonly used in many modules in CPAN. Similarly,

the use of the hybrid compiler and language Cython [37] allows calls to C and C++ code to be made from Python. Both XS and Cython are used extensively in scientific computing.

10.5.6 Third-Party Libraries and Unit Tests

Third-Party Libraries

The use of third-party libraries has long been a standard part of scientific software. The most common types of libraries included in the compilation of a scientific code in C or FORTRAN would bring in functions from linear algebra and numerical analysis. Typical libraries include BLAS, LAPACK, ATLAS, IMSL, and NAG, to name just a few. Table 10.8 collects key information about the most commonly used scientific libraries. Software such as Mathematica or MatLab have not been included here, as they may be considered full, standalone integrated development environments.

Most open-source libraries have had modules written in Perl or Python to permit the easy calling of third-party libraries from within shell scripts, which is an example of the mixing described in Sect. 10.5.5.

Unit Tests

Unit tests in software are small pieces of code that permit the *testing* of a program’s functions with test or mocked data. The phrase *unit* in unit tests refers to the process of gradually building test scripts in each component or unit of the codebase until the entire codebase is covered.

The purpose of testing the program with known data that should produce a known result is to automate the process of finding bugs in code when the codebase has changed. Testing a program for correctness of output is generally unnecessary for small programs. Testing programs for correctness becomes paramount when the codebase is tens of thousands, or even hundreds of thousands of lines of code, spread among hundreds to thousands of individual files. In the case of large codebases, having a mechanism to test the code against a reference (the unit tests) greatly aids finding bugs that occur when changes occur.

The software that links the unit test scripts in a given language with the code being tested are known as testing frameworks or harnesses. See [38] for details in the case of Perl and more generally [39]. Table 10.9 summarizes the harnesses that are currently used for C, C++, FORTRAN, Perl, and Python.

Table 10.7 Types of mixing techniques of languages

Type	Description	Technique/code	Comment
Data sharing	Blocks of data shared between languages	COMMON blocks and C structures have same name	C/FORTRAN
Code sharing	Blocks of code in one language call modules in another language	Inline and inline modules used in Perl, Python, resp.	Perl/Python

Table 10.8 Types of third-party libraries

Library name	Description	Link
BLAS	Linear algebra library	http://www.netlib.org/blas/
LAPACK	Linear algebra library	http://netlib.sandia.gov/lapack/
ATLAS	Automatically tuned linear algebra library	https://sourceforge.net/projects/math-atlas/
GSL	GNU scientific library	https://www.gnu.org/software/gsl/
IMSL	Numerical library (commercial)	https://www.imsl.com
NAG	Numerical library (commercial)	https://www.nag.com/

Table 10.9 Testing harnesses (frameworks)

Harness name	Description	Link/comment
CUnit	Unit testing in C	http://cunit.sourceforge.net/
Check	Unit testing in C	https://libcheck.github.io/check/
CppTest	Unit testing in C++	http://cpptest.sourceforge.net/

Edmund J. Mansky II Edmund J. Mansky II received his PhD from Georgia Institute of Technology in 1985. His theoretical work involves statistical mechanics of dense gases. In addition, his interests are three-body recombination processes and collisions involving Rydberg states of atoms and molecules at thermal and ultracold temperatures. His day job is programming heliophysics data for the scientific community.

Part B
Atoms

Part B presents the main concepts in the theoretical and experimental knowledge of atomic systems, including atomic structure and radiation. Ionization energies for neutral atoms and transition probabilities of selected neutral atoms are tabulated. The computational methods needed for very high precision approximations for helium are summarized. The physical and geometrical significance of simple multipoles is examined. The basic nonrelativistic and relativistic theory of electrons and atoms in external magnetic fields is given. Various properties of Rydberg atoms in external fields and in collisions are investigated. The sources of hyperfine structure in atomic and molecular spectra are outlined, and the resulting energy splittings and isotope shifts given. Precision oscillator strength and lifetime measurements, which provide stringent experimental tests of fundamental atomic structure calculations, are discussed. Ion beam spectroscopy is introduced, and individual applications of ion beam techniques are detailed. A basic description of neutral collisional line shapes is given, along with a discussion of radiation transfer in a confined atomic vapor. Many qualitative features of the Thomas–Fermi model are studied, and its later outgrowth into general density functional theory delineated. The Hartree–Fock and multiconfiguration Hartree–Fock theories, along with configuration interaction methods, are discussed in detail, and their application to the calculation of various atomic properties presented. Relativistic methods for the calculation of the atomic structure for general many-electron atoms are described. A consistent diagrammatic method for

calculating the structure of atoms and the characteristics of different atomic processes is given. An outline of the theory of atomic photoionization and the dynamics of the photon–atom collision process is presented. Those kinds of electron correlation that are most important in photoionization are emphasized. The process of autoionization is treated as a quasi-bound state imbedded in the scattering continuum, and a brief description of the main elements of the theory is given. Green’s function techniques are applied to the calculation of higher-order corrections to atomic energy levels, and also of transition amplitudes for radiative transitions of atoms. Basic quantum electrodynamic calculations, which are needed to explain small deviations from the solution to the Schrödinger equation in simple systems, are presented. Comparisons of precise measurements and theoretical predictions that provide tests of our knowledge of fundamental physics are made, focusing on several quantitative tests of quantum electrodynamics. Precise measurements of parity nonconserving effects in atoms could lead to possible modifications of the Standard Model, and thus uncover new physics. An approach to this fundamental problem is described. The problem of the possible variation of the fundamental constants with time is discussed in relation to atomic clocks and precision frequency measurements. The most advanced atomic clocks are described, and the current laboratory constraints on these variations are listed. Other atomic physics methods currently of interest in the search for new physics beyond the Standard Model are discussed.

Abstract

This chapter outlines the main concepts of atomic structure, with some emphasis on terminology and notation. Atomic radiation is discussed, in particular the wavelengths, intensities, and shapes of spectral lines, and a few remarks are made regarding continuous spectra. We include tabulations of ionization energies for neutral atoms and transition probabilities for persistent lines of selected neutral atoms and provide references to sources of atomic spectroscopic data.

Experimental techniques and the details of atomic theoretical methods are not covered in this chapter; these and a number of other subjects pertinent to atomic spectroscopy are treated in one or more of at least fifteen other chapters in this book.

Keywords

quantum number · oscillator strength · orbital angular momentum · coupling scheme · energy level · spectral line · wavelength · line broadening · line intensity · ionization energy · transition probability · reference data

11.1 Frequency, Wavenumber, Wavelength

The photon energy due to an electron transition between an upper atomic level k (of energy E_k) and a lower level i is

$$\Delta E = E_k - E_i = h\nu = hc\sigma = \frac{hc}{\lambda_{\text{vac}}}, \quad (11.1)$$

where ν is the frequency, σ the wavenumber in vacuum, and λ_{vac} the wavelength in vacuum. The most accurate spectroscopic measurements are determinations of transition frequencies, the unit being the hertz ($1 \text{ Hz} = 1 \text{ s}^{-1}$) or one of its multiples. Frequency, wavenumber, and wavelength (in vacuum) have equivalent relative precision, since the speed of light is exactly defined [1]. The most common wavelength units are the nanometer (nm), the angstrom ($1 \text{ \AA} = 10^{-1} \text{ nm}$) and the micrometer (μm , a.k.a. micron). The SI wavenumber unit is the inverse meter, but in practice wavenumbers are usually expressed in inverse centimeters: $1 \text{ cm}^{-1} = 10^2 \text{ m}^{-1}$, equivalent to $2.99792458 \times 10^4 \text{ MHz}$. Energy units and conversion factors are further discussed in Chap. 1.

11.2 Atomic States, Shells, and Configurations

A one-electron atomic *state* is defined by the quantum numbers $nlm_l m_s$ or $nlj m_j$, with n and l representing the principal quantum number and the orbital angular momentum quantum number, respectively. The allowed values of n are the positive integers, and $l = 0, 1, \dots, n - 1$. The quantum number j represents the angular momentum obtained by coupling the orbital and spin angular momenta of an electron, i.e., $\mathbf{j} = \mathbf{l} + \mathbf{s}$, so that $j = l \pm 1/2$. The magnetic quantum numbers m_l , m_s , and m_j represent the projections of the corresponding angular momenta along a particular direction; thus, for example, $m_l = -l, -l + 1, \dots, l$ and $m_s = \pm 1/2$.

The central field approximation for a many-electron atom leads to wave functions expressed in terms of products of such one-electron states [2–4]. Those electrons having the same principal quantum number n belong to the *shell* for that number. Electrons having both the same n value and l value belong to a *subshell*, all electrons in a particular subshell being *equivalent*. The notation for a *configuration* of N equivalent electrons is nl^N , the superscript usually being omitted for $N = 1$. A configuration of several subshells

is written as $n_1 l_1^{N_1} n_2 l_2^{N_2} \dots$. The numerical values of l are replaced by letters in writing a configuration, according to the code s, p, d for $l = 0, 1, 2$ and $f, g, h \dots$ for $l = 3, 4, 5 \dots$, the letter j being omitted.

The Pauli exclusion principle prohibits atomic states having two electrons with all four quantum numbers the same. Thus, the maximum number of equivalent electrons is $2(2l + 1)$. A subshell having this number of electrons is *full*, *complete*, or *closed*, and a subshell having a smaller number of electrons is *unfilled*, *incomplete*, or *open*. The $3p^6$ configuration thus represents a full subshell, and $3s^2 3p^6 3d^{10}$ represents a full shell for $n = 3$.

The *parity* of a configuration is *even* or *odd* according to whether $\sum_i l_i$ is even or odd, the sum being taken over all electrons (in practice only those in open subshells need to be considered).

11.3 Hydrogen and Hydrogen-Like Ions

For these atoms and ions, the quantum numbers n , l , and j adequately describe the energy structure of electronic shells [4, 5]. A particular *level* is denoted either by nl_j or by $nl^2 L_J$ with $L = l$ and $J = j$. The latter notation is somewhat redundant for one-electron spectra but is useful for consistency with more complex structures. The L values are written with the same letter code used for l values, but with capital letters. The *multiplicity* of the L term is equal to $2S + 1 = 2s + 1 = 2$. Written as a superscript, this number expresses the *doublet* character of the structure: each term for $L \geq 1$ has two levels with $J = L \pm 1/2$.

The Coulomb interaction between the nucleus and the single electron is dominant, so that the largest energy separations are associated with levels having different n . The hyperfine splitting of the ^1H $1s$ ground level is $1420405751.768(1) \text{ Hz}$ [6]. It results from the interaction of the proton and electron magnetic moments and gives rise to the famous 21 cm line. The separations of the $2n - 1$ excited levels having the same n are largely determined by relativistic contributions, including the spin–orbit interaction, with the result that each of the $n - 1$ pairs of levels having the same j value is almost degenerate; the separation of the two levels in each pair is mainly due to relatively small Lamb shifts (Sects. 29.7 and 28.3).

11.4 Alkalis and Alkali-Like Spectra

In the central field approximation there exists no angular-momentum coupling between a closed subshell and an electron outside the subshell, since the net spin and orbital angular momenta of the subshell are both zero. The nlj quantum numbers are, then, again appropriate for a single

electron outside closed subshells. However, the electrostatic interactions of this electron with the other electrons and with the nucleus yield a strong l -dependence of the energy levels [7]. The differing extent of *core penetration* for ns and np electrons can, in some cases, for example, give an energy difference comparable to or exceeding the difference between the np and $(n + 1)p$ levels. The spin-orbit fine-structure separation between the nl ($l > 0$) levels having $j = l - 1/2$ and $l + 1/2$ is relatively small.

11.5 Helium and Helium-Like Ions; LS Coupling

The energy structure of the normal $1snl$ configurations is dominated by the electron-nucleus and electron-electron Coulomb contributions [5]. In helium and in helium-like ions of the lighter elements, the separations of levels having the same n and having $l = s, p,$ or d are mainly determined by direct and exchange electrostatic interactions between the electrons, while the spin-orbit, spin-other orbit, and other relativistic contributions are much smaller. This is the condition for LS coupling, in which:

- The orbital angular momenta of the electrons are coupled to give a total orbital angular momentum $\mathbf{L} = \sum_i \mathbf{l}_i$.
- The spins of the electrons are coupled to give a total spin $\mathbf{S} = \sum_i \mathbf{s}_i$.

The combination of a particular S value with a particular L value comprises a spectroscopic *term*, the notation for which is ^{2S+1}L . The quantum number $2S + 1$ is the *multiplicity* of the term. The \mathbf{S} and \mathbf{L} vectors are coupled to obtain the total angular momentum, $\mathbf{J} = \mathbf{S} + \mathbf{L}$, for a *level* of the term; the level is denoted as $^{2S+1}L_J$.

The parity is indicated by appended degree symbols on odd parity terms.

For $1snl$ configurations, $L = l$ and $S = 0$ or 1 , i.e., the terms are *singlets* ($S = 0$) or *triplets* ($S = 1$). As examples of the He I structure, the ionization energy (energy required to remove one of the $1s$ electrons in the $1s^2$ ground configuration) is 24.5874 eV, the $1s2s$ $^3S-^1S$ separation is 0.7962 eV, the $1s2p$ $^3P^o-^1P^o$ separation is 0.2539 eV, and the $1s2p$ $^3P_2^o-^3P_0^o$ fine-structure spread is only 1.32×10^{-4} eV.

11.6 Hierarchy of Atomic Structure in LS Coupling

The centrality of LS coupling in the analysis and theoretical interpretation of atomic spectra has led to the acceptance of notations and nomenclature well adapted to discussions of particular structures and spectra [2]. The main elements

Table 11.1 Atomic structure hierarchy in LS coupling and names for groups of transitions between structural entities

Structural entity	Quantum numbers ^a	Group of all transitions
Configuration	$(n_i l_i)^{N_i}$	Transition array
System	$(n_i l_i)^{N_i} \gamma S$	Intrasystem transitions Intercombination transitions
Term	$(n_i l_i)^{N_i} \gamma SL$	Multiplet
Level	$(n_i l_i)^{N_i} \gamma SLJ$	Line
Level component	$(n_i l_i)^{N_i} \gamma SLJM$	Line component

^a The configuration may include several open subshells, as indicated by the i subscripts. The letter γ represents any additional quantum numbers, such as ancestral terms, necessary to specify a particular term

of the nomenclature are shown in Table 11.1, most of the structural entities having already been defined in the above discussions of simple spectra. The quantum numbers in the table represent a full description for complex configurations, and the accepted names for transitions between the structural elements are also given.

As an example, the Ca I $3d4p$ $^3D_2^o$ level belongs to the $^3D^o$ term. The $3d4s$ $^3D_2-3d4p$ $^3D_3^o$ line belongs to the corresponding $^3D-^3D^o$ triplet *multiplet*, one of those discussed by Russell and Saunders in their classic paper on the alkaline-earth spectra [8]. The $3d4s-3d4p$ transition array includes both the singlet and triplet multiplets, as well as any (LS -forbidden) *intercombination* or *intersystem* lines arising from transitions between levels of the singlet *system* and those of the triplet *system*. The order of the two terms in the transitions as written above, with the lower-energy term on the left, is standard in atomic spectroscopy. Examples of notations for complex configurations are given in Sect. 11.8.

11.7 Allowed Terms or Levels for Equivalent Electrons

11.7.1 LS Coupling

The allowed LS terms of a configuration consisting of two nonequivalent groups of electrons are obtained by coupling the \mathbf{S} and \mathbf{L} vectors of the groups in all possible ways, and the procedure may be extended to any number of such groups. Thus, the allowed terms for any configuration can be obtained from a table of the allowed terms for groups of equivalent electrons.

The configuration l^N has more than one allowed term of certain LS types if $l > 1$ and $2 < N < 4l$ (d^3-d^7 , f^3-f^{11} , etc.). The recurring terms of a particular LS term type from d^N and f^N configurations are assigned sequential index numbers in the tables of Nielson and Koster [9]; the index numbers stand for additional numbers having group-theoretical significance that serve to differentiate the recurring terms. The first of those additional quantum numbers is

Table 11.2 Allowed J -values for l_j^N equivalent electrons (jj) coupling

l_j^N	Allowed J -values
$l_{1/2}$	1/2
$l_{1/2}^2$	0
$l_{3/2}$ and $l_{3/2}^3$	3/2
$l_{3/2}^2$	0, 2
$l_{3/2}^4$	0
$l_{5/2}$ and $l_{5/2}^5$	5/2
$l_{5/2}^2$ and $l_{5/2}^4$	0, 2, 4
$l_{5/2}^3$	3/2, 5/2, 9/2
$l_{5/2}^6$	0
$l_{7/2}$ and $l_{7/2}^7$	7/2
$l_{7/2}^2$ and $l_{7/2}^6$	0, 2, 4, 6
$l_{7/2}^3$ and $l_{7/2}^5$	3/2, 5/2, 7/2, 9/2, 11/2, 15/2
$l_{7/2}^4$	0, 2, 4, 6
$l_{7/2}^8$	0

seniority [10]. It uniquely differentiates all recurring terms of d^N and most of f^N , except for a few terms of f^5 and f^9 , f^6 and f^8 , and f^7 . These remaining terms, which occur only in pairs, are further labeled A or B (in combination with seniority) to indicate Racah's separation of the two terms.

The index numbers of Nielson and Koster are in practice the most frequently used labels for the recurring terms of f^N configurations. Use of their index numbers for the recurring terms of d^N configurations perhaps has the disadvantage of substituting an arbitrary number for a quantum number (the seniority). The actual value of the seniority number is rarely needed, however, and a consistent notation for the d^N and f^N configurations is desirable. A table of the allowed LS terms of the l^N electrons for $l \leq 3$ is given in [10], with all recurring terms having the index numbers of Nielson and Koster as a following on-line integer. The group-theoretical labels are also listed. Thus, the $d^3\ ^2D$ term having seniority 3 is designated 2D_2 , instead of 2_3D , in this scheme; and the level having $J = 3/2$ is designated $^2D_{3/2}$.

11.7.2 jj Coupling

The Pauli exclusion principle restricts the set of possible J -values for a group of N equivalent electrons having the same j -value, l_j^N . The allowed J -values for such groups are given in Table 11.2 for $j = 1/2, 3/2, 5/2$, and $7/2$ (sufficient for $l \leq 3$). The $l_{7/2}^4$ group has two allowed levels for each of the J -values 2 and 4. The subscripts distinguishing the two levels in each case are the seniority numbers [11].

The allowed levels of the configuration nl^N may be obtained by dividing the electrons into sets of two groups

$nl_{l+1/2}^Q nl_{l-1/2}^R$, $Q + R = N$. The possible sets run from $Q = N - 2l$ (or zero if $N < 2l$) up to $Q = N$ or $Q = 2l + 2$, whichever is smaller. The (degenerate) levels for a set with both Q and R nonzero have wave functions defined by the quantum numbers $(\alpha J_1, \beta J_2)J$, with J_1 and J_2 deriving from the Q and R groups, respectively. The symbols α and β represent any additional quantum numbers required to identify levels. The J values of the allowed levels for each $(\alpha J_1, \beta J_2)$ subset are obtained by combining J_1 and J_2 in the usual way.

11.8 Notations for Different Coupling Schemes

In this section, we give enough examples to make clear the meaning of the different coupling-scheme notations. Not all the configurations in the examples have been identified experimentally, and some of the examples of a particular coupling scheme given for heuristic purposes may be physically inappropriate. Cowan [3] describes the physical conditions for the different coupling schemes and gives experimental examples.

11.8.1 LS Coupling (Russell–Saunders Coupling)

Some of the examples given below indicate notations bearing on the order of coupling of the electrons

1. $3d^7\ ^4F_{7/2}$
2. $3d^7(^4F)4s4p(^3P^\circ)\ ^6F_{9/2}^\circ$
3. $4f^7(^8S^\circ)6s6p(^4P)\ ^{11}P_5^\circ$
4. $3p^5(^2P^\circ)3d^2(^1G)\ ^2F_{7/2}^\circ$
5. $4f^{10}(^3K_2)6s6p(^1P^\circ)\ ^3L_6^\circ$
6. $4f^7(^8S^\circ)5d(^7D^\circ)6p\ ^8F_{13/2}$
7. $4f^7(^8S^\circ)5d(^9D^\circ)6s(^8D^\circ)7s\ ^9D_5^\circ$
8. $4f^7(^8S^\circ)5d(^9D^\circ)6s6p(^3P^\circ)\ ^{11}F_8$
9. $4f^7(^8S^\circ)5d^2(^1G)\ (^8G^\circ)6p\ ^7F_0$
10. $4f(^2F^\circ)\ 5d^2(^1G)6s(^2G)\ ^1P_1^\circ$

In the second example, the seven $3d$ electrons couple to give a 4F term, and the $4s$ and $4p$ electrons couple to form the $^3P^\circ$ term; the final $^6F^\circ$ term is one of nine possible terms obtained by coupling the 4F grandparent and $^3P^\circ$ parent terms. The next three examples are similar to the second. The meaning of the index number 2 following the 3K symbol in the fifth example is explained in Sect. 11.7.1.

The coupling in example 6 is appropriate if the interaction of the $5d$ and $4f$ electrons is sufficiently stronger than the $5d-6p$ interaction. The $^7D^\circ$ parent term results from coupling the $5d$ electron to the $^8S^\circ$ grandparent, and the $6p$ electron is then coupled to the $^7D^\circ$ parent to form the final

8F term. A space is inserted between the $5d$ electron and the $^7D^\circ$ parent to emphasize that the latter is formed by coupling a term ($^8S^\circ$) listed to the left of the space. Example 7 illustrates a similar coupling order carried to a further stage; the $^8D^\circ$ parent term results from the coupling of the $6s$ electron to the $^9D^\circ$ grandparent.

Example 8 is similar to examples 2–5, but in 8 the first of the two terms that couple to form the final 1F term, i.e., the $^9D^\circ$ term, is itself formed by the coupling of the $5d$ electron to the $^8S^\circ$ core term. Example 9 shows an $^8G^\circ$ parent term formed by coupling the $^8S^\circ$ and 1G grandparent terms. A space is again used to emphasize that the following ($^8G^\circ$) term is formed by the coupling of terms listed before the space.

A different order of coupling is indicated in the final example, the $5d^2\ ^1G$ term being coupled first to the external $6s$ electron instead of directly to the $4f$ core electron. The $4f$ ($^2F^\circ$) core term is isolated by a space to denote that it is coupled (to the $5d^2(^1G)6s\ ^2G$ term) only after the other electrons have been coupled. The notation in this particular case (with a single $4f$ electron) could be simplified by writing the $4f$ electron after the 2G term to which it is coupled. It appears more important, however, to retain the convention of giving the core portion of the configuration first.

The notations in examples 1–5 are in the form recommended by *Russell et al.* [12] and used in both the Atomic Energy States [13] and Atomic Energy Levels [10, 14] compilations. The spacings used in the remaining examples allow different orders of coupling of the electrons to be indicated without the use of additional parentheses, brackets, etc.

Some authors assign a short name to each (final) term, so that the configuration can be omitted in tables of classified lines, etc. The most common scheme distinguishes the low terms of a particular SL type by the prefixes a, b, c, \dots , and the high terms by z, y, x, \dots [14].

11.8.2 jj Coupling of Equivalent Electrons

This scheme is used, for example, in relativistic calculations. The lower-case j indicates the angular momentum of one electron ($j = l \pm 1/2$) or of each electron in an l_j^N group. Various ways of indicating which of the two possible j -values applies to such a group without writing the j -value subscript have been used by different authors; we give the j -values explicitly in the first four examples below. We use the symbols J_i and j to represent total angular momenta.

1. $(6p_{1/2}^2)_0$
2. $(6p_{1/2}^2\ 6p_{3/2})_{3/2}^\circ$
3. $(6p_{1/2}^2\ 6p_{3/2}^2)_2$

4. $4d_{5/2}^3\ 4d_{3/2}^2\ (9/2, 2)_{11/2}$
5. $4d_+^3\ 4d_-^2\ (9/2, 2)_{11/2}$

The relatively large spin–orbit interaction of the $6p$ electrons produces jj -coupling structures for the $6p^2$, $6p^3$, and $6p^4$ ground configurations of neutral Pb, Bi, and Po, respectively; the notations for the ground levels of these atoms are given as the first three examples above. The configuration in the first example shows the notation for equivalent electrons having the same j value l_j^N , in this case two $6p$ electrons each having $j = 1/2$. A convenient notation for a particular level ($J = 0$) of such a group is also indicated. The second example extends this notation to the case of a $6p^3$ configuration divided into two groups according to the two possible j values. A similar notation is shown for the $6p^4$ level in the third example; this level might also be designated $(6p_{3/2}^{-2})_2$, the negative superscript indicating the two $6p$ holes. The $(J_1, J_2)_J$ term and level notation shown on the right in the fourth example is convenient because each of the two electron groups $4d_{5/2}^3$ and $4d_{3/2}^2$ has more than one allowed total J_i value. The assumed convention is that J_1 applies to the group on the left ($J_1 = 9/2$ for the $4d_{5/2}^3$ group) and J_2 to that on the right. Example 5 shows another possible representation of example 4 using a minus in the subscript to denote $j = l - 1/2$ and a plus to denote $j = l + 1/2$.

11.8.3 J_1j or J_1J_2 Coupling

1. $3d^9(^2D_{5/2})4p_{3/2}\ (5/2, 3/2)_3^\circ$
2. $4f^{11}(^2H_{9/2}^\circ)6s6p(^3P_1^\circ)\ (9/2, 1)_{7/2}$
3. $4f^9(^6H^\circ)5d(^7H_8^\circ)6s6p(^3P_0^\circ)\ (8, 0)_8$
4. $4f^{12}(^3H_6)5d(^2D)6s6p(^3P^\circ)\ ({}^4F_{3/2}^\circ)\ (6, 3/2)_{13/2}^\circ$
5. $5f^4({}^5I_4)6d_{3/2}\ (4, 3/2)_{11/2}^\circ\ 7s7p(^1P_1^\circ)\ (11/2, 1)_{9/2}^\circ$
6. $5f_{7/2}^4\ 5f_{5/2}^5\ (8, 5/2)_{21/2}^\circ\ 7p_{3/2}\ (21/2, 3/2)_{10}$
7. $5f_{7/2}^3\ 5f_{5/2}^3\ (9/2, 9/2)_9\ 7s7p(^3P_2^\circ)\ (9, 2)_7^\circ$
8. $2s\ 2p_- \ 2p_+\ (0, 3/2)_{3/2}$
9. $[(2s\ 2p_-)_0\ 2p_+]_{3/2}$

The first five examples all have core electrons in LS coupling, whereas jj coupling is indicated for the $5f$ core electrons in examples 6 and 7. Since the J_1 and J_2 values in the final (J_1, J_2) term have already been given as subscripts in the configuration, the (J_1, J_2) term notations are redundant in all these examples. Unless separation of the configuration and final term designations is desired, as in some data tables, one may obtain a more concise notation by simply enclosing the entire configuration in brackets and adding the final J value as a subscript. Thus, the level in the first example

can be designated as $[3d^9(2D_{5/2})4p_{3/2}]_3^\circ$. If the configuration and coupling order are assumed to be known, still shorter designations may be used; for example, the fourth level above might then be given as $[(^3H_6)(^3P^\circ)(^4F_{3/2}^\circ)]_{13/2}$ or $(^3H_6, ^3P^\circ, ^4F_{3/2}^\circ)_{13/2}$. Similar economies of notation are of course possible, and often useful, in all coupling schemes. Example 8 shows a somewhat more compact representation of a case similar to example 6 with the j -values of the p electrons ($j = l \pm 1/2$) indicated by the plus and minus symbols in the subscripts. The s subshell does not need a subscript, since it has a unique possible j -value of $1/2$. The parent term $(0, 1/2)$ can be omitted before the last subshell $2p_+$, since the final term gives its J_1 -value, $J_1 = 0$, and the space before the last subshell makes the order of summation unambiguous. Another possible way to designate the same level is shown in example 9.

11.8.4 $J_1 l$ or $J_1 L_2$ Coupling ($J_1 K$ Coupling)

1. $3p^5(2P_{1/2}^\circ)5g^2[9/2]_5^\circ$
2. $4f^2(^3H_4)5g^2[3]_{5/2}$
3. $4f^{13}(^2F_{7/2}^\circ)5d^2(^1D) \ ^1[7/2]_{7/2}^\circ$
4. $4f^{13}(^2F_{5/2}^\circ)5d6s(^3D) \ ^3[9/2]_{11/2}^\circ$

The final terms in the first two examples result from coupling a parent-level J_1 to the orbital angular momentum of a $5g$ electron to obtain a resultant K , the K value being enclosed in brackets. The spin of the external electron is then coupled with the K angular momentum to obtain a pair of J values, $J = K \pm 1/2$ (for $K \neq 0$). The multiplicity (2) of such pair terms is usually omitted from the term symbol, but other multiplicities occur in the more general $J_1 L_2$ coupling (examples 3 and 4). The last two examples are straightforward extensions of $J_1 l$ coupling, with the L_2 and S_2 momenta of the *external* term (1D and 3D in examples 3 and 4, respectively) replacing the l and s momenta of a single external electron.

11.8.5 LS_1 Coupling (LK Coupling)

1. $3s^23p(^2P^\circ)4fG^2[7/2]_3$
2. $3d^7(^4P)4s4p(^3P^\circ)D^\circ \ ^3[5/2]_{7/2}^\circ$

The orbital angular momentum of the core is coupled with the orbital angular momentum of the external electron(s) to give the total orbital angular momentum L . The letter symbol for the final L value is listed with the configuration because this angular momentum is then coupled with the spin of the core (S_1) to obtain the resultant K angular momentum of

the final term (in brackets). The multiplicity of the $[K]$ term arises from the spin of the external electron(s).

11.8.6 Coupling Schemes and Term Symbols

The coupling schemes outlined above include those now most frequently used in calculations of atomic structure [3]. Any term symbol gives the values of two angular momenta that may be coupled to give the total electronic angular momentum of a level (indicated by the J -value). For configurations of more than one unfilled subshell, the angular momenta involved in the final coupling derive from two groups of electrons (either group may consist of only one electron). These are often an inner group of coupled electrons and an outer group of coupled electrons, respectively. In any case, the quantum numbers for the two groups can be distinguished by subscripts 1 and 2, so that quantum numbers represented by capital letters without subscripts are total quantum numbers for both groups. Thus, the quantum numbers for the two vectors that couple to give the final J are related to the term symbol as follows:

Coupling scheme	Quantum numbers for vectors that couple to give J	Term symbol
LS	L, S	^{2S+1}L
$J_1 J_2$	J_1, J_2	(J_1, J_2)
$J_1 L_2(\rightarrow K)$	K, S_2	$^{2S_2+1}[K]$
$LS_1(\rightarrow K)$	K, S_2	$^{2S_2+1}[K]$

11.9 Eigenvector Composition of Levels

The wave functions of levels are often expressed as eigenvectors that are linear combinations of basis states in one of the standard coupling schemes. Thus, the wave function $\Psi(\alpha J)$ for a level labeled αJ might be expressed in terms of LS coupling basis states $\Phi(\gamma SLJ)$

$$\Psi(\alpha J) = \sum_{\gamma SL} c(\gamma SLJ) \Phi(\gamma SLJ) . \quad (11.2)$$

The $c(\gamma SLJ)$ are expansion coefficients, and

$$\sum_{\gamma SL} |c(\gamma SLJ)|^2 = 1 . \quad (11.3)$$

The squared expansion coefficients for the various γSL terms in the composition of the αJ level are conveniently expressed as percentages, whose sum is 100%. Thus, the percentage contributed by the pure Russell–Saunders state γSLJ is equal to $100 \times |c(\gamma SLJ)|^2$. The notation for

Russell–Saunders basis states has been used only for concreteness; the eigenvectors may be expressed in any coupling scheme, and the coupling schemes may be different for different configurations included in a single calculation (with configuration interaction). *Intermediate coupling* conditions for a configuration are such that calculations in both LS and jj coupling yield some eigenvectors representing significant mixtures of basis states. Eigenvectors represented by the above equations are usually given in such a way that all terms in the summation use the same coupling scheme, and all eigenvectors for a given configuration use the same coupling scheme as well.

The largest percentage in the composition of a level is called the *purity* of the level in that coupling scheme. The coupling scheme (or combination of coupling schemes if more than one configuration is involved) that results in the largest average purity for all the levels in a calculation is usually best for naming the levels. With regard to any particular calculation, one does well to remember that, as with other calculated quantities, the resulting eigenvectors depend on a specific theoretical model and are subject to the inaccuracies of whatever approximations the model involves.

Theoretical calculations of experimental energy level structures have yielded many eigenvectors having significantly less than 50% purity in any coupling scheme. Since many of the corresponding levels have nevertheless been assigned names by spectroscopists, some caution is advisable in the acceptance of the level designations found in the literature. Moreover, the level designations, such as configuration and term labels, are not something permanent. Unlike the energy intervals, the wavefunctions and their composition are not directly observable. They are always a product of some theoretical interpretation. As theory evolves and improves with time, so does the interpretation of observed atomic properties, and, thus, some of the level designations are bound to change in the course of the development of the theory.

11.10 Ground Levels and Ionization Energies for Neutral Atoms

Fortunately, most of the ground levels of the neutral atoms have reasonably meaningful LS -coupling names, the corresponding eigenvector percentages lying in the range from $\approx 55\%$ to 100%. These names are listed in Table 11.3 except for Pb, Pa, U, and Np. The lowest few ground-configuration levels of these four atoms comprise better $[core](L_1S_1J_1)[valence]_j (J_1j)$ terms than LS -coupling terms, the $[core]$ and $[valence]$ shells being $6s^2$ and $6p^2$ for Pb and $5f^N$ and $6d7s^2$ for Pa, U, and Np. As noted in Sect. 11.8.2, the jj -coupling names given there for the ground levels of Bi and Po are more appropriate than the

alternative LS -coupling designations in Table 11.3. For the heaviest elements, Sg, Bh, and Hs, only the J -values of the final terms are known.

For brevity, the ionization energies in the table are given with no more than four digits after the decimal point. However, for all of the first 56 atoms, H through Ba, as well as for many of the heavier atoms, they are experimentally known with greater precision. The values in the table are from recent compilations [15, 16]. The National Institute of Standards and Technology (NIST) maintains an online *Atomic Spectra Database* (ASD) [15], which is updated with new and revised data every year. Each year, a few of the ionization energies tabulated here are revised. ASD provides full information about the uncertainties of the data and bibliographic references.

11.11 Zeeman Effect

The Zeeman effect is of special interest because of the importance of Zeeman data in the analysis and theoretical interpretation of complex spectra. In a weak field, the J value remains a valid quantum number, although in general a level is split into magnetic sublevels [3, 17]. The Landé g -value of such a level may be defined by the expression for the energy shift of its magnetic sublevel having magnetic quantum number M , which has one of the $2J + 1$ -values, $-J, -J + 1, \dots, J$

$$\Delta E = gM\mu_B B . \quad (11.4)$$

B is the magnetic flux density, and μ_B is the Bohr magneton ($\mu_B = e\hbar/2m_e$).

The wavenumber shift $\Delta\sigma$ corresponding to this energy shift is

$$\Delta\sigma = gM(0.46686B \text{ cm}^{-1}) , \quad (11.5)$$

with B representing the numerical value of the magnetic flux density in teslas. The quantity in parentheses, the Lorentz unit, is about 1 or 2 cm^{-1} for typical flux densities used to obtain Zeeman-effect data with classical spectroscopic methods. Accurate data can be obtained with much smaller fields, of course, by using higher-resolution techniques such as laser spectroscopy. Most of the g -values now available for atomic energy levels were derived by application of the above formula (for each of the two combining levels) to measurements of optical Zeeman patterns. A single transverse-Zeeman-effect pattern (two polarizations, resolved components, and sufficiently complete) can yield the J -value and the g value for each of the two levels involved.

Neglecting a number of higher-order effects, we can evaluate the g value of a level βJ belonging to a pure LS -

Table 11.3 Ground levels and ionization energies for neutral atoms

Z	Element	Ground configuration ^a			Ground level	Ionization energy (eV)	Z	Element	Ground configuration ^a				Ground level	Ionization energy (eV)

^a An element symbol in brackets represents the electrons in the ground configuration of that element

coupling term using the formula

$$g_{\beta SLJ} = 1 + \left\{ (g_e - 1) \frac{J(J+1) - L(L+1) + S(S+1)}{2J(J+1)} \right\}.$$

The independence of this expression from any other quantum numbers (represented by β) such as the configuration, etc., is important. The expression is derived from vector coupling formulas by assuming a g value of unity for a pure orbital angular momentum and writing the g value for a pure electron spin as g_e [18]. A value of 2 for g_e yields the Landé formula. If the anomaly of the magnetic dipole moment of the electron, arising from small quantum electrodynamics effects [19], is taken into account, the value of g_e is 2.0023193. *Schwinger* g values obtained with this more accurate value for g_e are given for levels of SL terms in [10].

The usefulness of g_{SLJ} -values is enhanced by their relation to the g -values in intermediate coupling. In the notation used in Eq. (11.2) for the wave function of a level βJ in intermediate coupling, the corresponding g -value is given by

$$g_{\beta J} = \sum_{\gamma SL} g_{SLJ} |c(\gamma SLJ)|^2, \quad (11.6)$$

where the summation is over the same set of quantum numbers as for the wave function. The $g_{\beta J}$ -value is, thus, a weighted average of the Landé g_{SLJ} -values, the weighting factors being just the corresponding component percentages.

Formulas for magnetic splitting factors in the J_1J_2 and J_1L_2 coupling schemes are given in [10, 18]. Some higher-order effects that must be included in more accurate Zeeman-effect calculations are treated by *Bethe* and *Salpeter* [5] and by *Wybourne* [18], for example. High-precision calculations for helium are given in [20]. See also Chaps. 14 and 15.

11.12 Term Series, Quantum Defects, and Spectral-Line Series

The Bohr energy levels for hydrogen or for a hydrogenic (one-electron) ion with nuclear charge Z are given by

$$E_n = -\frac{R_Z Z^2}{n^2}, \quad (11.7)$$

where R_Z is the Rydberg constant for the appropriate nuclear mass; R_Z can be found from the infinite-mass Rydberg constant

$$R_Z = \frac{R_\infty}{1 + \frac{m_e}{M_Z}}, \quad (11.8)$$

where m_e is the mass of the electron, and M_Z is the mass of the nucleus. Equation (11.7) gives the energy relative to the ionization limit. For a multielectron atom, the deviations of

a series of (core) nl levels from hydrogenic E_n -values may be due mainly to core penetration by the nl electron (low l -value series), or core polarization by the nl electron (high l -value series), or a combination of the two effects. In either case, it can be shown that these deviations can be approximately represented by a constant quantum defect δ_l in the Rydberg formula,

$$E_{nl} = -\frac{R_Z Z_c^2}{(n - \delta_l)^2} = -\frac{R_Z Z_c^2}{(n^*)^2}, \quad (11.9)$$

where Z_c is the charge of the core and $n^* = n - \delta$ is the effective principal quantum number. If the core includes only closed subshells, the E_{nl} -values are with respect to a value of zero for the (core) 1S_0 level, i.e., the 1S_0 level is the limit of the (core) nl series. If the quantities in Eq. (11.9) are taken as positive, they represent term values or ionization energies; the term value of the ground level of an atom or ion with respect to the ground level of the next higher ion is, thus, the principal ionization energy.

If the core has one or more open subshells, the series limit may be the barycenter of the entire core configuration, or any appropriate sub-structure of the core, down to and including a single level. The E_{nl} -values refer to the series of corresponding (core) nl structures built on the particular limit structure. The value of the quantum defect depends to some extent on which (core) nl structures are represented by the series formula.

The quantum defect in general also has an energy dependence that must be taken into account if lower members of a series are to be accurately represented by Eq. (11.9). For an unperturbed series, this dependence can be expressed by the extended Ritz formula

$$\begin{aligned} \delta &= n - n^* \\ &= \delta_0 + \frac{a}{(n - \delta_0)^2} + \frac{b}{(n - \delta_0)^4} + \dots, \end{aligned} \quad (11.10)$$

with $\delta_0, a, b \dots$ constants for the series (δ_0 being the limit value of the quantum defect for high series members) [21]. The value of a is usually positive for core-penetration series and negative for core-polarization series. A discussion of the foundations of the Ritz expansion and application to high precision calculations in helium is given in [22] (see also Chap. 12).

A spectral-line series results from either emission or absorption transitions involving a common lower level and a series of successive (core) nl upper levels differing only in their n values. The principal series of Na I, $3s^2S_{1/2} - np^2P_{1/2,3/2}^\circ$ ($n \geq 3$) is an example. The regularity of successive upper term values with increasing n (Eqs. (11.9), (11.10)) is, of course, observed in line series; the intervals between successive lines decrease in a regular manner towards higher wavenumbers, and the series of increasing wavenumbers converges towards the term value of the lower level as a limit.

11.13 Sequences

Several types of sequences of elements and/or ionization stages are useful because of regularities in the progressive values of parameters relating to structure and other properties along the sequences. All sequence names may refer either to the atoms and/or ions of the sequence or to their spectra.

11.13.1 Isoelectronic Sequence

A neutral atom and those ions of other elements having the same number of electrons as the atom comprise an isoelectronic sequence. (Note that a negative ion having this number of electrons is a member of the sequence.) An isoelectronic sequence is named according to its neutral member; for example, the Na I isoelectronic sequence.

11.13.2 Isoionic, Isonuclear, and Homologous Sequences

An isoionic sequence comprises atoms or ions of different elements having the same charge. Such sequences have probably been the most useful along the d and f-shell rows of the periodic table. Isoionic analyses have also been carried out along p-shell rows, however, and a fine-structure regularity covering spectra of the p-shell atoms throughout the periodic table is known [23].

The atom and successive ions of a particular element comprise the isonuclear sequence for that element.

The elements of a particular column and subgroup in the periodic table are homologous. Thus, the C, Si, Ge, Sn, and Pb atoms belong to a homologous sequence having np^2 ground configurations (Table 11.3). The singly ionized atoms of these elements comprise another example of a homologous sequence.

11.14 Spectral Wavelength Ranges, Dispersion of Air

The ranges of the most interest for optical atomic spectroscopy are:

~ 2–20 μm	Mid-infrared (IR)
700–2000 nm	Near IR
400–700 nm	Visible
200–400 nm	Near ultraviolet (UV)
100–200 nm	Vacuum UV (VUV) or far UV
10–100 nm	Extreme UV (EUV or XUV)
< 10 nm	Soft X-ray, X-ray

The above correspondence of names to ranges should not be taken as exact; the variation as to the extent of some of the named ranges found in the literature is considerable.

For regions longer than 200 nm, wavelengths in standard air are commonly tabulated. These wavelengths can be related to energy-level differences by conversion to the corresponding (vacuum) wavenumbers or frequencies [24, 25].

11.15 Wavelength Standards

In 2001, the Comité International des Poids et Mesures recommended values for optical frequency standards from stabilized lasers using various absorbing atoms, atomic ions, and molecules [26]. These frequencies range from 29,054,057,446,579 Hz (10.318436884460 μm ; relative standard uncertainty 1.4×10^{-13}) for a transition in OsO₄ to 1,267,402,452,889.92 kHz (236.54085354975 nm; relative standard uncertainty 3.6×10^{-13}) for a transition in the ¹¹⁵In⁺ ion [26].

Extensive tables of wavenumbers for molecular transitions in the mid-IR range of 2.3 to 20.5 μm are included in a calibration atlas published in 1998 [27]. Wavenumbers of Ar I [28] and Ar II [29] emission lines having uncertainties as small as 0.0003 cm^{-1} are included in tables for these spectra covering a broad range from 222 nm to 5.865 μm . Measurements of U and Th lines (575 to 692 nm) suitable for wavenumber calibration at uncertainty levels of 0.0003 or 0.0004 cm^{-1} were reported in [30]. Comprehensive tables of lines for U [31, 32], Th [33], and I₂ [34–37] are useful for calibration at uncertainty levels of 0.00003 to 0.003 cm^{-1} , the line list of the Th spectrum extending down to 235 nm.

A 1974 compilation gives reference wavelengths for some 5400 lines of 38 elements covering the range 1.5 nm to 2.5 μm , with most uncertainties between 10^{-5} and 2×10^{-4} nm [38]. The wavelengths for some 1100 Fe lines selected from the Fe/Ne hollow-cathode spectrum have been recommended for reference standards over the range 183 nm to 4.2 μm , with wavenumber uncertainties 0.001–0.002 cm^{-1} [39]. A comprehensive work on the Fe II spectrum [40] includes about 13,000 lines from VUV to far IR with wavenumber uncertainties between 0.0001 and 0.005 cm^{-1} . Wavelengths for about 3000 VUV and UV lines (110–400 nm) from a Pt/Ne hollow-cathode lamp have been determined with uncertainties of 0.0002 nm or less [15, 41]. More recent high-accuracy measurements of ultraviolet lines of Fe I, Ge I, Kr II, and Pt I, II include some wavelengths with uncertainties smaller than 10^{-5} nm [42]. The wavelengths tabulated for the Kr and Pt lines in [42] extend from 171 nm to 315 nm, and the accuracies of earlier measurements of a number of spectra useful for wavelength calibration are discussed.

11.16 Spectral Lines: Selection Rules, Intensities, Transition Probabilities, f Values, and Line Strengths

The selection rules for discrete transitions are given in Table 11.4.

11.16.1 Emission Intensities (Transition Probabilities)

In the absence of self-absorption and stimulated emission, the total power ϵ radiated in a spectral line of frequency ν per unit source volume and per unit solid angle is

$$\epsilon_{\text{line}} = (4\pi)^{-1} h\nu A_{ki} N_k, \quad (11.11)$$

where A_{ki} is the atomic transition probability and N_k the number per unit volume (number density) of excited atoms in the upper (initial) level k . For a homogeneous light source of length l and for the optically thin case, where all radiation escapes, the total emitted line intensity (SI quantity: radiance) is

$$\begin{aligned} I_{\text{line}} &= \epsilon_{\text{line}} l = \int_0^{+\infty} I(\lambda) d\lambda \\ &= (4\pi)^{-1} \left(\frac{hc}{\lambda_0} \right) A_{ki} N_k l, \end{aligned} \quad (11.12)$$

where $I(\lambda)$ is the specific intensity at wavelength λ , and λ_0 the wavelength at line center.

11.16.2 Absorption f -values

In absorption, the reduction of intensity of light passing through a medium is described by the quantity called the re-

duced absorption

$$W(\lambda) = \frac{[I(\lambda) - I'(\lambda)]}{I(\lambda)}, \quad (11.13)$$

where $I(\lambda)$ is the incident intensity at wavelength λ , e.g., from a source providing a continuous background, and $I'(\lambda)$ the intensity after passage through the absorbing medium. The total reduced absorption of a homogeneous and optically thin absorbing medium of length l for a spectral line arising from a transition between levels i and k is obtained by integrating the above equation

$$\begin{aligned} W_{ik} &= \int_0^{+\infty} W(\lambda) d\lambda \\ &= \frac{e^2}{4\epsilon_0 m_e c^2} \lambda_0^2 N_i f_{ik} l, \end{aligned} \quad (11.14)$$

where f_{ik} is the atomic (absorption) oscillator strength (dimensionless), λ_0 is the central wavelength of the line, N_i is the density of atoms in state i , and the other quantities are fundamental constants.

In astrophysics, the quantity given by the above equation is called the *equivalent width* of a spectral line [43]. Although it is not directly related to the width of the line profile, the term makes sense, as this quantity corresponds to the width of a rectangle having a unit height and the same area as the portion of the continuum absorbed by the spectral line.

11.16.3 Line Strengths

A_{ki} and f_{ik} are the principal atomic quantities related to line intensities. In theoretical work, the *line strength* S is also widely used (Chap. 22)

$$S = S(i, k) = S(k, i) = |R_{ik}|^2, \quad (11.15)$$

$$R_{ik} = \langle \psi_k | P | \psi_i \rangle, \quad (11.16)$$

Table 11.4 Selection rules for discrete transitions

	Electric dipole (E1) (allowed)	Magnetic dipole (M1) (forbidden)	Electric quadrupole (E2) (forbidden)
Rigorous rules	1. $\Delta J = 0, \pm 1$ (except $0 \not\rightarrow 0$)	$\Delta J = 0, \pm 1$ (except $0 \not\rightarrow 0$)	$\Delta J = 0, \pm 1, \pm 2$ (except $0 \not\rightarrow 0, 1/2 \not\rightarrow 1/2, 0 \not\rightarrow 1$)
	2. $\Delta M = 0, \pm 1$ (except $0 \not\rightarrow 0$ when $\Delta J = 0$)	$\Delta M = 0, \pm 1$ (except $0 \not\rightarrow 0$ when $\Delta J = 0$)	$\Delta M = 0, \pm 1, \pm 2$
	3. Parity change	No parity change	No parity change
With negligible configuration interaction	4. One electron jumping, with $\Delta l = \pm 1$, Δn arbitrary	No change in electron configuration; i.e., for all electrons, $\Delta l = 0$, $\Delta n = 0$	No change in electron configuration; or one electron jumping with $\Delta l = 0, \pm 2$, Δn arbitrary
For LS coupling only	5. $\Delta S = 0$	$\Delta S = 0$	$\Delta S = 0$
	6. $\Delta L = 0, \pm 1$ (except $0 \not\rightarrow 0$)	$\Delta L = 0$ $\Delta J = \pm 1$	$\Delta L = 0, \pm 1, \pm 2$ (except $0 \not\rightarrow 0, 0 \not\rightarrow 1$)

where ψ_i and ψ_k are the initial-state wavefunctions and the final-state wavefunctions, and R_{ik} is the *transition matrix element* of the appropriate multipole operator P (computation of R_{ik} involves an integration over spatial and spin coordinates of all N electrons of the atom or ion).

11.16.4 Relationships Between A , f , and S

The relationships between A , f , and S for electric dipole (E1, or “allowed”) transitions in SI units (A in s^{-1} , λ in m, S in $\text{m}^2 \text{C}^2$) are

$$A_{ki} = \frac{2\pi e^2}{m_e c \epsilon_0 \lambda^2} \frac{g_i}{g_k} f_{ik} = \frac{16\pi^3}{3h \epsilon_0 \lambda^3 g_k} S. \quad (11.17)$$

Numerically, in customary units (A in s^{-1} , λ in nm, S in atomic units, i.e., $a_0^2 e^2$),

$$A_{ki} = \frac{6.67025177 \times 10^{13}}{\lambda^2} \frac{g_i}{g_k} f_{ik} = \frac{2.0261269 \times 10^{15}}{\lambda^3 g_k} S, \quad (11.18)$$

and for S and ΔE in atomic units,

$$f_{ik} = \frac{2}{3} \left(\frac{\Delta E}{g_i} \right) S; \quad (11.19)$$

g_i and g_k are the statistical weights, which are obtained from the appropriate angular momentum quantum numbers. Thus, for the lower (upper) level of a spectral line, $g_{i(k)} = 2J_{i(k)} + 1$ and for the lower and upper terms of a multiplet, the g -values are calculated from the corresponding quantum numbers

$$\bar{g}_{i(k)} = \sum_{i(k)} (2J_{i(k)} + 1) = (2L_{i(k)} + 1) (2S_{i(k)} + 1). \quad (11.20)$$

Conversion relations between S and A_{ki} for the most common forbidden transitions are given in Table 11.5. Oscillator strengths f are rarely used for forbidden transitions, i.e., magnetic dipole (M1), electric quadrupole (E2), etc. However, the left-hand parts of Eqs. (11.17) and (11.18) are valid for any transition type and can be used to calculate f_{ik} from the normally tabulated A_{ki} -values.

[Numerical example: for the $1s2p\ ^1P_1^o - 1s3d\ ^1D_2$ (allowed) transition in He I at 667.815 nm (in air): $g_i = 3$; $g_k = 5$; $A_{ki} = 6.3705 \times 10^7 \text{ s}^{-1}$; $f_{ik} = 0.71028$; $S = 46.860 a_0^2 e^2$.]

Table 11.5 Conversion relations between S and A_{ki} for forbidden transitions

	SI units ^a	Numerically, in customary units ^b
Electric quadrupole	$A_{ki} = \frac{16\pi^5}{15h \epsilon_0 \lambda^5 g_k} S$	$A_{ki} = \frac{1.1199500 \times 10^{13}}{g_k \lambda^5} S$
Magnetic dipole	$A_{ki} = \frac{16\pi^3 \mu_0}{3h \lambda^3 g_k} S$	$A_{ki} = \frac{2.6973500 \times 10^{10}}{g_k \lambda^3} S$

^a A in s^{-1} , λ in m. Electric quadrupole: S in $\text{m}^4 \text{C}^2$. Magnetic dipole: S in $\text{J}^2 \text{T}^{-2}$

^b A in s^{-1} , λ in nm; S in atomic units: $a_0^4 e^2 = 2.01291442 \times 10^{-79} \text{ m}^4 \text{C}^2$ (electric quadrupole), $e^2 h^2 / 16\pi^2 m_e^2 = \mu_B^2 = 8.6007261 \times 10^{-47} \text{ J}^2 \text{ T}^{-2}$ (magnetic dipole). μ_B is the Bohr magneton.

11.16.5 Relationships Between Line and Multiplet Values

The relations between the total strength and f value of a multiplet (M) and the corresponding quantities for the lines of the multiplet (allowed transitions) are

$$S_M = \sum S_{\text{line}}, \quad (11.21)$$

$$f_M = (\bar{\lambda} \bar{g}_i)^{-1} \sum_{J_k, J_i} g_i \lambda(J_i, J_k) f(J_i, J_k); \quad (11.22)$$

$\bar{\lambda}$ is the weighted (*multiplet*) wavelength in vacuum

$$\bar{\lambda} = n \bar{\lambda}_{\text{air}} = \frac{hc}{\Delta E}, \quad (11.23)$$

where

$$\begin{aligned} \overline{\Delta E} &= \overline{E_k} - \overline{E_i} \\ &= (\bar{g}_k)^{-1} \sum_{J_k} g_k E_k - (\bar{g}_i)^{-1} \sum_{J_i} g_i E_i, \end{aligned} \quad (11.24)$$

\bar{g}_i and \bar{g}_k are defined by Eq. (11.20), and n is the refractive index of air.

11.16.6 Relative Strengths for Lines of Multiplets in LS Coupling

A general formula for the relative line strengths S_{rel} of fine-structure components of LS multiplets is given by Sobel'man [44]

$$S_{\text{rel}}(i, k, S) = \frac{(2J_i + 1)(2J_k + 1)}{2S + 1} \left\{ \begin{matrix} L_i & J_i & S \\ J_k & L_k & 1 \end{matrix} \right\}, \quad (11.25)$$

where the indexes i and k correspond to the initial and final levels, respectively, S is their common multiplicity, and the matrix in curly brackets is Wigner's 6- j -symbol. The values of S_{rel} in the above equation are normalized so that their sum over all multiplet components is unity. From this expression, it follows that the strongest, or principal, components of a multiplet are those for which the changes in J and L are

equal. The strongest of the principal lines correspond to the largest J -value of the initial level. The other, weaker components of the multiplet are called satellite lines. In order of decreasing intensity they are called the first-order satellites ($\Delta J = 0, \Delta L = \pm 1$) and second-order satellites ($\Delta J = +1, \Delta L = -1$ or $\Delta J = -1, \Delta L = +1$). A discussion of normalization of S_{rel} as well as extensive tables of their values are given in [45].

11.17 Atomic Lifetimes

The radiative lifetime τ_k of an atomic level k is related to the sum of transition probabilities to all levels i lower in energy than k

$$\tau_k = \left(\sum_i A_{ki} \right)^{-1}. \quad (11.26)$$

The *branching* fraction of a particular transition, say to state i' , is defined as

$$\frac{A_{ki'}}{\sum_i A_{ki}} = A_{ki'} \tau_k. \quad (11.27)$$

If only one branch (i') exists (or if all other branches may be neglected), one obtains $A_{ki'} \tau_k = 1$, and

$$\tau_k = 1/A_{ki'}. \quad (11.28)$$

Precision lifetime measurement techniques are discussed in Chaps. 18 and 19.

11.18 Regularities and Scaling

11.18.1 Transitions in Hydrogenic (One-Electron) Species

According to Eqs. (11.1) and (11.7), the nonrelativistic *energy* of a hydrogenic transition is

$$(\Delta E)_Z = (E_k - E_i)_Z = R_Z Z^2 (1/n_i^2 - 1/n_k^2). \quad (11.29)$$

Hydrogenic Z Scaling

The spectroscopic quantities for a hydrogenic ion of nuclear charge Z are related to the equivalent quantities in hydrogen ($Z = 1$) as follows (neglecting small differences in the values of R_Z)

$$(\Delta E)_Z = Z^2 (\Delta E)_H, \quad (11.30)$$

$$(\lambda_{\text{vac}})_Z = Z^{-2} (\lambda_{\text{vac}})_H, \quad (11.31)$$

$$S_Z = Z^{-2} S_H, \quad (11.32)$$

$$f_Z = f_H, \quad (11.33)$$

$$A_Z = Z^4 A_H. \quad (11.34)$$

For large values of Z , roughly $Z > 20$, relativistic corrections become noticeable and must be taken into account.

f -value Trends

f -values for high series members (large n' values) of hydrogenic ions decrease according to

$$f(n, l \rightarrow n', l \pm 1) \propto (n')^{-3}. \quad (11.35)$$

11.18.2 Systematic Trends and Regularities in Atoms and Ions with Two or More Electrons

Atomic quantities for a given state or transition in an *isoelectronic sequence* may be expressed as power series expansions in Z^{-1}

$$Z^{-2} E = E_0 + E_1 Z^{-1} + E_2 Z^{-2} + \dots, \quad (11.36)$$

$$Z^2 S = S_0 + S_1 Z^{-1} + S_2 Z^{-2} + \dots, \quad (11.37)$$

$$f = f_0 + f_1 Z^{-1} + f_2 Z^{-2} + \dots, \quad (11.38)$$

where E_0 , f_0 , and S_0 are hydrogenic quantities. For transitions in which n does not change ($n_i = n_k$), $f_0 = 0$, since states i and k are degenerate.

For equivalent transitions of *homologous atoms*, f values vary gradually. Transitions to be compared in the case of *alkalis* are [46]

$$\begin{aligned} (nl - n'l')_{\text{Li}} &\rightarrow [(n+1)l - (n'+1)l']_{\text{Na}} \\ &\rightarrow [(n+2)l - (n'+2)l']_{\text{Cu}} \rightarrow \dots \end{aligned}$$

Complex atomic structures, as well as cases involving strong cancellation in the integrand of the transition integral, generally do not adhere to this regular behavior.

11.19 Tabulations of Transition Probabilities

The A_{ki} -values for strong lines of selected elements are given in Table 11.6. Data for some lines of the main spectral series of hydrogen are given in Table 11.7.

Experimental and theoretical methods to determine A , f , or S -values, as well as atomic lifetimes are discussed in Chaps. 12, 18, 19, and 22.

Methods for critical evaluation of accuracy of experimental and theoretical transition probabilities have been developed over several decades by the NIST Atomic Spectroscopy Group [47, 48]. Examples of the work of this group can be found in [49, 50]. Comprehensive tables of A , f , and S , including forbidden lines, are collected in the NIST ASD [15].

For references to other sources of transition probability data, see Sect. 11.22.

Table 11.6 Wavelengths λ , upper energy levels E_k , statistical weights g_i and g_k of lower and upper levels, and transition probabilities A_{ki} for persistent spectral lines of neutral atoms. Many tabulated lines are resonance lines (marked “g”), where the lower energy level belongs to the ground term

^a Principal quantum numbers of the lower and upper levels

^b L_α is often called Lyman α , H_α = Balmer α , P_α = Paschen α

^c Wavelengths below 200 nm are in vacuum; values above 200 nm are in air

^d For transitions in hydrogen, $g_{i(k)} = 2(n_{i(k)})^2$, where $n_{i(k)}$, is the principal quantum number of the lower (upper) electron shell

^e The number in parentheses indicates the power of 10 by which the value has to be multiplied; uncertainties of these theoretical A-values are smaller than 0.3%

11.20 Spectral Line Shapes, Widths, and Shifts

Observed spectral lines are always broadened. The principal physical causes of spectral line broadening are Doppler and pressure broadening. The theoretical foundations of line broadening are discussed in Chaps. 20 and 63.

11.20.1 Doppler Broadening

Doppler broadening is due to the thermal motion of the emitting atoms. For a Maxwellian velocity distribution, the line shape is *Gaussian*; the full width at half maximum intensity (FWHM) is, in the same units as wavelength (λ),

$$\Delta\lambda_{1/2}^D = (7.16233 \times 10^{-7}) \lambda (T/M)^{1/2}; \quad (11.39)$$

T is the temperature of the emitters in K, and M the atomic weight in atomic mass units (u).

11.20.2 Pressure Broadening

Pressure broadening is due to collisions of the emitters with neighboring particles (also Chaps. 20 and 63). Shapes are often approximately Lorentzian, i.e., $I(\lambda) \propto \{1 + [(\lambda - \lambda_0)/\Delta\lambda_{1/2}]^2\}^{-1}$. In the following formulas, all FWHMs and wavelengths are expressed in nm, particle densities N in cm^{-3} , temperatures T in K, and energies E or I in cm^{-1} .

Resonance broadening (self-broadening) occurs only between identical species and is confined to lines with the upper or lower level having an electric dipole transition (resonance

line) to the ground state. The FWHM may be estimated as

$$\Delta\lambda_{1/2}^R \simeq 8.6 \times 10^{-28} \left(\frac{g_i}{g_k} \right)^{1/2} \lambda^2 \lambda_r f_r N_i, \quad (11.40)$$

where λ is the wavelength of the observed line; f_r and λ_r are the oscillator strength and wavelength of the resonance line, and g_k and g_i are the statistical weights of its upper and lower levels; N_i is the ground state number density.

For the $1s2p\ ^1P_1^o - 1s3d\ ^1D_2$ transition in He I [$\lambda = 667.815$ nm; $\lambda_r(1s^2\ ^1S_0 - 1s2p\ ^1P_1^o) = 58.4334$ nm; $g_i = 1$; $g_k = 3$; $f_r = 0.2762$] at $N_i = 1 \times 10^{18}$ cm $^{-3}$: $\Delta\lambda_{1/2}^R = 0.0036$ nm.

Van der Waals broadening arises from the dipole interaction of an excited atom with the induced dipole of a ground state atom. (In the case of foreign gas broadening, both the perturber and the radiator may be in their respective ground states.) An approximate formula [51] for the FWHM, strictly applicable to hydrogen and similar atomic structures only, is

$$\Delta\lambda_{1/2}^W \simeq 8.5 \times 10^{-11} \lambda^2 C_6^{2/5} (T/\mu)^{3/10} N, \quad (11.41)$$

where μ is the atom-perturber reduced mass in atomic mass units, N the perturber density, and C_6 the interaction constant; C_6 may be roughly estimated as follows

$$C_6 = C_k - C_i, \quad (11.42)$$

with

$$C_{i(k)} \simeq 9.1 \times 10^{-46} \alpha_d R_{i(k)}^2 [\text{m}^6/\text{s}], \quad (11.43)$$

where α_d is the mean dipole polarizability of the perturber atom,

$$\alpha_d \approx 4.5 \left(\frac{3I_H}{4E^*} \right)^2 a_0^3, \quad (11.44)$$

I_H being the ionization energy of hydrogen and E^* the energy of the first excited level of the perturber atom, and $R_{i(k)}^2$ are the mean squared radii of the wavefunctions of the initial and final levels of the transition,

$$R_{i(k)}^2 \approx 2.5 \left[\frac{I_H}{(I - E_{i(k)})} \right]^2 a_0^2, \quad (11.45)$$

where I is the ionization energy of the radiator. Van der Waals broadened lines are redshifted by about one-third the size of the FWHM.

For the $1s2p\ ^1P_1^o - 1s3d\ ^1D_2$ transition in He I, and with He as perturber: $\lambda = 667.815$ nm; $I = 198,311$ cm $^{-1}$; $E^* = E_i = 171,135$ cm $^{-1}$; $E_k = 186,105$ cm $^{-1}$; $\mu = 2$. At $T = 273$ K and $N = 1 \times 10^{18}$ cm $^{-3}$: $\Delta\lambda_{1/2}^W = 0.0012$ nm.

Stark broadening due to charged perturbers, i.e., ions and electrons, usually dominates resonance and van der Waals

Table 11.8 Values of Stark-broadening parameter $\alpha_{1/2}$ of the H β line of hydrogen (486.1 nm) for various temperatures and electron densities

T (K)	N_e (cm $^{-3}$)

broadening in discharges and plasmas. The FWHM for hydrogen lines is

$$\Delta\lambda_{1/2}^{S,H} = (2.50 \times 10^{-10}) \alpha_{1/2} N_e^{2/3}, \quad (11.46)$$

where N_e is the electron density. The half-width parameter $\alpha_{1/2}$ for the H β line at 486.1 nm, widely used for plasma diagnostics, is tabulated in Table 11.8 for some typical temperatures and electron densities [45]. This reference also contains $\alpha_{1/2}$ parameters for other hydrogen lines, as well as Stark width and shift data for numerous lines of other elements, i.e., neutral atoms and singly charged ions (in the latter, Stark widths and shifts depend linearly on N_e). Other tabulations of complete hydrogen Stark profiles exist. *Griem* [52] gives a theoretical foundation for treatment of Stark broadening of spectral lines in plasmas.

11.21 Spectral Continuum Radiation

11.21.1 Hydrogenic Species

Precise quantum-mechanical calculations exist only for hydrogenic species. The total power ϵ_{cont} radiated (per unit source volume and per unit solid angle, and expressed in SI units) in the wavelength interval $\Delta\lambda$ is the sum of radiation due to the recombination of a free electron with a bare ion (free-bound transitions) and bremsstrahlung (free-free transitions)

$$\begin{aligned} \epsilon_{\text{cont}} = & \frac{e^6}{2\pi c^2 \epsilon_0^3 (6\pi m_e)^{3/2}} N_e N_Z Z^2 \\ & \times \frac{1}{(kT)^{1/2}} \exp\left(-\frac{hc}{\lambda kT}\right) \frac{\Delta\lambda}{\lambda^2} \\ & \times \left\{ \frac{2Z^2 I_H}{kT} \sum_{n \geq (Z^2 I_H \lambda / hc)^{1/2}}^{n'} \frac{\gamma_{\text{fb}}}{n^3} \exp\left(\frac{Z^2 I_H}{n^2 kT}\right) \right. \\ & \left. + \bar{\gamma}_{\text{fb}} \left[\exp\left(\frac{Z^2 I_H}{(n' + 1)^2 kT}\right) - 1 \right] + \gamma_{\text{ff}} \right\}, \quad (11.47) \end{aligned}$$

where N_e is the electron density, N_Z the number density of hydrogenic (bare) ions of nuclear charge Z , I_H the ionization energy of hydrogen, n' the principal quantum number of

the lowest level for which adjacent levels are so close that they approach a continuum, and summation over n may be replaced by an integral (the choice of n' is rather arbitrary; n' as low as 6 can be found in the literature); γ_{fb} and γ_{ff} are the Gaunt factors, which are generally close to unity. (For the higher free-bound continua, starting with $n' + 1$, an average Gaunt factor $\bar{\gamma}_{fb}$ is used.) For neutral hydrogen, the recombination continuum forming H^- also becomes important [53].

In the equation above, the value of the constant factor before N_e is $6.065 \times 10^{-55} \text{ W m}^4 \text{ J}^{1/2} \text{ sr}^{-1}$. [Numerical example: for atomic hydrogen ($Z = 1$), the quantity ϵ_{cont} has the value $2.9 \text{ W m}^{-3} \text{ sr}^{-1}$ under the following conditions: $\lambda = 3 \times 10^{-7} \text{ m}$; $\Delta\lambda = 1 \times 10^{-10} \text{ m}$; $N_e (= N_{Z=1}) = 1 \times 10^{21} \text{ m}^{-3}$; $T = 12,000 \text{ K}$. The lower limit of the summation index n is 2; the upper limit n' has been taken to be 10. All Gaunt factors γ_{fb} , $\bar{\gamma}_{fb}$, and γ_{ff} have been assumed to be unity.]

11.21.2 Many-Electron Systems

For many-electron systems, only approximate theoretical treatments exist, based on the quantum-defect method [54]. For results of calculations for noble gases, see, e.g., [55, 56]. Experimental work is centered on the noble gases [57, 58]. Modifications of the continuum by autoionization processes must also be considered.

Near the ionization limit, the f values for bound-bound transitions of a spectral series ($n' \rightarrow \infty$) make a smooth connection to the differential oscillator strength distribution $df/d\epsilon$ in the continuum [3].

11.22 Sources of Spectroscopic Data

Access to most of the atomic spectroscopic databases currently online is given by links at the Plasma Gate server [59]. Extensive data from NIST compilations of atomic wavelengths, energy levels, and transition probabilities are available from the *Atomic Spectra Database* (ASD) at the NIST site [15]. Section 11.15 includes additional references for wavelength tables. The modern trend of online dissemination of digital data is exemplified by the Virtual Atomic and Molecular Data Centre (VAMDC) Consortium [60], which provides online access to many atomic and molecular spectroscopic databases through a unified portal.

William C. Martin William C. Martin's research included the measurement and energy-level analysis of atomic spectra. He also published a number of critical compilations of atomic spectroscopic data, including a large volume for the rare-earth elements. As a Scientist Emeritus at NIST, Dr. Martin continued to work on internet-accessible atomic spectra databases. He passed away in 2013.

Wolfgang Wiese Wolfgang Wiese is a physicist with extensive research background in atomic spectroscopy and in the critical tabulation of atomic reference data. He has worked at the National Institute of Standards and Technology for more than 40 years and has led the Atomic Physics Division from 1978 to 2004. He has authored 6 data volumes on Atomic Transition Probabilities, 15 book chapters and about 225 shorter research papers.

Alexander Kramida Alexander Kramida received his PhD from the Moscow Institute of Physics and Technology in 1981. He worked at the Institute for Spectroscopy of the Russian Academy of Sciences. Since 2003, he works at the National Institute of Standards and Technology, USA on analysis of atomic spectra and development of databases and tools for research in atomic and plasma physics.

Abstract

Exact analytic solutions to the Schrödinger equation are known only for hydrogen and other equivalent two-body systems (Chap. 9). However, very high precision approximations are now available for helium and other three-body systems that are essentially exact for all practical purposes. This chapter summarizes the computational methods and tabulates numerical results for the ground state and several excited states up to $n = 10$ and $L = 7$. General formulas are presented for the evaluation of matrix elements in Hylleraas coordinates. Relativistic and quantum electrodynamic effects are included, along with quantum defect extrapolations to states of higher n and

asymptotic expansions to states of higher angular momentum L . Radiative transitions are discussed and oscillator strengths tabulated for a wide variety of transitions.

helium · variational methods · Hylleraas coordinates · energies · relativistic and quantum electrodynamic corrections · asymptotic expansions · quantum defects · radiative transitions · oscillator strengths

12.1 Introduction

Exact analytic solutions to the Schrödinger equation are known only for atomic hydrogen and other equivalent two-body systems (Chap. 9). However, very high precision approximations are now available for helium, which are essentially exact for all practical purposes. This chapter summarizes the computational methods and tabulates numerical results for the ground state and several singly excited states. Similar methods can be applied to other three-body problems.

12.2 The Three-Body Schrödinger Equation

The Schrödinger equation for a three-body system consisting of a nucleus of charge Ze , mass M , and two electrons of charge $-e$ and mass m_e is

$$\left[\frac{1}{2M} P_N^2 + \frac{1}{2m_e} \sum_{i=1}^2 P_i^2 + V(\mathbf{R}_N, \mathbf{R}_i) \right] \Psi = E\Psi, \quad (12.1)$$

where $\mathbf{P}_i = (\hbar/i)\nabla_i$ and

$$V(\mathbf{R}_N, \mathbf{R}_i) = -\frac{Ze^2}{|\mathbf{R}_N - \mathbf{R}_1|} - \frac{Ze^2}{|\mathbf{R}_N - \mathbf{R}_2|} + \frac{e^2}{|\mathbf{R}_1 - \mathbf{R}_2|} \quad (12.2)$$

G. W. F. Drake (✉)
Dept. of Physics, University of Windsor
N9B 3P4 Windsor, ON, Canada
e-mail: gdrake@uwindsor.ca

depends only on the relative particle separations. Since the center of mass (c.m.) is then an ignorable coordinate, it can be eliminated by defining the relative particle coordinates

$$\mathbf{r}_i = \mathbf{R}_i - \mathbf{R}_N$$

to obtain

$$\left[\frac{1}{2\mu} \sum_{i=1}^2 \mathbf{p}_i^2 + \frac{1}{M} \mathbf{p}_1 \cdot \mathbf{p}_2 + V(\mathbf{r}_1, \mathbf{r}_2) \right] \Psi = E \Psi, \quad (12.3)$$

where $\mu = m_e M / (m_e + M)$ is the electron reduced mass, and the term $H_{\text{mp}} = \mathbf{p}_1 \cdot \mathbf{p}_2 / M$ is called the mass polarization operator. For computational purposes, it is usual to measure distance in units of $a_\mu = (m_e / \mu) a_0$ and energies in units of $e^2 / a_\mu = 2(\mu / m_e) R_\infty$, so that Eq. (12.3) assumes the dimensionless form

$$\left[-\frac{1}{2} \sum_{i=1}^2 \nabla_{\rho_i}^2 - \frac{\mu}{M} \nabla_{\rho_1} \cdot \nabla_{\rho_2} + V(\rho_1, \rho_2) \right] \Psi = \varepsilon \Psi, \quad (12.4)$$

where $\rho_i = \mathbf{r}_i / a_\mu$, $\varepsilon = E / (e^2 / a_\mu)$, and

$$V(\rho_1, \rho_2) = -\frac{Z}{\rho_1} - \frac{Z}{\rho_2} + \frac{1}{|\rho_1 - \rho_2|}. \quad (12.5)$$

The limit $\mu / M \rightarrow 0$ defines the infinite nuclear mass problem with eigenvalue ε_0 and eigenfunction Ψ_0 . If the mass polarization term is treated as a small perturbation, then the total energy assumes the form

$$E = \left[\varepsilon_0 + \frac{\mu}{M} \varepsilon_1 + \left(\frac{\mu}{M} \right)^2 \varepsilon_2 + \dots \right] \frac{\mu}{m_e} \frac{e^2}{a_0}, \quad (12.6)$$

where $\varepsilon_1 = -\langle \Psi_0 | \nabla_{\rho_1} \cdot \nabla_{\rho_2} | \Psi_0 \rangle$ determines the first-order specific mass shift, and ε_2 is the second-order coefficient. The common $(\mu / m_e) \varepsilon_0$ mass scaling of all eigenvalues determines the normal mass shift. Since $\mu / m = 1 - \mu / M$, the shift is $-(\mu / M) \varepsilon_0$.

12.2.1 Formal Mathematical Properties

Two-particle coalescences. The exact nonrelativistic wave function for any many-body system contains discontinuities or cusps in the spherically averaged radial derivative with respect to r_{ij} as $r_{ij} \rightarrow 0$, where $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$ is any interparticle coordinate. If the masses and charges are m_i and q_i , respectively, then the discontinuities are given by the Kato cusp condition [1]

$$\hbar^2 \left(\frac{\partial \bar{\Psi}}{\partial r_{ij}} \right)_{r_{ij}=0} = \mu_{ij} q_i q_j \Psi(r_{ij} = 0), \quad (12.7)$$

where $\mu_{ij} = m_i m_j / (m_i + m_j)$, and $\bar{\Psi}$ denotes the wave function averaged over a sphere centered at $r_{ij} = 0$. If Ψ vanishes at $r_{ij} = 0$, then its leading dependence on r_{ij} is of the form $r_{ij}^l Y_{lm}(\mathbf{r}_{ij})$, for some integer $l > 0$ [2]. Equation (12.7) applies to any Coulombic system. The electron–nucleus cusp in the wave functions for hydrogen provides a simple example.

Three-particle coalescences. Three-particle coalescences are described by the Fock expansion [3], as recently discussed by Myers et al. [4]. For the S -states of He-like ions, the expansion has the form

$$\Psi(\mathbf{r}_1, \mathbf{r}_2) = \sum_{j=0}^{\infty} \sum_{k=0}^{[j/2]} \mathcal{R}^j (\ln \mathcal{R})^k \phi_{j,k}, \quad (12.8)$$

where $[]$ denotes “greatest integer in”, and $\mathcal{R} = (r_1^2 + r_2^2)^{1/2}$ is the hyperradius. The leading coefficients are

$$\begin{aligned} \phi_{0,0} &= 1, \\ \phi_{1,0} &= -(Zr_1 + Zr_2 - \frac{1}{2}r_{12}) / \mathcal{R}, \\ \phi_{2,1} &= -2Z \left(\frac{\pi - 2}{3\pi} \right) \frac{\mathbf{r}_1 \cdot \mathbf{r}_2}{\mathcal{R}^2}. \end{aligned} \quad (12.9)$$

The next term $\phi_{2,0}$ is known in terms of a lengthy expression [4, 5], but higher terms have not yet been obtained in closed form. The Fock expansion has been proved convergent for all $\mathcal{R} < \frac{1}{2}$ [6] and extended to pointwise convergence for all \mathcal{R} [7, 8].

Asymptotic form. The long-range behavior of many-electron wave functions has been studied from several points of view [9–11]. The basic result of [12] is that at large distances, the one-electron density behaves as

$$\rho^{1/2}(r) \approx r^{Z^*/t-1} e^{-tr}, \quad (12.10)$$

where $t = (2I_1)^{1/2}$, I_1 is the first ionization potential (in a.u.), and $Z^* = Z - N + 1$ is the screened nuclear charge seen by the outer most electron. For hydrogenic systems with principal quantum number n , $I_1 = (Z^*)^2 / 2n^2$.

12.3 Computational Methods

12.3.1 Variational Methods

Most high-precision calculations for the bound states of three-body systems such as helium are based on the Rayleigh–Ritz variational principle. For any normalizable trial function Ψ_{tr} , the quantity

$$E_{\text{tr}} = \frac{\langle \Psi_{\text{tr}} | H | \Psi_{\text{tr}} \rangle}{\langle \Psi_{\text{tr}} | \Psi_{\text{tr}} \rangle} \quad (12.11)$$

satisfies the inequality $E_{\text{tr}} \geq E_1$, where E_1 is the true ground-state energy. Thus, E_{tr} is an upper bound to E_1 . The inequality is easily proved by expanding Ψ_{tr} in the complete basis set of eigenfunctions $\Psi_1, \Psi_2, \Psi_3, \dots$ of H with eigenvalues $E_1 < E_2 < E_3 < \dots$, so that

$$\Psi_{\text{tr}} = \sum_{i=1}^{\infty} c_i \Psi_i, \quad (12.12)$$

where the c_i are expansion coefficients. This can always be done in principle, even though the exact Ψ_i are not actually known. If Ψ_{tr} is normalized so that $\langle \Psi_{\text{tr}} | \Psi_{\text{tr}} \rangle = 1$, then $\sum_{i=1}^{\infty} |c_i|^2 = 1$, and

$$\begin{aligned} E_{\text{tr}} &= |c_1|^2 E_1 + |c_2|^2 E_2 + |c_3|^2 E_3 + \dots \\ &= E_1 + |c_2|^2 (E_2 - E_1) + |c_3|^2 (E_3 - E_1) + \dots \\ &\geq E_1, \end{aligned} \quad (12.13)$$

which proves the theorem.

The basic idea of variational calculations, then, is to write Ψ_{tr} in some arbitrarily chosen mathematical form with variational parameters (subject to normalizability and boundary conditions at the origin and infinity) and then adjust the parameters to obtain the minimum value of E_{tr} .

The minimization problem for the case of *linear* variational coefficients can be solved algebraically. For example, let

$$\chi_p(\alpha, \beta) = r_1^i r_2^j r_{12}^k e^{-\alpha r_1 - \beta r_2} \quad (12.14)$$

denote the members of a basis set, where p is an index labeling distinct triplets of nonnegative integer values for the powers $\{i, j, k\}$, and α, β are (for the moment) fixed constants determining the distance scale.

If Ψ_{tr} is expanded in the form

$$\Psi_{\text{tr}} = \sum_{p=1}^N c_p \chi_p(\alpha, \beta), \quad (12.15)$$

then the solution to the system of equations $\partial E_{\text{tr}} / \partial c_p = 0$, $p = 1, \dots, N$, is exactly equivalent to solving the N -dimensional generalized eigenvalue problem

$$\mathbf{H}\mathbf{c} = \lambda \mathbf{O}\mathbf{c}, \quad (12.16)$$

where \mathbf{c} is a column vector of coefficients c_p , and \mathbf{H} and \mathbf{O} have matrix elements $H_{pq} = \langle \chi_p | H | \chi_q \rangle$ and $O_{pq} = \langle \chi_p | \chi_q \rangle$. There are N eigenvalues $\lambda_1, \lambda_2, \dots, \lambda_N$, of which the lowest is an upper bound to E_1 .

Extension to excited states. By the Hylleraas–Undheim–MacDonald (HUM) theorem [13, 14], the remaining eigenvalues $\lambda_2, \lambda_3, \dots$ are also upper bounds to the exact energies E_2, E_3, \dots , provided that the spectrum is bounded from below. The HUM theorem is a consequence of the matrix

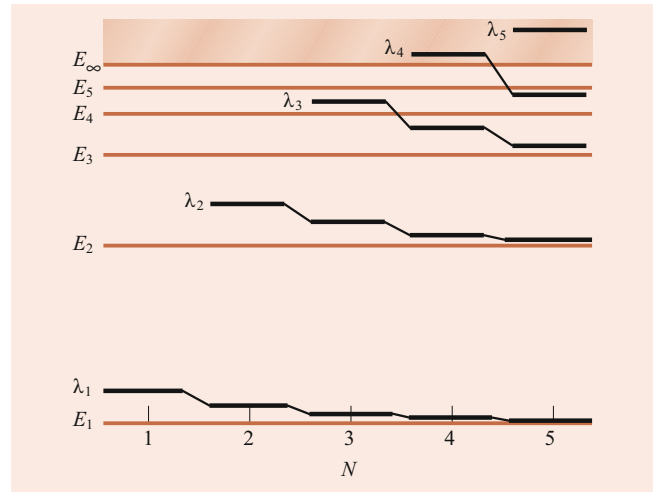

Fig. 12.1 Diagram illustrating the Hylleraas–Undheim–MacDonald Theorem. The λ_p , $p = 1, \dots, N$ are the variational eigenvalues for an N -dimensional basis set, and the E_i are the exact eigenvalues of H . The highest λ_p lie in the continuous spectrum of H

eigenvalue interleaving theorem, which states that as the dimensions of \mathbf{H} and \mathbf{O} are progressively increased by adding an extra row and column, the N old eigenvalues λ_p fall between the $N + 1$ new ones. Consequently, as illustrated in Fig. 12.1, all eigenvalues numbered from the bottom up must move inexorably downward as N is increased. Since the exact spectrum of bound states is obtained in the limit $N \rightarrow \infty$, no λ_p can cross the corresponding exact E_p on its way down. Thus, $\lambda_p \geq E_p$ for every finite N .

12.3.2 Construction of Basis Sets

Since the Schrödinger equation (12.4) is not separable in the electron coordinates, basis sets which incorporate the $r_{12} = |\mathbf{r}_1 - \mathbf{r}_2|$ interelectron coordinate are most efficient. The necessity for r_{12} terms also follows from the Fock expansion in Eq. (12.8). A basis set constructed from terms of the form Eq. (12.14) is called a Hylleraas basis set [15]. (The basis set is often expressed in terms of the equivalent variables $s = r_1 + r_2$, $t = r_1 - r_2$, $u = r_{12}$.)

With $\chi_p(\alpha, \beta)$ defined as in Eq. (12.14), the general form for a state of total angular momentum L is

$$\begin{aligned} \Psi_{\text{tr}} &= \sum_{l_1=0}^{[L/2]} \sum_p C_{p,l_1} \chi_p(\alpha, \beta) r_1^{l_1} r_2^{l_2} \mathcal{Y}_{l_1 L-l_1 L}^M(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2) \\ &\quad \pm \text{exchange}, \end{aligned} \quad (12.17)$$

where

$$\begin{aligned} \mathcal{Y}_{l_1 l_2 L}^M(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2) &= \sum_{m_1, m_2} Y_{l_1 m_1}(\hat{\mathbf{r}}_1) Y_{l_2 m_2}(\hat{\mathbf{r}}_2) \\ &\quad \times \langle l_1 l_2 m_1 m_2 | LM \rangle \end{aligned} \quad (12.18)$$

is the vector coupled product of angular momenta l_1, l_2 for the two electrons. The sum over p in Eq. (12.17) typically includes all terms in Eq. (12.14) with $i + j + k \leq \Omega$, where Ω is an integer determining a so-called *Pekeris shell* of terms, and the exchange term denotes the interchange of r_1 and r_2 with (+) for singlet states and (−) for triplet states. Convergence is studied by progressively increasing Ω . The number of terms is

$$N = \frac{1}{6}(\Omega + 1)(\Omega + 2)(\Omega + 3).$$

Basis sets of this type were used by many authors, culminating in the extensive high-precision calculations of Pekeris and coworkers [16] for low-lying states, using as many as 1078 terms. Their accuracy is not easily surpassed because of the rapid growth of N with Ω and because of numerical linear dependence in the basis set for large Ω . Recently, their accuracy has been surpassed by two principal methods. The first explicitly includes powers of logarithmic and half-integral terms in χ_p , as suggested by the Fock expansion [17–19]. The most accurate calculation to date is that of Schwartz [20] who obtained 35 significant figures for the nonrelativistic ground-state energy of helium. This is particularly effective for S -states. The second focuses directly on the multiple distance scales required for an accurate representation of the wave function by writing the trial function in terms of the double basis set [21]

$$\begin{aligned} \Psi_{\text{tr}} = & \sum_{l_1=0}^{[L/2]} \sum_p \left[C_{p,l_1}^{(1)} \chi_p(\alpha_1, \beta_1) + C_{p,l_1}^{(2)} \chi_p(\alpha_2, \beta_2) \right] \\ & \times r_1^{l_1} r_2^{l_2} \mathcal{Y}_{l_1 l_2 L}(\mathbf{r}_1, \mathbf{r}_2) \pm \text{exchange}, \end{aligned} \quad (12.19)$$

where each $\chi_p(\alpha, \beta)$ is of the form of Eq. (12.14) but with different values for the distance scales α_1, β_1 and α_2, β_2 in the two sets of terms. They are determined by a complete minimization of E_{tr} with respect to all four parameters, producing a natural division of the basis set into an asymptotic sector and a close-range correlation sector. The method produces a dramatic improvement in accuracy for higher-lying Rydberg states (where variational methods typically deteriorate rapidly in accuracy) and is also effective for low-lying S -states [22, 23]. Nonrelativistic energies accurate to 1 part in 10^{16} are obtainable with modest computing resources.

Another version of the variational method is the quasirandom (or stochastic) method in which nonlinear exponential parameters for all three of r_1, r_2 , and r_{12} are chosen at random from certain specified intervals [24, 25]. The method is remarkably accurate and efficient for low-lying states but subject to severe roundoff error.

12.3.3 Calculation of Matrix Elements

The three-body problem has the unique advantage that the full six-dimensional volume element (in the c.m. frame) can

be transformed to the product of a three-dimensional angular integral (ang) and a three-dimensional radial integral (rad) over r_1, r_2 , and r_{12} . The transformation is

$$\begin{aligned} \iint d\mathbf{r}_1 d\mathbf{r}_2 = & \int_0^{2\pi} d\phi \int_0^{2\pi} d\varphi_1 \int_0^{\pi} \sin\theta_1 d\theta_1 \\ & \times \int_0^{\infty} r_1 dr_1 \int_0^{\infty} r_2 dr_2 \int_{|r_1-r_2|}^{r_1+r_2} r_{12} dr_{12}, \end{aligned} \quad (12.20)$$

where θ_1, φ_1 are the polar angles of \mathbf{r}_1 , and ϕ is the angle of rotation of the triangle formed by $\mathbf{r}_1, \mathbf{r}_2$, and \mathbf{r}_{12} about the \mathbf{r}_1 direction. The polar angles θ_2, φ_2 are then dependent variables. The basic angular integral is

$$\begin{aligned} & \langle Y_{l_1 m_1}^*(\theta_1, \varphi_1) Y_{l_2 m_2}(\theta_2, \varphi_2) \rangle_{\text{ang}} \\ & = 2\pi \delta_{l_1 l_2} \delta_{m_1 m_2} P_{l_1}(\cos\theta), \end{aligned} \quad (12.21)$$

where $\cos\theta \equiv \hat{\mathbf{r}}_1 \cdot \hat{\mathbf{r}}_2$ denotes the radial function

$$\cos\theta = \frac{r_1^2 + r_2^2 - r_{12}^2}{2r_1 r_2}, \quad (12.22)$$

and $P_l(\cos\theta)$ is a Legendre polynomial. The angular integral over vector-coupled spherical harmonics is [26]

$$\begin{aligned} & \langle \mathcal{Y}_{l_1' l_2' L'}^{M'*}(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2) \mathcal{Y}_{l_1 l_2 L}^M(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2) \rangle_{\text{ang}} \\ & = \delta_{L'L'} \delta_{M,M'} \sum_{\Lambda} C_{\Lambda} P_{\Lambda}(\cos\theta), \end{aligned} \quad (12.23)$$

where

$$\begin{aligned} C_{\Lambda} = & \frac{1}{2} [(2l_1 + 1)(2l_1' + 1)(2l_2 + 1)(2l_2' + 1)]^{1/2} \\ & \times (-1)^{L+\Lambda} (2\Lambda + 1) \\ & \times \begin{pmatrix} l_1' & l_1 & \Lambda \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} l_2' & l_2 & \Lambda \\ 0 & 0 & 0 \end{pmatrix} \begin{Bmatrix} L & l_1 & l_2 \\ \Lambda & l_2' & l_1' \end{Bmatrix}, \end{aligned} \quad (12.24)$$

and the sum over Λ includes all nonvanishing terms. This can be extended to general matrix elements of tensor operators by further vector coupling [26].

Radial integrals. Table 12.1 lists formulas for the radial integrals arising from matrix elements of H , as well as those from the Breit interaction (Sect. 22.1.3). Although they can all be written in closed form, some have been expressed as infinite series in order to achieve good numerical stability. The exceptions are formulas 5 and 10 in the table, which became unstable as $\alpha \rightarrow \beta$. More elaborate techniques for these are discussed in [27]. Other cases can be derived by

Table 12.1 Formulas for the radial integrals $I_0(a, b, c; \alpha, \beta) = \langle r_1^a r_2^b r_{12}^c e^{-\alpha r_1 - \beta r_2} \rangle_{\text{rad}}$ and $I_0^{\log}(a, b, c; \alpha, \beta) = \langle r_1^a r_2^b r_{12}^c \ln r_{12} e^{-\alpha r_1 - \beta r_2} \rangle_{\text{rad}}$. $\psi(n) = -\gamma + \sum_{k=1}^{n-1} k^{-1}$ is the digamma function, ${}_2F_1(a, b; c; z)$ is the hypergeometric function, and $s = a + b + c + 5$. Except as noted, the formulas apply for $a \geq -1, b \geq -1, c \geq -1$

1.	$I_0(-2, -2, -1; \alpha, \beta) = \frac{2}{\alpha} \ln\left(\frac{\alpha + \beta}{\beta}\right) + \frac{2}{\beta} \ln\left(\frac{\alpha + \beta}{\alpha}\right)$
2.	$I_0(a, b, c; \alpha, \beta) = \frac{2}{c+2} \sum_{i=0}^{\lfloor (c+1)/2 \rfloor} \binom{c+2}{2i+1} [F_{a+2i+2, b+c-2i+2}(\alpha, \beta) + F_{b+2i+2, a+c-2i+2}(\beta, \alpha)] \quad (c \geq -1, s \geq 0)$ where $F_{p,q}(\alpha, \beta) = \begin{cases} \frac{q!}{(\alpha + \beta)^{p+1} \beta^{q+1}} \sum_{j=0}^q \frac{(p+j)!}{j!} \left(\frac{\beta}{\alpha + \beta}\right)^j & q \geq 0, p \geq 0 \\ \frac{p!}{\alpha^{p+q+2}} \sum_{j=p+q+1}^{\infty} \frac{j!}{(j-q)!} \left(\frac{\alpha}{\alpha + \beta}\right)^{j+1} & q < 0, p \geq 0 \\ 0^a & p < 0 \end{cases}$
3.	$I_0(a, b, c; \alpha, \alpha) = \frac{2^{c+3} s!}{(c+2)(2\alpha)^{s+1}} \left\{ \sum_{j=0}^{a+1} \binom{a+1}{j} (b+1)! \left[\frac{j!}{(j+b+2)!} - \frac{(j+c+2)!}{(j+b+c+4)!} \right] + (a \leftrightarrow b) \right\}$
4.	$I_0(-1, -1, -2; \alpha, \beta) = \frac{2 \ln(\alpha/\beta)}{\alpha^2 - \beta^2}$
5.	$I_0(a, b, -2; \alpha, \beta) = \frac{(a+1)!}{\alpha^{a+2}} \sum_{j=0}^{a+1} \frac{(b+1+j)!}{j!} \left[\frac{\alpha^j}{(\alpha + \beta)^{b+2+j}} - \frac{(-\alpha)^j}{(\beta - \alpha)^{b+2+j}} \right] \times \left[\ln\left(\frac{2\alpha}{\alpha + \beta}\right) - \psi(a+2-j) + \psi(1) \right] + (a \leftrightarrow b)$
6.	$I_0(a, b, -2; \alpha, \alpha) = \frac{2s!(a+1)!(b+1)!}{(2\alpha)^{s+1}} \left[\sum_{j=0}^{a+1} \frac{\psi(s+1-j) - \psi(a+2-j)}{j!(s-j)!} + (a \leftrightarrow b) \right]$
7.	$I_0(-1, -1, -3; \alpha, \beta) = \frac{2(\beta \ln \beta - \alpha \ln \alpha)}{\alpha^2 - \beta^2} + \frac{2[\psi(2) - \ln \varepsilon]^b}{\alpha + \beta}$
8.	$I_0(a, b, -3; \alpha, \beta) = \left[\frac{(a+1)!}{\alpha^{a+1}(\alpha + \beta)^{b+2}} \sum_{j=0}^a \frac{(b+1+j)!}{j!(a+1-j)} \left(\frac{\alpha}{\alpha + \beta}\right)^j + (a \leftrightarrow b) \right] - \frac{s! [\ln(\alpha\beta\varepsilon^2) - 2\psi(2)]}{(\alpha + \beta)^{s+1}} - \frac{(a+1)!(b+1)!}{(s+1)\alpha^{a+2}\beta^{b+1}} {}_2F_1\left(a+2, 1; s+2; \frac{\alpha-\beta}{\alpha}\right), \quad a \geq -1, b \geq -1$
9.	$I_0^{\log}(-1, -1, c; \alpha, \beta) = \frac{2(c+1)!}{\alpha^2 - \beta^2} \left[\frac{\ln \alpha - \psi(c+2)}{\alpha^{c+2}} - \frac{\ln \beta - \psi(c+2)}{\beta^{c+2}} \right]$
10.	$I_0^{\log}(a, b, c; \alpha, \beta) = \frac{(a+1)!}{(c+2)\alpha^{a+c+4}} \sum_{j=0}^{a+1} \frac{(b+1+j)!(a+c+3-j)!}{j!(a+1-j)!} \left[\frac{\alpha^j}{(\alpha + \beta)^{b+2+j}} - \frac{(-\alpha)^j}{(\beta - \alpha)^{b+2+j}} \right] \times \left[-\psi(a+c+4-j) + \frac{1}{c+2} + \ln \alpha \right] + (a \leftrightarrow b)$
11.	$I_0^{\log}(a, b, c; \alpha, \alpha) = \frac{2^{c+3} s!(b+1)!}{(c+2)(2\alpha)^{s+1}} \sum_{j=0}^{a+1} \binom{a+1}{j} \left\{ \left[\frac{j!}{(j+b+2)!} - \frac{(j+c+2)!}{(j+b+c+4)!} \right] \left[\psi(s+1) - \ln \alpha - \frac{1}{c+2} \right] + \frac{(a+c+3-j)!}{(s+1-j)!} [\psi(s+1-j) - \psi(a+c+4-j)] \right\} + (a \leftrightarrow b)$

^a Terms with $p < 0$ represent divergent parts which cancel from convergent differences between integrals with the same α and β
^b ε is the radius of an infinitesimal sphere about $r_{12} = 0$ which is omitted from the range of integration

use of the formula

$$\langle r_1^{-1} r_2^{-1} f(r_{12}) e^{-\alpha r_1 - \beta r_2} \rangle_{\text{rad}} = \frac{2}{\alpha^2 - \beta^2} \int_0^\infty (e^{-\beta r} - e^{-\alpha r}) r f(r) dr, \quad (12.25)$$

and then differentiating or integrating with respect to α or β to raise or lower the powers of r_1 and r_2 .

Total integral. The angular integral in Eq. (12.23) combined with the radial integrals from Table 12.1 yields the total integral

$$\langle \mathcal{Y}_{l_1 l_2}^{M*} \mathcal{Y}_{l_1' l_2'}^M f(a, b, c; \alpha, \beta) \rangle = \sum_{\Lambda} C_{\Lambda} I_{\Lambda}(a, b, c; \alpha, \beta), \quad (12.26)$$

where

$$I_\Lambda(a, b, c; \alpha, \beta) = \langle f(a, b, c; \alpha, \beta) P_\Lambda(\cos \theta) \rangle_{\text{rad}},$$

$$f(a, b, c; \alpha, \beta) = r_1^a r_2^b r_{12}^c e^{-\alpha r_1 - \beta r_2}.$$

Starting from I_0 and I_1 , the general I_Λ can be efficiently calculated from the recursion relations [26]

$$I_{\Lambda+1}(a, b, c; \alpha, \beta) = \frac{2\Lambda + 1}{c + 2} I_\Lambda(a - 1, b - 1, c + 2; \alpha, \beta) + I_{\Lambda-1}(a, b, c; \alpha, \beta), \quad c \neq -2 \quad (12.27)$$

$$I_{\Lambda+1}(a, b, -2; \alpha, \beta) = (2\Lambda + 1) I_\Lambda^{\text{log}}(a - 1, b - 1, 0; \alpha, \beta) + I_{\Lambda-1}(a, b, -2; \alpha, \beta), \quad c = -2, \quad (12.28)$$

where

$$I_\Lambda^{\text{log}}(a, b, c; \alpha, \beta) = \langle f(a, b, c; \alpha, \beta) \ln r_{12} P_\Lambda(\cos \theta) \rangle_{\text{rad}}.$$

The I_Λ^{log} integrals follow the recursion relation

$$I_{\Lambda+1}^{\text{log}}(a, b, c; \alpha, \beta) = \frac{(2\Lambda + 1)}{c + 2} \left[I_\Lambda^{\text{log}}(a - 1, b - 1, c + 2; \alpha, \beta) - \frac{1}{c + 2} I_\Lambda(a - 1, b - 1, c + 2; \alpha, \beta) \right] + I_{\Lambda-1}^{\text{log}}(a, b, c; \alpha, \beta). \quad (12.29)$$

Hamiltonian matrix elements. The general form of the Laplacian operator in terms of r_1, r_2, r_{12} variables is

$$\nabla_1^2 = \frac{1}{r_1^2} \frac{\partial}{\partial r_1} \left(r_1^2 \frac{\partial}{\partial r_1} \right) + \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) - \frac{l_1^2}{r_1^2} + \frac{2(r_1 - r_2 \cos \theta)}{r} \frac{\partial^2}{\partial r_1 \partial r} - 2(\nabla_1^Y \cdot \mathbf{r}_2) \frac{1}{r} \frac{\partial}{\partial r}, \quad (12.30)$$

and similarly for ∇_2^2 with subscripts 1 and 2 interchanged. The term ∇_1^Y is understood to act only on the $\mathcal{Y}_{l_1 l_2 L}^M(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2)$ part of the wave function. This term in ∇_1^2 can be easily evaluated by means of the effective operator replacement

$$\langle \mathcal{Y}_{l_1' l_2' L'}^{M*} \nabla_1^Y \cdot \mathbf{r}_2 \mathcal{Y}_{l_1 l_2 L}^M \rangle_{\text{ang}} \frac{1}{r_{12}} \frac{\partial g(r_{12})}{\partial r_{12}} \rightarrow \frac{g(r_{12})}{2r_1 r_2} \sum_\Lambda \tilde{C}_\Lambda P_\Lambda(\cos \theta) \quad (12.31)$$

for the angular part of the total integral, where

$$\tilde{C}_\Lambda = [l_1'(l_1' + 1) - l_1(l_1 + 1) - \Lambda(\Lambda + 1)] C_\Lambda. \quad (12.32)$$

The replacement in Eq. (12.31) becomes an equality after radial integration with any function $g(r_{12})$ in the integrand. The matrix elements of H between arbitrary basis functions defined by

$$\chi = r_1^a r_2^b r_{12}^c e^{-\alpha r_1 - \beta r_2} \mathcal{Y}_{l_1 l_2 L}^M(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2),$$

$$\chi' = r_1^{a'} r_2^{b'} r_{12}^{c'} e^{-\alpha' r_1 - \beta' r_2} \mathcal{Y}_{l_1' l_2' L}^M(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2),$$

can then be written in the explicitly Hermitian form (for infinite nuclear mass)

$$\langle \chi' | H | \chi \rangle = \frac{1}{8} \sum_\Lambda C_\Lambda \sum_{i=0}^2 \left[A_i^{(1)} I_\Lambda(a_+ - i, b_+, c_+; \alpha_+, \beta_+) + A_i^{(2)} I_\Lambda(a_+, b_+ - i, c_+; \alpha_+, \beta_+) + A_i^{(3)} I_\Lambda(a_+, b_+, c_+ - i; \alpha_+, \beta_+) \right], \quad (12.33)$$

where $a_\pm = a \pm a'$, $\alpha_\pm = \alpha \pm \alpha'$ etc., and

$$A_0^{(1)} = -\alpha_+^2 - \alpha_-^2 + 2\alpha_- \alpha_+ (c_-/c_+),$$

$$A_1^{(1)} = 2\{\alpha_+(a_+ + 2) + \alpha_- a_- - [\alpha_+ a_- + \alpha_-(a_+ + 2)](c_-/c_+)\} - 8Z,$$

$$A_2^{(1)} = -a_+^2 - a_-^2 - 2a_+ + 2a_-(a_+ + 1)(c_-/c_+) + 2l_1(l_1 + 1)(1 - c_-/c_+) + 2l_1'(l_1' + 1)(1 + c_-/c_+),$$

$$A_0^{(3)} = 0, \quad A_1^{(3)} = 8,$$

$$A_2^{(3)} = 2(c_+^2 - c_-^2),$$

with $(c_-/c_+) = 0$ for $c_+ = 0$. The $A_i^{(2)}$ are defined similarly to $A_i^{(1)}$ with the replacements $a \rightarrow b$, $\alpha \rightarrow \beta$, $l_1 \rightarrow l_2$. The term $A_1^{(3)} = 8$ corresponds to the electron–electron repulsion term e^2/r in H , and $-8Z$ in $A_1^{(1)}$ is the electron–nucleus attraction term. The overlap integral is

$$\langle \chi' | \chi \rangle = \sum_\Lambda C_\Lambda I_\Lambda(a_+, b_+, c_+; \alpha_+, \beta_+). \quad (12.34)$$

12.3.4 Other Computational Methods

Although not yet at the same level of accuracy as variational methods, certain nonvariational methods, such as finite element methods [28], solutions to the Faddeev equations [29], and the correlated-function hyperspherical-harmonic method [30], have their own advantages of flexibility and/or generality. A characteristic feature of these methods is that they provide direct numerical solutions to the three-body problem, which, in principle, converge pointwise to the exact solution rather than depending upon a globally optimized solution. Other methods particularly suited to doubly-excited states are discussed in Chap. 26 and Sect. 22.7.3.

12.4 Variational Eigenvalues

High-precision variational eigenvalues are available for all states of helium up to $n = 10$ and $L = 7$ [22, 23]. The non-relativistic values of ε_0 , ε_1 and ε_2 [Eq. (12.6)] are listed in Tables 12.2 and 12.3. Values of ε_0 for some of the low-lying states are updated with more recent results by *Aznabaev et al.* [31] as noted in Table 12.2. The ε_0 are the eigenvalues for infinite nuclear mass, and ε_1 and ε_2 , together with Eq. (12.6), give the finite mass corrections for the isotopes ^3He and ^4He . The values of μ/M can be calculated from

$$\frac{\mu}{M} = \left[\frac{M_A}{5.485\,799\,090\,65(16) \times 10^{-4}} - N + 1 \right]^{-1}, \quad (12.35)$$

where M_A is the atomic mass (in amu; see [32] for a tabulation), and N is the number of electrons. (For high-precision work, the helium electronic binding energy of 8.48×10^{-8} amu should be added to M_A .) For ^4He , one can use directly the accurately known value of m_e/m_α to calculate $\mu/M = 1/(m_\alpha/m_e + 1)$. Values of μ/M for the first several isotopes are listed in Table 12.4, and the corresponding energy coefficients for the $1s^2\ ^1S$ ground state are given in Table 12.5. For the higher-lying S -states up to $n = 24$, high precision eigenvalues have been obtained by *Nakashima and Nakatsuji* [33] by their free iterative-complement-interaction-method.

12.4.1 Expectation Values of Operators and Sum Rules

Expectation values for various powers of the radial coordinates, together with operators appearing in the Breit interaction, are listed in Table 12.6 for the ground state of helium and He-like ions. Included are all terms required to calculate $\langle V^2 \rangle$, and the oscillator strength sum rules [34]

$$S(-1) = \frac{2}{3} \langle (\mathbf{r}_1 + \mathbf{r}_2)^2 \rangle, \quad (12.36a)$$

$$S(0) = 2, \quad (12.36b)$$

$$S(1) = -\frac{4}{3}(\varepsilon_0 - \varepsilon_1), \quad (12.36c)$$

$$S(2) = \frac{2\pi Z}{3} \langle \delta(\mathbf{r}_1) + \delta(\mathbf{r}_2) \rangle, \quad (12.36d)$$

where $S(k) = \sum_n [\varepsilon_0(n^1P) - \varepsilon_0(1^1S)]^k f_{0n}$, with energies in a.u., and f_{0n} is the $1^1S - n^1P$ oscillator strength (Sect. 12.6.1).

12.5 Total Energies

As discussed in Chaps. 22 and 28, relativistic and QED corrections must be added to the nonrelativistic eigenvalues of Sect. 12.4 before a meaningful comparison with measured

transition frequencies can be made. The corrections are discussed in detail in [22, 35].

Using the fine-structure constant $\alpha \simeq 1/137$ as an expansion parameter, the terms in order of decreasing size are:

1. Relativistic corrections of $O(\alpha^2)$.

$$\begin{aligned} H_{\text{rel}} &= H_{\text{NFS}} + H_{\text{FS}}, \\ H_{\text{NFS}} &= H_{\text{mass}} + H_{\text{D}} + H_{\text{SSC}} + H_{\text{oo}}, \\ H_{\text{FS}} &= H_{\text{so}} + H_{\text{soo}} + H_{\text{ss}}. \end{aligned}$$

The various nonfine-structure (NFS) and fine-structure (FS) terms are defined in Sect. 22.1. The off-diagonal matrix elements of H_{FS} mix states of different spin and cause a breakdown of LS -coupling.

2. Anomalous magnetic moment corrections of $O(\alpha^3)$.

The general FS matrix elements between states with spins S and S' due to the anomalous magnetic moment a_e are (Sect. 22.7.3)

$$\begin{aligned} \langle \gamma S | H_{\text{FS}}^{\text{anom}} | \gamma' S' \rangle &= 2a_e \langle \gamma S | H_{\text{so}} + \frac{2}{3} \delta_{S,S'} H_{\text{soo}} \\ &\quad + \left(1 + \frac{1}{2} a_e\right) H_{\text{ss}} | \gamma' S' \rangle, \end{aligned} \quad (12.37)$$

where $a_e = (g_e - 2)/2 = \alpha/(2\pi) - 0.328\,479\alpha^2 + \dots$.

3. QED corrections of $O(\alpha^3)$. The lowest order QED corrections (including NFS anomalous magnetic moment terms) can be written in the form $\Delta_{L,1} + \Delta_{L,2}$, where

$$\Delta E_{L,1} = \frac{4}{3} Z \alpha^3 \left[\ln(Z\alpha)^{-2} + \frac{19}{30} - \ln k_0 \right] \langle \delta(\mathbf{r}_1) + \delta(\mathbf{r}_2) \rangle \quad (12.38)$$

$$\Delta E_{L,2} = \alpha^3 \left[\frac{89}{15} + \frac{14}{3} \ln \alpha - \frac{20}{3} \mathbf{s}_1 \cdot \mathbf{s}_2 \right] \langle \delta(\mathbf{r}_{12}) \rangle - \frac{4}{3} \alpha^3 Q, \quad (12.39)$$

$\ln k_0$ is the two-electron Bethe logarithm defined by

$$\ln k_0 = \frac{\sum_i |\langle 0 | \mathbf{p}_1 + \mathbf{p}_2 | i \rangle|^2 (E_i - E_0) \ln |E_i - E_0|}{\sum_i |\langle 0 | \mathbf{p}_1 + \mathbf{p}_2 | i \rangle|^2 (E_i - E_0)} \quad (12.40)$$

summed over all intermediate states and Q is the matrix element defined by

$$Q = \frac{1}{4\pi} \lim_{\epsilon \rightarrow 0} \sum_{i>j} \langle r_{12}^{-3}(\epsilon) + 4\pi(\gamma + \ln \epsilon) \delta(\mathbf{r}_{12}) \rangle \quad (12.41)$$

where γ is Euler's constant, and ϵ is the radius of an infinitesimal sphere about $r_{12} = 0$ that is excluded from the range of integration (i.e. the principal value of the divergent integral). These two-electron QED corrections are known as the Araki-Sucher terms [36, 37].

For a highly excited $1snl$ state, $\Delta E_{L,2} \rightarrow 0$, $\langle \delta(\mathbf{r}_1) + \delta(\mathbf{r}_2) \rangle \rightarrow Z^3/\pi$, $\ln k_0 \rightarrow \ln k_0(1s) = 2.984\,128\,555$, and $\Delta E_{L,1}$ reduces to the Lamb shift of the $1s$ core state

Table 12.2 Nonrelativistic eigenvalue coefficients ε_0 and ε_1 for helium

Table 12.4 Values of the reduced electron mass ratio μ/M , including binding energy corrections

Isotope	$\mu/M \times 10^4$
¹ H	5.443 205 7507(5)
² D	2.723 695 0538(2)
³ He	1.819 212 0630(16)
⁴ He	1.370 745 634 66(5)
⁶ Li	0.912 167 5131(2)
⁷ Li	0.782 020 2727(6)
⁹ Be	0.608 820 388(3)

(Sect. 29.7.1). Thus, $\Delta E_{L,1}$ represents the electron–nucleus part of the QED shift with the factor of Z^3/π replaced by the correct electron density at the nucleus. Accurate values of $\ln k_0$ for two-electron atoms and ions are tabulated in [38]. For the low-lying S -states and P -states of helium [25, 39],

$$\ln k_0(1^1S) = 2.983 865 861, \quad (12.42a)$$

$$\ln k_0(2^1S) = 2.980 118 365, \quad (12.42b)$$

$$\ln k_0(2^3S) = 2.977 742 459, \quad (12.42c)$$

$$\ln k_0(2^1P) = 2.983 803 377, \quad (12.42d)$$

$$\ln k_0(2^3P) = 2.983 690 995. \quad (12.42e)$$

For a $1snl$ state with large l , the asymptotic expansion [40, 41]

$$\begin{aligned} \ln k_0(1snl) \approx & \ln k_0(1s) + \frac{1}{n^3} \left(\frac{Z-1}{Z} \right)^4 \ln k_0(nl) \\ & + 0.316 205(6) Z^{-6} \langle r^{-4} \rangle_{nl} \\ & + \Delta\beta(1snl) \end{aligned} \quad (12.43)$$

becomes essentially exact. Here, $\ln k_0(nl)$ is the one-electron Bethe logarithm [42], and

$$\langle r^{-4} \rangle_{nl} = \frac{16(Z-1)^4 [3n^2 - l(l+1)]}{(2l-1)2l(2l+1)(2l+2)(2l+3)}. \quad (12.44)$$

The correction $\Delta\beta(1snl)$ for higher order terms is

$$\begin{aligned} \Delta\beta(1snl \ ^1L) = & 95.8(8) \langle r^{-6} \rangle - 845(19) \langle r^{-7} \rangle \\ & + 1406(50) \langle r^{-8} \rangle, \end{aligned} \quad (12.45)$$

$$\begin{aligned} \Delta\beta(1snl \ ^3L) = & 95.1(9) \langle r^{-6} \rangle - 841(23) \langle r^{-7} \rangle \\ & + 1584(60) \langle r^{-8} \rangle. \end{aligned} \quad (12.46)$$

For example, for the $1s4f \ ^1F$ state, $\beta(4 \ ^1F) = 2.984 127 1493(3)$.

For higher Z , $1/Z$, expansions of [38] should be used.

4. Relativistic finite mass corrections of $O(\alpha^2\mu/M)$.

Relativistic finite mass corrections come from two sources. First, a transformation to relative coordinates as in Eq. (12.3) is applied to the pairwise Breit interactions among the three

particles, generating the new terms [43]

$$\Delta = \Delta_{00} + \Delta_{\text{so}} + 2\frac{m_e}{M}H_{\text{so}},$$

where

$$\Delta_{00} = \frac{-Z\alpha^2 m_e}{2M} \sum_{i,j} \frac{1}{r_i} [\mathbf{p}_j \cdot \mathbf{p}_i + \hat{\mathbf{r}}_i \cdot (\hat{\mathbf{r}}_i \cdot \mathbf{p}_j) \mathbf{p}_i], \quad (12.47)$$

$$\Delta_{\text{so}} = \frac{Z\alpha^2 m_e}{M} \sum_{i \neq j} \frac{1}{r_i^3} \mathbf{r}_i \times \mathbf{p}_j \cdot \mathbf{s}_i. \quad (12.48)$$

Second, the mass polarization term H_{mp} in Eq. (12.3) generates second-order cross terms between H_{mp} and H_{rel} . If the wave functions are calculated by solving Eq. (12.4) in scaled atomic units, the H_{mp} correction is then automatically included to all orders, and the mass-corrected relativistic energy shift is (in units of e^2/a_0)

$$\Delta E_{\text{rel}} = \left(\frac{\mu}{m_e} \right)^3 \left(\left(\frac{\mu}{m_e} \right) H_{\text{mass}} + H_{\text{D}} + H_{\text{SSC}} + H_{00} + \Delta_{00} + \left(1 + \frac{2m_e}{M} \right) H_{\text{so}} + H_{\text{soo}} + H_{\text{ss}} + \Delta_{\text{so}} \right), \quad (12.49)$$

with $\mu/m_e = 1 - \mu/M$. The difference $\Delta E_{\text{rel}} - \langle H_{\text{rel}} \rangle_\infty$ calculated for infinite nuclear mass is the relativistic finite mass correction.

5. Higher-order corrections. All higher-order terms are now known in their entirety up to order α^4 Ry (or equivalently

$\alpha^6 mc^2$) [44] and the spin-dependent parts up to order α^5 Ry. The theory and a comparison with experiment are reviewed by Pachucki et al. [45]. The more accurate spin-dependent parts are particularly important in connection with the 2^3P_J fine structure splittings [46] and determinations of the fine structure constant from atomic spectroscopy [47]. Recoil terms of order $\alpha^4 m/M$ Ry are of importance in the interpretation of isotope shift measurements. The isotope shift has been extensively used to determine the nuclear charge radii of short-lived species such as the halo nuclei ^6He and ^8He [48].

For the energy terms of order α^4 Ry, the dominant electron–nucleus part is known from the one-electron Lamb shift to be

$$\Delta E'_{L,1} = Z\alpha^3 \left[\pi Z\alpha \left(\frac{427}{96} - 2 \ln 2 \right) + 0.538 931 \frac{\alpha}{\pi} \right] \times \langle \delta(\mathbf{r}_1) + \delta(\mathbf{r}_2) \rangle + O(\alpha^5), \quad (12.50)$$

and the electron–electron logarithmic part is [49]

$$\Delta E'_{L,2} = \pi\alpha^4 \ln \alpha^{-1} \langle \delta(r_{12}) \rangle, \quad (12.51)$$

As an example, $\Delta E'_{L,1}$ contributes -50.336 MHz and -88.267 MHz to the $2^1P - 2^1S$ and $2^3P_J - 2^3S_1$ transition frequencies, respectively, while the differences between theory and experiment are ≈ 1 MHz and ≈ -7 MHz for the two cases [35]. Thus, two-electron corrections (for example, relativistic corrections of relative order $Z\alpha$ to $\Delta E_{L,2}$) are evidently small.

Table 12.7 lists the calculated ionization energies for all states of helium up to $n = 10$ and $L = 7$. Some of the en-

^a Total of $\Delta E_{L,1} + \Delta E_{L,2}$ from [45].

^b Centroid value without fine structure. See [45].

tries have been updated with more recent results by *Pachucki* et al. [45] for the low-lying S and P -states, and by *Yerokhin* et al. [50] for the D -states. As noted in the latter reference, there is evidently a systematic discrepancy between theory and experiment for all the $nD-2S$ and $nD-2P$ transitions. Except for using an updated value for the Rydberg states, the other entries are the same as previously tabulated in [51].

For the D -states and beyond, the uncertainties are sufficiently small that these states can be taken as known points of reference in the interpretation of experimental transition frequencies. However, long-range Casimir–Polder corrections [52] are not included since they still lack experimental confirmation [53]. The QED shifts are the largest for the S and P -states. The contributions from $\Delta E_{L,1} + \Delta E'_{L,1}$ and $\Delta E_{L,2} + \Delta E'_{L,2}$ for these states are listed separately in Table 12.8. Applications to isotope shifts and measurements of the nuclear radius are discussed in Sects. 17.2 and 91.2.

12.5.1 Quantum Defect Extrapolations

As discussed in Sect. 15.1, the ionization energies of an isolated Rydberg series of states can be expressed in the form

$$W_n = R_M(Z-1)^2/n^{*2}, \quad (12.52)$$

where $Z-1$ is the screened nuclear charge, and n^* is the effective principal quantum number defined by an iterative solution to the equation

$$n^* = n - \delta(n^*), \quad (12.53)$$

where $\delta(n^*)$ is the *quantum defect* defined by the Ritz expansion

$$\delta(n^*) = \delta_0 + \frac{\delta_2}{(n-\delta)^2} + \frac{\delta_4}{(n-\delta)^4} + \dots, \quad (12.54)$$

with constant coefficients δ_i . The absence of *odd* terms in this series is a special property of the eigenvalues of Hamiltonians of the form $H_C + V$, where H_C is a pure one-electron Coulomb Hamiltonian, and V is a local, short-range, spherically symmetric potential of arbitrary strength (see [54] for further discussion). For the Rydberg states of helium, odd terms must be included in the Ritz expansion in Eq. (12.54) due to relativistic and mass polarization corrections, but they can be removed again by first adjusting the energies according to

$$W'_n = W_n - \Delta W_n, \quad (12.55)$$

where, to sufficient accuracy [54] [see the discussion following Eq. (12.68)]

$$\Delta W_n = R_M \left\{ \frac{-3\alpha^2(Z-1)^4}{4n^4} + \left(\frac{\mu}{M} \right)^2 \frac{(Z-1)^2}{n^2} \times \left[1 + \frac{5}{6}(\alpha Z)^2 \right] \right\}, \quad (12.56)$$

with $Z=2$ for helium. The quantum defect parameters listed in Table 12.9 provide accurate extrapolations to higher-lying Rydberg states, with

$$W_n = R_M/n^{*2} + \Delta W_n. \quad (12.57)$$

12.5.2 Asymptotic Expansions

The asymptotic expansion method [35, 55] rapidly increases in accuracy with increasing angular momentum L of the Rydberg electron, and can be used to high precision for $L \geq 7$. The method is based on a model in which:

1. The Rydberg electron, treated as a distinguishable particle, moves in the field of the core consisting of the He nucleus and a tightly bound $1s$ electron.
2. The core, as characterized by its various multipole moments, is perturbed by the electric field of the Rydberg electron.

Table 12.9 Quantum defects for the total energies of helium with the ΔW_n term subtracted [Eq. (12.56)]

A systematic perturbation expansion yields an asymptotic series of the form

$$\varepsilon_0^{nL} = -2 - \frac{(Z-1)^2}{2n^2} + a_0 \sum_{j=4}^N A_j \langle r^{-j} \rangle_{nL} \frac{e^2}{a_0}, \quad (12.58)$$

where the expectation value $\langle r^{-j} \rangle_{nL}$ is calculated with respect to the hydrogenic nL -electron wave function [56], and the series is truncated at the upper limit N , where the series begins diverging. The leading coefficients A_j are

$$A_4 = -\frac{1}{2}\alpha_1, \quad A_5 = 0, \quad A_6 = -\frac{1}{2}(\alpha_2 - 6\beta_1),$$

where α_k is the 2^k -pole polarizability of the hydrogenic core, and β_k is a nonadiabatic correction. The exact hydrogenic values are

$$\alpha_1 = \frac{9a_0^3}{2Z^4}, \quad \alpha_2 = \frac{15a_0^5}{Z^6}, \quad \beta_1 = \frac{43a_0^5}{8Z^6}.$$

All terms are known up to A_{10} (see [35, 55] for detailed results, and [57] for derivations and corrections to earlier work). The expansions for the terms ε_0 , ε_1 , and ε_2 in Eq. (12.6) for helium are [57]

$$\begin{aligned} \varepsilon_0^{nL} = & -2 - \frac{1}{2n^2} - \frac{9}{64}\langle r^{-4} \rangle + \frac{69}{512}\langle r^{-6} \rangle + \frac{3833}{15360}\langle r^{-7} \rangle \\ & - \left[\frac{55923}{65536} + \frac{957L(L+1)}{10240} \right] \langle r^{-8} \rangle - \frac{908185}{688128}\langle r^{-9} \rangle \\ & + \left[\frac{21035363}{6193152} + \frac{33275L(L+1)}{28672} \right] \langle r^{-10} \rangle \\ & + e^{(1,1)} - \frac{23}{20}e^{(1,2)}, \end{aligned} \quad (12.59)$$

$$\begin{aligned} \varepsilon_1^{nL} = & -\frac{9}{32}\langle r^{-4} \rangle + \frac{249}{256}\langle r^{-6} \rangle + \frac{319}{3840}\langle r^{-7} \rangle \\ & - \left[\frac{34\,659}{16\,384} + \frac{957L(L+1)}{5120} \right] \langle r^{-8} \rangle - \frac{14\,419}{3072} \langle r^{-9} \rangle \\ & + \left[\frac{155\,027\,773}{6\,193\,152} + \frac{24\,155L(L+1)}{8192} \right] \langle r^{-10} \rangle \\ & + 4e^{(1,1)} - \frac{53}{5}e^{(1,2)}, \end{aligned} \quad (12.60)$$

$$\begin{aligned} \varepsilon_2^{nL} = & -\frac{1}{2n^2} - \frac{45}{64}\langle r^{-4} \rangle + \frac{165}{512}\langle r^{-6} \rangle + \frac{2555}{3072}\langle r^{-7} \rangle \\ & - \left[\frac{268\,485}{32\,768} + \frac{957L(L+1)}{2048} \right] \langle r^{-8} \rangle + \frac{598\,909}{172\,032} \langle r^{-9} \rangle \\ & + \left[\frac{1148\,906\,421}{49\,545\,216} + \frac{629\,515L(L+1)}{114\,688} \right] \langle r^{-10} \rangle \\ & + 14e^{(1,1)} - \frac{251}{10}e^{(1,2)}. \end{aligned} \quad (12.61)$$

The terms $e^{(1,1)}$ and $e^{(1,2)}$ are second-order dipole-dipole and dipole-quadrupole perturbation corrections. Defining $f_p^L = (L+p)!/(L-p)!$, they are given by

$$\begin{aligned} e^{(i,j)} = & -\frac{(2-\delta_{j,k})2^{2i+2j+1}(2L-2i)!(2L-2j)!}{n^3(2L+2i+1)!(2L+2j+1)!} \\ & \times \left[\frac{2^{2i+2j}(2L-2i-2j)!A^{(i,j)}}{n^{2i+2j+2}(2L+2i+2j+1)!} + \frac{B^{(i,j)}}{n^{2i+2j+1}} \right], \end{aligned} \quad (12.62)$$

with

$$\begin{aligned} A^{(1,1)} = & 3n^2(3n^2-2f_1)(f_1-2)(45+623f_1^L+3640f_2^L \\ & + 560f_3^L), \\ B^{(1,1)} = & (9n^2-7f_1^L)(3n^2-f_1^L), \\ A^{(1,2)} = & -21n^6(94\,500+122\,850f_1^L-1126\,125f_2^L \\ & -18\,931\,770f_3^L-11\,171\,160f_4^L \\ & -1029\,600f_5^L-18\,304f_6^L) \\ & -15n^4(94\,500-444\,150f_1^L+7747\,425f_2^L \\ & +337\,931\,880f_3^L+375\,290\,190f_4^L \\ & +66\,518\,760f_5^L+2880\,416f_6^L+29\,568f_7^L) \\ & +9n^2f_1^L(90\,300-177\,450f_1^L+1738\,450f_2^L \\ & +133\,125\,575f_3^L+160\,040\,870f_4^L \\ & +29\,322\,216f_5^L+1293\,600f_6^L+13\,440f_7^L) \\ & +2f_1^Lf_2^Lf_3^L(45+252f_1^L-1680f_2^L-2240f_3^L), \\ B^{(1,2)} = & 315n^6+125n^4(3-5f_1^L)-7n^2f_1^L(43-39f_1^L) \\ & -27f_1^Lf_2^L. \end{aligned}$$

The accuracy of the expansion for the ε_0 , ε_1 , and ε_2 can be reliably estimated to be one-half of the last $\langle r^{-j} \rangle$ term included in the sum. Formulas for the $\langle r^{-j} \rangle$ are given in Table 12.10.

Table 12.10 Formulas for the hydrogenic expectation value $\langle r^{-j} \rangle \equiv (nl|r^{-j}|nl)$ in terms of

$$G_p^{nl} = \frac{2^p Z^p (2l-p+2)!}{n^{p+1} (2l+p-1)!}, \quad f_p^l = \frac{(l+p)!}{(l-p)!}.$$

j	$\langle r^{-j} \rangle (a_0)$
2	$\frac{1}{2}G_2^{nl}$
3	nG_3^{nl}
4	$G_4^{nl}(3n^2-f_1^l)$
5	$2G_5^{nl}[5n^3-n(3f_1^l-1)]$
6	$G_6^{nl}[35n^4-5n^2(6f_1^l-5)+3f_2^l]$
7	$2G_7^{nl}[63n^5-35n^3(2f_1^l-3)+n(15f_2^l-20f_1^l+12)]$
8	$G_8^{nl}[462n^6-210n^4(3f_1^l-7)+42n^2(5f_2^l-15f_1^l+14)-10f_3^l]$

10	$G_{10}^{nl}[6435n^8-6006n^6(2f_1^l-9)+1155n^4(6f_2^l-44f_1^l+81)-6n^2(210f_3^l-1365f_2^l+4648f_1^l-4566)+35f_4^l]$

The asymptotic formulas for the NFS relativistic corrections are [35, 58]

$$\begin{aligned} \langle H_{\text{mass}} + H_{\text{D}} \rangle \rightarrow & -\frac{\alpha^2 Z^4}{8} + h_1(nL) + \chi_1(nL) + \frac{(Z\alpha)^2}{2} \\ & \times \left[\frac{14}{3Z^4} \langle r^{-4} \rangle - \frac{5041}{240Z^6} \langle r^{-6} \rangle \right], \end{aligned} \quad (12.63)$$

$$\langle H_{\text{oo}} \rangle \rightarrow \frac{\alpha^2}{Z^2} \left[\langle r^{-4} \rangle + \frac{3(Z-1)}{Z^2} \langle r^{-5} \rangle - \frac{3(f_1^L+8)}{4Z^2} \langle r^{-6} \rangle \right], \quad (12.64)$$

where

$$h_1(nL) = \frac{\alpha^2(Z-1)^4}{2n^3} \left[\frac{3}{4n} - \frac{1}{L+\frac{1}{2}} \right] \quad (12.65)$$

is the leading one-electron Dirac energy, and

$$\begin{aligned} \chi_1(nL) = & \frac{\alpha^2 \alpha_1}{2} \left\{ 3 \left(\frac{Z-1}{n} \right)^2 \langle r^{-4} \rangle - (Z-1) \langle r^{-5} \rangle \right. \\ & - \frac{4(2L-2)!}{(2L+3)!} \left[4 \left(\frac{Z-1}{n} \right)^6 \left(n + \frac{9n^2-5f_1^L}{2L+1} \right) \right. \\ & \left. \left. + (Z-1)^2 \left(\frac{40f_2^L+70f_1^L-3}{2L+1} \right) \langle r^{-4} \rangle \right] \right\} \end{aligned} \quad (12.66)$$

is the correction due to the dipole perturbation of the Rydberg electron. The relativistic recoil terms due to mass polarization are

$$\begin{aligned} \langle H_{\text{mass}} + H_{\text{D}} \rangle_{\text{RR}} \rightarrow & \frac{\mu}{M} \left[\frac{22(Z\alpha)^2(Z-1)}{9Z^4} \langle r^{-4} \rangle + 2(Z-1)\chi_1(nL) \right] \\ & + \left(\frac{\mu}{M} \right)^2 \left[-\frac{5}{12} \left(\frac{\alpha Z(Z-1)}{n} \right)^2 + 4h_1(nL) \right], \end{aligned} \quad (12.67)$$

$$\begin{aligned} & \langle H_{00} \rangle_{RR} + \langle \Delta_{00} \rangle \\ & \rightarrow -\frac{\alpha^2 \mu}{M} \left[Z^4 + \frac{(Z-1)^4}{n^3} \left(\frac{1}{n} - \frac{3}{2L+1} \right) \right. \\ & \quad \left. - \frac{25[1+13f(Z)]}{16Z^2} \langle r^{-4} \rangle \right], \end{aligned} \quad (12.68)$$

with $f(Z) \simeq 1 + (Z-2)/6$. The $-(5/12)[\alpha Z(Z-1)/n]^2$ term in Eq. (12.67) is the dominant contribution in helium for $L \geq 4$. It is included in Eq. (12.56) for ΔW_n , along with the leading $1/n^2$ term from Eq. (12.61), and the $1/n^4$ term from Eq. (12.65). The complete relativistic finite mass correction includes also the mass-scaling terms $-(\mu/M)\langle 4H_{\text{mass}} + 3H_D + 3H_{00} \rangle$ obtained by expanding μ/m_e in Eq. (12.49). The $\langle \delta(\mathbf{r}_1) \rangle$ term is [59]

$$\begin{aligned} \pi \langle \delta(\mathbf{r}_1) \rangle & \rightarrow \frac{Z^3}{2} - \frac{31}{4Z^3} \langle r^{-4} \rangle + \frac{1447}{32Z^5} \langle r^{-7} \rangle \\ & \quad - \frac{31(Z-1)}{2Z^3} \left(\frac{\mu}{M} \right) \langle r^{-4} \rangle + \dots; \end{aligned} \quad (12.69)$$

$\langle \delta(\mathbf{r}_{12}) \rangle$ vanishes exponentially as $1/n^{2L+4}$ with increasing L . The complete asymptotic expressions for the FS matrix elements are summarized by the formulas

$$\begin{aligned} & \langle nL^3L_J | H_{\text{FS}} | nL^3L_J \rangle \\ & \rightarrow T_{nL}(J) \{ Z - 3 + 2S_L(J) + 2a_e[Z - 2 \\ & \quad + (2 + a_e)S_L(J)] + (\mu/M)[2 - 4S_L(J)] \}, \quad (12.70) \\ & \langle nL^3L_J | H_{\text{FS}} | nL^1L_J \rangle \\ & \rightarrow T_{nL}(L)(Z + 1 + 2a_e Z - 2\mu/M) \sqrt{L(L+1)}, \end{aligned} \quad (12.71)$$

where

$$\begin{aligned} T_{nL}(J) & = \begin{cases} -\alpha^2(L+1)\langle r^{-3} \rangle/4 & J = L-1, \\ -\alpha^2\langle r^{-3} \rangle/4 & J = L, \\ \alpha^2 L \langle r^{-3} \rangle/4 & J = L+1, \end{cases} \\ S_L(J) & = \begin{cases} 1 & J = L, \\ \pm 1/(2J+1) & J = L \pm 1. \end{cases} \end{aligned}$$

The asymptotic form for the QED term $\Delta E_{L,1}$ follows from Eq. (12.38) with the use of Eq. (12.69) for $\langle \delta(\mathbf{r}_1) \rangle$ and Eq. (12.43) for $\ln k_0$. The electron–electron part is

$$\Delta E_{L,2} \rightarrow -\frac{7\alpha^3}{6\pi} \left(\langle r^{-3} \rangle + \frac{3}{Z^2} \langle r^{-5} \rangle \right). \quad (12.72)$$

With the use of the formulas in this section, the variationally calculated ionization energies for the K -states ($L=7$) in Table 12.7 can be reproduced to within ± 20 Hz. For $L > 7$, the uncertainty becomes less than 1 Hz, up to the Casimir–Polder retardation effects, which have not been included.

12.6 Radiative Transitions

12.6.1 Basic Formulation

In a semiclassical picture, the interaction Hamiltonian with the radiation field is obtained by making the minimal coupling replacements

$$\begin{aligned} \mathbf{P}_N & \rightarrow \mathbf{P}_N - \frac{Ze}{c} \mathbf{A}(\mathbf{R}_N), \\ \mathbf{P}_i & \rightarrow \mathbf{P}_i + \frac{e}{c} \mathbf{A}_i(\mathbf{R}_i) \end{aligned} \quad (12.73)$$

in Eq. (12.1), where

$$\mathbf{A}(\mathbf{R}) = c \left(\frac{2\pi\hbar}{\omega\mathcal{V}} \right)^{1/2} \hat{\boldsymbol{\epsilon}} e^{i\mathbf{k}\cdot\mathbf{R}} \quad (12.74)$$

is the time-independent part of the vector potential $\mathbf{A}(\mathbf{r}, t) = \mathbf{A}(\mathbf{r})e^{-i\omega t} + \text{c.c.}$ for a photon of frequency ω , wave vector \mathbf{k} , and polarization $\hat{\boldsymbol{\epsilon}} \perp \mathbf{k}$ normalized to unit photon energy $\hbar\omega$ in volume \mathcal{V} . The linear coupling terms then yield

$$H_{\text{int}} = -\frac{Ze}{Mc} \mathbf{P}_N \cdot \mathbf{A}(\mathbf{R}_N) + \frac{e}{m_e c} \sum_{i=1}^2 \mathbf{P}_i \cdot \mathbf{A}(\mathbf{R}_i), \quad (12.75)$$

and from Fermi's Golden Rule, the decay rate for spontaneous emission from state γ to γ' is

$$w_{\gamma,\gamma'} d\Omega = \frac{2\pi}{\hbar} |\langle \gamma | H_{\text{int}} | \gamma' \rangle|^2 \rho_f, \quad (12.76)$$

where $\rho_f = \mathcal{V} \omega^2 d\omega / (2\pi c)^3 \hbar$ is the number of photon states with polarization $\hat{\boldsymbol{\epsilon}}$ per unit energy and solid angle in the normalization volume \mathcal{V} . In the long wavelength and electric dipole approximations, the factor $e^{i\mathbf{k}\cdot\mathbf{R}}$ in Eq. (12.74) is replaced by unity. After integrating over angles $d\Omega$ and summing over polarizations $\hat{\boldsymbol{\epsilon}}$, the decay rate reduces to

$$w_{\gamma,\gamma'} = \frac{4}{3} \alpha \omega_{\gamma,\gamma'} |\langle \gamma | \mathbf{Q}_p | \gamma' \rangle|^2, \quad (12.77)$$

where $\omega_{\gamma',\gamma}$ is the transition frequency and \mathbf{Q}_p is the velocity form of the transition operator

$$\mathbf{Q}_p = \frac{Z}{Mc} \mathbf{P}_N + \frac{1}{m_e c} \sum_{i=1}^N \mathbf{P}_i, \quad (12.78)$$

for the general case of N electrons. From the commutator $[H_0, \mathbf{Q}_r / \hbar \omega_{\gamma,\gamma'}] = \mathbf{Q}_p$, where H_0 is the field-free Hamiltonian in Eq. (12.1), the equivalent length form is

$$\mathbf{Q}_r = -\frac{i}{c} \omega_{\gamma,\gamma'} \left(Z \mathbf{R}_N - \sum_{i=1}^N \mathbf{R}_i \right). \quad (12.79)$$

After transforming to c.m. plus relative coordinates in paral-

with Eq. (12.3), the dipole transition operators become

$$\mathbf{Q}_p = \frac{Z_p}{mc} \sum_{i=1}^N \mathbf{p}_i, \quad \mathbf{Q}_r = \frac{i\omega_{\gamma,\gamma'}}{c} Z_r \sum_{i=1}^N \mathbf{r}_i, \quad (12.80)$$

with

$$Z_p = \frac{Zm_e + M}{M}, \quad Z_r = \frac{Zm_e + M}{Nm_e + M},$$

and H_0 now contains the H_{mp} term. If Eq. (12.3) is solved exactly for the states $|\gamma\rangle$ and $|\gamma'\rangle$, then the identity

$$\langle \gamma | \mathbf{Q}_p | \gamma' \rangle = \langle \gamma | \mathbf{Q}_r | \gamma' \rangle \quad (12.81)$$

is satisfied to all orders in m_e/M . For a neutral atom, $N = Z$ and $Z_r = 1$. If the oscillator strength is defined by

$$\begin{aligned} f_{\gamma',\gamma} &= \frac{2m_e\omega_{\gamma',\gamma}}{3\hbar} \left(\frac{Z_r}{Z_p} \right) |\langle \gamma' | \sum_{i=1}^N \mathbf{r}_i | \gamma \rangle|^2 \\ &= \frac{2}{3m_e\hbar\omega_{\gamma',\gamma}} \left(\frac{Z_p}{Z_r} \right) |\langle \gamma' | \sum_{i=1}^N \mathbf{p}_i | \gamma \rangle|^2, \end{aligned} \quad (12.82)$$

then the sum rule $\sum_{\gamma'} f_{\gamma',\gamma} = N$ remains valid, independent of m_e/M . The decay rate, summed over final states and av-

eraged over initial states, is

$$\bar{w}_{\gamma,\gamma'} = -\frac{2\alpha\hbar\omega_{\gamma,\gamma'}}{m_e c^2} Z_p Z_r \bar{f}_{\gamma,\gamma'}, \quad (12.83)$$

where $\bar{f}_{\gamma,\gamma'} = -(g_\gamma/g_{\gamma'})\bar{f}_{\gamma',\gamma}$ is the (negative) oscillator strength for photon emission, and $g_\gamma, g_{\gamma'}$ are the statistical weights of the states.

12.6.2 Oscillator Strength Table

Table 12.11 provides arrays of nonrelativistic oscillator strengths among various states of helium, including the effects of finite nuclear mass as a separate factor. In the absence of mass polarization, the correction factor would be $(1 + \mu/M)^{-1} \simeq 1 - \mu/M$. Mass polarization effects are particularly strong for P -states and for transitions with $\Delta n = 0$.

The largest relativistic correction comes from singlet-triplet mixing between states with the same n, L , and J (e.g. 3^1D_2 and 3^3D_2) due to H_{FS} . The wave functions obtained by diagonalizing the 2×2 matrices $\mathbf{H}_0 + \mathbf{H}_{\text{NFS}} + \mathbf{H}_{\text{FS}}$ are then

$$\begin{aligned} \Psi(n^1L_L) &= \Psi_0(n^1L_L) \cos \theta + \Psi_0(n^3L_L) \sin \theta \\ \Psi(n^3L_L) &= -\Psi_0(n^1L_L) \sin \theta + \Psi_0(n^3L_L) \cos \theta. \end{aligned}$$

Values of $\sin \theta$ are listed in Table 12.12. The corrected oscillator strengths $\tilde{f}_{\gamma,\gamma'}$ for the singlet (s) and triplet (t) components of a $\gamma \rightarrow \gamma'$ transition can then be calculated from the values in Table 12.11 according to

$$\begin{aligned} \tilde{f}_{\gamma,\gamma'}^{\text{ss}} &= \omega_{\gamma,\gamma'}^{\text{ss}} \left(X_{\gamma,\gamma'}^{\text{ss}} \cos \theta_\gamma \cos \theta_{\gamma'} + X_{\gamma,\gamma'}^{\text{tt}} \sin \theta_\gamma \sin \theta_{\gamma'} \right)^2, \\ \tilde{f}_{\gamma,\gamma'}^{\text{tt}} &= \omega_{\gamma,\gamma'}^{\text{tt}} \left(X_{\gamma,\gamma'}^{\text{ss}} \sin \theta_\gamma \sin \theta_{\gamma'} + X_{\gamma,\gamma'}^{\text{tt}} \cos \theta_\gamma \cos \theta_{\gamma'} \right)^2, \\ \tilde{f}_{\gamma,\gamma'}^{\text{st}} &= \omega_{\gamma,\gamma'}^{\text{st}} \left(X_{\gamma,\gamma'}^{\text{ss}} \cos \theta_\gamma \sin \theta_{\gamma'} - X_{\gamma,\gamma'}^{\text{tt}} \sin \theta_\gamma \cos \theta_{\gamma'} \right)^2, \\ \tilde{f}_{\gamma,\gamma'}^{\text{ts}} &= \omega_{\gamma,\gamma'}^{\text{ts}} \left(X_{\gamma,\gamma'}^{\text{ss}} \sin \theta_\gamma \cos \theta_{\gamma'} - X_{\gamma,\gamma'}^{\text{tt}} \cos \theta_\gamma \sin \theta_{\gamma'} \right)^2, \end{aligned}$$

where $X_{\gamma,\gamma'}^{\text{ss}} = (f_{\gamma,\gamma'}^{\text{ss}}/\omega_{\gamma,\gamma'}^{\text{ss}})^{1/2}$, and similarly for $X_{\gamma,\gamma'}^{\text{tt}}$. From Eq. (12.82), $X_{\gamma,\gamma'}$ is proportional to the dipole length form of the transition operator, for which there are no spin-dependent relativistic corrections [60]. The mixing corrections are particularly significant for D - F and F - G transitions, where intermediate coupling prevails. The two-state approximation becomes increasingly accurate with increasing L , but for P -

states, where $\sin \theta$ is small, states with $n' \neq n$ must also be included [61].

12.7 Future Perspectives

The variational calculations, together with quantum defect extrapolations for high n and asymptotic expansions for high L , provide essentially exact results for the entire singly-excited spectrum of helium. In this sense, helium joins hydrogen as a fundamental atomic system. The dominant uncertainties arise from two-electron QED effects beyond the current realm of standard atomic physics. Transition frequencies from the $1s2s^1S_0$ state are now known to better than ± 0.5 MHz (± 1.8 parts in 10^9) [62], and the fine structure intervals in the $1s2p^3P$ state have been measured to an accuracy exceeding 1 kHz [63]. Comparisons with theory [64, 65] hold the promise of determining an “atomic physics” value for the fine structure constant. Transition frequencies among the $n = 10$ states are known even more accurately [53]. Recent progress in the use of the isotope shift to deduce the size of the nucleus from the nuclear volume effect (Sect. 91.2) has attracted a great deal of attention, especially for neutron-rich “halo” nuclei such as ^6He and ^{11}Li .

Abstract

Often symmetries in the experiment limit the number of nonvanishing multipoles, and frequently only populations proportional to diagonal elements of the density matrix are significant. This chapter studies the physical and geometrical significance of simple multipoles and examines whether symmetries allow a complete characterization of the ensemble with state populations. More thorough treatments can be found elsewhere [1].

Keywords

density matrix · total angular momentum · multipole moment · atomic ensemble · state manifold

A typical atomic experiment involves the preparation of an atomic or molecular ensemble, its perturbation by a combination of collisions and external fields, and the characterization of the perturbed system through detection of emitted or scattered particles or quanta. The ensemble can be described by its density matrix, whose full specification generally requires elements between every pair of states in a complete basis set, and whose elements generally depend on spatial posi-

tion, velocity, and time. The time development of such an ensemble may depend on interactions among the atoms of the ensemble with each other, with external fields, and with external perturbers. Most problems burdened by this much detail are intractable, but fortunately, significant simplifications can usually be made.

In this chapter, only ensembles of homogeneously excited, independent atoms are considered. The spatial and velocity distribution of the atoms is thus assumed to be independent of the quantum-state distribution, and the total density matrix can be factored into the product of a phase-space distribution with a state density matrix that is independent of position and velocity. The assumption is severe and prevents us from treating cases of radiation transfer (Chap. 20) where the degree of excitation varies as a function of position or problems of velocity-selective laser excitation. Nevertheless, many experiments in atomic physics do use ensembles that are well-described by our assumption, and even in more complex cases, our model can often serve as a starting point for analysis. Typical of the experiments for which our approach is well suited are collisionally induced polarization relaxation experiments in a gas cell, either of an excited state or of an optically pumped ground state. In addition, we shall for the most part focus on a few isolated manifolds, usually a ground-state manifold and one or two excited-state manifolds. Each manifold, we assume, can be described by a given eigenvalue J of the total angular momentum. The qualifier *isolated* means that coherences between manifolds oscillate rapidly in time compared to other processes and can be ignored. These assumptions permit a great simplification and frequently allow a decoupling of the equations of motion, as shown below. The density matrix within each state manifold can be described by multipole moments, which are coefficients of the expansion of the density matrix in irreducible tensor operators, as described in Chap. 7. Each state multipole is associated with a physical electric or magnetic moment in the atom.

The amount of information which can be imparted to, or obtained from, an atomic ensemble is limited by the finite

 e-mail: baylis@uwindsor.ca

number of accessible multipole moments. The nature of that information may depend on the time evolution of the multipoles in external fields and their relaxation through collisions. The ideal experiment is a *complete* measurement that determines all the multipoles. Often *over-complete* experiments can be designed, but there is little reason for determining redundant information unless consistency checks are important.

13.1 Polarization and Multipoles

An ensemble is said to be *polarized* if there is a nonstatistical distribution of atoms in magnetic sublevels. The type of polarization can be described by the *multipoles* that exist. In many experiments, symmetries in the preparation or detection of the ensemble limit the detectable polarizations to ones caused by different sublevel populations. One can then employ the relatively simple *population* (or *diagonal*) representation. The more general case is discussed in the next section.

As an introduction to the concepts, consider an atomic manifold of total angular momentum $3/2$, for example an excited alkali $P_{3/2}$ state. There are four magnetic sublevels $|m\rangle$ with $m = \pm 3/2, \pm 1/2$ so that state populations are given by a four-dimensional population–density vector

$$\mathbf{N} = \begin{pmatrix} N_{3/2} \\ N_{1/2} \\ N_{-1/2} \\ N_{-3/2} \end{pmatrix}, \quad (13.1)$$

where N_m is the density of atoms in state $|m\rangle$. If there are no external fields, the time evolution of \mathbf{N} is given by

$$\dot{\mathbf{N}} = \mathbf{S} - \Gamma \mathbf{N} - \boldsymbol{\gamma} \cdot \mathbf{N}, \quad (13.2)$$

where \mathbf{S} is the source vector and gives the excitation rate to the various sublevels, Γ is the radiative decay rate, assumed the same for all levels, and $\boldsymbol{\gamma}$ is the collisional matrix, whose elements $-\gamma_{mn}$ give the collisional transition rate from n to m .

The equation of motion is most easily solved if the basis used for the state space exploits the symmetry. Define the *spherical* orthonormal basis of vectors

$$\hat{\mathbf{T}}_0 = \frac{1}{2} \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}, \quad \hat{\mathbf{T}}_1 = \frac{1}{\sqrt{20}} \begin{pmatrix} 3 \\ 1 \\ -1 \\ -3 \end{pmatrix}, \quad (13.3)$$

$$\hat{\mathbf{T}}_2 = \frac{1}{2} \begin{pmatrix} 1 \\ -1 \\ -1 \\ 1 \end{pmatrix}, \quad \hat{\mathbf{T}}_3 = \frac{1}{\sqrt{20}} \begin{pmatrix} 1 \\ -3 \\ 3 \\ -1 \end{pmatrix}. \quad (13.4)$$

(These relations follow from the \mathbf{T}_{LM} with $M = 0$. See Sects. 13.2 and 13.3). The population vector \mathbf{N} can be expanded

$$\mathbf{N} = \sum_{L=0}^4 n_L \hat{\mathbf{T}}_L, \quad (13.5)$$

where the coefficients $n_L = \mathbf{N} \cdot \hat{\mathbf{T}}_L$ contain all the knowable information about the population distribution. The coefficient n_L is called the $2L$ multipole moment of the ensemble. In particular,

$$n_0 = \frac{1}{2} \sum_m N_m$$

is twice the population of the entire ensemble;

$$n_1 = 5^{-1/2} \sum_m m N_m = \frac{2n_0 \langle J_z \rangle}{\sqrt{5}}$$

is the *orientation* (associated with a physical magnetic-dipole moment) of the system,

$$n_2 = \frac{1}{3} n_0 \langle 3J_z^2 - J^2 \rangle$$

is the *alignment* (electric quadrupole moment), and

$$n_3 = \frac{2n_0}{\sqrt{45}} \langle J_z(5J_z + 1 - 3J^2) \rangle$$

is the octupole moment of \mathbf{N} . The source vector \mathbf{S} is readily expanded in the same basis.

If the collisions are isotropic, as is usually approximately the case in gas-cell experiments, then the collision matrix $\boldsymbol{\gamma}$ is invariant under rotations and

$$\boldsymbol{\gamma} \cdot \hat{\mathbf{T}}_L = \gamma_L \hat{\mathbf{T}}_L. \quad (13.6)$$

The equation of motion Eq. (13.2) is separated into four uncoupled scalar equations

$$\dot{n}_L = S_L - \Gamma n_L - \gamma_L n_L. \quad (13.7)$$

If the source term $S_L = \mathbf{S} \cdot \hat{\mathbf{T}}_L$ is constant, Eq. (13.7) have the simple solutions

$$n_L(t) = n_L(\infty) + [n_L(0) - n_L(\infty)] \exp[-(\Gamma + \gamma_L)t], \quad (13.8)$$

with the steady-state value

$$n_L(\infty) = \frac{S_L}{\Gamma + \gamma_L}. \quad (13.9)$$

The detection of such multipoles is discussed at the end of Sect. 13.4.

13.2 The Density Matrix in Liouville Space

If in the example of the last section the state basis is changed, say by rotating the axis of quantization, then populations are generally no longer sufficient to characterize the ensemble. In the new basis, the ensemble will have been prepared in a coherent superposition of states. An adequate description for the quantum state of an ensemble in a manifold of n quantum states requires an $n \times n$ density matrix $\rho(t)$ as discussed in Chap. 7.

The density matrix may be considered a vector in a space, called *Liouville space*, of n^2 dimensions. A convenient set of complex orthonormal basis vectors in this space is given by the irreducible tensor operators T_{LM}

$$T_{LM}^* \cdot T_{L'M'} := \text{Tr}\{T_{LM}^\dagger T_{L'M'}\} = \delta_{LL'} \delta_{MM'}, \quad (13.10)$$

where the trace (Tr) expression is appropriate for the usual $n \times n$ matrix representations of the T_{LM} . Every quantum operator on the manifold can be expanded in the basis $\{T_{LM}\}$, and in particular the density matrix has an expansion

$$\rho(t) = \sum_{LM} \rho_{LM}(t) T_{LM}, \quad (13.11)$$

with time-dependent coefficients

$$\begin{aligned} \rho_{LM}(t) &= T_{LM}^* \cdot \rho(t) := \text{Tr}\{T_{LM}^\dagger \rho(t)\} \\ &= N \langle T_{LM}^\dagger \rangle \end{aligned} \quad (13.12)$$

that are identified with the multipole moments of the ensemble. Here, $\langle \dots \rangle$ indicates the average value over the ensemble and $N = \text{Tr}\{\rho\}$ is the normalization of the density matrix ρ , which is often set equal to unity but is sometimes more conveniently set equal to the total density of atoms in the manifold.

The T_{LM} are defined to transform under rotations as spherical harmonics Y_{LM} [2, 3]. The expansion Eq. (13.11) splits the density matrix into basis vectors T_{LM} which contain the geometric information and scalar coefficients (the multipole moments) $\rho_{LM}(t)$ which contain the physical information about state distributions.

The time dependence of $\rho(t)$ is given by the Schrödinger equation and in the interaction picture takes the form

$$i\hbar \dot{\rho} = [V, \rho], \quad (13.13)$$

where V is the interaction due to external fields (including radiation) and collisions. When V is expanded and second-order perturbation theory is applied, the time evolution Eq. (13.13) can be expressed in a form analogous to Eq. (13.2) but with an extra term [1]

$$\dot{\rho} = S - \Gamma \cdot \rho - \gamma \cdot \rho - iL_0 \cdot \rho, \quad (13.14)$$

where L_0 is the *Liouville operator* arising from the interaction V_0 with slowly varying external fields. Its matrix elements with ρ are

$$(L_0 \cdot \rho)_{mn} = \hbar^{-1} [V_0, \rho]_{mn} = (\omega_m - \omega_n) \rho_{mn}, \quad (13.15)$$

where $\omega_m - \omega_n$ are the field-induced frequency splittings between the states.

For example, in a weak magnetic field $B_0 \hat{z}$ oriented along the quantization axis \hat{z} , $V_0 = \omega_0 J_z$ where $\omega_0 = g_j \mu_B B_0 / \hbar$. Since $[J_z, T_{LM}] = M \hbar T_{LM}$ (see Chap. 7, then assuming that the collisions are isotropic and that the radiative decay rate is the same for all states of the manifold, the expansion of ρ in T_{LM} decouples the equation of motion Eq. (13.14) into multipoles

$$\dot{\rho}_{LM} = S_{LM} - \Gamma \rho_{LM} - \gamma_L \rho_{LM} - iM \omega_0 \rho_{LM}, \quad (13.16)$$

with the solution

$$\begin{aligned} \rho_{LM}(t) &= \rho_{LM}(\infty) + [\rho_{LM}(0) - \rho_{LM}(\infty)] \\ &\quad \times \exp[-(\Gamma + \gamma_L + iM \omega_0)t] \end{aligned} \quad (13.17)$$

comprising a transient part that decays as it precesses at the angular rate ω_0 plus a steady-state part that predicts the collisionally broadened Hanle effect (Chap. 18)

$$\rho_{LM}(\infty) = \frac{S_{LM}}{\Gamma + \gamma_L + iM \omega_0}. \quad (13.18)$$

If $M = 0$, the solutions reduce to the field-independent ones given in Eq. (13.9). On the other hand, any stray field that is not aligned with an induced multipole moment can rotate the moment and possibly cause systematic measurement errors if not taken into account. Measurements of γ_L in a gas cell at temperature T are frequently used to determine thermally averaged multipole-relaxation cross sections Q_L , defined by

$$\gamma_L = N \bar{v} Q_L, \quad (13.19)$$

where N is the density of perturbers, and the mean relative velocity is $\bar{v} = 2\pi^{-1/2} (2kT/\mu)^{1/2}$, with μ the reduced mass of the polarized-atom/perturber system. Many semiclassical and full quantum calculations of such cross sections have been made, both for atoms [1, 4] and for molecules [5].

13.3 Diagonal Representation: State Populations

An ensemble is said to be in a *coherent state* when one or more of the off-diagonal elements of the density matrix do not vanish. In a manifold of angular momentum substates of

a single total angular momentum j , the ensemble has coherence if and only if it is not axially symmetric, that is, if and only if $[\rho, J_z] \neq 0$. In an ensemble lacking coherence, or one in which any coherence that is present does not affect the observation, only the $N = 2j + 1$ diagonal elements of the $N \times N$ density matrix, those that represent state populations, need be considered. In terms of multipoles, only the N elements ρ_{L0} then play a role; the ρ_{LM} elements with $M \neq 0$ can be safely ignored. Such a *diagonal representation* is valid whenever (1) the time evolution of the system is axially symmetric and (2) either the preparation of the system or its detection is axially symmetric.

13.4 Interaction with Light

A polarized system can be prepared in a variety of ways, including beam splitting in external fields, collisional excitation (including beam-foil excitation of fast beams), or radiative excitation with directed and/or polarized light. Several options for the detection of multipoles also exist, including the measurement of the anisotropy and/or polarization of scattered particles or photons. In this section, the interaction of the atomic ensemble with dipole radiation is considered.

It is convenient to define a *detection operator* for electric dipole radiation of polarization $\hat{\epsilon}$ by

$$\mathbf{D}_\lambda(\hat{\epsilon}) = \sum_\mu \hat{\epsilon} \cdot \mathbf{d} |\lambda\mu\rangle \langle \lambda\mu| \mathbf{d} \cdot \hat{\epsilon}^* \quad (13.20)$$

for decay to the state λ . Here, $\mathbf{d} = \sum_k e r_k$ is the dipole-moment operator of the atom and μ is a magnetic sublevel of λ . The detection operator is a vector in Liouville space and can be expanded in irreducible tensor operators according to

$$\mathbf{D}_\lambda(\hat{\epsilon}) = \sum_{LM} D_{\lambda LM}(\hat{\epsilon}) \mathbf{T}_{LM}, \quad (13.21)$$

where

$$\begin{aligned} D_{\lambda LM}(\hat{\epsilon}) &= \mathbf{T}_{LM}^* \cdot \mathbf{D}_\lambda(\hat{\epsilon}) \\ &= B_L(\lambda) \Phi_{LM}(\hat{\epsilon}), \end{aligned} \quad (13.22)$$

with the dynamics contained in

$$B_L(\lambda) = (-1)^{\lambda+L+j+1} |d_{j\lambda}|^2 \left\{ \begin{matrix} 1 & L & 1 \\ j & \lambda & j \end{matrix} \right\}, \quad (13.23)$$

and the angular dependence in

$$\begin{aligned} \Phi_{LM}(\hat{\epsilon}) &= (2L+1)^{1/2} \sum_{rs} \hat{\epsilon} \cdot \hat{\mathbf{r}}(\hat{\epsilon} \cdot \hat{\mathbf{s}})^* \\ &\times (-1)^{1-s} \begin{pmatrix} 1 & L & 1 \\ r & \lambda & -s \end{pmatrix}. \end{aligned} \quad (13.24)$$

Here, $\hat{\mathbf{r}}$ and $\hat{\mathbf{s}}$ range over the unit spherical tensors of rank one, namely $\pm \hat{\mathbf{1}} = \mp(\hat{x} \pm i\hat{y})/\sqrt{2}$ and $\hat{\mathbf{0}} = \hat{z}$ (see also *Omont* [6], who gives tables of Φ_{LM}), and $d_{j\lambda}$ is a reduced matrix element of \mathbf{d} .

The intensity of radiation of polarization $\hat{\epsilon}'$ emitted by an excited ensemble of atoms with state density matrix ρ in its radiative decay to level λ is

$$\begin{aligned} \rho^* \cdot \mathbf{D}_\lambda(\hat{\epsilon}') &= \sum_{m,n,\mu} \langle \lambda\mu | \mathbf{d} \cdot \hat{\epsilon}'^* | m \rangle \rho_{mn} \langle n | \mathbf{d} \cdot \hat{\epsilon}' | \lambda\mu \rangle \\ &= \sum_{LM} \rho_{LM} D_{\lambda LM}, \end{aligned} \quad (13.25)$$

and by selection of polarization or spatial distribution, individual multipole components $D_{\lambda LM}$ and hence ρ_{LM} can be determined. The source terms S_{LM} excited by electric-dipole radiation from an isotropic ground state are given by a linear combination of $D_{\lambda LM}$

$$S_{LM} = (2\pi)^2 \sum_{\lambda, \hat{\epsilon}} u_{\hat{\epsilon}}(\lambda) D_{\lambda LM}(\hat{\epsilon}), \quad (13.26)$$

where $u_{\hat{\epsilon}}(\lambda)$ is the energy density of exciting radiation with polarization vector $\hat{\epsilon}$ per unit energy. From the $3-j$ symbol in Eq. (13.24), only the $L = 0, 1,$ and 2 components of ρ are observable unless the splitting of the Zeeman sublevels of λ are spectroscopically resolved. Similarly, if the ground state is unpolarized and its Zeeman sublevels unresolved, then only $L = 0, 1,$ and 2 components of ρ can be excited. To excite higher-order multipoles, the ground state can be polarized by optical pumping [7].

As an example, consider the axially symmetric system discussed in Sect. 13.1 with $j = 3/2$ in the excited state and $\lambda = 1/2$ in the ground state. Only the four diagonal elements of $\mathbf{D}(\hat{\epsilon}')$,

$$\begin{aligned} D_m(\hat{\epsilon}') &= \sum_\mu | \langle jm | \hat{\epsilon}' \cdot \mathbf{d} | \lambda\mu \rangle |^2 \\ &= |d_{j\lambda}|^2 \sum_{\mu r} | \hat{\epsilon}' \cdot \hat{\mathbf{r}} |^2 \begin{pmatrix} \lambda & 1 & j \\ -\mu & r & m \end{pmatrix}^2, \end{aligned}$$

are needed for the $2j + 1$ values of $m = -j, \dots, j$, where μ ranges over the $2\lambda + 1$ values from $-\lambda$ to λ and $r = \pm 1, 0$. One finds directly

$$\begin{aligned} \mathbf{D}(\hat{\epsilon}') &= \frac{|d_{j\lambda}|^2}{12} \\ &\times \left[|\hat{\epsilon}' \cdot \hat{\mathbf{1}}|^2 \begin{pmatrix} 3 \\ 1 \\ 0 \\ 0 \end{pmatrix} + |\hat{\epsilon}' \cdot \hat{\mathbf{0}}|^2 \begin{pmatrix} 0 \\ 2 \\ 2 \\ 0 \end{pmatrix} + |\hat{\epsilon}' \cdot \hat{\mathbf{1}}|^2 \begin{pmatrix} 0 \\ 0 \\ 1 \\ 3 \end{pmatrix} \right]. \end{aligned} \quad (13.27)$$

The detected signal of polarization $\hat{\epsilon}'$ is proportional to $N \cdot \mathbf{D}(\hat{\epsilon}')$, where N is the population–density vector Eq. (13.1). Some of the state polarization can be monitored by looking at polarized dipole radiation. If the emitted light is observed as it propagates perpendicular to the polarization vector, the intensities are given to within an overall constant of proportionality by

$$I_{\sigma\pm} = \mathbf{D}(\pm\hat{\mathbf{i}}) \cdot N, \quad I_{\pi} = \mathbf{D}(\hat{\mathbf{o}}) \cdot N, \quad (13.28)$$

$$I_{\sigma} = \mathbf{D}(\hat{\xi}) \cdot N = \frac{1}{2}(I_{\sigma+} + I_{\sigma-}), \quad (13.29)$$

where $\hat{\xi}$ is any real unit vector (linear polarization vector) in the xy -plane. The intensities of polarized radiation may also be given in terms of Stokes parameters [8] (see also Chap. 7). By expanding N in the spherical basis vectors T_L as in Eq. (13.5), one obtains a detected signal

$$\begin{aligned} N \cdot \mathbf{D}(\hat{\epsilon}') &= \sum_{L=0}^{2j+1} n_L D_{\lambda L 0} & (13.30) \\ &= \frac{|d_{j\lambda}|^2}{12} \left[2n_0 + \sqrt{5} \left(|\hat{\epsilon}' \cdot \hat{\mathbf{i}}|^2 - |\hat{\epsilon}' \cdot -\hat{\mathbf{i}}|^2 \right) n_1 \right. \\ &\quad \left. + \left(3|\hat{\epsilon}' \cdot \hat{\mathbf{o}}|^2 - 1 \right) n_2 \right]. & (13.31) \end{aligned}$$

Thus there is no way to monitor the octupole polarization n_3 from the dipole radiation since $D_{\lambda L M} = 0$ for $L > 2$. To monitor the orientation n_1 , the circular polarization must be measured

$$\frac{\sqrt{5} n_1}{3 n_0} = \frac{I_{\sigma+} - I_{\sigma-}}{2I_{\sigma} + I_{\pi}}, \quad (13.32)$$

since the coefficient $D_{\lambda L 0}$ vanishes for any linear polarization. Conversely, from

$$\frac{n_2}{2n_0} = \frac{I_{\sigma} - I_{\pi}}{2I_{\sigma} + I_{\pi}}, \quad (13.33)$$

alignment is given by linear polarization. However, the denominator in both cases is different from that common in polarization measurements, and indeed, the ratio $(I_{\sigma+} - I_{\sigma-})/(I_{\sigma+} + I_{\sigma-})$ is *not* proportional to the orientation but contains a contribution from the alignment, and $(I_{\sigma} - I_{\pi})/(I_{\sigma} + I_{\pi})$ is not linear in the alignment. The expressions for other total angular momenta j are the same except for the numerical coefficients on the LHS of Eqs. (13.32) and (13.33). Finally, if the desire is to measure the total excited-state population n_0 without any polarization component (which might rotate in stray external fields), one can choose linear polarization at an angle to make $D_{\lambda 2 0}$ disappear, namely at the *magic angle* $\theta = \arccos(3^{-1/2}) = 54.74^\circ$. Of course, the same angle may be chosen to excite an unpolarized population.

13.5 Extensions

Although the discussion here has focused on cell experiments in which collisional perturbations are isotropic and state manifolds with a given total angular momentum j are well isolated, the concept of state multipoles is also useful in many applications where the collision symmetry is lower and where states with different j values interact, possibly due to the presence of fine and hyperfine structure [1]. Applications have been made in electron–atom collisions (Chap. 7), atom–atom collisions [9], and atom–molecule collisions [5].

Abstract

Interest in the effect that electric and magnetic fields have on the internal structure of atoms is as old as quantum mechanics itself. In practical terms, an atom’s spectrum acts as its signature, and so it is important to understand how electric and magnetic fields alter this characteristic. In this chapter, a summary of the basic nonrelativistic and relativistic theory of electrons and atoms in external magnetic fields is given. Extensions to the case of very strong fields are then introduced for both types of fields.

14.1 Electron in a Uniform Magnetic Field

14.1.1 Nonrelativistic Theory

The nonrelativistic Hamiltonian (in Gaussian units) for an electron in an external field \mathbf{A} is [1]

$$H = \frac{1}{2m} \left(\mathbf{p} - \frac{e}{c} \mathbf{A} \right)^2 - \boldsymbol{\mu} \cdot \mathbf{B} + eV, \quad (14.1)$$

where \mathbf{A} is the vector potential and V is the scalar potential. The second term in Eq. (14.1) must be included to account for the interaction of the electron magnetic moment with an external magnetic field. The potentials \mathbf{A} and V are only defined to within a gauge transformation [2]:

$$\mathbf{A}' = \mathbf{A} + \nabla f, \quad V' = V - \frac{1}{c} \frac{\partial f}{\partial t}. \quad (14.2)$$

We choose the gauge $\nabla \cdot \mathbf{A} = 0$ in which the momentum operator $\mathbf{p} = i\hbar \nabla$ and vector potential \mathbf{A} commute. \mathbf{B} is a constant uniform magnetic field with vector potential

$$\mathbf{A} = \frac{1}{2} \mathbf{B} \times \mathbf{r}. \quad (14.3)$$

$\boldsymbol{\mu}$ is the magnetic moment of the electron:

$$\boldsymbol{\mu} = \frac{1}{2} g_e \mu_B \boldsymbol{\sigma}, \quad (14.4)$$

where the σ_i are the Pauli spin matrices, $\mu_B = e\hbar/2m_e c$ is the Bohr magneton and g_e is the electron g -factor which accounts for the anomalous magnetic moment of the electron (see Sect. 29.4).

Consider now the case of a free electron in a constant uniform field in the z -direction with no scalar potential, i.e., $V = 0$ in Eq. (14.1). This case also describes an atom in the limit of strong magnetic fields such that the Coulomb interactions are negligible. In this case, which is different from Eq. (14.3), we have

$$\mathbf{B} = B\hat{z} \text{ with } \begin{cases} A_x = -By \\ A_y = Ax = 0 \end{cases}. \quad (14.5)$$

For this field, the operators μ_z , p_x and p_z commute with the Hamiltonian and are therefore conserved. Calling their respective eigenvalues μ_z , p_x and p_z , with $-\infty \leq p_x, p_y \leq \infty$, the eigenstates are written as

$$\psi = e^{i(p_x x + p_z z)/\hbar} \varphi(y). \quad (14.6)$$

Calling $y_0 = -cp_x/eB$, φ satisfies

$$\begin{aligned} & -\frac{\hbar^2}{2m} \frac{d^2}{dy^2} \varphi + \frac{1}{2} m \omega_B^2 (y - y_0)^2 \varphi \\ & = \left(E + \mu_z B - \frac{p_z^2}{2m} \right) \varphi, \end{aligned} \quad (14.7)$$

which is the Schrödinger equation for a one-dimensional harmonic oscillator with angular frequency $\omega_B = |e|B/mc$, the cyclotron frequency of the electron. The solutions to Eq. (14.7) give the eigenstates for an electron in an external homogeneous magnetic field. They are called *Landau levels* [1] with energies given by

$$E_n = \left(n + \frac{1}{2} + m_s \right) \hbar \omega_B + \frac{p_z^2}{2m}, \quad (14.8)$$

where $\hbar m_s = \pm \hbar/2$ is the eigenvalue of the z -component of the spin operator s , and eigenfunctions given by

$$\begin{aligned} \varphi_n(y) &= \frac{1}{\sqrt{\pi^{1/2} a_B 2^n n!}} \\ &\times \exp\left(-\frac{(y - y_0)^2}{2a_B^2}\right) H_n\left(\frac{y - y_0}{a_B}\right), \end{aligned} \quad (14.9)$$

where $a_B = \sqrt{\hbar/m\omega_B}$ and the H_n are Hermite polynomials [3].

14.1.2 Relativistic Theory

The relativistic analog of Eq. (14.1) is given by the Dirac Hamiltonian

$$H_D = c\boldsymbol{\alpha} \cdot \left(\mathbf{p} - \frac{e}{c} \mathbf{A} \right) + \beta mc^2 + eV, \quad (14.10)$$

where $\boldsymbol{\alpha}$ and β are the 4×4 matrices defined by Eq. (9.61). The eigenfunctions of the Dirac Hamiltonian Eq. (14.10) are written as four-dimensional spinors:

$$\psi_D = \begin{pmatrix} \psi^{(1)} \\ \psi^{(2)} \\ \psi^{(3)} \\ \psi^{(4)} \end{pmatrix} \equiv \begin{pmatrix} \phi_1 \\ \phi_{-1} \\ \chi_1 \\ \chi_{-1} \end{pmatrix} \equiv \begin{pmatrix} \phi \\ \chi \end{pmatrix}, \quad (14.11)$$

where ϕ and χ are two-dimensional (Pauli) spinors and ϕ_i and χ_i are functions of the coordinates of the electron.

In the case $V = 0$, the lower component χ can be eliminated in the eigenvalue equation $H_D \psi = E \psi$ to obtain a Hamiltonian equation for ϕ only, similar to Eq. (14.1) [4]. For a field defined by Eq. (14.5) one writes ϕ in the form (as in the nonrelativistic case)

$$\phi = e^{i(p_x x + p_z z)/\hbar} f(y). \quad (14.12)$$

Here, $f(y)$ satisfies the equation

$$\begin{aligned} & -\frac{\hbar^2}{2m} \frac{d^2}{dy^2} \varphi + \frac{1}{2} m \omega_B^2 (y - y_0)^2 \varphi \\ & = \left(\frac{E^2 - m^2 c^4}{2mc^2} + \mu_z B - \frac{p_z^2}{2m} \right) \varphi, \end{aligned} \quad (14.13)$$

which reduces to the nonrelativistic form Eq. (14.7) in the limit $E \rightarrow mc^2$. In Eq. (14.13), the term involving μ is not included arbitrarily as in Eq. (14.1) but is a consequence of $H_D \phi$, which predicts the value $g = 2$. The value g_e used in Eq. (14.4) includes radiative corrections to the Dirac value.

From Eq. (14.13) we obtain

$$E_n^2 = 2mc^2 \left[\frac{mc^2}{2} + \left(n + \frac{1}{2} + m_s \right) \hbar \omega_B + \frac{p_z^2}{2m} \right], \quad (14.14)$$

and the eigenfunctions $\psi_{m_s}^D$ are

$$\begin{aligned} \psi_{1/2}^D &= N \begin{pmatrix} \frac{E + mc^2}{c} \psi_n \\ 0 \\ p_z \psi_n \\ -\frac{i\hbar}{a_B} \sqrt{2n} \psi_{n-1} \end{pmatrix}, \\ \psi_{-1/2}^D &= N \begin{pmatrix} 0 \\ \frac{E + mc^2}{c} \psi_n \\ \frac{i\hbar}{a_B} \sqrt{2(n+1)} \psi_{n+1} \\ -p_z \psi_n \end{pmatrix}, \end{aligned} \quad (14.15)$$

where ψ_n is defined as in Eqs. (14.6) and (14.9), and N is a normalization constant.

14.2 Atoms in Uniform Magnetic Fields

14.2.1 Anomalous Zeeman Effect

Consider now the nonrelativistic Hamiltonian for a one-electron atom in the presence of an external magnetic field \mathbf{B} . The one-electron Hamiltonian can be written as [5]

$$H = \frac{1}{2m} \mathbf{p}^2 - \frac{1}{4\pi\epsilon_0} \frac{Ze^2}{r} + \xi(r) \mathbf{L} \cdot \mathbf{S} + \frac{\mu_B}{\hbar} (\mathbf{L} + g_e \mathbf{S}) \cdot \mathbf{B} + \frac{e^2}{8mc^2} (\mathbf{B} \times \mathbf{r})^2, \quad (14.16)$$

where

$$\xi(r) = \frac{1}{2m^2 c^2} \frac{Ze^2}{4\pi\epsilon_0} \frac{1}{r^3}. \quad (14.17)$$

The anomalous Zeeman effect corresponds to the case of *weak* magnetic fields such that the magnetic interaction is small compared with the $\mathbf{L} \cdot \mathbf{S}$ spin-orbit term. The energy shifts are obtained from a perturbation of Eq. (14.16) with $\mathbf{B} = 0$. The unperturbed wave functions are eigenfunctions of L^2 , S^2 , J^2 and J_z , with $\mathbf{J} = \mathbf{L} + \mathbf{S}$, but are not eigenfunctions of L_z or S_z . The energy levels with given values of l , s and j split in the presence of a field defined by Eq. (14.5) according to

$$\Delta E_{m_j} = g \mu_B B m_j, \quad (14.18)$$

where g is the *Landé splitting factor* given by

$$g = g_l \frac{j(j+1) - s(s+1) + l(l+1)}{2j(j+1)} + g_e \frac{j(j+1) + s(s+1) - l(l+1)}{2j(j+1)}, \quad (14.19)$$

where g_e is defined by Eq. (14.4), and $g_l = 1 - m_e/M$ to lowest order in m_e/M , where m_e is the electron mass and M is the nuclear mass. To a first approximation, it is often sufficient to take $g_e = 2$ (the Dirac value) and $g_l = 1$. In the case of a many-electron atom, j , l and s are replaced by the *total* angular momenta J , L and S . In the one-electron case (neglecting corrections to g_l or g_e) the g -value is simply

$$g \approx \frac{j + \frac{1}{2}}{l + \frac{1}{2}}, \quad (14.20)$$

which shows that the splitting of the $j = l + \frac{1}{2}$ levels is larger than that of the $j = l - \frac{1}{2}$ levels. The selection rules for the splitting of spectral lines are $\delta m_j = 0$ for components polarized parallel to the field (π components), and $\delta m_j = \pm 1$ for those perpendicular to the field (σ components).

14.2.2 Normal Zeeman Effect

For moderately strong fields up to $B \approx 10^4$ T, the quadratic $(\mathbf{B} \times \mathbf{r})^2$ term in Eq. (14.16) can be neglected. If the spin-

orbit interaction term is also neglected, then the energies relative to the field-free eigenvalues E_n are given by

$$E_n(B) = E_n + \mu_B B (m_l + 2m_s). \quad (14.21)$$

The selection rules for transitions are $\Delta m_s = 0$ and $\Delta m_l = 0, \pm 1$. The transition energy of a spectral line is split into three components, the *Lorentz triplet*

$$\Delta E_n = \Delta E_{n,0} + (\Delta m_l) \hbar \omega_L, \quad (14.22)$$

where $\Delta E_{n,0}$ is the transition energy in the absence of a field, and $\omega_L = |e|B/2m$ is the Larmor frequency. Transitions with $\Delta m_l = 0$ produce the π line at the unshifted transition energy; transitions with $\Delta m_l = \pm 1$ produce the shifted σ lines. Lorentz triplets can be observed in many-electron atoms in which the total spin is zero.

14.2.3 Paschen–Back Effect

We add now to the results of the last section the first-order perturbation caused by the spin-orbit term. The calculation can be performed in closed form for hydrogenic atoms, for which the contribution to the energy of the level n is [6]

$$\begin{aligned} \Delta E_n &= 0, \quad \text{for } l = 0 \\ \Delta E_n &= \frac{\alpha^4 Z^4 \mu c^2}{2n^3} m_l m_s \\ &\quad \times \left[l \left(l + \frac{1}{2} \right) (l + 1) \right], \quad \text{for } l \neq 0 \end{aligned} \quad (14.23)$$

where μ is the reduced mass, $\mu = mM/(m+M)$. A general expression of the relativistic solution for the Paschen–Back effect can be written for the one-electron case in the Pauli approximation in which the eigenstates are given in terms of ϕ in Eq. (14.11). Call ϕ_{\pm}^0 the eigenfunctions with no external field corresponding to $j = l \pm \frac{1}{2}$ with unperturbed energies E_{\pm}^0 respectively. In terms of the dimensionless variables

$$\begin{aligned} \eta &= \frac{\mu_B B}{E_+ - E_-}, \quad \epsilon = \sqrt{1 + \eta \frac{4m_j}{2l+1} + \eta^2}, \\ \gamma &= \frac{1}{\epsilon} \left(1 + \eta \frac{4m_j}{2l+1} \right), \end{aligned} \quad (14.24)$$

the energies E_{\pm} and wave functions ϕ_{\pm} of the states, in the presence of the field B , are

$$E_{\pm} = \frac{E_{\pm}^0}{2} (1 \pm \epsilon + 2m_j \eta) + \frac{E_{\mp}^0}{2} (1 \mp \epsilon - 2m_j \eta) \quad (14.25)$$

and

$$\phi_{\pm} = \pm \sqrt{\frac{1 \pm \gamma}{2}} \phi_+^0 + \sqrt{\frac{1 \mp \gamma}{2}} \phi_-^0. \quad (14.26)$$

14.3 Atoms in Very Strong Magnetic Fields

The case of *very* strong magnetic fields (i.e., $B > 10^4$ T), such as those encountered at the surface of neutron stars, is also called the *quadratic Zeeman effect*, as the last term in Eq. (14.16) is dominant. In this range, perturbation calculations fail to yield good results as the field is too large, and even at fields of the order $B \approx 10^7$ T the Landau high B approximation of Eqs. (14.8) and (14.9) is not adequate.

Very accurate calculations have been performed using variational finite basis set techniques for both the relativistic Dirac and nonrelativistic Schrödinger Hamiltonians. The calculations use the following relativistic basis set [7] that includes nuclear size effects (R is the nuclear size) and contains both asymptotic limits, the Coulomb limit for $B = 0$ and the Landau limit for $B \rightarrow \infty$:

$$\psi_{nl}^{(k,v)} = \begin{cases} r^{q_k-1+2n} e^{-a_{nv}^{(k)} r^2 - \beta \rho^2} \Omega_k & r \leq R \\ b_{nv}^{(k)} r^{\gamma_v-1+n} e^{-\lambda r - \beta \rho^2} \Omega_k & r > R \end{cases} \quad (14.27)$$

with

$$\Omega_k = (\cos \theta)^{l-|m_k|} (\sin \theta)^{|m_k|} e^{im_k \phi} \omega_k, \quad (14.28)$$

where

$$\begin{aligned} n &= 0, 1, \dots, N_r, \quad k = 1, 2, 3, 4, \quad v = 1, 2, 3, 4, \\ q_1 &= q_2 = k_0, \quad q_3 = q_4 = k'_0, \\ m_k &= \mu - \sigma_k/2, \quad \sigma_1 = \sigma_3 = 1, \quad \sigma_2 = \sigma_4 = -1. \end{aligned}$$

Here, k refers to the component $\psi^{(k)}$ in Eq. (14.11), and λ and β are variational parameters. The power of r at the origin is given by

$$k_0 = \begin{cases} |\kappa| & \text{if } \kappa < 0 \\ |\kappa| + 1 & \text{if } \kappa > 0, \end{cases} \quad (14.29)$$

$$k'_0 = \begin{cases} |\kappa| + 1 & \text{if } \kappa < 0 \\ |\kappa| & \text{if } \kappa > 0, \end{cases} \quad (14.30)$$

The index v refers to the two regular and two irregular solutions for $r > R$ that match the corresponding powers at the origin k_0 and k'_0 .

$$\gamma_1 = \gamma_0, \quad \gamma_2 = \gamma_0 + 1, \quad \gamma_3 = -\gamma_0, \quad \gamma_4 = -\gamma_0 + 1, \quad (14.31)$$

$$\gamma_0 = \sqrt{\kappa^2 - (\alpha Z)^2}, \quad \kappa = \mp \left(v \pm \frac{1}{2} \right) + \frac{1}{2}, \quad (14.32)$$

$$\begin{aligned} \omega_1 &= \begin{pmatrix} \vartheta_1 \\ 0 \end{pmatrix}, & \omega_2 &= \begin{pmatrix} \vartheta_{-1} \\ 0 \end{pmatrix}, \\ \omega_3 &= \begin{pmatrix} 0 \\ i\vartheta_{-1} \end{pmatrix}, & \omega_4 &= \begin{pmatrix} 0 \\ i\vartheta_1 \end{pmatrix}, \end{aligned} \quad (14.33)$$

Table 14.1 Relativistic ground state binding energy $-E_{\text{gs}}/Z^2$ and finite nuclear size correction $\delta E_{\text{nuc}}/Z^2$ (in a.u.) of hydrogenic atoms for various magnetic fields B (in units of 2.35×10^5 T). δE_{nuc} should be added to E_{gs}

where ϑ_k is a two-component Pauli spinor: $\sigma_z \vartheta_k = k \vartheta_i$. For even (odd) parity states, the value of l for the large components ($k = 1, 2$) is an even (odd) number greater than or equal to $|m_k|$ up to $2N_\theta$ (for even parity) or $2N_\theta + 1$ (for odd parity), while for the small components ($k = 3, 4$) it is an odd (even) number greater than or equal to $|m_k|$ up to $2N_\theta + 1$ (for even parity) or $2N_\theta$ (for odd parity), since the small component has a different nonrelativistic parity than the large component. The coefficients $a_{nv}^{(k)}$ and $b_{nv}^{(k)}$ are determined by the continuity condition of the basis functions and their first derivatives at R . For a point nucleus, the section $r \leq R$ is omitted; for a nonrelativistic calculation, take $\alpha = 0$ in the basis set.

Table 14.1 presents relativistic (Dirac) energies for the ground state of one-electron atoms. Values for a point nucleus and finite nuclear size corrections are given. Table 14.2

Table 14.3 Relativistic corrections $\delta E = (E - E_{NR})/|E_R|$ to the non-relativistic energies E_{NR} for the ground state and $n = 2$ excited states of hydrogen in an intense magnetic field B (in units of 2.35×10^5 T). The numbers in brackets denote powers of 10

B	δE_{gs}	B	$\delta E_{2S,-1/2}$	$\delta E_{2P,-1/2}$
0.1	-1.08[-5]	1[-6]	-1.66[-5]	-1.43[-5]

5000	2.78[-5]	100	-3.9[-5]	-1.0[-4]

presents the relativistic energies for $n = 2$ excited states of hydrogen with the (negligible) finite nuclear size correction included.

Table 14.3, which displays the relativistic corrections of the energies of the previous two tables, presents one of the most interesting relativistic results: the change in sign of the relativistic correction of the energy of the ground state at $B \approx 10^7$ T.

14.4 Atoms in Electric Fields

14.4.1 Stark Ionization

An external electric field \mathbf{F} introduces the perturbing potential

$$V = -\mathbf{d} \cdot \mathbf{F}, \quad (14.34)$$

where

$$\mathbf{d} = \sum_i q_i \mathbf{r}_i \quad (14.35)$$

is the dipole moment of the atom, and i runs over all electrons in the atom. In the case of strong external electric fields, bound states do not exist because the atom ionizes. Consider a hydrogenic atom in a static electric field

$$\mathbf{F} = F \hat{z}. \quad (14.36)$$

The total potential acting on the electron is then

$$V_{\text{tot}}(\mathbf{r}) = -\frac{e^2 Z}{4\pi\epsilon_0 r} + eFz. \quad (14.37)$$

Consider the z -dependence of this potential. Call $\rho = \sqrt{x^2 + y^2}$ and $v(z, \rho) = V(x, y, z)$. Unlike the Coulomb case in which $v_{\text{Coul}}(\pm\infty, \rho) = 0$ resulting in an infinite number of bound states, now $v(\pm\infty, \rho) = \pm\infty$ and v has a local maximum. On the z axis, this maximum occurs at $z_{\text{max}} = -\sqrt{Z|e|/(4\pi\epsilon_0 F)}$ for which $v(z_{\text{max}}, 0) = 0$. There is then a potential barrier through which the electron can tunnel, i.e.,

there are no bound states any longer but *resonances*. The potential barrier is shallower the stronger the field; the well can contain a smaller number of bound states and ionization occurs.

14.4.2 Linear Stark Effect

The electric field Eq. (14.36) produces a dipole potential

$$V_F = eFz = eFr \sqrt{\frac{4\pi}{3}} Y_{10}(\hat{\mathbf{r}}), \quad (14.38)$$

which does not preserve parity. A first-order perturbation calculation for the energy

$$E_n^{(1)} = \langle n | V_F | n \rangle \quad (14.39)$$

yields null results unless the unperturbed states are degenerate with states of opposite parity.

In the remainder of this chapter, atomic units will be used. Final results for energies can be multiplied by $2R_\infty hc$ to translate to SI or other units. The calculation can be carried out in detail for the case of hydrogenic atoms [8]. In this case it is convenient to work in parabolic coordinates: φ denotes the usual angle in the xy -plane, and

$$\begin{aligned} \xi &= r + z, \\ \eta &= r - z. \end{aligned} \quad (14.40)$$

The Hamiltonian for a hydrogenic atom with a field $V_F = \frac{1}{2} F (\xi - \eta)$ from Eq. (14.38) is

$$(\xi + \eta)H = \xi h_+(\xi) + \eta h_-(\eta). \quad (14.41)$$

The wave function is written in the form

$$\Psi(\xi, \eta, \varphi) = \frac{1}{\sqrt{2\pi Z}} \psi_+(\xi) \psi_-(\eta) e^{im_l \varphi}, \quad (14.42)$$

with the ψ_\pm satisfying

$$h_\pm(x) \psi_\pm(x) = E \psi_\pm(x), \quad (14.43)$$

where $x = \xi$ for ψ_+ and $x = \eta$ for ψ_- , and

$$h_\pm(x) = -\frac{2}{x} \frac{d}{dx} \left(x \frac{d}{dx} \right) - \frac{2Z_\pm}{x} + \frac{m_l^2}{2x^2} \mp \frac{1}{2} Fx, \quad (14.44)$$

with

$$Z = Z_+ + Z_-. \quad (14.45)$$

Using the notation

$$\begin{aligned} \epsilon &= \sqrt{-2E}, \\ n_\pm &= Z_\pm / \epsilon - \frac{1}{2} (|m_l| + 1), \\ n &= n_+ + n_- + |m_l| + 1, \end{aligned}$$

$$\begin{aligned} n_+, N_- &= 0, 1, \dots, n - |m_l| + 1, \\ |m_l| &= 0, 1, 2, \dots, n - 1, \\ \delta n &= n_+ - n_-, \end{aligned} \quad (14.46)$$

where n is the principal quantum number, the unperturbed eigenfunctions are

$$\psi_{\pm}(x) = \frac{\epsilon n_{\pm}!^{\frac{1}{2}}}{(n_{\pm} + |m_l|)!^{\frac{1}{2}}} e^{-\frac{1}{2}\epsilon x} (\epsilon x)^{\frac{1}{2}|m_l|} L_{n_{\pm}}^{(|m_l|)}(\epsilon x), \quad (14.47)$$

where the $L_b^{(a)}$ are generalized Laguerre polynomials (Sect. 9.4.2). The zero-order eigenvalues are

$$Z_{\pm}^{(0)} = \left(n_{\pm} + \frac{m_l + 1}{2} \right) \epsilon. \quad (14.48)$$

The first-order perturbation yields

$$\begin{aligned} Z_{\pm}^{(1)} &= \pm \frac{1}{4} \frac{F}{\epsilon^2} [6n_{\pm}(n_{\pm} \\ &+ m_l + 1) + m_l(m_l + 3) + 2]. \end{aligned} \quad (14.49)$$

From these

$$\epsilon = \frac{Z}{n} - \frac{3}{2 F \left(\frac{n}{Z} \right)^2 \delta_n}, \quad (14.50)$$

and to first order in F ,

$$\begin{aligned} E &= -\frac{1}{2}\epsilon^2 \approx E^{(0)} + E^{(1)}, \\ E^{(0)} &= -\frac{1}{2} \frac{Z^2}{n^2}, \\ E^{(1)} &= \frac{3}{2} \frac{F}{Z} n \delta_n. \end{aligned} \quad (14.51)$$

14.4.3 Quadratic Stark Effect

A perturbation linear in the field F yields no contribution to nondegenerate states (e.g., the ground state $n_+ = n_- = m = 0$; $n = 1$). In this case, the lowest order contribution comes from the *quadratic Stark effect*, the contribution of order F^2 . The quadratic perturbation to a level $E_n^{(0)}$ caused by a general electric field \mathbf{F} can be written in terms of the symmetric tensor α_{ij}^n as

$$E_n^{(2)} = -\frac{1}{2} \alpha_{ij}^n F_i F_j, \quad (14.52)$$

with

$$\alpha_{ij}^n = -2 \sum_{m \neq n} \frac{\langle n | d_i | m \rangle \langle m | d_j | n \rangle}{E_n - E_m}, \quad (14.53)$$

where d_i is defined in Eq. (14.35).

Table 14.4 Relativistic dipole polarizabilities for the ground state of hydrogenic atoms

Z	$\alpha_{\text{rel}}^{n=1} Z^4 / (a_0^3)$
1	4.4997515
5	4.4937883
10	4.4751644
20	4.4008376
30	4.2775621
40	4.1062474
50	3.8881792
60	3.6250295
70	3.3188659
80	2.9721524
90	2.5877205
100	2.1686483

For a field Eq. (14.36),

$$\Delta E_n = -\frac{1}{2} \alpha^n F^2, \quad (14.54)$$

where

$$\alpha^n \equiv \alpha_{zz}^n = -2e^2 \sum_{m \neq n} \frac{|\langle n | z | m \rangle|^2}{E_n - E_m}. \quad (14.55)$$

In terms of Eq. (14.46), a general nonrelativistic expression for the *dipole polarizability* of hydrogenic ions is [9]

$$\alpha^n = \frac{a_0^3 n^4}{8Z^4} (17n^2 - 3\delta_n^2 - 9m_l^2 + 19). \quad (14.56)$$

For the ground state of hydrogenic atoms,

$$\alpha^{n=1} = \frac{9a_0^3}{2Z^4}. \quad (14.57)$$

Table 14.4 lists the *relativistic* values for the ground state polarizability $\alpha_{\text{rel}}^{n=1}$, obtained by calculating Eq. (14.55) using relativistic variational basis sets [10]. The values are interpolated by

$$\alpha^{n=1} = \frac{a_0^3}{Z^4} \left[\frac{9}{2} - \frac{14}{3} (\alpha Z)^2 + 0.53983 (\alpha Z)^4 \right]. \quad (14.58)$$

14.4.4 Other Stark Corrections

Third Order Corrections

For the energy correction cubic in the external field Eq. (14.36), one obtains [9]

$$\begin{aligned} E^{(3)} &= \frac{3}{32} F^3 \left(\frac{n}{Z} \right)^7 \\ &\times \delta_n (23n^2 - \delta_n^2 + 11m_l^2 + 39). \end{aligned} \quad (14.59)$$

Relativistic Linear Stark-Shift of the Fine Structure of Hydrogen

For a Stark effect small relative to the fine structure, the degenerate levels corresponding to the same value of j split according to

$$\delta_m E_{nj} = \frac{3}{4} \sqrt{n^2 - \left(j + \frac{1}{2}\right)^2} \frac{nm}{j(j+1)} F. \quad (14.60)$$

Other Stark Corrections in Hydrogen

The expectation value of the delta function, is, in a.u. [11],

$$2\pi \langle 1s | \delta(\mathbf{r}) | 1s \rangle = 2 - 31F^2. \quad (14.61)$$

For the Bethe logarithm β defined by

$$\beta_{1s} = \frac{\sum_n |\langle 1s | \mathbf{p} | n \rangle|^2 (E_n - E_{1s}) \ln |E_n - E_{1s}|}{\sum_n |\langle 1s | \mathbf{p} | n \rangle|^2 (E_n - E_{1s})}, \quad (14.62)$$

the result is [12]

$$\beta_{1s} = 2.290\,981\,375\,205\,552\,301 + 0.316\,205(6) F^2. \quad (14.63)$$

These results are useful in calculating an asymptotic expansion for the two-electron Bethe logarithm [13].

14.5 Recent Developments

The drastic change of an atom's internal structure in the presence of external electric and magnetic fields is shown most clearly through the changes induced in its spectral features. Of these features, avoided crossings are a distinctive example. Recent work in this area by *Férez* and *Dehesa* [14] has suggested the use of Shannon's information entropy [15], defined by

$$S = - \int \rho(\mathbf{r}) \ln \rho(\mathbf{r}) d\mathbf{r}, \quad (14.64)$$

where $\rho(\mathbf{r}) = |\psi(\mathbf{r})|^2$, as an indicator or predictor of such irregular features of atomic spectra. By studying some excited states of hydrogen in parallel fields it was shown that, for the states involved, a marked confinement of the electron cloud and an information-theoretic exchange occurs when the magnetic field strength is adjusted adiabatically through the region of an avoided crossing. The field strengths studied are characteristic of compact astronomical objects, such as white dwarfs and neutron stars.

Although the effects of strong magnetic fields on the structure and dynamics of hydrogen have been known for some time, knowledge of the helium atom in such fields has only recently become sufficient for comparison with astrophysical observations [16–18]. As one example of their importance, such studies have proven critical in showing the

presence of helium in the atmospheres of certain magnetic white dwarfs [19].

In recent years, the increased sophistication and resolution of observation techniques has not only increased the number of known astronomical objects, but also motivated the study of the effects of strong fields on heavier atoms [20].

Another interesting area of current research concerns the relationship between quantum mechanics and classically chaotic systems. For these studies, Rubidium Rydberg atoms are an ideal system since laboratory fields can easily push the atom to the strong-field limit [21–23].

For a very useful review of various topics up to 1998 see [24]; a more concise review, concerning the electronic structure of atoms, molecules, and bulk matter, including some properties of dense plasma, in strong fields, is given in [25].

Pedro Goldman Professor Pedro Goldman completed a Ph.D. in Relativistic Atomic Physics at the University of Windsor. His work in atomic physics includes pioneering work on relativistic variational basis sets, relativistic calculations for many-electron atoms and diatomic molecules, accurate calculations for atoms in strong magnetic fields and accurate calculations of QED energy corrections and of the energy levels of Helium. Presently his research is directed to the optimization of the radiation therapy of tumours. He has as well received numerous teaching awards.

Mark M. Cassar Mark M. Cassar received his Ph.D. from the University of Windsor, Canada in 2003. His past research focused on high-precision theoretical calculations for the energy level structure of three-body atomic and molecular systems. He is currently working on applications of artificial intelligence in medicine.

Abstract

Rydberg atoms are those in which the valence electron is in a state of high principal quantum number n . They are of historical interest since the observation of Rydberg series helped in the initial unraveling of atomic spectroscopy [1]. Since the 1970s, these atoms have been studied mostly for two reasons. First, Rydberg states are at the border between bound states and the continuum, and any process that can result in either excited bound states or ions and free electrons usually leads to the production of Rydberg states. Second, the exaggerated properties of Rydberg atoms allow experiments to be done that would be difficult or impossible with normal atoms.

15.1 Wave Functions and Quantum Defect Theory

Many of the properties of Rydberg atoms can be calculated accurately using quantum defect theory, which is easily understood by starting with the H atom [2]. We shall use atomic units, as discussed in Sect. 1.2. The Schrödinger equation for the motion of the electron in a H atom in spherical coordinates is

$$\left(-\frac{1}{2}\nabla^2 - \frac{1}{r}\right)\Psi(r, \theta, \phi) = E\Psi(r, \theta, \phi), \quad (15.1)$$

where E is the energy, r is the distance between the electron and the proton, and θ and ϕ are the polar and azimuthal angles of the electron's position. Equation (15.1) can be separated, and its solution expressed as the product

$$\Psi(r, \theta, \phi) = R(r)Y_{\ell m}(\theta, \phi), \quad (15.2)$$

where ℓ and m are the orbital and azimuthal-orbital angular momentum (i.e., magnetic) quantum numbers, and $Y_{\ell m}(\theta, \phi)$ is a normalized spherical harmonic; $R(r)$ satisfies the radial equation

$$\frac{d^2R(r)}{dr^2} + \frac{2dR(r)}{rdr} + 2ER(r) + \frac{2R(r)}{r} = \frac{\ell(\ell + 1)R}{r^2}, \quad (15.3)$$

which has the two physically interesting solutions

$$R(r) = \frac{f(\ell, E, r)}{r}, \quad (15.4)$$

$$R(r) = \frac{g(\ell, E, r)}{r}. \quad (15.5)$$

The f and g functions are the regular and irregular Coulomb functions, which are the solutions to a variant of Eq. (15.3). As $r \rightarrow 0$, they have the forms [3]

$$f(\ell, E, r) \propto r^{\ell+1}, \quad (15.6)$$

$$g(\ell, E, r) \propto r^{-\ell}, \quad (15.7)$$

irrespective of whether E is positive or negative. As $r \rightarrow \infty$, for $E > 0$ the f and g functions are sine and cosine waves, i.e., there is a phase shift of $\pi/2$ between them. For $E < 0$, it is useful to introduce ν , defined by $E = -1/2\nu^2$, and for $E < 0$ as $r \rightarrow \infty$

$$f = u(\ell, \nu, r) \sin \pi \nu - v(\ell, \nu, r) e^{i\pi \nu}, \quad (15.8)$$

$$g = -u(\ell, \nu, r) \cos \pi \nu + v(\ell, \nu, r) e^{i\pi(\nu+1/2)}, \quad (15.9)$$

where u and v are exponentially increasing and decreasing functions of r . As $r \rightarrow \infty$, $u \rightarrow \infty$ and $v \rightarrow 0$.

Requiring that the wave function be square integrable means that as $r \rightarrow 0$, only the f function is allowed. Equation (15.8) shows that the $r \rightarrow \infty$ boundary condition requires that $\sin \pi \nu$ be zero or ν an integer n , leading to the hydrogenic Bohr formula for the energies

$$E = -\frac{1}{2n^2}. \quad (15.10)$$

The classical turning point of an s wave occurs at $r = 2n^2$, and the expectation values of positive powers of r reflect the location of the outer turning point, i.e.,

$$\langle r^k \rangle \approx n^{2k}. \quad (15.11)$$

The expectation values of negative powers of r are determined by the properties of the wave function at small r . The normalization constant of the radial wave function scales as $n^{-3/2}$, so that $R(r) \propto n^{-3/2} r^{\ell+1}$ for small r . Accordingly, the expectation values of negative powers of r , except r^{-1} , and any properties that depend on the small r part of the wave function, scale as n^{-3} . Using the properties of the wave function and the energies, the n -scaling of the properties of Rydberg atoms can be determined.

The primary reason for introducing the Coulomb waves instead of the more common Hermite polynomial solution for the radial function is to set the stage for single-channel quantum defect theory, which enables us to calculate the wave functions and properties of one-valence electron atoms such as Na. The simplest picture of an Na Rydberg atom is an electron orbiting a positively charged Na^+ core consisting of 10 electrons and a nucleus of charge +11. The ten electrons are assumed to be frozen in place with spherical symmetry about the nucleus, so their charge cloud is not polarized by the outer valence electron, although the valence electron can penetrate the ten-electron cloud. When the electron penetrates the charge cloud of the core electrons, it sees a potential well deeper than $-1/r$ due to the decreased shielding of the +11 nuclear charge. For Na and other alkali atoms, we assume that there is a radius r_c such that for $r < r_c$ the potential is deeper than $-1/r$, and for $r > r_c$ it is equal to $-1/r$. As a result of the deeper potential at $r < r_c$, the radial wave function is pulled into the core in Na, relative to H, as shown in

Fig. 15.1 Radial wave functions for H and Na showing that the Na wave function is pulled in toward the ionic core

Fig. 15.1. For $r \geq r_c$, the potential is a Coulomb $-1/r$ potential, and $R(r)$ is a solution of Eq. (15.3), which can be expressed as

$$R(r) = [f(\ell, \nu, r) \cos \tau_\ell - g(\ell, \nu, r) \sin \tau_\ell] / r, \quad (15.12)$$

where τ_ℓ is the radial phase shift.

Near the ionization limit, $E \approx 0$, and as a result, the kinetic energy of the Rydberg electron is greater than $1/r_c$ (≈ 10 eV) when $r < r_c$. As a result, changes in E of 0.10 eV, the $n = 10$ binding energy, do not appreciably alter the phase shift τ_ℓ , and we can assume τ_ℓ to be independent of E . The ℓ dependence of τ_ℓ arises because the centrifugal $\ell(\ell+1)/r$ term in Eq. (15.3) excludes the Rydberg electron from the region of the core in states of high ℓ . Applying the $r \rightarrow \infty$ boundary condition to the wave function of Eq. (15.12) leads to the requirement that the coefficient of u vanish, i.e.,

$$\cos \tau_\ell \sin(\pi \nu) + \sin \tau_\ell \cos(\pi \nu) = 0, \quad (15.13)$$

which implies that $\sin(\pi \nu + \tau_\ell) = 0$ or $\nu = n - \tau_\ell / \pi$. Usually τ_ℓ / π is written as δ_ℓ and termed the quantum defect, and the energies of members of the $n\ell$ series are written as

$$E = -\frac{1}{2(n - \delta_\ell)^2} = -\frac{1}{2n^{*2}}, \quad (15.14)$$

where $n^* = n - \delta_\ell$ is often termed the effective quantum number (Sect. 12.5.1).

Knowledge of the quantum defect δ_ℓ of a series of ℓ states determines their energies, and it is a straightforward matter to calculate the Coulomb wave function specified in Eq. (15.12) using a Numerov algorithm [4, 5]. This procedure gives wave functions valid for $r \geq r_c$, which can be used to calculate many of the properties of Rydberg atoms with great accuracy. The effect of core penetration on the energies is easily seen in the energy level diagram of Fig. 15.2. The Na $\ell \geq 2$ states have the same energies as hydrogen, while the s and p states, with quantum defects of 1.35 and 0.85, respectively, lie far below the hydrogenic energies.

Although it is impossible to discern in Fig. 15.2, the Na $\ell \geq 2$ states also lie below the hydrogenic energies. For these

Fig. 15.2 Energy levels of Na and H

states, it is not core penetration but core polarization that is responsible for the shift to lower energy. Contrary to our earlier assumption that the outer electron does not affect the inner electrons if $r > r_c$, the outer electron polarizes the inner electron cloud even when $r > r_c$, and the energies of even the high ℓ states fall below the hydrogenic energies. The leading term in the polarization energy is due to the dipole polarizability of the core, α_d . For high ℓ states, it gives a quantum defect of [6]

$$\delta_\ell = \frac{3\alpha_d}{4\ell^5}. \quad (15.15)$$

Quantum defects due primarily to core polarization rarely exceed 10^{-2} , while those due to core penetration are often greater than 1.

15.2 Optical Excitation and Radiative Lifetimes

Optical excitation of the Rydberg states from the ground state or any other low-lying state is the continuation of the photoionization cross section σ_{PI} below the ionization limit. The photoionization cross section, discussed more extensively in Chap. 25, is approximately constant at the limit. Above and below the limit the average photoabsorption cross section is the same, as evidenced by the fact that a discontinuity is not evident in an absorption spectrum, i.e., it is not possible to see where the unresolved Rydberg states end and the contin-

uum begins. Nonetheless, below the limit the cross section is structured by the Δn spacing of $1/n^3$ between adjacent members of the Rydberg series. In any experiment, there is a finite resolution $\Delta\omega$ with which the Rydberg states can be excited. It can arise, for example, from the Doppler width or a laser linewidth. This resolution determines the cross section σ_n for exciting the Rydberg state of principal quantum number n . Explicitly, σ_n is given by

$$\sigma_n = \frac{\sigma_{PI}}{n^3 \Delta\omega}. \quad (15.16)$$

A typical value for σ_{PI} is 10^{-18} cm^2 . For a resolution $\Delta\omega = 1 \text{ cm}^{-1}$ ($6 \times 10^{-6} \text{ a.u.}$) the cross section for exciting an $n = 20$ atom is $3 \times 10^{-17} \text{ cm}^2$.

From the wave functions of the Rydberg states, we can also derive the n^{-3} dependence of the photoexcitation cross section. The dipole matrix element from the ground state to a Rydberg state only involves the part of the Rydberg state wave function near the core. At small r , the Rydberg wave function only depends on n through the n^{-3} normalization factor, and as a result, the squared dipole matrix element between the ground state and the Rydberg state and the cross section both have an n^{-3} dependence.

Radiative decay, which is covered in Chap. 18, is, to some extent, the reverse of optical excitation. The general expression for the spontaneous transition rate from the $n\ell$ state to the $n'\ell'$ state is the Einstein A coefficient, given by [2]

$$A_{n\ell, n'\ell'} = \frac{4}{3} \mu_{n\ell, n'\ell'}^2 \omega_{n\ell, n'\ell'}^3 \frac{\alpha^3 g_{>}}{2g_n + 1}, \quad (15.17)$$

where $\mu_{n\ell, n'\ell'}$ and $\omega_{n\ell, n'\ell'}$ are the electric dipole matrix elements and frequencies of the $n\ell \rightarrow n'\ell'$ transitions, g_n and $g_{n'}$ are the degeneracies of the $n\ell$ and $n'\ell'$ states, and $g_{>}$ is the greater of g_n and $g_{n'}$. The lifetime $\tau_{n\ell}$ of the $n\ell$ state is obtained by summing the decay rates to all possible lower energy states. Explicitly,

$$\frac{1}{\tau_{n\ell}} = \sum_{n'\ell'} A_{n\ell, n'\ell'}. \quad (15.18)$$

Due to the ω^3 factor in Eq. (15.17), the highest frequency transition usually contributes most heavily to the total radiative decay rate, and the dominant decay is likely to be the lowest lying state possible. For low- ℓ Rydberg states, the lowest lying ℓ' states are bound by orders of magnitude more than the Rydberg states, and the frequency of the decay is nearly independent of n . Only the squared dipole moment depends on n , as n^{-3} , because of the normalization of the Rydberg wave function at the core. Consequently, for low- ℓ states,

$$\tau_{n\ell} \propto n^3. \quad (15.19)$$

As a typical example, the 10f state in H has a lifetime of $1.08 \mu\text{s}$ [7].

The highest ℓ states, with $\ell = n - 1$, have radiative lifetimes with a completely different n dependence. The only possible transitions are $n \rightarrow n - 1$, with frequency $1/n^3$. In this case, the dipole moments reflect the large size of both the n and $n - 1$ states and have the n^2 scaling of the orbital radius. Using Eq. (15.17) for $\ell = n - 1$ leads to

$$\tau_{n(n-1)} \propto n^5. \quad (15.20)$$

Another useful lifetime, τ_n , is that corresponding to the average decay rate of all ℓ, m states of the same n . It scales as $n^{4.5}$ [2, 8].

Equation (15.17) describes spontaneous decay to lower lying states driven by the vacuum. At room temperature, 300 K, there are many thermal photons at the frequencies of the $n \rightarrow n \pm 1$ transitions of Rydberg states for $n \geq 10$, and these photons drive transitions to higher and lower states [9]. A convenient way of describing blackbody radiation is in terms of the photon occupation number \bar{n} , given by

$$\bar{n} = \frac{1}{e^{\hbar\omega/kT} - 1}. \quad (15.21)$$

The stimulated emission or absorption rate $K_{n\ell, n'\ell'}$ from state $n\ell$ to state $n'\ell'$ is given by

$$K_{n\ell, n'\ell'} = \frac{4}{3} \mu_{n\ell, n'\ell'}^2 \omega_{n\ell, n'\ell'}^3 \frac{\alpha^3 \bar{n} g_{>}}{2g_n + 1}. \quad (15.22)$$

Summing these rates over n' and ℓ' gives the total blackbody decay rate $1/\tau_n^{\text{bb}}$. Explicitly,

$$\frac{1}{\tau_n^{\text{bb}}} = \sum_{n'\ell'} K_{n\ell, n'\ell'}. \quad (15.23)$$

The resulting lifetime τ_n^{T} at any given temperature is given by

$$\frac{1}{\tau_n^{\text{T}}} = 1/\tau_{n\ell} + 1/\tau_n^{\text{bb}}. \quad (15.24)$$

For low- ℓ states with $10 < n < 20$, blackbody radiation produces a 10% decrease in the lifetimes, but for high- ℓ states of the same n , it reduces the lifetimes by a factor of 10. Since $1/\tau_n^{\text{bb}} \propto n^{-2}$, this term must dominate normal spontaneous emission at high n .

The above discussion of spontaneous and stimulated transitions is based on the implicit assumption that the atoms are in free space. If the atoms are in a cavity, which introduces structure into the blackbody and vacuum fields, the transition rates are significantly altered [10]. These alterations are described in Chap. 83. If the cavity is tuned to a resonance, it increases the transition rate by the finesse of the cavity (approximately the Q for low-order modes). On the other hand, if the cavity is tuned between resonances, the transition rate is suppressed by a similar factor.

15.3 Electric Fields

As a starting point, consider the H atom in a static electric field \mathcal{E} in the z -direction and focus on the states of principal quantum number n . The field couples ℓ and $\ell \pm 1$ states of the same m by the electric dipole matrix elements. Since the states all have a common zero field energy of $-1/2n^2$, and the off-diagonal Hamiltonian matrix elements are all proportional to \mathcal{E} , the eigenstates are field-independent linear combinations of the zero field ℓ states of the same m , and the energy shifts from $-1/2n^2$ are linear in \mathcal{E} . In this first-order approximation, the energies are given by [2]

$$E = -\frac{1}{2n^2} + \frac{3}{2}(n_1 - n_2)n\mathcal{E}, \quad (15.25)$$

where n_1 and n_2 are parabolic quantum numbers (Sect. 9.1.2), which satisfy

$$n_1 + n_2 + |m| + 1 = n. \quad (15.26)$$

Consider the $m = 0$ states as an example. The $n_1 - n_2 = n - 1$ state is shifted up in energy by $\frac{3}{2}n(n - 1)\mathcal{E}$ and is called the extreme blue Stark state, and the $n_2 - n_1 = n - 1$ state is shifted down in energy by $\frac{3}{2}n(n - 1)\mathcal{E}$ and is called the extreme red Stark state. These two states have large permanent dipole moments, and in the red (blue) state, the electron spends most of its time on the downfield (upfield) side of the proton as shown in Fig. 15.3, a plot of the potential along

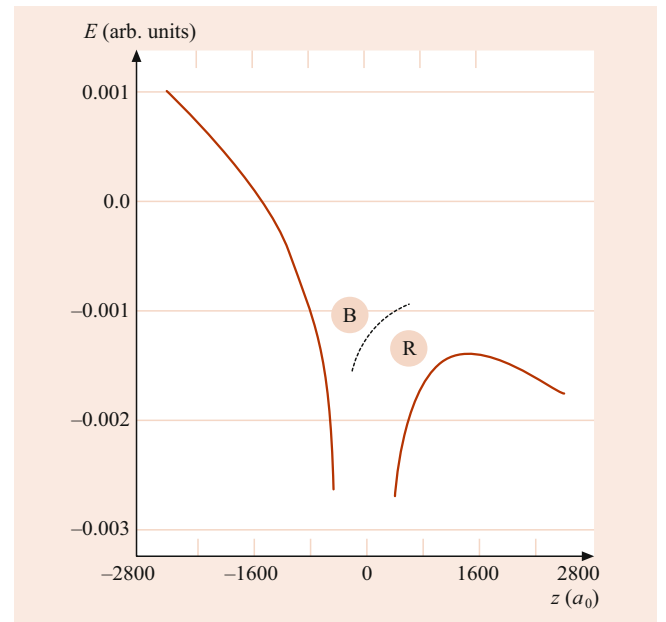

Fig. 15.3 Combined Coulomb–Stark potential along the z -axis when a field of 5×10^{-7} a.u. (2700 V/cm) is applied in the z -direction (solid lines). The extreme red state (R) is near the saddle point, and the extreme blue (B) state is held on the upfield side of the atom by an effective potential (dashed line) roughly analogous to a centrifugal potential

Fig. 15.4 Energies of Na $m = 0$ levels of $n \approx 20$ as a function of electric field. The shaded region is above the classical ionization limit

the z -axis. We have here ignored the electric dipole couplings to other n states, which introduce small second-order Stark shifts to lower energy. As implied by Eq. (15.26), states of higher m have smaller shifts. In particular, the circular $m = \ell = n - 1$ state has no first-order shift since there are no degenerate states to which it is coupled by the field.

The Stark effect in other atoms is similar, but not identical to that observed in H. This point is shown by Fig. 15.4, a plot of the energies of the Na $m = 0$ levels near $n = 20$. The energy levels are similar to those of H in that most of the levels exhibit apparently linear Stark shifts from the zero field energy of the high- ℓ states. The differences, however, are twofold. First, the levels from s and p states with nonzero quantum defects join the manifold of Stark states at some nonzero field, given approximately by [4]

$$\mathcal{E} = \frac{2\delta'_\ell}{3n^5}, \quad (15.27)$$

where δ'_ℓ is the magnitude of the difference between δ_ℓ and the nearest integer. Second, there are avoided crossings between the blue $n = 20$ and red $n = 21$ Stark states. In H, these states would cross, but in Na they do not because of the finite sized Na^+ core, which also leads to the nonzero quantum defects of the ns and np states.

Field ionization is both intrinsically interesting and of great practical importance for the detection of Rydberg atoms [11]. The simplest picture of field ionization can be understood with the help of Fig. 15.4. The potential along the z -axis of an atom in a field \mathcal{E} in the z -direction is given by

$$V = -\frac{1}{r} - \mathcal{E}z. \quad (15.28)$$

If an atom has an energy E relative to the zero field limit, it can ionize classically if the energy E lies above the saddle point in the potential. The required field is given by

$$\mathcal{E} = \frac{E^2}{4}. \quad (15.29)$$

Ignoring the Stark shifts and using $E = -1/2n^2$ yields the expression

$$\mathcal{E} = \frac{1}{16n^4}. \quad (15.30)$$

The H atom ionizes classically as described above or by quantum mechanical tunneling, which occurs at slightly lower fields. Since the tunneling rates increase exponentially with field strength, typically an order of magnitude for a 3% change in the field, specifying the classical ionization field is a good approximation to the field, which gives an ionization rate of practical interest. The red and blue states of H ionize at very different fields, as shown by Fig. 15.5, a plot of the $m = 0$ Stark states out to the fields at which the ionization rates are 10^6 s^{-1} [12]. First, note the crossing of the levels of different n mentioned earlier. Second, note that the red states ionize at lower fields than the blue states do, in spite of the fact that they are lower in energy. In the red states, the electron is close to the saddle point of the potential of Fig. 15.3, and it ionizes according to Eq. (15.29). If the Stark shift of the extreme red state to lower energy is taken into account, Eq. (15.30) becomes

$$\mathcal{E} = \frac{1}{9n^4}. \quad (15.31)$$

In the blue state, the electron is held on the upfield side of the atom by an effective potential roughly analogous to a cen-

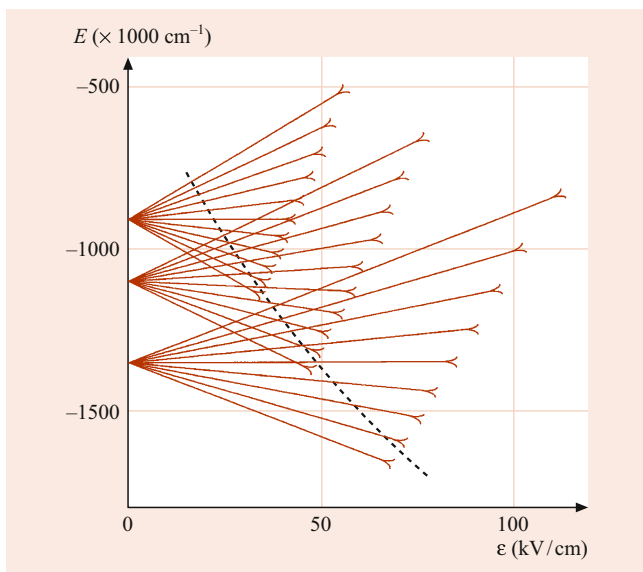

Fig. 15.5 Energies of H $m = 0$ levels of $n = 9, 10,$ and 11 as functions of electric field. The widths of the levels due to ionization broaden exponentially with fields, and the onset of the broadening indicated is at an ionization rate of 10^6 s^{-1} . The broken line indicating the classical ionization limit, $E = E^2/4$, passes near the points at which the extreme red states ionize

trifugal potential, as shown by Fig. 15.3. At the same field, the blue state's energy is lower relative to the saddle point of its potential, shown by the broken line of Fig. 15.3, than is the energy of the red state relative to the saddle point of its potential, given by Eq. (15.28) and shown by the solid line of Fig. 15.3. As shown by the broken line of Fig. 15.5, the classical ionization limit of Eq. (15.29) is simply a line connecting the ionization fields of the extreme red Stark states. All other states are stable above the classical ionization limit. In the Na atom, ionization of $m = 0$ states occurs in a qualitatively different fashion [12]. Due to the finite size of the Na^+ core, crossings are avoided between the blue and red Stark states of different n , as is shown by Fig. 15.4. In the region above the classical ionization limit, shown by the shaded region of Fig. 15.4, the same coupling between hydrogenically stable blue states and the degenerate red continua leads to autoionization of the blue states [13]. As a result, all states above the classical ionization limit ionize at experimentally significant rates. In higher m states, the core coupling is smaller, and the behavior is more similar to H.

Field ionization is commonly used to detect Rydberg atoms in a state selective manner. Experiments are most often conducted at or near zero field, and afterwards the field is increased in order to ionize the atoms. Exactly how the atoms pass from the low field to the high ionizing field is quite important. The passage can be adiabatic, diabatic, or anything in between. The selectivity is best if the passage is purely adiabatic or purely diabatic, for in these two cases, unique paths are followed.

In zero field, optical excitation from a ground s state leads only to final np states. In the presence of an electric field, all the Stark states are optically accessible, because they all have some p character. The fact that all the Stark states are optically accessible from the ground state allows the population of arbitrary ℓ states of nonhydrogenic atoms by a technique called Stark switching [6, 14]. In any atom other than H, the ℓ states are nondegenerate in zero field, and each of them is adiabatically connected to one, and only one, high field Stark state, as shown by Fig. 15.4. If one of the Stark states is excited with a laser and the field reduced to zero adiabatically, the atoms are left in a single zero field ℓ state.

In zero field, the photoionization cross section is structureless. However, in an electric field, it exhibits obvious structure, sometimes termed strong field mixing resonances. Specifically, when ground state s atoms are exposed to light polarized parallel to the static field, an oscillatory structure is observed in the cross section, even above the zero field ionization limit [15]. The origin of the structure can be understood with the aid of a simple classical picture [16, 17]. The electrons ejected in the downfield direction can simply leave the atom, while the electrons ejected in the upfield direction are reflected back across the ionic core and also leave the atom in the downfield direction. The wave packets corresponding to these two classical trajectories are added, and they can interfere constructively or destructively at the ionic core, depending on the phase accumulation of the reflected wave packet. Since the phase depends on the energy, there is an oscillation in the photoexcitation spectrum. This model suggests that no oscillations should be observed for light polarized perpendicular to the static field, and none are. The oscillations can also be thought of as arising from the remnants of quasistable extreme blue Stark states that have been shifted above the ionization limit, and, using this approach or a WKB approach, one can show that the spacing between the oscillations at the zero field limit is $\Delta E = \mathcal{E}^{3/4}$ [18, 19]. Further discussion can be found in Chap. 16.

The initial photoexcitation experiments were done using narrow bandwidth lasers, so that the time dependence of the classical pictures was not explicitly observed. Using mode locked lasers it has been possible to create a variety of Rydberg wave packets [20, 21] and observe, in effect, the classical motion of an electron in an atom. Of particular interest is that it has been possible to directly observe the time delay of the ejection of electrons subsequent to excitation in an electric field [22].

15.4 Magnetic Fields

To first order, the energy shift of a Rydberg atom due to a magnetic field B (the Zeeman effect) is proportional to the angular momentum of the atom. Since the states op-

tically accessible from the ground state have low angular momenta, the energy shifts are the same as those of low-lying atomic states. In contrast, the second-order diamagnetic energy shifts are proportional to the area of the Rydberg electron's orbit and scale as $B^2 n^4$ [23]. The diamagnetic interaction mixes the ℓ states, allowing all to be excited from the ground state, and produces large shifts to higher energies. The energy levels as a function of the magnetic field are reminiscent of the Stark energy levels shown in Fig. 15.5, differing in that the energy shifts are quadratic in the magnetic field.

One of the most striking phenomena in magnetic fields is the existence of quasi-Landau resonances, spaced by $\Delta E = 3\hbar B/2$, in the photoionization cross section above the ionization limit [24]. The origin of this structure is similar to the origin of the strong field mixing resonances observed in electric fields. An electron ejected in the plane perpendicular to the B fields is launched into a circular orbit and returns to the ionic core. The returning wave packet can be in or out of phase with the one leaving the ionic core, and, thus, can interfere constructively or destructively with it. While the electron motion in the xy -plane is bound, motion in the z -direction is unaffected by the magnetic field and is unbounded above the ionization limit, leading to resonances of substantial width. The Coulomb potential does provide some binding in the z -direction and allows the existence of quasi-stable three-dimensional orbits [25].

15.5 Microwave Fields

Strong microwave fields have been used to drive multiphoton transitions between Rydberg states and to ionize them. Here, we restrict our attention to ionization. Ionization by both linearly and circularly polarized fields has been explored with both H and other atoms.

Hydrogen atoms have been studied with linearly polarized fields of frequencies up to 36 GHz [26]. When the microwave frequency $\omega \ll 1/n^3$, ionization of $m = 0$ states occurs at a field of $\mathcal{E} = 1/9n^4(E^2/4)$, which is the field at which the extreme red Stark state is ionized by a static field. Due to the second-order Stark effect, the blue and red shifted states are not quite mirror images of each other, and when the microwave field reverses, transitions between Stark states occur. There is a rapid mixing of the Stark states of the same n and m by a microwave field, and all of them are ionized at the same microwave field amplitude, $\mathcal{E} = 1/9n^4$. Important points are that no change in n occurs, and the ionization field is the same as the static field required for ionization of the extreme red Stark state. As ω approaches $1/n^3$, the field falls below $1/9n^4$ due to Δn transitions to higher lying states, allowing ionization at lower fields. This form of ionization can be well described as the transition to the classically chaotic

regime [27]. For $\omega > 1/n^3$, the ionization field is more or less constant, and for $\omega > 1/2n^2$, the process becomes photoionization.

The ionization of nonhydrogenic atoms by linearly polarized fields has also been investigated at frequencies of up to 30 GHz, but the result is very different from the hydrogenic result. For $\omega \ll 1/n^3$ and low m , ionization occurs at a field of $\mathcal{E} \approx 1/3n^5$ [28]. This is the field at which the $m = 0$ extreme blue and red Stark states of principal quantum number n and $n + 1$ have their avoided crossing. For $n = 20$, this field is ≈ 500 V/cm, as shown by Fig. 15.4. How ionization occurs can be understood with a simple model based on a time-varying electric field. As the microwave field oscillates in time, atoms follow the Stark states of Na shown in Fig. 15.4. Even with very small field amplitudes, transitions between the Stark states of the same n are quite rapid because of the zero field avoided crossings. If the field reaches $1/3n^5$, the avoided crossing between the extreme red n and blue $n + 1$ state is reached, and an atom in the blue n Stark state can make a Landau–Zener transition to the red $n + 1$ Stark state. Since the analogous red–blue avoided crossings between higher lying states occur at lower fields, once an atom has made the $n \rightarrow n + 1$ transition, it rapidly makes a succession of transitions through higher n states to a state that is itself ionized by the field.

The Landau–Zener description given above is somewhat oversimplified in that we have ignored the coherence between field cycles. When it is included, we see that the transitions between levels are resonant multiphoton transitions. While the resonant character is obscured by the presence of many overlapping resonances, the coherence substantially increases the $n \rightarrow n + 1$ transition probability even when $\mathcal{E} < 1/3n^5$. The fields required for ionization calculated using this model are lower than $1/3n^5$, in agreement with the experimental observations. Nonhydrogenic Na states of high m behave like H, because no states with significant quantum defects are included, and the $n \rightarrow n + 1$ avoided crossings are vanishingly small.

Experiments on ionization of alkali atoms by circularly polarized fields of frequency ω show that for $\omega \ll 1/n^3$, a field amplitude of $\mathcal{E} = 1/16n^4$ is required for ionization [29]. This field is the same as the static field required. In a frame rotating with frequency ω , the circularly polarized field is stationary and cannot induce transitions, so this result is not surprising. On the other hand, when the problem is transformed to the rotating frame, the potential of Eq. (15.28) is replaced by

$$V = -\frac{1}{r} - \mathcal{E}x - \frac{\omega^2 \rho^2}{2}, \quad (15.32)$$

where $\rho^2 = x^2 + y^2$, and we have assumed the field to be in the x -direction in the rotating frame. This potential has a saddle point below $\mathcal{E} = 1/16n^4$ [30]. As n , or ω , is raised

so that $\omega \rightarrow 1/n^3$, the experimentally observed field falls below $1/16n^4$, but not so fast as implied by Eq. (15.32). Equation (15.32) is based solely on energy considerations, and ionization at the threshold field implied by Eq. (15.32) requires that the electron escape over the saddle point in the rotating frame at nearly zero velocity. For this to happen, when ω approaches $1/n^3$, more than n units of angular momentum must be transferred to the electron, which is unlikely. Models based on a restriction of the angular momentum transferred from the field to the Rydberg electron are in better agreement with the experimental results. Small deviations of a few percent from circular polarization allow ionization at fields as low as $\mathcal{E} = 1/3n^5$. This sensitivity can be understood as follows. In the rotating frame, a field with slightly elliptical polarization appears to be a large static field with a superimposed oscillating field at frequency 2ω . The oscillating field drives transitions to states of higher energy, allowing ionization at fields less than $\mathcal{E} = 1/16n^4$.

In the regime in which $\omega > 1/n^3$, microwave ionization of nonhydrogenic atoms is essentially the same as it is in H [31]. In this regime, the microwave field couples states differing in n by more than 1, and the pressure or absence of quantum defects is not so important. Consequently, only for $\omega > 1/n^3$ is the microwave ionization of H and other atoms different.

15.6 Collisions

Since Rydberg atoms are large, with geometric cross sections proportional to n^4 , one might expect the cross sections for collisions to be correspondingly large. In fact, such is often not the case. A useful way of understanding collisions of neutral atoms and molecules with Rydberg atoms is to imagine an atom or molecule M passing through the electron cloud of an Na Rydberg atom. There are three interactions

$$e^- - \text{Na}^+, \quad e^- - M, \quad M - \text{Na}^+. \quad (15.33)$$

The long-range $e^- - \text{Na}^+$ interaction determines the energy levels of the Na atom. The short-range of the $e^- - M$ and $M - \text{Na}^+$ interactions makes it likely that only one will be important at any given time. This approximation, termed the binary encounter approximation, is described in Chap. 60. The $M - \text{Na}^+$ interaction can only lead to cross sections of $\approx 10\text{--}100 \text{ \AA}^2$. On the other hand, since the electron can be anywhere in the cloud, the cross sections due to the $e^- - M$ interaction can be as large as the geometric cross section of the Rydberg atom. Accordingly, we focus on the $e^- - M$ interaction.

Consider a thermal collision between M and an Na Rydberg atom. Typically, M passes through the electron cloud slowly compared with the velocity of the Rydberg electron, and it is the $e^- - M$ scattering that determines what happens

in the M -Na collision, as first pointed out by *Fermi* [32]. First, consider the case where M is an atom. There are no energetically accessible states of atom M that can be excited by the low-energy electron, so the scattering must be elastic. The electron can transfer very little kinetic energy to M , but the direction of the electron's motion can change. With this thought in mind, we can see that only the collisional mixing of nearly degenerate ℓ states of the same n has very large cross sections. The ℓ -mixing cross sections are approximately geometric at low n [33]. If the M atom comes anywhere into the Rydberg orbit, scattering into a different ℓ state occurs. At high n , the cross section decreases, because the probability distribution of the Rydberg electron becomes too dilute, and it becomes increasingly likely that the M atom will pass through the Rydberg electron's orbit without encountering the electron. The n at which the peak ℓ -mixing cross section occurs increases with the electron scattering length of the atom. While ℓ -mixing cross sections are large, n changing cross sections are small ($\approx 100 \text{ \AA}^2$) since they cannot occur when the Rydberg electron is anywhere close to the outer turning point of its orbit [34].

If M is a molecule, there are likely to be energetically accessible vibrational and rotational transitions that can provide energy to or accept energy from the Rydberg electron, and this possibility increases the likelihood of n changing collisions with Rydberg atoms [11]. Electronic energy from the Rydberg atom must be resonantly transferred to rotation or vibration in the molecule. In heavy or complex molecules, the presence of many rotational-vibrational states tends to obscure the resonant character of the transfer, but in several light systems, the collisional resonances have been observed clearly [11].

Using the large Stark shifts of Rydberg atoms it is possible to tune the levels so that resonant energy transfer between two colliding atoms can occur [35] by the resonant dipole-dipole coupling,

$$Vd = \frac{\mu_1 \mu_2}{R^3}. \quad (15.34)$$

Here, μ_1 and μ_2 are the dipole matrix elements of the upward and downward transitions in the two atoms, and R is their separation. At room temperature, this process leads to enormous cross sections, substantially in excess of the geometric cross sections. At the low temperatures ($300 \mu\text{K}$) attainable using cold atoms, the atoms do not move, and, therefore, cannot collide. However, resonant dipole-dipole energy transfer is still observed due to the static dipole-dipole interactions of not two but many atoms [36, 37].

Since Rydberg atoms are easily perturbed by electric fields, it is hardly a surprise that collisions of charged particles with Rydberg atoms have large cross sections. In cold Rydberg atom samples, these large cross sections can lead to the spontaneous evolution to a plasma, since the macroscopic positive charge of the cold ions can trap any liberated

electrons, leading to impact ionization for a large part of the Rydberg atom sample [38, 39].

15.7 Autoionizing Rydberg States

The bound Rydberg atoms considered thus far are formed by adding the Rydberg electron to the ground state of the ionic core. It could equally well be added to an excited state of the core [40]. Figure 15.6 shows the energy levels of the ground 5s state of Sr⁺ and the excited 5p state. Adding an $n\ell$ electron to the 5s state yields the bound Sr 5s $n\ell$ state, and adding it to the excited 5p state gives the doubly excited 5p $n\ell$ state, which is coupled by the Coulomb interaction to the degenerate 5s $\epsilon\ell'$ continuum. The 5p $n\ell$ state autoionizes at the rate $\Gamma_{n\ell}$ given by [41]

$$\Gamma_{n\ell} = 2\pi |\langle 5p n \ell | V | 5s \epsilon \ell' \rangle|^2, \quad (15.35)$$

where V denotes the Coulomb coupling between the nominally bound 5p $n\ell$ state and the 5s $\epsilon\ell'$ continuum. A more general description of autoionization can be found in Chap. 26.

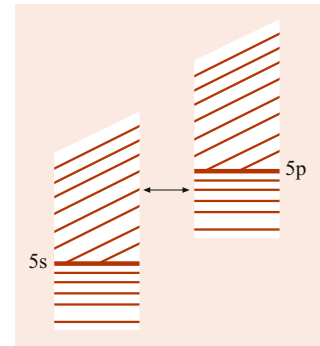

A simple picture, based on superelastic electron scattering from the Sr⁺ 5p state, gives the scaling of the autoionization rates of Eq. (15.35) with n and ℓ . The $n\ell$ Rydberg electron is in an elliptical orbit, and each time it comes near the core it has an n -independent probability γ_ℓ of scattering superelastically from the Sr⁺ 5p ion, leaving the core in the 5s state and gaining enough energy to escape from the Coulomb potential of the Sr⁺ core. The autoionization rate of the 5p $n\ell$ state is obtained by multiplying γ_ℓ by the orbital frequency of the $n\ell$ state, $1/n^3$, to obtain

$$\Gamma_{n\ell} = \frac{\gamma_\ell}{n^3}. \quad (15.36)$$

Equation (15.36) displays the n dependence of the autoionization rate explicitly and the ℓ dependence through γ_ℓ . As ℓ increases, the closest approach of the Rydberg electron to the Sr⁺ is at a larger orbital radius, so that superelastic scattering becomes progressively less probable, and γ_ℓ decreases rapidly with increasing ℓ . The simple picture of autoionization given above implies a finite probability of autoionization each time the $n\ell$ electron passes the ionic core, so the probability of an atom remaining in the autoionizing state should resemble stair steps [42], which can be directly observed using mode locked laser excitation and detection [43].

To a first approximation, the Sr 5p $n\ell$ states can be described by the independent electron picture used above, but in states converging to higher lying states of Sr⁺, the independent electron picture fails. Consider the Sr⁺ $\ell \geq 4$ states of $n > 5$. They are essentially degenerate, and the field due to an outer Rydberg electron converts the zero field ℓ states to superpositions much like Stark states. The outer electron

Fig. 15.6 Sr⁺ 5s and 5p states (—); the Rydberg states of Sr converging to these two ionic states are shown by (—), the continuum above the two ionic levels (///). The 5p $n\ell$ states are coupled to the 5s $\epsilon\ell'$ continua and autoionize

polarizes the Sr⁺ core, so that the outer electron is in a potential due to a charge and a dipole, and the resulting dipole states of the outer electron display a qualitatively different excitation spectrum than do states such as the 5p $n\ell$ states, which are well described by an independent particle picture [44]. When both electrons are excited to very high-lying states, with the outer electron in a state of relatively low ℓ , the classical orbits of the two electrons cross. Time domain measurements, made using wave packets, show that, in this case, autoionization is likely to occur in the first orbit of the outer electron [45].

semiclassical methods · quantum chaos · Rydberg states · recurrence spectroscopy · closed orbits · external fields

Abstract

Semiclassical approximations provide a connection between quantum mechanics and classical mechanics. That relationship is problematic when classical orbits are chaotic. Highly excited states of atoms have provided a laboratory for the study of this relationship. When classical trajectories are orderly, corresponding quantum spectra and wave-functions display the same type of order. When they are chaotic, the quantum spectrum is very complex, but short closed classical orbits are connected

16.1 Introduction

Confronting classical and quantum mechanics in systems whose classical motion is chaotic is one of the fundamental problems of physics, as evidenced by the enormous outpouring of research during the last three decades. Introductions to chaotic classical dynamics are given in [1, 2], and detailed discussions of quantum manifestations of classical chaos are given in [3–5]. Highly excited Rydberg atoms in external fields play a prominent role in this quest because they are among the best known examples of quantum systems whose classical counterparts are chaotic [6–11]. For a wide variety of field configurations and field strengths, their spectra can be measured to high precision. At the same time, since their Hamiltonians are known analytically, they are equally amenable to accurate theoretical investigations using either classical or quantum mechanics. This chapter is focused on semiclassical descriptions of Rydberg atoms in strong static fields. Related information on atoms in strong fields can be found in Chap. 14 of this Handbook, on Rydberg atoms in Chap. 15, and on the interaction of atoms with strong laser fields in Chaps. 76 and 78. Atomic units will be used throughout this chapter.

Various configurations of external fields have been studied:

1. an electric field, which in hydrogen leads to separable and, therefore, integrable classical dynamics;
2. a magnetic field, which produces a transition from regular to chaotic classical dynamics and which sparked the interest in Rydberg atoms as prototype examples for the study of the quantum-classical correspondence [7, 12–14] and references therein;
3. parallel electric and magnetic fields [15];
4. crossed electric and magnetic fields, which break all continuous symmetries of the unperturbed atom and, thus, allow one to study the transition from regularity to chaos in three coupled degrees of freedom [16–20].

The hydrogen atom is the prototype example for states with a single highly excited electron under the influence of strong external fields. For an electron in the hydrogen ground state, the influence of external electric or magnetic fields becomes comparable to that of the nuclear Coulomb field when the field strengths are in the order of the atomic units of electric field strength, $F_0 = e/(4\pi\epsilon_0 a_0) = 5.142\,206\,42(44) \times 10^{11}$ V/m, or magnetic field strength, $B_0 = \hbar/(ea_0^2) = 2.350\,517\,42(20) \times 10^5$ T, which are far beyond experimental reach. However, the relative importance of the external fields scales with the principal quantum number n as $n^4 F$ and $n^3 B$, so that for highly excited atoms, laboratory fields can easily be “strong”. In a nonhydrogenic atom, the influence of the inner-shell electrons can be summarized by means of a short-range effective core potential or a set of quantum defects [21, 22]. For laboratory field strengths, the core is too small to be appreciably influenced by the external fields. For this reason, the field-free quantum defects can be used to model core effects even in the presence of external fields [23].

The Hamiltonian for a hydrogen atom in a \hat{z} -directed magnetic field and an electric field of arbitrary orientation is, in atomic units,

$$H = \frac{\mathbf{p}^2}{2} - \frac{1}{r} + \frac{1}{2} B L_z + \frac{1}{8} B^2 \rho^2 + \mathbf{r} \cdot \mathbf{F} = E, \quad (16.1)$$

where $\rho^2 = x^2 + y^2$ and L_z is the angular momentum component along the magnetic field axis. The dynamics depends on four parameters: the field strengths F and B , the energy E , and the angle between the fields. We can reduce the number of independent parameters by one if we exploit a scaling property of the Hamiltonian. In terms of the scaled quantities

$$\begin{aligned} \tilde{\mathbf{r}} &= w^{-2} \mathbf{r}, & \tilde{\mathbf{p}} &= w \mathbf{p}, \\ \tilde{E} &= w^2 E, & \tilde{F} &= w^4 F, \end{aligned} \quad (16.2)$$

with the scaling parameter

$$w = B^{-1/3}, \quad (16.3)$$

the scaled Hamiltonian reads

$$\tilde{H} = \frac{\tilde{\mathbf{p}}^2}{2} - \frac{1}{\tilde{r}} + \frac{1}{2} \tilde{L}_z + \frac{1}{8} \tilde{\rho}^2 + \tilde{\mathbf{r}} \cdot \tilde{\mathbf{F}} = \tilde{E}. \quad (16.4)$$

The scaled dynamics, thus, depends only on three parameters: the scaled energy \tilde{E} and the scaled electric field strength \tilde{F} and its polar angle. If the fields are parallel, then the scaled angular momentum \tilde{L}_z is conserved, and it can be regarded as another fixed parameter, so, for example, if there is no electric field and $\tilde{L}_z = 0$ the scaled dynamics depends only on the scaled energy \tilde{E} .

16.2 Semiclassical Approximations

In Rydberg states, as in other highly excited quantum states, the deBroglie wavelength of the electron is short compared to the range over which the potential energy varies, so semiclassical approximations are appropriate means for insightful calculations. The semiclassical approximation in one dimension is a standard topic in textbooks on quantum mechanics, but satisfactory treatments in higher dimension are not common in textbooks. Therefore, below we give a brief description of semiclassical theory in two dimensions, which is adequate for many studies of Rydberg atoms in fields.

Semiclassical approximations are typically constructed using numerical computations of classical trajectories. The semiclassical approximation in two dimensions is easiest to explain by thinking about elastic scattering of particles of mass m and energy E from a fixed potential energy $V(r)$ having long-range attraction and short-range repulsion [24]. In Fig. 16.1, a stream of classical particles comes in from the left and interacts with such a potential energy fixed at the ori-

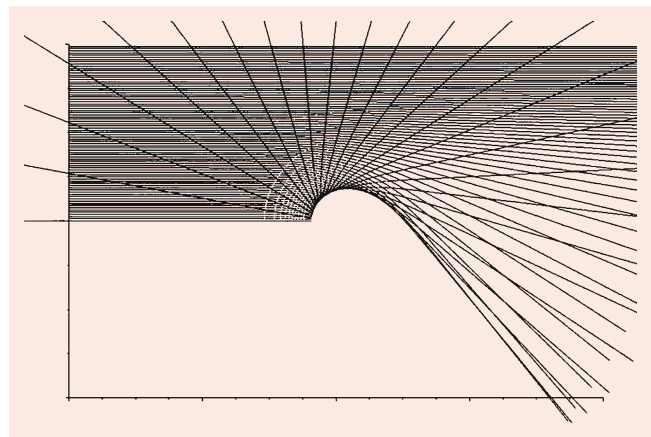

Fig. 16.1 Two-dimensional scattering with long-range attraction and short-range repulsion. (Figure kindly provided by C. Schleif)

gin. The radial (r) and angular (ϕ) motions are described by

$$\begin{aligned} \frac{dr}{dt} &= \left[\left(\frac{2}{m} \right) \left(E - V(r) - \frac{l^2}{2mr^2} \right) \right]^{1/2} \\ \frac{d\phi}{dt} &= \frac{l}{mr^2} \end{aligned} \quad (16.5)$$

(l = angular momentum). Particles having a large impact parameter b are only slightly deflected by the long-range attractive force. For smaller b , there is more deflection downward, which is said to be the negative scattering angle. The deflection reaches an extremum (the negative scattering angle has a minimum, called the “rainbow angle”), and then at smaller b , when the repulsive force dominates, particles are scattered upward, which is the positive scattering angle, until when $b = 0$, the scattering angle equals π (backward scattering).

The complete family of classical paths defines a dynamically allowed region of the plane, and two paths arrive at each point in this allowed region. The boundary between allowed and forbidden regions is called a “caustic”. (The dynamically forbidden region is much larger than the energetically forbidden region; the latter is the interior of a circle around the origin, where the potential energy exceeds the incident kinetic energy. The caustic touches the energetically forbidden region only on the trajectory having $b = 0$ [24]. Paths at larger b never touch the energetically forbidden region because of angular momentum repulsion, $l^2/2mr^2$.)

Two properties of this family of classical trajectories are needed for the calculation of a semiclassical approximation to the quantum wave function, the classical actions and the classical densities. On each path, the position $\mathbf{q}(t, b) = [x(t, b), z(t, b)]$ and the momentum $\mathbf{p}(t, b) =$

$[p_x(t, b), p_z(t, b)]$ are single-valued vector functions of time and of the impact parameter. The classical action is likewise a single-valued function of (t, b) ,

$$S(t, b) = \int_{t_0}^t \left[\mathbf{p}(t, b) \cdot \frac{\partial \mathbf{q}(t, b)}{\partial t} \right] dt. \quad (16.6)$$

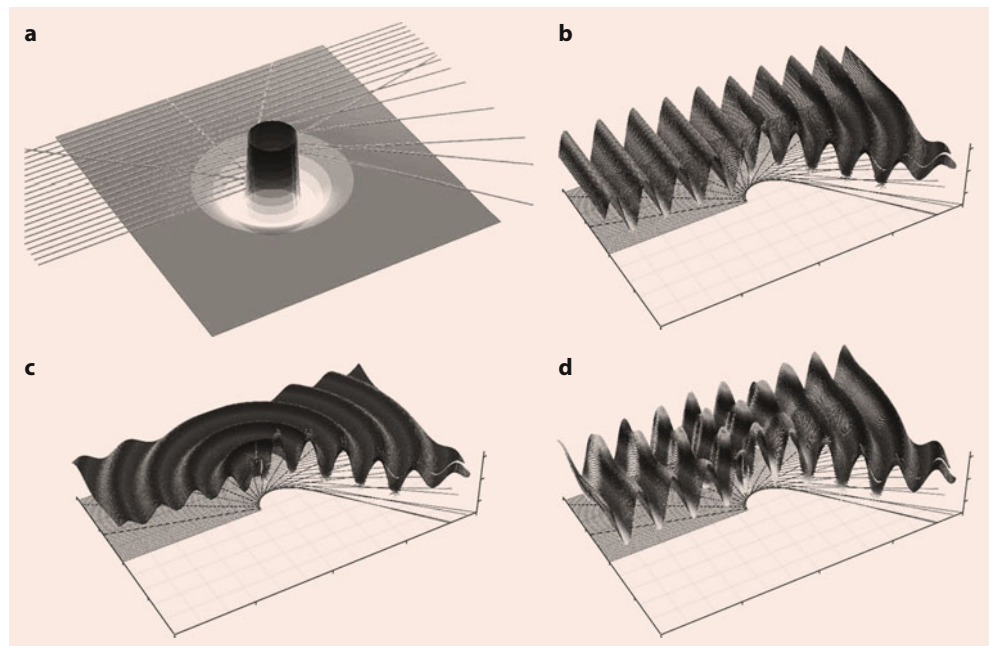

The classical density describes the fact that trajectories approaching the target represent a uniform flow, neighboring paths converge at the caustic, and scattered paths diverge from each other. This density is given by the function

$$\begin{aligned} \rho(t, b) &= \left| \left[\frac{J(t_0, b)}{J(t, b)} \right] \right|, \\ \text{where } J(t, b) &= \frac{\partial \mathbf{q}}{\partial(t, b)} = \frac{\partial(x, z)}{\partial(t, b)}, \end{aligned} \quad (16.7)$$

where t_0 is the initial time on each trajectory.

To construct a semiclassical wave function, we need to express the classical action and density as functions of position \mathbf{q} . Since two paths arrive at each point in the allowed region, these quantities are two-valued functions of \mathbf{q} . Each path that touches the caustic is divided into an “incident” (*Inc*) portion, prior to touching the caustic, and a “scattered” (*Scat*) portion, after touching the caustic. At large b , where paths never touch the caustic, the entire path is regarded as “*Inc*”, even the part that is going away from the target. (Quantum-mechanical descriptions of such collisions use an expansion in radial functions times spherical harmonics, and the radial function is divided into incoming and outgoing waves. The caustic does not coincide with the distance of

Fig. 16.2 Potential energy, trajectories, and wave functions for two-dimensional scattering with long-range attraction and short-range repulsion. (a) The potential energy, with a well and a barrier, and some trajectories from Fig. 16.1 shown in perspective. (b) Trajectories and the “incident” term in the wave function. (c) Trajectories and the “scattered” term in the wave function. (d) The complete wave function in the classically allowed region. (Figure kindly provided by C. Schleich)

closest approach of each trajectory, so our description of “incident” and “scattered” terms in the semiclassical wave function does not correspond directly to radial incoming and outgoing waves.)

Numerical inversion and interpolation of the relationship between \mathbf{q} and (t, b) gives two-valued action and density functions, $S_\alpha(\mathbf{q}), \rho_\alpha(\mathbf{q})$, with $\alpha = (\text{Inc}, \text{Scat})$. Then the semiclassical approximation to the wave function in the allowed region is given by a sum of an “incident” and a “scattered” wave function,

$$\psi_\alpha(\mathbf{q}) = [\rho_\alpha(\mathbf{q})]^{1/2} \exp\left(i\left[\frac{S_\alpha(\mathbf{q})}{\hbar} - \frac{\mu_\alpha\pi}{2}\right]\right),$$

$$\alpha = (\text{Inc}, \text{Scat}). \quad (16.8)$$

The absolute square of each term is the associated classical density, and the phase is the classical action with a correction $\mu_\alpha\pi/2$, where μ_α is called the Maslov index. In this case, $\mu_I = 0, \mu_S = 1$. The incident and scattered and full wave functions are shown in Fig. 16.2b–d. One sees refraction of the *Inc* term following the classical trajectories, and reflection producing the nearly circular outgoing *Scat* term. In the full wave function, one sees interference between these two waves.

Momentum-vector-fields are gradients of the two-valued action function, $\mathbf{p}_\alpha(\mathbf{q}) = \nabla S_\alpha(\mathbf{q})$, so $\nabla \times \mathbf{p}_\alpha(\mathbf{q}) = 0$. Any family of trajectories that forms a momentum-vector field with vanishing curl forms what in optics is called a “normal congruence” (in modern language, such a momentum-vector field defines a “Lagrangian manifold” in phase space). From any such vector field, a corresponding semiclassical wave function Eq. (16.8) can be constructed. Further details and mathematical theory are given in [24–28].

16.3 Regular Trajectories and Regular Wave Functions

We return now to Rydberg states of atoms in fields. At energies below the ionization threshold, there are bound trajectories that stay in a finite region of space. Figure 16.3 shows a path in cylindrical coordinates (ρ, z) followed by an electron in the presence of the attractive Coulomb force of a nucleus at the origin and forces from electric and magnetic fields directed along the z -axis. This is an example of a “regular” trajectory. The path is a perturbed Kepler ellipse; the eccentricity and orientation of the ellipse change continuously with time such that the ellipse does not close on itself. Also, the cylindrical coordinate ρ cannot be negative, so in this picture, the ellipse is folded over across itself.

For weak electric and magnetic fields, the principal action is approximately conserved, and its associated principal quantum number n is a good quantum number. If the fields

are parallel, then the z -component of angular momentum L_z is conserved, and quantized as $m\hbar$. However, the total angular momentum is not conserved, and ℓ is not a good quantum number. It is replaced by an approximately conserved quantity, which can be written in various ways. *Solov’ev* [29] and *Herrick* [30] wrote it as

$$\Lambda = 4A^2 - 5A_z^2, \quad (16.9)$$

where A is the Laplace–Runge–Lenz vector

$$A = \frac{1}{\sqrt{-2E}} \left(\frac{1}{2}(\mathbf{p} \times \mathbf{L} - \mathbf{L} \times \mathbf{p}) - \frac{\mathbf{r}}{r} \right). \quad (16.10)$$

Waterland et al. [15] used hydrogenic action and angle variables and classical perturbation theory to write the conserved quantity in the form

$$F(\text{eccentricity, orientation}) \simeq \text{constant} \equiv f^0. \quad (16.11)$$

Detailed analysis of either of these functions, Eq. (16.9) or Eq. (16.11), gives an understanding of all details of the regular classical trajectories.

This regular path winds around in the (ρ, z) plane such that it forms four well-defined curl-free momentum-vector fields $\mathbf{p}_\alpha(\mathbf{q})$, with each having a well-defined density $\rho_\alpha(\mathbf{q})$. Accordingly, each of these four vector-fields “support” a semiclassical wave function of the form Eq. (16.8), and the full wave function is a linear combination of these four terms. However, it is necessary to combine the terms in such a way that the full semiclassical wave function corresponds to a quantum wave function that satisfies the boundary conditions, $\psi(\rho, z) \rightarrow 0$ as $\rho \rightarrow \infty, z \rightarrow \pm\infty$. This requires quantization conditions.

In the 4-D phase space (\mathbf{q}, \mathbf{p}) , any surface having fixed energy E and satisfying Eq. (16.11) forms a 2-D torus labeled by (E, f^0) , and the exact trajectory lies very close to

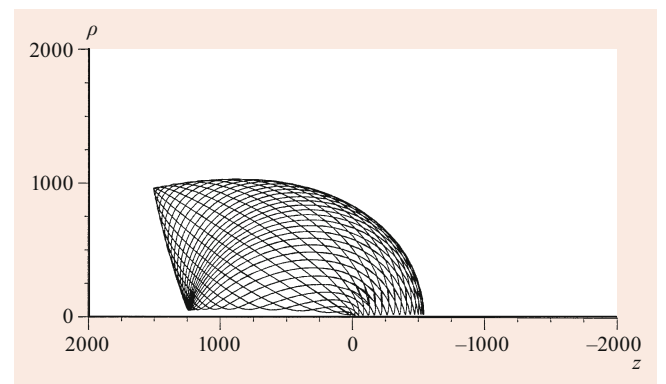

Fig. 16.3 A regular trajectory of an atomic electron in parallel electric and magnetic fields. This one has appropriately quantized action variables, so it is an “eigentrajjectory”, from which a semiclassical eigenfunction can be calculated

this surface. Any 2-D torus (the surface of a donut) has two distinct fundamental loops that cannot be shrunk to a point. Action variables are defined as

$$\mathbf{S}_j(E, f^0) = \int_j \mathbf{p}(\mathbf{q}; E, f^0) \cdot d\mathbf{q}, \quad j = 1, 2 \quad (16.12)$$

around each of the two fundamental loops of each torus [25, 28, 31–33]. The tori form continuous families, since E and f^0 vary continuously. Out of those continuous families of tori, we select a discrete set having appropriately quantized values of action variables

$$\mathbf{S}_j(E, f^0) = \left(k_j + \frac{\mu_j}{4}\right)2\pi\hbar, \quad j = 1, 2; \quad (16.13)$$

k_j is a positive integer, and μ_j is a Maslov index (equal to 2 in this case). Those discrete tori are called “eigentori”, and the trajectories on them are called “eigentrajectories”.

The momentum-vector fields associated with each eigentrajjectory, with their associated densities and action functions, “support” a quantized semiclassical wave function. The local wavelength of the α semiclassical term is $\lambda_\alpha = 2\pi\hbar/|\mathbf{p}_\alpha(\mathbf{q})|$, and the quantization condition ensures that there will be a properly quantized number of wavelengths associated with each fundamental loop of each eigentorus. Thus, the corresponding exact quantum wave function will satisfy the necessary boundary conditions.

In Fig. 16.4 is shown the complete quantum wave function (absolute squared) associated with the eigentrajjectory that was shown in Fig. 16.3. (This eigenfunction was computed by accurate quantum methods, with no reference to the semiclassical wave function.) We see that the wave function primarily occupies the same region of space as the eigentrajjectory, diffracting into the nearby classically forbidden region. The local wavelength and density of the quantum

Fig. 16.4 Below is the eigentrajjectory that was shown in Fig. 16.3, and above is an accurate eigenfunction for a Rydberg state of an electron in an atom in parallel electric and magnetic fields

wave function are consistent with the local momentum and density of the eigentrajjectory [15].

This case illustrates the general principles for systems having regular trajectories [3, 4, 34, 35]. (1) Regular bound trajectories wind around a finite region of space such that they form curl-free momentum-vector fields. In the phase space of dimension $2n$, bound regular trajectories lie on tori of dimension n . (2) Upon an appropriately quantized set of these regular trajectories, one can construct semiclassical wave functions such that the corresponding exact quantum wave function satisfies the necessary boundary conditions. In the simple cases (in the absence of tunneling), there is a one-to-one correspondence between eigentrajectories and eigenfunctions. (3) All trajectories are regular if the equations of motion are separable (i.e., the Hamilton–Jacobi equation is separable), or, more generally, if the system has n degrees of freedom and n conservation laws (technically, n “isolating integrals of the motion”). (4) Analysis of the conservation laws tells us everything we might want to know about the structure of the trajectories. (5) For weak perturbations of a system having regular trajectories, most of the trajectories are regular (Kolmogorov–Arnold–Moser (KAM) theorem [36–38]).

16.4 Chaotic Trajectories and Irregular Wave Functions

An example of a chaotic trajectory is shown in Fig. 16.5. As in Fig. 16.3, this is one continuous curve showing a path in (ρ, z) -space followed by a classical electron in the Coulomb field of a nucleus at the origin and a magnetic field along the z -axis (no applied electric field). In contrast to the curve shown in Fig. 16.3, which is similar to a machine-wound spool of twine, this path looks like a bowl of spaghetti that got dropped on the floor. Nevertheless, there is short-time order in the path: far from the nucleus, the electron’s path is close to a helix, circling around a magnetic field line, while close to the nucleus it is close to a Kepler ellipse. However, we can see no long-time order in this path. If we could draw a curve inside of which the magnetic field were negligible and outside of which the Coulomb field were negligible, we could say that the magnetic field scatters the electron from one Kepler orbit to another, or we could say that the Coulomb field scatters the electron from one helix to another; either way, the long-time behavior is chaotic. Such trajectories arise when magnetic and Coulomb forces compete but neither dominates everywhere [7, 39]. This happens as the energy approaches the ionization limit, or if the magnetic field becomes extremely strong (in the kilotesla range).

There is a second way that chaos arises in Rydberg states of atoms. The quantum or classical Hamiltonian for a hy-

Fig. 16.5 A chaotic trajectory of an atomic electron in a strong magnetic field. (Courtesy of Donald Noid)

drogen atom in an electric field is separable in parabolic coordinates, so all bound trajectories lie on tori. However for all other atoms, the small ion core scatters the electron from one torus to another, and the long-time behavior is chaotic. One may compare the motion to that of a billiard ball on a rectangular table containing a small round barrier [40–43].

Some properties of chaotic trajectories are the following. (1) They have a sensitive dependence on initial conditions: a small displacement of initial conditions grows exponentially, restricting predictability to short times. (2) Even in a chaotic system, there is order on short time scales. The trajectories obey Newton’s laws, and if the forces are smooth functions of position, then the paths are smooth functions of initial conditions (according to property (1), they become horrible and even uncomputable functions, but they are, in principle, smooth – as time increases, the derivative of final position with respect to initial position becomes gargantuan but finite). Thus, chaos is a long-time property of classical trajectories. (3) While regular bound trajectories are restricted to n -dimensional tori in the $2n$ -dimensional phase space, chaotic trajectories may fill the energy shell, in the sense of approaching arbitrarily closely to any point in it. Accordingly, at any spatial point, (ρ, z) , the magnitude of the momentum is determined by conservation of energy, but the direction of the momentum is not. Therefore, a path does not form a curl-free momentum-vector field, indeed, it does not form a momentum-vector field at all. Therefore, we cannot use chaotic trajectories to build quantum wave functions in the way that is done for regular trajectories. This is the “problem of quantum chaos”: if classical trajectories of a given system are chaotic, what can be said about the quantum states? For reviews of this problem see [3, 4, 34, 44]. Here, we discuss only Rydberg atoms in static fields.

Two general principles apply. (A) Long-time chaos in classical mechanics carries over to irregular behavior of individual energy levels and individual eigenfunctions – these are most visible at high resolution of energy. (B) Short-time order in classical mechanics carries over to short-time order in quantum mechanics, and that in turn is connected to the

large-scale structure of the energy spectrum and other quantum properties – these are most visible at low resolution of energy. Thus, different manifestations of chaos appear when we look at the spectrum on different scales [35].

16.4.1 Small-Scale Structure

In Chap. 15, Fig. 15.5 shows energy levels of hydrogen in an electric field. It is seen that energy levels from different values of principal quantum number n cross each other. This is because the Schrodinger equation (as well as the Hamilton–Jacobi equation) is separable in parabolic coordinates. All bound motions are, therefore, regular, and states that cross have different parabolic quantum numbers. Figure 15.4 shows energy levels of sodium in an electric field. Now the states avoid crossing. The ion core scatters the electron from one parabolic state to another, and all eigenstates of the full Hamiltonian are superpositions of many different parabolic states. In this case, the avoided crossings are a quantum manifestation of the classical chaos that arises from core scattering. These figures suggest that regular behavior allows lots of degeneracies and near-degeneracies, but chaotic behavior produces avoided crossings, thus pushing eigenvalues apart.

This repulsion of energy levels shows up in nearest-neighbor statistics of the energies. For each energy eigenvalue, define s to be the absolute value of the energy gap to its nearest neighboring eigenvalue, and then for a large collection of eigenvalues find the probability distribution $P(s)$ of values of s . This is the nearest-neighbor spacing distribution. For Rydberg states of atoms, this nearest-neighbor spacing distribution was computed in [40] and is shown in Fig. 16.6, first for hydrogen, and then for lithium. The stepped line is the histogram, and the two dashed lines are an exponential, which permits lots of near-degeneracies, as is seen in regular spectra, and a Wigner distribution, $P(s) = (\pi/2)s \exp(-\pi s^2/4)$, which goes to zero as $s \rightarrow 0$, consistent with irregular spectra and their avoided crossings.

Fig. 16.6 Nearest-neighbor spacing distribution for Rydberg states of hydrogen (*above*) and for lithium (*below*). The stepped curve is the histogram computed from the spectrum; the light and heavy dashed lines are, respectively, an exponential and a Wigner distribution [40]

16.4.2 Large-Scale Structure of Energy Spectra

If instead of looking at individual quantum states, we average the properties of these states over a finite band of energies, then a relationship to classical periodic orbits appears. This connection was first recognized by *Gutzwiller* [4], and experiments and theory on Rydberg states of atoms have shown the connection most clearly [45–47].

The first experimental evidence came from measurements of the absorption spectrum of atoms in magnetic fields [12–14]. At “low” energies, meaning absorption to Rydberg states around $n \approx 30$ in laboratory magnetic fields (≈ 6 T), spectral lines fall into orderly sequences, quantitatively described by the regular trajectories and wave functions discussed above. With increasing energy, the spectrum becomes messier, partly because of chaotic dynamics and partly because levels are not well resolved. Then at higher energies, orderly oscillations appear. The wavelength of these oscillations on the energy axis ΔE_1 is related to the return time T_1 of a closed orbit perpendicular to the magnetic field, $\Delta E_1 = 2\pi\hbar/T_1$.

Later, when the absorption spectrum of a hydrogen atom in a 6 T magnetic field was measured [14], it was found that the spectrum could be Fourier-decomposed into a sum of sinusoidal oscillations,

$$\text{Abs}(E) \simeq \sum_j C_j \sin\left(\frac{T_j E}{\hbar} + \Delta_j^0\right), \quad (16.14)$$

and that these T_j are times of returning classical orbits of the electron. The shortest returning orbits produce oscillations of longest wavelength (on the energy axis), and successively longer returning orbits produce oscillations of successively shorter wavelength. This observation was the birth of recurrence spectroscopy, a different way of thinking about absorption spectra: instead of examining individual energy levels, the Fourier-transform of the absorption spectrum provides measures of closed classical orbits of the electron as it moves in the Coulomb field of the nucleus and the applied electric and magnetic fields [17, 48–53]. (In the case of atomic absorption spectra, the semiclassical connection is to orbits that are closed at the nucleus, not to periodic orbits.)

The physical picture is shown in Fig. 16.7. Light shining on an atom (like a vibrator in a ripple tank, sending out a continuous stream of water waves) produces a continuous stream of electron waves moving out from the atom in all directions, with energy close to the ionization threshold. That is a quantum process. However, when the waves move away, we can follow the waves by following the corresponding “rays”, the outgoing classical trajectories. At large distances, the trajectories and waves are turned around by the applied fields. Some trajectories and waves go out in directions such that they return to the atom after a while. When they do, the waves refract and diffract around the atom, producing a steady stream of incoming waves, which interfere with the steady stream of outgoing waves, producing the oscillations that are visible in the absorption spectrum. This physical picture leads to a quantitative formula,

$$\text{Abs}(E; B, F) = \sum_j C_j(E; B, F) \sin(\Delta_j(E; B, F)). \quad (16.15)$$

Here, j labels the closed orbits, and $\Delta_j(E; B, F)$ is a phase, in which the most important term is the classical action integrated around the closed orbit. The duration of the closed orbit is $T_j = \partial\Delta_j/\partial E$, which recovers the approximate formula Eq. (16.14). The coefficient $C_j(E; B, F)$ is slowly varying with energy and magnetic and electric field strengths; it contains factors representing the angular distribution of outgoing waves, and the (square root of) the classical density associated with the returning trajectories [45, 46]. This coefficient is called the “recurrence amplitude”, and its absolute square is the “recurrence strength”.

Fig. 16.7 Clockwise from *lower left*. Light shining on an atom (1) produces a continuous stream of outgoing electron waves (2), having energy close to the ionization threshold. When those waves get away from the atom, we can follow them by following the corresponding “rays” or classical trajectories (3). These trajectories travel away (4), pass through a caustic (5), a focus (6), and another caustic (7). We have drawn trajectories that return to the vicinity of the nucleus (8). When they do, they refract (9), and the waves diffract (10) around the nucleus, producing a steady stream of incoming waves that overlap the initial state (11) and interfere with the outgoing waves, producing interference oscillations in the absorption spectrum

Scaled-variable methods provide important improvements to the experimental measurements [13]. The structure, size, and return times of orbits change with energy and field strengths, but it turns out that (for $F = 0$ and $L_z = 0$) the shapes of classical orbits depend only on the scaled energy, which is $\varepsilon = EB^{-2/3}$ (Eq. (16.2)). At constant scaled energy, the classical action is proportional to $w = B^{-1/3}$, and the coefficient $C_j(E; B)$ is nearly constant. It follows that if the absorption spectrum is measured varying E and B simultaneously to hold ε fixed, and the absorption is recorded as a function of w , then the oscillations become almost perfectly sinusoidal, and the recurrence spectrum becomes a set of sharp peaks, one at the scaled classical action of each returning orbit. An example of a scaled-variable recurrence spectrum for hydrogen in a magnetic field is shown in Fig. 16.8 [54].

For atoms in an electric field F with no magnetic field present, the scaled energy is $\varepsilon = EF^{-1/2}$. For this case, a family of recurrence spectra is drawn in a single graph in

Fig. 16.9 [55]. At all energies there is a closed orbit of the electron that goes up parallel to the electric field; its recurrence peak is barely visible in the upper left part of the figure. In certain ranges of energies, many other closed orbits are present. Some are shown at the bottom of Fig. 16.9, labeled (m/n) , meaning m cycles of motion transverse to the field during n cycles of motion parallel to the field. The scaled actions of these orbits are close to the scaled action of n cycles of the parallel orbit. If we gradually lower the scaled energy, there is a point at which each of these closed orbits splits (bifurcates) out of the parallel orbit. At that point, orbits neighboring the parallel orbit return strongly focused on the residual ion, and the recurrence strength is large. Such points are marked in the figure.

The detailed analysis of many such experiments has led to advances in classical and semiclassical mechanics. (1) In a magnetic field, one can see bifurcation and proliferation of closed orbits as order changes to chaos with increasing ε .

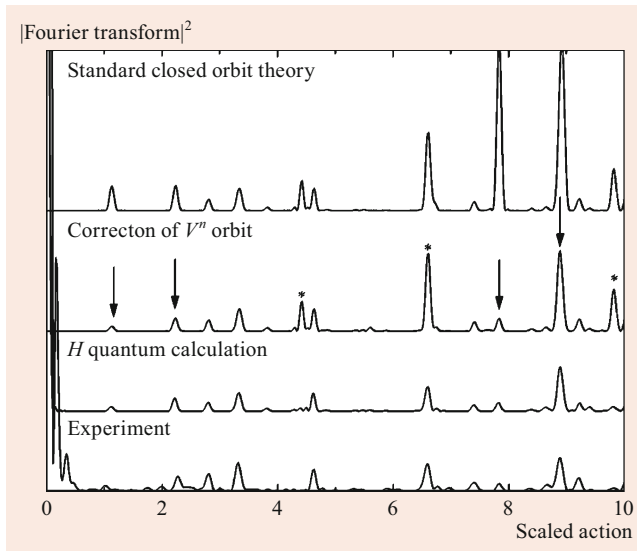

Fig. 16.8 A scaled-variable recurrence spectrum for hydrogen in a magnetic field. The location of each peak is the scaled action of a closed orbit; the height of each is the recurrence strength for that orbit. Arrows and asterisks mark corrections to simple semiclassical theory because of divergences near bifurcations [54]

Mathematical theory shows that there are just five generic patterns of bifurcations of periodic orbits. In atomic systems, these generic patterns are modified by symmetries. Calcula-

tions and theory show the shapes of bifurcated orbits. Also, sequences of bifurcations can be understood by reduction of the Hamiltonian to a local normal form. Measurements of recurrence spectra – intrinsically a quantum wave-interference phenomenon – have provided the most detailed and precise observations of bifurcations of classical periodic orbits and closed orbits [48, 56–63]. (2) Breaking cylindrical symmetry, by varying the angle between applied fields, weakens the recurrences in a systematic way. Breaking time symmetry, by applying a slowly oscillating field, has the same effect, and allows the electron orbit to be reconstructed from the recurrence spectrum [50, 51, 64]. (3) Semiclassical approximations diverge at bifurcations because there are boundaries between classically allowed and forbidden regions. The divergences are repaired by diffraction integrals such as Airy functions or Fresnel-type integrals. Diffraction into forbidden regions and also above-barrier reflection of waves produces “ghost recurrences” [54, 59, 61, 63, 65–71] (4) For nonhydrogenic atoms, the ion core scatters electrons from one returning orbit to another, producing “combination recurrences” [40, 72–75]. (5) Similar concepts give a theory of “width-weighted spectra”, related to energy-averaged decay rates of atoms [76].

Finally, we mention that recurrence spectroscopy associated with Rydberg states helped to stimulate the study of periodic orbits and their bifurcations in molecular systems [77–80].

Fig. 16.9 Many recurrence spectra for an atom in an electric field are drawn in a single graph [55]. The curves in the horizontal plane represent the scaled action of the parallel orbit and its repetitions as a function of scaled energy. Locations of bifurcations are marked with small open circles. New orbits created in bifurcations have almost the same action as the corresponding return of the parallel orbit. Measured recurrence strengths are shown in the vertical direction. Recurrences are especially strong at scaled energies slightly lower than bifurcations. Orbits created by bifurcation of the parallel orbit are shown along the bottom. The 2/4, 4/6, and 6/8 orbits are repetitions of the 1/2, 2/3, and 3/4 orbits, respectively, so their shapes are identical

16.4.3 Chaotic Ionization

At energies high enough that the electron can escape, we have a “chaotic scattering” system, or, for photoionization, a chaotic “half-collision”, or chaotic transport problem. The situation is closely related to the modern version of transition state theory of chemical reaction rates, and also has a connection with asteroid escape rates [81–86]. Consider the following experiment (which, as of this writing, has not yet been performed). An atom in a magnetic (and possibly electric) field is excited by a short laser pulse to an energy that permits escape of the electron. (The ideal experiment will excite to the minimum range of energies allowed by the uncertainty principle.) We might expect that the excited atom would decay by ionization exponentially with time. In fact, however, electrons come out in a chaotic sequence of short pulses. Classical calculations show that a graph of the time required for the electron to escape from the atom versus its initial direction has a fractal structure [87–91]. This fractal does not have the perfectly regular self-similar structure of mathematical fractals such as the Cantor set [92–95], nor is it a fractal with only statistical self-similarity. It is a distinct type, which has been called an “epistrophic” fractal.

The definition and characterization of such fractals is given in [96–99], and application to the chaotic escape of electrons from atoms in fields is given in [100–106]. Quantum calculations [107] verify that the predictions obtained from this fractal description are correct, at least for short times. It appears that epistrophic fractals occur commonly (perhaps generically) in chaotic scattering because they have been identified both theoretically and experimentally in the escape of particles or light or sound from a vase-shaped cavity [108–110], and theoretically in the escape of atoms from a trap [111], ballistic atom pumps [112–114], fluid flow [115, 116], and perhaps also in the dynamics of the buckling of a nanobeam [117].

16.5 Nuclear-Mass Effects

So far, only the relative motion of the electron with respect to the ionic core has been described. This is appropriate if the nucleus can be assumed to be infinitely heavy and, thus, not to take part in the motion. To include the effects of a finite nuclear mass, the description must start from the coupled two-body Hamiltonian and then work toward a separation of the internal dynamics from the center-of-mass (CM) motion.

It turns out that in the presence of a magnetic field, unlike for the field-free two-body problem, a complete separation of the relative and CM motions is impossible. Instead, only a pseudo-separation can be achieved, where the relative and CM motions remain coupled through a new constant of motion called the pseudomomentum \mathbf{K} [118]. This coupling

introduces a number of novel effects into the dynamics [119–123].

The influence of the CM motion on the internal dynamics is twofold. On the one hand, the motion of the atom in the magnetic field causes an induced electric field (motional Stark effect). On the other hand, the kinetic energy of the CM motion gives rise to an additional confining potential for the internal motion that could, in principle, locate the electron at a large distance from the nucleus, and produce atomic states with a huge dipole moment. Conversely, the motion of the CM is driven by the internal motion, the most strongly so in the case of vanishing pseudomomentum. It, thus, reflects the transition from regular to chaotic internal dynamics: regular internal motion leads to regular CM motion, whereas chaotic internal dynamics can give rise to chaotic behavior of the CM.

16.6 Quantum Theories

This chapter has focused on semiclassical theories and the connections between classical trajectories and quantum wave functions in excited states of atoms in fields. For more information on quantum theory of atoms in fields, the reader is referred to [124–126].

John Delos John Delos received a PhD in Chemistry from MIT and spent most of his career in physics at William and Mary. His research interests have been in classical and semiclassical mechanics, atomic collisions, order and chaos, and excited states of atoms in fields. Currently, he studies heart rates and respiration of infants in neonatal intensive care units.

Thomas Bartsch Thomas Bartsch received a PhD in Theoretical Physics from the University of Stuttgart, was a Postdoctoral Fellow at Georgia Tech, and is now Senior Lecturer in Mathematics at Loughboro University, UK. His research is centered on applications of nonlinear dynamics to atomic and molecular processes.

Turgay Uzer Professor Turgay Uzer obtained his doctorate at Harvard and was a Postdoctoral Fellow at CalTech. Currently he is Regent's Professor in Physics at Georgia Institute of Technology. His research interests include: Rydberg atoms and molecules, semiclassical theories, nonlinear dynamics/chaos, intramolecular energy transfer, and chemical reactivity.

Abstract

Hyperfine structure in atomic and molecular spectra is a result of the interaction between electronic degrees of freedom and nuclear properties other than the dominant one, the nuclear Coulomb field. It includes splittings of energy levels (and thus of spectral lines) from magnetic dipole and electric quadrupole interactions (and higher multipoles, on occasion). Isotope shifts are experimentally entangled with hyperfine structure, and the so-called field effect in the isotope shift can be naturally included as part of hyperfine structure. Studies of hyperfine structure can be used to probe nuclear properties, but they are an equally important probe of the structure of atomic systems, providing especially good tests of atomic wave functions near the nucleus. There are also isotope shifts owing to the mass differences between different nuclear species, and the study of these shifts provides useful atomic information, especially about correlations between electrons.

Hyperfine effects are usually small and often, but not always, it is sufficient to consider only diagonal matrix elements for the atomic or molecular system and for the nuclear system. In some cases, however, matrix elements off-diagonal in the atomic space, even though small, can be of importance; one possible result is to cause admixtures sufficient to make normally *forbidden* transitions possible.

Keywords

hyperfine structure · isotope shift · mass shift · tensor operator · diagonal matrix element

In the diagonal case, one can picture each electron undergoing elastic scattering from the nucleus and returning to its initial bound state. As pointed out by *Casimir* [1, 2], however, the *internal conversion* of nuclear gamma-ray transitions involves the inelastic down-scattering from an excited nuclear state to a lower one as an electron goes from an initial bound state to the continuum. By further conversion of bound to continuum states, one sees the connection with electron scattering from the nucleus – elastic, inelastic, and break-up. Hyperfine structure of outer-shell electronic states is at the low momentum-transfer end of this chain of related processes.

Some of the standard textbooks which discuss hyperfine structure are [3–10] and a few newer texts [11–14]. Especially relevant are [15–19] and the conference proceedings [20–22].

The study of hyperfine structure in free atoms, ions, and molecules is part of the more extensive research area of hyperfine interactions, which includes the study of atoms and molecules in matter, both at rest, for example as part of the structure of a solid, and moving, such as ions moving through condensed or gaseous matter. This more general subject also includes the ways in which atomic electrons shield the nucleus, or anti-shield it, from external or collective fields. Thus nuclear magnetic resonance, nuclear quadrupole reso-

nance, electron-nuclear double resonance, recoilless nuclear absorption and emission, nuclear orientation, production of polarized beams, and many other widely used techniques, are intimately connected with hyperfine effects.

Though hyperfine effects are ordinarily small in electronic systems, they can become much larger in *exotic* atoms: those with a heavier lepton or hadron as the *light* particle. Hyperfine effects are typically related to light particle density at the nucleus, or to expectation values of r^{-3} , and thus scale as the cube of the light particle mass. The study of muonic atoms has contributed importantly to knowledge of the nuclear charge distribution [23–26]. There has been considerable interest in pionic atoms, where the strong interaction also contributes to hyperfine structure (e.g., [27, 28]), and also in kaonic, antiprotonic, and other hadronic *atoms* [29, 30]. See especially [31] for recent work on antiprotonic helium.

Some other examples of interaction between atomic and nuclear degrees of freedom are discussed in Chap. 91.

17.1 Splittings and Intensities

17.1.1 Angular Momentum Coupling

When the nuclear system is in an isotropic environment, each nuclear state β has a definite value of nuclear angular momentum $I_\beta \hbar$, where the possible values of I_β are related to the number of nucleons (protons plus neutrons) in the same way as those for J_α are related to the number of electrons in electronic state $|\alpha\rangle$. The nuclear operators, eigenstates, and eigenvalues are related to each other in the same way as for atomic angular momentum by

$$\begin{aligned} I^2|\beta\rangle &= I_\beta(I_\beta + 1)|\beta\rangle, \\ I_z|\beta\rangle &= M_\beta|\beta\rangle, \end{aligned} \quad (17.1)$$

in units with $\hbar = 1$. Shift operators move the system from one M -value to another, as for the atomic system (see Chap. 2), and the operator I is the generator of rotations. When the combined atomic-nuclear system is considered, in an isotropic environment, it is the total angular momentum of the combined system defined by

$$\mathbf{F} = \mathbf{J} + \mathbf{I}, \quad (17.2)$$

that has definite values. The state of the combined system can be labeled by γ , so that

$$\begin{aligned} F^2|\gamma\rangle &= F_\gamma(F_\gamma + 1)|\gamma\rangle, \\ F_z|\gamma\rangle &= M_\gamma|\gamma\rangle. \end{aligned} \quad (17.3)$$

The shift operators are defined as before, and it is now \mathbf{F} that is the generator of rotations of the (combined) system, or of the coordinate frame to which the system is referred.

By the rules of combining angular momenta, the possible values of the quantum number F are separated by integer steps and run from an upper limit of $J_\alpha + I_\beta$ to a lower limit of $|J_\alpha - I_\beta|$. The number of possible eigenvalues F is the smaller of $2J_\alpha + 1$ and $2I_\beta + 1$. Experimental values of the nuclear quantum number I may be found in a number of compilations [32–34].

17.1.2 Energy Splittings

Electromagnetic interactions between atomic electrons and the nucleus can be expanded in a multipole series

$$\begin{aligned} H_{eN} &= \sum_k \mathbf{T}^k(\mathbf{N}) \cdot \mathbf{T}^k(\mathbf{e}), \\ &\equiv \sum_{k,q} (-1)^q T_q^k(\mathbf{N}) T_{-q}^k(\mathbf{e}) \end{aligned} \quad (17.4)$$

where $\mathbf{T}^k(\mathbf{N})$ is an irreducible tensor operator of rank k operating in the nuclear space, and similarly $\mathbf{T}^k(\mathbf{e})$ operates in the space of the electrons. Since one is taking diagonal matrix elements (in the nuclear space, at least) in states that are to a very good approximation eigenstates of the parity operator, only even electric multipoles (E0, E2, etc.) and odd magnetic multipoles (M1, M3, etc.) contribute to the series. The effects of the parity nonconserving weak interaction are considered in Chap. 28.

The term with $k = 0$ contributes directly to the structure (and fine structure) of atomic systems, and its dominant contributions come from the external r^{-1} electrostatic field of the nucleus. The *hyperfine* Hamiltonian is defined by subtracting that term to obtain

$$\begin{aligned} H_{\text{hfs}} &= \sum_i [T^0(\mathbf{N})T^0(i) - (-Ze^2/r_i)] \\ &+ \sum_{k=1} \mathbf{T}^k(\mathbf{N}) \cdot \mathbf{T}^k(\mathbf{e}), \end{aligned} \quad (17.5)$$

where Z is the nuclear charge number. The difference between the Ze^2/r term(s) and the full monopole term is called the *field effect* or *finite nuclear size effect* in the isotope shift, and the remaining terms contribute dipole ($k = 1$), quadrupole ($k = 2$), and higher multipoles in hyperfine structure.

Since the hyperfine Hamiltonian can be expressed as a multipole expansion, its contributions to the pattern of energy levels for the various F values in a given J_α, I_β multiplet in first-order perturbation theory can be described

relatively simply in terms of $3-j$ and $6-j$ symbols. The contribution of the term which is the scalar product of electron and nuclear operators of multipole k is

$$\begin{aligned} \Delta E_k(JIF, JIF) &= (-)^{J+I+F} \begin{Bmatrix} J & J & k \\ I & I & F \end{Bmatrix} \\ &\times \left[\begin{pmatrix} J & k & J \\ J & 0 & -J \end{pmatrix} \begin{pmatrix} I & k & I \\ I & 0 & -I \end{pmatrix} \right]^{-1} A_k, \quad (17.6) \end{aligned}$$

where for $k \geq 1$,

$$A_k = \langle JJ | \mathbf{T}^k(\mathbf{e}) | JJ \rangle \cdot \langle II | \mathbf{T}^k(\mathbf{N}) | II \rangle. \quad (17.7)$$

The commonly used hfs coefficients A , B , etc., are related to the A_k by

$$A = A_1/IJ, \quad B = 4A_2, \quad C = A_3, \quad D = A_4. \quad (17.8)$$

The isotope shift A_0 is the matrix element of the reduced monopole operator.

The pattern of the splitting depends on the total angular momentum F wholly through the $6-j$ symbol. Since for $k = 0$ the value of the $6-j$ symbol is independent of F , the monopole term shifts all levels of the hyperfine multiplet equally, independent of the value of F .

The F -dependence of the dipole contribution can be found from the fact that the same $6-j$ symbol would appear for any scalar product of $k = 1$ operators, for example $\mathbf{J} \cdot \mathbf{I}$. But in this product space, with J , I , and F all good quantum numbers, the diagonal matrix elements of $\mathbf{J} \cdot \mathbf{I}$ are just

$$\langle \mathbf{J} \cdot \mathbf{I} \rangle = \frac{1}{2} [F(F+1) - J(J+1) - I(I+1)], \quad (17.9)$$

so that

$$\begin{aligned} \Delta E_1(JIF, JIF) &= \frac{1}{2} A [F(F+1) - J(J+1) - I(I+1)], \quad (17.10) \end{aligned}$$

where, in terms of reduced matrix elements according to the convention of *Brink* and *Satchler* [35, p. 152], (the first version given in Sect. 2.8.4)

$$\begin{aligned} A &= [J(J+1)]^{-1/2} \langle J | \mathbf{T}^1(\mathbf{e}) | J \rangle [I(I+1)]^{-1/2} \\ &\times \langle I | \mathbf{T}^1(\mathbf{N}) | I \rangle. \quad (17.11) \end{aligned}$$

A is the magnetic dipole hyperfine structure constant for the atomic level J and nuclear state I . M1 hfs shows the same pattern of splittings as spin-orbit fine structure, described sometimes as the *Landé interval rule*.

Electric quadrupole hfs is described by the quadrupole hyperfine structure constant B . If we define the quantity $K = [F(F+1) - J(J+1) - I(I+1)]$, then

$$\begin{aligned} \Delta E_2(JIF, JIF) &= \frac{(\frac{1}{4}B)[3K(K+1)/2 - 2J(J+1)I(I+1)]}{J(2J-1)I(2I-1)}. \quad (17.12) \end{aligned}$$

The constant B is related to the tensor operators by

$$\begin{aligned} \frac{1}{4}B &= [J(2J-1)/(J+1)(2J+3)]^{-1/2} \\ &\times \langle J | \mathbf{T}^2(\mathbf{e}) | J \rangle \\ &\times [I(2I-1)/(I+1)(2I+3)]^{-1/2} \\ &\times \langle I | \mathbf{T}^2(\mathbf{N}) | I \rangle. \quad (17.13) \end{aligned}$$

For higher multipoles, see [36].

The multipole expansion is important because it is valid for relativistic as well as nonrelativistic situations, and for nuclear penetration effects (hyperfine anomalies discussed in Sect. 17.3.3) as well as for normal hyperfine structure. Its limitation comes from its nature as a first-order diagonal perturbation. Off-diagonal contributions, even when small, can perturb the pattern, but, more importantly, can lead to misleading values for the A_k coefficients, including the isotope shift.

17.1.3 Intensities

When hyperfine structure is observed as a splitting in an optical transition between different atomic levels, there are relations between the intensities of the components. The general rule for reduced matrix elements of a tensor operator operating in the first part of a coupled space is [35, p. 152]

$$\begin{aligned} \langle JIF | Q^\lambda(\mathbf{e}) | J'IF' \rangle &= (-1)^{\lambda+I+F'+J} (2F'+1)^{1/2} \begin{Bmatrix} F & F' & \lambda \\ J' & J & I \end{Bmatrix} \\ &\times (2J+1)^{1/2} \langle J | Q^\lambda(\mathbf{e}) | J' \rangle. \quad (17.14) \end{aligned}$$

For a dipole transition ($\lambda = 1$) connecting atomic states J and J' , with fixed nuclear spin I , the line strength $S_{FF'}$ of the hyperfine component connecting F and F' is related to the line strength $S_{JJ'}$ by

$$S_{FF'} = (2F+1)(2F'+1) \begin{Bmatrix} F & F' & 1 \\ J' & J & I \end{Bmatrix}^2 S_{JJ'}. \quad (17.15)$$

17.2 Isotope Shifts

Two distinct mechanisms contribute to isotope shifts in atomic energy levels and transition energies. First, there are shifts due to the different mass values of the isotopes; these *mass shifts* can again be separated into two kinds, the normal mass shift and the specific mass shift. Second, there are shifts due to different nuclear charge distributions in different isotopes. Shifts of this sort are called *field shifts*, and can be considered to be the monopole part of the hyperfine interaction.

The usual convention is to describe an isotope shift in a transition as positive when the line frequency is greater for the heavier isotope.

17.2.1 Normal Mass Shift

The *normal mass shift* occurs already for one-electron atoms, where the energy scale in the c.m. frame for the electron–nucleus system is directly proportional to the reduced mass of the system, $\mu = mM/(M + m)$, where m is the mass of the electron and M that of the nucleus. The two natural limits are those of an infinitely heavy nucleus, where $\mu = m$, and positronium, where $\mu = \frac{1}{2}m$. The normal mass shift applies to all levels of all atomic systems. The fractional shift in frequency between isotopes of mass M_H and M_L is given by

$$(v_H - v_L)/v_H = m(M_H - M_L)/M_H(M_L + m), \quad (17.16)$$

or

$$(v_H - v_L)/v_L = m(M_H - M_L)/(M_H + m)M_L. \quad (17.17)$$

The normal mass shift between deuterium and protonic hydrogen is $(v_D - v_H)/v_H = 2.721 \times 10^{-4}$, amounting to 4.15 cm^{-1} (0.179 nm) for Balmer α . It decreases rapidly for heavy elements, with $\Delta v/v \approx (A_H - A_L)/(1823A_H A_L)$, where the A -values are the atomic mass numbers; for the pair $^{208}\text{Pb} - ^{206}\text{Pb}$, $\Delta v/v$ is then 2.56×10^{-8} , corresponding to a wavelength shift of 0.000014 nm for a line at 550 nm .

17.2.2 Specific Mass Shift

When the system has more than two particles the situation is more complicated; in particular, the center of mass of any particular electron and the nucleus is no longer the center of mass of the whole system. When c.m. motion is removed from the Hamiltonian, there remains a set of *mass polarization* terms

$$H_{\text{mp}} = \frac{1}{M} \sum_{j < k} \mathbf{p}_j \cdot \mathbf{p}_k, \quad (17.18)$$

where M is the nuclear mass and \mathbf{p}_j is the momentum of the j th electron. The matrix elements of these terms can be strongly state-dependent, and the difference in their contributions for isotopes of different mass is called the *specific mass shift* (SMS). For a transition $a \rightarrow b$, the lowest-order SMS between isotopes A and A' is

$$\Delta v(a, b; A, A') = K^{a,b}(M_A - M_{A'})/M_A M_{A'}, \quad (17.19)$$

where

$$K^{a,b} = \langle a | \sum_{j < k} \mathbf{p}_j \cdot \mathbf{p}_k | a \rangle - \langle b | \sum_{j < k} \mathbf{p}_j \cdot \mathbf{p}_k | b \rangle. \quad (17.20)$$

It was earlier thought that the SMS, like the normal mass shift, was always very small for heavy atoms, but that has turned out not to be the case.

Since the operator $\mathbf{p}_1 \cdot \mathbf{p}_2$ resembles the product of two dipole transition operators, the matrix elements of H_{mp} vanish between simple product-type wave functions unless allowed by dipole selection rules. For example, in the $1s n\ell$ 1L and 3L states of helium, the only nonvanishing diagonal terms are the $\ell = 1$ exchange terms $\pm \langle 1s(1)np(2) | \mathbf{p}_1 \cdot \mathbf{p}_2 | np(2)1s(1) \rangle$, with $(-)$ for singlet states and $(+)$ for triplet states. The resulting Hughes–Eckart level shift [37] is positive for singlets and negative for triplets. For other states, $\langle H_{\text{mp}} \rangle$ acquires a nonzero value due to electron correlation (configuration mixing) effects, but the resulting level shifts are correspondingly smaller. Detailed tabulations for many states of helium, including second-order corrections, are given by Drake and Yan [38].

For other atoms, the diagonal matrix elements of H_{mp} within a single electron configuration are weighted by the same coefficients as those that weight the Slater exchange integral G^1 . Relativistic corrections have been given by Stone [39, 40]. Bauche and Champeau [18] provide a useful discussion of the SMS, as does King [16].

Among recent results, we mention high-precision experimental work on the difference in the splittings $2^3S_1 - 2^3P_J$ between ^4He and ^3He [41–43], which can be compared with theoretical results [43–45], and an extensive multi-isotope study in Sm II, in which isotope-shift results are used to deduce structure information for a number of levels [46].

17.2.3 Field Shift

The field shift is due to different electric monopole interactions within the nucleus for different nuclei. Since the field shift is state-dependent, it contributes to the isotope shift of electronic transition frequencies. When field shifts occur between different isomeric levels of the same nuclear species, they are called *isomer shifts*.

Following *Seltzer* [47], (see also the summary in *Fricke et al.* [48]), a level shift can be written as

$$\Delta E = -e^2 \int [\rho_N(A) - \rho_N(A')] \times \left[r_N^{-1} \int \rho_e d\tau_e - \int r_e^{-1} \rho_e d\tau_e \right] d\tau_N. \quad (17.21)$$

The electronic factor inside the second bracket can be fitted as an even power series in r_N , starting with r_N^{2j+1} . The result is that the field shift for a transition a is

$$\Delta v(a, AA') = F^a \lambda^{AA'}, \quad (17.22)$$

with

$$\lambda^{AA'} = \delta \langle r^2 \rangle_{AA'} + (C_2/C_1) \delta \langle r^4 \rangle_{AA'} + (C_3/C_1) \delta \langle r^6 \rangle_{AA'} + \dots, \quad (17.23)$$

where $\delta \langle r^k \rangle_{AA'} = \langle r^k \rangle_A - \langle r^k \rangle_{A'}$. The term F^a is an electronic factor proportional to the change in electron density at the nucleus between the initial and final electronic states; in the simplest perturbation approach F^a is equal to $-(4\pi/6)Ze^2\Delta\rho_e(0)$, where $\Delta\rho_e(0)$ is the electron density at the nucleus in the lower atomic state minus that in the upper (see Sect. 91.2). The ratios C_2/C_1 etc., which weight the higher even moments, depend only on Z and not on the particular transition; values are tabulated in [47, 49, 50], as are F -factors for K X-ray transitions. This approach has been generalized and reformulated by *Blundell et al.* [50].

Measurements of isotope shifts of optical lines have long played an important role in the determination of nuclear rms radii. A more comprehensive picture of nuclear charge distributions can be found by combining optical isotope shift results with those for X-ray lines and for transitions in muonic atoms, together with results of elastic electron scattering from nuclei; a compilation of the results of such an analysis is to be found in *Fricke et al.* [48].

17.2.4 Separation of Mass Shift and Field Shift

From the measured isotope shift for a spectral line a between a pair of isotopes A and A' , one can define a *residual isotope shift* by subtracting the normal mass shift. The residual shift is the sum of two terms, each with an electronic factor and a nuclear factor

$$\Delta v_{a,AA'} = K^a(M_A - M_{A'})/M_A M_{A'} + F^a \lambda^{AA'}. \quad (17.24)$$

If the field shift is assumed to be negligible, the electronic factor K^a can be extracted. Similarly, if the SMS is assumed to be negligible, from the ratios $\Delta v(a, A_1 A_2)/\Delta v(a, A_3 A_4)$, ratios of $\lambda(A_1 A_2)/\lambda(A_3 A_4)$ can be obtained, and the ratios

$\Delta v(a, A_1 A_2)/\Delta v(b, A_1 A_2)$ give ratios of the electronic factors F^a/F^b .

If both contributions have to be considered, one can gain information from a *King plot* [16, 51] in which a *modified residual shift* $\Delta v'(a, AA')$ for line a is defined as

$$\Delta v'(a, AA') = \Delta v(a, AA') M_A M_{A'} / (M_A - M_{A'}). \quad (17.25)$$

(Some authors modify the whole shift, without subtracting the normal mass shift; since the isotopic mass dependence is the same for the two mass-shift contributions, the separation proceeds as before, but with an altered definition of the constant K .) For each isotope pair AA' , this defines a point in the King plot whose ordinate is, e.g., $\Delta v'(a, AA')$ and whose abscissa is $\Delta v'(b, AA')$. If the assumed additivity is valid, one finds a linear relationship between the modified shifts for line a and those for another line b according to

$$\Delta v'(a, AA') = (F^a/F^b) \Delta v'(b, AA') + K^a - K^b (F^a/F^b). \quad (17.26)$$

From the slope of the line one has the ratio of F -factors for the two lines, and from the intercept a relation between the K -factors. A sometimes useful variant of the King plot involves choosing a pair of isotopes, say B and B' as a reference pair [16, 48]. A *reduced shift* $\Delta v''(a, AA')$ is then defined as

$$\Delta v''(a, AA') = \frac{\Delta v(a, AA') M_A M_{A'} (M_B - M_{B'})}{(M_A - M_{A'}) M_B M_{B'}}, \quad (17.27)$$

and $\Delta v''(a)$ is plotted versus $\Delta v''(b)$.

It is not in general possible to extract F - and K -values for individual transitions from optical isotope shifts alone, unless one has at least one calculated or otherwise reliably known value. Information about nuclear charge distributions, however, and isotopic changes in them, is available from other sources, including X-ray isotope shifts, muonic X-rays, and elastic electron scattering from nuclei. Calculated electronic factors for K X-ray transitions can be expected to be more reliable than those for optical transitions. The effects of finite nuclear size are much bigger in muonic than electronic atoms, and screening effects much smaller. Combined analyses of all four types of data lead to the best current knowledge of changes in nuclear charge parameters, and thus contribute to knowledge of the electronic factors F^a and K^a for optical transitions [48].

17.3 Hyperfine Structure

We discuss first *normal* hyperfine structure, in which terms coming from penetration of electrons into the nuclear charge and current distributions can be neglected; such contributions, the *anomalous* hyperfine structure, are briefly discussed in Sect. 17.3.3. See also Sect. 22.7.4.

17.3.1 Electric Multipoles

The electric quadrupole tensor operators, when penetration is neglected, are

$$\mathbf{T}^2(N) = \rho_N(\mathbf{r}_N)r_N^2\mathbf{C}^{(2)}, \quad (17.28)$$

where ρ_N is the nuclear charge density, and

$$\mathbf{T}^2(e_i) = -er_i^{-3}\mathbf{C}^{(2)}(i). \quad (17.29)$$

The matrix element of $\mathbf{T}^2(N)$ that occurs in the expansion coefficient A_2 is just $e/2$ times the nuclear quadrupole moment Q :

$$eQ = 2\langle II|\mathbf{T}^2(N)|II\rangle. \quad (17.30)$$

Experimental values of Q are tabulated by *Raghavan* [32] and more recently discussed by *Pyykkö* [52]. The matrix element of $\mathbf{T}^2(e)$, summed over all electrons, also has a simple semiclassical interpretation [7];

$$\begin{aligned} \langle JJ|\mathbf{T}^2(e)|JJ\rangle &= (e/2)q_J \\ &= (1/2)\langle\partial^2V/\partial z^2\rangle_{JJ}, \end{aligned} \quad (17.31)$$

where V is the electrostatic potential at the nucleus due to the electrons. The quadrupole splitting constant can thus be expressed as

$$B = 4A_2 = e^2Qq_J = eQ\langle\partial^2V/\partial z^2\rangle_{JJ}. \quad (17.32)$$

Because the matrix elements of spherical harmonics in $l sj$ -coupled states are independent of l (aside from the parity requirement that $l + l' + k$ be even), the one-electron matrix elements of $\mathbf{T}^2(e)$ are [36]

$$\begin{aligned} \langle l sj|\mathbf{T}^2(e)|l' sj'\rangle \\ = -e\langle l sj|\mathbf{C}^{(2)}|l' sj'\rangle \int r^{-3}(gg' + ff')dr, \end{aligned} \quad (17.33)$$

where g and f are the large and small r -multiplied Dirac radial functions, and the right-hand reduced matrix element is equal to $(-1)^{k-1}C_{\frac{1}{2}0\frac{1}{2}}^{jkj'}$ with $k = 2$ [35, p. 153].

Electric hexadecapole hyperfine structure follows similar rules [36]. While there is considerable indirect evidence that many nuclear states have nonzero E4 moments [53], their effect on hyperfine structure has been identified only occasionally [54, 55].

17.3.2 Magnetic Multipoles

For the magnetic multipole modes, when penetration effects are neglected, and when the the nuclear current is taken to be

a sum of the orbital-current and spin-current contributions of individual nucleons, the nuclear tensor operator can be written as the sum

$$\begin{aligned} \mathbf{T}^k(N) &= (e\hbar/2m_p c) \sum_n [k(2k-1)]^{1/2} r_n^{k-1} \\ &\times \left[2g_{ln}(k+1)^{-1}(\mathbf{C}^{(k-1)}\mathbf{L}_n)^{(k)} \right. \\ &\left. + g_{sn}(\mathbf{C}^{(k-1)}\mathbf{S}_n)^{(k)} \right], \end{aligned} \quad (17.34)$$

where $e\hbar/2m_p c$ is the nuclear magneton, and in the extreme single-nucleon model the orbital g -factors g_{ln} are 1 for protons and 0 for neutrons, while the spin g -factors g_{sn} are 5.585694701(56) for protons and $-3.82608546(90)$ for neutrons. Similarly, for electron i , the atomic Mk operator can be written

$$\mathbf{T}^k(e_i) = ie[(k+1)/k]^{1/2} r_i^{-k-1} (\boldsymbol{\alpha}_i \mathbf{C}_i^{(k)})^{(k)}. \quad (17.35)$$

For the magnetic dipole case, the nuclear operator of Eq. (17.29) becomes

$$\mathbf{T}^1(N) = (e\hbar/2m_p c) \sum_n (g_{ln}\mathbf{L}_n + g_{sn}\mathbf{S}_n). \quad (17.36)$$

The nuclear currents, however, are more complicated in the strongly interacting and relatively dense environment of real nuclear systems; renormalized g -factors can be used to take some such effects into account. For the quenching of spin matrix elements, see *Castel* and *Towner* [56]; for the M1 mode, the effective g -factor is typically in the neighborhood of 0.5 or 0.6 of the free-space value. It is also sometimes useful to consider effective orbital g -factors, but the effective value is smaller, with $g_{\text{eff}}/g_{\text{free}} = 1.05 - 1.1$ [57]. The matrix element of $\mathbf{T}^1(N)$ is the nuclear magnetic dipole moment

$$\mu = \langle II|\mathbf{T}^1(N)|II\rangle. \quad (17.37)$$

Experimental values of μ are tabulated by *Raghavan* [32].

In the semiclassical picture where $\Delta E = -\boldsymbol{\mu} \cdot \mathbf{B}(0)$, the contributions to $\mathbf{B}(0)$ from the orbital and spin magnetism of the i -th electron are

$$\mathbf{B}_l(0) = -2\mu_0 r_i^{-3} \mathbf{l}_i, \quad (17.38)$$

$$\mathbf{B}_s(0) = 2\mu_0 r_i^{-3} (10)^{1/2} [\mathbf{s}_i \mathbf{C}_i^{(2)}]^{(1)}, \quad (17.39)$$

while the *contact* term for s-electrons is

$$\mathbf{B}_c(0) = -(16\pi/3)\mu_0 \rho_i(0) \mathbf{s}. \quad (17.40)$$

The one-electron matrix elements of $\mathbf{T}^1(e)$ are [36]

$$\begin{aligned} \langle l sj|\mathbf{T}^1(e)|l' sj'\rangle &= -e(\kappa + \kappa') \langle l sj|\mathbf{C}^{(1)}|l' sj'\rangle \\ &\times \int r^{-2}(fg' + gf')dr, \end{aligned} \quad (17.41)$$

where for a given combination lsj , $\kappa = (l - j)(2j + 1)$, and l_x is the opposite-parity orbital quantum number of the small Dirac component, $l_x = l + 1$ for $j = l + 1/2$, $l_x = l - 1$ for $j = l - 1/2$. Recent high precision calculations for the hyperfine structure of helium and lithium, including relativistic corrections and second-order effects, have recently been done by *Pachucki* [58, 59].

Magnetic octupole hyperfine structure [60, 61] follows similar rules [36, 62]. Systems studied in recent years include Eu I excited states [63].

17.3.3 Hyperfine Anomalies

When the electron density is nonzero inside the nucleus, the interaction with different kinds of nuclear current density is in general different; there is, for example, a sensitivity to differing radial distributions of spin and orbital currents. The result is that the ratio of A -values for two isotopes is not necessarily the same as the ratio of nuclear g -factors [64]. The anomaly for two nuclear species a and b is characterized by

$${}^a\Delta^b = (A_a/A_b)(g_a/g_b) - 1. \quad (17.42)$$

Δ is seldom larger than a few per cent. The theory for the M1 mode was worked out by *Bohr* and *Weisskopf* [65]; there are relatively recent reviews of theory and experiment [66, 67], and an especially clear exposition of the semiclassical limit [68]. Recent experimental results include transitions in isotopes of La II [69], and the ground state of hydrogenlike thallium [70]. Anomalies are expected to be considerably smaller for the electric mode.

Abstract

The accuracy of oscillator strength and lifetime measurements has improved greatly in the past twenty years. Nevertheless, these high accuracies have been achieved for only a restricted number of lines belonging to a few elements and ionization stages [1]. Large numbers of precision measurements must still be made as improved experimental oscillator strengths are needed, both as tests of theoretical concepts, and for diagnostics and engineering applications.

Keywords

oscillator strength · decay curve · lifetime measurement · pulse electron beam · multiplex detection

18.1 Introduction

A spectral line arising from a radiative transition between atomic states i and k is characterized by its wavelength λ_{ik} , its intensity and its shape. In the limit of free atoms, the in-

tensity per atom is determined by the emission transition rate A_{ik} or absorption oscillator strength f_{ki} , and the shape by the natural width $\Gamma_i = \hbar/\tau_i$, where τ_i is the lifetime of the excited state. While classical spectroscopic methods provide precise wavelength measurements (1 part in 10^8 or better; Chap. 11), it has only recently been possible to measure oscillator strengths and lifetimes to better than a few percent, as discussed in this chapter. Examples of applications which require an accurate knowledge of these quantities are the interpretation of astrophysical data (Chap. 86), atmospheric physics (Chap. 88), combustion, the modeling and diagnosis of thermonuclear plasmas, nonlinear optics (Chap. 76), isotope separation (Chap. 17), and the development of new types of lasers (Chap. 75).

Precision measurements of oscillator strengths and lifetimes also provide stringent tests of atomic structure calculations. These quantities are very sensitive to the wave functions and the approximations used, particularly in cases where electron correlations (Sect. 24.2.1) and relativistic effects (Sect. 23.1) are significant. They provide experimental tests of fundamental theory; for example, of quantum electrodynamic corrections (Chap. 28), and of the nonconservation of parity predicted by the unified electro-weak theory (Sect. 32.1).

In applications where only modest precision is required, semi-empirical parameterizations involving quantum defects, charge screening and polarization allow a few precise measurements to be extrapolated along isoelectronic, homologous, isoionic and Rydberg sequences. Similar methods have been applied to the atomic energy levels themselves (Sect. 11.13). They allow one to produce a very large data base of moderate precision [2].

The spontaneous transition rate A_{ik} (Sect. 11.16.2) is the probability per unit time (s^{-1}) for an atom in any one of the g_i states of the energy level i to make a transition to any of the g_k states of the level k . The lifetime τ_i is then given by $1/\tau_i = \sum_k A_{ik}$. The branching fraction for the k th channel of the decay of level i is defined as $F_B = \tau_i A_{ik}$, and the branching ratio (Sect. 11.17) between two decay channels is

$R_B = A_{ik}/A_{ij}$. Emission and absorption rate constants differ by a factor of λ_{ik}^2 , and the absorption oscillator strength f_{ki} (Sect. 11.17) is defined by

$$g_k f_{ki} = C \lambda_{ik}^2 g_i A_{ik}, \quad (18.1)$$

where $C = (32\pi^3 \alpha a_0^2 \text{Ry})^{-1} = 1.49919 \times 10^{-14} \text{ nm}^{-2} \text{ s}$. Because of this relationship, the words transition rate and oscillator strength will be used almost interchangeably.

18.2 Oscillator Strengths

Oscillator strengths can be determined directly through absolute emission, absorption, or dispersion measurements, or through the combined measurement of branching ratios and lifetimes. Direct measurements compare different transitions at the same time, and require sample equilibrium, a knowledge of the absolute number density, and an absolute intensity measurement. These are in contrast to time-resolved lifetime measurements, which compare relative intensities from the same transition at different times, and require no absolute measurements. However, lifetime measurements yield oscillator strengths directly only in cases where a single decay transition channel exists, such as the lowest excited level in an atom or ion. Thus, combined measurements of lifetimes and branching ratios are often used where high precision values for oscillator strengths are required. Both absorption and dispersion measurements involve the number density of the lower level of the transition, whereas emission measurements involve that of the upper level.

18.2.1 Absorption and Dispersion Measurements

Absorption measurements involve placing a sample of atoms (for example, in a gas cell, an atomic beam, an arc, a shock tube, or within the vapor column in a furnace) between a continuous light source and a spectrometer. For an isolated spectral line, the absorption cross section for a beam of photons of frequency ν passing through the sample is

$$\sigma_{ik}(\nu) = \pi \alpha (\hbar/m) g(\nu) f_{ik}, \quad (18.2)$$

where $g(\nu)$ is the spectral distribution function per unit frequency normalized so that $\int_0^\infty g(\nu) d\nu = 1$. If there are N atoms per unit volume, the absorption coefficient is $k_\nu = N\sigma(\nu)$. The integrated intensity lost after passing through

a distance L of the sample is

$$\begin{aligned} \int_0^\infty \Delta I(\nu) d\nu &= I_0 \int_0^\infty (1 - \exp^{-\sigma_{ik}(\nu)NL}) d\nu \\ &\simeq I_0 \pi \alpha (\hbar/m) NL f_{ik}, \end{aligned} \quad (18.3)$$

where the second line applies if the sample is optically thin. Otherwise, the integral can be calculated directly, if $g(\nu)$ is known, to determine f_{ik} by the curve-of-growth method.

The Furnace Method

High precision absorption measurements have been achieved by *Blackwell* and co-workers [3], who have used the furnace method to study the astrophysically important neutral iron spectrum. These measurements have quoted accuracies of 0.5% on a relative scale, and 2.5% on an absolute scale. This accuracy was obtained through the use of a stable and isothermal furnace, low-noise spectral intensity recording techniques, and two identical high resolution spectrometers for the simultaneous recording of pairs of absorption lines. By selecting successive line pairs of a suitable oscillator strength ratio and adjusting the temperature and vapor pressure in the furnace, a large dynamic range of oscillator strengths could be covered. Recently, corroborative studies of the uncertainties quoted in these measurements have been undertaken, including tests that are coupled to other methods that use combinations of lifetime and branching ratio measurements [3].

The Hook Method

The absorption measurements described above determine the oscillator strength from the line intensity. An alternative absorptive approach is the anomalous dispersion or *hook* method, which determines the oscillator strength from the index of refraction at wavelengths near the edge of an absorption line [1]. The advantages of this method are its large dynamic range, its insensitivity to the line shape, and the fact that it does not saturate. The absorbing gas is placed in one arm of an interferometer and a compensator is placed in the other arm. This leads to the formation of oblique interference fringes with two characteristic hooks symmetric about the center of an absorption line. The oscillator strength is determined by the wavelength separation W between the hooks. Defining $K = \lambda_{ik} N_f$, where N_f is the number of fringes per unit wavelength, then

$$f_{ik} = \frac{\pi K W^2}{\lambda_{ik}^3 \alpha^2 a_0 NL}, \quad (18.4)$$

where a_0 is the Bohr radius.

Synchrotron Radiation

Storage ring synchrotron radiation facilities now provide a source of continuum radiation that can extend the wavelength range of absorption measurements. A technique [4] has been developed and applied that utilizes a hollow cathode discharge as an absorbing sample, synchrotron radiation as a continuum source, and a CCD array for vacuum ultraviolet (VUV) detection. Here relative oscillator strengths were obtained using two separate detection systems. However, VUV calibration standards are presently lacking (Sect. 18.2.4), and will be required to obtain independent tests (Sect. 18.2.3) of sets of branching fractions.

18.2.2 Emission Measurements

Emission methods use, for example, a hollow cathode, wall-stabilized arc, or shock tube to excite the source. Recent developments in the methods of Fourier transform spectrometry (FTS) [5, 6] offer several advantages over grating spectroscopy, as discussed next.

Fourier Transform Spectrometry

As opposed to the dispersive nature of a grating spectrograph, FTS uses interference effects from a Michelson interferometer. All radiation admitted to the spectrometer is thus incident on the detectors at all times, but different wavelengths are distinguished by their spatial modulation frequencies. The interferogram from all sinusoidal signals is sampled at a prescribed interval of path length, and compared with a laser of known frequency following the same optical path. The spectrum is recovered from the interferogram by means of a fast Fourier transform (Sect. 8.1.3). Thus, for an FTS instrument, the spectral range is determined by the sampling step size, whereas the resolution depends on the maximum path difference (this is in contrast to a grating spectrometer where the sampling step determines the resolution, and the scan length determines the spectral range).

The FTS method provides a number of attractive features in precision oscillator strength measurements. The axial symmetry and the replacement of the slit by a larger aperture can provide a throughput that is two orders of magnitude greater than that of a grating instrument of the same resolution. The precision and reproducibility are determined by the laser standard and the linearity of the wavenumber scale. The resolution can be increased as necessary to resolve a specific source line. The superior resolution allows blending and self-absorption to be more readily detected. The spectral range is limited only by detectors and filters. Recently, uv FTS instruments have been constructed that operate from the visible down to 175 nm. Since all wavelengths are observed at all times, errors from drifts in source conditions during scanning are reduced.

Hollow Cathode Lamps

Hollow cathode discharge lamps are used extensively for emission branching fraction measurements [5]. These lamps can generate an emission spectrum of essentially any element, and the relatively low collision rates result in line profiles that are narrow and primarily Doppler broadened. The narrow line width is a major advantage when studying line-rich spectra. The low collision rates also imply that the discharges are far from local thermodynamic equilibrium (LTE). However, this does not affect the determination of branching fractions, where only the relative strengths of lines from a common upper level are measured. These measurements can then be put on an absolute basis if lifetime measurements are available for all of the upper levels.

18.2.3 Combined Absorption, Emission and Lifetime Measurements

By combining measurements obtained in emission with those obtained in absorption (or dispersion) to obtain branching ratios, and then incorporating lifetime measurements, it is possible to use a scheme that requires no knowledge of level populations [1]. The scheme was originally proposed by Ladenburg in 1933, and its various modern implementations are known as *leap-frogging*, *linkage* and *bow ties*.

The principle of *leap-frogging* or *linkage* is illustrated in Fig. 18.1a. The decay of level 1 is unbranched, so the $1 \rightarrow 2$ transition rate is assumed known (kn) from a lifetime measurement. This is used to specify the $2 \rightarrow 3$ oscillator strength using relative absorption (ab) measurements for the $2 \rightarrow 1 : 2 \rightarrow 3$ oscillator strength ratio (and appropriate factors of the wavelengths and degeneracies). In a similar manner, this is subsequently combined with relative emission (em) measurements of the $3 \rightarrow 2 : 3 \rightarrow 4$ branching ratio to determine the $3 \rightarrow 4$ transition rate.

The principle of *bow ties* is illustrated in Fig. 18.1b. The two branching ratios for $1 \rightarrow 2 : 1 \rightarrow 4$ and for $3 \rightarrow 2 : 3 \rightarrow 4$

Fig. 18.1 Illustration of methods for the determination of ratios of oscillator strengths (ab = absorption, em = emission, kn = known)

are measured in emission (em). The two oscillator strength ratios for $2 \rightarrow 1 : 2 \rightarrow 3$ and for $4 \rightarrow 1 : 4 \rightarrow 3$ are measured in absorption (ab). After correction for wavelength and degeneracy factors between f and A values, these relationships are combined into a quantity known as the *bow tie ratio*, which would be unity for ideally accurate measurements. A significant deviation from unity can be used to trace the observations that are in error. Figure 18.1b is a *simple bow tie* connecting two upper and two lower levels with four transitions. Higher order sets of measurements can be similarly coupled; for example, a set of transitions between three lower levels and three upper levels can be coupled by nine simple bow ties.

In cases where both lifetime and complete branching ratio measurements exist for the same upper level, then the branching ratios can be normalized to branching fractions divided by the lifetime to obtain absolute transition probabilities.

18.2.4 Branching Ratios in Highly Ionized Atoms

In highly ionized atoms, many measurements of lifetimes in the 1–5% accuracy range have been made by ANDC (Sect. 18.3.2) analysis of beam–foil measurements. However, little work exists for the precision measurement of branching ratios in highly ionized atoms, where an intensity calibration of the detection equipment is particularly difficult. In beam-foil excitation, for example, Doppler broadening and Doppler shifts, polarization due to anisotropic excitation, and the short wavelength (≤ 200 nm) nature of the radiation are not well-suited for use with standard techniques for calibrating grating spectrometer and detection systems by the use of calibrated lamps. Calibrations have been carried out using synchrotron radiation, or through the use of previously known branching ratios.

One way in which lifetime measurements are used to determine branching ratios involves precision studies of the lifetimes of the individual fine structure components of a multiplet decay. If one fine structure level has a decay channel that is not available to the other levels (for example, a spin-changing transition or an autoionization mode made possible by a J -dependent intermediate coupling) then the transition rate of the extra channel can be determined by differential lifetime measurements.

The use of Si(Li) detectors in the measurement of very short wavelength radiation in highly ionized atoms also offers possibilities for branching ratio measurements. Since these devices can specify the photon energy from pulse height information without the need for a spectrometer, they can be calibrated for detection efficiency as a function of energy. This type of detection was recently used to determine the branching ratio of the magnetic dipole channel to the

two-photon decay channel in the $2s\ 2S_{\frac{1}{2}}$ state in one-electron krypton [7].

Although radiometric calibration standards are available for $\lambda > 280$ nm, technical challenges exist for their extension to shorter wavelengths. The urgent need for these standards and their desired characteristics have been discussed by Lawler et al. [4], and an operational prescription for combining sources of uncertainty in their specification has been presented by Sikström et al. [8]. A semi-empirical method for obtaining line intensity standards in the VUV has also been proposed [9, 10] that uses intermediate coupling (IC) amplitudes deduced from measured energy level data to obtain intensity ratios. This utilizes the observation that the ns^2np^2 and $ns^2np(n+1)s$ configurations in the Si, Ge and Sn isoelectronic sequences exhibit negligible configuration interaction, hence the intensity ratios within their transition arrays are accurately prescribed by the IC amplitudes. For the neutral atoms the transitions occur in the visible region, and measurements confirm the validity of the empirical values. Thus, isoelectronic extensions can yield VUV standards.

18.3 Lifetimes

The total transition rate summed over all decay channels can be measured either through frequency-resolved studies of the level width, or through time-resolved studies of the level lifetime. In order to determine the natural linewidth in a field-free spectroscopic measurement, either the lifetime must be very short, or the Doppler, pressure, and instrumental broadenings must be made very small. Line widths have been determined using Fabry–Perot spectrometry at very low temperatures and pressures, and in beam–foil studies of radiative transitions in which the lower level decays very rapidly via autoionization. The linewidth can also be determined through the use of the phase shift method. Here modulated excitation is applied to the source, thus producing similarly modulated emitted radiation, and the width can be specified from the phase shift between the two signals. Other methods involve resonance fluorescence techniques, where sub-Doppler widths are obtained because the width of the exciting radiation selects a subset of particle motions within the sample. Resonance fluorescence techniques that can be used to determine level widths include zero-field level crossing (the Hanle effect), high-field level crossing, and double optical resonance methods, but the Hanle effect is the most common.

18.3.1 The Hanle Effect

In its most commonly used form, the Hanle effect makes use of polarized resonance radiation to excite atoms in the presence of a known variable magnetic field. The mag-

netic substates of the sample are anisotropically excited, and the subsequent radiation possesses a preferred angular distribution. By applying the magnetic field in a direction perpendicular to the anisotropy, the angular distribution is made to precess, producing oscillations in the radiation observed at a fixed angle. At infinite precessional frequency the intensity would be proportional to the instantaneous average angular intensity, but at finite precessional frequency it depends upon the decay that has occurred during each quarter rotation. Measured as a function of magnetic field, the emitted intensity has a Lorentzian shape centered about zero field with a width that depends on the lifetime and g -factor of the level [2].

18.3.2 Time-Resolved Decay Measurements

The most direct method for the experimental determination of level lifetimes is through the time-resolved measurement of the free decay of the fluorescence radiation following a cutoff of the source of excitation. An important factor limiting the accuracy is the repopulation of the level of interest by cascade transitions from higher-lying levels. For this reason, decay curve measurements fall into two classes: those that involve selective excitation of the level of interest, thus eliminating cascading altogether; and those that use correlations between cascade connected decays to account for the effects of cascades.

Selective Excitation

Lifetime measurements accurate to within a few parts in 10^3 have been obtained through selective excitation produced when appropriately tuned laser light is incident on a gas cell or a thermal beam, or on a fast ion beam (Sect. 19.1). With a gas cell or thermal beam, the timing is obtained by a pulsed laser and delayed coincidence detection. With a fast ion beam, time-of-flight methods are used. In either case, after removal of the background, the decay curve of intensity versus time is a single exponential, and the lifetime is obtained from its semilogarithmic slope. Laser-excited time-of-flight studies were first carried out by observing the optical decay of the ion in flight following excitation using a laser beam which crossed the ion beam. In these studies, the laser light was tuned to the frequency of the desired absorption transition either through the use of a tunable dye laser, or by varying the angle of intersection to exploit the Doppler effect. Recent measurements have utilized diode laser excitation in this geometry [11]. A number of adaptations of this technique have been developed in which the laser and ion beams are made to be collinear, and are switched into and out of resonance within a segment of the beam by use of the Doppler effect [12]. The collinear geometry can provide a longer excitation region and less scattering of laser

Table 18.1 Measured np^2P_J lifetimes

Atom	n	J	τ (ns)
Li	2	1/2	27.20(20) ^a , 27.29(4) ^b
Na	3	1/2	16.38(8) ^c , 16.40(3) ^b , 16.30(2) ^d
	3	3/2	16.36(2) ^c , 16.25(2) ^d
Mg ⁺	3	1/2	3.854(30) ^d
	3	3/2	3.810(40) ^e
Ca ⁺	4	1/2	7.07(7) ^f , 7.098(20) ^g
	4	3/2	6.87(6) ^f , 6.924(19) ^g

Ba ⁺	6	1/2	7.92(8) ^l
	6	3/2	6.312(16) ^m

^a [26], ^b [27], ^c [28], ^d [29], ^e [30], ^f [31], ^g [32], ^h [33], ⁱ [34], ^j [35], ^k [36], ^l [11], ^m [37]

light into the detector than occurs in the crossed beam geometry. In one adaptation [13], excitation occurs within an electrostatic velocity switch, and the time resolution is obtained by physically moving the velocity switch. In another adaptation [12], the ion beam is accelerated with a spatially varying voltage ramp. The resonance region is moved relative to a fixed detector by time-sweeping either the laser tuning or the ramp voltage.

While these selective excitation methods totally eliminate the effects of cascade repopulation, they are generally limited to levels in neutral and singly ionized atoms that can be accessed from the ground state by strongly absorptive E1 transitions, and the selectivity itself is a limitation. Many very precise measurements have been made by these techniques, but they have primarily involved $\Delta n = 0$ resonance transitions in neutral alkali atoms and singly ionized alkali-like ions. A summary of these measurements is given in Table 18.1, and a comparison of these values with theoretical calculations is given in [14].

Advances have recently been made in the measurement of transition probabilities of long-lived metastable levels. Through a laser probing technique [15] using an ion storage ring, an extremely long lifetime (28 s) has been measured [16]. The metastable level is populated in the ion source and preserved in the storage ring until it is destructively probed at variable times after excitation. The laser light is collinearly merged with the beam and tuned to a transition that promotes the population of the metastable level to a higher unstable level. The fluorescence subsequently emitted by this unstable level gives a relative measure of the population of the metastable level. Thus, by varying the de-

lay time between the excitation and the laser probing, a decay curve of the population remaining is obtained.

Nonselective Excitation

Much more general access can be obtained by nonselective excitation methods, such as pulsed electron beam bombardment of a gas cell or gas jet, or in-flight excitation of a fast ion beam by a thin foil. Pulsed electron beam excitation can be achieved either through use of a suppressor grid, or by repetitive high frequency deflection of the beam across a slit so as to chop the beam. Particularly in the case of weak lines, the high frequency deflection technique offers the advantages of high current and sharp cutoff times. The high currents yield high light levels, so that high resolution spectroscopic methods can be used to eliminate the effects of line blending. Pulsed electron excitation methods are well suited to measurements in neutral and near neutral ions (although for very long lifetimes in ionized species, the decay curves can be distorted if particles escape from the viewing volume through the Coulomb explosion effect [17]). However, for highly ionized atoms, the only generally applicable method is thin foil excitation of a fast ion beam. Nonselective excitation techniques can also be applied to measurements such as the phase shift method [18] and the Hanle effect [19], in which case cascade repopulation also can become a serious problem. However, most of the attempts to eliminate or account for cascade effects have occurred in decay curve studies.

In beam-foil studies, the excitation is created in the dense solid environment of the foil, after which the ions emerge into a field free, collision free, high vacuum region downstream from the foil. A time-resolved decay curve is obtained by translating the foil upstream or downstream relative to the detection apparatus. The beam is a very tenuous plasma, which has both advantages and disadvantages. The low density avoids the effects of collisional de-excitation and radiation trapping, but also produces relatively low light levels. This requires fast optical systems with a corresponding reduction in wavelength dispersion, and care must be taken to avoid blending of these Doppler broadened lines. Methods have been developed by which grating monochromators can be refocused to a moving light source, thus utilizing the angular dependence of the Doppler effect to narrow and enhance the lines.

In these nonselective excitation methods, the decay curve involves a sum of many exponentials, one corresponding to the primary level, and one to each level that cascades (either directly or indirectly) into it. Decay exponentials do not comprise an orthogonal set of functions, and the representation of an infinite sum by a finite sum through curve fitting methods (Sect. 8.1.2) can lead to large errors. Fortunately, alternative methods to exponential curve fitting exist, which permit the accurate extraction of lifetimes to be made from correlated sets of nonselectively populated decay curves.

ANDC Method

Precision lifetime values have been extracted from cascade-affected decay curves by a technique known as the arbitrarily normalized decay curve (ANDC) method (Sect. 19.1.1, [20]), which exploits dynamical correlations among the cascade-related decay curves. These correlations arise from the rate equation that connects the population of a given level to those of the levels that cascade directly into it. The instantaneous population of each level n is, to within constant factors ξ_n involving the transition probabilities and detection efficiencies, proportional to the intensity of radiation $I_n(t)$ emitted in any convenient decay branch. In terms of these intensities, the population equation for the level n can be written in terms of its direct cascades from levels i as

$$\frac{dI_n}{dt}(t_p) = \sum_i \xi_i I_i(t_p) - I_n(t_p)/\tau_n. \quad (18.5)$$

Thus, if all decay curves are measured at the same discrete intervals of time t_p , the population equation provides a separate independent linear relationship among these measured decay curves for each value of t_p , with common constant coefficients given by the lifetime τ_n and the normalization parameters ξ_i . Although the sum over cascades is formally unbounded, the dominant effects of cascading from highly excited states are often accounted for by indirect cascading through the lower states, in which case the sum can be truncated after only a few terms. ANDC analysis consists of using this equation to relate the measured $I_k(t_p)$ (using numerical differentiation or integration) to determine τ_k and the ξ_i through a linear regression. If all significant direct cascades have been included, the goodness-of-fit will be uniform for all time subregions, indicating reliability. If important cascades have been omitted or blends are present, the fit will vary over time subregions, indicating a failure of the analysis. Very rugged algorithms have been developed [21] that permit accurate lifetimes to be extracted even in cases where statistical fluctuations are substantial, and studies of the propagation and correlation of errors have been made. Clearly the ANDC method is most easily applied to systems for which repopulation effects are dominated by a small number of cascade channels. Further applications are discussed in Sect. 19.1.1.

18.3.3 Other Methods

Coincidence measurements provide another method for elimination of cascade effects. While the low count rates and correspondingly high accidental rates make the application of these methods difficult for optical spectra, the use of Si(Li) detectors for the very short wavelength emission in very highly ionized systems offers new possibilities [22] for these measurements.

Another method of accounting for cascading involves the combined use of a laser and beam–foil excitation [23, 24]. The beam–foil excitation provides a source of ions in excited states, and a chopped laser is used to stimulate transitions between two excited states. By subtracting the decay curves obtained with laser on and with laser off, the cascade-free, laser-produced portion of the decay curve is obtained.

18.3.4 Multiplexed Detection

Recently, the detection efficiency and reliability of beam–foil measurements have been improved through the use of position sensitive detectors (PSD), which permits measurement of decay curves as a function both of wavelength and of time since excitation. The PSD is mounted at the exit focus of the analyzing monochromator, where it records all lines within a given wavelength interval simultaneously, including reference lines with the same Doppler shifts. Decay curves can be constructed by integrating over a line profile, and that profile can be examined for exponential content to eliminate blending. The time dependent backgrounds underlying the decay curves are directly available from the neighboring channels.

The use of multiplexed detection greatly enhances the data collection efficiency, and causes many possible systematic errors to cancel in differential measurements. Effects such as fluctuations in the beam current, degradation of the foil, divergence of the beam, etc., affect all decay curves in the same way.

The most accurate measurement [25] made by beam–foil excitation ($\pm 0.26\%$) used a type of multiplexed detection in which two spectrometers simultaneously viewed the decays of the 1P_1 and 3P_1 levels of the $1s3p$ configuration in neutral helium. The 1P_1 emission exhibited the desired multi-exponential decay curve (with only weak cascading), whereas the 3P_1 emission exhibited a zero field quantum beat pattern superimposed on its decay because of the anisotropic excitation of that level. The quantum beats provided an in-beam time base calibration which permitted this high precision.

Abstract

A knowledge of the spectra of ionized atoms is of importance in many fields. A wide variety of light sources are available for the study of such spectra. In recent years, techniques coming under the broad headings of fast ion beams and ion traps have been used extensively for such studies. This chapter will consider the advantages each technique has for particular applications.

19.1 Spectroscopy Using Fast Ion Beams

A beam of ionized atoms has several advantages as a spectroscopic source. Unlike arcs, sparks, and high-temperature plasmas, the ions can be studied in an environment that is free of electric and magnetic fields and relatively free of interparticle collisions [1]. Standard accelerator techniques can be used to produce a well-collimated, mass-analyzed beam of ions having a low velocity spread. In principle, virtually any charge state of any element, isotopically pure if required, can be obtained. Finally, the well-defined velocity of the ions permits the study of processes evolving in time in terms of their spatial evolution along the beam. This is particularly important in the case of lifetime measurements.

19.1.1 Beam–Foil Spectroscopy

A beam of ions passing through a thin (50–200 nm) foil emerges in a range of ionization states, with the mean charge state increasing with the incident energy [2]. Thin foils made from a light element, usually carbon, are used to minimize particle scattering and energy straggling. Thus, a F^+ beam of 0.5 MeV that enters a carbon foil emerges with a mean charge of about $+2e$, while a Xe ion beam at 180 MeV emerges with a mean charge of about $+29e$ and a charge state distribution that may be some five to ten units wide. Inside the foil, the swift ions encounter a high (solid-state) electron density, frequent collisions, electron loss, and likely excitation to core and multiply excited levels. Upon leaving the foil, excitation stops, and the ions travel on in a low-electron density vacuum, while the remaining or recaptured electrons decay to lower states by electron or photon emission.

The beam–foil interaction is a highly nonselective excitation process, which is an advantage for spectroscopic studies but causes a problem of complexity for lifetime measurements. (Methods for tackling this problem are discussed

in Sect. 18.3.2.) A major disadvantage of the beam–foil light source is its low intensity; consequently, spectrometers equipped with position sensitive detectors, which permit the simultaneous recording of information over a certain spectral range, offer a greatly improved detection efficiency (Sects. 46.3, 46.4) compared to the earlier scanning monochromators.

The probability that more than one electron in a given ion will be collisionally excited or be captured in an excited state is high relative to other light sources, and hence the technique has been used extensively to study doubly and multiply excited states [3] (Sect. 68.1). The interaction also favors the production of high- L Rydberg states [4] (Chap. 15). At low incident ion energies, electron capture can give a downstream beam containing neutral and even negative ions. The first observation of photon emission between bound states in a negative ion was achieved using beam–foil excitation [5]. A more recent example of multiple excitation in a negative ion is the identification in lithium-like He^- of the $2p^3\ ^4S^o$ state in which all three electrons are excited [6, 7]. The observation of the same triply excited level in neutral Li has resulted in one of the most precise (40 ppm) wavelength measurements in beam–foil spectroscopy [8]. Multiple excitation of few-electron systems has since found new interest in X-ray laser experiments targeting atoms or small clusters.

An ion beam of reduced energy 0.5 MeV/amu travels at a speed of about 3% of the speed of light or about 1 cm/ns. The time resolution inherent in the geometry of the beam–foil source can also be used to aid in the identification of transitions from long-lived states, such as intercombination transitions [9] (Sect. 11.16). Here, the beam–foil spectrum is first recorded close to the foil and then far downstream (a few mm to a few cm); *far* in this context means that the short-lived states have had time to decay. The intercombination (or other long-lived) transitions are then easily identified by their relatively strong intensity in the (overall much weaker) downstream spectrum. This has been a decisive step in identifying laboratory lines with lines in the solar corona [10, 11]. A recent example of beam–foil spectroscopic analysis is given in [12].

One problem with using fast ions as a light source for precision wavelength measurements is the inevitable Doppler shift and broadening of the spectral lines. However, the latter can be largely removed by appropriately refocusing some spectrometers [13, 14]. Furthermore, since the Doppler width varies with the wavelength, and the linewidth of a given grating spectrometer used on a fast ion beam is usually dominated by spectrometer geometry, not by diffraction, Doppler broadening often becomes less important in measurements at shorter wavelengths, as in the UV or EUV. This is the primary range of emission from the more highly ionized atoms, and that is where beam–foil spectroscopy really comes into its own. For example, the leading terms omitted in calculations of the wavelengths of the $1s2s^3S - 1s2p\ ^3P^o$

transitions in He-like ions [15] scale as Z^4 . Hence, measurements made with higher- Z ions need not have as high a precision for a meaningful test of the calculation as would be required for a low- Z ion. The beam–foil measurement for the leading ($J = 1$ to $J = 2$) component in Ni^{26+} [16] has an uncertainty of 0.02%, which is about equal to that in the calculation. The two values agree well within this limit. (Naturally, measurements taken using the beam–laser techniques discussed in Sect. 19.1.3 yield results with a much higher precision, but such measurements are restricted to low- Z ions because of the excitation energy steps and transition wavelengths involved; the theoretical uncertainties in this case are also much smaller. An exception are hyperfine studies at high nuclear charge, see Sect. 19.2.)

In beam–foil lifetime measurements, the intensity of a given transition is studied as a function of the time that has elapsed since excitation, usually by stepping the foil upstream. Because of the nonselective nature of the excitation, the decay curve of a given atomic level of interest usually consists of a sum of exponential terms, one term corresponding to the primary level being studied and the other terms to higher-lying levels involved in repopulating that level. The analysis of such decay curves can be problematic. Several computer routines have been developed to tackle this problem, such as DISCRETE [17] and HOMER [18]. One useful trick here is to record the decay curve for each of the major transitions repopulating a given primary level and then include the lifetimes obtained for those transitions as fixed parameters in fitting the decay curves for that primary level. A more rigorous method to include the decay data from the repopulating transitions in the analysis of the primary lifetime is the ANDC (arbitrarily normalized decay curves) technique described in detail in Sect. 18.3.2. Whether the atomic lifetime measurement proceeds by such cascade measurements or is analyzed by cascade modeling, it is essential to understand the complexity of the individual decay scheme to obtain a reliable result and error estimate.

An additional problem may arise in the measurement of very short lifetimes, which tend to be associated with short-wavelength transitions for which no lenses are available to focus the beam at the spectrometer entrance slit. The observation region is then defined by the spectrometer aperture and extends for a finite length along the beam that can be comparable to, or even greater than, the decay length for that transition. Here, it is necessary to fit the decay curve including the vignettted region around the foil [19, 20]. Lifetimes in the picosecond regime have been successfully measured in this way.

19.1.2 Beam–Gas Spectroscopy

While the use of a gas target in place of a foil has the obvious advantage that it cannot break, the loss of a tightly

localized excitation region means that the fine time resolution of the beam–foil light source is largely lost. The beam–gas source, however, has two main advantages. First, the passage of a beam of fast, highly stripped ions through a neutral gas results in the production of recoil ions from the target gas (Sect. 69.2). If produced by collisions at large impact parameters, such recoil ions move very slowly relative to the beam ions, thus reducing the Doppler broadening problem mentioned earlier. Second, it is possible to study the details of the interaction between the gas and beam ions, such as charge-exchange (CX) reactions, as they occur, rather than merely observing their consequences. Such experiments have experienced a resurgence with the advent of the ECR ion source [21, 22]. A recent example of such work is given in [23].

The low recoil ion velocities largely point at right angles away from the primary ion beam trajectory, and by exploiting geometry, the Doppler effect in the observation may be reduced to the limit imposed by the thermal motion of the target gas atoms. Recoil ion spectroscopy is, therefore, a useful procedure for precision wavelength measurements for highly stripped ions, such as He-like Ar¹⁶⁺ recoil ions produced by a beam of 2 GeV U⁷⁰⁺ ions [24]. The energies and charge states of the recoil ions may be determined using standard time-of-flight techniques [25], and detecting the recoil ions in coincidence with their progenitor ions yields information on the dependence of the recoil energy on the details of the ionizing collision [26]. In later developments, the differentially pumped gas target has first been replaced by a supersonic jet target which reduces the thermal motion of the target particles, and then by a cold atom sample in an atom trap; replacing optical detection by position-sensitive fast-timing detectors for all collision products, the technique of COLTRIMS (cold target recoil ion momentum spectroscopy) can now be employed to study the momentum distribution of the collision partners (developed largely by the groups of H. Schmidt-Böcking (Frankfurt) and C. L. Cocke (Manhattan, Kansas)). Similar detection techniques have recently been applied to atomic targets under high-power short-pulse laser impact.

Measurements made on the projectile ions themselves also yield useful information about electron-capture processes. The strength of such a process is described in terms of its cross section (Sect. 67.1.2). Recent work has shifted from measurements of the total cross section for electron capture to more detailed studies of the individual capture channels [27]. Such studies provide much more stringent tests of theoretical models of ion–atom charge transfer processes. They often involve such techniques as spectroscopy of the optical radiation or of the Auger electrons (Sect. 26.1.1) emitted by the ions after electron exchange. This topic is covered in Chaps. 55, 68, and 69. A further example is the study by *Prior et al.* [28] of the angular distribution of

Auger electrons emitted by doubly excited states formed in hydrogen-like projectile ions with an energy of 40 keV, following double-electron capture from target helium atoms. They found that significant alignment of the magnetic substates of the projectile ions can result from electron capture. Such anisotropies in the Auger electron emission demonstrate the danger of using single-angle measurements to determine cross sections.

19.1.3 Beam–Laser Spectroscopy

As for the beam–foil source, excitation of a beam of fast ions by a transverse tuneable laser produces the localized excitation required for high temporal resolution. Now, however, the excitation is highly selective, permitting the population of just a single level. The laser-induced-fluorescence (LIF) signal as a function of the distance along the beam from the excitation region is, therefore, described by a single exponential decay, for which an exact analysis with rigorous error bounds is possible. The restriction to levels that can be accessed by electric dipole (E1) transitions from the ground, and metastable levels may be overcome by combining laser excitation with a nonselective mode of excitation, as in beam–gas–laser [29, 30] or beam–foil–laser [31] measurements. A discussion of precision lifetime measurements using laser excitation of a fast beam is given in Sect. 18.3.2. Here, the discussion will be limited to precision optical spectroscopy. Examples of precision beam–laser wavelength measurements may be found in [32, 33]. A further example is the measurement of the spin-forbidden $1s2s\ ^1S_0$ – $1s2p\ ^3P_1$ interval in N⁵⁺ [34], where the experimental value, 986.321(7) cm^{−1} is in agreement with the calculated value, 986.58(30) cm^{−1} [34]. An example of a similar measurement in a molecular ion is given in [35], while a recent study of the hyperfine structure in a rare-earth ion is given in [36].

A major aim in beam–laser spectroscopy is to minimize the width of the LIF signal. The instrumental linewidth of the laser itself can be reduced to below 1 kHz, so that the width of the LIF signal is usually dominated by the velocity spread of the ions and by the divergences of the ion and laser beams. The effects of beam divergence can be minimized by using a collinear geometry, in which the ion and laser beams are parallel. If the angle between the ion and laser beams is θ , the Doppler-shifted laser frequency, as measured in the ion's rest frame, is $f_L(1 - \beta \cos \theta)$, where f_L is the laser frequency, and $\beta = v/c$ and is much less than unity. Hence, the range in frequency resulting from a beam divergence $\Delta\theta$ is given by $f_L\beta \sin \theta \Delta\theta$, which tends to zero as θ tends to zero. One disadvantage of the collinear geometry is that, if the laser is brought into resonance with an atomic transition by adjusting the ion velocity and/or the laser frequency, the LIF signal

is produced over the entire overlap region between the ion and laser beams. The resonance can be restricted to a desired region by setting the ion velocity to be slightly off resonance. The velocity can then be adjusted locally for resonance with the laser by passing the ion beam through a Faraday cage electrode to which an adjustable voltage is applied [37, 38]. Here, the width of the resonance signal is usually dominated by the spread in the ion velocity, $c \Delta\beta$, usually arising in the ion source being used. The width resulting from a given $\Delta\beta$ can, therefore, be reduced by using a higher ion velocity. This is known as kinematic compression. In terms of the ion energy E , the range in the ion energy ΔE , and the ion mass M , the Doppler width of the LIF signal is given by $f_L \Delta E / (2Mc^2 E)^{1/2}$, and, thus, decreases as E is increased.

A more significant improvement in frequency resolution is made possible by including rf resonance in a laser double-resonance experiment. Here, the ions are brought into resonance with an off-resonance laser using two separate Faraday cage electrodes. The first resonance depletes the population in the ion state from which excitation occurs, thus weakening the second resonance signal. An rf field is then applied to the ions between the two electrodes. Tuning the frequency of this field over the region that corresponds to fine or hyperfine-structure intervals in the ion can then repopulate the state from which laser excitation occurs, thus reestablishing the second laser LIF resonance signal. The width of the resonance signal is now determined by the *transit-time broadening* that results from the finite time spent by the ions in the rf field. For example, in the experiments by Sen et al. [38] with a beam of $^{131}\text{Eu}^+$ ions at 1.35 keV, the width of the laser-rf double-resonance signal was 59 kHz, compared with a width of 45 MHz obtained using a single LIF resonance.

19.1.4 Other Techniques of Ion-Beam Spectroscopy

Ion beams find uses in many other applications, three of the main areas involving storage rings (discussed in Sect. 19.2.2), merged beams, and studies of the ion-surface interaction at grazing incidence. Merged beam experiments usually study recombination processes involving electrons and atomic or molecular ions (Sect. 58.1 regarding recombination processes). The advantage of using merged beams is that the time development of the processes may be studied spatially, while maintaining a low relative velocity between the ions and the electrons. This permits measurements at the low energies of importance in studies of Rydberg state formation and in some astrophysical applications. A very different type of experiment studies the ion-surface interaction using a well-collimated ion beam at grazing incidence on a clean, flat surface. Such experiments have revealed very

large atomic orientations [39]. This orientation can be passed on to the nuclei of the atoms via the hyperfine interaction, thus providing a source of oriented nuclei.

19.2 Spectroscopy Using Ion Traps

A basic purpose of ion traps is to confine ions to the field of view of detectors for time intervals that are much longer than the radiative lifetimes of long-lived atomic levels of possible interest. At thermal energies, the ion velocities are large enough to leave a typical detection zone within microseconds. Electrostatic (Kingdon), magnetic (Penning), and radiofrequency (Paul) traps have served for this task for decades (Chap. 79), with recent additions to the armory by electrostatic mirrors of various shapes [40, 41]. Two trap varieties of particular interest for spectroscopy, the electron beam ion trap and the heavy-ion storage ring, will be treated in Sects. 19.2.1 and 19.2.2, respectively.

Collisions with the neutral atoms and molecules of the residual gas cause charge exchange, and thus loss of the ion species. Therefore, an ultrahigh vacuum is of primary importance. Over the last four decades the figure of merit has moved from pressures of about 10^{-8} mbar to about 10^{-11} mbar. Further improvements can be expected from working with traps at liquid helium temperature; in fact, even ion traps as large as an ion storage ring at Aarhus (Sect. 19.2.1) have been cooled considerably to vary both the vacuum and the amount of blackbody radiation experienced by ions in weakly bound states. The new cryogenic storage ring CSR in Heidelberg has been designed for operation at a temperature of 10 K and lower, mainly in order to improve the vacuum to about 10^{-14} mbar for the benefit of longer storage times also for low-energy ions, as they dominate the interstellar medium.

The energy steps in multiply charged ions are regularly larger than what is available from lasers, at least for excitation from the ground state. Hence, single-ion trapping and laser spectroscopic investigation are rarely an option for these ions; many ions are needed to provide a sufficiently strong emission signal. The production of quantities of multiply charged ions used to be achieved by electron bombardment of a dilute gas inside the trap volume or by ablation from a surface. Evidently, this is detrimental to any subsequent measurements, since the residual gas is still present. Precision work like mass spectrometry that exploits the ion cyclotron motion of stored ions or detailed studies of the radiative processes (including the effects of the interrogating laser field) in ions nowadays employ a sequence of ion traps. In a first trap, the ions of interest are produced and possibly cooled by laser light or other mechanisms, and then, by applying electric fields, the ions of interest are moved to a second trap that works under better vacuum conditions or

that can be more finely tuned. In the same sense, a heavy-ion storage ring is usually being fed by an isotopically pure, charge-state selected ion beam. Any loss of ions, measured by whatever means, is thus hoped to be strictly proportional to the loss of the ion species of primary interest.

19.2.1 Electron Beam Ion Traps

Electron beam ion traps (EBIT) make use of the attractive potential of a high-density electron beam, as well as of the space charge compensation that is provided by the electron beam to any ion cloud already trapped. Most electron beam ion traps generate the high-current density electron beam by feeding the beam from an electron gun into a magnetic field that then compresses and guides the beam. In most cases, superconducting magnets with fields of 3 to 8 T are used, and current densities of the order of 10^4 A/cm² are reached. This high current density corresponds to an electron density of the order of 10^{11} /cm³. In the face of the high cost of liquid helium, a number of newer electron beam ion traps use high-temperature superconducting magnet coils or even permanent magnets. These devices are limited to lower magnetic field strengths and forfeit the ultimate benefit of deep cryocooling for extremely high vacuum; thus, they do not reach quite as high in maximum ion charge state. The low-density environment, roughly comparable to tokamak discharges, is one of the factors that renders the electron beam ion trap a very interesting device for laboratory astrophysics. The magnetic field helps to confine any ion cloud that is produced from the residual gas (or gas bled in) or from injected low charge ions. However, the ions could move away along the magnetic field lines, if they were not stopped by potential barriers provided by electrically charged drift tubes. Obviously, the basic design is the same as that of a Penning trap, with the permanent electron beam added. In fact, EBIT with the electron beam on has been said to operate in electronic trapping mode [42]; while the same device with the electron beam off (*magnetic trapping mode*) still works as a Penning trap. This option of producing an ion cloud with intense electron bombardment and then studying the ions without the electron beam present is the basis for a variety of experiments on charge exchange (CX) reactions and long-lived excited levels [43] (see below).

The first working electron beam ion trap, EBIT-I, has been set up at Livermore [44, 45]. The successful operation instigated an upgrade to SuperEBIT, the first such machine able to completely ionize all naturally occurring elements [46]. The EBIT operating principles have, for example, been described by *Currell* [47]. Based mostly on the Livermore design, more than a dozen high-charge state ion EBITs are now either running or under construction around the world, complemented by about as many of the low-charge state variety.

Ionization of ions trapped in the combination of electrical fields proceeds as long as the electron beam energy is high enough to overcome the ionization potential. Thus, the highest charge state can be preselected by the appropriate choice of the electron beam energy. The technical effort required to reach, for example, bare uranium in SuperEBIT is much smaller than in an ion accelerator. In both cases, the ionization is achieved by frequent energetic collisions of ions with electrons. In SuperEBIT, the ions are (practically) stationary, and the design energy of SuperEBIT, 250 keV, has been shown to be sufficient to remove even the last electron of uranium (or all but two from californium). At a heavy-ion accelerator, in contrast, the electrons are stationary (in a foil target), and the ions are fast. Consequently, an ion energy per nucleon that is higher by the proton/electron mass ratio is required—some 500 MeV/amu. Such energetic ion beams are only available in a few large accelerator laboratories, whereas an electron beam ion trap with its auxiliary equipment fits into an office-sized laboratory space. Of course, there are experiments that need the specific properties of either fast ion beams or stationary ions, so both types of devices have their specific merit.

The ions in an EBIT are not only stationary in the sense that they are localized in a cloud, and their motion constrained by the magnetic field. Moreover, their energy (temperature) can also be controlled by the height of the potential barriers. The voltages on the confining drift tubes are usually chosen to be few hundred volts. This makes for barrier potentials $+qeU$ (charge state q , elementary charge e , voltage U) that are higher for highly charged ions than for low-charge state ions. This benefits the confinement of highly charged ions both directly and indirectly; while light ions (residual gas or purposely bled in gases) may become fully ionized by the collisions with the electron beam and by charge exchange (which deepens the trap they experience), they still have a higher chance than heavier ions to evaporate from the trap and, thus, they cool the remaining ion cloud. Under typical conditions, the ion cloud may have a temperature of a few keV. This can be lowered by introducing a cooling gas and by lowering the potential barriers. With Cs⁴⁵⁺ in the trap, this has been demonstrated by reducing the (thermal) Doppler spread of X-ray emission lines until it was smaller than the natural linewidth of the emitter, thus yielding a measurement of femtosecond-level lifetimes from the line broadening seen in highly resolved X-ray spectra [48].

Another group of femtosecond lifetime levels are the $2s^2 2p^5 3d$ levels in the Ne-like ion Fe¹⁶⁺. The decays show up in the EUV spectra of terrestrial and astrophysical plasmas, and the line ratios persistently deviate from theoretical prediction. This has led to various hypotheses about distortions caused in the astrophysical environment. However, Livermore EBIT data have long since agreed with the astrophysical observations, practically invalidating the

speculations about environmental influences. However, the cleanest experiment on this problem so far used a classical fundamental atomic physics scheme. An ion cloud in the Heidelberg-built FLASH-EBIT was prepared to hold Fe^{16+} ions as the highest charge state, and the cloud was irradiated by light from the LCLS X-ray laser, scanning the wavelength across the photoexcitation resonance (near 800 eV photon energy). In order to extract the resonance fluorescence signal from the various noise contributions, the signal was gated to the subpicosecond pulse length of the X-ray laser, following the example of the first such experiment at the (EUV) FLASH facility [49]. (A control measurement lowered the electron beam energy in the ion trap so that no Fe^{16+} ions were produced.) The experiment confirmed the discrepancy between experimental and theoretically computed line ratios [50].

The other good atomic level lifetime measurement range of an EBIT reaches from a few microseconds (limited by practical switching issues) to many milliseconds. Under direct optical (X-ray, EUV, visible) observation of a spectral feature, the electron beam is used to produce an ion cloud with ions of a desired charge state. When the electron beam is stopped, all direct excitation and prompt emission ceases. Any later photon signal relates to delayed emission from long-lived levels or from excitation by charge transfer collisions (highly charged ions capturing electrons from the residual gas atoms). Charge exchange (CX) is an important ion loss mechanism, and the CX signal also serves as a monitor of the number of ions remaining in the trap. However, the CX can proceed via any of many intermediate levels, each of which provides only a weak signal, so that a wide-band photon detector is required for collecting sufficient statistics. Owing to the excellent vacuum in cryogenic EBITs, trapping times of many seconds, if not minutes, have been observed [43]. The ion loss rate is the major correction to the apparent decay time of the delayed photon signal. For atomic level lifetimes of a few milliseconds and less, this correction is small (a few percent or less). EBIT lifetime measurements that take this correction into account yield results that agree with those from heavy-ion storage rings [51] and that are, at uncertainties of 0.5% and less, remarkably consistent with theory in a case for which the theory can do very well (Fig. 19.1). This observation can be turned around and interpreted as a demonstration of the reliability of the experimental techniques that can then be applied to more complex cases in which theory evidently has problems (for examples, see [52–57]).

An example is the electric-dipole (E1) forbidden decays in the ground configuration of multielectron ions. The various levels of the ground configuration are easily excited in many plasmas, and the relative level population can serve for density diagnostics if the collision rate is comparable to or lower than the radiative decay rate by, for example, mag-

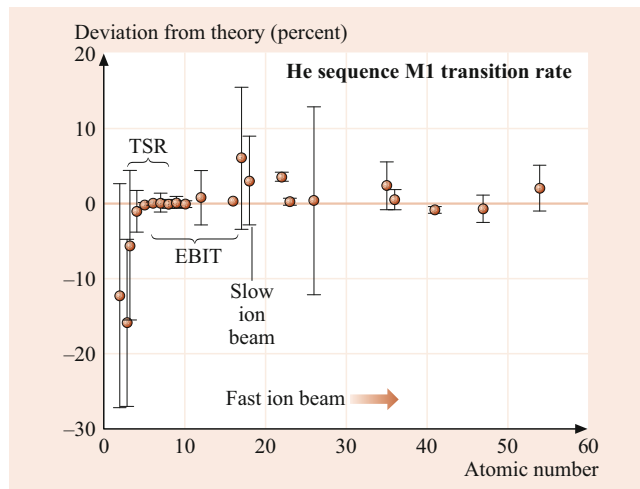

Fig. 19.1 The lifetime of the $1s2s\ ^3S_1$ level in the He isoelectronic sequence varies by 15 orders of magnitude from He (about 6000 s) to Xe^{52+} (a few picoseconds). The deviation of selected experimental results from calculations is shown, and the dominant experimental techniques for the various lifetime ranges indicated. The consistency of experimental results from a heavy-ion storage ring (TSR Heidelberg) and an electron beam ion trap (Livermore EBIT-II) with theory in the range up to $Z = 16$ is impressive (after [52], updated)

netic dipole (M1) transition. These transitions give rise to the coronal lines first seen in the solar corona during eclipses. Theoretically, the M1 transition rate is strictly proportional to a geometry factor (a matrix element derived by Racah algebra) and to the third power of the transition energy. Interestingly, there is a relatively large QED correction of 0.45% to this transition rate that is associated with the electron anomalous magnetic moment (EAMM). A radiative lifetime measurement of an accuracy better than 0.45% would thus be capable to test QED in a special case. Few atomic lifetime measurements (at a heavy-ion storage ring or EBIT) have returned such accurate results yet, and only one of these has concerned an M1 transition [54, 55]. Although the transition of interest in this case occurs in the simplest atomic system with such M1 transitions, the ground state of a boron-like ion, the calculated transition rates available in the literature scatter by much more than the assumed QED correction. In fact, at present, most of the predictions lie closer to the experimental finding without the QED correction. Consequently, although experimental data are available, this test of QED has to be postponed until classical quantum mechanics can treat such a few-electron atomic system with sufficiently high accuracy. Incidentally, the famous corona lines in astrophysics are not very well known in wavelength, probably because the astrophysical source (the solar corona) is easily visible only during eclipses and not very brightly, and because most laboratory light sources have too high a density to produce these E1-forbidden lines, which are easily outshone by the much brighter E1 transitions. Low-density EBIT to the rescue: the E1-forbidden lines have been used

to demonstrate the capabilities of optical spectroscopy at the Heidelberg EBIT [58] and also the feasibility of laser excitation of trapped ions [59]. The optical resolving power is so high that the Zeeman splitting in the 6 T field of the Heidelberg EBIT dominates the line profile.

An EBIT is an excellent light source for precision spectroscopy of highly charged ions because it not only gives access to all charge states of all elements but does so at low particle densities, at a relatively low source temperature (Doppler spread), and without any notable need for a Doppler correction of the wavelength scale (as with fast ion beams or rapidly expanding plasma plumes or solar ejections). Of particular interest to precision spectroscopy have been the ions with a single valence electron (Li, Na, Cu isoelectronic sequences) that are rather amenable to calculation. Such spectra of ions up to $Z = 60$ or 70 have been measured at low-density plasmas like the tokamak, and they have been found to agree well with theory. Higher charge states were then reached in laser-produced plasmas (Sect. 46.1.2), but the wavelength results seemed to deviate from the theoretical trend that had supported the tokamak results. There also were (very few) high-nuclear charge Z data from fast ion beams. Electron beam ion trap data have now confirmed that the trend of the tokamak data was correct and that theory [including second-order quantum electrodynamics (QED) contributions] provides a good description of the $n = 3$ (Na sequence) [60] and $n = 4$ levels (Cu sequence) [61] up to $Z = 92$, within the 40 ppm error margin of the EBIT results for the heaviest Cu-like ions. The agreement with theory for the Zn-like ions of the same elements used to be much poorer and has only recently made significant progress [62–64]. As the QED contributions in Cu-like and Zn-like ions are rather similar, this must be a problem of theory with the computational treatment of two (and more) valence electrons in the same shell.

The same situation is found with Na-like and Mg-like ions. While (mostly) EBIT measurements had established the isoelectronic trend of the resonance line wavelengths in Na-like ions up to uranium with an uncertainty on the order of 100 ppm quite a number of years ago, and basically in agreement with advanced theoretical computations, the much fewer data for Mg-like ions beyond Xe met a wide scatter of computational predictions. This unsatisfactory situation has only very recently been clarified by some better data and a few computations (see data and references in [65–67]), and the key transitions are now considered to be known to within 100 ppm. However, the same type of computation nowadays yields the resonance lines in Al-like ions (three electrons in the $n = 3$ valence shell) only to about 500 ppm reliability and progressively worse for more electrons. Again, the QED part of the computations that plays a major role at high Z is considered to be much better established than the quantum mechanical interaction of the electrons in the open

shells. The number of ($n = 2$) valence shell electrons is very restricted in Li-like and Be-like ions, and computations of these ions are competitive in accuracy with measurements. For this reason, some experiments actually address Li-like ions as stand-ins for H-like ions, which are more difficult to produce and may suffer from other obstacles, such as the line broadening of decays that involve $n = 2$ levels which in H-like ions can decay to $n = 1$. Here are two examples.

The dominant contributions of quantum electrodynamics (QED) to the binding energy of electrons scale with the fourth power of the nuclear charge Z , and, therefore, they are largest in the heaviest elements. The binding energy scales with Z^2 , and the fine structure splitting with Z^4 . Hence, measurements of the $n = 1$ level energy aim for uranium ($Z = 92$), while for the $n = 2$ levels, the QED contribution amounts to a fairly constant (Z -independent) fraction of the fine structure interval. The $n = 2$ Lamb shift amounts to roughly $1/8$ of the $n = 1$ level Lamb shift correction. Various experimental boundary conditions have to be considered in finding the optimum setting for a practical determination of the (QED) contributions. There also are theoretical considerations. The atomic systems purportedly under best theoretical control are H-like ions, with only one electron in total. However, the isotope $^{208}_{82}\text{Pb}$ has a doubly magic and, thus, rather spherical nucleus, which is beneficial for accurate calculations, whereas the uranium isotopes offer stronger fields and, thus, larger QED effects but with a nonspherical nucleus, the actual shape of which is less well established, causing some uncertainty in the accurate computation of the atomic structure. Nevertheless, uranium is a long-standing goal of experiments aiming at the ground state Lamb shift. H-like ions of uranium have been studied with fast ion beams (beam-foil/gas spectroscopy, see Sect. 19.1) at GSI Darmstadt and at the Livermore SuperEBIT. The resonance lines, $1s-2p$, with their energy of about 100 keV, fall into the hard-X-ray range, and the ground state Lamb shift of about 470 eV (of which roughly 60% and 40% are due to QED and finite nuclear size contributions, respectively) amounts to a small fraction of the transition energy. The lifetime broadening due to the short lifetime of the upper level is superimposed on the instrumental linewidth. At a fast ion beam, there also is the Doppler shift and Doppler broadening to correct for. At GSI, the highly charged ions were therefore produced as naked ions ($\text{U}92^+$) by ion-foil interaction at a high ion beam energy (for example, at 360 MeV/amu) and then decelerated by about a factor of 6 or 7 in an ion storage ring (which somewhat alleviates the Doppler correction problem). In this ring, some of the ions captured an electron from a gas jet target, so that the $n = 2$ levels might be populated and their X-ray decay be observed by a granular detector set. The X-ray spectrum was recorded in coincidence with (U^{91+}) ions, that is, after electron capture at the gas jet [68]. The year 2000 result for the ground state Lamb shift of 468(13) eV

was improved by a factor of 3 by replacing the gas jet target by free electrons from the electron cooler of the storage ring serving as the target a few years later [69]. The Livermore SuperEBIT experiment took a different route [70]. A high-resolution flat-field grazing incidence spectrograph recorded the $2s-2p_{1/2}$ transition of U^{89+} near 44 Å and determined a transition energy of 280.645 (15) eV. The result was close to earlier results obtained by Doppler-tuned spectroscopy of a fast ion beam [71] or by a measurement of dielectronic recombination in a heavy-ion storage ring combined with atomic structure calculations [72] but significantly more precise and more accurate than all the earlier studies. The SuperEBIT experimental result was then combined with theory values about the U^{89+} $2s-2p$ transition, as well as with theory values on U^{91+} , and a value for the U^{91+} $1s$ Lamb shift was determined that yielded a two-loop QED contribution of -1.27 ± 0.45 eV. This is the first time that any such two-loop contribution has ever been tested by experiment.

Hyperfine Structure

For decades, atomic spectroscopy has been employed to gain information on the nucleus via the hyperfine interaction of the nuclear spin with the unpaired electrons in the outer shells. However, only s electrons have a finite probability to be found inside the nucleus (rendering them most sensitive to the short-range nuclear fields). At the same time, the hyperfine splitting observable in atomic spectra grows with the third power of the nuclear charge and, thus, with Z^3 . Heavy elements have many electrons, and a detailed theoretical interpretation of hyperfine structure consequently requires a detailed understanding of an atomic system with many electrons. It would be highly advantageous to have only a single electron interacting with the nucleus, that is, an H-like ion. As discussed above, such ions can be produced at heavy-ion accelerators or in electron beam ion traps, and both have been employed in the quest for hyperfine measurements on one-electron heavy ions, mostly aiming at isotopes near the doubly magic nucleus $^{208}_{82}\text{Pb}$. The line of primary interest is from the transition between the hyperfine levels of the $1s$ ground state—the very transition that gives rise to the hydrogen 21 cm line used in radioastronomy. For heavy ions near Pb, the upper level has a millisecond-range lifetime. For two isotopes (of Bi and Pb), this transition has been induced by laser radiation in a heavy-ion storage ring [73], and for five isotopes (of Re, Ho, and Tl) emission spectroscopy at the SuperEBIT electron beam ion trap [74] was successful. Using the ion cloud (with its cross section largely determined by an electron beam diameter of about 70 μm) as a light source without a further entrance slit, a high-efficiency transmission grating spectrometer, and a position-sensitive detector, lines from two Tl isotopes were recorded simultaneously [74]. The differential effects of the two nuclei yielded additional information on the charge distribution in the nucleus, on top of the

magnetic moment distribution that makes up the dominant effect. These results are required for a better interpretation of parity nonconservation (PNC; Sect. 32.1) measurements of neutral Tl atoms, in which the nuclear magnetic moments have so far been treated only as a point dipole. The experimental data on the $1s$ hyperfine structure are in reasonable agreement with theoretical results based on various models. In order to clarify the validity of the model assumptions, the measurements have been extended to $n = 2$ levels, using Li-like ions for practical reasons. Moreover, a comparison of the hyperfine data for $n = 1$ and $n = 2$ levels of H- and Li-like ions, respectively, of the same isotope would enable a better differentiation of nuclear field and QED contributions to the result [75]. The most fundamental hyperfine interval in Li-like ions is between the sublevels of the $2s$ level, corresponding (for Bi^{80+}) to a transition in the infrared. While this transition was searched for (and not found in various attempts) in a laser resonance experiment on a fast ion beam at GSI Darmstadt, the Livermore SuperEBIT was employed in an indirect search, observing the $2s-2p_{1/2,3/2}$ transitions in the X-ray [76] and EUV [77] ranges, respectively. These transitions include the hyperfine intervals as part of the much larger transition energies. While less sensitive to the hyperfine structure, such measurements cover a much wider range of search. Both SuperEBIT measurements turned out results for the $2s_{1/2}$ hyperfine structure intervals that were compatible with prediction but not quite precise enough to distinguish between the individual calculations. Very recently, the laser resonance experiments at GSI Darmstadt succeeded on, both, H-like and Li-like ions of ^{209}Bi and yielded results with the full sensitivity of direct measurements [78, 79]. The much anticipated combination of hyperfine structure information on both ions indicates a significant discrepancy with theory [80].

One of the pertinent problems in astrophysics is the cataloguing of spectral lines in all spectral ranges, both for identifying spectral features and, thus, learning about the composition of a light source, and for modeling of the light source in order to understand its *operating conditions*. Even data bases that claim *practical completeness*, however, are found to be grossly incomplete in the EUV and soft-X-ray ranges that have been opened to high-resolution observations by the grating spectrometers on board the *Chandra*, *XMM-Newton*, and *Hinode* spacecrafts. Here, observations at electron beam ion traps fill in much of the needed data, at comparable quality. Moreover, an EBIT as a kind of analog computer does more than provide correct line positions; the spectra show line ratios from a light source with known electron energy (and the option of known temperature by simulating a Maxwellian energy distribution [81]) and particle density. This serves both as a check on collisional-radiative models and as an immediate data resource for astrophysics.

Most X-ray data from EBITs have been collected using solid state detectors [Si(Li), Ge] that offer high detection efficiency (large solid angle) and signal timing on the microsecond scale but feature poor spectral resolution. High-resolution instruments like crystal spectrometers are necessary to analyze spectra in any detail; equipped with position-sensitive detectors, such instruments do much better than scanning spectrometers in terms of data collection rate and calibration. However, they suffer from the low diffraction efficiency of the crystals. Recently, a new device, the microcalorimeter, has started to show its interesting properties. In these devices, small absorbers at mK-temperatures show a measurable temperature increase when absorbing an X-ray photon, and the signal is proportional to the deposited photon energy [82]. The linewidth of the best devices is below 10 eV (not as good as a crystal spectrometer but much better than a traditional solid state diode), the sensor pixels can be grouped in arrays to make for a larger area and for cross references among pixels (which helps with calibration and with the rejection of cosmic ray events), and the signal processing is fast enough to permit time resolution on the millisecond range. A spaceflight engineering spare has been used at the Livermore EBITs to study, for example, soft-X-rays of light elements as seen from CX near comets [83], or measure the (10 ms) time constant of the M3 decay in a Ni-like ion (Xe^{26+}). The hyperfine interaction with the nuclear spin can modify this electronic level lifetime, which was demonstrated by using isotope-separated isotopes ^{132}Xe and ^{129}Xe [84]. The results agreed with theoretical expectations [85].

High Multipole Order Radiation

Much of the above deals with the successive experimental exploration of the consequences of the multipole expansion of the electromagnetic radiation field in classical electrodynamics, which in the 1920s O. Laporte phrased into selection rules for transitions in the atom, and the corresponding multipole orders ascribed to transition types, such as (E1, M1, E2, M2), and so on. The nonexistence of electromagnetic monopole radiation follows the strict rule that $J = 0$ levels do not connect radiatively with other $J = 0$ levels. In spite of this, *Beiersdorfer* et al. recognized an X-ray line in the spectrum of the Ne-like ion Ar^{8+} that fits to the energy of the $3p^5 3s$ $J = 0$ level decaying to the $3p^6$ $J = 0$ ground state [86]. The line intensity grew with the magnetic field strength in the environment (tokamak plasma or EBIT) and suggested that the magnetic field plays a decisive role. Indeed, the distortion of the usual spherical symmetry of the atom/ion by the external field was seen as the clue to the process, and the transition mediated by a field-induced admixture of a $J = 1$ wave function component to the upper $J = 0$ level. Consequently, this line might serve as a high-magnetic field diagnostic, for example, in astrophys-

ical plasmas. A series of radiative lifetime measurements in an EBIT of the $3p^5 3s$ $J = 2, 0$ levels in Ne-like Fe^{16+} ions [87, 88] later yielded the M2 decay rate of the $J = 2$ level, the M1 decay rate (in the same configuration) of the $J = 0$ level, and the magnetic-field induced ground state transition rate of the latter level. The M2 rate result is much more precise than the scatter of various predictions, the measured M1 rate agrees well with computations, and the B-field induced rate is in reasonable agreement with theory [89].

Last, but not least, the well-defined and adjustable electron beam energy in an EBIT permits detailed studies of the interaction of fast electrons with highly charged ions. This includes, for example, the spectroscopy of dielectronic recombination (DR) resonances or the exploration of radiative recombination (RR) (Chap. 59). These processes can be investigated up to the highest ion charges, where relativistic and QED contributions (like the generalized Breit interaction) matter.

19.2.2 Heavy-Ion Storage Rings

With foil-excited ion beams and long level-lifetimes, decay curves spread out along the beam, and the signal from a given width of the field of view may drop to the detector background level. The decay lengths of microsecond lifetime levels are on the order of 10 m, and those of millisecond levels are tens of kilometers, which is clearly prohibitive in a linear arrangement. In such cases, it is advantageous to curve the beam line around on itself, forming a storage ring, in which the ions pass in front of the detector over and over again. Heavy-ion storage rings need excellent vacuum conditions (10^{-11} mbar and better) to reach storage times of seconds, minutes, or hours, depending on the electronic structure of the stored ions and on the ion beam energy. The dominant loss processes are electron capture and loss, small angle scattering, and large angle (inelastic) scattering as with any fast ion beams [90], but these are aggravated here by the much longer path lengths.

Storage rings (for example, TSR Heidelberg (now moved to an isotope separator at CERN), ASTRID Aarhus, CRYRING Stockholm (now in a new lease-of-life at GSI Darmstadt), ESR Darmstadt, and the new storage rings at the upcoming FAIR facility at the same compound), with magnetic dipoles and quadrupoles for beam transport and focusing, sort the stored particles by their momentum. The typical ion beam energies range from a few dozen keV total to hundreds of MeV per nucleon (ESR). Electrostatic storage rings (ELISA Aarhus, DESIREE Stockholm, CSR Heidelberg, and more under construction) only have electrical fields and select by particle energy, usually below about 100 keV (for a review, see [91]). They are more suitable for low-charge heavy ions and ion molecules, including

biomolecules, than the magnetic rings that can handle very fast particles. Magnetic storage rings usually have electron cooler sections in which a *cool* electron beam (with a low longitudinal velocity spread from kinematic compression) of almost the same velocity as the circulating ion beam is merged with the latter for a path of a few meters (and is then deflected out again). By scattering among electrons and ions, the momentum spread of the electrons (small) and ions (larger) equilibrates, leaving the ion beam with a narrower momentum distribution and, thus, cooled. Cooling, which typically takes a few seconds, improves the storage behavior of the ion beam and the energy resolution of, for example, dielectronic recombination (DR) studies (Chap. 59). For these, the same electron cooler is now tuned to provide electrons at a well-defined but different velocity. Thus, the electron cooler can serve as an electron target, without the complications of a foil target in beam–foil spectroscopy. The difference velocity can be chosen from a wide range, including zero. Extremely low energy collisions are being investigated for the study of DR and for the recombination of molecular radicals. When a beam of molecular ions is injected, storage is long enough to let some of the internal degrees of freedom relax, and then a beam of molecular ions that are closer to their ground state can be extracted.

A cooled ion beam, with its narrow velocity distribution, is also of interest for laser–ion interaction studies, offering higher resolution and better signals. Laser-assisted electron capture in the electron cooler, as well as laser spectroscopy on high-lying levels populated by DR, are possible. One of the problems with precision wavelength measurements involving fast ions is, as always, the accurate determination of the velocity, as a step towards determining Doppler corrections. At TSR Heidelberg, a beam of Li^+ ions was subjected to a laser beam from ahead, tuned to one of the $2s-2p$ transitions. A second laser beam from behind probed the position of the Lamb dip in the velocity distribution and, thus, assured that it would meet the same velocity group of the multi-MeV stored ions. Accurate off-line calibrations of the laser frequencies then permitted a test of the Doppler formula to a relative precision of 2.2×10^{-7} [92]. This research has since been extended to higher ion velocities at the ESR storage ring at GSI Darmstadt.

The Doppler shift determination in any observation of fast ions requires accurate angle measurements. These are nontrivial, because the detection efficiency of any finite size spectrometer or extended detector may be nonuniform as a function of position or angle. One technique calls for segmented (*granular*) X-ray detectors, the strips of which are calibrated individually [68]. Relativity changes the emission pattern seen in the laboratory rest frame to one that favors forward emission. This is beneficial for zero-degree spectroscopy, that is, an observation along the ion beam path. At ESR Darmstadt, bare ions captured an electron in the

electron cooler section, and the resulting X-rays were detected from straight ahead (behind the next dipole magnet that deflected the ion beam). This geometry maximizes the Doppler shift but minimizes the uncertainty relating to geometry. Also, after electron capture, the ion in the bending magnet section follows a trajectory that differs from that of the unperturbed ions. The ion can be detected and, in coincidence with the X-ray detector, make for a very clean and charge-specific spectrum. Similar coincidence measurements make it possible to use a low-pressure gas jet target in a high-energy ion storage ring, evaluating only coincidences of X-ray photons and charge-changing events [68]. Fast ions (energetic enough to achieve the desired charge state) can also be decelerated in a storage ring, which helps to do systematic checks of the Doppler effect and to work at lower Doppler shift [68].

As mentioned in Sect. 19.2.1, laser-resonance techniques have been used to find the ground-state hyperfine transition in two H-like heavy isotopes. In one of them, the lifetime was also measured by recording the fluorescence decay from the ion beam after switching off the laser [73]. For lower charge states, one can exploit the excitation that ions carry into the ring from their production in the ion source or from stripping processes in the injector accelerator [93]. Lifetimes from half a millisecond to several seconds have been measured this way by passive observation [52], with an accuracy of better than 0.2% in favorable cases. Other techniques use excitation by DR in the ring [94] or laser probing of the remaining metastable level population, so that fluorescence is emitted near a photomultiplier detector [95]. With a stored beam of negative ions, even blackbody radiation may be sufficient to photodetach the weakly bound last electron; the ensuing neutral atom is not deflected at the next bending section and leaves the ring to be detected. All in all, lifetime measurements at ion storage rings reach from 1 μs to about 1 min. The lower limit is related to the time the ions need to circulate in the storage ring, whereas the upper limit depends on the vacuum in the ring vessel and, thus, on ion loss processes associated with collisions of the beam ions with the residual gas. Cold vessels such as in the new cryogenic storage ring (CSR) will push this limit up. Such an extension of the measurement capability to atomic lifetimes on the order of many minutes is necessary for the study of E1-forbidden radiative processes in the low-charge state atomic and molecular ions of the interstellar medium.

19.2.3 Conclusions

In conclusion, beam–foil spectroscopy is very useful because of its inherent time resolution, and the efficient excitation at high and observation at low electron density. Atomic lifetime measurements are feasible over about four orders of magni-

tude, from a few picoseconds to many nanoseconds, and are achieved basically by virtue of geometry that is exploited by mechanical displacements. Because of the nonselective excitation, only a few beam–foil lifetime measurements have reached error bars smaller than 5%.

Heavy-ion storage rings pose the spectroscopic problem of large Doppler shifts, which with considerable effort can also be exploited for laser spectroscopy making use of the shift in wavelength between laboratory and moving ion rest frames. Practical atomic lifetime measurements have been done in the five orders of magnitude range from about 1 millisecond to some hundred seconds; this range will widen with better vacuum in cryogenic systems. A fair number of these lifetime measurements have reached uncertainties of less than 1%.

Electron beam ion traps yield access to the spectra of all elements and all charge states, they do not suffer from Doppler shift, and they grant options for high spectral resolution. They are a very economical tool to produce highly charged ions, but they are best for levels that are excited directly from the ground state. In terms of atomic lifetime measurements, femtosecond lifetimes can be measured spectroscopically via line broadening. Electronic lifetime measurements (with fast switching of the electron beam energy) work in the range from microseconds to seconds (six orders of magnitude), and possibly more in future clean traps.

Fig. 19.1 shows how the above three techniques have been applied to cover a very wide range of level lifetimes of a fundamental M1 transition along the isoelectronic sequence of two-electron spectra. The predicted Z^{10} dependence of this M1 transition rate is fully corroborated by experiment. However, further atomic structure insight requires even higher accuracy of the experiment. Some of the most precise atomic lifetime measurements ever achieved were done at EBITs, with uncertainties of a small fraction of 1%. Multitrap arrangements that separate ion production from measurement are coming into use in various laboratories. The combination of an EBIT for ion production at low particle density and a subsequent ion storage ring for lifetime measurements on a single ion species and charge state appear particularly promising in the quest for tests of the QED contribution to the M1 transition rate [57].

Elmar Träbert Elmar Träbert has pursued beam-foil spectroscopic measurements (spectra and ps/ns-lifetimes) in the EUV and X-ray ranges at Bochum, Oxford, GSI Darmstadt, and various other places. Since the 1990s, his work has expanded to ms/s-range atomic lifetime measurements at the TSR heavy-ion storage ring Heidelberg, and to electron beam ion traps (EBIT), mostly at Livermore.

Eric Pinnington Eric Pinnington obtained his PhD in Physics at Imperial College in 1962. Prior to joining the University of Alberta in 1965, he held an NRC Postdoctoral Fellowship at McMaster University in Hamilton, Ontario, and an Alexander von Humboldt Fellowship at the Max Planck Institute for Astrophysics in Munich. He was elected Fellow of the American Physical Society in 1995. He became Professor Emeritus of Physics in 1997.

Abstract

The shapes of collisionally broadened atomic lines is a topic almost as old as Fraunhofer's discovery of the existence of discrete lines. *Lorentz* provided the first quantitative theory in 1906 [1], and *Weisskopf* advanced this to the *impact theory* by 1933 [2]. *Holtzmark* [3], *Kuhn* [4] and *Margenau* [5] meanwhile developed the *quasistatic* or *statistical* theory which describes the line wing, and *Jablonski* put this on a quantum mechanical footing in the context of free–free molecular radiation [6, 7]. By the 1940s, satellite bands in the line wings, and a variety of high and low pressure line shapes and broadening rates had been measured. Initial confusion regarding the validity of the contrasting *impact* versus *static* approaches was largely resolved by unified treatments of the Fourier integral theory [8–13]. *Baranger* then provided a quantum basis for the impact theory, including level degenera-

cies [14]. Descriptions can be found in a variety of reviews and references therein, including [2, 5, 15–20]. The broadening of molecular lines involves the additional complication of rotationally nonadiabatic collisions; this was initially addressed by *Anderson* [12, 13] and later with great thoroughness by *van Kranendonk* [21]. This chapter and most of the above theories are concerned with neutral atomic gases, which is sometimes called *pressure broadening*. In plasmas, electron, ion, and neutral collisions all contribute to the line shapes and strengths; thus the emitted lines provide a powerful diagnostic of plasma conditions. Neither molecular nor plasma broadening will be covered here; the latter is reviewed in [17–20, 22], and in Chaps. 51 and 63.

20.1 Collisional Line Shapes

The neutral-gas theories described above generally used phenomenological or long range forms of the atomic and molecular interactions, and most measurements were not sufficiently detailed to test the validity of these parameterizations or the theoretical approximations. A great deal of the work since mid century has been directed towards obtaining more realistic and accurate descriptions of these interactions and of the full line shapes. In addition, many new types of observations have stimulated variations on the basic theories and descriptions. This includes topics such as collision-induced forbidden transitions, satellite shapes, spectral and polarization redistribution, orientation and alignment effects, Doppler-free spectroscopy and very low temperature collisions. Most of these topics are beyond the scope of this brief and basic description of neutral collisional line shapes.

20.1.1 Voigt Line Shape

An atomic (or molecular or ionic) line has an intrinsic Lorentzian shape that reflects the Fourier transform of the exponentially decaying spontaneous emission. For a spontaneous decay rate Γ , the fullwidth at half maximum (FWHM) is $\Delta\omega = \Gamma$. Due to the Maxwellian distribution of atomic velocities v in a thermal vapor, and the Doppler shift $\Delta\omega_D = v/\lambda$ where $\lambda = \lambda/(2\pi)$ and λ is the wavelength, the resonance frequencies of atoms in the laboratory frame have a Gaussian distribution. The Doppler width of this distribution is approximately $\omega_0 u/c$, where ω_0 is the resonant frequency and u is the mean thermal velocity. The full line shape is thus a convolution of the natural Lorentzian with the thermal Gaussian; a Voigt profile. In the presence of collisions, the line from each atom broadens, shifts and becomes asymmetric, and this is normally convoluted with the Gaussian velocity distribution to obtain the complete line shape. Collisions may also cause weak or dipole-forbidden transitions to become stronger as well as broader.

20.1.2 Interaction Potentials

Theories of collisional line shapes consider an ensemble average of collisional interactions. For atomic gases, the description of each individual collision or interaction generally starts with a molecular model for a pair of interacting atoms, since the Born–Oppenheimer approximation is appropriate for thermal atomic collisions (electron velocities \gg nuclear velocities) [23]. The radiative transition then occurs between adiabatic electronic molecular states that separate to the atomic states of the transition under consideration. The notation $V_u(R)$ denotes the electronic energy of the upper state, and $V_g(R)$ the lower state, where R is the internuclear separation, and the total atomic energies are E_1 and E_0 with $E_1 - E_0 = h\omega_0$ (Fig. 20.1). The next simplification is to assume that the atom-pair statistically branch into adiabatic motion along each of the molecular states associated with the initial atomic state, and radiation to each of the final states is summed independently, assuming they are also completely adiabatic. This ignores an inevitable nonadiabatic coupling between the states as their energy separation decreases to zero at large R , but as discussed below this has been shown to have a very minor effect on line broadening. The single-collision problem then reduces to calculating the spectrum of a molecular transition between each upper and lower pair of adiabatic states, for each initial state of internuclear motion and all possible final motions, and summing these weighted by the rate of initial collisional motions. However, such calculations are only necessary to elucidate particular quantum features, because the *classical oscillator approximation*, *impact approximation*, *quasistatic approximation*, and *classical*

Fig. 20.1 Diagrammatic representation of a free–free molecular radiative transition and the classical Franck–Condon principle. Adiabatic potentials (V_u and V_g), the difference potential equal to the classical transition frequency (*dashed*), nuclear kinetic energies and wave functions $\Phi_u(R)$ and $\Phi_g(R)$ are indicated. The position R_c is the classical radiation position for the initial (E_u) and final (E_g) energies shown

Franck–Condon principle provide major conceptual and calculational simplifications. These are presented in the context of free–free transitions in the following sections.

20.1.3 Classical Oscillator Approximation

Consider a free–free molecular radiative transition of energy $\hbar\omega = E_u - E_g$ between upper (u) and lower (g) states of total energy E_u and E_g , as shown in Fig. 20.1. Each elastic scattering state is the product of an electronic adiabatic state $\phi(r, R)$ and a nuclear motion state $\Phi(R)$ of the molecule. The electronic states u and g have effective potentials

$$V_q^e = V_q + \frac{l(l+1)}{R^2}, \quad (20.1)$$

where $q = u$ or g . Examples of such $V(R)$ and $\Phi(R)$ for the case of $l = 0$ are shown in Fig. 20.1. The electric dipole radiation operator that couples these states is normally a weak perturbation that does not alter these potentials or wave functions. For definiteness assume the atom is initially in the upper state, and that an atom pair approach with kinetic energy \mathcal{T}_i and separate with \mathcal{T}_f , as indicated. The intensity I , or transition probability, is proportional to the squared matrix element of the dipole operator $er = e \sum_i r_i$ between initial and final states

$$\begin{aligned} I &\propto \left| \int d^3R \int d^3r \Phi_u(R)^* \phi_u(r, R)^* er \phi_g(r, R) \Phi_g(R) \right|^2 \\ &= \mu^2 \left| \int d^3R \Phi_u(R)^* \Phi_g(R) \right|^2, \end{aligned} \quad (20.2)$$

where the last factor is the Franck–Condon factor, μ is the dipole moment, here assumed to be the atomic value independent of R , and $d^3R = 4\pi R^2 dR$ for diatomics. The $\Phi(R)$ can be represented, in the WKB approximation, as

$$R\Phi_q = k_q^{-1/2} \exp \left[-i \int_0^\infty dR k_q(R) \right], \quad (20.3)$$

where

$$k_q = \frac{\left\{ 2M \left[E_q - V_q^e(R) \right] \right\}^{1/2}}{\hbar} \quad (20.4)$$

and M is the reduced mass of the atom pair ($\hbar^2 k^2 / (2M)$ is the kinetic energy in Fig. 20.1).

The integrand in the second line of Eq. (20.2) then contains $\exp[i \int d^3R (k_u - k_g)]$. If one multiplies $k_u - k_g$ by $(k_u + k_g) / (k_u + k_g)$, the exponent becomes

$$\frac{2M(\omega - \omega_c)}{\hbar(k_u + k_g)},$$

and if one further defines a variable $t(R)$ by $dt = dR/v(R)$ with $v(R) = \hbar(k_u + k_g)/2M$, the exponent becomes $i \int \omega_c(t') dt' - i\omega t$, where

$$\omega_c(R) = \frac{V_u(R) - V_g(R)}{\hbar} \quad (20.5)$$

and $R(t)$ is the classical trajectory in the average potential. Thus, the Franck–Condon factor reduces to the squared Fourier transform of $\exp[i \int^t \omega_c(t') dt']$, where $\hbar\omega_c(R) = V_u(R) - V_g(R)$ (Fig. 20.1). This is the *classical oscillator approximation* (COA), in which the atoms are considered to be a classical oscillator at $\omega_c(R)$ during the collisional interaction, and $R(t)$ is the classical orbit.

The \sqrt{k} in the denominator of the WKB wave function leads to $1/v(R)$ in the nuclear density at R , again corresponding to classical motion. This COA is used as the starting point in many line shape calculations. It is apparent that the COA breaks down when the initial- and final-state orbits are significantly different, or when the Born–Oppenheimer or WKB approximation is not valid. However, the COA is normally a very good approximation for thermal atomic vapors when $\hbar(\omega - \omega_0) \ll k_B T$, since most orbits are then straight lines within the R region that yields the observed radiation.

One further conceptual and mathematical simplification is to subtract ω_0 from $\omega_c(t')$ and from ω by defining $\Delta\omega_c = \omega_c - \omega_0$ and $\Delta\omega = \omega - \omega_0$. The Franck–Condon factor in Eq. (20.2) then becomes

$$I(\omega) = \left(\frac{4\mu^2 \omega^4}{3c^3} \right) \times \left| \int dt \exp \left[i \int^t \Delta\omega_c(t') dt' - i\Delta\omega t \right] \right|_{av}^2, \quad (20.6)$$

where the prefactors that yield the correct intensity are explained in [12, 13] (Sect. 11.6). The average is, in general, over a sequence of collisions leading to an integral over collision velocity and impact parameter, weighted by the rate of occurrence.

In the next section, the character of the broadened line core is obtained by the traditional method of evaluating Eq. (20.6) using the impact approximation.

20.1.4 Impact Approximation

Atomic collisions in thermal vapors typically occur in a time interval $\tau_c < 1$ ps, whereas the time between significant collisions is much longer at vapor pressures below a few atmospheres. Thus, one can consider the atom as radiating its unperturbed frequency ω_0 most of the time, but occasionally suffering a rapid, strong perturbation. If the duration of a collision is τ_c , then $\phi(t) = \int^t \Delta\omega_c(t') dt'$ in the exponent of Eq. (20.6) undergoes a net phase shift $\Delta\theta$ in a time τ_c , and is constant between collisions. If $\Delta\omega \ll 1/\tau_c$, then one can approximate this phase shift as instantaneous; this is the essential assumption of the *impact approximation*. When the factor $\exp[i\Delta\theta(b, v)]$, which then occurs in Eq. (20.6) is averaged over collision rates with velocity v and impact parameter b this leads to $(\gamma_c - i\delta)t$ in place of $\phi(t)$, where γ_c and δ are given by [15]

$$\gamma_c = \int_0^\infty n(v) v dv \int_0^\infty 2\pi b [1 - \cos \Delta\theta(b, v)] db,$$

$$\delta = \int_0^\infty n(v) v dv \int_0^\infty 2\pi b \sin \Delta\theta(b, v) db.$$

Including the spontaneous emission dipole decay rate $\exp(-\Gamma t/2)$, the Fourier integral produces the normalized Lorentzian line shape

$$I(\omega) = \frac{(\Gamma/2 + \gamma_c)}{\pi[(\Gamma/2 + \gamma_c)^2 + (\Delta\omega - \delta)^2]}. \quad (20.7)$$

The full line shape is then a Voigt profile with a Lorentzian-component half width $\Gamma + 2\gamma_c$ and a shift of δ from ω_0 . The shift can be understood as the perturbed oscillator frequency advancing relative to ω_0 by the average value of $\sin \Delta\theta$, or alternately as indicating the direction of the frequency shift of $V_u - V_g$. The Lorentz approximation corresponds to taking $1 - \cos \Delta\theta = 1$ or 0 , with the former representing a collision. This gives $\gamma = 1/\Delta t_c$, where Δt_c is the average time between strong collisions.

The b for which $\Delta\theta(b, \langle v \rangle) = 1$ is called the Weisskopf radius (R_W). The collisional line width $2\gamma_c$ can be thought of as

a collisional rate $n\langle v \rangle Q$, where $Q = \pi R_W^2$. The importance of R_W is that γ_c and δ result primarily from atomic interactions in the region $R \approx R_W$. Since the size of an electronic wave function increases with increasing excitation energy, $|\Delta V(R)| = |V(R) - V(\infty)|$ is normally larger for the upper state of a transition. (High Rydberg states can be an exception.) Since $\Delta\theta = 1$ for $b = R_W$ and $\Delta\theta \approx (\Delta V/\hbar)\tau_c$, then $\Delta V(R_W) \approx \hbar/\tau_c$. For a typical $\tau_c = 1$ ps this implies $\Delta V(R_W)/(hc) \approx 5 \text{ cm}^{-1}$, which is a relatively weak, long range interaction. Thus, reasonable approximations to the necessary $V(R)$ can often be obtained from atomic perturbation theory. Simple expressions for γ_c and δ are obtained for $V_i - V_f = A/R^n$ with $n > 2$ [24]. The case of $n = 3$ corresponds to the resonant interaction between identical atoms, while $n = 6$ corresponds to the van der Waals interaction, which holds at long range for foreign gas interactions. This result for one pair of adiabatic states must be averaged over all of the pairs that separate to each atomic state.

Higher order approximations obtain an asymmetric line, rather than a pure Lorentzian, due to the asymmetry of $\Delta V(R)$ [24]. In the line core this asymmetry appears as a multiplicative correction $1 + \Delta\omega/D$, where $|D| \approx 1/\tau_c$ [25], and with increasing detuning it increases until at $|\Delta\omega| > 1/\tau_c$ the static wing approaches the quasistatic limit described in Sect. 20.1.7. If $\Delta V(R)$ changes monotonically with decreasing R , only one side of the line has a static contribution and the other, antistatic side falls off exponentially at $|\Delta\omega| > \tau_c$ [11]. However, this situation is seldom observed, as more than one difference potential generally contributes and there is usually a static contribution on both sides of the line. Another factor that produces a small divergence from the Voigt profile is the velocity dependence of the shift and width. When combined with the higher velocities of atoms emitting or absorbing in the Doppler wing, this produces an asymmetry in the Doppler wings [26, 27].

20.1.5 Examples: Line Core

It is possible to deconvolve a Voigt line shape to separate the Doppler and Lorentzian components, and thereby deduce broadenings of considerably less than the Doppler width ([28] and references therein). However, the broadening is most easily observed at perturber densities where the collisional broadening exceeds the Doppler broadening. Such a pressure-dependent line shape is shown in Fig. 20.2, for a range of perturber density n_p such that the broadening exceeds the Doppler width and hyperfine structure, yet the line core is described by the impact theory [29]. In Fig. 20.2 the normalized line intensity has been divided by n_p ; as the line wings are proportional to n_p they are constant in such a plot, while the line center broadens and shifts with increasing n_p . For this case of fairly heavy atoms, $(2\pi c\tau_c)^{-1} = \Delta k_c$ corre-

Fig. 20.2 Normalized line shape of the Rb $5P_{3/2}-5S_{1/2}$ transition broadened by Kr, for Kr densities of $4.5, 9, 18,$ and $27 \times 10^{18} \text{ cm}^{-3}$ (top to bottom). Hyperfine structure and instrumental resolution cause $\approx 0.3 \text{ cm}^{-1}$ of the broadening shown

Fig. 20.3 Normalized intensity in the wings of the Rb $5P_{3/2}-5S_{1/2}$ transition broadened by Kr, in frequency units of $k = 1/\lambda$. The measured spectrum in (a) is from [29, 37, 39]. The *solid line* is at 310 K and the *dashed line* at 540 K. The difference potentials corresponding to the A, B and X states of Rb-Kr, taken from [36], are shown in (b)

sponds to $\approx 0.5 \text{ cm}^{-1}$, and the line becomes asymmetric and non-Lorentzian beyond $\approx 1 \text{ cm}^{-1}$ (Fig. 20.3a); the red wing intensity falls more slowly and the blue wing more rapidly than $(\Delta\omega)^{-2}$. This behavior is typical for most heavy perturbers, and is attributed to a long range attractive V_u which dominates $V_u - V_g$.

Fig. 20.4 Calculated line shapes of the Cs($^9P_{1/2}$ - $^6S_{1/2}$) line broadened by Xe at the densities indicated (from [16]). The assumed interaction is based on measured line shapes, but data corresponding to the calculated conditions are not available

For the lowest n_p shown in Fig. 20.2, a convolution with the Doppler, hyperfine and instrumental broadenings showed that the line is essentially a symmetric Lorentzian for $|\Delta k| < \Delta k_c$ [29]. However, at the highest density, the half-height point is beginning to fall outside of Δk_c ; the impact approximation is marginally valid for describing the half width of the line at this density. Most early experiments were done at more than 10 times this density [15]; most of the line-core was at $|\Delta k| > \Delta k_c$ and describable by the static theory (Sect. 20.1.7) rather than the impact approximation. The impact approximation was also not valid under these conditions because collisions overlap in time. These very broad lines are well represented by the multiple-perturber, static theories that assume scalarly additive perturber interactions [5, 8]. This transition between an impact and quasistatic line core, and to multiple perturber interactions, occurs at lower pressures for transitions to higher states, as the interactions have a longer range. In addition, nearby intensity peaks or satellites often occur, and strongly affect the line as pressure increases. An example calculation, based on an interpretation of measured spectra [16], is shown in Fig. 20.4. This shows how a line with a satellite feature progressively broadens and finally blends with the satellite as n_p increases.

With the advent of saturated-absorption (Doppler free) spectroscopy, collisional line broadening can be measured at much lower densities, where $2\gamma_c \ll \Delta\omega_D$. In principle, this can allow measurement of line broadenings and shifts,

although with a complication that affects the line shape; the same collisions that produce optical phase shifts also change the atomic velocity. These velocity changes have a minor effect outside the Doppler envelope where high pressure measurements are normally made, but they are quite important in saturated absorption line shapes. This affects primarily the low intensity wings of the line, so it does not prevent measuring the broadening and shift of the nearly Lorentzian core. Details can be found in [30] and references therein. Two-photon absorption yields Doppler free lines that are not affected by velocity changing collisions. This provides the most exacting test of line shapes. These narrow lines are precisely Lorentzian, with a broadening that reflects the upper state interaction since this is usually much stronger than that of the ground state. The technique has been used to measure the broadening of two photon transitions to many excited states [31, 32].

20.1.6 Δ and γ_c Characteristics

Since 1970, neutral broadening has generally been measured in the $|\Delta\omega| < 1/\tau_c$ region where the impact approximation and Eq. (20.7) is valid. Measurements through 1982 are tabulated in [16], and through 1992 in [33]. More recent measurements are tabulated in the NIST Reference Data bibliography, which is accessible (free) at the web site <http://physics.nist.gov/PhysRefData>. These involve primarily metal vapor resonance lines broadened by noble gases. For collisions with the heavier (more polarizable) gases, the sizes of these measured broadening rate coefficients generally fall within a factor of 10 range, and approximately fit the prediction of Eq. (20.7) with $\Delta V_u(R) - \Delta V_g(R) = C_6 R^{-6}$ [34] and C_6 given by a simple effective quantum number formula. This occurs because the potentials are fairly close to van der Waals for $R \geq R_W$ and the broadening is insensitive to details of the potentials at $R < R_W$ since $\cos \Delta\theta$ in Eq. (20.7) averages to ≈ 0 for the closer (strong) collisions. It also occurs because the full quantum solution for broadening by a van der Waals interaction, with Zeeman degeneracies, yields nearly the same result as the above single-level theory with an average C_6 [35].

For the heavy, more polarizable perturbers, the excited state interactions are attractive and red shifts occur, but the measured shifts have a very poor correlation with the van der Waals prediction. As b decreases and $\Delta\theta(b, v)$ increases, $\sin \Delta\theta$ oscillates and major cancellations occur in the average of $\sin \Delta\theta$ in Eq. (20.7). The shift is therefore only a fraction of the broadening and is very sensitive to the interaction throughout the region $R \approx R_W$. This often differs considerably from the van der Waals form, at the typical $\approx 5 \text{ cm}^{-1}$ interaction energy at R_W . The shape of the red wing just beyond $\Delta\omega_c$ also frequently fails to fit that expected for a van

der Waals interaction [29]. Thus, the often good agreement of γ_c with van der Waals numbers is not a reliable indicator of the actual $V(R)$ in the relevant R region, even for heavy noble gas perturbers.

For He and sometimes Ne perturbers, a repulsive interaction due to charge overlap normally dominates at $R \approx R_W$, causing a blue shift as well as a larger broadening than the van der Waals prediction.

20.1.7 Quasistatic Approximation

The impact approximation is valid for $|\Delta\omega| \ll 1/\tau_c$, where the $1/\tau_c$ is typically $1\text{--}10\text{ cm}^{-1}$. For larger $|\Delta\omega|$ the line shape becomes asymmetric, with higher intensity on the wing corresponding to the long-range $V_u(R) - V_g(R)$. At large detunings where $\Delta\omega \gg 1/\tau_c$ a major simplification occurs. The COA describes the interacting atom pair as an oscillator of frequency $\omega_c(R) = [V_u(R) - V_g(R)]/\hbar$ when at separation R . Since R is time dependent during the classical orbit, ω_c is as well and the Fourier spectrum is broadened relative to the simple distribution of $\omega_c(t)$ that occurs during the orbit. But if the motion is sufficiently slow, the intensity at ω reduces to the probability of finding the atom pair at the appropriate $R(\omega = \omega_c)$. The spectrum then reduces, at low pressure, to the probability distribution of pair separations R , subject to Eq. (20.5) between R and ω . This is the binary quasistatic, static, or statistical spectrum, which accurately describes most line wings for $|\Delta\omega| > 1/\tau_c$. When the pressure is large enough to yield a significant probability of one perturber at $R \leq R_c$, multiple-perturber interactions must also be considered as in [5].

This intuitive deduction of the statistical spectrum from the COA [4] can also be obtained more formally from Eq. (20.6) by expanding the exponent about the time during a collision when $\omega_c(t) = \omega$. Alternatively, it follows directly from Eq. (20.2) using WKB wave functions to evaluate free-free molecular Franck–Condon factors [6, 7]. This result is identical to the classical Franck–Condon principle (CFCP), originally established in the context of bound–bound molecular radiation.

The CFCP yields important insights for all molecular radiation. Again consider Eq. (20.2) with the substitution of the WKB wave functions ϕ_q , given below it. Examples of ϕ_u and ϕ_g are given in Fig. 20.1. For large detunings $\omega - \omega_0$, as shown in Fig. 20.1, the integrand on the right side oscillates rapidly everywhere except at the stationary phase point R_c , where $k_u = k_g$. As a consequence, the dominant contribution to the integral occurs at R_c and one can consider the transition to be localized at R_c . Since $k_u(R_c) = k_g(R_c)$, $\mathcal{T}_u(R_c) = \mathcal{T}_g(R_c) = \mathcal{T}_c$ also holds, and as can be seen in Fig. 20.1 it then follows that $\hbar\omega = V_u(R_c) - V_g(R_c)$. Thus, radiation at frequency ω occurs when the atoms are near

R_c , where the electronic state energies differ by $\hbar\omega$. Note that this holds for all initial kinetic energies and angular momenta, as long as the conditions for validity of the Born–Oppenheimer and WKB approximations hold for the initial and final nuclear motions. This is the CFCP, which is equivalent to the classical-oscillator model for radiation at large detunings from the atomic transition.

Another insight evident from Fig. 20.1 is that the photon energy associated with the frequency difference $\omega - \omega_c$ is supplied by nuclear kinetic energy $\hbar(\omega - \omega_0) = \mathcal{T}_i - \mathcal{T}_f$. This transformation of nuclear into electronic energy takes place as the nuclei move from large R to R_c on one $V(R)$ and back to large R on the other.

If an absorbing or emitting atom interacts as $V_i(R)$ with a density n_p of perturbers in a vapor of temperature T , the probability of a perturber at separation $R \rightarrow R + dR$ is $n_p 4\pi R^2 \exp[-V_i(R)/(k_B T)] dR$ if the interatomic motion is in equilibrium. Inverting Eq. (20.5) for $R(\omega)$ yields $dR = d\omega/(d\omega/dR)$, and this pair of relations yields the (single perturber) quasistatic (QS) spectrum

$$I(\omega) = N n_p \Gamma 4\pi R(\omega)^2 \times \exp\left[\frac{-V_i(\omega)}{k_B T}\right] \left/ \left[\frac{d\omega(R)}{dR} \right] \right., \quad (20.8)$$

where N is the radiator density and $I(\omega)$ the radiation per unit volume and frequency interval.

Figure 20.3a gives an example of far wing emission line shapes versus photon energy in units of cm^{-1} , for the Kr broadened Rb D2 line for which $\Delta k_c \approx 0.7\text{ cm}^{-1}$. These data are normalized by perturber density, so they are independent of perturber density for the density region of the experiment. The excited state produces two $V_u(R)$, called the A and B states, while the ground state produces one $V_g(R)$, called the X state. Each of these potentials has a single minimum at long range and is strongly repulsive at close range, but the well depths and positions are very different [36]. This causes the complex forms of $V_u(R) - V_g(R)$ that are shown in Fig. 20.3b. There I have plotted $\ln(R)$ vertically and $\ln(\Delta V(R)/(hc))$ horizontally, where ΔV refers to $V_A - V_X$ and $V_B - V_X$. The right side of Eq. (20.8) can also be written as the exponential and constant factors times $dR^3(\omega)/d\omega$. Since $\ln[R^3(\omega)] \propto \ln[R(\omega)]$, the static spectrum at $\Delta k = \Delta\omega/(2\pi c)$ is proportional to the slopes of the curves in Fig. 20.3b, divided by $|\Delta k|$ due to the $\ln(\Delta k)$ horizontal axis. One can see qualitatively that the overall spectrum follows such a relation to the lines in Fig. 20.3b; in fact in most spectral regions this relation is quantitatively accurate.

The temperature dependence in Fig. 20.3a corresponds to the exponential factors in Eq. (20.8) [37]. At large R , both $\Delta V(R)$ are attractive, and this causes a large intensity on the negative Δk (red) wing. However, once $|\Delta k|$ exceeds

$\approx 20 \text{ cm}^{-1}$, where $V_B - V_X$ reverses direction, the red wing intensity drops rapidly. This extremum in $\Delta V(R)$ causes a satellite at $\approx -20 \text{ cm}^{-1}$, although it is spread out by the finite collision speed and does not cause a distinct peak in the spectrum. Satellite features are discussed in more detail in the next paragraph. The antistatic blue wing drops rapidly for several decades, then suddenly flattens beyond $\approx 10 \text{ cm}^{-1}$ due to the positive portion of $V_B - V_X$ at small R . The remaining blue wing is the B–X band, and has a satellite at $\approx 350 \text{ cm}^{-1}$ as $V_B - V_X$ passes through another extremum. The theory predicts this at 800 cm^{-1} , but clearly represents all the basic aspects correctly. This satellite is also spread out by finite collision speed, but a definite intensity peak remains. The red wing beyond $\approx 50 \text{ cm}^{-1}$ is the A–X band. The feature near -1000 cm^{-1} is due to the exponential factor in Eq. (20.8), not an extremum in $\Delta V(R)$; the feature essentially disappears if the normalized intensity is extrapolated to infinite temperature.

20.1.8 Satellites

In regions of the wing where the intensity falls slowly with increasing frequency, motional broadening of the static spectrum is not noticeable and the static spectrum is a good approximation. However, if $\Delta V(R)$, or equivalently $\omega_c(R)$, has an extremum at some R_S , the denominator of Eq. (20.8) is zero at $\omega(R_S) = \omega_S$. This produces a local maximum, or satellite, in the far wing intensity, as seen in Fig. 20.3a at 350 cm^{-1} . If one expands $\omega(R)$ in a Taylor series about $R = R_S$ this produces in Eq. (20.8) a square root divergence of finite area, with no intensity beyond ω_S . The area under this feature is meaningful, but not its shape; the quasistatic assumption is clearly not valid for such sharp features. The more accurate satellite shape is obtained by returning to Eq. (20.2) and expanding $V_u(R)$, $V_g(R)$ and the WKB wave functions about R_S , or using Eq. (20.6) with $\omega_c(t)$ expanded about $t(R_S)$. Sando and Wormhoudt used the former method to obtain a universal satellite shape [38]. Szudy and Baylis improved the expansion to yield a smooth transition to the quasistatic spectrum at smaller detunings [34]. This result is nearly the same as Sando et al. in the spectral region of the satellite, but it more accurately connects to the adjacent static line wing. Intensity undulations between the satellite and the line occur in this calculation; these arise from alternating constructive and destructive interference between two contributions to the same frequency from $R > R_S$ and $R < R_S$. This can not be seen in the low resolution of Fig. 20.3a, but such undulations are seen near the 350 cm^{-1} satellite [39]. At antistatic detunings beyond ω_S , which are not quasistatically allowed, the calculated intensities decay exponentially. This is also observed experimentally [39] and is the same behavior predicted for the antistatic wing of a line [11].

At higher perturber densities and closer to the line core, corresponding to larger R interactions, the multiple perturber probability distribution must be included. If the interactions are additive, this leads to a secondary satellite at twice the detuning of the low pressure satellite, as seen in Fig. 20.4.

The wings of a collisionally broadened atomic line are molecular radiation. In the context of molecular bound state spectroscopy, a satellite is a *head of band heads*, corresponding to a frequency region where bound–bound band heads congregate. This occurs, of course, at the classical satellite frequency and when $V_u(R) - V_g(R)$ has an extremum [40].

An extremum in $\Delta V(R)$ is the most common cause of satellites, but similar looking features can occur for other reasons. Forbidden bands often appear in the wings of forbidden atomic transitions, due to an increase in the transition dipole moment $\mu(R)$ resulting from the collisional interaction. These are described, in the QS approximation, by Eq. (20.8) with Γ replaced by $\Gamma(R)$. If $\Gamma(R)$ increases rapidly with decreasing R , the intensity increases as ω moves into the far wing until the dR^3 and exponential factors cause a net decrease at small R . This leads to forbidden bands far from the atomic frequency, such as those in [41]. In some cases, a collision-induced feature also appears at the frequency of the forbidden transition. The shapes of such features, which also include radiative collisions, in which both atoms change state, are calculated and reviewed in [42].

A variety of related line shape phenomena has been investigated, including the relation between absorbed and emitted wavelengths (spectral redistribution), the dependence of fluorescence polarization on absorbed wavelength (polarization redistribution), and high power effects. Some references regarding these phenomena are [43–47].

20.1.9 Bound States and Other Quantum Effects

The validity of the QS spectrum requires the validity of the WKB approximation in the initial and final state, but it is not restricted to free–free molecular transitions. In fact, the equilibrium probability distribution in Eq. (20.8) must include bound states in an attractive $V_i(R)$. The QS spectrum describes the *average* behavior of bound–free and bound–bound molecular bands, as well as the free–free radiation implied by the above method of derivation. The quantum character is expressed in the discrete bound–bound lines that make up this average, and in *Condon oscillations*, where the intensity oscillates about the average $I_{QS}(\omega)$. The latter occur as oscillations in Franck–Condon factors in the bound–bound case, and as smooth oscillations in bound–free spectra and low resolution bound–bound spectra. An additional quantum feature occurs in regions of the spectrum dominated by classical turning points, usually at the far edge of a line wing where the intensity is dropping rapidly. There,

quantum tunneling past the edge of the classically allowed region spreads the spectrum. Yet another is the energy $h\omega_0/2$ of the ground vibrational state, which effectively adds to $k_B T$ in Eq. (20.8) for attractive V_1 . All of these quantum features become more pronounced as the reduced mass decreases; examples and details can be found in [40, 48–50].

20.1.10 Einstein A and B Coefficients

The relationship between absorption coefficient $B_{12}(\omega)$, stimulated emission coefficient $B_{21}(\omega)$ and spontaneous emission coefficient $A_{21}(\omega)$ are given by the Einstein relations; $A_{21}/B_{21} = 8\pi h\lambda^{-3}$ and $B_{21}/B_{12} = g_1/g_2$. These relations are most familiar for atomic lines, but if they are referred to the density of absorbers $dN_g/d\omega$ and emitters $dN_u/d\omega$ that emit or absorb at ω , then they also apply to the wings of lines, i.e.,

$$k(\omega) = B_{12}(\omega) \left(\frac{2\pi h}{\lambda} \right) \left(\frac{g_u}{g_g} \right) \frac{dN_g}{d\omega} \\ = \frac{1}{4} \lambda^2 A_{21}(\omega) \left(\frac{g_u}{g_g} \right) \frac{dN_g}{d\omega}, \quad (20.9)$$

$$g(\omega) = \frac{1}{4} \lambda^2 A_{21}(\omega) \frac{dN_u}{d\omega}, \quad (20.10)$$

$$I(\omega) = \hbar\omega A_{21}(\omega) \frac{dN_u}{d\omega}. \quad (20.11)$$

Here $k(\omega)$ is the absorption coefficient due to lower state atoms, $g(\omega)$ is the stimulated emission coefficient and $I(\omega)$ the spontaneous emission due to excited state population, and g_u and g_g are the statistical weights of the atomic states. For absorbing atoms of density N_g and perturber density n_p , the QS approximation with equilibrated internuclear motion sets

$$\frac{dN_g}{d\omega} = N_g n_p 4\pi R^2 \frac{dR}{d\omega} \exp\left(-\frac{V_g}{k_B T}\right), \quad (20.12)$$

and equivalently for a radiating atom density N_u with perturber interaction V_u . Normally most of the radiation, and $dN_g/d\omega$, is concentrated at the atomic line, so integrating over $d\omega$ near the line leads to the relations

$$\int_0^\infty k(\omega) d\omega = \frac{1}{2} \lambda^2 A_{21} N_g \left(\frac{g_u}{g_g} \right), \quad (20.13)$$

$$\int_0^\infty I(\omega) d\omega = A_{21} N_u \left(\frac{\hbar\omega}{2\pi} \right), \text{ etc.} \quad (20.14)$$

Note that

$$\frac{g(\omega)/N_u}{k(\omega)/N_g} \propto \exp\left(-\frac{\hbar\omega}{k_B T}\right); \quad (20.15)$$

if N_u/N_g is also in equilibrium at T , this yields the correct equilibrium relation between $k(\omega)$, $g(\omega)$, $I(\omega)$, and a black body spectrum. While these relations are much more general than the QS theory, the latter provides a helpful conceptual basis. The above expressions in terms of spontaneous emission thus cover all cases.

20.2 Radiation Trapping

Atoms and ions efficiently absorb their own resonance radiation, and their emission can be reabsorbed before escaping a vapor. Molecules are less efficient absorbers, since each electronic transition branches into multiple-line bands, but interesting effects result if such reabsorption occurs. This emission and reabsorption process is fundamental to the formation of stellar lines, where it is called *radiation transfer*, and to confined vapors and plasmas where it is also called *radiation diffusion* or *trapping*. Fraunhofer's observation of dark lines in the stellar spectrum result from this radiation transfer process. Highly sophisticated treatments of line formation in inhomogeneous and nonequilibrium plasmas containing many species [19, 20] also apply to laboratory plasmas, but the simplifications inherent in a one- or two-element, confined plasma with cylindrical or planar symmetry leads to easier treatments. This sections discusses only a uniform density and temperature, confined atomic vapor.

The fluorescent lamp in which 254 nm mercury radiation diffuses to the walls and excites a phosphor, provides a prime example of radiation trapping. Its improvement motivated the seminal *Biberman* [51, 52] and *Holstein* [53, 54] theories, continuing through modern theory and experiment that is particularly relevant to electrodeless and compact lamps. Dense clouds of cold, trapped atoms are also influenced by radiation trapping. Reference [55] provides an excellent overview of this topic, which we will not discuss here. The effect of radiation trapping on the *polarization* of fluorescent radiation played a major role in developing a correct understanding of the coherent response of atoms to radiation. This is reviewed in [44], and will not be covered here. *Molisch* and *Oehry* [56] have provided a detailed discussion of research on radiation transport up to 1998.

20.2.1 Holstein–Biberman Theory

An atom in a dense vapor may be excited by externally applied radiation plus the fluorescence from other excited atoms within the vapor, and it will decay by spontaneous emission (neglecting stimulated emission). This is expressed

by the Holstein–Biberman equation

$$\frac{dn(\mathbf{r}, t)}{dt} = S(\mathbf{r}, t) + \gamma \int_{\text{vol}} K(\mathbf{r} - \mathbf{r}') n(\mathbf{r}', t) d^3 \mathbf{r}' - \gamma n(\mathbf{r}, t), \quad (20.16)$$

where $n(\mathbf{r}, t)$ is the excited state density at position \mathbf{r} , $S(\mathbf{r}, t)$ is the excitation rate due to externally applied radiation, γ is the spontaneous emission rate, the kernel $K(\mathbf{r} - \mathbf{r}')$ is the probability of a reabsorption at \mathbf{r} due to fluorescence by an atom at \mathbf{r}' , and the integral is over the vapor filled volume [51–54]. Since $K(\mathbf{r}, \mathbf{r}')$ is assumed the same for all excited atoms, this contains an implicit assumption that all atoms emit the same fully redistributed spectrum. The solution of this linear integral equation, subject to boundary values at the vapor boundary, can be expressed as a sum over an orthogonal set of solutions $n(\mathbf{r}, t)_i = n(\mathbf{r})_i \exp(-g_i \gamma t)$ of the homogeneous equation

$$n(\mathbf{r}, t) = \sum_{i=1}^{\infty} a(t)_i n(\mathbf{r})_i, \quad (20.17)$$

where, if $S(\mathbf{r}, t) = S(\mathbf{r})f(t)$, then $a(t)_i = \bar{a}_i \int_{-\infty}^t f(t') \times \exp[-g_i \gamma (t - t')] dt'$ and $\bar{a}_i = \int S(\mathbf{r}) n(\mathbf{r})_i d^3 \mathbf{r}$. Here $n(\mathbf{r}, t)_i$ is the i th normal mode and $g_i \gamma$ is the decay rate of this mode, as it would decay without change in its shape $n(\mathbf{r})_i$ from a pulse of excitation.

Two shapes of vapor regions have been studied in detail: an infinitely long cylinder of radius R and the region between two infinite parallel plates with separation L . The first three symmetric modes of the latter slab geometry are shown with unit height in Fig. 20.5. A spatial integration over the normalized $i = 1$ or fundamental mode yields 1 and all others

Fig. 20.5 The first three symmetric eigenfunctions ($j = 0, 2, 4$) of radiation trapping between slab windows, for a Doppler line profile, from [57–59]. The windows are at ± 1

integrate to zero, so $a(t)_1$ equals the total excited state population. g_1 is the escape probability; i.e., the probability of photon escape averaged over the fundamental mode distribution of emitters $n(\mathbf{r})_1$. Since $n(\mathbf{r}, t)$ must be everywhere positive, the negative contributions of the higher order modes only reduce the density in some regions. The g_i can vary from 0 to 1 and increase with increasing i , so that higher order modes die out faster after pulsed excitation. The ratios of decay rates is $g_1 : g_3 : g_5 = 1 : 3.7 : 6.4$ for the symmetric slab modes shown in Fig. 20.5. For steady state excitation, Eq. (20.17) yields $a(t)_i = \bar{a}_i / g_i \gamma$, so the lower order modes are more heavily weighted because they decay more slowly. The fundamental mode decay rate $g_1 \gamma$ is of primary interest in most situations, and we will now discuss its properties.

The kernel $K(x)$ is the probability of fluorescence transport over a distance x followed by reabsorption, averaged over the emitted frequency distribution. It is conceptually useful to express it in terms of the spectrally averaged transmission $T(x)$

$$K(x) = \frac{1}{4\pi x^2} \frac{dT(x)}{dx}, \quad (20.18)$$

$$T(x) = \int_0^{\infty} \mathcal{L}(\omega) \exp[-k(\omega)x] d\omega,$$

where $\mathcal{L}(\omega)$ is the emission line shape normalized to unit area, and $x = |\mathbf{r} - \mathbf{r}'|$. If one assumes that the fluorescence frequency of an atom does not depend on the frequency it absorbed (i.e., complete spectral redistribution), this leads to $k(\omega) = \kappa \mathcal{L}(\omega)$, where $\kappa = (\lambda^2 / 8\pi) (g_u / g_g) n \Gamma$ and g_u and g_g are statistical weights. This simplification applies under most conditions and will be used here; its range of validity and more accurate treatments are discussed below.

The transmission factor $\mathcal{L}(\omega)$ and the integrand of Eq. (20.18) are shown in Fig. 20.6, for a Gaussian line shape and several values of $k_0 x$, where k_0 is the line center absorption coefficient. At small $k_0 x$, the transmitted spectrum is similar to $\mathcal{L}(\omega)$; for these conditions $T(x) \simeq \exp(-k_{av} x)$, where $k_{av} \simeq 0.7 k_0$ is the average attenuation. For $k_0 x > 5$, the transmission is small except at the edges of the line. The transmitted radiation is then predominately in the ω region near ω_1 , defined by $k_0 x \mathcal{L}(\omega_1) = 1$. Since the integrand is sharply peaked near ω_1 , this leads to simple analytic forms for $T(x)$. In the large $k_0 x$ limit, $T(x) \simeq [k_0 x (\pi \ln k_0 x)^{1/2}]^{-1}$ in the Gaussian case, and $T(x) \simeq (\pi k_0 x)^{-1/2}$ for a Lorentzian line shape. These asymptotic forms of $T(x)$ are compared with the exact $T(x)$ in Fig. 20.7; $T(x)$ follows the asymptotic formulas for $k_0 x > 5$ and 10, respectively. $T(x)$ for several Voigt line shapes is also shown in Fig. 20.7; these follow the Gaussian $T(x)$ at smaller $k_0 x$, then rise above as ω_1 moves into the Lorentzian wing.

For radiative escape from a cell, transmission over distances near the cell dimension (R or L) is most important,

Fig. 20.6 Gaussian emission spectrum $\mathcal{L}(\omega)$ (short-dash line), transmissions $T(\omega)$ (long-dash lines), and transmitted intensities (solid lines) for $k_0 x = 2, 10,$ and 50

Fig. 20.7 Transmission $T(x)$ versus distance in units of $k_0 x$, for Voigt line shapes with the a parameters indicated, where $a = (\ln 2)^{1/2} \Delta\omega_{\text{Lor}}/\Delta\omega_{\text{Gauss}}$. The Gaussian limit corresponds to $a = 0$ and the Lorentzian limit to $a = 1$. The Holstein, large $k_0 x$, approximations are also indicated

since transport over this distance often escapes the vapor and transport over much smaller distances does not have much effect. The escape probability g_1 , averaged over the fundamental mode distribution, is close to $T(R)$ or $T(L/2)$, while the higher order modes are related to the same asymptotic forms of $T(x)$ at smaller distances. Thus, in the large $k_0 L$ slab case,

$$g_i = \frac{G_i}{k_0 L (\frac{1}{2} \ln k_0 L)^{1/2}} \quad \text{Gaussian line} \quad (20.19a)$$

$$g_i = \frac{G'_i}{(k_0 L)^{1/2}} \quad \text{Lorentzian line,} \quad (20.19b)$$

with $G_i = 1.03$ and $G'_i \simeq 0.65$. For an infinite cylinder, the same equations hold with $L/2 \rightarrow R$ and slightly larger G_i values. Exact G_i and G'_i values can be found in [57–59].

20.2.2 Additional Factors

As noted above, the line shape of a two-level atom in a thermal vapor is a Voigt shape; a convolution of a Lorentzian of width $\Gamma + 2\gamma_c$ with a Gaussian of width $\Delta\omega_D$. In most cases, $\Delta\omega_D \gg \Gamma$, so in the absence of a buffer gas the line shape is nearly Gaussian at low density (n). As a result, ω_1 is in the Gaussian region of the line at low density and g_1 behaves similarly to the Gaussian transmission in Fig. 20.7 with x replaced by the confinement dimension. k_0 is proportional to n , so from Eq. (20.19a) g_1 is approximately inversely proportional to n for $k_0 L > 5$. As n increases, ω_1 moves further into the wing of the line, and when ω_1 reaches the Lorentzian tail of the Voigt line profile a transition to Eq. (20.19b) occurs, where k_0 corresponds to a purely Lorentzian line. (That the core of the line does not have a Lorentzian shape does not matter, since the fraction of emission well into the Lorentzian wing is nearly the same as that of a pure Lorentzian line.)

In the absence of a collision, a two level atom reradiates in its rest frame the same frequency it absorbed. Thermal motion redistributes this coherent scattering frequency within the Doppler envelope when the emission and absorption are in different directions, but it does not transfer it into the natural Lorentzian wing outside the Doppler envelope. This leads to the property that an atomic vapor will scatter frequencies in the natural wing, but will not emit in this wing unless it absorbed there or is excited by or during a collision. With line broadening collisions, a fraction $\Gamma/(\Gamma + 2\gamma_c)$ of optical attenuation is coherently scattered and a fraction $2\gamma_c/(\Gamma + 2\gamma_c)$ is redistributed into *incoherent* emission with a Lorentzian spectrum of width $\Gamma + 2\gamma_c$ centered at $\omega_0 + \delta$ in the reference frame of the moving atom. This redistributed emission can escape in the Lorentzian wing of the Voigt line. In this radiation transport problem, the consequence is that Eq. (20.19b) with $k_0 = n(\lambda^2/2\pi)(\Gamma/\gamma_c)(g_u/g_g)$, corresponding to a Lorentzian with $\Gamma_{\text{Total}} = 2\gamma_c$ not $\Gamma + 2\gamma_c$, provides the best approximation to g_1 in the density region where ω_1 is in the Lorentzian wing of the line. Since $k_0 \propto n/\gamma_c$ and in the absence of a buffer gas $\gamma_c = k_c n$, where k_c is the rate coefficient for self broadening collisions, g_1 becomes independent of n . In fact, $k_c \propto \Gamma$ as well, so g_1 is also independent of Γ . For the case of a $J = 0$ ground state and a $J = 1$ excited state, $g_1 = 0.21(\lambda/L)^{1/2}$; the broadening coefficient for other cases can be found in [60]. If the broadening is due to a buffer gas, $\gamma_c = k_c n_B$ in Eq. (20.19b) yields

$$g_1 \propto \left(\frac{n_B}{n}\right)^{1/2}; \quad (20.20)$$

this has been studied in [61].

Post et al. have numerically evaluated g_1 for all values of $k_0 L$ for slab and cylinder geometries, by integrating the radiative escape probability $g(z)$ over the fundamental mode distribution $N(z)$, where z is the position between the windows [62]. To obtain $g(z)$ they integrate over the angular

distribution of the emission, using $T(x)$ from the exact line shape. Thus all features of the calculation correspond to the Holstein–Biberman theory for an isolated line without approximation. As will now be discussed real atomic vapors are generally not that simple.

Many atomic *lines* have multiple components due to hyperfine structure and isotope shifts; some components are isolated while others are separated by less than a Doppler line width and overlap. The absorption line shape then becomes a weighted sum over components, each with an equivalent Voigt shape. In a high density vapor or a plasma, collisions will usually distribute the excited state population between the isotopes and hyperfine states in proportion to their isotopic fraction and statistical weight. The emission line shape $\mathcal{L}(\omega)$ is then a similarly weighted distribution over components. Since radiation only escapes in the wings of a line component at high k_0L , overlapping components act almost as a single component. If the line has M isolated components, the right-hand side of Eqs. (20.19a) and (20.19b) become sums over the fraction f_j of the intensity in the j component times the escape probability for that component. The latter is obtained, for large k_0L , by replacing k_0 with $k_0 f_j$ in Eqs. (20.19a) and (20.19b). The net result, after summing over components, is an increase in g_1 by a factor of $\approx M$ in the Gaussian case and $\approx M^{1/2}$ in the Lorentzian. This approximation was obtained by Holstein in the context of the Hg 254 nm radiation under conditions appropriate to the fluorescent lamp [63]. Walsh made a more detailed study of these overlapping components [64], and the dependence of g_1 on the ratio of line separation to Doppler width is also given in [65].

20.2.3 Measurements

The overall behavior of g_1 versus n is shown in Fig. 20.8 for the Na($3P_{3/2}$) or D2 resonance line in pure Na vapor (i.e., the $3p^2P_{3/2} - 3s^2S_{1/2}$ transition) [65, 66]. In this type of experiment the fundamental mode decay rate is established by a combination of optimally exciting that spatial mode and of waiting until the fluorescence decay is exponential in time after termination of the excitation. A transition to approximately $1/n$ behavior, corresponding to Eq. (20.19a), is seen to occur at $k_0L/2 \approx 5$. At $k_0L/2 \approx 100$ the transition to n^0 behavior, corresponding to a self-broadened Lorentzian line in Eq. (20.19b), can be seen. The behavior at $k_0L < 5$ fits the Milne diffusion theory [67] as well as the Post et al. theory shown as a solid line; this is also similar to $T(L/2)$, as seen in Fig. 20.7. For $5 < k_0L/2 < 100$, the behavior is similar to Eq. (20.19a) (dashed line), but the Post et al. theory (solid line) is $\approx 20\%$ higher due to the inclusion of the Na hyperfine structure (hfs splitting \simeq Doppler width). For $k_0L/2 > 1000$,

Fig. 20.8 Radiative escape probability g_1 for Na vapor excited to the $3P_{3/2}$ state, for a slab geometry. The Holstein (H) approximation for the $3P_{3/2}-3S_{1/2}$ (D2) line and the $3P_{1/2}-3S_{1/2}$ (D1) line are indicated as *dashed lines*. The Post-type (P) calculation of [80] for the D2 line is indicated as a *solid line*. *Solid squares* are data from [66], and *open circles* are data from [65]. The effective escape probability corresponds to the D2 line rate at low densities but a combination of D1 and D2 at high densities

the Post theory converges to the Holstein–Lorentzian-line result with $\Gamma_{\text{Total}} = 2\gamma_c$.

The experiment is complicated in the $50 < k_0L/2 < 500$ region by fine structure mixing [66]. The $3P_{3/2}$ state was excited, but at high densities, collisions populate the $3P_{1/2}$ state, which has a smaller g_1 than the $3P_{3/2}$ state (Fig. 20.8). At low densities, $g_1^{\text{eff}} = g_1(3P_{3/2})$, and at high densities these states are statistically populated and $g_1^{\text{eff}} = \frac{1}{3}g_1(3P_{1/2}) + \frac{2}{3}g_1(3P_{3/2})$. The transition density where the fine structure mixing rate R equals Γ_{eff} is indicated in Fig. 20.8. The theory is also complicated in this intermediate k_0L region by the necessity of including incomplete frequency redistribution [62]; this leads to the dip in g_1 near $k_0L \approx 500$. While the overall behavior of the data in Fig. 20.8 is consistent with the Post et al. theory, there is $\approx 30\%$ systematic discrepancy at $k_0L/2 = 10-100$ and the dip near 500 is not seen. Part of this difference probably results from the experimental geometry, which was between a slab and a cylinder of radius $R = L/2$; g_1 for the cylinder is 17% larger than the slab value used in Fig. 20.8.

The fundamental mode decay rate has also been measured for the Hg 254 nm [68] and 185 nm [62] lines, for the Ne resonance line [69] and for the Ar resonance line [70]. The Hg measurements are complicated by multiple isotopes and hyperfine structure, producing a mixture of partially overlapping and isolated lines combined with density-dependent uncertainties in excited state populations of the various isotopes. Serious efforts to model and measure these effects

have been made [62, 64, 68, 71]. The Ne and Ar measurements have similar complications, as will now be discussed.

In essence, g_1 behaves like the Gaussian $T(x = L/2)$ in Fig. 20.7 until n is large enough for ω_1 to approach the collision induced Lorentzian wing of the Voigt line. g_1 then decreases more slowly since the line wing does not fall off as rapidly as a Gaussian. With continued increase in n , ω_1 moves further into the Lorentzian wing, a broader spectral region escapes and g_1 reaches a minimum. Finally, when the entire escaping spectral region is Lorentzian, g_1 reaches the constant value described above. Independent and detailed treatments of this density region, including incomplete frequency redistribution, predict a dip in g_1 as seen in Fig. 20.8 [62, 70, 72, 73]. However, this has not been clearly confirmed experimentally. In Fig. 20.8 this dip occurs where fine structure mixing also occurs, and in addition the data are higher than the calculations throughout this n region. Post et al. [62] did observe such a dip for the Hg (149 nm) resonance line, but the data do not fit the calculation at other densities; hyperfine and isotopic structure within the line cause major complications. This long-standing issue has finally been clarified by *Menningen* and *Lawler* [74], who measured the decay of the Hg (185 nm) resonance line following laser excitation. They observed a clear dip in g_1 due to incomplete redistribution. They also carried out sophisticated Monte Carlo simulations, obtaining g_1 values that compared favorably with the measurements. By extending the simulations over a large range of a parameter space, they constructed an analytic formula for g_1 of a single-component line in cylindrical geometry [75]. This formula includes effects of incomplete frequency redistribution and varying ratios of Doppler broadening, radiative broadening and collisional broadening, so that it can be applied to any resonance line. *Payne* et al. [70] did not observe the predicted dip for the Ar resonance line; again a minor isotope with an isolated line occurs and could be very important at these high optical depths. *Phelps* [69] reported such a dip for the Ne 74.3 nm resonance line, but with rather large uncertainties due to the necessity of correcting for other collisional effects. Again there are isotopes with isolated lines that may have affected the data. Thus, experiments have verified the essential aspects of the above theories, but quantitative agreement in all aspects has not yet been achieved.

The fact that the escaping radiation is concentrated in the wings of the line, near the unity optical depth point ω_1 , is reflected in the emitted spectrum. Calculated examples are shown in [73]; the Gaussian case looks somewhat like the transmitted spectra in Fig. 20.6 for $x \approx L/4$. These spectra, and all results described so far, are calculated assuming no motion of the atoms. This is appropriate in the central region of the vapor, because the distance moved in an excited state lifetime ($L_v = v/\Gamma$) is much smaller than L . In fact, resonant collisions between excited and ground state

atoms further limits the distance an excited atom moves in one direction before transfer of excitation. However, near the window or wall of the container, atomic motion will cause wall collisions of excited atoms and loss of radiation. This loss will be primarily within the Doppler core of the line, since these frequencies can only escape if emitted near the vapor edge. This loss depends on the excited state density in the neighborhood of the wall, and can be significant if $L_v > 1/k_0$. The excited atom density near the wall must be self consistent with the radiation transport and wall quenching. This situation has been modeled and studied experimentally ([76] and references therein).

Additional aspects of radiation trapping, such as higher-order spatial modes and non-uniform absorber distributions, can be significant in lighting plasmas (and trapped atom clouds). Propagator function techniques have been developed for modeling radiation transport when the excitation has unusual temporal or spatial character [77, 78]. Non-uniform absorber spatial distributions can be particularly important at high power densities, and have been considered in [79].

Abstract

The key idea in Thomas–Fermi theory and its generalizations is the replacement of complicated terms in the kinetic energy and electron–electron repulsion energy contributions to the total energy by relatively simple functionals of the electron density ρ . This chapter first describes Thomas–Fermi theory and then its various generalizations that attempt to correct, with varying success, some of its deficiencies. It concludes with an overview of the Hohenberg–Kohn and Kohn–Sham density functional theories.

Keywords

density functional theory · neutral atom · external potential · electronic probability density · Scott correction

21.1 Introduction

In the early years of quantum physics, *Thomas* [1] and *Fermi* [2–5] independently invented a simplified theory, subsequently known as *Thomas–Fermi theory*, to describe nonrelativistically an atom or atomic ion with a large nuclear charge Z and a large number of electrons N . Many qualitative features of this model can be studied analytically, and the precise solution can be found by solving numerically a nonlinear ordinary differential equation. *Lenz* [6] demonstrated that this equation for the electrostatic potential could be derived from a variational expression for the energy as a functional of the electron density. Refinements to Thomas–Fermi theory include a term in the energy functional to account for electron exchange effects introduced by *Dirac* [7] and nonlocal gradient corrections to the kinetic energy introduced by *von Weizsäcker* [8].

Although the Hartree–Fock method or other more elaborate techniques for calculating electronic structure now provide much more accurate results (Chaps. 22–24), Thomas–Fermi theory provides quick estimates and global insight into the total energy and other properties of a heavy atom or ion. A rigorous analysis of Thomas–Fermi theory by *Lieb* and *Simon* [9, 10] showed that it is asymptotically exact in that it yields the correct leading asymptotic behavior, for both the total nonrelativistic energy and the electronic density, in the limit as both Z and N tend to infinity, with the ratio Z/N fixed. (In a real atom, of course, relativistic and other effects become increasingly important as Z increases.) However, Thomas–Fermi theory has the property that molecules do not bind, as first noted by *Sheldon* [11] and proved by

e-mail: jdmorgan@udel.edu

Teller [12]. That the interatomic potential energy curve for a homonuclear diatomic molecule is purely repulsive was demonstrated by Balázs [13].

This *no binding* property of clusters of atoms was used by Lieb and Thirring [14] to prove the *stability of matter*, in the sense that as the number of particles increases, the total nonrelativistic energy decreases only linearly rather than as a higher power of the number of particles, as it would if electrons were bosons rather than fermions. Lieb went on to explore the mathematical structure of the modifications of the Thomas–Fermi model when gradient terms (von Weizsäcker) and/or exchange (Dirac) terms are included [15, 16]. A review article by Spruch [17] explicates the linkage between long-developed physical intuition and the mathematically rigorous results obtained in the 1970s and 1980s. The older literature was reviewed by Gombás [18, 19] and by March [20].

An outgrowth of Thomas–Fermi theory is the general density functional theory initiated by Hohenberg and Kohn [21] and by Kohn and Sham [22], as discussed in Sect. 21.4.

21.2 Thomas–Fermi Theory and Its Extensions

21.2.1 Thomas–Fermi Theory

In a D -dimensional Euclidean space, the expectation value of the electronic kinetic energy operator in a quantum state ψ can be approximated by

$$\frac{\hbar^2}{m_e} 2\pi^2 \frac{D}{D+2} \left(\frac{D}{2\Omega_D} \right)^{2/D} \int \rho^{(D+2)/D}(\mathbf{r}) d^D r, \quad (21.1)$$

where

$$\Omega_D = \frac{D\pi^{D/2}}{\Gamma(1 + \frac{D}{2})} \quad (21.2)$$

is the surface area of a unit hypersphere in D dimensions [17, p. 176]. These expressions can easily be derived by considering the energy levels of a system of a large number of noninteracting fermions confined to a D -dimensional box. Specialization to the physically interesting case of $D = 3$ yields the well-known expression

$$\frac{\hbar^2}{m_e} 2\pi^2 \frac{3}{5} \left(\frac{3}{2\Omega_3} \right)^{2/3} \int \rho^{5/3}(\mathbf{r}) d\mathbf{r}, \quad (21.3)$$

where

$$\Omega_3 = \frac{3\pi^{3/2}}{\Gamma(1 + \frac{3}{2})} = 4\pi. \quad (21.4)$$

The electron–nucleus attraction energy in a three-dimensional space is given exactly by

$$\int \rho(\mathbf{r}) V(\mathbf{r}) d\mathbf{r}, \quad (21.5)$$

where $V(\mathbf{r})$ is the Coulomb potential due to a single nucleus [$V(\mathbf{r}) = -Z/r$] or several nuclei [$V(\mathbf{r}) = -\sum_i Z_i/|\mathbf{r} - \mathbf{R}_i|$]. The electron–electron Coulomb repulsion energy in a three-dimensional space is approximated by

$$U[\rho] = \frac{1}{2} \int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}', \quad (21.6)$$

which tends to overestimate the actual repulsion energy because it includes the self-energy of the densities of individual electrons. This is, however, a higher-order effect for a system with a large number of electrons concentrated in a small region of space. As was suggested by Fermi and Amaldi [23], this overestimation can be approximately corrected for an atom with N electrons by multiplying this term by the ratio of the number of ordered pairs of different electrons to the total number of ordered pairs

$$\frac{N(N-1)}{N^2} = 1 - \frac{1}{N}. \quad (21.7)$$

This is approximately correct for an atom, with many electrons concentrated close together, but it would still be an overestimate for a diffuse system, such as one composed of N electrons and N protons separated by large distances of $O(R)$, for which the ground-state electron–electron repulsion term should be proportional to $\frac{1}{2}N(N-1)/R$ rather than to N times a constant of $O(1)$. For this reason, the Fermi–Amaldi correction, which complicates the mathematical analysis without eliminating the unphysical overestimation of the electron–electron repulsion term, is not usually included. It is evident that the treatment of both the electronic kinetic energy term and the electron–electron repulsion energy term depends on the assumption that the number N of electrons (actually, the number of electrons *per atom*) is large. Hence, the Thomas–Fermi model is sometimes called the *statistical model* of an atom.

The three contributions to the total energy are now added together, and one seeks to minimize their sum, the Lenz functional [6]

$$E[\rho] = \frac{\hbar^2}{m_e} 2\pi^2 \frac{3}{5} \left(\frac{3}{2\Omega_3} \right)^{2/3} \int \rho^{5/3}(\mathbf{r}) d\mathbf{r} + \int \rho(\mathbf{r}) V(\mathbf{r}) d\mathbf{r} + \frac{1}{2} \int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}', \quad (21.8)$$

over all admissible densities ρ . The mathematical question now arises: what is an admissible density? The answer was provided by Lieb and Simon [9, 10]: a density for which both

$$\int \rho(\mathbf{r}) d\mathbf{r}, \quad (21.9)$$

the total number of electrons, and

$$\int \rho^{5/3}(\mathbf{r}) d\mathbf{r}, \quad (21.10)$$

which is proportional to the estimate of their kinetic energy, are finite, automatically yields finite values of the other terms in the expression for the energy. As Lieb and Simon proved, the minimization of this functional over all such densities yields a well-determined result.

Carrying out the variation of $E[\rho]$ with respect to ρ yields the Euler–Lagrange equation

$$0 = \frac{\hbar^2}{m_e} 2\pi^2 \left(\frac{3}{2\Omega_3} \right)^{2/3} \rho^{2/3}(\mathbf{r}) + V(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' . \quad (21.11)$$

The sum of the last two terms is, of course, the negative of the total electrostatic potential $\phi(\mathbf{r})$, so one sees that in Thomas–Fermi theory, the density is proportional to the 3/2-power of the potential. To simplify subsequent manipulations, let

$$\frac{\hbar^2}{m_e} 2\pi^2 \left(\frac{3}{2\Omega_3} \right)^{2/3} = \frac{\hbar^2}{2m_e} (3\pi^2)^{2/3} = \gamma_p , \quad (21.12)$$

so that

$$\gamma_p \rho^{2/3}(\mathbf{r}) = \phi(\mathbf{r}) . \quad (21.13)$$

By Poisson’s theorem,

$$-\nabla^2 \phi = 4\pi \left[\sum_i Z_i \delta^{(3)}(\mathbf{r} - \mathbf{R}_i) - \rho(\mathbf{r}) \right] , \quad (21.14)$$

and from Eq. (21.13) one has $\rho = \gamma_p^{-3/2} \phi^{3/2}$, so from the integral equation for the electronic density ρ , one obtains the differential equation

$$-\nabla^2 \phi = 4\pi \left[\sum_i Z_i \delta^{(3)}(\mathbf{r} - \mathbf{R}_i) - \gamma_p^{-3/2} \phi^{3/2} \right] , \quad (21.15)$$

for the potential ϕ . In the case of a single nucleus, the usual separation of variables in spherical polar coordinates yields for ϕ the ordinary differential equation

$$\frac{1}{r} \frac{d^2}{dr^2} (r\phi) = 4\pi \gamma_p^{-3/2} \phi^{3/2} , \quad (21.16)$$

whose similarity to Emden’s equation, which Eddington used to study the internal constitution of stars, was recognized by Milne [24]. The numerical solution of this equation with the appropriate boundary conditions at $r = 0$ and $r = \infty$ was discussed extensively by Baker [25], and accurate solutions tabulated by Tal and Levy [26]. The numerical solution determines that the total energy of a neutral atom is

$$E = -3.67874521\dots \gamma_p^{-1} Z^{7/3} \\ = -1.53749024\dots Z^{7/3} \text{Ry} . \quad (21.17)$$

Another possibility is to do the constrained minimization over all densities that obey

$$\int \rho(\mathbf{r}) d\mathbf{r} = \lambda , \quad (21.18)$$

where λ is the number of electrons, which for purposes of mathematical analysis is allowed to be nonintegral. One then introduces a Lagrange multiplier $-\mu$, the *chemical potential*, to correspond with this constraint, and thereby obtains the Euler–Lagrange equation

$$0 = \frac{\hbar^2}{m_e} 2\pi^2 \left(\frac{3}{2\Omega_3} \right)^{2/3} \rho^{2/3}(\mathbf{r}) + V(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' + \mu , \quad (21.19)$$

which holds wherever ρ is positive. As was shown by Lieb and Simon [9, 10], this procedure, too, is well defined. The analogue of Eq. (21.13), the relationship between the density and the electrostatic potential for the neutral atom, is now

$$\gamma_p \rho^{2/3}(\mathbf{r}) = [\phi(\mathbf{r}) - \mu]_+ , \quad (21.20)$$

where $[f]_+ = \max(f, 0)$. The corresponding differential equation for the potential ϕ is

$$-\nabla^2 \phi = 4\pi \left[\sum_i Z_i \delta^{(3)}(\mathbf{r} - \mathbf{R}_i) - \gamma_p^{-3/2} [\phi(\mathbf{r}) - \mu]_+^{3/2} \right] . \quad (21.21)$$

Lieb and Simon rigorously proved a large number of results concerning the solution of the Thomas–Fermi model. When $V(\mathbf{r})$ is a sum of Coulomb potentials arising from a set of nuclei of positive charges Z_i , with $\sum_i Z_i = Z$, then the energy $E(\lambda)$ is a continuous, monotonically decreasing function of λ for $0 \leq \lambda \leq Z$, and its derivative $dE/d\lambda$ is the chemical potential $-\mu(\lambda)$, which vanishes at $\lambda = Z$. For λ in this range, there is a unique minimizing density ρ , whereas for $\lambda > Z$ there is no unique minimizing ρ , since one can place arbitrarily large clumps of charge with arbitrarily low positive energies arbitrarily far away from the nuclei. In the atomic case, with a single nucleus, $\rho(\mathbf{r})$ is a spherically symmetric monotonically decreasing function of r .

Moreover, for an atom or atomic ion, the Thomas–Fermi density obeys the *virial theorem*

$$2\langle \mathcal{T} \rangle = -\langle V \rangle = -2E , \quad (21.22)$$

and for a neutral atom the electronic kinetic energy, electron–nucleus attraction energy, and electron–electron repulsion

energy terms in the expression for the total energy satisfy the ratios 3 : -7 : 1.

It is straightforward to examine the behavior of the Thomas–Fermi density ρ in the limit as either $r \rightarrow 0$ or $r \rightarrow \infty$. For large r , the electron density vanishes identically outside a sphere of finite radius for a positive ion. For a neutral atom, the ordinary differential equation (21.16) for the potential ϕ can be analyzed to show that

$$\phi(r) \simeq \gamma_p \left(\frac{3\gamma_p}{\pi} \right)^2 r^{-4}, \quad (21.23)$$

from which it follows that

$$\rho(r) \simeq \left(\frac{3\gamma_p}{\pi} \right)^3 r^{-6}, \quad (21.24)$$

independent of Z . This implies that as $Z \rightarrow \infty$, a neutral atom described by the Thomas–Fermi model has a finite size defined in terms of a radius within which all but a fixed amount of electronic probability density is located. For example, if one defines the size of an atom as that value of r_a for which

$$\int_{|r| \geq r_a} \rho(\mathbf{r}) d\mathbf{r} = \frac{1}{2}, \quad (21.25)$$

one finds that in the large- Z limit

$$r_a = \left(\frac{8\pi}{3} \right)^{1/3} \frac{3\gamma_p}{\pi}. \quad (21.26)$$

In atomic units, $\gamma_p = \frac{1}{2}(3\pi^2)^{2/3}$, and

$$r_a = (9\pi)^{2/3} a_0 \simeq 9.3 a_0, \quad (21.27)$$

which is about what one would expect for a *real* nonrelativistic atom with a large nuclear charge Z . On the other hand, the characteristic distance scale in Thomas–Fermi theory, defined as the *average* value of r , or in terms of a radius within which a fixed *fraction* of electronic probability density is located, is proportional to $Z^{-1/3}$, which shrinks to 0 as $Z \rightarrow \infty$. The resolution of this paradox is that outside the typical *core* scale of distance set by $Z^{-1/3}$, within which most of the electron density is located, there resides in the *mantle* region a fraction of electrons proportional to $Z^{2/3}/Z = Z^{-1/3}$, and almost all of these are concentrated within a sphere of radius of about $10 a_0$.

Moving deeper into the core and approaching the nucleus, the $-Z/r$ singularity in the electron–nucleus Coulomb potential dominates the smeared-out electron–electron potential, so one readily finds that

$$\rho(r) \simeq \left(\frac{Z}{\gamma_p r} \right)^{3/2}. \quad (21.28)$$

This singularity is integrable but unphysical, since it arises from the approximation of the local kinetic energy by $\rho^{5/3}$, which breaks down where ρ is rapidly varying on a length scale proportional to $1/Z$. In a *real* nonrelativistic heavy atom governed by the Schrödinger equation, the actual electron density at the nucleus is finite, being proportional to Z^3 . This unphysical singularity in the electron density in Thomas–Fermi theory can be eliminated by adding a gradient correction to the Thomas–Fermi kinetic energy term, as discussed in the following section.

21.2.2 Thomas–Fermi–von Weizsäcker Theory

The semiclassical approximation Eq. (21.3) for the quantum kinetic energy in terms of a power of the density is capable of improvement, particularly in regions of space where the density is rapidly varying. The incorporation of such corrections leads to a gradient expansion for the kinetic energy [27]. The leading correction is of the form

$$\frac{\hbar^2}{2m} \int |(\nabla \rho^{1/2})(\mathbf{r})|^2 d\mathbf{r}. \quad (21.29)$$

Addition of such a term to the Thomas–Fermi expression for the kinetic energy yields a theory that avoids many of the unphysical features of ordinary Thomas–Fermi theory at very short and moderately large distances. The more important points, as rigorously proved in Lieb’s review article [15, 16], are as follows. The leading features of the energy are unchanged; for large Z , the energy $E(Z)$ of a neutral atom or atomic ion is still proportional to $Z^{7/3}$, but now there enter higher-order corrections arising from the gradient terms of order $Z^{7/3}Z^{-1/3} = Z^2$ and higher powers of $Z^{-1/3}$. The maximum number of electrons that can be bound by an atom of nuclear charge Z is no longer exactly Z , but a slightly larger number; thus, Thomas–Fermi–von Weizsäcker theory allows for the formation of negatively charged atomic ions. It was further proven by *Benguria* and *Lieb* [28] that in the Thomas–Fermi–von Weizsäcker model a neutral atom can bind at most one extra electron, and that a neutral molecule can bind at most as many extra electrons as it has nuclei.

The effect on the electronic density ρ is more profound. While the general shape and properties of ρ in the *core* and *mantle* regions is unchanged, the fact that $\nabla \rho^{1/2}$ need not, and in general does not, vanish when ρ vanishes on some surface implies that for a positive ion ρ no longer vanishes outside of a sphere, as it does in the case of Thomas–Fermi theory, but instead extends over all space. For positive ions, neutral atoms, and negative ions alike, *differential inequality* techniques [29] can be used to show that $\rho(r)$ decays exponentially for large r , with the constant in the exponential proportional to $(\mu(\lambda))^{1/2}$. For small r , the gradient terms

dominate the energy expression, so one finds that the electronic density no longer diverges as $r \rightarrow 0$, but instead tends to a finite limit, with a first derivative that obeys a relation analogous to the Kato cusp condition [30]

The study of molecules within the Thomas–Fermi–von Weizsäcker model involves several subtleties and pitfalls, which can lead to physical absurdities. Since two neutral atoms with different nuclear charges will, in general, have different chemical potentials, a pair of such atoms placed a long distance apart will *spontaneously ionize*, with a small amount of electric charge being transferred from one to the other until the chemical potentials of the positively charged ion and the negatively charged ion become equal. The result is a long-range Coulomb attraction between them [31]. This phenomenon does *not* occur in the real world, since the amount of electric charge that can be transferred is quantized in units of $-e$, and it is empirically true that the smallest atomic ionization potential exceeds the largest atomic electron affinity. For two neutral atoms with the same nuclear charges, the situation is more subtle. Nonetheless, a careful analysis shows that in this case, too, although no spontaneous ionization occurs, there is a long-range attractive interaction between them arising from the overlap of the exponentially small tails of the electron clouds. Since electron correlation is not included in this model, it could not be expected to describe attractive van der Waals forces.

In summary, the Thomas–Fermi–von Weizsäcker model yields a more realistic picture of a single atom than does the Thomas–Fermi model. However, it does not provide a useful picture for understanding the interaction between atoms at large distances. These kinds of unphysical features provide a glimpse into the complicated nature of the universal density functional, which must include terms that rigorously suppress an unphysical feature like spontaneous ionization of a distant pair of heteronuclear atoms [32, 33]. It is evident from the mathematical properties of Thomas–Fermi–von Weizsäcker theory and related models that a density functional that fixes up the Thomas–Fermi expression simply by adding a few gradient terms and/or simple exchange terms and the like must still differ in important ways from the universal density functional, particularly for properties of extended systems.

21.2.3 Thomas–Fermi–Dirac Theory

The effect of the exchange of electrons can be approximated, following Dirac [7], by including in the Thomas–Fermi energy functional an expression of the form

$$-\frac{1}{4\pi^3}(3\pi^2)^{4/3} \int \rho^{4/3}(\mathbf{r})d\mathbf{r} . \quad (21.30)$$

Minimization of the resulting Thomas–Fermi–Dirac energy functional over all admissible densities ρ whose integral is λ yields a well-defined $E(\lambda)$, which has the correct behavior for $\lambda \leq Z$, and it has been shown that for an atom, the exchange correction to the energy is of order $Z^{5/3}$. However, this model exhibits unphysical behavior for $\lambda > Z$, because one can obtain a completely artificial lowering of the energy by placing many small clumps of electrons a large distance from the nucleus, for which the negative $\int \rho^{4/3}d\mathbf{r}$ term dominates the energy expression [15, 16]. At the conclusion of his original article, Dirac clearly stated that the correction he had derived, although giving a better approximation in the interior of an atom, gives a *meaningless result for the outside of the atom* [7]. It is, therefore, clear that any physically reasonable theory must somehow profoundly modify this correction in the region where the electronic density is very small.

21.2.4 Thomas–Fermi–von Weizsäcker–Dirac Theory

One can also include the Dirac exchange correction in the Thomas–Fermi–von Weizsäcker energy functional. In this case, however, the mathematical foundations of the theory are still incomplete ([15, 16, pp. 638–639]). Nonetheless, it is clear that this theory, too, suffers from the unphysical lowering of the energy by small clumps of electrons at large distances from the nucleus.

In summary, one can say that the inclusion of Dirac’s exchange correction in its most straightforward form leads to an improvement of energies for positive ions or neutral atoms but to unphysical behavior for systems where the charge of the electrons exceeds the nuclear charge, in line with Dirac’s own observations on the limitations of his correction [7]. Here, we again see a manifestation of how complicated the behavior of the true universal density functional must be.

21.2.5 Thomas–Fermi Theory with Different Spin Densities

As was remarked by Lieb and Simon [10], it is possible to consider a variant of Thomas–Fermi theory with a pair of spin densities ρ_α and ρ_β for the spin-up and spin-down electrons, with the two adding together to produce the total electronic density ρ . This theory was rigorously formulated and analyzed by Goldstein and Rieder [34]. Because the problem is nonlinear, the mathematical complications are substantial, and the theory is not a trivial extension of ordinary Thomas–Fermi theory. Goldstein and Rieder first considered the case where the total number of electrons of each type of spin is specified in advance [35]. There is no mathematical obstacle to constructing such a spin-

polarized Thomas–Fermi theory, but it does not yield the kind of spontaneous spin-polarization that one observes in the ground states of many real quantum mechanical atoms and molecules, which is not surprising in view of the fact that such spin-polarization in accord with Hund’s first rule arises from exchange and correlation effects not included in this simple functional. However, in the case where the electronic spins (but *not* their currents) are coupled to an external magnetic field, the ground state is naturally spin-polarized [34].

21.3 Nonrelativistic Energies of Heavy Atoms

Thomas–Fermi theory suggests that Eq. (21.17) provides the leading term in a power series expansion for the nonrelativistic energy of a neutral atom of the form

$$E(Z) = -(c_7 Z^{7/3} + c_6 Z^{6/3} + c_5 Z^{5/3} + \dots), \quad (21.31)$$

with $c_7 = 1.53749024\dots \text{Ry}$, $c_6 = -1 \text{ Ry}$, and $c_5 \simeq 0.5398 \text{ Ry}$. The c_6 term was first calculated by Scott [36] from the observation that it arises from the energy of the innermost electrons for which the electron–electron interaction can be neglected. The difference between the exact and Thomas–Fermi energies for this case of noninteracting electrons yields the correct c_6 [17, 37]. A mathematically nonrigorous but physically insightful justification of the Scott correction was provided in 1980 by Schwinger [38]. This result has now been rigorously proved, with upper and lower bounds coinciding [39–43].

The c_5 term is much more subtle, since it arises from a combination of effects from the exchange interaction and from the bulk motion of electrons in the Thomas–Fermi potential. A general analytic procedure devised by Schwinger [44] yields the above value, in good agreement with a much earlier estimate by March and Plaskett [45].

A numerical check of these results, based on a fit to Hartree–Fock calculations for Z up to 290 with correlation corrections, yielded the values [46] $c_5 = 0.55 \pm 0.02 \text{ Ry}$ and $c_4 \simeq 0$. It seems likely that, because of shell structure, the terms c_4 and beyond have an oscillatory dependence on Z [47]. The oscillatory structure and other refinements of Thomas–Fermi theory are considered in a series of papers by Englert and Schwinger [48–54] and a book by Englert [55].

Iantchenko, Lieb, and Siedentop [56] proved Lieb’s *strong Scott conjecture* that for small r , the rescaled density for the exact quantum system converges to the sum of the densities of the bound noninteracting hydrogenic orbitals; the properties of this function were explored by Heilman and Lieb [57]. Fefferman and Seco [58] rigorously proved the correctness of Schwinger’s procedure for calculating not just the $O(Z^{6/3})$ Scott correction but also the $O(Z^{5/3})$ exchange term. Their full proof includes a demonstration that the Hartree–Fock en-

ergy agrees with the exact quantum energy through $O(Z^{5/3})$, with an error of smaller order [59]. Numerous auxiliary theorems and lemmas are published in [60–63]. Progress toward obtaining higher-order oscillatory terms is described in [64–68]. The analytical evaluation of accurate approximations to the energy of a heavy atom, or at least of the contributions to that energy of all but the few outermost electronic orbitals, would be of particularly great value if it led to the construction of more accurate and better justified pseudopotentials [69–72] for describing the valence orbitals.

21.4 General Density Functional Theory

The literature on general density functional theory and its applications is enormous, so any bibliography must be selective. The reader interested in learning more could begin by consulting a number of review articles [73–79], collections of articles [80–82], conference proceedings [83–93], and the textbooks by Parr and Yang [94] and by Dreizler and Gross [95].

21.4.1 The Hohenberg–Kohn Theorem for the One-Electron Density

In 1964, Hohenberg and Kohn [21] argued that there exists a universal density functional $F[\rho]$, independent of the external potential $V(\mathbf{r})$, such that minimization of the sum

$$F[\rho] + \int \rho(\mathbf{r})V(\mathbf{r})d\mathbf{r}, \quad (21.32)$$

subject to the constraint

$$\int \rho(\mathbf{r})d\mathbf{r} = N \text{ (a positive integer)}, \quad (21.33)$$

yields the ground state energy of a quantum-mechanical N -electron system moving in this external potential. However, Hohenberg and Kohn’s theorem is like a mathematical *existence theorem*; no procedure exists to calculate this unknown universal functional explicitly, which surely is extremely complicated if it can be written down at all in closed form. (E. Bright Wilson, however, defined it, implicitly and whimsically, as follows: “Take the ground-state density and integrate it to find the total number of electrons. Find the cusps in the density to locate all nuclei, and then use the cusp condition – that the radial derivative of the density at the cusp is minus twice the nuclear charge density at each cusp – to determine the charges on each nucleus. Finally solve Schrödinger’s equation for the ground-state density or any other property that is desired” (paraphrased by B. I. Dunlap, in [89, p. 3], from J. W. D. Connolly).)

Moreover, Hohenberg and Kohn glossed over two problems: it is not clear *a priori* that every well-behaved ρ is derivable from a well-behaved properly antisymmetric many-electron wave function (the so-called *n*-representability problem, since *n* was used by Hohenberg and Kohn to represent the density of electrons), and it is also not clear *a priori* that every well-behaved density ρ can be derived from a quantum-mechanical many-electron wave function ψ , which is the properly antisymmetric ground-state wave function for a system of electrons moving in some external potential $V(\mathbf{r})$ (the so-called *v*-representability problem, since Hohenberg and Kohn used *v* in place of V).

The *n*-representability problem was solved by *Gilbert* [96] and by *Harriman* [97], who gave a prescription for starting from an arbitrary well-behaved ρ and from it constructing a many-electron wave function ψ that generated that ρ [33, 98]. The *v*-representability problem is much more formidable, as demonstrated by the discovery that there are well-behaved densities ρ that are *not* the ground-state densities for any fermionic system in an external potential V [98, 99]. Following *Percus*' definition of a universal kinetic energy functional for independent fermion systems [100], *Levy* [101] proposed to circumvent this *v*-representability problem by modifying the definition of $F[\rho]$ so that instead of being defined in terms of densities that might not be *v*-representable, it is defined as

$$F[\rho] = \min[\psi, (T + V)\psi], \quad (21.34)$$

with the minimum being taken over all properly antisymmetric normalized ψ 's that yield that ρ .

A great deal of effort has been devoted to trying to find approximate representations of the universal functional $F[\rho]$. One route is mathematical, and features a careful exploration of the abstract properties that $F[\rho]$ must have. Another route is numerical, and can be characterized as involving the guessing of some *ansatz* with a general resemblance to Thomas-Fermi-von Weizsäcker-Dirac theory, with some flexible parameters determined by least-squares fitting of the energies resulting from insertion of Hartree-Fock densities into the trial functional to theoretical Hartree-Fock energies, or the like. If, however, the basic *ansatz* exhibits unphysical features in the case of negatively charged ions or heteronuclear molecules, it is not likely that the optimization of parameters in that *ansatz* will get one closer to the true universal density functional. In the opinion of this writer, significant progress in density functional theory based solely upon the one-electron density is likely to require a major revolution in our mathematical understanding of this field, with a useful procedure made explicit for constructing progressively better approximations to the universal density functional, which, like π or other transcendental numbers, will probably never be written down exactly in closed form. Moreover, the numerical solution of the highly nonlinear Euler-Lagrange equations for

a very complicated density functional is likely to require large amounts of computer time, as well as problems with landing in local minima of the energy.

21.4.2 The Kohn-Sham Method for Including Exchange and Correlation Corrections

Density functional theory posed solely in terms of the one-electron density and based upon the Hohenberg-Kohn variational principle provides no general procedure for accurately calculating relatively small energy differences such as excitation energies, ionization potentials, electron affinities, or the binding energies of molecules. There is, however, a powerful method inspired by the Hohenberg-Kohn variational principle, which has been used with great success in the calculation of such quantities. This is the Kohn-Sham variational method [22].

The key idea in the Kohn-Sham variational method is to replace the nonlocal exchange term in the Hartree-Fock equations with an exchange-correlation potential, which, at least in principle, can be used to determine energies exactly. The oldest, simplest, and most common *ansatz* used for the exchange-correlation potential involves the local density approximation (LDA), in which one assumes that the exchange-correlation potential for the actual system under study has the same functional form as does the exchange-correlation potential for a uniform interacting gas of electrons. If the density is not too small or not too rapidly varying, the exchange part of this potential can be approximated by $\rho^{1/3}$, which appears in Dirac's first-order approximation for exchange energies, with a systematic procedure for deriving higher-order corrections in a gradient expansion. The correlation part of this potential is accurately known from *Ceperley* and *Alder*'s quantum Monte Carlo calculation of the properties of the uniform electron gas [102]. One, therefore, retains the important features of the quantum theory based on wave functions, with a determinantal approximation to ψ , while approximately including exchange and correlation effects through a simply computable effective potential. Higher corrections, which are important for quantitative accuracy, can be incorporated by taking account of the variation of ρ by means of a gradient expansion [27] involving $\nabla\rho$ and higher derivatives [95, Chap. 7], thus yielding a generalized gradient approximation (GGA) for the exchange-correlation potential.

The Kohn-Sham procedure has become the backbone for the vast majority of accurate calculations of the electronic structure of solids [78, 92]. In the 1990s, motivated by *Becke*'s work on constructing simple gradient-corrected exchange potentials [103–109], and incorporating the *Lee, Yang, and Parr* (LYP) expression for the correlation potential [110] derived from *Colle* and *Salvetti*'s correlation-energy formula [111–113], the Kohn-Sham method is find-

ing increasing application in efficiently estimating relatively small energy differences of relevance to chemistry [114–116] (However, Becke's gradient-corrected exchange potential does *not* have the correct $1/r$ behavior at large r , as was observed by several authors [117–119]). For definitive results, however, one must still resort to an *ab initio* theory that, at least in principle, converges toward the correct result.

The generation of improved generalized gradient approximations has recently become a growth industry, with increasingly many proposals of increasingly greater complexity [103, 110, 119–131]. Inevitably, some expressions work better for some properties than for others. It is found that usually most of the errors in the long-range tails of the exchange and correlation potentials tend to cancel each other, thus leading to better overall energies than one could reasonably expect [132]. Under these circumstances, it is important to have benchmarks for testing the accuracy of the various approximations. Such comparisons have been carried out for two important sets of two-electron systems [133–135]:

1. A pair of electrons moving in harmonic potential wells and coupled by the Coulomb repulsion, which yields an exactly solvable system.
2. Helium-like ions of variable nuclear charge Z , for which extremely accurate energies and wave functions are available, which take account of the behavior of the exact but unknown wave function in the vicinity of all two-particle coalescences and the three-particle coalescence.

The results indicate that the approximate exchange-correlation potentials differ quite considerably from the true exchange-correlation potentials, thus indicating the need for further analytical work in understanding how to design accurate exchange-correlation potentials and for devising tests of exchange-correlation potentials for larger atoms and for molecules.

Another important way of testing the validity of various approximate exchange and correlation potentials is checking whether they obey inequalities imposed by such general properties as scaling and the Hellmann–Feynman theorem. Such general tests were devised by *Levy* and his co-workers [136–145], who found that many of the commonly used approximate potentials violate general inequalities that must be obeyed by the exact potential. These abstract results are helpful in designing potentials that should be better approximations to the true potential.

21.4.3 Density Functional Theory for Excited States

The Hohenberg–Kohn theorem and the Kohn–Sham method were originally formulated in terms of the ground electronic state. These techniques can be extended to calculate

the ground state of a given symmetry [146], but that leaves unresolved the issue of using density functional theory to calculate the energies of excited states for a given symmetry. Using the Rayleigh–Ritz principle for ensembles, general abstract procedures for generalizing density functional theory to excited state calculations were formulated by *Theophilou* [147] and by several other workers [148–158]. Unfortunately, the errors typically seem to be much larger than for ground-state density functional theory.

21.4.4 Locality of Density Functional Theory

Although the locality of DFT was proved for a large class of functionals [159–161], this issue has come under dispute. The question that has been raised is whether there exists an exact Thomas–Fermi model for noninteracting electrons. If such an exact model does not exist, as it is a direct consequence of the Hohenberg–Kohn theorem, then DFT would be incomplete.

Nesbet [162–166] argued that such a theory would be inconsistent with the Pauli exclusion principle for atoms of more than two electrons (or for a two-electron atom where both electrons are in the same spin state). The contention is that if only the total electron density were normalized (which corresponds to only one Lagrange multiplier), as in the TF model, then no shell structure can exist; hence such a system would violate the exclusion principle.

A counterexample was constructed by *Lindgren* and *Salomonson* [167] showing that shell structure can, indeed, be generated through a single Lagrange multiplier. In addition, they verified numerically that a local Kohn–Sham potential can reproduce to high accuracy the many-body electron density and the $2s$ eigenvalue for the $1s2s^3S$ state of neutral helium.

21.4.5 Relativistic and Quantum Field Theoretic Density Functional Theory

At a formal level, one can discuss the development of density functional theory for a relativistic system of electrons. For an overview of this challenging subject, see the discussions by *Dreizler* and *Gross* [95, Chap. 8] and by *Dreizler* [168]. Much of the formalism carries over, but no good way of incorporating vacuum polarization corrections has yet been found.

21.5 Recent Developments

A recent article by *J.P. Solovej* [169] illustrates the good qualitative agreement of the Thomas–Fermi model's predictions of the sizes of atoms with Z from 1 to 50 with the empirical determinations of their radii in crystals by *W.L.*

Bragg [170] and J.C. Slater [171], and presents some new conjectures about asymptotic formulas for the upper and lower limits of the radii and ionization energies of atoms as $Z \rightarrow \infty$ (of course, ignoring relativistic effects).

Many of the important articles by Elliott Lieb and his numerous coworkers on Thomas–Fermi theory and its extensions and their applications to understanding atomic structure and the stability of bulk matter were conveniently reprinted in a single large volume in 2001 [172]. A more readily comprehensible overview of the main results of this large body of work, and of the mathematical theorems used to obtain them, was published by Lieb and Seiringer in 2010 [173].

Ever since the mid-1990s there has continued to be exponentially growing interest in applications of density functional theory of the Kohn–Sham variety to atoms and molecules, especially those of chemical relevance that are too large for accurate *ab initio* electronic structure calculations. The awarding of the 1998 Nobel Prize in Chemistry to Walter Kohn and John A. Pople recognized their individual contributions to this increasingly important field. Their Nobel lectures were published the following year in the *Reviews of Modern Physics* [174, 175].

In a review article published in 2012, Kieron Burke illustrated the exponential growth in the numbers of articles on density functional theory published each year and noted they would soon exceed 10,000 articles per year [176]. Since a comprehensive summary of the wide-ranging developments in density functional theory during the past two decades is not feasible within the limited space available for this supplementary section, I will briefly cite some of the most extensive surveys of various aspects of this field that have appeared since 1995.

Many aspects of density functional theory were reviewed in four consecutive volumes of *Topics in Current Chemistry* published in 1996 [177–180], and in 1999 an entire volume of *Advances in Quantum Chemistry* was devoted to density functional theory [181]. This has also been the subject of several textbooks [182–185] and conference proceedings [186–188]. The International Conferences on Density Functional Theory and Its Applications have been held in various European cities ever since 1995 in odd-numbered years. Recently, Burke [176] and Becke [189] and Yu, Li, and Truhlar [190] published review articles in the *Journal of Chemical Physics*.

An article by Perdew and coworkers provides qualitative explanations of many of the features and paradoxes of Kohn–Sham density functional theory [191]. Tension persists between the proponents of computational methods who seek primarily to develop density functionals with relatively few parameters that obey mathematically derived constraints in the never-ending quest to approach ever more closely the unattainable “Holy Grail” of the exact density functional

(e.g., [192]), and the developers and users of density functionals with few mathematical constraints and many adjustable parameters optimized for a class of molecules to generate predictions of the properties of similar molecules [193–195].

Within the context of Kohn–Sham density functional theory, Constantin, Snyder, Perdew, and Burke investigated the ionization potentials of neutral atoms and the behavior of the “ionization density”, defined as $[4q\pi r^2(\rho_{\text{atom}}(r) - \rho_{\text{ion}}(r))]$, where “ion” refers to the singly charged atomic ion with one electron removed, for Z up to 2938, corresponding to a noble gas atom with a filled outer shell with row number $n = 25$ [196]. Their results indicate that as Z increases, the periodic properties of atoms persist and tend to distinct limits as $Z \rightarrow \infty$, and that the averages of these periodic properties within a “shell” are close to the values given by Thomas–Fermi theory. These results are of mathematical interest, but of course, real atoms with such large nuclear charges do not exist, and even if they did, the effects of relativity and quantum electrodynamics would be profound not just on the orbitals in the “core” but also in the “mantle” and even in the outermost shell. Indeed, because the s-orbitals of atoms have appreciable probability density near the nucleus, there are significant relativistic effects on the physical and chemical properties of atoms already in the 6th period of the periodic table with atomic number Z running upward from 55 (cesium) [197, 198]. Both the unusual color of gold ($Z = 79$) and the unusually low melting point of mercury ($Z = 80$) are striking consequences of relativistic effects on the orbitals in the outermost shell of these atoms [199, 200]. See Chap. 23 for a review of the methodology for performing accurate relativistic calculations of the properties of atoms and atomic ions with large values of Z .

Recent attention has been paid to the use in density functional theory of the Lieb–Oxford lower bound to the indirect part of the Coulomb energy [201]

$$\langle \Psi V_{ee} \rangle \Psi - U[\rho_\Psi] \geq -C_D \int d^D r (\rho_\Psi(\mathbf{r}))^{(D+1)/D}, \quad (21.35)$$

where $\langle \Psi V_{ee} \rangle \Psi$ is the expectation value of the interelectronic interaction energy operator for an electronic wavefunction Ψ , and $U[\rho_\Psi]$ is the approximation to it with the corresponding one-electron density $\rho_\Psi(\mathbf{r})$ defined in Eq. (21.6), and C_D is a dimension-dependent constant ($D = 2$ or 3) for which upper and lower bounds have been derived with various improvements. (As of 2016 it had been established that $1.4119 \leq C_3 \leq 1.6358$.) Mirtschink, Seidl, and Gori-Giorgi demonstrated that this global lower bound obtained by integrating over all space cannot be converted into a local lower bound on the exchange–correlation potential $\epsilon_{xc}(\mathbf{r})$, which for large $|\mathbf{r}|$ decreases proportionally to $1/|\mathbf{r}|$, since such a lower bound would be violated in the outer regions of atoms or in the bond region of stretched molecules, where $\rho_\Psi(\mathbf{r})$ decreases exponentially with distance from the nuclei [202]. A further study

of densities $\rho_\psi(\mathbf{r})$, which challenge the Lieb–Oxford bound and thus provide lower bounds to C_3 , was published by *Seidl, Vuckovic, and Gori-Giorgi* [203]. Generalizations of the original Lieb–Oxford bound that include integrals involving the absolute value of the gradient of ρ and/or the gradient of fractional powers of ρ were constructed by *Benguria, Bley, and Loss* [204] and by *Lewin and Lieb* [205]. Clearly, there is ample room for further theoretical improvements in this area, both in tightening the lower and upper bounds for C_3 in the original Lieb–Oxford bound and in finding other bounds with more complicated functionals of ρ_ψ .

Developments in time-dependent density functional theory for chemical systems have been surveyed in several review articles and books [206–210]. A subtle point that was appreciated only recently is that the singularities in the electron–nucleus and electron–electron potential energies cause severe problems for the existence of Taylor series expansions in time [211, 212], which were used in the original Runge–Gross approach [213].

Acknowledgements I am grateful to Cyrus Umrigar and Michael P. Teter of Cornell University for generously providing sabbatical support in the spring of 1995. I should also like to thank them, as well as Elliott Lieb and Mel Levy, for helpful discussions. This work was supported by my National Science Foundation grant PHY-9215442.

Abstract

This chapter describes variational methods for the determination of wave functions either in nonrelativistic (*LS*), quasi relativistic Breit–Pauli (*LSJ*), or Dirac (*jj*) theory. The emphasis is on Hartree–Fock and multiconfiguration Hartree–Fock theory with reference to similar Dirac theory. Although the underlying mathematics of the latter is technically different because of the properties of Dirac spinors, we draw parallels between the nonrelativistic and relativistic formulations that lay the foundation of, respectively, the Atomic Structure Package (ATSP) [1, 2] and the General Relativistic Atomic Structure Package (GRASP) [3, 4]. Some results from the application of these multiconfiguration methods are presented for a number of atomic properties. Although framed entirely in terms of nonrelativistic calculations, the present chapter reveals a pattern that can be, and actually is, explored in the review article of variational theory [5] as in the following Chap. 23 on *Relativistic Atomic Structure*.

complete active space · configuration state functions · Hamiltonians · multiconfiguration wave functions · orbital rotation · quantum defect · Rydberg series · variational methods

22.1 Nonrelativistic and Relativistic Hamiltonians

A fully covariant relativistic many-body theory requires a field-theoretical approach, i.e., the use of quantum electrodynamics (QED) [6]. Although relativistic QED is the accepted theory describing the interaction of charged particles with the Maxwell field, it is too complicated to use for all but the simplest atomic structures. Almost all atomic structure calculations are, therefore, usually based on Hamil-

tonian models. For a time-independent Hamiltonian, we may look for stationary solutions Ψ of the wave equation

$$(H - E)\Psi = 0, \quad (22.1)$$

where H is the Hamiltonian operator for the system and E the total energy. The operator H depends on the system (atomic, molecular, solid state, etc.) as well as the underlying quantum mechanical formalism (nonrelativistic, Dirac–Coulomb, or Dirac–Coulomb–Breit, etc.). All these Hamiltonians are of the form $T + V$, where T refers to the kinetic energy operator, and V approximates the electron–nucleus and electron–electron interactions.

22.1.1 Schrödinger’s Hamiltonian

Deriving V from the (point) Coulomb interactions of the classical potentials and describing the nucleus of charge Z as a point-charged nucleus of infinite mass, the nonrelativistic Schrödinger Hamiltonian of a N -electron atom is, in atomic units (see Chap. 1 for their definition),

$$H_{\text{nr}} = -\frac{1}{2} \sum_{i=1}^N \left(\nabla_i^2 + \frac{2Z}{r_i} \right) + \sum_{i<j} \frac{1}{r_{ij}}, \quad (22.2)$$

where r_i is the distance of electron i from the nucleus, and r_{ij} is the distance between electron i and electron j . The term $-Z/r$ represents the nuclear attraction and $1/r_{ij}$ the interelectron repulsion. The operator H_{nr} has both a discrete and continuous spectrum; for the former, the solution of Eq. (22.1), $\Psi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)$, has a probability interpretation and, consequently, must be square integrable.

22.1.2 Dirac–Coulomb(–Breit) Hamiltonian

Relativistic quantum mechanics [7] is required for a description of the atomic system when the electrons probe regions of spaces near the atomic nucleus. A good approximation for the relativistic Hamiltonian based on Dirac theory for a many-electron atomic system is the Dirac–Coulomb (DC) Hamiltonian [8, 9]

$$\begin{aligned} H_{\text{DC}} &= \sum_{i=1}^N h_{\text{D}}(i) + \sum_{j>i=1}^N \frac{1}{r_{ij}} \\ &= \sum_{i=1}^N [c\boldsymbol{\alpha}_i \cdot \mathbf{p}_i + V_{\text{nuc}}(r_i) + c^2(\beta_i - 1)] \\ &\quad + \sum_{j>i=1}^N \frac{1}{r_{ij}}, \end{aligned} \quad (22.3)$$

where h_{D} is the one-electron Dirac operator (shifted for the energy to coincide with nonrelativistic conventions), $\boldsymbol{\alpha}$ and β are usual 4×4 Dirac matrices, c is the speed of light ($c = 1/\alpha = 137.035\,999\,139(31)$ a. u.) according to the 2014 CODATA [10], and $\mathbf{p} = -i\nabla$ is the electron momentum operator. For each electron, β appearing in the relativistic single-electron Dirac kinetic energy is replaced by $\beta - 1$ to align the nonrelativistic rest energy of the electron, $E = 0$, and the relativistic one, $E = m_e c^2$. The nuclear potential $V_{\text{nuc}}(r)$ can be approximated as $-Z/r$, as it is in Eq. (22.2), but this point nuclear charge model ignores the fact that real nuclei often have nonspherical charge density distributions that have physical effects (isotope shifts, hyperfine structures, etc.). A spherical average density distribution $V_{\text{nuc}}(r)$ is, therefore, frequently included when modeling heavier atoms. A more realistic nuclear charge distribution can be a uniform nuclear charge distribution, a Fermi distribution, or other nuclear models deduced from nuclear scattering experiments (Chap. 23).

In Eq. (22.3), the electron–electron interaction is simply taken to be the static potential, while the full electron–electron interaction should be included to approach QED. The effective interaction of electrons depends of the choice of gauge potential. Their derivation in terms of the exchange of virtual photons leading to different gauge-dependent versions can be found in Chap. 23. In the Coulomb gauge, the low-frequency limit of the virtual exchanged photon between two electrons introduced in QED gives the Breit interaction

$$H_{\text{Breit}} = - \sum_{j>i=1}^N \frac{1}{2r_{ij}} \left[(\boldsymbol{\alpha}_i \cdot \boldsymbol{\alpha}_j) + \frac{(\boldsymbol{\alpha}_i \cdot \mathbf{r}_{ij})(\boldsymbol{\alpha}_j \cdot \mathbf{r}_{ij})}{r_{ij}^2} \right] \quad (22.4)$$

that approximates the magnetic interaction and retardation effects. The addition of Eqs. (22.3) and (22.4) defines the Dirac–Coulomb–Breit (DCB) Hamiltonian.

22.1.3 Breit–Pauli Hamiltonian

For small velocities ($v \ll c$), it is possible to derive the Breit–Pauli Hamiltonian

$$H_{\text{BP}} = H_{\text{nr}} + H_{\text{rel}}, \quad (22.5)$$

from the nonrelativistic limit of $H_{\text{DCB}} = H_{\text{DC}} + H_{\text{Breit}}$ [11, 12]; H_{rel} contains the relativistic corrections to the nonrelativistic Hamiltonian Eq. (22.2) up to the relative order $(\alpha Z)^2$ in energy [13] and may again be subdivided into nonfine structure (NF) and fine structure (F) contributions

$$H_{\text{rel}} = H_{\text{NF}} + H_{\text{F}}. \quad (22.6)$$

The NF contributions

$$H_{\text{NF}} = H_{\text{mass}} + H_{\text{Darwin}} + H_{\text{ssc}} + H_{\text{oo}} \quad (22.7)$$

shift nonrelativistic energy levels without splitting the levels. The mass-velocity term

$$H_{\text{mass}} = -\frac{\alpha^2}{8} \sum_i \nabla_i^4 \quad (22.8)$$

corrects for the variation of mass with velocity; the one- and two-body Darwin terms

$$H_{\text{Darwin}} = -\frac{\alpha^2 Z}{8} \sum_i \nabla_i^2 r_i^{-1} + \frac{\alpha^2}{4} \sum_{i<j} \nabla_i^2 r_{ij}^{-1} \quad (22.9)$$

are the corrections of the one-electron Dirac equation due to the retardation of the electromagnetic field produced by an electron; the spin–spin contact term

$$H_{\text{SSC}} = -\frac{8\pi\alpha^2}{3} \sum_{i<j} (\mathbf{s}_i \cdot \mathbf{s}_j) \delta(\mathbf{r}_{ij}) \quad (22.10)$$

accounts for the interaction of the spin magnetic moments of two electrons occupying the same space; the orbit–orbit interaction

$$H_{\text{OO}} = -\frac{\alpha^2}{2} \sum_{i<j} \left(\frac{\mathbf{p}_i \cdot \mathbf{p}_j}{r_{ij}} + \frac{\mathbf{r}_{ij}(\mathbf{r}_{ij} \cdot \mathbf{p}_i) \cdot \mathbf{p}_j}{r_{ij}^3} \right) \quad (22.11)$$

accounts for the interaction of two orbital moments.

The F contributions

$$H_F = H_{\text{so}} + H_{\text{soo}} + H_{\text{ss}}, \quad (22.12)$$

split the nonrelativistic energy levels into a series of closely-spaced fine structure levels. The nuclear spin–orbit interaction

$$H_{\text{so}} = \frac{\alpha^2 Z}{2} \sum_i \frac{1}{r_i^3} (\mathbf{l}_i \cdot \mathbf{s}_i) \quad (22.13)$$

represents the interaction of the spin and angular magnetic moments of an electron in the field of the nucleus. The spin–other–orbit term

$$H_{\text{soo}} = -\frac{\alpha^2}{2} \sum_{i \neq j} \left(\frac{\mathbf{r}_{ij}}{r_{ij}^3} \times \mathbf{p}_i \right) \cdot (\mathbf{s}_i + 2\mathbf{s}_j), \quad (22.14)$$

and the spin–spin term

$$H_{\text{ss}} = \alpha^2 \sum_{i<j} \frac{1}{r_{ij}^3} \left[\mathbf{s}_i \cdot \mathbf{s}_j - \frac{3}{r_{ij}^2} (\mathbf{s}_i \cdot \mathbf{r}_{ij})(\mathbf{s}_j \cdot \mathbf{r}_{ij}) \right], \quad (22.15)$$

arise from spin-dependent interactions with the other electrons in the system.

The Breit–Pauli approximation is usually only applied to light atoms but provides satisfactory results even up to $Z = 26$ – 30 for Na-like to Ar-like ions [14]. A finite nucleus correction can be readily estimated for small- Z nuclei from the value of the electron density calculated at the point-charge nucleus [15].

22.2 Many-Electron Wave Functions

The atomic wave function Ψ , an approximate solution of the wave equation (22.1) for a many-electron atomic system, is expanded in terms of configuration state functions (CSF) that can be expressed in terms of sums of Slater determinants built on one-electron orbitals [5].

22.2.1 Nonrelativistic Orbitals and LS Configuration State Functions

In the nonrelativistic approximation, the assignment of nl quantum numbers to electrons specifies a configuration, often written as $(n_1 l_1)^{q_1} (n_2 l_2)^{q_2} \dots (n_m l_m)^{q_m}$, where q_i is the occupation of subshell $(n_i l_i)$. Associated with each subshell are one-electron spin-orbitals

$$\phi(r, \theta, \varphi, \sigma) = \frac{1}{r} P_{nl}(r) Y_{lm_l}(\theta, \varphi) \chi_{m_s}(\sigma),$$

where $P_{nl}(r)$ is the radial function, $Y_{lm_l}(\theta, \varphi)$ a spherical harmonic, and $\chi_{m_s}(\sigma)$ a spinor. Each CSF is a linear combination of products of one-electron spin-orbitals, one for each electron in the system, such that the sum is an eigenfunction of the total angular momenta operators L^2 , L_z , and the total spin operators S^2 , S_z . It can be considered to be a product of radial factors, one for each electron, an angular and a spin factor obtained by vector coupling methods. It is also required to be antisymmetric with respect to the interchange of any pair of electron coordinates. Often, the specification of the configuration and the final LS quantum numbers are sufficient to define the configuration state, but this is not always the case. Additional information about the order of coupling or the seniority of a subshell of equivalent electrons may be needed. Let γ specify the configuration information and any additional information about coupling to uniquely specify the configuration state function denoted by $\Phi(\gamma LS)$. Using the building rules as detailed in [5], the most general form of a given CSF obtained by coupling the m subshell functions from left to right is

$$\begin{aligned} \Phi(\gamma L S M_L M_S) &\equiv |\gamma L S M_L M_S\rangle \\ &\equiv |(n_1 l_1)^{w_1} \alpha_1 \nu_1 L_1 S_1 (n_2 l_2)^{w_2} \alpha_2 \nu_2 L_2 S_2 L_{12} S_{12} \\ &\quad \cdot (n_3 l_3)^{w_3} \alpha_3 \nu_3 L_3 S_3 L_{123} S_{123} \dots \\ &\quad \cdot (n_m l_m)^{w_m} \alpha_m \nu_m L_m S_m L S M_L M_S\rangle, \end{aligned} \quad (22.16)$$

where the additional numbers α_i and ν_i uniquely specify the single-shell (i) state when there is more than one term with the same $L_i S_i$ value.

The wave function for a many-electron system is usually labeled in the same manner as a CSF and generally desig-

nates the largest component. Thus, in the LS approximation,

$$\Psi(\gamma LS) = \sum_{\alpha=1}^M c_{\alpha} \Phi(\gamma_{\alpha} LS). \quad (22.17)$$

However, cases are known where the configuration states are so highly mixed that no dominant component can be found. Then the assignment is made using other criteria. Clearly, no two states should have the same label.

In the LSJ scheme, the angular- and spin-momenta are coupled to form an eigenstate of the total momenta J^2 , J_z . The label often still includes an LS designation, as in $2p^2\ ^3P_2$, but only the subscript J is a good quantum number. Thus,

$$\Psi(\gamma LSJ) = \sum_{\alpha=1}^M c_{\alpha} \Phi(\gamma_{\alpha} L_{\alpha} S_{\alpha} J). \quad (22.18)$$

22.2.2 Relativistic Dirac Orbitals and jj Configuration State Functions

In the Dirac–Coulomb(–Breit) framework, the radial functions now are a pair of spinors, as in the solution of the hydrogenic equations where

$$\phi_{n\kappa m}(r, \theta, \varphi) = \frac{1}{r} \begin{pmatrix} P_{n\kappa}(r) \Omega_{\kappa m}(\theta, \varphi) \\ i Q_{n\kappa}(r) \Omega_{-\kappa m}(\theta, \varphi) \end{pmatrix}, \quad (22.19)$$

with

$$\kappa = \begin{cases} -(l+1) & \text{for } j = l + \frac{1}{2} \quad (\kappa \text{ negative}) \\ +l & \text{for } j = l - \frac{1}{2} \quad (\kappa \text{ positive}) \end{cases}; \quad (22.20)$$

$P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$ are, respectively, the radial functions of the large and small components of the Dirac spinor. Note that in the nonrelativistic limit ($c \rightarrow \infty$), $P_{n\kappa} \rightarrow P_{nl}$ and $Q_{n\kappa}$ is order α in the Pauli approximation [11]. The relativistic configurations are written as $(n_1\kappa_1)^{q_1}(n_2\kappa_2)^{q_2} \dots (n_m\kappa_m)^{q_m}$, where q_i is the occupation of subshell $(n_i\kappa_i)$. The relativistic equivalent of Eq. (22.17) is

$$\Psi(\gamma J) = \sum_{\alpha=1}^M c_{\alpha} \Phi(\gamma_{\alpha} J). \quad (22.21)$$

where each relativistic CSF, written in jj coupling, has the following form

$$\begin{aligned} \Phi(\gamma JM_J) &\equiv |\gamma JM_J\rangle \\ &\equiv |(n_1\kappa_1)^{w_1} \alpha_1 \nu_1 J_1 (n_2\kappa_2)^{w_2} \alpha_2 \nu_2 J_2 J_{12} \\ &\quad \cdot (n_3\kappa_3)^{w_3} \alpha_3 \nu_3 J_3 J_{123} \dots \\ &\quad \cdot (n_m\kappa_m)^{w_m} \alpha_m \nu_m J_m JM_J\rangle. \end{aligned} \quad (22.22)$$

22.3 Variational Principle

In all cases, the angular functions for one-electron orbitals are known. What needs to be determined in the nonrelativistic or Breit–Pauli schemes are the radial functions, $P(nl; r)$ or, in the relativistic case, the radial functions $P(n\kappa; r)$ and $Q(n\kappa; r)$. What differs for the different approaches are the underlying Hamiltonians and their one-electron radial functions [5].

Variational theory shows the equivalence between solutions of the wave equation, $(H - E)\psi = 0$, and stationary solutions of an energy functional. For bound states where approximate solutions Ψ are restricted to a square integrable subspace, say $\tilde{\mathcal{H}}$, the best solutions are those for which the energy functional

$$\mathcal{E}(\Psi) = \frac{\langle \Psi | H | \Psi \rangle}{\langle \Psi | \Psi \rangle} \quad (22.23)$$

is stationary. The condition $\delta\mathcal{E}(\Psi) = 0$ for all allowed variations $\delta\Psi$ leads to

$$\langle \delta\Psi | H - E | \Psi \rangle = 0, \quad \forall \delta\Psi \in \tilde{\mathcal{H}}, \quad E = \mathcal{E}(\Psi). \quad (22.24)$$

Several results readily follow. The eigenvalues of H are bounded from below. Let $E_0 \leq E_1 \leq \dots$. Then,

$$E_0 \leq \mathcal{E}(\Psi), \quad \forall \Psi \in \tilde{\mathcal{H}}. \quad (22.25)$$

Consequently, for any approximate wave function, the computed energy is an upper bound to the exact lowest eigenvalue. By the Hylleraas–Undheim–MacDonald theorem (Sect. 12.3.1) the computed excited states are also upper bounds to the exact eigenvalues, provided that the correct number of states lies below.

The Rayleigh–Ritz variational methods work the same way for Dirac and Schrödinger equations at the one-electron level: in both schemes, the bound eigenvalues have a lower bound. The dominant electron–electron interaction giving positive energy contributions, one can extend this conclusion to many-electron systems, allowing us to set up the Hartree–Fock and Dirac–Hartree–Fock methods in the same way [8] (Chap. 23).

22.4 Hartree–Fock and Dirac–Hartree–Fock Methods

In the nonrelativistic Hartree–Fock (HF) approximation, the approximate wave function consists of only one configuration state function. The radial function of each spin–orbital is assumed to depend only on the nl quantum numbers. These are determined using the variational principle and the non-relativistic Schrödinger Hamiltonian.

The energy functional can be written as an energy expression for the matrix element $\langle \Phi(\gamma LS) | H | \Phi(\gamma LS) \rangle$. Racah algebra may be used to evaluate the spin–angular contributions, resulting in two types of radial integrals.

One-body Let \mathcal{L} be the differential operator

$$\mathcal{L} = \frac{d^2}{dr^2} + \frac{2Z}{r} - \frac{\ell(\ell+1)}{r^2}. \quad (22.26)$$

Then,

$$I(nl, n'l') = -\frac{1}{2} \int_0^\infty P(nl; r) \times \mathcal{L}P(n'l'; r) dr. \quad (22.27)$$

Two-body The other integrals arise from the multipole expansion of the two-electron Coulomb interaction

$$\frac{1}{r_{12}} = \sum_k \frac{r_{<}^k}{r_{>}^{k+1}} P^k(\cos \theta), \quad (22.28)$$

where θ is the angle between the vectors \mathbf{r}_1 and \mathbf{r}_2 , and $r_{<}$, $r_{>}$ are the lesser and greater of r_1, r_2 , respectively. In general, let a, b, c, d be four nl quantum numbers, two from the left (bra) and two from the right (ket) CSF. Then,

$$R^k(ab, cd) = \int_0^\infty \int_0^\infty P(a; r_1) P(b; r_2) \times \frac{r_{<}^k}{r_{>}^{k+1}} P(c; r_1) P(d; r_2) dr_1 dr_2, \quad (22.29)$$

which is called a Slater integral. It has the symmetries

$$R^k(ad, cb) \equiv R^k(cb, ad) \equiv R^k(cd, ab) \\ \equiv R^k(ab, cd).$$

In the Hartree–Fock approximation, the Slater integrals that occur depend on only two sets of quantum numbers. These special cases are denoted separately as

$$F^k(a, b) \equiv R^k(ab, ab) \quad \text{and} \\ G^k(a, b) \equiv R^k(ab, ba). \quad (22.30)$$

The former is the direct interaction between a pair of orbitals, whereas the latter arises from the exchange operator.

The energy expression may be written as

$$\mathcal{E}(\gamma LS) = \sum_i^m q_i \left[I(n_i l_i, n_i l_i) + \frac{q_i - 1}{2} \sum_{k=0}^{2l_i} f_k(i, i) F^k(n_i l_i, n_i l_i) \right] + \sum_{j < i} q_i q_j \left[\sum_{k=0}^{2 \min(l_i, l_j)} f_k(i, j) F^k(n_i l_i, n_j l_j) + \sum_{k=|l_i - l_j|}^{l_i + l_j} g_k(i, j) G^k(n_i l_i, n_j l_j) \right]. \quad (22.31)$$

In general, the coefficients $f_k(i, j)$ and $g_k(i, j)$ depend not only on the configuration, but also on the subshells coupling tree γ leading to the final LS symmetry. An extremely useful concept, introduced by Slater, is the *average energy of a configuration*, $\mathcal{E}(\text{av})$. This is a weighted average of all possible LS terms, where the weighting factor is the term degeneracy $g_{LS} = (2L + 1)(2S + 1)$. In this case, the coefficients have simple formulas that only depend on the angular orbital momenta involved in the interaction, i.e., on the configuration

$$f_k(i, i) = f_k^{av}(l_i, l_i) = 1, \quad k = 0, \\ = -\left(\frac{2l_i + 1}{4l_i + 1} \right) \begin{pmatrix} l_i & k & l_i \\ 0 & 0 & 0 \end{pmatrix}^2, \quad k > 0 \\ f_k(i, j) = f_k^{av}(l_i, l_j) = \delta_{k,0}, \quad i \neq j \\ g_k(i, j) = g_k^{av}(l_i, l_j) \\ = -\frac{1}{2} \begin{pmatrix} l_i & k & l_j \\ 0 & 0 & 0 \end{pmatrix}^2, \quad i \neq j. \quad (22.32)$$

In the more general case, expression Eq. (22.31) involving the number of interacting pairs, $q_i(q_i - 2)/2$ and $q_i q_j$ for equivalent and nonequivalent electrons respectively, still holds, but these coefficients may become shell dependent for a given angular momenta pair. The part of the expression that depends on $P(n_i l_i; r)$, for example, is the negative of the removal energy of the entire $(n_i l_i)^{q_i}$ subshell, say $-\bar{\mathcal{E}}[(n_i l_i)^{q_i}]$, a negative quantity. The stationary condition for a Hartree–Fock solution applies to this expression, but since the variations must be constrained in order to satisfy orthonormality assumptions, Lagrange multipliers λ_{ij} need to be introduced. The stationary condition applies to the functional

$$\mathcal{F}[P(n_i l_i)] = -\bar{\mathcal{E}}[(n_i l_i)^{q_i}] + \sum_j \delta_{i,j} \lambda_{ij} \langle P(n_i l_i) | P(n_j l_j) \rangle. \quad (22.33)$$

Applying the variational conditions to each of the integrals and dividing by $-q_i$, we get the equation

$$\left(\frac{d^2}{dr^2} + \frac{2}{r} [Z - Y(n_i l_i; r)] - \frac{l_i(l_i + 1)}{r^2} - \varepsilon_{ii} \right) P(n_i l_i; r) = \frac{2}{r} X(n_i l_i; r) + \sum_{j \neq i} \delta_{l_i, l_j} \varepsilon_{ij} P(n_j l_j; r), \quad (22.34)$$

where

$$\begin{aligned} Y(n_i l_i; r) &= (q_i - 1) \sum_k f_k(i, i) Y^k(n_i l_i n_i l_i; r) \\ &\quad + \sum_{j \neq i} q_j \sum_k f_k(i, j) Y^k(n_j l_j n_j l_j; r), \\ X(n_i l_i; r) &= \sum_{j \neq i} q_j \sum_k g_k(i, j) Y^k(n_i l_i n_j l_j; r) \\ &\quad \times P(n_j l_j; r), \end{aligned} \quad (22.35)$$

with

$$Y^k(ab; r) = r \int_0^\infty \frac{r^k}{r^{k+1}} P(a; s) P(b; s) ds. \quad (22.36)$$

The above is the standard derivation for Hartree–Fock differential equations. Numerical methods for their solution treat the exchange and Lagrange multiplier contributions as part of an inhomogeneous term [16] even though the equation is of eigenvalue type.

22.4.1 Diagonal Energy Parameters and Koopmans' Theorem

The diagonal (ε_{ii}) and off-diagonal (ε_{ij}) energy parameters are related to the Lagrange multipliers by $\varepsilon_{ii} = 2\lambda_{ii}/q_i$ and $\varepsilon_{ij} = \lambda_{ij}/q_i$. In fact,

$$\varepsilon_{ii} = \frac{2}{q_i} \bar{E}[(n_i l_i)^{q_i}] - (q_i - 1) \sum_k f_k(i, i) F^k(n_i l_i, n_i l_i), \quad (22.37)$$

where $\bar{E}[(n_i l_i)^{q_i}]$ is the Hartree–Fock value of the removal energy functional $\bar{E}[(n_i l_i)^{q_i}]$. In the special case where $q_i = 1$, ε_{ii} is twice the removal energy or ionization energy. This is often referred to as Koopmans' theorem.

22.4.2 Hartree–Fock Operator

By introducing an exchange operator, \bar{X} , Eq. (22.34) can be written as an eigenvalue problem. Applying the stationary

condition, the variation of each orbital a results in a system of m coupled eigenvalue equations where m is the number of orbitals. The equations are coupled by the orthogonality constraints. For a CSF (like $1s^2 2s$) with only two orbitals a, b , subject to orthogonality, the equations have the form [17]

$$\begin{bmatrix} H^a & 0 \\ 0 & H^b \end{bmatrix} \begin{bmatrix} P_a \\ P_b \end{bmatrix} = \begin{bmatrix} \varepsilon_{aa} & \varepsilon_{ab} \\ \varepsilon_{ba} & \varepsilon_{bb} \end{bmatrix} \begin{bmatrix} P_a \\ P_b \end{bmatrix}, \quad (22.38)$$

where H^a , for example, is the integro-differential operator

$$\begin{aligned} H^a &= q_a \left[-\frac{1}{2} \frac{d^2}{dr^2} - \frac{Z}{r} + \frac{l_a(l_a + 1)}{2r^2} \right] \\ &\quad + Y(a; r) + \bar{X}(a; r), \end{aligned} \quad (22.39)$$

and

$$\bar{X}(a; r) P_a(r) = \sum_{bk} g_{abk} \left(\frac{Y^k(ab; r)}{r} \right) P_b(r). \quad (22.40)$$

Contributions to the direct potential $Y(a; r)$ arise from the $F^k(ab)$ integrals in the energy functional, whereas contributions to the exchange potential $\bar{X}(a; r)$ arise from the $G^k(ab)$ terms. In other words, for the exchange contributions, the function $P_a(r)$ is part of an integrand, making the equation an integro-differential equation of eigenvalue type when $\varepsilon_{ab} = 0$.

In these equations, where the variation is *not* divided by an occupation number, the matrix (ε_{ab}) is called the energy matrix [16] and is symmetric since its elements are directly related to Lagrange multipliers ensuring orthonormality. Consequently,

$$\begin{aligned} \varepsilon_{aa} &= \langle P_a | H^a | P_a \rangle, & \varepsilon_{ab} &= \langle P_b | H^a | P_a \rangle, \\ \varepsilon_{ba} &= \langle P_a | H^b | P_b \rangle, & \varepsilon_{bb} &= \langle P_b | H^b | P_b \rangle. \end{aligned} \quad (22.41)$$

Equation (22.39) represents the conditions that a stationary solution must satisfy when single orbitals are perturbed. In Hartree's book [18] this was the only condition. In fact, the variational principle requires a solution be stationary for *all* allowed perturbations. The latter includes orthogonal transformations. The condition that a solution be stationary to such transformations leads to an implicit condition that a solution must satisfy and not a computational procedure.

Orthogonal transformations of orbitals are related to the "rotation" of orbitals in orbital space. In a two-dimensional space, such a transformation can be defined in terms of a single parameter $\epsilon \in [-1, 1]$ as in

$$\mathbf{O} = \begin{bmatrix} 1 & -\epsilon \\ \epsilon & 1 \end{bmatrix} / \sqrt{1 + \epsilon^2}, \quad (22.42)$$

where $1/\sqrt{1+\epsilon^2} = \cos(\theta)$ and θ represents the angle of rotation. The radial transformation $P^* = OP$ allows the effect of a rotation on the energy to be expanded in powers of ϵ , namely,

$$E(\epsilon) = E(0) + g\epsilon + g'\epsilon^2 + \text{higher-order terms},$$

where g represents the gradient of the energy with respect to rotation, and $E(0)$ is the energy before orbitals are rotated. Then the stationary condition

$$\frac{\partial E}{\partial \epsilon} = 0 = g + 2g'\epsilon \quad (22.43)$$

leads to $\epsilon = -g/(2g')$. When this condition is satisfied, rules for determining g and g' from the energy expression are given in [19]. When g and g' are both zero, a unique solution does not exist, as for $1s^2 2s^2$.

22.4.3 Brillouin's Theorem

The Hartree–Fock approximation has some special properties not possessed by other single configuration approximations. One such property is referred to as satisfying Brillouin's theorem.

Let $\Phi^{\text{HF}}(\gamma LS)$ be a Hartree–Fock configuration state function (CSF), where γ denotes the configuration and coupling scheme. With $\Phi^{\text{HF}}(\gamma LS)$ are associated the m Hartree–Fock radial functions $P^{\text{HF}}(n_1 l_1; r)$, $P^{\text{HF}}(n_2 l_2; r)$, ..., $P^{\text{HF}}(n_m l_m; r)$. To this set may be added virtual orbitals that maintain the necessary orthonormality conditions. Let one of the radial functions (nl) be replaced by another ($n'l$), either occupied or virtual, without any change in the coupling of the spin–angular factor. Let the resulting function be denoted by $F(nl \rightarrow n'l)$.

The perturbation of the Hartree–Fock radial function, $P(nl; r) \rightarrow P^{\text{HF}}(nl; r) + \epsilon P(n'l; r)$ induces a perturbation $\Phi^{\text{HF}}(\gamma LS) \rightarrow \Phi^{\text{HF}}(\gamma LS) + \epsilon F(nl \rightarrow n'l)$. But the Hartree–Fock energy is stationary with respect to such variations and so,

$$\langle \Phi^{\text{HF}}(\gamma LS) | H | F(nl \rightarrow n'l) \rangle = 0. \quad (22.44)$$

If the function $F(nl \rightarrow n'l)$ is a CSF for a configuration γ^* , or proportional to one, then Brillouin's theorem is said to hold between the two configuration states. It may happen that $F(nl \rightarrow n'l)$ is a linear combination of CSFs. An example is the $2p \rightarrow 3p$ replacement from $2p^3 {}^2P$, yielding a linear combination of $\{2p^2({}^1S)3p, 2p^2({}^3P)3p, 2p^2({}^1D)3p\}$, the linear combination being determined by coefficients of fractional parentage. Thus, Brillouin's theorem will not hold for any of the three individual configuration states in the above equation, only for a specific linear combination.

When perturbations are in the form of a rotation of orbitals it has the form $F(nl \rightarrow n'l, n'l \rightarrow -nl)$. For $1s^2 2s^2 {}^2S$, the simultaneous perturbations, $F(1s \rightarrow 2s, 2s \rightarrow -1s)$, lead to a linear combination of $\{1s 2s^2 {}^2S, 1s^3 {}^2S\}$. The CSF for the $1s^3 {}^2S$ is identically zero by antisymmetry, and so Brillouin's theorem holds for the lithium-like ground state. In the $1s 2s^3 {}^3S$ state, neither the $1s \rightarrow 2s$ nor the $2s \rightarrow 1s$ substitutions are allowed; in fact, it can be shown that for these states, Brillouin's theorem holds for all monoexcited configurations. The same is not true for $1s 2s^1 {}^1S$ where the simultaneous perturbations lead to the condition

$$\langle \Phi^{\text{HF}}(1s 2s^1 {}^1S) | H | [\Phi(1s^2) - \Phi(2s^2)] \rangle = 0. \quad (22.45)$$

Thus, Brillouin's theorem is not obeyed for either the $\Phi(1s^2)$ or $\Phi(2s^2)$ CSF in an HF calculation for $1s 2s$.

The importance of Brillouin's theorem lies in the fact that certain interactions have already been included to first order. This has the consequence that certain classes of diagrams can be omitted in many-body perturbation theory [20].

22.4.4 The Dirac–Hartree–Fock Equations

In jj -coupling, many subshells split into two subshells, so occupation numbers are different. For example, $2p^6 \rightarrow 2p_-^2 2p_+^4$, where $2p_- \equiv 2p_{j=1/2}$ and $2p_+ \equiv 2p_{j=3/2}$. Instead of one second-order differential equation, the Dirac–Hartree–Fock equations are a pair of first-order equations

$$\begin{aligned} q_a \begin{bmatrix} V(a; r) & -c \left[\frac{d}{dr} - \frac{\kappa_a}{r} \right] \\ c \left[\frac{d}{dr} + \frac{\kappa_a}{r} \right] & V(a; r) - 2c^2 \end{bmatrix} \begin{bmatrix} P_a(r) \\ Q_a(r) \end{bmatrix} \\ = \sum_b \epsilon_{ab} \delta_{\kappa_a \kappa_b} \begin{bmatrix} P_b(r) \\ Q_b(r) \end{bmatrix}, \end{aligned} \quad (22.46)$$

where $V(a; r) = (V_{\text{nuc}}(r) + Y(a; r) + \bar{X}(a; r))$. In this expression, $V_{\text{nuc}}(r)$ is the effective electron–nucleus potential at radius r that can take into account the finite size of the nuclear charge distribution, $Y(a; r)$ is the direct potential, and $\bar{X}(a; r)$ contains the exchange contributions in integro-differential form as described above in the HF method. For bound state solutions, the boundary conditions are $P_a(r) = 0$ at $r = 0$ and $r \rightarrow \infty$, as well as for $Q_a(r)$. A more detailed discussion is presented in Chap. 23.

22.4.5 Numerical Solution of Variational Equations

Numerical methods based on finite differences for the integro-differential equations [21] are implemented in both

ATSP [1, 2] and GRASP [3, 4] computer codes. Both methods perform outward and inward integration procedures with energy adjustments to match the joins. Because the equations are of eigenvalue type with many solutions, node counting is needed to control the convergence to a particular solution. Because of orbital rotation, node counting is an art since nodes with small amplitudes in the tail region may need to be ignored. Both codes rely on several methods to solve the equations in the event that the default method fails.

When radial functions (nonrelativistic or relativistic) are expressed as expansions over a B-spline basis, and the Galerkin method is used for determining the expansion coefficients, the equations can be solved using matrix eigenvalue methods. These have been implemented in a B-spline Hartree–Fock program, named SPHF for (B-)“Spline Hartree-Fock” [19].

Given a grid of strictly increasing knots, $t_i, i = 0, \dots, n_v, t_{i-1} < t_i$, where t_0 and t_{n_v} are knots of multiplicity k , the B-spline functions $B_i^k(r), i = 1, \dots, n_v$ form a basis for piecewise polynomial functions that are polynomials of degree $k - 1$ in each interval and whose derivatives up to order $k - 2$ are continuous at the interior knots. The number of basis elements is $n_s = n_v + k - 1$, where each basis function is nonzero over k adjacent intervals. Furthermore, only $B_1^k(r)$ is nonzero at $r = t_0$, and $B_{n_s}(r)$ is nonzero at $r = t_{n_v}$. For atoms, $t_0 = 0$, and the last grid point is referred to as R . Thus, the grid defines a sequence of subintervals over the range $[0, R]$. The spline basis is determined recursively as

$$B_i^k(r) = \frac{r - t_i}{t_{i+k-1} - t_i} B_i^{k-1}(r) + \frac{t_{i+k} - r}{t_{i+k} - t_{i+1}} B_{i+1}^{k-1}(r), \quad (22.47)$$

where

$$B_i^1 = \begin{cases} 1, & t_i \leq r \leq t_{i+1} \\ 0, & \text{otherwise} \end{cases}. \quad (22.48)$$

A radial function for orbital a , say $P(a; r)$, in this piecewise polynomial function space has associated with it a vector $a = (a_1, a_2, \dots, a_{n_s})$ of expansion coefficients so that

$$P(a; r) = \sum_{i=1}^{n_s} a_i B_i^k(r). \quad (22.49)$$

Note that as an argument, a simply denotes an orbital. For bound orbitals the boundary conditions are $a_1 = a_{n_s} = 0$, but for additional numerical stability we apply two boundary conditions at the end of the range (equivalent to $P(R) = P'(R) = 0$), namely $a_{n_s-1} = a_{n_s} = 0$. Additional boundary conditions could also be applied at the origin to enforce r^{l+1} behavior but has not been applied in this program. The L_2 norm in this function space is

$$|P(a; r)|^2 = a^t B a,$$

where $B = B(i, j)$ is the matrix of overlap integrals,

$$B(i, j) = \int B_i^k(r) B_j^k(r) dr.$$

It is a symmetric, positive definite, banded matrix of bandwidth $2k_s - 1$.

Given an energy expression for a Hartree–Fock wave function, assuming for the time being that there are no orthogonality constraints, and applying the variational principle to it [19], yields the generalized eigenvalue problem

$$(H^a - \varepsilon_{aa} B) a = 0, \quad (22.50)$$

where H^a and B are matrices of size $n_s \times n_s$ before boundary conditions are applied. When exchange terms are present, the matrix H^a is a full matrix. Thus, a is the m^{th} eigenvector of the generalized eigenvalue problem, where m depends on the nl quantum numbers and possible orthogonality constraints, with $m = 1$ being the lowest eigenvalue satisfying the orthogonality constraints.

When two orbitals, a and b , are constrained through orthogonality and both are varied, Lagrange multipliers $\varepsilon_{aa}, \varepsilon_{ab} = \varepsilon_{ba}, \varepsilon_{bb}$ must be introduced, and the equations for the pair become [17]

$$\begin{bmatrix} H^a & \\ & H^b \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} - \begin{bmatrix} \varepsilon_{aa} & \varepsilon_{ab} \\ \varepsilon_{ba} & \varepsilon_{bb} \end{bmatrix} \begin{bmatrix} B a \\ B b \end{bmatrix} = 0. \quad (22.51)$$

Projection operators may then be applied to eliminate the off-diagonal Lagrange multipliers so that each equation then becomes a generalized eigenvalue problem.

Since the matrix H^a depends on current estimates of orbitals, an iterative method of solution is needed. For singly occupied orbitals, the eigenvalue method is ideal, but for multiply occupied orbitals, the equations can be viewed as a system of nonlinear equations for which the Newton–Raphson method can yield quadratic convergence. The SCF process, in which orbitals are updated one at a time, has been implemented as follows:

```

For each orbital i = 1, nwf
  For each orbital j = 1, nwf
    call rotate (i, j), if needed
  compute H
  if qsum(i) = 1 or orbital estimates are not accurate,
    then apply projection operators, if necessary,
    and call HF-eigenvalue procedure
  else
    call HF-Newton-Raphson procedure

```

In the above, $qsum(i)$ is the occupation number of orbital i , and nwf is the number of one-electron wave functions

or radial functions. Results to machine accuracy can be obtained.

The DBSR [22] code uses spline methods for solving Dirac–Hartree–Fock equations. Technically, the Hartree–Fock method assumes a single CSF, but it is convenient to relax the definition in the relativistic case to the equivalent of a nonrelativistic Hartree–Fock calculation. For example, the $2p^3\ ^3P_{3/2}$ nonrelativistic CSF is a linear combination of $2p^3$, $2p^22p_-$, and $2p2p_-^2$, $J = 3/2$ CSFs in jj -coupling.

An advantage of the eigenvalue method is that, once the HF or DHF potential has been determined, the set of all eigenstates having the same boundary conditions at $r = R$ can be computed, where R defines the range of the desired bound state. This set of eigenstates defines a complete basis for perturbation theory based calculations (Chap. 24).

A feature of B-spline Galerkin methods is that the spectrum for the second-order Schrödinger radial equation and the pair of first-order equations are not the same. This can readily be confirmed by comparing results from $y'' = -\lambda^2 y$ and $y' = \lambda z$, $z' = -\lambda y$, where both y and z are expanded in a basis of B-splines of the order k . However, if z is expanded in a basis of order $k - 1$, and y is a function expanded in a basis of order k , then the equation $y' = -\lambda z$ can be solved exactly since both y' and z are in the same $k - 1$ function space. However, an error would be introduced when z is expanded in a basis of order k that the Galerkin method would minimize. The most important result is that expansions in a $(k, k - 1)$ basis reproduce an R -matrix boundary condition [23], which is important in R -matrix theory for continuum processes.

22.4.6 Properties of Hartree–Fock Solutions

Term dependence The radial distribution for a given nl orbital may depend significantly on the LS term. A well-known example is the $1s^22s2p$ configuration in Be, which may couple to form either a $^3P^\circ$ or $^1P^\circ$ term. The energy expression differs only in the exchange interaction, $\pm(1/3)G^1(2s, 2p)$, where the $+$ refers to $^1P^\circ$ and the $-$ to $^3P^\circ$. Clearly, the energies of these two terms differ. What is not quite as obvious is the extent to which the $P(2p; r)$ radial functions differ for the two states. The most affected orbital is the one that is least tightly bound, which, in this case, is the $2p$ orbital. Figure 22.1 shows the two radial functions. The $^1P^\circ$ $2p$ orbital is far more diffuse (not as localized) as the one for 3P . Such a change in an orbital is called LS term dependence.

Orbital collapse Another phenomenon, called *orbital collapse*, occurs when an orbital rapidly contracts as a function of the energy. This could be an LS -dependent effect, but it can also occur along an isoelectronic sequence. This effect

Fig. 22.1 A comparison of the $2p$ Hartree–Fock radial functions for the $1s2p\ ^1,^3P^\circ$ states of Be

is most noticeable in the high- l orbitals with large angular momenta. In hydrogen, the mean radius of an orbital is $\langle r \rangle = (1/2)[3n^2 - l(l + 1)]a_0$. Thus, the higher- l orbitals are more contracted; but in neutral systems, the high- l orbitals have a higher energy and are more diffuse. This is due, in part, to the $l(l + 1)/r^2$ angular momentum barrier that appears in the definition of the \mathcal{L} operator. In the Hartree model, it is possible for $V(r) + l(l + 1)/r^2$ to have two wells: an inner well and an outer shallow well [24]. As the lowest eigenfunction changes rapidly from the outer well to the inner well, as Z changes, orbital collapse is said to occur.

Quantum defects and Rydberg series Spectra of atoms often exhibit phenomena associated with a Rydberg series of states where one of the electrons is in an nl orbital, with n assuming a sequence of values. An example is the $1s^22snd\ ^3D$ series in Be, $n = 3, 4, 5, \dots$. For such a series, a useful concept is that of a quantum defect parameter δ . In hydrogen, the ionization energy (I_P) in atomic units is $1/(2n^2)$. In complex neutral systems, the effective charge would be the same at large r . As n increases, the mean radius becomes larger, and the probability of the electron being in the hydrogen-like potential increases. Thus, one could define an effective quantum number, $n^* = n - \delta$, such that

$$I_P(nl) = \frac{1/2}{(n - \delta)^2}. \quad (22.52)$$

For ionized systems, the equation must be modified to $I_P(nl) = (1/2)[(Z - N + 1)/(n - \delta)]^2$.

Often, this parameter is defined with respect to observed data, but it can also be used to evaluate Hartree–Fock energies, where $I_P = \varepsilon_{nl, nl}/2$, so that

$$\varepsilon_{nl, nl} = \left(\frac{Z - N + 1}{n - \delta} \right)^2.$$

Table 22.1 The effective quantum number and quantum defect parameters of the $2snd$ Rydberg series in Be

n	3D		1D	
	n^*	$\delta(nl)$	n^*	$\delta(nl)$
3	2.968	0.032	3.014	-0.014
4	3.960	0.040	4.012	-0.012
5	4.957	0.043	5.013	-0.013
6	5.955	0.045	6.013	-0.013

Table 22.1 shows the effective quantum number and quantum defect for the Hartree–Fock $2snd$ 3D and 1D orbitals in Be as a function of n . For the triplet spectrum, the quantum defect is positive, whereas for the singlet it is negative. This is the effect of exchange. Note that as n increases, the quantum defect becomes constant. This observation is often the basis for determining ionization potentials from observed data.

22.5 Multiconfiguration (Dirac)-Hartree–Fock Method

The Hartree–Fock method predicts many atomic properties remarkably well, but when analyzed carefully, systematic discrepancies can be observed. Consider the ionization potentials tabulated in Table 22.2 compared with the observed values. In these calculations, the energy of the ion was computed using the same radial functions as for the atom. Thus, no *relaxation* effects were included.

The observed data include other effects as well, such as relativistic effects, finite mass and volume of the nucleus, but these are small for light atoms. For these systems, the largest source of discrepancy arises from the fact that the Hartree–Fock solution is an independent particle approximation to the exact solution of Schrödinger’s equation. Neglected entirely is the notion of *correlation in the motion of the electrons*; each electron is assumed to move independently in a field determined by the other electrons. For this reason, the error in the energy was defined by Löwdin [25], to be the correlation energy, that is,

$$E^{\text{corr}} = E^{\text{exact}} - E^{\text{HF}}. \quad (22.53)$$

Table 22.2 Observed and Hartree–Fock ionization potentials for the ground states of neutral atoms, in eV (also Table 22.3)

Atom	Obs.	HF	Diff.
Li	5.39	5.34	0.05
Be	9.32	8.42	0.90
B	8.30	8.43	-0.13
C	11.26	11.79	-0.53
N	14.53	15.44	-0.91
O	13.62	14.45	-0.85
F	17.42	18.62	-1.20
Ne	21.56	23.14	-1.58

In this definition, E^{exact} is not the observed energy—it is the exact solution of Schrödinger’s equation, which itself is based on a number of assumptions.

22.5.1 Z -Dependent Theory

An indication of the important correlation corrections can be obtained from a perturbation theory study of the exact wave function. In the following section, we closely follow the approach taken by Layzer et al. [26] in the study of the Z -dependent structure of the total energy.

Let us introduce a new scaled length, $\rho = Zr$. Then, the Hamiltonian becomes

$$H = Z^2(H_0 + Z^{-1}V), \quad (22.54)$$

where

$$H_0 = -\frac{1}{2} \sum_i \left(\nabla_i^2 + \frac{2}{\rho} \right), \quad (22.55)$$

$$V = \sum_{i>j} \frac{1}{\rho_{ij}}, \quad (22.56)$$

and Schrödinger’s equation becomes

$$(H_0 + Z^{-1}V)\psi = (Z^{-2}E)\psi. \quad (22.57)$$

With $Z^{-1}V$ regarded as a perturbation, the expansions of ψ and E in the powers of Z^{-1} are

$$\psi = \psi_0 + Z^{-1}\psi_1 + Z^{-2}\psi_2 + \dots \quad (22.58)$$

in the ρ unit of length, and

$$E = Z^2(E_0 + Z^{-1}E_1 + Z^{-2}E_2 + Z^{-3}E_3 + \dots). \quad (22.59)$$

The zero-order equation is

$$H_0\psi_0 = E_0\psi_0. \quad (22.60)$$

The solutions of this equation are products of hydrogenic orbitals.

Let $|(nl)vLS\rangle$ be a configuration state function constructed by vector coupling methods from products of hydrogenic orbitals. Here, (nl) represents a set of N quantum numbers $(n_1l_1, n_2l_2, \dots, n_Nl_N)$ and v any additional quantum numbers, such as the coupling scheme or seniority needed to distinguish the different configuration states. Then,

$$H_0|(nl)vLS\rangle = E_0|(nl)vLS\rangle, \quad (22.61)$$

$$E_0 = -\frac{1}{2} \sum_i \frac{1}{n_i^2}. \quad (22.62)$$

Since E_0 is independent of the l_i , different configurations may have the same E_0 ; that is, E_0 is degenerate. According to first-order perturbation theory for degenerate states, ψ_0 then is a linear combination of the degenerate configuration state functions $|(nl')v'LS\rangle$ with the same set of principal quantum numbers n_i and parity π . The coefficients are components of an eigenvector of the interaction matrix $\langle (nl')v'LS|V|(nl)vLS\rangle$, and E_1 is the corresponding eigenvalue. This is the set of configurations referred to as the *complex* by Layzer [27] and denoted by the quantum numbers $(n)\pi LS$. The relativistic generalization of the non-relativistic Z -dependent theory of many-electron atoms was described by Layzer and Bahcall [28].

The zero-order wave function ψ_0 describes the many-electron system in a general way. It can be shown that the square of the expansion coefficients of ψ_0 over the degenerate set of configuration states can be interpreted as a probability that the many-electron system is in that configuration state, that ψ_1 is then a weighted linear combination of first-order corrections to each such configuration state. Let us now assume the nondegenerate case where $\psi_0 = \Phi(\gamma LS)$. The configurations interacting with γLS are of two types: those that differ by a single electron (single substitution S) and those that differ by two electrons (double substitution D). The former can be further subdivided into three categories:

- (i) Those that differ from γLS by one principal quantum number but retain the same spin–angular coupling. These configuration states are part of *radial correlation*.
- (ii) Those that differ by one principal quantum number but differ in their coupling. If the only change is the coupling of the spins, the configuration states are part of *spin polarization*.
- (iii) Those that differ in the angular momentum of one electron and are accompanied by a change in angular coupling of the configuration state and possibly also the spin coupling. The latter represent *orbital polarization*.

The sums over intermediate states involve infinite sums. In practice, the set of orbitals is finite. In the nondegenerate case, these orbitals can be divided into occupied orbitals and unoccupied, or virtual, orbitals, depending on whether or not they occur in the *reference configuration* that defines γLS . Single and double (SD) replacements of occupied orbitals by other occupied or virtual orbitals generate the set of configurations that interact with ψ_0 . Consider the $1s^2 2s$ ground state of Li and the $\{1s, 2s, 3s, 4s, 2p, 3p, 4p, 3d, 4d, 4f\}$ set of orbitals, which we will refer to as the $n = 4$ set. The $1s$ and $2s$ orbitals are occupied, and all the other orbitals are virtual orbitals, vl . The set of replacements can then be classified as described in Table 22.3.

The above discussion has considered only the Z -dependence of the wave function, but the notion can readily

Table 22.3 Classification of replacements from the $1s^2 2s$ ground state of Li. The $1s$ and $2s$ orbitals are occupied, and all the other orbitals are virtual orbitals, vl

Replacement	Configuration	Type of correlation
$1s \rightarrow 2s$	$1s2s^2$	Radial and spin polarization
$2s \rightarrow vs$	$1s^2 vs$	Radial
$1s \rightarrow vs$	$1svs(^1S)2s$	Radial
	$1svs(^3S)2s$	Spin polarization
$1s2s \rightarrow vlv'l$	$1svl v'l$	Core polarization
$1s^2 \rightarrow vlv'l$	$2svl v'l$	Core

be extended to other properties. For example, in transition studies, the dipole transition matrix element decreases as $1/Z$, whereas the transition energy increases linearly with Z for $\Delta n = 0$ transitions, and quadratically as Z^2 otherwise. A first-order theory for oscillator strengths (FOTOS) [29] is based on similar concepts.

22.5.2 The MC(D)HF Approximation

In the multiconfiguration Hartree–Fock (MCHF) method, the wave function is approximated by a linear combination of orthogonal configuration states so that

$$\Psi(\gamma LS) = \sum_i^M c_i \Phi(\gamma_i LS), \quad (22.63)$$

where

$$\sum_i^M c_i^2 = 1.$$

Then the energy expression becomes

$$\mathcal{E}[\Psi(\gamma LS)] = \sum_i^M \sum_j^M c_i c_j H_{ij}, \quad (22.64)$$

where

$$H_{ij} = \langle \Phi(\gamma_i LS) | H | \Phi(\gamma_j LS) \rangle. \quad (22.65)$$

Because $H_{ij} = H_{ji}$, the sum over i, j may be limited to the diagonals and the lower part of the matrix $\mathbf{H} = (H_{ij})$, called the *interaction matrix*. Let $\mathbf{c} = (c_i)$ be a column vector of the expansion coefficients, also called *mixing coefficients*. Then the energy of the system is

$$E = \mathbf{c}^T \mathbf{H} \mathbf{c}. \quad (22.66)$$

Let \mathbf{P} be the column vector of radial functions, $(P_a, P_b, \dots)^T$. Since the interaction matrix elements depend on the radial functions, it is clear that the energy functional depends on both \mathbf{P} and \mathbf{c} .

In deriving the MCHF equations, the energy needs to be expressed in terms of the radial functions and c . From the theory of angular momenta, it follows that

$$H_{ij} = \sum_{ab} q_{ab}^{ij} I(a, b) + \sum_{abcd;k} v_{abcd;k}^{ij} R^k(ab, cd), \quad (22.67)$$

where the sum over ab or $abcd$ covers the occupied orbitals of configuration states i and j .

Substituting into the energy expression Eq. (22.64) and interchanging the order of summation, we get

$$\mathcal{E}(\Psi) = \sum_{ab} q_{ab} I(a, b) + \sum_{abcd;k} v_{abcd;k} R^k(ab, cd), \quad (22.68)$$

where

$$q_{ab} = \sum_i \sum_j c_i c_j q_{ab}^{ij} \quad \text{and} \\ v_{abcd;k} = \sum_i \sum_j c_i c_j v_{abcd;k}^{ij}.$$

In this form, the energy is expressed as a list of integrals and their contribution to the energy, a form suitable for the derivation of the MCHF radial equations.

As in the derivation of the Hartree–Fock equations, the stationary principle must be applied to a functional that includes Lagrange multipliers for all the orthonormality constraints. Thus,

$$\mathcal{F}(\mathbf{P}, \mathbf{c}) = \mathcal{E}(\Psi) + \sum_{a < b} \delta_{\ell_a, \ell_b} \lambda_{ab} \langle a | b \rangle - E \sum_i c_i^2. \quad (22.69)$$

In deriving the stationary conditions with respect to variations in c_i , the most convenient form for $\mathcal{E}(\Psi)$ is Eq. (22.64), which leads to the secular equation

$$\mathbf{H} \mathbf{c} = E \mathbf{c}. \quad (22.70)$$

Thus, the Lagrange multiplier E is the total energy of the system.

The requirement of a stationary condition with respect to variations in the radial functions leads to a system of equations with exactly the same form as the Hartree–Fock equations except: (i) the occupation numbers q_{aa} are no longer integers but rather *expected* occupation numbers, and (ii) the operator $\tilde{X}(a; r)$ arises not only from the exchange of electrons within a configuration state but also from interactions between configuration states. Differential equation methods divide the variation of the energy functional by q_{aa} . Since the latter may approach zero, the associated diagonal energies become large, but this no longer implies a large binding energy [30, 31]. Computationally, methods such as

those used for eigenvalue methods that retain the symmetry of the energy matrix are preferred.

A solution of the MCHF problem requires the simultaneous solution of the secular equation and the variational radial equations. When the latter are assumed to be given, then only the secular problem needs to be solved, and the problem is called a *configuration interaction* (CI) problem. If any radial function is optimized, the calculation is called a *multiconfiguration Hartree–Fock* (MCHF) calculation. The iterative procedure for its solution is the MCHF-SCF method, the details of which can be found in [21].

The derivation of the MCDHF equations is very similar [5], using a configuration space spanned by relativistic CSFs and the DCB Hamiltonian for building the interaction matrix.

22.5.3 Systematic Methods

For MCHF calculations with only a few configuration states, the latter must be carefully chosen. According to first-order perturbation theory, the expansion coefficient is $c_i = \langle \Phi_i | H | \Phi_0 \rangle / (E_0 - E_i)$. Clearly, configurations near in energy to the state under investigation are candidates for a strong interaction, but it is also important to remember the numerator in this expression. Generally, the latter is large if the electrons in the two configurations occupy the same region of space. Thus, in the ground state of beryllium, the strongest mixing is with $2p^2\ ^1S$, even though the energy of the latter is far removed from the energy of $2s^2\ ^1S$. In highly ionized systems, the complex identifies the configurations that might interact strongly, but for neutral systems, there are many exceptions, particularly in atoms such as the transition metals where the 4s and 4p subshells may be filled before the 3d subshell.

For large-scale computation, it is desirable to define the configuration states systematically in terms of an active set (AS) of orbitals. Several notations are commonly used for this set. A very simple designation is *the $n = 4$ active set* in that all orbitals up to and including those with principal quantum number $n = 4$ are included. Another notation common in quantum chemistry is one where the number of orbitals of each symmetry is specified, as in 4s3p2d1f.

Closely associated with this set is the set of configuration states that can be generated. The latter is referred to as the complete active space (CAS). Often, the CAS is defined relative to a set of closed shells (or subshells) common to all configurations. For example, the complex for the $3s^2 3p^2\ ^3P$ ground state of Si, is a neon-like core, $1s^2 2s^2 2p^6$, coupled to the $\{N = 4, \pi = \text{even},\ ^3P\}$ CAS of the active set $\{3s, 3p, 3d\}$. If the AS is extended to $\{3s, 3p, 3d, 4s, 4p, 4d, 4f\}$, then all single, double, triple, quadruple (SDTQ) replacements from the outer four electrons are generated. Of course, the number

of CSF increases rapidly, both with the size of the active set and with the number of electrons N defining the CAS. The size of a CAS expansion in neon $\{N = 10, \pi = \text{even}, {}^1\text{S}\}$ grows from 4567 CSFs for the $3s2p1d$ AS to 3986026 CSFs for $4s3p2d1f$. For this reason, other models may be used, such as multireference singles and doubles (MR–SD) modeled on the results of Z -dependent perturbation theory. These multireference functions may be extended to include all important contributors to a wave function. Calculations in which correlation is restricted to a few outer electrons is called *valence correlation*.

A consequence of a CAS expansion is that the MCHF problem may be over determined: a rotation of radial functions of the same symmetry merely transforms the CSFs and the expansion coefficients. The wave function and energy do not change. When similar situations occur in Hartree–Fock theory, Koopmans’ theorem requires that the Lagrange multiplier associated with the rotation be set to zero. In MCHF calculations, the degree of freedom is usually used to eliminate a CSF or, more precisely, to determine that solution for which a specific CSF has a zero expansion coefficient. A generalized Brillouin’s theorem (GBT) then holds. In the case of the helium ground state (or any ns^2 pair function), applying GBT leads to the *natural orbital expansion* of the form $\{1s^2, 2s^2, 3s^2, \dots, 2p^2, 3p^2, \dots, 3d^2, \dots\}$ in which all CSF differ by two electrons. For other symmetries, such as $1s2p^3P^\circ$, a *reduced form* [32] can also be defined in which all CSF differ by two electrons, but now involves different sets of orthonormal radial functions for the different partial waves as in $\{1s2p_1, 2s3p_1, 3s4p_1, \dots, 2p_23d_1, 3p_24d_1, \dots\}$. Such expansions yield the fastest rate of convergence, but are difficult to apply in complex systems. For a history of Brillouin’s theorem and its use in solving multiconfiguration self-consistent field problems, see [33].

22.5.4 Excited States

For ground states or atomic states lowest in their symmetry, the variational procedure is a minimization procedure, and consequently any approximate energy is an upper bound. For all others, the energies are stationary. Such calculations may be difficult. One of the most difficult has been the HF calculation for $1s2s^1\text{S}$ and, once obtained, is disappointing since the energy is too low. Excited state calculations become minimization problems through the use of the Hylleraas–Undheim–MacDonald theorem (Sect. 12.3.1). Consider a CAS calculation over the active set $\{1s, 2s\}$ for which the CSFs are $\{1s^2, 1s2s, 2s^2\}$. In determining orbitals, we have a degree of freedom, so one CSF may be removed. Selecting $2s^2$ has the consequence that the eigenvalue for the $1s2s$ state to be determined is now the second eigenvalue, and, hence, an upper bound to the exact energy.

The description of excited states that are members of a Rydberg series is often challenging. The $3snl\ ^{1,3}\text{L}$ ($L = l$) series in magnesium is a good example. In the single Hartree–Fock approximation, the desired solution can be selected by counting the number of expecting nodes of the spectroscopic orbitals, as a starting point for further MCHF calculations. Rydberg series are often strongly perturbed by multiply-excited states whose relative position in the spectrum changes along the isoelectronic sequence and whose description may be more difficult. The description of the $3p3d$ perturber of the $3snf\ ^{1,3}\text{F}^\circ$ that is the fourth state of its symmetry for Al II ($Z = 13$) illustrates this [34]. In the MCHF approximation, the approximation $\{3s4f, 3p3d\}$ can, in principle, represent the interaction of $3p3d$ with the entire $3snf$ series, the variationally determined $4f$ orbital including the contribution from the entire nf series according to GBT. However, difficulties are encountered with the variational procedure in that part of the series ($4s4f$ to $3s6f$) interacts with $3p3d$ so as to raise the total energy whereas the remainder interacts so as to lower the energy. Some variationally equivalent representation has to be found to circumvent these problems [34, 35].

22.5.5 Autoionizing States

The MCHF variational method may be applied to core excited states imbedded in the continuum, provided that certain CSFs with filled shells are omitted. An example is $1s2s2p^2P^\circ$ of lithium. An MCHF calculation omitting $1s^2np$ configuration states represents the localized charge distribution of a state in the continuum. However, including $1s^22p$ and optimizing on the second eigenvalue would make the energy an upper bound. Otherwise a saddle-point variational method, as described in Chap. 26 is needed for such states.

22.6 Configuration Interaction Methods

Configuration interaction (CI) methods differ from variational methods like MC(D)HF in that the radial functions are assumed to be fixed, and, hence, known in advance. There are several situations where these methods can be used effectively.

MCHF with Breit–Pauli Since the Breit–Pauli operators are valid only as first-order perturbations, variational calculations for the Breit–Pauli Hamiltonian are not justified. Instead, MCHF calculations are performed to provide a basis for LSJ wave functions of Eq. (22.18). The expansion coefficients are obtained as a CI calculation. Usually, such expansions are a concatenation of the expansions of all the LS terms of a configuration and possibly some close lying

configurations. Most Breit–Pauli codes require a single orthonormal basis. An example is the ATSP code [2]. In order to have an orbital basis that simultaneously describes the correlation of all these LS terms from a systematic procedure, the MCHF derivation described earlier has been extended to derive systems of coupled equations for linear combinations of energy functionals, one for each LS term and eigenstate. With this extension, it has been possible to perform *spectrum* calculations in which all LSJ levels up to a certain point in the spectrum are included. This requires a balanced correlation approach, so that the energy differences with respect to the ground state are in good agreement with the observed excitation energy. Once wave functions have been obtained for each level, transition probabilities can be computed. With all E1 transitions between these levels and some E2/M1 transitions, the lifetimes of levels can be obtained [36].

Full-core methods The full-core plus correlation method (FCPC) [37] is a configuration interaction method. It is mostly used for an atomic system in which a well-defined *core* is present. For example, in a system such as the three-electron $1s^2nl$ or the four-electron $1s^2nl'n'l'$, the system has a $1s1s$ core. In this case, the wave function for an N -electron system is written as

$$\Psi(1, 2, 3, \dots, N) = \mathcal{A}\phi_{1s1s}(1, 2) \sum_i C_i \Phi_i(3, 4, \dots, N) + \mathcal{A} \sum_j D_j \psi_j(1, 2, 3, \dots, N),$$

where $\phi_{1s1s}(1, 2)$, the wave function of the core, is used as a single term, and \mathcal{A} denotes antisymmetrization. The relaxation of the core and other correlation effects are accounted for by the last term in this equation. The correlation effect of the $1s1s$ core is, in general, very strong, and it is difficult to fully account for this effect in a conventional N -electron wave function. If inaccurate results are obtained from such a wave function, it may be difficult to distinguish between errors coming from the core part or from the other parts. In the FCPC method, the correlation effect in $\phi_{1s1s}(1, 2)$ can be precalculated to a desired accuracy, such that ψ_j no longer contains the contribution from the unperturbed core. In physical processes such as ionization, optical transitions and others, the $1s1s$ core wave function in the final state does not change much from that of the initial state. Using the same $\phi_{1s1s}(1, 2)$ for the core may minimize possible errors due to the inaccuracy of the core wave function. The application of this method is not limited to systems with $1s1s$ cores. For example, for the lithium-like $1s2snp^4P^\circ$, for $n \geq 4$, the $1s2s^3S$ can also be considered as an appropriate *core*.

From a computational viewpoint, the FCPC wave function has the advantage that it reduces the matrix size of the secular equation substantially. This drastically reduces the memory

and CPU time needed on a computer. This method has been quite successful in getting accurate results for four-electron systems, as shown in Table 22.4. See [38] for more details.

Slater type orbitals The essential characteristic of a radial function can be well represented by the expansion

$$P_{nl}(r) = \sum_j c_{jnl} \phi_{jnl}(r),$$

where

$$\phi_{jnl}(r) = \left(\frac{(2\xi_{jnl})^{2I_{jnl}+1}}{(2I_{jnl})} \right)^{1/2} r^{I_{jnl}} \exp(-\xi_{jnl}r)$$

is a *Slater type orbital* (STO). Optimized sets of parameters have been tabulated for many Hartree–Fock wave functions, and these may be used to represent the core [43]. Others may be added and selected orbitals *exponent optimized* (only the exponent is varied), so as to augment the basis. This method has been used effectively by Hibbert as implemented in the *Configuration Interaction Version 3* program [44].

Spline basis The analytic basis methods described in the previous section have some similarities with MCHF in that linear combinations of STOs first represent orbitals, which then define the CSFs. These bases result in extensive cancellation as shown by Hansen et al. [45]. An expansion in B-spline basis functions, $B_i^k(r)$, which are a basis for a piecewise polynomial subspace (Chap. 8), provide a more flexible basis with very little cancellation in this representation.

By solving a radial equation with a well-chosen potential using the spline Galerkin method that leads to a matrix eigenvalue problem, a complete set of orbitals for a piecewise polynomial space can be obtained. The resulting orthogonal orbital basis may then be used in CI calculations. Such methods were reviewed by Hansen et al. [45]. Methods that deal directly with the primitive B-spline basis have been applied to the study of Rydberg series [47], although orthogonality to target orbitals was still required. More recently, by using nonorthogonal theory, an R -matrix-CI method that leads to a generalized eigenvalue problem was developed. As in the

Fig. 22.2 Contraction of the correlation orbitals from valence, core-valence, and core-core correlation MCHF calculations of Be $1s^2 2s^2 \ ^1S$. The two thick red lines correspond to the spectroscopic 1s (no node) and 2s (one node) Hartree-Fock frozen orbitals. Other lines represent the radial distributions of the correlation orbitals of the $n = 4$ active set. Note the location of the maxima of the different types of orbitals (taken from [46])

close-coupling approximation, the wave function is expressed in terms of one or more *targets*, each coupled to a Rydberg orbital, and an arbitrary number of pseudo states. Each Rydberg orbital is expressed as a linear combination of B-splines, but there is no requirement of orthogonality of the Rydberg orbital to the orbitals defining the target function [48].

PCFI method The MCHF orbitals being optimized on a given energy functional lie in the region where their interaction with the reference orbitals is found to be the most favorable, as revealed for the beryllium ground state by the progressive radial collapse of correlation orbitals when going from a valence (VV) $\{1s^2 2s^2 \ ^1S, 1s^2 n l n' l\}$, a core-valence (CV) $\{1s^2 2s^2 \ ^1S, 1s 2s n l n' l\}$, to a core (CC) $\{1s^2 2s^2 \ ^1S, 2s^2 n l n' l\}$ SD-MCHF calculation [49]. This is illustrated in Fig. 22.2 [46] for the three separate $n = 4$ active set calculations of valence, core-valence, and core correlation. This observation allows us to target specific correlation components through the optimization of appropriate virtual orbitals by tailoring the CSFs expansions to the desired effect through the orbital occupation numbers. This strategy is exploited in the partition correlation function interaction (PCFI) approach [46] that combines preoptimized MCHF basis through a compact configuration interaction matrix that takes higher-order effects into account. The price to pay is the appearance of radial nonorthogonalities in the matrix elements coupling the different CSF subspaces, which can be still performed efficiently using radial orbital biorthonormal transformations followed by adequate eigenvector counter-transformations [50]. The advantages of such an approach can be measured by the results reported in Table 22.5 for the beryllium ground state comparing CAS-MCHF results based on a single orthonormal orbital set with PCFI results obtained by diagonalizing an (8×8) interaction matrix. In the latter approach, an $n = 3$ valence-CAS calculation on $1s^2 \{2s, 2p, 3s, 3p, 3d\}^2 \ ^1S$ is first performed to get a zero-

order multireference wave function. The resulting orbitals are kept frozen in three subsequent MCHF calculations targeting VV, CV, and CC correlation. Each of these three independent MCHF calculations provides a tailored set of correlation orbitals for a given active set n . The three PCFs are as such finally combined with the five CSFs of the multireference expansion in a (8×8) configuration interaction matrix. The results are promising when realizing the huge gain in computational time for the PCFI approach in comparison with the CAS-MCHF approach, with a resulting lower total energy for active sets $n \geq 5$. One should, however, be aware that the number of optimized orbitals is sensitively different: for $n = 5$, the numbers of radial functions are 15 and 33 in the CAS-MCHF and PCFI approach, respectively. By (partially) deconstraining the mixing coefficients within each PCF subspace, one converges to the correct limits and keeps the tremendous advantage of improved convergence rates that comes from the use of several orbital sets [51]. Reducing ultimately each PCF to a single CSF with its own orbital basis leads to a nonorthogonal configuration interaction approach. This approach has been successfully used to estimate the doublet-quartet energy separation of neutral boron with the spectroscopic accuracy [52].

Table 22.5 Comparison of CAS-MCHF and PCFI total energies (in hartrees) for the ground state of beryllium with increasing orbital active sets. NCSF corresponds to the size M of the CSF expansion Eq. (22.17)

22.7 Atomic Properties

The discussion so far has concentrated entirely on determining accurate wave functions based on expressions for the energy. Energy levels are a byproduct of such calculations, but once a wave function is known, a number of atomic properties can be evaluated [53].

22.7.1 Transition Data—Allowed and Forbidden Lines

The most fundamental quantity for the probability of a transition from an initial state i to a final state f is the reduced matrix element related to the line strength by

$$S^{1/2} = \langle \Psi_i || O || \Psi_f \rangle, \quad (22.71)$$

where O is the transition operator. In the case of the electric dipole transition, there are two frequently used forms: the length form $O = \sum_j \mathbf{r}_j$ and the velocity form, $O = \sum_j \nabla_j / E_{if}$, where $E_{if} = E_f - E_i$. For exact *nonrelativistic* wave functions, the two forms are equivalent, but for approximate wave functions, the matrix elements, in general, differ. Thus, the computation of the line strength and the oscillator strength, or f -value, where

$$f = \frac{(2/3)E_{if}S}{(2S_i + 1)(2L_i + 1)},$$

forms a critical test of the wave function in nonrelativistic theory and also the model describing a many-electron system. The same operators are often also used in Breit–Pauli calculations. In this case, the velocity form of the operator has neglected some terms of order $(\alpha Z)^2$, and the length value is preferred. When transition rates are computed for all transitions between a set of levels, their accuracy varies. The latter depends on both the transition energy and the line strength. Usually, the accuracy of the energy level structure can be evaluated by a comparison of computed wavelengths with observation, even if only for a few lines. For calculations where wave functions predict energy levels in good agreement with observation, the discrepancy between length and velocity transition rates serve as a good “indicators of accuracy”. For relativistic calculations, transition rates for intercombination lines are accompanied by extensive cancellation and have less accuracy [54, 55].

Some well-known discrepancies between theory and experiment existed for more than a decade for the resonance transitions of Li and Na. For the nonrelativistic 2s–2p transition in Li, a full-core CI [56] calculation produced f -values of (0.74704, 0.74704, 0.75378) for the length, velocity, and acceleration forms, respectively. When relativistic corrections were included, the value changed to

^a [60]

0.74715, in agreement with a number of theories, tabulated to only four decimal places. A fast beam-laser experiment by *Gaupp* et al. [57], yielded a value of 0.7416 ± 0.0012 , but this value was revised in 1996 by a beam-gas-laser experiment in perfect agreement with theory [58]. In the case of the resonance transition in Na, when theory included correlation in the core as well as core-polarization and some relativistic effects, results were in agreement with an almost simultaneous cascade of new experimental values [59].

For MCHF calculations of transition data, an important consideration is that the matrix element is between two different states. For independently optimized wave functions, the orbitals of the initial and final states are not orthonormal, as assumed when Racah algebra techniques are used to evaluate the transition matrix element. Through the use of biorthogonal transformations, the orbitals and the coefficients of expansion of the wave functions of the initial and final state can be transformed efficiently so that standard Racah algebra techniques may be applied [50]. Table 22.6 shows the convergence of an MCHF calculation for the ground state of Boron from independently optimized wave functions.

Similar systematic strategies are used with relativistic expansions, demonstrating that large-scale calculations can give transition energies of spectroscopic accuracy, i.e., with an accuracy comparable to the one obtained from observations, as well as transition rates with estimated uncertainties of a few percent for a broad range of ions [61]. However, some surprising puzzles remain. A recent one is the theory-observation discrepancy in the 3C/3D f -value ratio in Fe XVII for which several large-scale MCHF+BP and MCDHF calculations are all in remarkable agreement, providing a theoretical ratio larger than observed by 36% [62, 63]. Nonlinear dynamical modeling with its nonequilibrium plasma effects was neglected in the analysis of experimental data and might explain some of the discrepancies [64].

22.7.2 Electron Affinities

By definition, the electron affinity is $A_e = E(A) - E(A^-)$. Thus, it is the energy difference between Hamiltonians dif-

fering by one electron. Correlation plays a very important role in the binding of the extra electron in the negative ion. For small systems such as Li, the electron affinity has been computed [65] to experimental accuracy [66] of (0.6176 ± 0.0002) eV. It has been known for a long time that the alkali metals have a positive electron affinity, but only recently has it been found, theoretically [67] and experimentally [68], that some of the alkaline earths may also be able to bind an extra electron. The d-electrons need to play a strong role, so Be and Mg, do not have a positive A_e , but according to the most recent experimental measurement, the electron affinity for Ca is 18 meV [69]. A calculation based on the spline methods and using a model potential with adjustable parameters to describe the core, obtained a value of 17.7 meV [70] in close agreement with experiment.

Atomic systems such as Ca are often thought of as two-electron systems and, indeed, for qualitative descriptions, many observations can be explained. A number of physical effects need to be considered when predicting such electron affinities:

- (i) Valence correlation is crucial for obtaining binding.
- (ii) Intershell correlation between the valence electrons and the core (core polarization) is also important. The first electron may polarize the core considerably, but this is reduced by the second electron since the two avoid each other dynamically and prefer to be on opposite sides of the core.
- (iii) Core rearrangement, which occurs because of the presence of one or more outer electrons and is particularly large if any of these penetrate the core. In the case of Ca^+ , the fixed-core Hartree–Fock energy of $3d^2D$ state is 300 meV higher if computed in the fixed potential of the Ca^{2+} ion compared with a fully variational calculation!
- (iv) Intracore exclusion effects due to the presence of an extra valence electron that reduces the correlation of the core.
- (v) Relativistic shift effects, which are present in observed levels and are particularly important for s-electrons.

Model potential methods attempt to capture all but valence correlation in a potential so that calculations for calcium, for example, can proceed as for a two-electron system. A review of various theoretical approaches, many of which include different effects, may be found in [71].

22.7.3 Metastable States and Autoionization

States above an ionization threshold may decay via a radiationless transition to a continuum. When the interaction with the continuum is spin-forbidden, the state is metastable. The

$nsnp^2^4P$ of negative ions, for example, decay through Breit–Pauli interactions with $nsnp^2$ doublets. The latter, in turn, interact with continuum states, thus opening a decay channel. Such metastable states may be treated as bound states.

The foundation for the theory of autoionization was laid down by *Fano* [72], where he developed a configuration interaction (CI) theory for autoionization. Let $\Psi_b(N; \gamma LS)$ be a normalized, multiconfiguration component of a discrete perturber for an N -electron system, in which all orbitals are bound orbitals, decaying exponentially for large r . Let Ψ_k be an asymptotically normalized continuum component of the wave function, also for an N -electron system, at energy E , of the form,

$$\Psi_k(N; E \gamma' LS) = |\Psi_b(N-1; \beta \tilde{L} \tilde{S}) \cdot \phi(kl) LS\rangle, \quad (22.72)$$

where $\Psi_b(N-1; \beta \tilde{L} \tilde{S})$ is a bound MCHF wave function for the $(N-1)$ -electron target system. Then, in the LS -coupling scheme, the width of the autoionizing state is given by the *Golden Rule*

$$\Gamma = 2\pi V_{E_0}^2, \quad (22.73)$$

where

$$V_{E_0} = \langle \Psi_b(N; \gamma LS) | H - E_0 | \Psi_k(N; E_0 \gamma' LS) \rangle. \quad (22.74)$$

A similar formula can be derived for the LSJ -scheme and the Breit–Pauli Hamiltonian. In the above equation, $E_0 = \langle \Psi_b(N; \gamma LS) | H | \Psi_b(N; \gamma LS) \rangle$. The energy of the core, or target, is $E_{\text{target}} = \langle \Psi_b(N-1; \beta \tilde{L} \tilde{S}) | H | \Psi_b(N-1; \beta \tilde{L} \tilde{S}) \rangle$, where H in the latter equation is the Hamiltonian for an $(N-1)$ -electron system.

The wave function for the continuum component is assumed to have only one unknown, namely $\phi(kl) = P_{kl}(r) |ls\rangle$, the one-particle continuum function, where $|ls\rangle$ is the known spin–angular part. The radial equation for $P_{kl}(r)$ has exactly the same form as Eq. (22.34), except that $\varepsilon_{nl, nl} = -k^2$, where $E_0 = E_{\text{target}} + k^2/2$. The radial function can be obtained iteratively using an SCF procedure from outward integration.

One of the more accurate calculations of a lifetime is that for $\text{He}^- 1s2s2p^4P_{5/2}^o$ by *Miecznik et al.* [73]. In this case, a lifetime of $345 \pm 10 \mu\text{s}$ was found and compared with the experimental value of $350 \pm 15 \mu\text{s}$ [74]. In this LSJ state, the $^4P^o$ interacts with the $1s^2kf^2F^o$. It was found that correlation in the target of the continuum orbital modified the lifetime. In calculations like these, it is always a question whether orthogonality conditions should be applied [as in projection operator formalism (Chap. 26)]. Some theorems relating to this question were published by *Brage et al.* [75].

The position and widths of autoionizing resonances can also be determined from the study of photoionization or photodetachment using a spline Galerkin method together with

inverse iteration. No boundary condition needs to be applied at the end of the range of integration, nor is there an inner and outer region. Resonance properties are obtained from a fitting of the cross section [76]. Nonorthogonal, spline-based R -matrix methods with an inner and outer region have also been developed, where there is no need for the *Buttle correction* and, at the same time, the nonorthogonality eliminates the need of certain pseudo states [77]. For an extensive review of the application of splines in atomic and molecular physics, see [78].

22.7.4 Nuclear Effects

Line isotope shifts The isotope shift observed in atomic transitions can be separated into a mass shift and a field shift. The mass shift is due to differences in the nuclear mass of the isotopes and is the dominant effect for light atoms. The volume shift arises from the finite volume of the nuclear charge distribution and is important for heavy atoms. From a physical point of view, the field shift is the more interesting, since it yields information about differences in the nuclear charge distribution between the isotopes.

The isotope shift in a transition is given as the difference between the shift for the upper and lower level. The individual shifts are often large, but cancel, and therefore it is necessary to calculate them very accurately in order to get a reliable value for the difference. The energy shifts are evaluated in first-order perturbation theory with wave functions obtained from the zero-order Schrödinger Hamiltonian, H_0 .

Mass shift Up to this point, the nuclear mass has been taken to be infinite. If instead it has a finite value M , an N -electron atom turns into an $(N + 1)$ -particle dynamical system. A transformation to center of mass \mathbf{R} plus relative coordinates $\mathbf{r}'_i = \mathbf{r}_i - \mathbf{r}_{\text{nuc}}$ yields the transformed Hamiltonian [79] (Chap. 12)

$$H = \frac{P^2}{2M_{\text{tot}}} + \sum_{i=1}^N \frac{p_i^2}{2\mu} + \sum_{i<j}^N \frac{\mathbf{p}'_i \cdot \mathbf{p}'_j}{M} + V(\mathbf{r}'_i), \quad (22.75)$$

where $M_{\text{tot}} = M + Nm_e$ is the total mass, and $\mu = Mm_e/(M + m_e)$ is the reduced mass. The first term is the kinetic energy of the center of mass, which can be omitted if \mathbf{R} is an ignorable coordinate. Introducing the scaled distances $\rho_i = \mathbf{r}'_i/a_\mu$, where $a_\mu = (m_e/\mu)a_0$ is the scaled Bohr radius, and assuming the potential as entirely Coulombic, H takes the form

$$H = -\frac{1}{2} \sum_{i=1}^N \nabla_{\rho_i}^2 - \frac{\mu}{M} \sum_{i<j}^N \nabla_{\rho_i} \cdot \nabla_{\rho_j} + V(\rho_i) \quad (22.76)$$

in units of e^2/a_μ . This can be written in the form $H = H_0 + H_{\text{MP}}$, where H_0 includes the first and last terms of Eq. (22.76), and

$$H_{\text{MP}} = -\frac{\mu}{M} \sum_{i<j}^N \nabla_{\rho_i} \cdot \nabla_{\rho_j} \frac{e^2}{a_\mu} \quad (22.77)$$

is the additional *mass polarization* term.

Equation (22.76) gives rise to two kinds of mass shifts. First, since H is identical to the infinite mass Hamiltonian, all its eigenvalues E_0 are multiplied by $a_0/a_\mu = \mu/m_e$, resulting in the *normal mass shift* (nms)

$$\Delta E_{\text{nms}} = -\frac{\mu}{M} E_0. \quad (22.78)$$

Second, if H_{MP} is treated as a first-order perturbation, then the resulting *specific mass shift* (sms) is

$$\Delta E_{\text{sms}} = \langle \Psi_0 | H_{\text{MP}} | \Psi_0 \rangle \frac{e^2}{a_\mu}, \quad (22.79)$$

where Ψ_0 is an eigenvector of H_0 . The specific mass shift parameter S_{sms} is defined by

$$S_{\text{sms}} = \langle \Psi_0 | -\sum_{i<j}^N \nabla_{\rho_i} \cdot \nabla_{\rho_j} | \Psi_0 \rangle. \quad (22.80)$$

Field shift The field shift of an atomic energy level is due to the extended nuclear charge distribution. The field inside the nucleus deviates from the Coulomb field of a point charge, and this is reflected in the calculated levels. For light atoms, the resulting energy correction to the level E_0 is expressed in terms of the nonrelativistic electron probability at the origin, $|\Psi(0)|^2$

$$E_{\text{fs}} = \frac{2\pi}{3} Z \langle r_N^2 \rangle |\Psi(0)|^2, \quad (22.81)$$

where $\langle r_N^2 \rangle$ is the mean square radius of the nucleus. For heavier atoms ($Z > 10$), it becomes necessary to include a relativistic correction factor. Numerical values of this correction factor can be found in [15].

Table 22.7 shows the convergence of an MCHF calculation for the specific mass shift parameter and the electron density at the nucleus of the ground state of boron II as the active set increases. The calculated $^{11}\text{B}-^{10}\text{B}$ isotope shift is 13.3 mÅ with an estimated uncertainty of 1%. The size of the isotope shift is similar to the limit of resolution of the Goddard High Resolution Spectrograph aboard the Hubble Space Telescope [80].

The above theoretical concepts apply to nonrelativistic systems. For relativistic ones, both the mass and field shifts need to be reformulated in the four-component relativistic formalism [81]. A recent example of useful application in nuclear physics can be found in [82].

Table 22.7 Specific mass shift parameter and electron density at the nucleus as a function of the active set

Active set	S_{sms} (arb. u.)	$ \psi(0) ^2$
HF	0.00000	72.629
2s 1p	-0.02017	72.452

5s 4p 3d 2f 1g	0.60169	72.501
6s 5p 4d 3f 2g 1h	0.59803	72.503
7s 6p 5d 4f 3g 2h 1i	0.59709	72.504

Hyperfine structures The magnetic hyperfine structure (hfs) is due to an interaction between the magnetic field generated by the electrons and the nuclear magnetic dipole moment. The interaction couples the nuclear and electronic angular momenta to a total momentum $\mathbf{F} = \mathbf{I} + \mathbf{J}$, and the interaction energy can be written as the expectation value of a scalar product between an electronic and a nuclear tensor operator [83] (Chap. 17)

$$W_{M1}(J) = \langle \gamma_I \gamma_J I J F M_F | \mathbf{T}^{(1)} \mathbf{M}^{(1)} | \gamma_I \gamma_J I J F M_F \rangle. \quad (22.82)$$

The nuclear operator $\mathbf{M}^{(1)}$ is related to the scalar magnetic dipole moment, μ_I , according to

$$\langle \gamma_I I I | M_0^{(1)} | \gamma_I I I \rangle = \mu_I. \quad (22.83)$$

The magnetic dipole moments are known quantities, obtained with high accuracy from experiments. For a recent tabulation see [84].

The electronic operator is

$$\begin{aligned} \mathbf{T}^{(1)} = & \frac{\alpha^2}{2} \sum_{i=1}^N \left\{ 2I^{(1)}(i)r_i^{-3} \right. \\ & - g_s \sqrt{10} [C^{(2)}(i) \times s^{(1)}(i)]^{(1)} r_i^{-3} \\ & \left. + g_s \frac{8}{3} \pi \delta(\mathbf{r}_i) s^{(1)}(i) \right\}, \quad (22.84) \end{aligned}$$

where $g_s = 2.0023193$ is the electron spin g -factor, $\delta(\mathbf{r})$ the three-dimensional delta function, and $C_q^{(k)} = \sqrt{4\pi/(2k+1)} Y_{kq}$, with Y_{kq} being a normalized spherical harmonic. The first term of the electronic operator represents the magnetic field generated by the orbiting electric charges and is called the orbital term. The second term represents the field generated by the orbiting magnetic dipole moments, which are coupled to the spin of the electrons. This is the spin-dipole term. The last term represents the contact interaction between the nuclear magnetic dipole moment and the electron magnetic moment. It is called the Fermi contact term and contributes only for s-electrons.

By uncoupling I and J that constitute the components $\mathbf{F} = \mathbf{I} + \mathbf{J}$, the interaction energy can be rewritten as

$$\begin{aligned} W_{M1}(J) = & (-1)^{I+J-F} W(IJII; F1) \\ & \times \langle \gamma_J J | \mathbf{T}^{(1)} | \gamma_J J \rangle \langle \gamma_I I | \mathbf{M}^{(1)} | \gamma_I I \rangle, \quad (22.85) \end{aligned}$$

where $W(IJII; F1)$ is a W coefficient of Racah. When the magnetic dipole interaction constant

$$A_J = \frac{\mu_I}{I} \frac{1}{[J(J+1)(2J+1)]^{\frac{1}{2}}} \langle \gamma_J J | \mathbf{T}^{(1)} | \gamma_J J \rangle \quad (22.86)$$

is introduced, the energy is given by

$$W_{M1}(J) = \frac{1}{2} A_J C, \quad (22.87)$$

where $C = F(F+1) - J(J+1) - I(I+1)$. In theoretical studies, the A -factor is often given as a linear combination of the hyperfine parameters [85]

$$a_l = \langle \gamma_L S M_L M_S | \sum_i l_0^{(1)}(i) r_i^{-3} | \gamma_L S M_L M_S \rangle, \quad (22.88)$$

$$a_d = \langle \gamma_L S M_L M_S | \sum_i 2C_0^{(2)}(i) s_0^{(1)}(i) r_i^{-3} | \gamma_L S M_L M_S \rangle, \quad (22.89)$$

$$a_c = \langle \gamma_L S M_L M_S | \sum_i 2s_0^{(1)}(i) r_i^{-2} \delta(r_i) | \gamma_L S M_L M_S \rangle, \quad (22.90)$$

where $M_L = L$ and $M_S = S$. These parameters correspond to the orbital, spin-dipole, and Fermi contact term of the electronic operator.

The electric hyperfine structure is due to the interaction between the electric field gradient produced by the electrons and the nonspherical charge distribution of the nucleus. The interaction energy is

$$W_{E2}(J) = \langle \gamma_I \gamma_J I J F M_F | \mathbf{T}^{(2)} \mathbf{M}^{(2)} | \gamma_I \gamma_J I J F M_F \rangle, \quad (22.91)$$

where the nuclear operator $\mathbf{M}^{(2)}$ is related to the scalar electric quadrupole moment, Q , according to

$$\langle \gamma_I I I | M_0^{(2)} | \gamma_I I I \rangle = \frac{Q}{2}. \quad (22.92)$$

The electronic operator is

$$\mathbf{T}^{(2)} = - \sum_{i=1}^N C^{(2)}(i) r_i^{-3} \quad (22.93)$$

and represents the electric field gradient. By introducing the electric quadrupole interaction constant B ,

$$\begin{aligned} B_J = & 2Q \left(\frac{J(2J-1)}{(J+1)(2J+1)(2J+3)} \right)^{\frac{1}{2}} \\ & \times \langle \gamma_J J | \mathbf{T}^{(2)} | \gamma_J J \rangle, \quad (22.94) \end{aligned}$$

Table 22.8 MCHF hyperfine constants (in MHz) for the $1s^2 2s 2p^1 P^\circ$ state of B II

Active set	^{10}B		^{11}B	
	A_1	B_1	A_1	B_1
HF	60.06	8.338	179.36	4.001
2s 1p	60.22	8.360	179.83	4.011
3s 2p 1d	60.98	8.193	182.11	3.932
4s 3p 2d 1f	60.05	7.677	179.34	3.684
5s 4p 3d 2f 1g	60.48	7.764	180.62	3.725
6s 5p 4d 3f 2g 1h	60.85	8.052	181.71	3.864
7s 6p 5d 4f 3g 2h 1i	60.81	8.002	181.60	3.840

the interaction energy can be written as

$$W_{E2}(J) = B_J \frac{\frac{3}{4}C(C+1) - I(I+1)J(J+1)}{2I(2I-1)J(2J-1)}. \quad (22.95)$$

In many cases, the electric hyperfine interaction is weaker than the magnetic one and manifests itself as a small deviation from the Landé interval rule for the magnetic hfs.

Nuclear parameters can be extracted from observed hyperfine structures if the electronic part of the interaction can be calculated accurately. A recent illustration is the determination of the nuclear electric moment $Q(^{67}\text{Zn})$ from the theoretical estimation of the electric field gradient using elaborate correlation models for MC(D)HF calculations [86]. A tabulation of nuclear quadrupole moments is given in [87].

Table 22.8 shows the convergence of an MCHF active space calculation for two different isotopes for the $1s^2 2s 2p^1 P^\circ$ state of B II [80]. Some oscillations are observed since each new layer of orbitals may localize in different regions of space. Ab-initio studies of hyperfine structure parameters are definitely helpful for assessing the reliability of hyperfine constants extracted from observed spectra. A nice example is given by recent work reconciling theory with observation through the reinterpretation of saturation spectra of low lying states of $^{14,15}\text{N}$ [88]. Relativistic effects on hyperfine constants can be much more important than expected, even for light, a-priori nonrelativistic systems, such as neutral fluorine [89]. The inclusion in the Hamiltonian of the Breit–Pauli terms that mix terms having different LS -symmetries [Eq. (22.18)] can be crucial in some specific cases, as confirmed by fully relativistic MCDHF calculations [90].

Isotope shifts on electron affinities In neutral oxygen, it has been found that there is an “anomalous” isotope effect [91] corresponding to a larger electron affinity for the lightest isotope. In all systems considered in the second and third periods of the periodic table ($^{7,9,11}\text{Be}^-$, $^{13,13,14}\text{C}^-$, $^{16,17,18}\text{O}^-$, $^{28,30}\text{Si}^-$, $^{32,34}\text{S}^-$, $^{35,37}\text{Cl}^-$) chlorine is the only pair

for which the normal mass shift dominates the counteracting specific mass shift contribution and, therefore, has an isotope shift that can be qualified as “normal” [92]. The predictive value of MCHF calculations can be illustrated by the theoretical estimation of the IS on the carbon electron affinity, $E_a(^{13}\text{C}) - E_a(^{12}\text{C}) = -7.04 \text{ m}^{-1}$, which has been confirmed by the photodetachment microscopy measurements ($= -7.3(6) \text{ m}^{-1}$) [93].

22.8 Summary

More comprehensive treatments of atomic structure may be found in [8, 9, 24, 94]. Atomic structure packages are available in [1–4] for many of the calculations described in the present chapter. Reviews of the application of systematic procedures to the prediction of atomic properties are available in [49, 95–97]. As has been mentioned at different places, atomic structure methods and their implementation in ATSP and GRASP are very similar. Advanced nonrelativistic (MCHF) and relativistic (MCDHF) multiconfiguration methods for the calculation of energies and wave functions of complex atoms are considered in detail in [5]. An extension of this review paper focusing on the applications is in progress [98].

Charlotte Froese Fischer Charlotte Froese Fischer is Professor Emerita of Computer Science at Vanderbilt University and an Affiliate Professor at the University of British Columbia. She is a Fellow of the Division of Atomic and Molecular Physics as well as the Royal Society of Canada. Her research interests are computational atomic structure theory for predicting atomic properties, particularly transition probabilities in complex spectra.

Michel Godefroid Michel Godefroid is Research Director Emeritus of the "Fonds National de la Recherche Scientifique" (F.R.S.-FNRS) and full Professor at Université libre de Bruxelles (Brussels, Belgium), teaching physical chemistry and atomic and molecular physics. His research is mainly focused on the development of original and efficient computational strategies for describing electron correlation and relativistic effects on atomic structures and properties.

Abstract

Relativistic quantum mechanics is required for the description of atoms and molecules whenever their orbital electrons probe regions of space with high potential energy near the atomic nuclei. Primary effects of a relativistic description include changes to spatial and momentum distributions, spin–orbit interactions, quantum electrodynamic corrections such as the Lamb shift, and vacuum polarization. Secondary effects in many-electron systems arise from shielding of the outer electrons by the distributions of electrons in penetrating orbitals; they change orbital binding energies and dimensions and so modify the order in which atomic shells are filled in the lower rows of the periodic table. All these mechanisms must be considered in any attempt to estimate observable quantities to spectroscopic accuracy.

Relativistic atomic and molecular structure theory can be regarded as a simplification of the fundamental description provided by quantum electrodynamics (QED). This treats the atom or molecule as an assembly of electrons and atomic nuclei interacting primarily by exchanging photons. This model is far too difficult and general for most purposes, and simplifications are required. The most important of these is the representation of the nuclei as classical charge distributions, or even as point particles.

I. Grant (✉)

Oxford, UK

Since the motion of the nuclei is usually slow relative to the electrons, it is often adequate to treat the nuclear motion nonrelativistically, or even to start from nuclei in fixed positions, correcting subsequently for nuclear motion.

The emphasis in this chapter is on relativistic methods for the calculation of atomic structure for general many-electron atoms based on an effective Hamiltonian derived from QED in the manner sketched in Sect. 23.2 below. An understanding of the Dirac equation, its solutions and their numerical approximation, is essential material for studying many-electron systems, just as the corresponding properties of the Schrödinger equation underpin Chap. 22. Indeed, recent software developments aimed to improve the performance of atomic structure calculations apply to relativistic as much as to nonrelativistic programs. We shall use atomic units throughout. Where it aids interpretation, we shall, however, insert factors of c , m_e and \hbar . In these units, the velocity of light, c , has the approximate numerical value $\alpha^{-1} = 137.035999139$ (31), as recommended in [1], where α is the fine structure constant.

23.1 Mathematical Basics

23.1.1 Relativistic Notation: Minkowski Space-Time

An *event* in Minkowski space-time is defined by a *contravariant* four-vector $x = \{x^\mu\}$ ($\mu = 0, 1, 2, 3$), where $x^0 = ct$ is the time coordinate, and x^1, x^2, x^3 are Cartesian coordinates in three-space. We shall use the Einstein suffix convention, in which matched pairs of upper and lower Greek subscripts are assumed to be summed over all values 0, 1, 2, 3, whenever convenient. The metric of Minkowski space is defined by

$$g = (g_{\mu\nu}) = (g^{\mu\nu}) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \quad (23.1)$$

where $g_{\mu\nu} = g^{\mu\nu}$ are called *metric coefficients*. *Covariant* four-vectors x_μ are related to contravariant four-vectors by

$$x_\mu = g_{\mu\nu} x^\nu \quad \text{and} \quad x^\nu = g^{\nu\mu} x_\mu.$$

The bilinear form

$$(x, y) = x_\nu y^\nu = x^\mu g_{\mu\nu} y^\nu = x^\mu y_\mu \quad (23.2)$$

is an *inner product* on Minkowski space, invariant under Lorentz transformations. See also Sect. 23.1.4.

23.1.2 Lorentz Transformations

Lorentz transformations are defined as linear mappings Λ such that

$$(\Lambda x, \Lambda y) = (x, y), \quad (23.3)$$

so that

$$g_{\mu\nu} = \Lambda^\rho{}_\mu g_{\rho\sigma} \Lambda^\sigma{}_\nu. \quad (23.4)$$

This furnishes 10 equations connecting the 16 components of Λ ; at most 6 components can be regarded as independent parameters. The (infinite) set of Λ matrices forms a regular matrix group (with respect to matrix multiplication) called the Lorentz group, \mathcal{L} , designated $O(3,1)$ [2, 3].

23.1.3 Classification of Lorentz Transformations

Rotations Lorentz transformations with matrices of the form

$$\Lambda = \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{R} \end{pmatrix}, \quad (23.5)$$

where $\mathbf{R} \in \text{SO}(3)$ is an orthogonal 3×3 matrix with determinant $+1$, and $\mathbf{0}$ is a null three-dimensional column vector, correspond to three-dimensional space rotations. They form a group isomorphic to $\text{SO}(3)$.

Boosts Lorentz transformations with matrices of the form

$$\Lambda = \begin{pmatrix} \gamma(v) & \gamma(v)\mathbf{v} \\ \gamma(v)\mathbf{v} & \mathbf{I}_3 + (\gamma(v) - 1)\mathbf{nn}^\top \end{pmatrix}, \quad (23.6)$$

with $\mathbf{v} = v\mathbf{n}$ a three-dimensional column vector, $|\mathbf{n}| = 1$, $v = |\mathbf{v}|$ and $\gamma(v) = (1 - v^2/c^2)^{-1/2}$, are called *boosts*. The matrix Λ describes an *active* transformation from an inertial frame in which a free classical particle is at rest to another inertial frame in which its velocity is \mathbf{v} .

Boosts form a submanifold of \mathcal{L} although they do not in general form a subgroup. However, the set of boosts in a fixed direction \mathbf{n} form a one-parameter subgroup.

Discrete transformations The matrices

$$P = \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & -\mathbf{I}_3 \end{pmatrix}, \quad T = \begin{pmatrix} -1 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{I}_3 \end{pmatrix} \quad (23.7)$$

with $PT = -\mathbf{I}_4$ are called *discrete* Lorentz transformations and form a subgroup of the Lorentz group along with the identity \mathbf{I}_4 . The matrix P performs *space* or *parity inversion*; the matrix T performs *time reversal*.

Infinitesimal Lorentz transformations The proper Lorentz transformations close to the identity are of particular importance; they have the form

$$\begin{aligned} \Lambda^\mu{}_\nu &= \delta^\mu{}_\nu + \epsilon \omega^\mu{}_\nu + \dots, \\ (\Lambda^{-1})^\mu{}_\nu &= \delta^\mu{}_\nu - \epsilon \omega^\mu{}_\nu + \dots, \end{aligned} \quad (23.8)$$

where $\omega^\mu{}_\nu = g^{\mu\rho}\omega_{\rho\nu}$, $\omega_{\mu\nu} = -\omega_{\nu\mu}$, and ϵ is infinitesimal. The *infinitesimal generators*, components $\omega_{\mu\nu}$, can be treated as quantum mechanical observables; see Sect. 23.2.1.

The Lorentz group The Lorentz group \mathcal{L} is a Lie group with a six-dimensional group manifold that has four connected components, namely

$$\mathcal{L}_+^\uparrow \equiv \{ \Lambda \in \mathcal{L} \mid \Lambda^0{}_0 \geq 1, \det \Lambda = +1 \}, \quad (23.9)$$

$$\mathcal{L}_-^\uparrow \equiv \{ \Lambda \in \mathcal{L} \mid \Lambda^0{}_0 \geq 1, \det \Lambda = -1 \} = P \mathcal{L}_+^\uparrow, \quad (23.10)$$

$$\mathcal{L}_+^\downarrow \equiv \{ \Lambda \in \mathcal{L} \mid \Lambda^0{}_0 \leq 1, \det \Lambda = -1 \} = T \mathcal{L}_+^\uparrow, \quad (23.11)$$

$$\mathcal{L}_-^\downarrow \equiv \{ \Lambda \in \mathcal{L} \mid \Lambda^0{}_0 \leq 1, \det \Lambda = +1 \} = PT \mathcal{L}_+^\uparrow. \quad (23.12)$$

The connected component \mathcal{L}_+^\uparrow containing the identity is a Lie subgroup of \mathcal{L} called the *proper Lorentz group*. All its group elements can be obtained from boosts and rotations. It is not simply connected because the subgroup of rotations is not simply connected. The group is also noncompact as the subset of boosts is homeomorphic to \mathcal{R}^3 .

These topological properties of \mathcal{L}_+^\uparrow are essential for understanding the properties of relativistic wave equations. In particular, the multiple connectedness forces the introduction of spinor representations and the appearance of half-integer angular momenta or spin.

23.1.4 Contravariant and Covariant Vectors

Contravariant four-vectors (such as events x) transform according to the rule

$$a^\mu \mapsto a^{\mu'} = \Lambda^{\mu'}{}_\nu a^\nu. \quad (23.13)$$

Covariant four-vectors can be formed by writing

$$a_\mu = g_{\mu\nu} a^\nu, \quad (23.14)$$

so that

$$a^\mu a_\mu = a^\mu g_{\mu\nu} a^\nu = (a, a) \quad (23.15)$$

is invariant with respect to Lorentz transformations. Similarly, we can construct a contravariant four-vector from

a covariant one by writing

$$a^\mu = g^{\mu\nu} a_\nu. \quad (23.16)$$

The transformation law for covariant vectors is, therefore,

$$a_\mu \mapsto a'_\mu = [\Lambda^{-1}]^\nu{}_\mu a_\nu. \quad (23.17)$$

The most important example of a covariant vector is the four-momentum operator

$$p_\mu = i \frac{\partial}{\partial x^\nu} \quad \mu = 0, 1, 2, 3. \quad (23.18)$$

From this, we derive the *contravariant* four-momentum operator with components p^μ by writing

$$\begin{aligned} p^\mu &= g^{\mu\nu} p_\nu \\ &= \left(i \frac{\partial}{\partial x^0}, -i \frac{\partial}{\partial x^1}, -i \frac{\partial}{\partial x^2}, -i \frac{\partial}{\partial x^3} \right), \end{aligned} \quad (23.19)$$

in agreement with nonrelativistic expressions.

23.1.5 Poincaré Transformations

More generally, a Poincaré transformation is obtained by combining Lorentz transformations and space-time translations:

$$\Pi(x) = \Lambda x + a. \quad (23.20)$$

The set of all Poincaré transformations, $\Pi = (a, \Lambda)$, with the composition law

$$(a_1, \Lambda_1)(a_2, \Lambda_2) = (a_1 + \Lambda_1 a_2, \Lambda_1 \Lambda_2), \quad (23.21)$$

also forms a group, \mathcal{P} .

Properties of the Lorentz and Poincaré groups will be introduced as needed. For a concise account of their properties, see [4]. For more details on relativistic quantum mechanics in general, see textbooks such as [4, 5].

23.2 Dirac's Equation

We present Dirac's equation for an electron in a classical electromagnetic field defined by the four-potential $A_\mu(x)$:

Covariant form

$$\{ \gamma^\mu [p_\mu - e A_\mu(x)] - m_e c \} \psi(x) = 0. \quad (23.22)$$

where

$$\gamma^\mu (\mu = 0, 1, 2, 3), \text{ are } 4 \times 4 \text{ matrices.}$$

$\psi(x)$ is a four-component spinor wave function.

Here, and elsewhere in this chapter, identity matrices are omitted when it is safe to do so.

Dirac gamma matrices

- Anticommutation relations:

$$\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu = 2g^{\mu\nu} .$$

- Standard representation:

$$\gamma^0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

$$\gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}, \quad i = 1, 2, 3 ,$$

where σ_i ($i = 1, 2, 3$) are Pauli matrices [2–5].

Noncovariant form In the majority of atomic structure calculations, a frame of reference is chosen in which the nuclear center is taken to be fixed at the origin. In this case, it is convenient to write Dirac's equation in noncovariant form. Then, functions of

$$x = (x^0, \mathbf{x}) ,$$

where $x^0 = ct$, can be regarded as functions of the time t and the position three-vector \mathbf{x} , so that Eq. (23.22) is replaced by

$$i \frac{\partial}{\partial t} \psi(\mathbf{x}, t) = \hat{\mathbf{h}}_D \psi(\mathbf{x}, t) , \quad (23.23)$$

where the scalar and three-vector potentials are defined by

$$\phi(\mathbf{x}, t) = cA^0(\mathbf{x}, t) , \quad (23.24)$$

$$\mathbf{A}(\mathbf{x}, t) = [A^1(\mathbf{x}, t), A^2(\mathbf{x}, t), A^3(\mathbf{x}, t)] ,$$

and

$$\hat{\mathbf{h}}_D = c\boldsymbol{\alpha} \cdot [\mathbf{p} - e\mathbf{A}(\mathbf{x}, t)] + e\phi(\mathbf{x}, t) + \beta m_e c^2 \quad (23.25)$$

defines the Dirac Hamiltonian. The 4×4 matrices $\boldsymbol{\alpha}$, with Cartesian components $(\alpha^1, \alpha^2, \alpha^3)$, and β , have the standard representation

$$\beta = \gamma^0 = \begin{pmatrix} I_2 & 0 \\ 0 & -I_2 \end{pmatrix}, \quad (23.26)$$

$$\alpha^i = \gamma^0 \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ \sigma^i & 0 \end{pmatrix}, \quad i = 1, 2, 3 . \quad (23.27)$$

23.2.1 Characterization of Dirac States

The solutions of Dirac's equation span representations of the Lorentz and Poincaré groups, whose infinitesimal generators can be identified with physical observables. The Lorentz group algebra has ten independent self-adjoint infinitesimal generators; these can be taken to be the components p^μ of the four-momentum (which generate displacements

in each of the four coordinate directions), the three generators, J_i , of rotations about each space-coordinate axis, and the pseudovector w_μ . The irreducible representations can be characterized by invariants

$$(p, p) = m_e^2 c^2 , \quad (23.28)$$

$$(w, w) = -m_e^2 c^2 s^2 = -\frac{3}{4} m_e^2 c^2 , \quad (23.29)$$

where p is the momentum four-vector and \mathbf{s} is a three-vector defined in terms of Pauli matrices by

$$s_i = \frac{1}{2} \sigma_i , \quad i = 1, 2, 3 ,$$

which can be interpreted as the electronic angular momentum (intrinsic spin) in its rest frame. For more details, see [4] and the original papers [6–9].

23.2.2 The Charge-Current Four-Vector

Dirac's equation (23.22) is covariant with respect to Lorentz Eq. (23.3) and Poincaré Eq. (23.20) transformations, provided that there exists a nonsingular 4×4 matrix $S(\Lambda)$ with the property

$$\psi'(x) = S(\Lambda) \psi[\Lambda^{-1}(x - a)] . \quad (23.30)$$

The matrices $S(\Lambda)$ are characterized by the equation

$$S^{-1}(\Lambda) \gamma^\lambda S(\Lambda) = \Lambda^\lambda{}_\mu \gamma^\mu . \quad (23.31)$$

The most important observable expression required in this chapter is the *charge-current four-vector*

$$j^\mu = ec \bar{\psi}(x) \gamma^\mu \psi(x) , \quad (23.32)$$

where the Dirac adjoint is defined by

$$\bar{\psi}(x) = \psi^\dagger(x) \gamma^0 , \quad (23.33)$$

and the dagger denotes spinor conjugation and transposition. Since

$$\begin{aligned} \bar{\psi}'(x) &= \bar{\psi}[\Lambda^{-1}(x - a)] \gamma^0 S(\Lambda)^\dagger \gamma^0 \\ &= \bar{\psi}[\Lambda^{-1}(x - a)] S^{-1}(\Lambda) , \end{aligned}$$

$j^\mu(x)$ transforms as a four-vector

$$j^\mu(x) = \Lambda^\mu{}_\nu j^\nu(x)$$

by virtue of Eq. (23.31). The component $j^0(x)$ can be interpreted as a multiple of the *charge density* $\rho(x)$,

$$j^0(x) = ec\rho(x) = ec \bar{\psi}(x) \gamma^0 \psi(x) = ec \psi^\dagger(x) \psi(x) \quad (23.34)$$

and the space-like components as the *current density*

$$j^i(x) = ec\bar{\psi}(x)\gamma^i\psi(x) = ec\psi^\dagger(x)\alpha^i\psi(x). \quad (23.35)$$

The charge–current density satisfies a continuity equation, which in noncovariant form reads

$$\frac{\partial\rho(x)}{\partial t} + \sum_{i=1}^3 \frac{\partial j^i(x)}{\partial x^i} = 0,$$

or, in covariant notation,

$$\partial_\mu j^\mu = 0. \quad (23.36)$$

This is readily proved by using the Dirac equation (23.22) and its Dirac adjoint. Equation (23.36) is clearly invariant under Poincaré transformations, and this yields the important property that *electric charge* is conserved in Dirac theory.

23.3 QED: Relativistic Atomic and Molecular Structure

23.3.1 The QED Equations of Motion

The conventional starting point [10–13] for deriving equations of motion in quantum electrodynamics (QED) is a Lagrangian density of the form

$$\mathcal{L}(x) = \mathcal{L}_{\text{em}}(x) + \mathcal{L}_e(x) + \mathcal{L}_{\text{int}}(x). \quad (23.37)$$

The first term is the Lagrangian density for the free electromagnetic field, $F^{\mu\nu}(x)$,

$$\mathcal{L}_{\text{em}}(x) = -\frac{1}{4}F^{\mu\nu}F_{\mu\nu}, \quad (23.38)$$

and the second term is the Lagrangian density for the electron–positron field in the presence of the external potential $A_{\text{ext}}^\mu(x)$,

$$\mathcal{L}_e(x) = \bar{\psi}(x)\{\gamma_\mu[p^\mu - eA_{\text{ext}}^\mu(x)] - m_e c\}\psi(x). \quad (23.39)$$

We assume that the electromagnetic fields are expressible in terms of the four-potentials by

$$F^{\mu\nu} = \partial^\mu A_{\text{tot}}^\nu - \partial^\nu A_{\text{tot}}^\mu,$$

where

$$A_{\text{tot}}^\mu(x) = A_{\text{ext}}^\mu(x) + A^\mu(x)$$

is the sum of a four-potential $A_{\text{ext}}^\mu(x)$ describing the fields generated by classical external charge–current distributions, and a quantized field $A^\mu(x)$, which through

$$\mathcal{L}_{\text{int}}(x) = -j_\mu(x)A^\mu(x), \quad (23.40)$$

accounts for the interaction between the uncoupled electrons and the radiation field. The field equations deduced from Eq. (23.37) are

$$\begin{aligned} \{\gamma_\mu[p^\mu - A_{\text{ext}}^\mu(x)] - m_e c\}\psi(x) &= \gamma_\mu A^\mu(x)\psi(x) \\ \partial_\mu F^{\mu\nu}(x) &= j^\nu(x) \end{aligned} \quad (23.41)$$

and clearly exhibit the coupling between the fields.

Quantum electrodynamics requires the solution of the system Eq. (23.41) when $A^\mu(x)$, $\psi(x)$ and its adjoint $\bar{\psi}(x)$ are quantized fields. This presentation is purely formal it ignores all questions of zero-point energies, normal ordering of operators, choice of gauge associated with the quantized photon field, or the need to include (infinite) counterterms to render the theory finite.

23.3.2 The Quantized Electron–Positron Field

Furry’s bound interaction picture of QED [10, 14] exploits the fact that a one-electron model is often a good starting point for a more accurate calculation of atomic or molecular properties. The electrons are described by a field operator

$$\psi(x) = \sum_{E_m > E_F} a_m \psi_m(x) + \sum_{E_n < E_F} b_n^\dagger \psi_n(x), \quad (23.42)$$

where $E_F \geq -mc^2$ is a *Fermi level* separating the states describing electrons (bound and continuum) from the positron states (lower continuum) in the chosen time-independent model potential $V(\mathbf{r})$. Equation (23.42) is written as if the spectrum were entirely discrete, as in finite matrix models; more generally, this must be replaced by integrals over the continuum states together with a sum over the bound states. We assume that the amplitudes $\psi_m(x)$ are orthonormal (which can be achieved, for example, by enclosing the system in a finite box). The operators a_m and a_m^\dagger , respectively, annihilate and create electrons, and b_n and b_n^\dagger perform the same role for vacancies in the *negative energy* states, which we interpret as antiparticles (positrons). These operators satisfy the *anticommutation* rules (Chap. 6.1.1)

$$\begin{aligned} [a_m, a_{m'}^\dagger]_+ &= \delta_{m,m'}, \\ [b_n, b_{n'}^\dagger]_+ &= \delta_{n,n'}, \end{aligned} \quad (23.43)$$

where $[a, b]_+ = ab + ba$. All other anticommutators vanish. The operator representing the number of electrons in state m is then

$$N_m = a_m^\dagger a_m, \quad (23.44)$$

having the eigenvalues 0 or 1; the states of a system of non-interacting electrons and positrons can, therefore, be labeled by listing the occupation numbers, 0 or 1 of the one-electron states participating.

We define the *vacuum state* as the (reference) state $|0\rangle$ in which $N_m = N_n = 0$ for all m, n , so that

$$a_m|0\rangle = b_n|0\rangle = 0. \quad (23.45)$$

The operator representing the total number of particles is given by

$$N = \int \psi^\dagger(x)\psi(x)d\mathbf{x} = \sum_{E_m > E_F} N_m + \sum_{E_n < E_F} (1 - N_n).$$

This is not quite satisfactory: N is infinite for the vacuum state, $N_m = N_n = 0 \forall m, n$, as are the total charge and energy of the vacuum.

These infinite *zero-point* values can be eliminated by introducing *normal ordered operators*. A product of annihilation and creation operators is in normal order if it is rearranged so that all annihilation operators are to the right of all creation operators. Such a product has a null value in the vacuum state. In performing the rearrangement, each anticommutator is treated as if it were zero. We denote normal ordering by placing the operators between colons. Thus, $: a_m^\dagger a_m := a_m^\dagger a_m$ whilst $: b_n b_n^\dagger := -b_n^\dagger b_n$. This means that if we *redefine* N by

$$N = \int : \psi^\dagger(x)\psi(x) : d\mathbf{x} = \sum_{E_m > E_F} N_m - \sum_{E_n < E_F} N_n, \quad (23.46)$$

then $\langle 0|N|0\rangle = 0$. The same trick eliminates the infinity from the total energy of the vacuum;

$$\begin{aligned} H_0 &= \int : \psi^\dagger(x)\hat{\mathbf{h}}_D\psi(x) : d\mathbf{x} \\ &= \sum_{E_m > E_F} N_m E_m - \sum_{E_n < E_F} N_n E_n, \end{aligned} \quad (23.47)$$

so that $\langle 0|H_0|0\rangle = 0$.

The current density operator is given by the commutator of two field variables

$$j^\mu(x) = -\frac{1}{2}ec[\bar{\psi}(x)\gamma^\mu, \psi(x)], \quad (23.48)$$

where the Dirac adjoint, $\bar{\psi}(x)$, is defined by Eq. (23.33). The definition Eq. (23.48) differs from Eq. (23.32) by expressing the total current as the difference between the electron (negatively charged) and positron (positively charged) currents. We can write

$$j^\mu(x) =: j^\mu(x) : + ec \text{Tr}[\gamma^\mu S_F(x, x)], \quad (23.49)$$

where $S_F(x, y)$ is the Feynman causal propagator, defined below. Since $\langle 0|: j^\mu(x) : |0\rangle = 0$, the last term in Eq. (23.49) is the *vacuum polarization current* due to the asymmetry

between positive and negative energy states induced by the external field. From this, the net charge of the system is

$$\begin{aligned} Q &= \frac{1}{c} \int j^0(x) d^3x \\ &= -e \left(\sum_{E_m > E_F} N_m - \sum_{E_n < E_F} N_n \right) + Q_{\text{vac}}; \end{aligned} \quad (23.50)$$

Q_{vac} is the total charge of the vacuum, which vanishes for free electrons but is finite in the presence of an external field (the phenomenon of *vacuum polarization*). Note that whilst Q is conserved for all processes, the total number of particles need not be; it is always possible to add virtual states incorporating electron–positron pairs without changing Q .

23.3.3 Quantized Electromagnetic Field

The four-potential of the quantized electromagnetic field can be expressed in terms of a spectral expansion over the field modes in, for example, plane waves

$$\begin{aligned} A_\mu(x) &= \int \frac{d^3k}{2(2\pi)^3 k_0} \sum_{\lambda=0}^3 \left[q^{(\lambda)}(k) \epsilon_\mu^{(\lambda)}(k) e^{-ik \cdot x} \right. \\ &\quad \left. + q^{(\lambda)\dagger}(k) \epsilon_\mu^{(\lambda)*}(k) e^{ik \cdot x} \right]. \end{aligned} \quad (23.51)$$

The vectors $\epsilon_\mu^{(\lambda)}(k)$ describe the polarization modes; there are four linearly independent vectors, which may be assumed real, for each k on the positive light cone. Two of these ($\lambda = 1, 2$) can be chosen perpendicular to the photon momentum \mathbf{k} (*transverse polarization*); one component ($\lambda = 3$) along \mathbf{k} (*longitudinal polarization*), and the final component ($\lambda = 0$) is time like (*scalar polarization*). The operators $q^{(\lambda)}(k)$ and $q^{(\lambda)\dagger}(k)$ describe, respectively, photon absorption and emission. They satisfy commutation relations

$$\begin{aligned} [q^{(\lambda)}(k), q^{(\lambda')\dagger}(k')] &= \delta_{\lambda, \lambda'} \delta_{k, k'}, \quad \lambda, \lambda' = 1, 2, 3, \\ [q^{(0)}(k), q^{(0)\dagger}(k')] &= -\delta_{k, k'}; \end{aligned} \quad (23.52)$$

all other commutators vanish. The photon vacuum state, $|0\rangle_\gamma$, is such that

$$q^{(\lambda)}(k)|0\rangle_\gamma = 0. \quad (23.53)$$

Further details may be found in the texts [10–13].

23.3.4 QED Perturbation Theory

The textbook perturbation theory of QED, see for example [10, 11, 13, 15] and other works, has been adapted for

applications to relativistic atomic and molecular structure and is also the source of methods of nonrelativistic many-body perturbation theory (MBPT). We offer a brief sketch emphasizing details not found in the standard texts.

The perturbation expansion The Lagrangian approach leads to an interaction Hamiltonian

$$H_1 = - \int j^\mu(x) A_\mu(x) \, dx . \quad (23.54)$$

In the interaction representation, this gives an equation of motion

$$i\hbar \partial_t |\Phi(t)\rangle = H_1(t) |\Phi(t)\rangle , \quad (23.55)$$

where $|\Phi(t)\rangle$ is the QED state vector, and

$$H_1(t) = \exp\left(\frac{iH_0 t}{\hbar}\right) H_1 \exp\left(\frac{-iH_0 t}{\hbar}\right) ,$$

where $H_0 = H_{\text{em}} + H_c$ is the Hamiltonian for the uncoupled photon and electron–positron fields. If $S(t, t')$ is the *time development* operator such that

$$|\Phi(t)\rangle = S(t, t') |\Phi(t')\rangle ,$$

then

$$i\hbar \partial_t S(t, t') = H_1(t) S(t, t') .$$

The equivalent integral equation, incorporating the initial condition $S(t, t) = 1$,

$$S(t, t_0) = 1 - \frac{i}{\hbar} \int_{t_0}^t H_1(t_1) S(t_1, t_0) dt_1 , \quad (23.56)$$

can be solved iteratively, giving

$$S(t, t_0) = 1 + \sum_{n=1}^{\infty} S^{(n)}(t, t_0) , \quad (23.57)$$

where

$$S^{(n)}(t, t_0) = \left(\frac{-i}{\hbar}\right)^n \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \int_{t_0}^{t_{n-1}} dt_n \\ \times H_1(t_1) H_1(t_2) \cdots H_1(t_n) .$$

This can be put into a more symmetric form by using *time-ordered* operators. Define the T -product of two operators by

$$T[A(t_1)B(t_2)] = \begin{cases} A(t_1)B(t_2) , & t_1 > t_2 \\ \pm B(t_2)A(t_1) , & t_2 > t_1 \end{cases} , \quad (23.58)$$

where the *positive* sign refers to the product of photon operators and the *negative* sign to electrons. Then,

$$S^{(n)}(t, t_0) = \frac{(-i/\hbar)^n}{n!} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \int_{t_0}^{t_{n-1}} dt_n \\ \times T[H_1(t_1)H_1(t_2) \cdots H_1(t_n)] . \quad (23.59)$$

The operator $S(t, t')$ relates the state vector at time t to the state vector at some earlier time $t' < t$. Its matrix elements, therefore, give the transition amplitudes for different processes, for example the emission or absorption of radiation by a system or the outcome of scattering of a projectile from a target. The techniques for extracting cross sections and other observable quantities from the S -operator are described at length in the texts [10, 11, 13, 15].

Although the use of normal ordering means that the charge and mass of the reference state, the vacuum, is zero, it fails to remove other infinities due to the occurrence of divergent integrals. The method of extracting finite quantities from this theory involves *renormalization* of the charge and mass of the electron. We shall refer especially to [13, Chap. 8] for a detailed discussion. The most difficult technical problems are posed by *mass renormalization*. Formally, we modify the interaction Hamiltonian to read

$$j^\mu(x) A_\mu(x) - \delta M(x) ,$$

where $\delta M(x)$ is the *mass renormalization operator*

$$\delta M(x) = \frac{1}{2} \delta m [\bar{\psi}(x), \psi(x)] ,$$

where δm is infinite.

A further problem is that electrons in a many-electron atom or molecule move in a potential that is quite unlike that of the bare nucleus. It is, therefore, useful to introduce a local *mean field* potential, say $U(x)$, representing some sort of average interaction with the rest of the electron charge distribution, so that the zero-order orbitals satisfy

$$[c\boldsymbol{\alpha} \cdot \mathbf{p} + \beta c^2 + V_{\text{nuc}}(\mathbf{x}) + U(\mathbf{x}) - E_m] \psi_m(\mathbf{x}) = 0 . \quad (23.60)$$

With this starting point, the interaction Hamiltonian becomes

$$H_1(x) = H_1^{(1)}(x) + H_1^{(2)}(x) , \quad (23.61)$$

where

$$H_1^{(1)}(x) = -U(x), \quad H_1^{(2)}(x) = j^\mu(x) A_\mu(x) - \delta M(x) ,$$

and the electron current is defined in terms of the mean field orbitals of Eq. (23.60). The expression $H_1^{(2)}(x)$ is sometimes referred to as a *fluctuation potential*. The term $j^\mu(x) A_\mu(x)$ is proportional to the electron charge, e , which serves as an ordering parameter for perturbation expansions.

Effective interactions Although the S-matrix formalism provides in principle a complete computational scheme for many-electron systems, it is generally too cumbersome for practical use, and approximations are necessary. Usually, this is a matter of selecting a subset of dominant contributions to the perturbation series, depending on the application. We are faced with the evaluation of T -products of the form

$$T[\phi(t_1)\phi(t_2)\cdots\phi(t_n)],$$

which is done using Wick's theorem [13, p. 25].

In the simplest case,

$$T[\phi(t_1)\phi(t_2)] = :\phi(t_1)\phi(t_2): + \langle 0|T[\phi(t_1)\phi(t_2)]|0\rangle. \quad (23.62)$$

The vacuum expectation value is called a *contraction*. More generally, we have

$$\begin{aligned} T[\phi(t_1)\phi(t_2)\cdots\phi(t_n)] &= :\phi(t_1)\phi(t_2)\cdots\phi(t_n): \\ &+ \{\langle 0|T[\phi(t_1)\phi(t_2)]|0\rangle : \phi(t_3)\cdots\phi(t_n) : + \text{permutations}\} \\ &+ \{\langle 0|T[\phi(t_1)\phi(t_2)]|0\rangle \langle 0|T[\phi(t_3)\phi(t_4)]|0\rangle \\ &\quad \times : \phi(t_5)\cdots\phi(t_n) : + \text{permutations}\} \dots \end{aligned}$$

This result has the effect that a T -product with an odd number of factors vanishes. A rigorous statement can be found in all standard texts; each term in the expansion gives rise to a Feynman diagram that can be interpreted as the amplitude of a physical process. As an example, consider the simple but important case

$$S^{(2)} = \frac{(ie)^2}{2!} T[j^\mu(x)A_\mu(x) \cdot j^\nu(y)A_\nu(y)]. \quad (23.63)$$

One of the terms (there are others) found by using Wick's Theorem is

$$j^\mu(x)j^\nu(y)\langle 0|T[A_\mu(x)A_\nu(y)]|0\rangle.$$

We can see that this involves the contraction of two photon amplitudes

$$-\frac{1}{2}D_{F\mu\nu}(x-y) = \langle 0|T[A_\mu(x)A_\nu(y)]|0\rangle,$$

which plays the role of a *propagator* Eq. (23.69); it relates the photon amplitudes at two space-time points x, y . With the introduction of a spectral expansion for the electron current Eq. (23.48), the contribution to the energy of the system becomes

$$\frac{1}{2} \sum_{pqrs} : a_p^\dagger a_q^\dagger a_s a_r : \langle pq|V|rs\rangle, \quad (23.64)$$

which can be interpreted, in the familiar language of ordinary quantum mechanics, as the energy of two electrons due to the electron–electron interaction V , which is directly related to the photon propagator.

23.3.5 Propagators

Propagators relate field variables at different space-time points. Here we briefly define those most often needed in atomic and molecular physics.

Electrons Define Feynman's causal propagator for the electron–positron field by the contraction

$$S_F(x_2, x_1) = \langle 0|T[\psi(x_2)\bar{\psi}(x_1)]|0\rangle. \quad (23.65)$$

This has a spectral decomposition of the form

$$S_F(x_2, x_1) = \begin{cases} \sum_{E_m > E_F} \psi_m(x_2)\bar{\psi}_m(x_1) & t_1 > t_2, \\ -\sum_{E_n < E_F} \psi_n(x_2)\bar{\psi}_n(x_1) & t_1 < t_2, \end{cases} \quad (23.66)$$

which ensures that positive energy solutions are propagated forwards in time and negative energy solutions backwards in time in accordance with the antiparticle interpretation of the negative energy states. By noting that the stationary state solutions $\psi_m(x)$ have time dependence $\exp(-iE_m t)$, we can write Eq. (23.66) in the form

$$\begin{aligned} S_F(x_2, x_1) &= \frac{1}{2\pi i} \int_{-\infty}^{\infty} \sum_n \frac{\psi_n(\mathbf{x}_2)\bar{\psi}_n(\mathbf{x}_1)}{E_n - z(1 + i\delta)} e^{-iz(t_2 - t_1)} dz \\ &= \frac{1}{2\pi i} \int_{-\infty}^{\infty} G(\mathbf{x}_2, \mathbf{x}_1, z) \gamma^0 e^{-iz(t_2 - t_1)} dz, \end{aligned} \quad (23.67)$$

where δ is a small positive number, the sum over n includes *the whole spectrum*, and where the Green's function $G(\mathbf{x}_2, \mathbf{x}_1, z)$, in the specific case in which the potential of the external field $a^\mu(x)$ has only a scalar time-independent part, $V_{\text{nuc}}(\mathbf{x})$, satisfies

$$\begin{aligned} [c\boldsymbol{\alpha} \cdot \mathbf{p} + \beta c^2 + (V_{\text{nuc}}\mathbf{x}) - z]G(\mathbf{x}, \mathbf{y}, z) \\ = \delta^{(3)}(\mathbf{x}_2 - \mathbf{x}_1); \end{aligned} \quad (23.68)$$

$G(\mathbf{x}_2, \mathbf{x}_1, z)$ is a meromorphic function of the complex variable z with branch points at $z = \pm c^2$, and two cuts (c^2, ∞) and $(-\infty, -c^2)$ along the real axis. The poles lie on the segment $(-c^2, c^2)$ at the bound eigenvalues of the Dirac Hamiltonian for this potential.

Photons We construct the photon propagator $D_{F\mu\nu}(x_2 - x_1)$ in a similar manner:

$$-\frac{1}{2}D_{F\mu\nu}(x_2 - x_1) = \langle 0|T[A_\mu(x_2)A_\nu(x_1)]|0\rangle, \quad (23.69)$$

where μ_0 is the permeability of the vacuum. This has the integral representation

$$\begin{aligned} D_{F\mu\nu}(x_2 - x_1) &= g_{\mu\nu}D_F(x_2 - x_1) \\ &= -g_{\mu\nu} \frac{i}{(2\pi)^4} \int d^4q D(q^2), \end{aligned} \quad (23.70)$$

where

$$D(q^2) = \frac{1}{q^2 + i\delta},$$

and δ is a small positive number. This is not unique, as the four-potentials depend on the choice of gauge; for details, see [11, Sect. 77]. The various forms for the electron–electron interaction given below express such gauge choices.

23.3.6 Effective Interaction of Electrons

The expression Eq. (23.63) can be viewed in several ways: it is the interaction of the current density $j^\mu(x)$ at the space-time point x with the four-potential due to the current $j^\mu(y)$; the interaction of the current density $j^\mu(y)$ with the four-potential due to the current $j^\mu(x)$; or, as is commonly assumed in nonrelativistic atomic theory, the effective interaction between two charge density distributions, as represented by Eq. (23.64). In terms of the corresponding Feynman diagram, it can be thought of as the energy due to the exchange of a virtual photon.

The form of V depends on the choice of gauge potential, as follows.

Feynman gauge

$$\begin{aligned} & \langle pq|V|rs\rangle \\ &= \int \int \psi_p^\dagger(\mathbf{x})\psi_r(\mathbf{x})v_{sq}^F(\mathbf{x},\mathbf{y})\psi_q^\dagger(\mathbf{y})\psi_s(\mathbf{y})d^3x d^3y, \end{aligned} \quad (23.71)$$

where

$$v_{sq}^F(\mathbf{x},\mathbf{y}) = \frac{e^{i\omega_{sq}R}}{R}(1 - \boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y), \quad (23.72)$$

with

$$\mathbf{R} = \mathbf{x} - \mathbf{y}, \quad R = |\mathbf{R}|, \quad \omega_{sq} = \frac{E_s - E_q}{c}.$$

This interaction gives both a real and an imaginary contribution to the energy; only the former is usually taken into account in structure calculations. Since the orbital indices are dummy variables, it is usual to symmetrize the interaction kernel by writing

$$\bar{v}^F(\mathbf{x},\mathbf{y}) = \frac{1}{2} \left[v_{sq}^F(\mathbf{x},\mathbf{y}) + v_{rp}^F(\mathbf{x},\mathbf{y}) \right],$$

which places the orbitals on an equal footing.

Coulomb gauge Here, the Feynman propagator is replaced by that for the Coulomb gauge, giving

$$\begin{aligned} v_{sq}^T(\mathbf{x},\mathbf{y}) &= \frac{e^{i\omega_{sq}R}}{R} - \left[\boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y \frac{e^{i\omega_{sq}R}}{R} \right. \\ &\quad \left. + (\boldsymbol{\alpha}_x \cdot \nabla)(\boldsymbol{\alpha}_y \cdot \nabla) \frac{e^{i\omega_{sq}R} - 1}{\omega_{sq}^2 R} \right], \end{aligned} \quad (23.73)$$

in which the operator ∇ involves differentiation with respect to \mathbf{R} . Symmetrization is also used with this interaction.

Breit operator The *low-frequency limit*, $\omega_{rp} \rightarrow 0$, $\omega_{sq} \rightarrow 0$, is known as the Breit interaction:

$$\lim_{\omega_{rp}, \omega_{sq} \rightarrow 0} v_{sq}^T(\mathbf{x},\mathbf{y}) = \frac{1}{R} + v^B(\mathbf{R}), \quad (23.74)$$

where

$$v^B(\mathbf{R}) = -\frac{1}{2R} \left(\boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y + \frac{\boldsymbol{\alpha}_x \cdot \mathbf{R} \boldsymbol{\alpha}_y \cdot \mathbf{R}}{R^2} \right).$$

Gaunt operator This is a further approximation in which $v^B(\mathbf{R})$ is replaced by

$$v^G(\mathbf{R}) = -\frac{\boldsymbol{\alpha}_x \cdot \boldsymbol{\alpha}_y}{R}, \quad (23.75)$$

the residual part of the Breit interaction being neglected.

Comments The choice of gauge should not influence the predictions of QED for atomic and molecular structure when the perturbation series is summed to convergence, so that it should not matter if the unapproximated effective operators are taken in Feynman or Coulomb gauge. However, this need not be true at each order of perturbation. It has been shown that the results are equivalent, order by order, if the orbitals have been defined in a *local* potential, but not otherwise. There have also been suggestions that the Feynman operator introduces spurious terms in lower orders of perturbation that are canceled in higher orders [16]. For this reason, most structure calculations have used Coulomb gauge.

It is often argued, following *Bethe and Salpeter* [17, Sect. 38], that the Breit interaction should only be used in first-order perturbation theory. The reason is the approximation $\omega \rightarrow 0$. However, it takes into account the dominant magnetic interactions in self-consistent field calculations. The Coulomb gauge operator Eq. (23.73) has also been used in relativistic configuration interaction calculations but so far not in self-consistent calculations.

23.4 Many-Body Theory For Atoms

The development of a practical relativistic theory of atomic structure remains a challenging problem. Recently, there have been studies of the feasibility of merging the QED approach with many-body perturbation theory MBPT to perform *accurate* QED calculations on light elements [18, 19], but these remain unimplemented. Dzuba et al. [20] attempt to treat properties of superheavy elements (with atomic numbers $Z > 100$) using relativistic configuration interaction combined with perturbation theory, an approach that has features similar to those used in the GRASP2K programs [21] on which this chapter focuses.

GRASP2K is based on RMCDFH, a relativistic Dirac Hartree–Fock self-consistent field program using the Dirac–Coulomb Hamiltonian with a basis of trial atomic state functions (ASFs) that are linear combinations of configurational state functions (CSFs). As well as determining the coefficients of this linear combination, the program determines an orthonormal basis of Dirac four-component orbitals on which the CSFs are built. This constructs a multireference (MR) first approximation for the basic atomic states of interest, which can then be improved (electron correlation) by extending the MR CSF and orbital bases systematically, keeping the MR orbitals frozen. A relativistic configuration interaction (RCI) program incorporating the Breit interaction and approximations for QED corrections demonstrates how well the model converges. The general strategy is much the same as that used for the nonrelativistic models described in more detail in Chap. 22 [22].

23.4.1 Effective Hamiltonians

The models that are closest to QED are those in which the full electron–electron interaction is included, usually in Coulomb gauge. We define a Fock space Hamiltonian

$$H_{\text{DCB}} = H_0 + H_1 + H_2, \quad (23.76)$$

where, as in Eq. (23.47),

$$H_0 = \sum_{E_m > E_F} N_m E_m - \sum_{E_n < E_F} N_n E_n, \quad (23.77)$$

in which the states are those determined with respect to a mean-field central potential $U(\mathbf{x})$ as in Eq. (23.60)

$$[c\boldsymbol{\alpha} \cdot \mathbf{p} + \beta c^2 + V_{\text{nuc}}(\mathbf{x}) + U(\mathbf{x}) - E_m] \psi_m(\mathbf{x}) = 0,$$

and

$$H_1 = - \sum_{pq} : a_p^\dagger a_q : \langle p | U(\mathbf{x}) | q \rangle,$$

$$H_2 = \frac{1}{2} \sum_{pqrs} : a_p^\dagger a_q^\dagger a_r a_s : \langle pq | V | sr \rangle.$$

Here, the sums run only over states p with $E_p > E_F$; this means that states with $E_p < E_F$ are treated as inert.

The models are named according to the choice of V from Sect. 23.5.3.

Dirac–Coulomb–Breit models These incorporate the *full* Coulomb gauge operator Eq. (23.73) or the less accurate Breit operator Eq. (23.74). The fully retarded operator is usually taken in the symmetrized form. The Gaunt operator Eq. (23.75) is sometimes considered as an approximation to the Breit operator.

Dirac–Coulomb models Here, the electron–electron interaction is just the static $1/R$ potential. Note that although the equations are relativistic, the choices of electron–nucleus interaction all implicitly restrict these models to a frame in which the nuclei are fixed in space. The full electron–electron interaction is gauge invariant; however, it is common to start from the Dirac–Coulomb operator, in which case the gauge invariance is lost. Since radiative transition rates are sensitive to loss of gauge invariance [23], the choice of potential in Eq. (23.76) can make a big difference. Such choices may also affect the rate of convergence in correlation calculations in which the relativistic parts of the electron–electron interaction are treated as a second, independent, perturbation.

23.4.2 Nonrelativistic Limit: Breit–Pauli Hamiltonian

The nonrelativistic limit of the Dirac–Coulomb–Breit Hamiltonian is described in Chap. 22. The derivation is given in many texts, for example [11, 13, 17], and in principle involves the following steps:

1. Express the relativistic four-spinor in terms of nonrelativistic Pauli two-spinors of the form (Sect. 22.2)

$$\phi_{nlm_l m_s}(\mathbf{x}) = \text{const.} \frac{P_{nl}(r)}{r} Y_{lm_l}(\theta, \phi) \chi_{m_s}(\sigma), \quad (23.78)$$

where χ_{m_s} is a two-component eigenvector of the spin operator \mathbf{s} to lowest order in $1/c$.

2. Extract effective operators to order $1/c^2$.

Thus, the Breit–Pauli Hamiltonian is written as the sum of terms of Sect. 22.2, which can be correlated with specific parts of the parent relativistic operator:

1. One-body terms originate from the Dirac Hamiltonian: they are H_{mass} (Sect. 22.8), the one-body part of H_{Darwin} (Sect. 22.9) and the spin–orbit couplings H_{so} (Sect. 22.13) and H_{soo} (Sect. 22.14). The forms given in these equations assume that the electron interacts with a point-charge nucleus and only require the Coulomb part of the electron–electron interaction.
2. Two-body terms, including the two-body parts of H_{Darwin} (Sect. 22.9), the spin–spin contact term H_{ssc} (Sect. 22.10), the orbit–orbit term H_{oo} (Sect. 22.11), and the spin–spin term H_{ss} (Sect. 22.15) originate from the Breit interaction.

23.4.3 Perturbation Theory: Nondegenerate Case

We give a brief resumé of the Rayleigh–Schrödinger perturbation theory following *Lindgren* [24]. The material pre-

sented here supplements the general discussion of perturbation theory in Chap. 5. First consider the simplest case with a nondegenerate reference state Φ belonging to the Hilbert space \mathcal{H} satisfying

$$H_0|\Phi\rangle = E_0|\Phi\rangle, \quad (23.79)$$

which is a first approximation to the solution of the full problem

$$H|\Psi\rangle = E|\Psi\rangle, \quad H = H_0 + V. \quad (23.80)$$

Next, introduce a projection operator P such that

$$P = |\Phi\rangle\langle\Phi|, \quad P|\Phi\rangle = |\Phi\rangle,$$

and its complement $Q = 1 - P$, projecting onto the complementary subspace $\mathcal{H} \setminus \{\Phi\}$. With the *intermediate normalization*

$$\langle\Phi|\Psi\rangle = \langle\Phi|\Phi\rangle = 1,$$

it follows that

$$P|\Psi\rangle = |\Phi\rangle\langle\Phi|\Psi\rangle = |\Phi\rangle,$$

so that the perturbed wave function can be decomposed into two parts:

$$|\Psi\rangle = (P + Q)|\Psi\rangle = |\Phi\rangle + Q|\Psi\rangle.$$

Thus, with intermediate normalization,

$$E = \langle\Phi|H|\Psi\rangle = E_0 + \langle\Phi|V|\Psi\rangle.$$

We now use this decomposition to write Eq. (23.80) in the form

$$(E_0 - H_0)|\Psi\rangle = (V - \Delta E)|\Psi\rangle, \quad (23.81)$$

where $\Delta E = \langle\Phi|V|\Psi\rangle$. Thus,

$$(E_0 - H_0)Q|\Psi\rangle = Q(V - \Delta E)|\Psi\rangle. \quad (23.82)$$

Introduce the *resolvent operator*

$$R = \frac{Q}{E_0 - H_0}, \quad (23.83)$$

which is well-defined except on $\{\Phi\}$. Then the perturbation contribution to the wave function is

$$Q|\Psi\rangle = R(V - \Delta E)|\Psi\rangle = R(V|\Psi\rangle - |\Psi\rangle\langle\Phi|V|\Psi\rangle).$$

The *Rayleigh–Schrödinger* perturbation expansion can now be written

$$\begin{aligned} |\Psi\rangle &= |\Phi\rangle + |\Psi^{(1)}\rangle + |\Psi^{(2)}\rangle + \dots \\ E &= E_0 + E^{(1)} + E^{(2)} + \dots \end{aligned}$$

The contributions are ordered by the number of occurrences of V , the leading terms being

$$\begin{aligned} |\Psi^{(1)}\rangle &= RV|\Phi\rangle, \\ |\Psi^{(2)}\rangle &= (RVRV - R^2VPV)|\Phi\rangle, \end{aligned}$$

and so on. The corresponding contribution to the energy can then be found from

$$E^{(n)} = \langle\Phi|V|\Psi^{(n-1)}\rangle.$$

23.4.4 Perturbation Theory: Open-Shell Case

Consider now the case in which there are several unperturbed states, $|\Phi^{(a)}\rangle$, $a = 1, 2, \dots, d$, having the same energy E_0 , which span a d -dimensional linear subspace (the *model space*) $\mathcal{M} \subset \mathcal{H}$, so that

$$H_0|\Phi^{(a)}\rangle = E_0|\Phi^{(a)}\rangle, \quad a = 1, 2, \dots, d.$$

Let P be the projector onto \mathcal{M} and Q onto the orthogonal subspace \mathcal{M}^\perp .

The perturbed states $|\Psi^{(a)}\rangle$, $a = 1, 2, \dots, d$ are related to the unperturbed states by the *wave operator* Ω ,

$$|\Psi^{(a)}\rangle = \Omega|\Phi^{(a)}\rangle, \quad a = 1, 2, \dots, d.$$

The *effective Hamiltonian*, H_{eff} , is defined so that

$$H_{\text{eff}}|\Phi^{(a)}\rangle = E^{(a)}|\Phi^{(a)}\rangle,$$

and thus

$$\Omega H_{\text{eff}}|\Phi^{(a)}\rangle = E^{(a)}|\Psi^{(a)}\rangle = H\Omega|\Phi^{(a)}\rangle.$$

Thus, on the domain \mathcal{M} we can write an operator equation

$$\Omega H_{\text{eff}}P = H\Omega P, \quad (23.84)$$

known as the Bloch equation. We partition H_{eff} so that

$$H_{\text{eff}}P = (H_0 + V_{\text{eff}})P,$$

enabling a reformulation of Eq. (23.84) as the commutator equation

$$[\Omega, H_0]P = (V\Omega - \Omega V_{\text{eff}})P. \quad (23.85)$$

With the intermediate normalization convention of Sect. 23.4.3, this becomes

$$|\Psi^{(a)}\rangle = P|\Phi^{(a)}\rangle,$$

so that $P\Omega P = P$ and

$$H_{\text{eff}}P = PH\Omega P, \quad V_{\text{eff}}P = PV\Omega P.$$

Then Eq. (23.85) can be put in the final form

$$[\Omega, H_0]P = (V\Omega - \Omega PV\Omega)P. \quad (23.86)$$

The general Rayleigh–Schrödinger perturbation expansion can now be generated by expanding the wave operator order by order

$$\Omega = 1 + \Omega^{(1)} + \Omega^{(2)} + \dots,$$

and inserting into Eq. (23.86), resulting in a hierarchy of equations

$$\begin{aligned} [\Omega^{(1)}, H_0]P &= (V - PV)P = QVP, \\ [\Omega^{(2)}, H_0]P &= (QV\Omega^{(1)} - \Omega^{(1)}PV)P, \end{aligned}$$

and so on, with $H_{\text{eff}}^{(n)} = PV\Omega^{(n-1)}$.

23.4.5 Perturbation Theory: Algorithms

The techniques of QED perturbation theory of Sect. 23.3.4 can be utilized to give computable expressions for perturbation calculations order by order. They exploit the second quantized representation of operators of Sect. 23.4.1 along with the use of diagrams to express the contributions to the wave operator and the energy as sums over virtual states. The use of Wick’s theorem to reduce products of normally-ordered operators, and the *linked-diagram* or *linked-cluster* theorem are explained in *Lindgren’s* article [24] and Chap. 5. Further references and discussion of features that can exploit vector-processing and parallel-processing computer architectures may be found in [25].

The theory can also be recast so as to sum certain classes of terms to completion. This depends on the possibility of expressing the wave operator as a normally ordered exponential operator

$$\Omega = \{\exp S\} = 1 + \{S\} + \frac{1}{2!}\{S^2\} + \dots,$$

where the normally ordered operator S is known as the *cluster* operator. Expanding S order by order leads to the *coupled cluster expansion* (Chaps. 5 and 28).

23.5 Spherical Symmetry

A popular starting point for most calculations in atomic and molecular structure is the independent particle central field approximation. This assumes that the electrons move independently in a potential field of the form

$$\begin{aligned} A_0(x) &= \frac{1}{c}\phi(r), \quad r = |\mathbf{x}|; \\ A_i(x) &= 0, \quad i = 1, 2, 3. \end{aligned} \quad (23.87)$$

Clearly, $\phi(r)$ is left unchanged by any rotation about the origin, $r = 0$, but transforms as the component $A_0(x)$ of a four-vector under other types of Lorentz and Poincaré transformation such as boosts or translations. However, solutions in central potentials of this form have a simple form that is convenient for further calculation.

With this restriction on the four-potential, Dirac’s Hamiltonian becomes

$$\hat{\mathbf{h}}_D = \{c\boldsymbol{\alpha} \cdot \mathbf{p} + e\phi(r) + \beta m_e c^2\}. \quad (23.88)$$

Consider stationary solutions with energy E satisfying

$$\hat{\mathbf{h}}_D \psi_E(x) = E \psi_E(x).$$

Since $\hat{\mathbf{h}}_D$ is invariant with respect to rotation about $r = 0$, it commutes with the generators J_1, J_2, J_3 mentioned in Sect. 23.1.1, corresponding to components of the total angular momentum \mathbf{j} of the electron, usually decomposed into an orbital part \mathbf{l} and a spin part \mathbf{s} ,

$$\mathbf{j} = \mathbf{l} + \mathbf{s}, \quad (23.89)$$

where

$$\begin{aligned} l_j &= i\epsilon_{jkl}x_k\partial_l, \quad j = 1, 2, 3, \\ s_j &= \frac{1}{2}\epsilon_{jkl}\sigma_{kl}, \quad j = 1, 2, 3. \end{aligned}$$

23.5.1 Eigenstates of Angular Momentum

We can construct simultaneous eigenstates of the operators \mathbf{j}^2 and j_3 by using the product representation $\mathcal{D}^{(l)} \times \mathcal{D}^{(1/2)}$ of the rotation group $\text{SO}(3)$, which is reducible to the Clebsch–Gordan sum of two irreps

$$\mathcal{D}^{(l+1/2)} \oplus \mathcal{D}^{(l-1/2)}. \quad (23.90)$$

We construct a basis for each irrep from products of basis vectors for $\mathcal{D}^{(1/2)}$ and $\mathcal{D}^{(l)}$, respectively. $\mathcal{D}^{(1/2)}$ is a two-dimensional representation spanned by the simultaneous

eigenstates ϕ_σ of \mathbf{s}^2 and s_3

$$\mathbf{s}^2 \phi_\sigma = \frac{3}{4} \phi_\sigma, \quad s_3 \phi_\sigma = \sigma \phi_\sigma, \quad \sigma = \pm \frac{1}{2},$$

for which we can use two-rowed vectors

$$\phi_{1/2} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad \phi_{-1/2} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

The representation $\mathcal{D}^{(l)}$ is $(2l + 1)$ -dimensional; its basis vectors can be taken to be the spherical harmonics

$$\{Y_l^m(\theta, \varphi) \mid m = -l, -l + 1, \dots, l\},$$

so that

$$\begin{aligned} \mathbf{I}^2 Y_l^m(\theta, \varphi) &= l(l + 1) \hbar^2 Y_l^m(\theta, \varphi), \\ l_3 Y_l^m(\theta, \varphi) &= m \hbar Y_l^m(\theta, \varphi). \end{aligned}$$

We shall assume that spherical harmonics satisfy the standard relations

$$l_\pm Y_l^m(\theta, \varphi) = [l(l + 1) - m(m \pm 1)]^{1/2} \hbar Y_l^{m \pm 1}(\theta, \varphi),$$

where $l_\pm = l_1 \pm l_2$, so that

$$\begin{aligned} Y_l^m(\theta, \varphi) &= \left(\frac{2l + 1}{4\pi} \right)^{1/2} C_l^m(\theta, \varphi), \\ C_l^m(\theta, \varphi) &= (-1)^m \left(\frac{(l - m)!}{(l + m)!} \right)^{1/2} P_l^m(\theta) e^{im\varphi}, \quad \text{if } m \geq 0, \\ C_l^{-m}(\theta, \varphi) &= (-1)^m C_l^m(\theta, \varphi)^*. \end{aligned} \quad (23.91)$$

Basis functions for the representations \mathcal{D}^j with $j = l \pm \frac{1}{2}$ have the form

$$\begin{aligned} \chi_{j,m,a}(\theta, \varphi) \\ = \sum_\sigma \left\langle l, m - \sigma, \frac{1}{2}, \sigma \mid l, \frac{1}{2}, j, m \right\rangle Y_l^{m-\sigma}(\theta, \varphi) \phi_\sigma, \end{aligned} \quad (23.92)$$

where $\langle l, m - \sigma, \frac{1}{2}, \sigma \mid l, \frac{1}{2}, j, m \rangle$ is a Clebsch–Gordan coefficient with

$$\begin{aligned} l &= j - \frac{1}{2}a, \quad a = \pm 1, \\ m &= -j, -j + 1, \dots, j - 1, j. \end{aligned}$$

[The order of coupling is significant, and great confusion results from a mixing of conventions. Here, we couple in the order l, s, j . The same spin-angle functions are obtained if we use the order s, l, j but there is a phase difference $(-1)^{l-j+1/2} = (-1)^{(l-a)/2}$. You have been warned!]

Inserting explicit expressions for the Clebsch–Gordan coefficients gives

$$\begin{aligned} \chi_{j,m,-1}(\theta, \varphi) &= \begin{pmatrix} -\left(\frac{j+1-m}{2j+2} \right)^{1/2} Y_{j+1/2}^{m-1/2}(\theta, \varphi) \\ \left(\frac{j+1+m}{2j+2} \right)^{1/2} Y_{j+1/2}^{m+1/2}(\theta, \varphi) \end{pmatrix}, \\ \chi_{j,m,1}(\theta, \varphi) &= \begin{pmatrix} \left(\frac{j+m}{2j} \right)^{1/2} Y_{j-1/2}^{m-1/2}(\theta, \varphi) \\ \left(\frac{j-m}{2j} \right)^{1/2} Y_{j-1/2}^{m+1/2}(\theta, \varphi) \end{pmatrix}. \end{aligned} \quad (23.93)$$

The vectors Eq. (23.93) satisfy

$$\begin{aligned} \mathbf{j}^2 \chi_{j,m,a} &= j(j + 1) \chi_{j,m,a}, \quad \mathbf{s}^2 \chi_{j,m,a} = \frac{3}{4} \chi_{j,m,a}, \\ \mathbf{I}^2 \chi_{j,m,a} &= l(l + 1) \chi_{j,m,a}, \quad l = j - \frac{1}{2}a, \quad a = \pm 1. \end{aligned} \quad (23.94)$$

The parity of the angular part is given by $(-1)^l$, with the two possibilities distinguished by means of the operator

$$K' = -(\mathbf{j}^2 - \mathbf{I}^2 - \mathbf{s}^2 + 1) = -(2\mathbf{s} \cdot \mathbf{I} + 1), \quad (23.95)$$

so that

$$K' \chi_{j,m,a} = k' \chi_{j,m,a}, \quad k' = -\left(j + \frac{1}{2} \right) a, \quad a = \pm 1.$$

The basis vectors are orthonormal on the unit sphere with respect to the inner product

$$\begin{aligned} &(\chi_{j',m',a'} \mid \chi_{jma}) \\ &= \int \int \chi_{j',m',a'}^\dagger(\theta, \varphi) \chi_{j,m,a}(\theta, \varphi) \sin \theta \, d\theta \, d\varphi \\ &= \delta_{j',j} \delta_{m',m} \delta_{a',a}. \end{aligned} \quad (23.96)$$

23.5.2 Dirac Hamiltonian in Spherical Coordinates

Eigenstates of Dirac's Hamiltonian Eq. (23.88) in spherical coordinates with a spherically symmetric potential $V(r) = e\phi(r)$,

$$\hat{\mathbf{h}}_D \psi_E(\mathbf{r}) = E \psi_E(\mathbf{r}), \quad (23.97)$$

are also simultaneous eigenstates of \mathbf{j}^2 , of j_3 and of the operator

$$K = \begin{pmatrix} K' & 0 \\ 0 & -K' \end{pmatrix}, \quad (23.98)$$

where K' is defined in Eq. (23.95) above. Denote the corresponding eigenvalues by j, m and κ , where

$$\kappa = \pm \left(j + \frac{1}{2} \right). \quad (23.99)$$

Then the simultaneous eigenstates take the form

$$\psi_{E\kappa m}(\mathbf{r}) = \frac{1}{r} \begin{pmatrix} P_{E\kappa}(r)\chi_{\kappa,m}(\theta, \varphi) \\ iQ_{E\kappa}(r)\chi_{-\kappa,m}(\theta, \varphi) \end{pmatrix}, \quad (23.100)$$

where $\kappa = -(j + 1/2)a$ is the eigenvalue of K' , and the notation $\chi_{\kappa,m}$ replaces the notation $\chi_{j,m,a}$ used previously in Eq. (23.92). The factor i in the lower component ensures that, at least for bound states, the radial amplitudes $P_{E\kappa}(r)$, $Q_{E\kappa}(r)$ can be chosen to be real. This decomposition into radial and angular factors exploits the identity

$$\begin{aligned} \boldsymbol{\sigma} \cdot \mathbf{p} \left[\frac{F(r)}{r} \chi_{\kappa,m}(\theta, \varphi) \right] \\ = i\hbar \frac{1}{r} \left(\frac{dF}{dr} + \frac{\kappa F}{r} \right) \chi_{-\kappa,m}(\theta, \varphi) \end{aligned} \quad (23.101)$$

and gives, writing $\varepsilon = E - mc^2$, the radial equation

$$t_\kappa u_{E\kappa} = \varepsilon u_{E\kappa}, \quad u_{E\kappa} = \begin{pmatrix} P_{E\kappa}(r) \\ Q_{E\kappa}(r) \end{pmatrix}, \quad (23.102)$$

$$t_\kappa = cJ \frac{d}{dr} + \frac{W_\kappa(r)}{r},$$

$$J = -i\sigma^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

$$W_\kappa(r) = \begin{pmatrix} -Z(r) & c\kappa \\ c\kappa & -2mc^2r - Z(r) \end{pmatrix},$$

where the potential $\phi(r)$ of Eq. (23.87) has been expressed in terms of $\phi(r) = -Z(r)/r$.

This equation requires suitable boundary conditions, which are discussed in more detail in Sects. 23.5.3 and 23.5.4.

Angular density distributions It is a remarkable fact that the angular density distribution

$$A_{\kappa,m}(\theta, \varphi) = \chi_{\kappa,m}(\theta, \varphi)^\dagger \chi_{\kappa,m}(\theta, \varphi), \quad (23.103)$$

where $m = -j, -j + 1, \dots, j - 1, j$, is independent of the sign of κ ; the equivalence of

$$\begin{aligned} A_{j+1/2,m}(\theta, \varphi) &= \frac{1}{4\pi} \frac{(j-m)!}{(j+m)!} \\ &\times \left[(j-m+1)^2 \left| P_{j+1/2}^{m-1/2}(\mu) \right|^2 + \left| P_{j+1/2}^{m+1/2}(\mu) \right|^2 \right], \end{aligned}$$

and

$$\begin{aligned} A_{-(j+1/2),m}(\theta, \varphi) &= \frac{1}{4\pi} \frac{(j-m)!}{(j+m)!} \\ &\times \left[(j+m)^2 \left| P_{j-1/2}^{m-1/2}(\mu) \right|^2 + \left| P_{j-1/2}^{m+1/2}(\mu) \right|^2 \right], \end{aligned}$$

where $\mu = \cos \theta$ was demonstrated by *Hartree* [26].

Table 23.1 Relativistic angular density functions

$ \kappa $	$ m $	$4\pi A_{ \kappa ,m}(\theta, \varphi)$
1	$\frac{1}{2}$	1
2	$\frac{3}{2}$	$\frac{3}{2} \sin^2 \theta$
	$\frac{1}{2}$	$\frac{1}{2}(1 + 3 \cos^2 \theta)$
3	$\frac{5}{2}$	$\frac{15}{8} \sin^4 \theta$
	$\frac{3}{2}$	$\frac{3}{8} \sin^2 \theta (1 + 15 \cos^2 \theta)$
	$\frac{1}{2}$	$\frac{3}{4} (3 \cos^2 \theta - 1)^2 + 3 \sin^2 \theta \cos^2 \theta$

Table 23.2 Nonrelativistic angular density functions

l	$ m $	$4\pi A_{l,m}(\theta, \varphi)_{nr}$
0	0	1
1	1	$\frac{3}{2} \sin^2 \theta$
	0	$3 \cos^2 \theta$
2	2	$\frac{15}{8} \sin^4 \theta$
	1	$\frac{15}{2} \sin^2 \theta \cos^2 \theta$
	0	$\frac{5}{4} (3 \cos^2 \theta - 1)^2$

Angular densities for the lowest $|\kappa|$ values are given in Table 23.1. The corresponding nonrelativistic angular densities

$$\begin{aligned} A_{l,m}(\theta, \varphi)_{nr} &= \left| Y_l^m(\theta, \varphi) \right|^2 \\ &= \frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!} \left| P_l^{|m|}(\mu) \right|^2 \end{aligned}$$

are listed in Table 23.2.

Radial density distributions The probability density distribution $\rho_{E\kappa m}(\mathbf{r})$ associated with the stationary state Eq. (23.100) is given by

$$\begin{aligned} \rho_{E,\kappa,m}(\mathbf{r}) \\ = \frac{1}{r^2} \left[|P_{E,\kappa}(r)|^2 A_{\kappa,m}(\theta, \varphi) + |Q_{E,\kappa}(r)|^2 A_{-\kappa,m}(\theta, \varphi) \right]. \end{aligned} \quad (23.104)$$

Since $A_{\kappa,m}$ does not depend on the sign of κ , the angular part can be factored so that

$$\rho_{E,\kappa,m}(\mathbf{r}) = \frac{D_{E,\kappa}(r)}{r^2} A_{|\kappa|,m}(\theta, \varphi),$$

where

$$D_{E,\kappa}(r) = |P_{E,\kappa}(r)|^2 + |Q_{E,\kappa}(r)|^2 \quad (23.105)$$

defines the *radial density* distribution.

Subshells in jj coupling The notion of a *subshell* depends on the observation that the set $\{\psi_{E,\kappa,m}, m = -j, \dots, j\}$ have a common radial density distribution. The simplest atomic

Table 23.3 Spectroscopic labels and angular quantum numbers

Label:	s	\bar{p}	p	\bar{d}	d	\bar{f}	f
$\kappa = -(j + \frac{1}{2})a$	-1	+1	-2	+2	-3	+3	-4
$j = l + \frac{1}{2}a$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{7}{2}$
a	1	-1	1	-1	1	-1	1
$l = j - \frac{1}{2}a$	0	1	1	2	2	3	3
$\bar{l} = j + \frac{1}{2}a$	1	0	2	1	3	2	4

model is one in which the electrons move independently in a mean field central potential. Since

$$\sum_{m=-j}^j \rho_{E,\kappa,m}(\mathbf{r}) = \frac{2j+1}{4\pi} \frac{D_{E,\kappa}(r)}{r^2}, \quad (23.106)$$

a state of $2j + 1$ independent electrons, with one in each member of the set $\{\psi_{E,\kappa,m}, m = -j, \dots, j\}$, has a spherically symmetric probability density. If E belongs to the point spectrum of the Hamiltonian, then Eq. (23.106) gives a distribution localized in r , and we refer to the states $\{E, \kappa, m\}, m = -j, \dots, j$ as belonging to the subshell $\{E, \kappa\}$.

The notations in use for Dirac central field states are set out in Table 23.3. Here, l is associated with the orbital angular quantum number of the upper pair of components and \bar{l} with the lower pair. Note the useful equivalence

$$\kappa(\kappa + 1) = l(l + 1).$$

Defining $\bar{\kappa} := -\kappa$ we have also $\bar{\kappa}(\bar{\kappa} + 1) = \bar{l}(\bar{l} + 1)$.

23.5.3 Solutions Near the Nucleus

Textbooks on quantum electrodynamics usually contain extensive discussions of the formalism associated with the Dirac equation but rarely go beyond the treatment of the hydrogen atom (Chap. 11). *Greiner's* textbook [5] is an honorable exception, with many worked examples. A more exhaustive list of problems in which exact solutions are known is contained in [27]; it is particularly rich in detail about equations of motion and Green's functions in external electromagnetic fields of various configurations, coherent states of relativistic particles, and charged particles in quantized plane wave fields. It also incorporates discussion of extensions of the Dirac equations due to Pauli, which include explicit interaction terms arising from anomalous magnetic or electric moments.

Atoms and molecules with more than one electron are not soluble analytically, so that numerical models are needed to make predictions. The solutions are sensitive to boundary conditions, on which we focus in this section. For large r , solutions of Eq. (23.102) can be found proportional

to $\exp(\pm\lambda r)$, where

$$\lambda = +\sqrt{c^2 - \frac{E^2}{c^2}}. \quad (23.107)$$

Thus, λ is *real* when $-c^2 \leq E \leq c^2$, and *pure imaginary* otherwise.

Singular point at $r = 0$ Singularities of the nuclear potential near $r = 0$ have a major influence on the nature of solutions of the Dirac equation. Suppose that the potential has the form

$$V(r) = -\frac{Z(r)}{r}, \quad (23.108)$$

so that $Z(r)$ is the effective charge seen by an electron at radius r from the nuclear center. The dependence of $Z(r)$ on r may reflect the finite size of the nuclear charge distribution, so far treated as a point, or the screening due to the environment. Assume that $Z(r)$ can be expanded in a power series of the form

$$Z(r) = Z_0 + Z_1 r + Z_2 r^2 + \dots \quad (23.109)$$

in a neighborhood of $r = 0$. This property characterizes a number of well-used models

1. *Point nucleus:* $Z_0 \neq 0; Z_n = 0, n > 0$.
2. *Uniform nuclear charge distribution:*

$$V(r) = \begin{cases} -\frac{3Z}{2a} \left(1 - \frac{r^2}{3a^2}\right), & 0 \leq r \leq a, \\ -\frac{Z}{r}, & r > a. \end{cases} \quad (23.110)$$

This gives the expansion $Z_0 = 0, Z_1 = -3Z/2a, Z_2 = 0, Z_3 = +Z/2a^3, Z_n = 0$ for $n > 3$ when $r \leq a$ and $Z_0 = Z; Z_n = 0$ when $r > a$.

3. *Fermi distribution:* The nuclear charge density has the form

$$\rho_{\text{nuc}}(r) = \frac{\rho_0}{1 + \exp[(r-a)/d]},$$

where ρ_0 is chosen so that the total charge on the nucleus is Z .

Other nuclear models, reflecting the density distributions deduced from nuclear scattering experiments, can be found in the literature.

Series Solutions near $r = 0$ Any solution for the radial amplitudes of Dirac's equation in a central potential with

$$u(r) = \begin{pmatrix} P(r) \\ Q(r) \end{pmatrix}, \quad (23.111)$$

with radial density

$$D(r) = P^2(r) + Q^2(r),$$

can be expanded in a power series near the singular point at $r = 0$ in the form

$$u(r) = r^\gamma (u_0 + u_1 r + u_2 r^2 + \dots), \quad (23.112)$$

where

$$u_k = \begin{pmatrix} p_k \\ q_k \end{pmatrix}, \quad k = 1, 2, \dots,$$

and γ, p_k, q_k are constants that depend on the nuclear potential model.

Point nuclear models For a Coulomb singularity, $Z_0 \neq 0$, the leading coefficients satisfy

$$\begin{aligned} -Z_0 p_0 + c(\kappa - \gamma)q_0 &= 0, \\ c(\kappa + \gamma)p_0 - Z_0 q_0 &= 0, \end{aligned} \quad (23.113)$$

so that

$$\begin{aligned} \gamma &= \pm \sqrt{\kappa^2 - \frac{Z_0^2}{c^2}}, \\ \frac{q_0}{p_0} &= \frac{Z_0}{c(\kappa - \gamma)} = \frac{c(\kappa + \gamma)}{Z_0}. \end{aligned} \quad (23.114)$$

Finite nuclear models Finite nuclear models, for which $Z_0 = 0$, have no singularity in the potential at $r = 0$. The indicial equation (23.114) reduces to $\gamma = \pm|\kappa|$, so that for $\kappa < 0$,

$$P(r) = p_0 r^{l+1} + O(r^{l+3}), \quad (23.115)$$

$$Q(r) = q_1 r^{l+2} + O(r^{l+4}), \quad (23.116)$$

with

$$\begin{aligned} \frac{q_1}{p_0} &= \frac{(E - mc^2 + Z_1)}{[c(2l + 3)]}, \\ q_0 &= p_1 = 0, \end{aligned}$$

and for $\kappa \geq 1$,

$$P(r) = p_1 r^{l+1} + O(r^{l+3}), \quad (23.117)$$

$$Q(r) = q_0 r^l + O(r^{l+2}), \quad (23.118)$$

$$\begin{aligned} \frac{p_1}{q_0} &= -\frac{(E - mc^2 + Z_1)}{[c(2l + 1)]}, \\ p_0 &= q_1 = 0. \end{aligned}$$

In both cases, the solutions consist of either purely *even* powers or purely *odd* powers of r , contrasting strongly with the point nucleus case, where both even and odd powers are present in the series expansion.

The nonrelativistic limit For a solution linked to a nonrelativistic state with orbital angular momentum l , one expects the nonrelativistic limit

$$P(r) = O(r^{l+1}), \quad c \rightarrow \infty.$$

The limiting behavior reveals some significant features.

Finite nuclear models The behavior is entirely regular:

$$P(r) = O(r^{l+1}), \quad Q(r) = O(c^{-1}) \rightarrow 0.$$

Point nuclear models Since

$$\gamma = |\kappa| - \frac{Z^2}{2c^2|\kappa|} + \dots,$$

Equation (23.114) shows that the leading coefficient p_0 vanishes in the limit so that,

$$P(r) \approx p_1 r^{l+1} [1 + O(r^2)], \quad \text{when } \kappa \geq 1, \quad l = \kappa. \quad (23.119)$$

All higher powers of *odd* relative order vanish in the limit for both components. The behavior in the case $\kappa < 0$ is entirely regular.

23.5.4 Bound states: $r \rightarrow \infty$

Square integrable solutions require $\int D_{E,\kappa}(r) dr$ to be finite; since the solutions are smooth, except possibly near the singular endpoints $r \rightarrow 0$ and $r \rightarrow \infty$, we focus on the behavior at the endpoints:

For *real* values of λ the condition

$$\int_R^\infty D_{E,\kappa}(r) dr < \infty, \quad 0 < R < \infty,$$

requires that $P_{E\kappa}(r), Q_{E\kappa}(r)$ are proportional to $\exp(-\lambda r)$ with $\lambda > 0$. This means that bound states can only exist

when E lies in the interval $-c^2 \leq E \leq c^2$. Outside this interval, solutions are necessarily of scattering type and so

$$\int_R^\infty D_{E,\kappa}(r) dr$$

diverges when $|E| > c^2$.

Near the origin, we require

$$\int_0^{R'} D_{E,\kappa}(r) dr < \infty, \quad R' > 0.$$

Since $D_{E,\kappa}(r) \approx r^{\pm 2\gamma}$ as $r \rightarrow 0$, this condition holds when $\pm\gamma > -\frac{1}{2}$. Only the solution with $\gamma > 0$ satisfies the condition when $|\gamma| > \frac{1}{2}$, or $Z < \alpha^{-1} \sqrt{\kappa^2 - 1/4}$, and the solution with $\gamma < 0$ must be disregarded. This corresponds to the *limit point case* of a second-order differential operator [28]. In the special case $|\kappa| = 1$ or $j = \frac{1}{2}$, this limits Z to be smaller than $c\sqrt{3}/2 \approx 118.6$. For $Z > c\sqrt{3}/2$, both solutions are square integrable near the origin (the *limit circle case*), and the differential operator is no longer essentially self-adjoint.

The Coulomb potential must have a finite expectation for any physically acceptable solution, so that we also require

$$\int_0^{R'} D_{E,\kappa}(r) \frac{dr}{r} < \infty, \quad R' > 0.$$

This is always satisfied by the solution with $\gamma > 0$ for all $|Z| < \alpha^{-1}|\kappa|$, but not by the solution with $\gamma < 0$. Imposing this condition restores essential self-adjointness (on a more restricted domain) for $118 < Z \leq 137$.

23.5.5 Hydrogenic Atoms

Hydrogenic solutions reveal dynamical effects of relativity in the absence of screening by orbital electrons. In this case, $Z_0 = Z$, $Z_n = 0$, $n > 0$. When $-c^2 < E < c^2$, we have bound states. The parameter λ , Eq. (23.107), can conveniently be written,

$$\lambda = \frac{Z}{N}, \quad (23.120)$$

so that rearranging Eq. (23.107) gives

$$E = +c^2 \sqrt{1 - \frac{Z^2}{N^2 c^2}}, \quad (23.121)$$

essentially equivalent to Sommerfeld's fine structure formula. In the formal nonrelativistic limit, $c \rightarrow \infty$, we have

$$E = c^2 - \frac{Z^2}{2N^2} + O\left(\frac{1}{c^2}\right),$$

so that N is closely related to the principal quantum number, n , appearing in the Rydberg formula.

Define the *inner quantum number*

$$n_r = -\gamma + \frac{NE}{c^2}, \quad n_r = 0, 1, 2, \dots$$

Substitute for E from Eq. (23.121) to get

$$\begin{aligned} N &= [(n_r + \gamma)^2 + \alpha^2 Z^2]^{1/2} \\ &= [n^2 - 2n_r(|\kappa| - \gamma)]^{1/2}, \end{aligned} \quad (23.122)$$

where $n = n_r + |\kappa|$ is the *principal quantum number*, the exact equivalent of the principal quantum number of the non-relativistic state to which the Dirac solution reduces in the limit $c \rightarrow \infty$. With this notation, the radial amplitudes for bound hydrogenic states are

$$\begin{aligned} P_{E\kappa}(r) &= \mathcal{N}_{E\kappa} \left(c + \frac{E}{c} \right)^{1/2} \rho^\gamma e^{-\rho/2} \\ &\quad \times [-n_r M(-n_r + 1, 2\gamma + 1; \rho) \\ &\quad + (N - \kappa) M(-n_r, 2\gamma + 1; \rho)] \end{aligned} \quad (23.123)$$

$$\begin{aligned} Q_{E\kappa}(r) &= \mathcal{N}_{E\kappa} \left(c - \frac{E}{c} \right)^{1/2} \rho^\gamma e^{-\rho/2} \\ &\quad \times [-n_r M(-n_r + 1, 2\gamma + 1; \rho) \\ &\quad - (N - \kappa) M(-n_r, 2\gamma + 1; \rho)], \end{aligned} \quad (23.124)$$

where $\rho = 2\lambda r$ and

$$\mathcal{N}_{E\kappa} = \left(\frac{\alpha Z}{2N^2(N - \kappa)} \cdot \frac{\Gamma(2\gamma + n_r + 1)}{n_r! [\Gamma(2\gamma + 1)]^2} \right)^{1/2}$$

is the normalization constant. For definitions of the confluent hypergeometric functions $M(a, b; c; z)$, see [29, Sect. 13.1].

Table 23.4 lists expectation values of simple powers of the radial variable $\rho = 2Zr/N$ from [30] and [31]. Simple algebra, using the inequalities $\gamma < |\kappa|$ and $N < n$, yields the inequality

$$\langle \rho^s \rangle_{n\kappa} < \langle \rho^s \rangle_{nl}, \quad s > 0;$$

the inequality is reversed for $s < 0$. In the same way, it is easy to deduce that relativistic hydrogenic eigenvalues lie below the nonrelativistic eigenvalues

$$\epsilon_{n\kappa} < \epsilon_{nl}.$$

Thus, in the absence of screening, Dirac orbitals both *contract* and are *stabilized* with respect to their nonrelativistic counterparts. The relativistic and nonrelativistic expectation values approach each other as the *relativistic coupling constant*, $Z/c = \alpha Z \rightarrow 0$. This formal *nonrelativistic limit* is approached as $\alpha \rightarrow 0$ or $c \rightarrow \infty$, in which the speed of light is regarded as infinite.

Table 23.4 Radial moments $\langle \rho^s \rangle$

s	Nonrelativistic	Relativistic
2	$2n^2[5n^2 + 1 - 3l(l + 1)]$	$2[N^2(5N^2 - 2\kappa^2)R^2(N) + N^2(1 - \gamma^2) - 3\kappa N^2 R(N)]$
1	$3n^2 - l(l + 1)$	$-\kappa + (3N^2 - \kappa^2)R(N)$
0	1	1
-1	$\frac{1}{2n^2}$	$\frac{n\gamma + (\kappa - \gamma) \kappa }{2\gamma N^3}$
-2	$\frac{1}{2n^3(2l + 1)}$	$\frac{\kappa^2 R(N)}{2\gamma^2 N^3(2\gamma - \text{sgn}\kappa)}$
-3	$\frac{1}{4n^3 l(l + 1)(2l + 1)}$	$\frac{N^2 + 2\gamma^2 \kappa^2 - 3N^2 \kappa R(N)}{4N^5 \gamma(\gamma^2 - 1)(4\gamma^2 - 1)}$

Note: $R(N) = \sqrt{1 - Z^2/N^2 c^2}$

23.5.6 The Free Electron Problem in Spherical Coordinates

The radial equation (23.102) for the free electron ($V(r) = 0$) gives a pair of first-order ordinary differential equations

$$\begin{aligned} (mc^2 - E)P_{E\kappa}(r) &= c \left(\frac{d}{dr} - \frac{\kappa}{r} \right) Q_{E\kappa}(r), \\ c \left(\frac{d}{dr} + \frac{\kappa}{r} \right) P_{E\kappa}(r) &= (mc^2 + E)Q_{E\kappa}(r), \end{aligned} \quad (23.125)$$

from which we deduce that

$$\begin{aligned} \frac{d^2 P_{E\kappa}(r)}{dr^2} + \left(p^2 - \frac{\kappa(\kappa + 1)}{r^2} \right) P_{E\kappa}(r) &= 0, \\ \frac{d^2 Q_{E\kappa}(r)}{dr^2} + \left(p^2 - \frac{\bar{\kappa}(\bar{\kappa} + 1)}{r^2} \right) Q_{E\kappa}(r) &= 0, \end{aligned} \quad (23.126)$$

where $p^2 = m^2 c^2 - E^2/c^2 = \mathbf{p} \cdot \mathbf{p}$ and the angular quantum numbers κ and $\bar{\kappa}$ are associated, respectively, with the upper and lower components. These are defining equations of Riccati–Bessel functions [29, Sect. 10.1.1] of orders l and \bar{l} , respectively, where

$$\kappa(\kappa + 1) = l(l + 1), \quad \bar{\kappa}(\bar{\kappa} + 1) = \bar{l}(\bar{l} + 1).$$

Thus, the solutions of Eq. (23.126) are functions of the variable $x = pr$ of the form

$$P_{E\kappa}(r) = Ax f_l(x), \quad Q_{E\kappa}(r) = Bx f_{\bar{l}}(x),$$

where the ratio of A and B is determined by Eq. (23.125), and where $f_l(x)$ is a spherical Bessel function of the first, second, or third kind [29, Sect. 10.1.1]. Thus,

$$\begin{aligned} P_{E\kappa}(r) &= \mathcal{N} \left(\frac{E + mc^2}{\pi E} \right)^{1/2} x f_l(x), \\ Q_{E\kappa}(r) &= \mathcal{N} \text{sgn}(\kappa) \left(\frac{E - mc^2}{\pi E} \right)^{1/2} x f_{\bar{l}}(x). \end{aligned} \quad (23.127)$$

Equations (23.125) require that Riccati–Bessel solutions of the same type be chosen for both components. The possibilities are:

Standing waves The two solutions of the same type are $f_l(x) = j_l(x)$, $f_l(x) = y_l(x)$. The $j_l(x)$ are bounded everywhere, including the singular points $x = 0$, $x \rightarrow \infty$ and have zeros of order l at $x = 0$. The $y_l(x)$ are bounded at infinity but have poles of order $l + 1$ at $x = 0$.

Progressive waves The spherical Hankel functions (functions of the third kind) are linear combinations

$$h_l^{(1)}(x) = j_l(x) + iy_l(x), \quad h_l^{(2)}(x) = j_l(x) - iy_l(x).$$

Recalling that p is real if and only if $|E| > mc^2$, we see that $h_l^{(1)}(x), h_l^{(2)}(x)$ are bounded as $x \rightarrow \infty$ and have poles of order $l + 1$ at $x = 0$. Notice that when $|E| < mc^2$, which does not occur for a free particle, p becomes pure imaginary, and no solution that is finite at both singular points exists.

The normalization constant \mathcal{N} can be determined by using the well-known result

$$\int_0^\infty j_l(pr) j_l(p'r) r^2 dr = \frac{\pi}{2p^2} \delta(p - p').$$

The choice $\mathcal{N} = 1$ ensures that

$$\int_0^\infty D_{E\kappa}(r) dr = \delta(p - p').$$

Noting that

$$\delta(E - E') = \left| \frac{dp}{dE} \right| \delta(p - p'),$$

and $dp/dE = c^2 p/E$ gives

$$\int_0^\infty D_{E\kappa}(r) dr = \delta(E - E'),$$

when $\mathcal{N} = (|E|/c^2 p)^{1/2}$.

23.6 Numerical Methods for the Radial Dirac Equation

The main drive for understanding methods of numerical approximation of Dirac's equation in atomic and molecular physics comes from their application to many-electron systems. Approximate wave functions for atomic or molecular states are usually constructed from products of one-electron orbitals, and their determination exploits knowledge gained from the treatment of one-electron problems. Whilst the numerical methods described in this section are strictly one-electron in character, the extension to many-electron problems is relatively straightforward.

23.6.1 Dirac's Equation on a Finite Domain

Physical observables are represented in quantum theory by self-adjoint operators on a suitable Hilbert space¹. In scattering calculations, for example using the R-matrix or CCC methods, it is usual to divide the region of interest into an inner and an outer part, with appropriate boundary conditions at the interface. As first pointed out by Bloch [33], it is essential to take account of the boundary conditions on a finite region if the Hamiltonian operator is to be self-adjoint. Bloch's analysis was for Schrödinger Hamiltonians, but the argument applies equally to the Dirac differential operator on a finite region $\mathcal{V} \in \mathbb{R}^3$. Then, since

$$\begin{aligned} (\phi, \hat{\mathbf{h}}_D \psi)_\mathcal{V} - (\hat{\mathbf{h}}_D \phi, \psi)_\mathcal{V} &= -ic \int_{\mathcal{V}} \nabla \cdot [\phi^\dagger \boldsymbol{\alpha} \psi] d\mathbf{r} \\ &= -ic \int_{\partial\mathcal{V}} [\phi^\dagger \boldsymbol{\alpha} \psi] \cdot \mathbf{n} dS \end{aligned}$$

does not vanish, where \mathbf{n} and dS are the outward normal and surface element on the region's smooth boundary $\partial\mathcal{V}$, the operator $\hat{\mathbf{h}}_D$, Eq. (23.25), on \mathcal{V} is not self-adjoint. Following Bloch [33], we can construct a *self-adjoint operator*, $\hat{\mathbf{H}}_D$ on \mathcal{V} as

$$\hat{\mathbf{H}}_D = \hat{\mathbf{h}}_D + \mathcal{L}, \quad (23.128)$$

where the radial parts are

$$\begin{aligned} t_\kappa &= cJ \frac{d}{dr} + \frac{W_\kappa(r)}{r}, \\ J &= -i\sigma^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \\ W_\kappa(r) &= \begin{pmatrix} -Z(r) & c\kappa \\ c\kappa & -2mc^2r - Z(r) \end{pmatrix}, \end{aligned}$$

¹ For the mathematical definition of a self-adjoint Hermitian operator, see [32, p. 255].

and the Bloch operator is

$$\mathcal{L} = \delta(\mathbf{r} - \boldsymbol{\rho}) \frac{c}{2} [\mathcal{B} + i\boldsymbol{\alpha} \cdot \mathbf{n}],$$

where \mathcal{B} is a 4×4 symmetric matrix chosen so that $(\phi, \hat{\mathbf{H}}_D \psi)_\mathcal{V} - (\hat{\mathbf{H}}_D \phi, \psi)_\mathcal{V} = 0$, and $\boldsymbol{\rho}$ ranges over points on the boundary $\partial\mathcal{V}$ with normal \mathbf{n} .

In most practical applications, \mathcal{V} is the spherical shell bounded by radii R_1 and R_2 [34]. In this case, we need only consider the Dirac radial operator t_κ for symmetry κ , augmented by the Bloch operators [34, Eq. (35)]

$$l_R(r) = \frac{c}{2} \delta(r - R) \begin{pmatrix} \beta(R) & 1 \\ -1 & -\frac{1}{\beta(R)} \end{pmatrix}, \quad (23.129)$$

where $\beta(R) = -Q(R)/P(R)$ is the required ratio of the radial components on the spherical shell radius R . The radial Dirac operator

$$T_\kappa = t_\kappa + l_{R_1} - l_{R_2} \quad (23.130)$$

is then self-adjoint on the spherical shell $R_1 \leq r \leq R_2$.

Values of $\beta(R_1)$ as $R_1 \rightarrow 0$ can be derived from Sect. 23.5.2. For a *point charge nucleus* Z ,

$$\beta(R_1) = -\frac{(\kappa + \gamma)c}{Z}, \quad R_1 \rightarrow 0, \quad (23.131)$$

and for a finite size nucleus,

$$\beta(R_1) = \begin{cases} -\frac{(\epsilon + Z_1)R_1}{(2l + 3)c}, & \kappa < 0 \\ +\frac{(2l + 1)c}{(\epsilon + Z_1)R_1}, & \kappa > 0 \end{cases} \quad (23.132)$$

At the outer boundary, R_2 , a common choice assumes that the components are roughly nonrelativistic, so that we can use the Pauli approximation,

$$Q(r) \approx \frac{1}{2c} \left(\frac{dP}{dr} + \frac{\kappa P}{r} \right) \left[1 + O\left(\frac{1}{c^2}\right) \right], \quad (23.133)$$

$$\beta(R_2) = -\frac{(b + \kappa)}{2R_2c}, \quad (23.134)$$

where $b = (dP/dr)/P$ has a prescribed value, often taken to be zero.

23.6.2 Expansion Methods

The idea of expressing HF trial functions as a linear combination of analytic functions was first promoted by Hall [35] and Roothaan [36]. Kim [37, 38] was the first to adapt the method for DHF models, but with limited success [39, Sect. 9.3]. He used STO functions $\{r^\nu \exp(-\lambda_m r)\}$, $m = 1, \dots, N$ for both large and small components. In 1975, Kagawa [40, 41] tried integer powers instead of the noninteger

γ with similar results. In 1981, *Drake and Goldman* [42] used $\{r^{\nu+i} \exp(-\lambda r), i = 0, \dots, N-1\}$. This basis worked well for negative κ states in hydrogenic atoms but gave a single spurious eigenvalue for positive κ , which they just ignored. Various test calculations are included in their 1988 review [43, Sect. IV].

Quantum chemists began to explore relativistic molecular structure calculations with Gaussian type orbitals in the late 1970s, often with catastrophic results. This initiated heated controversy for many years. Quantum chemists were mostly unaware of the criteria set out in Sect. 23.6.4. In the Schrödinger case, the usual variational formulation is legitimized by the fact that the spectrum has a finite lower bound. The spectrum of the Dirac Hamiltonian is unbounded above and below, so that the apparent absence of a finite lower bound for the bound state spectrum was the most popular explanation for this *variational collapse*.

The two most popular remedies to be investigated were *kinetic balance* and *projection operators*. Kinetic balance, suggested by *Lee and McLean* [44], advocated augmenting a GTO basis, common to both large and small components, with additional functions to “balance the set kinetically”. This appeared to *fix up* the problem for the upper spectrum but introduced spurious states, mainly in the lower part of the spectrum, as well as increasing the size of the small component basis set. This approach violates many of the criteria for acceptable basis sets in Sect. 23.6.4 and has now been dropped.

Projection operators to select trial solutions of “positive energy” to get rid of the troublesome “negative energy” states were also suggested as a remedy. This is easy to do for free electrons, where the operators $\Lambda^\pm = (\hat{\mathbf{h}}_D \pm E)/2|E|$ select positive/negative energy solutions. There is no corresponding simple formula in the presence of a potential. The *negative energy sea* also depends upon the choice of potential; perturbing the potential (as long as it does not change the domain of the Hamiltonian) induces a unitary transformation on the basis, which inevitably mixes the unperturbed positive and negative energy states. A relativistic calculation on a hydrogenic atom in which the nuclear charge is perturbed gives incorrect answers if the negative energy contribution to the perturbation series is omitted [45]. This means disaster for “no-pair” formulations of the bound-state QED advocated in, for example [46], which aim to eliminate the negative energy sea from bound state calculations.

23.6.3 Finite Basis Set Formalism

Assume that each solution of the target problem is approximated as a linear combination

$$\psi_{\kappa m}(\mathbf{r}) = \frac{1}{r} \sum_j \begin{pmatrix} c_{\kappa j}^L f_{\kappa j}^L(r) \chi_{\kappa, m}(\theta, \varphi) \\ i c_{\kappa j}^S f_{\kappa j}^S(r) \chi_{-\kappa, m}(\theta, \varphi) \end{pmatrix}, \quad (23.135)$$

where $c_{\kappa j}^L, c_{\kappa j}^S$ $j = 1, \dots, N$, are arbitrary constants, and $f_{\kappa j}^L(r)$ and $f_{\kappa j}^S(r)$ are real, so that each term in the sum Eq. (23.135) has the same structure. This enables us to construct a *Rayleigh quotient*

$$W[\psi] = \frac{\langle \psi | \hat{\mathbf{h}}_D | \psi \rangle}{\langle \psi | \psi \rangle}, \quad (23.136)$$

where both $\langle \psi | \hat{\mathbf{h}}_D | \psi \rangle$ and $\langle \psi | \psi \rangle$ are quadratic expressions in the expansion coefficients c_j^L, c_j^S . By requiring that $W[\psi]$ shall be stationary with respect to arbitrary variations in the expansion coefficients, we arrive at the matrix eigenvalue equation

$$\mathbf{f}_\kappa \begin{pmatrix} \mathbf{c}^L \\ \mathbf{c}^S \end{pmatrix} = \epsilon \begin{pmatrix} \mathbf{S}_\kappa^{LL} & 0 \\ 0 & \mathbf{S}_\kappa^{SS} \end{pmatrix} \begin{pmatrix} \mathbf{c}^L \\ \mathbf{c}^S \end{pmatrix}, \quad (23.137)$$

where the matrix Hamiltonian is denoted by

$$\mathbf{f}_\kappa = \begin{pmatrix} \mathbf{V}_\kappa^{LL} & c \mathbf{\Pi}_\kappa^{LS} \\ c \mathbf{\Pi}_\kappa^{SL} & \mathbf{V}_\kappa^{SS} - 2mc^2 \mathbf{S}_\kappa^{SS} \end{pmatrix};$$

$\mathbf{c}^L, \mathbf{c}^S$ are N -vectors, and $\mathbf{V}_\kappa^{LL}, \mathbf{V}_\kappa^{SS}, \mathbf{S}_\kappa^{LL}, \mathbf{S}_\kappa^{SS}, \mathbf{\Pi}_\kappa^{LS}$ and $\mathbf{\Pi}_\kappa^{SL}$ are all finite $N \times N$ matrices. Using superscripts T to denote either of the letters L, S , the elements of the matrices are defined by

$$S_{\kappa ij}^{TT} = \int_0^\infty f_{i\kappa}^T(r) f_{j\kappa}^T(r) dr, \quad (23.138)$$

$$V_{\kappa ij}^{TT} = \int_0^\infty f_{i\kappa}^T(r) V(r) f_{j\kappa}^T(r) dr, \quad (23.139)$$

and

$$\Pi_{\kappa ij}^{LS} = \int_0^\infty f_{i\kappa}^L(r) \left(-\frac{d}{dr} + \frac{\kappa}{r} \right) f_{j\kappa}^S(r) dr, \quad (23.140)$$

$$\Pi_{\kappa ij}^{SL} = \int_0^\infty f_{i\kappa}^S(r) \left(\frac{d}{dr} + \frac{\kappa}{r} \right) f_{j\kappa}^L(r) dr. \quad (23.141)$$

If $f_{i\kappa}^L(r)$ and $f_{i\kappa}^S(r)$ vanish at both $r = 0$ and $r \rightarrow \infty$, then a simple integration by parts shows that $\mathbf{\Pi}_\kappa^{LS}$ and $\mathbf{\Pi}_\kappa^{SL}$ are Hermitian conjugate matrices.

23.6.4 Physically Acceptable Basis Sets

So far, we have not defined basis functions $f_{j\kappa}^L(r)$ and $f_{j\kappa}^S(r)$ with acceptable properties. We expect the generalized eigenproblem Eq. (23.137) to have a pure point spectrum with three pieces: N eigensolutions with $E < -mc^2$ ($\epsilon < -2mc^2$) representing the lower continuum; $N_b < N$ eigensolutions

in the gap $-mc^2 < E < mc^2$ corresponding to bound states ($-2mc^2 < \epsilon < 0$), and $N - N_b$ eigensolutions with $E > mc^2$ ($\epsilon > 0$) representing the upper continuum.

Physically acceptable bases are, in practice, confined to a box of radius R and have the following properties:

- A. They should exploit the Dirac central-field structure of Eq. (23.135) with the correct symmetry properties.
- B. Sect. 23.5.3 sets out boundary conditions to be satisfied by $f_{i\kappa}^L(r)$ and $f_{i\kappa}^S(r)$ near the nucleus. These are essential as the electromagnetic properties of the nucleus drive the electronic dynamics of the atom.
- C. Sect. 23.5.4 sets out boundary conditions as $r \rightarrow R$. Many suitable basis sets are square integrable on \mathbb{R}^3 and have negligible amplitudes on the boundary. Scattering calculations involve wave functions having a finite amplitude on $r = R$; see Sect. 23.6.1
- D. Acceptable spinor basis functions should satisfy the *kinetic matching* (Pauli) relation

$$\begin{aligned} i\hbar \frac{f_{i\kappa}^S(r)}{r} \chi_{-\kappa,m}(\theta, \varphi) \\ = \text{const.} \lim_{c \rightarrow \infty} \boldsymbol{\sigma} \cdot \mathbf{p} \frac{f_{i\kappa}^L(r)}{r} \chi_{\kappa,m}(\theta, \varphi). \end{aligned} \quad (23.142)$$

The nonrelativistic reduction of the Dirac equation to Schrödinger's equation [5, p. 97] depends upon the operator identity

$$\mathbf{p}^2 = (\boldsymbol{\sigma} \cdot \mathbf{p})(\boldsymbol{\sigma} \cdot \mathbf{p}).$$

In the relativistic basis set formalism, the matrix equivalent of this equation is

$$T_{lij} = \lim_{c \rightarrow \infty} \frac{1}{2} \sum_{k=1}^N \Pi_{\kappa ik}^{LS} \Pi_{\kappa kj}^{SL}. \quad (23.143)$$

The criterion Eq. (23.142) or, in terms of radial amplitudes Eq. (23.133), ensures that

$$\begin{aligned} T_{lij} = \frac{1}{2} \int_0^\infty f_{i\kappa}^L(r) \\ \times \left(-\frac{d^2}{dr^2} + \frac{l(l+1)}{r^2} \right) f_{j\kappa}^L(r) dr, \end{aligned}$$

the ij -element of the familiar nonrelativistic radial kinetic energy matrix T_l for orbital angular momentum l [47, 48].

Another way of viewing this result is to observe that for a general basis set, the sum over a finite set of intermediate states, k , in Eq. (23.143) is necessarily incomplete.

The Hermitian conjugacy property, $\Pi_{\kappa ij}^{LS} = \Pi_{\kappa ji}^{SL}$ ensures that the omitted terms give real and nonnegative contributions. Thus, other choices of basis set cause Eq. (23.143) to *underestimate* the nonrelativistic kinetic energy [47], resulting in spuriously large relativistic energy corrections.

- E. Basis functions in the domain of the Dirac operator must give finite expectation values for all observables; the meaning of this statement can be made precise in a functional analytic discussion such as in [4]. Some implications for the finite basis set approach are given in the author's paper [49], which discusses the convergence of expectation values of standard Dirac operators with trial functions constructed from acceptable basis functions. Here, the main importance is that a (possibly singular) multiplicative operator $V(r)$ (say, $-Z/r$) has *finite* $N \times N$ matrices $\mathbf{V}_{\kappa}^{LL}, \mathbf{V}_{\kappa}^{SS}$. In particular, both matrices must have a *lowest eigenvalue* $V_{\min}^{(N)}$, say. Consider now the quantity $(\psi | \hat{\mathbf{h}}_D(\lambda) | \psi)$, where

$$\hat{\mathbf{h}}_D(\lambda) = (c\boldsymbol{\alpha} \cdot \mathbf{p} + \beta m_e c^2) + \lambda V(r).$$

With $\lambda = 0$, we have a free Dirac particle with a two-branched continuous spectrum $E > mc^2$ and $E < -mc^2$. A negative definite $V(r)$ always has an expectation bounded below by $V_{\min}^{(N)}$; clearly we want

$$V_{\min}^{(N)} \geq V_{\min} > -2mc^2, \quad (23.144)$$

for all values of N . So, if we increase λ from 0 to 1, the eigenvalues of trial solutions corresponding to eigenvalues in the upper continuum at $\lambda = 0$ will be smoothly decreasing functions of λ bounded below by V_{\min} for all values of N . It follows that *the upper set of eigenvalues has a fixed lower bound* in the gap $(-mc^2, mc^2)$. If the basis set satisfies suitable completeness criteria in an appropriate Hilbert space as $N \rightarrow \infty$ (see [49, 50] for more details) and if Eq. (23.144) holds for all values of N , the sequence $\{E_{N+i}^{(N)}, i = 1, 2, \dots\}$ of approximate eigenvalues will converge to limiting values $\{E_i, i = 1, 2, \dots\}$ in $(-mc^2, mc^2)$. Thus, relativistic and nonrelativistic Rayleigh–Ritz approximations converge in the same way [48, 50].

The way in which relativistic solutions approach the nonrelativistic solutions in the limit $c \rightarrow \infty$ is easy to understand in the light of this picture. Using the same basis functions for the nonrelativistic trial function as the Dirac large component, we see that the energies have a common lower bound V_{\min} independent of c . The states of interest vary as $c \rightarrow \infty$ but without changing the character of the upper spectrum. The lower spectrum disappears to $-\infty$ leaving the familiar nonrelativistic picture.

23.6.5 Basis Sets Defined on \mathbb{R}^3

A. L-Spinors

L-spinors [50] are related to Dirac hydrogenic functions in much the same way as Sturmian functions [51, 52] are related to Schrödinger hydrogenic functions (Sect. 23.3). They are solutions of the differential equation system

$$\begin{bmatrix} 1 - \frac{(N_{n_r, \kappa} + n_r + \gamma)}{x} & -\frac{d}{dx} + \frac{\kappa}{x} \\ \frac{d}{dx} + \frac{\kappa}{x} & 1 + \frac{(N_{n_r, \kappa} - n_r - \gamma)}{x} \end{bmatrix} \times \begin{bmatrix} f_{n_r, \kappa}^L(x) \\ f_{n_r, \kappa}^S(x) \end{bmatrix} = 0, \quad (23.145)$$

where $x = 2\lambda r$ and $\lambda > 0$ is constant. This choice ensures that $f_{n_r, \kappa}^L(x)$ tends smoothly to the corresponding Coulomb Sturmian in the nonrelativistic limit $c \rightarrow \infty$ [50]. If $\lambda = Z/N_{n_r, \kappa}$, then $f_{n_r, \kappa}^L(x)$, $f_{n_r, \kappa}^S(x)$, respectively, coincide with the Dirac-Coulomb eigenfunctions $P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$ having principal quantum number $n = n_r + |\kappa|$. The explicit form for L-spinors, in terms of Laguerre polynomials (Chap. 9.3.2), $L_{n_r}^{(2\gamma)}(x)$, is

$$f_{\kappa, n_r}^{(L)}(x) = \mathcal{N}_{n_r, \kappa} x^\gamma e^{-x/2} \times \left[-(1 - \delta_{n_r, 0}) L_{n_r-1}^{(2\gamma)}(x) + \frac{(N_{n_r, \kappa} - \kappa)}{(n_r + 2\gamma)} L_{n_r}^{(2\gamma)}(x) \right], \quad (23.146)$$

$$f_{\kappa, n_r}^{(S)}(x) = \mathcal{N}_{n_r, \kappa} x^\gamma e^{-x/2} \times \left[-(1 - \delta_{n_r, 0}) L_{n_r-1}^{(2\gamma)}(x) - \frac{(N_{n_r, \kappa} - \kappa)}{(n_r + 2\gamma)} L_{n_r}^{(2\gamma)}(x) \right], \quad (23.147)$$

where

$$\mathcal{N}_{n_r, \kappa} = \left(\frac{n_r! (2\gamma + n_r)}{2N_{n_r, \kappa} (N_{n_r, \kappa} - \kappa) \Gamma(2\gamma + n_r)} \right)^{1/2} \quad (23.148)$$

is chosen so that the diagonal elements g_{n_r, n_r}^κ of the Gram (or overlap) matrix are unity for both large and small components. Both Gram matrices are tridiagonal with nonzero off-diagonal elements

$$g_{n_r, (n_r+1)}^{(\kappa)} = g_{(n_r+1), n_r}^{(\kappa)} = \frac{\eta^T}{2} \left(\frac{(n_r + 1)(2\gamma + n_r + 1)(N_{n_r, \kappa} - \kappa)}{N_{n_r, \kappa} N_{(n_r+1), \kappa} (N_{(n_r+1), \kappa} - \kappa)} \right)^{1/2}, \quad (23.149)$$

where $T = L, S$, $\eta^L = -1$ and $\eta^S = +1$. This convention facilitates the construction of the blocks of the matrix Hamiltonian Eq. (23.137), which are banded when the operators are the powers r^n , $n > -1$. The properties of Laguerre polynomials ensure that the matrix of the Coulomb poten-

tial is diagonal. For a full discussion of L-spinor properties, orthogonality, completeness, and applications to hydrogenic atoms, see [50]. The paper demonstrates numerical convergence of expectation values of observables, sum rules, and perturbation expansions, including contributions from negative energy (positronic) states. L-spinor properties have also been exploited in the Relativistic Convergent Close-Coupling Method devised by Fursa, Bray, and Bostock for the calculation of cross sections of electron collisions with atoms and ions. For a detailed tutorial on the RCCC method with extensive references and applications involving two-electron and quasi two-electron targets, see Bostock [53]. L-spinors are also useful for studies of isolated atoms in strong electromagnetic fields (Chap. 14). The equivalent nonrelativistic Coulomb Sturmians have been used for a long time to study the Zeeman effect on high Rydberg levels, especially in the region where chaotic behavior is expected [54] (Chap. 16).

B. S-Spinors

S-spinors have the functional form of the *most nearly nodeless* L-spinors characterized by the minimal value of n_r and can be viewed as the relativistic analogues of Slater functions (STOs). When κ is negative, take $n_r = 0$, so that

$$f_{\kappa, 0}^{(L)}(x) = -f_{\kappa, 0}^{(S)}(x) = \mathcal{N}_{\kappa, 0} x^\gamma \exp\left(\frac{-x}{2}\right) \frac{N_{0, \kappa} - \kappa}{2\gamma} L_0^{(2\gamma)}(x).$$

When κ is positive, we must take $n_r = 1$, and then

$$f_{\kappa, 1}^{(L)}(x) = \mathcal{N}_{1, \kappa} x^\gamma e^{-x/2} \times \left[-L_0^{(2\gamma)}(x) + \frac{N_{1, \kappa} - \kappa}{1 + 2\gamma} L_1^{(2\gamma)}(x) \right],$$

$$f_{\kappa, 1}^{(S)}(x) = \mathcal{N}_{1, \kappa} x^\gamma e^{-x/2} \times \left[-L_0^{(2\gamma)}(x) - \frac{N_{1, \kappa} - \kappa}{1 + 2\gamma} L_1^{(2\gamma)}(x) \right].$$

These can be simplified by inserting the explicit expressions $L_0^{(2\gamma)}(x) = 1$, $L_1^{(2\gamma)}(x) = 2\gamma + 1 - x$. We define a *set of S-spinors* with exponents $\{\lambda_m, m = 1, 2, \dots, N\}$ by rewriting the above in the form

$$f_m^{(T)}(r) = (A^T + B^T r) r^\gamma e^{-\lambda_m r}, \quad (23.150)$$

where $T = L, S$,

$$\left. \begin{aligned} A^L &= A^S = 1, \quad B^L = B^S = 0 \quad \text{for } \kappa < 0, \\ A^L &= \frac{(\kappa + 1 - N_{1, \kappa})(2\gamma + 1)}{2(N_{1, \kappa} - \kappa)} \\ A^S &= \frac{(\kappa - 1 - N_{1, \kappa})(2\gamma + 1)}{2(N_{1, \kappa} - \kappa)} \\ B^L &= B^S = 1 \end{aligned} \right\} \quad \text{for } \kappa > 0, \quad (23.151)$$

and

$$\gamma = \sqrt{\frac{\kappa^2 - Z^2}{c^2}}, \quad N_{1,\kappa} = \sqrt{\kappa^2 + 2\gamma + 1}.$$

The choice of the set of positive real exponents $\{\lambda_m, m = 1, 2, \dots, N\}$, must be such as to optimize Rayleigh–Ritz convergence [49]. In particular, if *one* particular exponent is chosen to have the value $\lambda_m = Z/N_{n_r,\kappa}$, then the corresponding S-spinor is a true hydrogenic solution. Clearly, S-spinors inherit the desirable properties of L-spinors and, in particular, satisfy criteria A–D.

All elements of the matrix Hamiltonian of the Dirac hydrogenic problem can be expressed in terms of Euler’s integral for the gamma function [29, Sect. 6.1.1]:

$$\Gamma(z) = k^z \int_0^\infty t^{z-1} e^{-kt} dt, \quad (\Re z > 0, \Re k > 0)$$

and are, therefore, readily written down and evaluated. The effectiveness of this method depends upon the choice of exponent set; see Sect. D below. We refer to calculations using this scheme for many-electron systems in Sect. 23.8.

C. G-Spinors

The G-spinors are the relativistic analogues of nonrelativistic spherical Gaussians (SGTO), popular in quantum chemistry for studying the electronic structure of atoms and molecules. They satisfy the relativistic boundary conditions for a *finite size* nuclear charge density distribution at $r = 0$ and are, therefore, the most convenient for relativistic molecular electronic structure calculations. The matching requirement gives

$$f_m^{(S)}(r) = \text{const.} \left(\frac{d}{dr} + \frac{\kappa}{r} \right) f_m^{(L)}(r). \quad (23.152)$$

Thus, if

$$f_m^{(L)}(r) = \mathcal{N}_{l,m}^{(L)} r^{l+1} e^{-\lambda_m r^2},$$

then

$$f_m^{(S)}(r) = \mathcal{N}_{l,m}^{(S)} r^l [(\kappa + l + 1) - 2\lambda_m r^2] e^{-\lambda_m r^2}. \quad (23.153)$$

Note that the $\kappa + l + 1$ vanishes when $\kappa < 0$, so that the radial amplitude $r^{-1} f_m^{(S)}(r)$ is never singular, even in the s -state case when $\kappa = -1, l = 0$.

D. Exponent Sets for S- and G-Spinors

Quantum chemists are familiar with the use of nonrelativistic STO and GTO basis sets, and there are extensive collections of optimized exponents that permit economical calculations for the calculations of many atoms and molecules [59–62].

These sets are also a good starting point for relativistic calculations.

An effective alternative to optimization, especially for atoms, is to use geometrical sequences $\{\lambda_m\}$ of the form

$$\lambda_m = \alpha_N \beta_N^{m-1}, \quad m = 1, 2, \dots, N, \quad (23.154)$$

which depend upon just two parameters α_N, β_N . A convenient way to do this is to find a pair $\alpha_{N_0}, \beta_{N_0}$ for small N_0 , say $N_0 = 9$, in a cheap and simple nonrelativistic calculation and then to increase N systematically using relations such as

$$\frac{\alpha_N}{\alpha_{N_0}} = \left(\frac{\beta_N - 1}{\beta_{N_0} - 1} \right)^a, \quad \text{or} \quad \frac{\ln \beta_N}{\ln \beta_{N_0}} = \left(\frac{N_0}{N} \right)^b,$$

where a, b are positive constants. Experience shows that no linear dependence problems (caused by ill-conditioning of the \mathbf{S}^T matrices) are encountered when $\beta_N > 1.2$ for S-spinors, with N up to about 30 or $\beta_N > 1.5$ for G-spinors with N up to about 50.

23.6.6 B-Splines

The comprehensive review [58] of B-splines in atomic and molecular physics introduces it as “one of the most significant developments” of recent years. However, it barely mentions applications to relativistic calculations, beginning in the 1980s, which have much promise for future work in both atomic and molecular structures and collision processes.

Here, we discuss the use of B-splines as basis functions for relativistic atomic calculations in the spirit of Sect. 23.6.1. Although this leads to generalized eigenproblems similar to those of Sect. 23.6.3, expansion in a finite number of piecewise polynomial functions implies confinement to a finite interval $[R_1, R_2]$, so that we need to take proper account of the boundary conditions,

$$F(r) \approx \sum_i c_i B_i^k(r). \quad (23.155)$$

Full details of B-spline properties are given in the book by *de Boor* [59] and in [58, Sect. 2]. The basis functions $B_i^k(r)$ of order k are polynomials of degree $k - 1$ that are nonzero on an interval $t_i \leq r < t_{i+k}$. The coefficients c_i are chosen so that the approximation is continuous up to a certain order at each of the *knots*, t_i , separating adjacent intervals. The knots are often grouped in an increasing set of *breakpoints* $\xi_1, \xi_2, \dots, \xi_{l+1}$, such that $\xi_j = t_{\mu_{j-1}} = \dots = t_{\mu_{j-1} + \mu_j}$ of multiplicity μ_j . It is usual to choose $\mu_1 = \mu_{l+1} = k$ with $\mu_j = 1$ elsewhere [58, Sect. 2].

B-splines are defined recursively, starting with

$$B_i^1(r) = 1; \quad t_i \leq r < t_{i+1}, \quad B_i^1(r) = 0, \quad (23.156)$$

otherwise, followed by

$$B_i^k(r) = \frac{r - t_i}{t_{i+k-1} - t_i} B_i^{k-1}(r) + \frac{t_{i+k} - r}{t_{i+k} - t_{i+1}} B_{i+1}^{k-1}(r), \quad (23.157)$$

for $k = 2, 3, \dots$. In applying this to the Dirac Hamiltonian, it is clear that we are dealing with a finite interval $[R_0, R_1]$ so that we need to take care with what happens at the endpoints.

B-Splines on Finite Intervals

The analysis of the radial Dirac operator in Sect. 23.6.1 revealed that t_κ must be replaced by T_κ to take account of the boundary conditions at the ends of the interval, where

$$T_\kappa = t_\kappa + l_{R_2} - l_{R_1}. \quad (23.158)$$

is then self-adjoint on the spherical shell $R_1 \leq r \leq R_2$. The Bloch operators are defined by

$$l_R(r) = \frac{c}{2} \delta(r - R) \begin{pmatrix} \beta(R) & 1 \\ -1 & -\frac{1}{\beta(R)} \end{pmatrix}, \quad (23.159)$$

where $\beta(R) = -Q(R)/P(R)$ is the required ratio of the radial components on the spherical shell radius R ; suitable values at R_1 and R_2 are given in Sect. 23.6.1.

The Galerkin Equations

The set $\{B_i^k(r)\}$ can be assembled in a vector $\mathbf{B}^k(r)$, so that we approximate the radial components by

$$P(r) \approx \mathbf{B}^k(r)^\dagger \cdot \mathbf{p}, \quad Q(r) \approx \mathbf{B}^k(r)^\dagger \cdot \mathbf{q}, \quad (23.160)$$

where \mathbf{p}, \mathbf{q} are coefficient vectors. Using the notation of Eq. (23.137), the Galerkin equations are

$$\begin{pmatrix} \widehat{\mathbf{V}} & c\Pi \\ c\Pi^\dagger & \widehat{\mathbf{V}} - 2mc^2\mathbf{S} \end{pmatrix} \begin{pmatrix} \mathbf{p} \\ \mathbf{q} \end{pmatrix} = \varepsilon \begin{pmatrix} \mathbf{Sp} \\ \mathbf{Sq} \end{pmatrix}, \quad (23.161)$$

where the symmetric matrices $\mathbf{S}, \widehat{\mathbf{V}}$ have elements

$$S_{ij} = \int B_i^k(r) B_j^k(r) dr, \quad (23.162)$$

$$\widehat{V}_{ij} = V_{ij} + \delta_{iN} \delta_{jN} \beta(R_2) - \delta_{i1} \delta_{j1} \beta(R_1)$$

$$\text{with } V_{ij} = \int B_i^k(r) V(r) B_j^k(r) dr, \quad (23.163)$$

and

$$\Pi_{ij} = \int B_i^k(r) \left(-\frac{d}{dr} + \frac{\kappa}{r} \right) B_j^k(r) dr + \frac{1}{2} \left[B_i^k(s) B_j^k(s) \right]_{R_1}^{R_2} \quad (23.164)$$

$$\Pi_{ij}^\dagger = \int B_i^k(r) \left(+\frac{d}{dr} + \frac{\kappa}{r} \right) B_j^k(r) dr - \frac{1}{2} \left[B_i^k(s) B_j^k(s) \right]_{R_1}^{R_2}. \quad (23.165)$$

Integration by parts shows that $\Pi_{ij}^\dagger = \Pi_{ji}$, so that the matrix Hamiltonian

$$\mathbf{H} = \begin{pmatrix} \widehat{\mathbf{V}} & c\Pi \\ c\Pi^\dagger & \widehat{\mathbf{V}} - 2mc^2\mathbf{S} \end{pmatrix} \quad (23.166)$$

is real symmetric, as expected. Note that the integrands are nonzero when the product $B_i^k(r) B_j^k(r)$ is nonzero and that the Bloch operator contributes to all submatrices in \mathbf{H} .

Johnson et al. [60, 61], following earlier work on relativistic ion-ion collisions by Bottcher and Strayer [62], popularized the use of a basis of B-splines in relativistic atomic calculations. The method has mainly been of use in relativistic many-body calculations on the spectra of heavy ions. However, their method had important defects, notably the appearance of spurious and rapidly oscillating solutions with eigenvalues zero or distant from the bound states of interest. Although they discarded the spurious solutions in subsequent MBPT and QED calculations, the results cannot be regarded as a fully satisfactory representation of the physics. Subsequently, several investigations, for example by Shabaev et al. [63] and by Igarashi [64, 65], have used the ideas of kinetic balance in relativistic B-spline calculations, suggesting analogies with Sect. 23.6.4. The arguments of that section, designed for expansions in analytic radial basis functions defined on the whole of $0 \leq r \leq R$ are not applicable to piecewise polynomial expansions in B-splines.

More successfully, Fischer and Parpia explored the spline-Galerkin approach for the Dirac equation [66], and Fischer and Zatsarinny [67] more recently used a formulation similar to the one above but with B-splines of different orders k_p, k_q with $|k_q - k_p| = 1$. This scheme has now been applied successfully to R-matrix calculations of electron collisions with atoms [67–69]. Zatsarinny published the BSR computer package for R-matrix calculations [70] and also the DBSR_HF program [71] DHF calculations.

23.7 Finite Differences

The numerical approximation of eigensolutions of the first-order system of differential equations (23.102) can be achieved by more or less standard finite difference methods given in texts such as [72]. For states in either continuum, $E > mc^2$ or $E < -mc^2$, the calculation is completely specified as an *initial value problem* for a prescribed value of E starting from power series solutions in the neighborhood of $r = 0$. Solutions of this sort exist for all values of (complex) E except at the bound states in the gap $-mc^2 < E < mc^2$. Here, we focus on what is characterized as a *two-point boundary value problem* in which each eigenstate and its eigenvalue E are determined simultaneously.

Suppose that the radial coordinate r is expressed in terms of a smooth differentiable function $f(s)$ of a new independent variable s and let $\varepsilon_{n\kappa} = E_{n\kappa} - mc^2$ be the energy eigenvalue relative to the nonrelativistic zero of energy. Then Eq. (23.102), generalized by the addition of a two-vector $X(s)$ on the right-hand side, can be written

$$J \frac{du}{ds} + \frac{1}{c} \frac{dr}{ds} [r \varepsilon - W(s)] u(s) = X(s) \frac{dr}{ds}, \quad (23.167)$$

where

$$J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

$$W_\kappa(r) = \begin{pmatrix} -Z(r) & c\kappa \\ c\kappa & -2mc^2r - Z(r) \end{pmatrix},$$

with $Z(r) = -rV(r)$

$$u(s) = \begin{pmatrix} P_{n\kappa} \\ Q_{n\kappa} \end{pmatrix}.$$

When discretizing, we define s on a uniform grid so that

$$s_n = nh, \quad n = 0, 1, 2, \dots, N.$$

Common choices for the mapping $s \rightarrow r = f(s)$ are

$$r_n = r_0 e^{s_n},$$

$$A r_n + \log\left(1 + \frac{r_n}{r_0}\right) = s_n,$$

for suitable values of the parameters r_0 and h , and where A is a constant, chosen so that the spacing in r_n increases exponentially for small values of n and approaches a constant for large values of n . The exponentially increasing spacing is appropriate for tightly bound solutions, but a nearly linear spacing is advisable to ensure numerical stability in the tails of extended and continuum solutions.

The finite difference approach involves a marching process, in which $u(r_n)$ is constructed from values at nearby grid points. There are many such algorithms that generate oscillatory solutions in the interval from the origin to a radius close to the turning point for classical motion. Beyond this point, we want a bound state solution that is of negative exponential character and to suppress any parasitic increasing solution. It is usual, therefore, to employ a *double shooting* method, marching from both $s_0 = 0$ and $s_N = Nh$ along the grid towards an intermediate *join* point s_n , $n = J$, adjusting ϵ until the trial solutions have the right number of nodes and have left and right-limits where they meet that agree to a preset tolerance (commonly about one part in 10^8).

The *deferred correction* method [39, 73] allows the precision of the numerical approximation in a self-consistent field calculation to be improved as the iteration converges.

Consider the simplest implicit linear difference scheme for the first-order system

$$\frac{dy}{ds} = F[y(s), s],$$

based on the trapezoidal quadrature rule

$$z_{j+1} = z_j + \frac{h[F_{j+1} + F_j]}{2}, \quad (23.168)$$

which has a local truncation error $O(h^2)$. The precision with which the grid point estimates z_j approach $y(s_j)$ can be improved at greater cost per iterative cycle by adding higher-order difference terms to the right-hand side of Eq. (23.168). These can be estimated by evaluating the added terms using the result from the previous iteration. This leaves the numerical stability properties of the simple scheme Eq. (23.168) unchanged but increases the accuracy of successive estimates z_j .

To apply this to the Dirac system, write $f(s) = dr/ds$ and

$$A_j^\pm = J \mp \frac{h f(s_j) W(s_j)}{2c}.$$

In a further generalization that is used in MCDHF problems, we replace the electron-nucleus potential $Z(r)$ by the discretized vectors $U_j^{(v)}, X_j^{(v)}$, which may change from one iteration to the next. The first iteration is

$$A_{j+1}^{+(0)} U_{j+1}^{(1)} - A_j^{-(0)} U_j^{(1)}$$

$$+ \varepsilon^{(0)} \frac{h}{2c} [r_{j+1} f(s_{j+1}) U_{j+1}^{(1)} + r_j f(s_j) U_j^{(1)}]$$

$$= \frac{h}{2} [f(s_{j+1}) X_{j+1}^{(0)} + f(s_j) X_j^{(0)}], \quad (23.169)$$

and subsequent iterations have the form

$$A_{j+1}^{+(v)} U_{j+1}^{(v+1)} - A_j^{-(v)} U_j^{(v+1)}$$

$$+ \varepsilon^{(v)} \frac{h}{2c} [r_{j+1} f(s_{j+1}) U_{j+1}^{(v+1)} + r_j f(s_j) U_j^{(v+1)}]$$

$$= \frac{h}{2} [f(s_{j+1}) X_{j+1}^{(v)} + f(s_j) X_j^{(v)}]$$

$$+ \frac{1}{12} \delta^3 U_{j+1/2}^{(v)} + \dots, \quad (23.170)$$

where $\delta^3 U_{j+1/2}^{(v)}$ is the third-order difference correction using the result of the previous iteration [29, Sect. 25.1.2]. Higher-order difference corrections (at least to order 5) are included in modern codes to improve the accuracy and numerical stability of weakly bound solutions. This deferred correction algorithm can be shown to converge asymptotically to the required solution of the differential system with a local truncation error $O(h^{2p+2})$ when using central differences of order h^{2p+1} [74].

23.8 Many-Electron Atoms

The first attempt to formulate a numerical method to solve the DHF relativistic self-consistent field problem was published in 1935 by *Swirles* [75]. This predated both Racah’s essential contributions to the quantum theory of angular momentum in 1942 and 1943 and the computer age, without which this chapter could not have been written. The reformulation [76], exploiting both Racah algebra and finite difference methods, was followed by several implementations in the following decade [39, Sect. 10]. Whilst these early calculations showed promise, it was clear that MCDHF methods were the next step, leading to *Desclaux’s* code [77, 78] and the Oxford MCDHF code [79], a precursor of GRASP2K [21]. More details on the formulation and numerical methods of GRASP2K can be found in [39, 73] and [80, Chap. 5].

This development has been free of the controversy surrounding variational methods on which the numerical algorithms are based, in stark contrast to the heated debates over expansion methods. The essential reason is that the finite difference algorithms assume that the solutions are of bound state type; the kinetic energy is always positive, and the boundary conditions, especially at the nucleus, are those needed to ensure that the trial functions, expressed as numerical values on the radial grid, are similar to the nonrelativistic equivalents, so that the arguments of Sect. 23.6.4 apply in the same way.

So far, the twenty-first century has seen major improvements in the modeling of many-electron atoms and ions for both astrophysical and terrestrial applications. This has been fostered in part by access to increasingly powerful computer resources but also by a drive to improve the accuracy of atomic calculations, so that today it is possible to claim that results have “spectroscopic accuracy” in favorable situations [81]. The ability to work with matrices constructed from different orthonormal basis sets is a major technical advance. It makes it possible to start with a reference model that includes the most important CSFs for the states of interest, to study different types of electron correlation independently, and then to see how they interact. The search for efficient ways to improve the modeling of electron correlation continues [22, 82].

23.8.1 Atomic States

Relativistic atomic structure calculations assign a trial wave function, ASF (atomic state function), to each atomic state of interest. In programs such as GRASP2K, each ASF is a linear combination of CSFs (configuration state functions), each of which is an antisymmetrized product of N Dirac atomic orbitals (satisfying Pauli’s exclusion principle), with

given total angular momentum and parity. The construction of CSFs symmetrized in this way using Racah algebra as developed by Fano has been described in [73, Sect. 2]. Newer codes such as GRASP2K have used second quantization in both angular momentum and spin spaces [21, 83] to reformulate the construction, resulting in much faster execution.

23.8.2 Atomic Orbitals

Four-component Dirac central field orbitals with the structure of Eq. (23.100) are the building blocks needed for CSFs. Ideally, they should comprise an orthonormal set, mathematically complete in a suitable function space, so as to guarantee convergence as the set dimension increases. In practice, the sets are often far from complete, so that error estimation is difficult if not impossible. All the methods described in Sect. 23.6 have been used to generate numerical orbital bases.

23.8.3 Slater Determinants

An antisymmetric state of N independent electrons in configuration space can be constructed in the form

$$\begin{aligned} & \{ \alpha_1, \alpha_2, \dots, \alpha_N \} \\ & = \langle \mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n | a_{\alpha_1}^\dagger a_{\alpha_2}^\dagger \dots a_{\alpha_N}^\dagger | 0 \rangle \\ & = \frac{1}{N!} \begin{vmatrix} \psi_{\alpha_1}(\mathbf{x}_1) & \psi_{\alpha_2}(\mathbf{x}_1) & \dots & \psi_{\alpha_N}(\mathbf{x}_1) \\ \psi_{\alpha_1}(\mathbf{x}_2) & \psi_{\alpha_2}(\mathbf{x}_2) & \dots & \psi_{\alpha_N}(\mathbf{x}_2) \\ \dots & \dots & \dots & \dots \\ \psi_{\alpha_1}(\mathbf{x}_N) & \psi_{\alpha_2}(\mathbf{x}_N) & \dots & \psi_{\alpha_N}(\mathbf{x}_N) \end{vmatrix}, \end{aligned} \quad (23.171)$$

This *Slater determinant* is an antisymmetric eigenfunction of H_0 with energy eigenvalue $\sum_{n=1}^N E_{\alpha_n}$ and of the angular momentum projection $J_z = \sum j_{z,\alpha_n}$ corresponding to the eigenvalue $M = \sum m_{\alpha_n}$. Defining the parity of a Dirac electron orbital as that of its upper component, $(-1)^{l_{\alpha_n}}$, we see that this has parity $\prod_n (-1)^{l_{\alpha_n}}$. Eigenfunctions of \mathbf{J}^2 and \mathbf{J}_z are linear combinations of Slater determinants of the type of Eq. (23.171).

23.8.4 Configurational States

Configurational state functions (CSF) having specified total angular momentum J and parity Π are of the form

$$\begin{aligned} \phi(\gamma JM) & = \sum_{\{m_{\alpha_n}\}} \langle \gamma JM | m_{\alpha_1}, m_{\alpha_2}, \dots, m_{\alpha_N} \rangle \\ & \times \{ \alpha_1, \alpha_2, \dots, \alpha_N \}, \end{aligned} \quad (23.172)$$

where $\langle \gamma JM | m_{\alpha_1}, m_{\alpha_2}, \dots, m_{\alpha_N} \rangle$ is a generalized Clebsch–Gordon coefficient, and γ defines the angular momentum coupling scheme.

An *electron configuration* is an assignment of the N -electrons to an orbital set $\{\alpha_1, \alpha_2, \dots, \alpha_N\}$. If the configuration belongs to a single subshell, then the states share a common set of labels $\{n, \kappa\}$, where n is the principal quantum number. In jj -coupling, the N_α *subshell states* of equivalent electrons can, therefore, be labeled $\alpha^{N_\alpha}, \gamma_\alpha, J_\alpha$, where γ_α distinguishes degenerate states of the same J_α . For jj -coupling, such labels are needed only for $j \geq \frac{5}{2}$. The *seniority scheme*, [73, Sects. 2.3, 2.4], provides a complete classification for $j < \frac{9}{2}$. A list of states of configurations j^N , classified in terms of the *seniority number* v and of *total angular momentum* J , appears in Table 23.5. Rudzikas [84] presents an equivalent classification using quasispin, which is used in GRASP2K.

23.8.5 ASFs and CSF

Atomic state functions (ASF) are linear superpositions of CSFs, of the form

$$\Psi(\gamma \Pi J) = \sum_{\alpha=1}^N c_\alpha \phi(\gamma_\alpha J), \quad (23.173)$$

where c_α are a set of (normally) real coefficients, and we have dropped the common label M . They are obtained by diagonalizing the chosen Hamiltonian in a basis of CSFs $\{\phi(\gamma_\alpha J)\}$. The orbitals used to construct the CSFs can be generated along with the c_α in a multiconfigurational self-consistent field calculation, for example, using the RMCDHF program of GRASP2K [21].

23.8.6 Matrix Construction

A full presentation of the reduction of matrix elements between CSFs to computable form is beyond the scope of this chapter. There is an extensive literature [39, 73, 84]. Second quantization and diagrammatic methods of the quantum theory of angular momentum express matrix elements between atomic CSFs of all one and two-electron operators treated in this chapter to a linear combination of radial integrals. A full implementation within the jj -coupling seniority scheme is exploited in the GRASP2K programs [21, 83].

23.8.7 Dirac–Hartree–Fock–Breit

The construction of Dirac–Hartree–Fock–Breit models mirrors the nonrelativistic pattern described in Chap. 22; rela-

Table 23.5 j^N configurational states in the seniority scheme. The multiplicity of each unresolved degenerate state is indicated by a superscript

	5	$\frac{3}{2}, \frac{5}{2}, \frac{7}{2}, \frac{9}{2}, \frac{11}{2}, \frac{13}{2}, \frac{15}{2}, \frac{17}{2}, \frac{19}{2}, \frac{25}{2}$	

tivistic counterparts of Koopmans’ theorem, fixed-core approximations, Brillouin’s theorem are easy to obtain. The fact that, for example, np orbitals (with $\kappa = -2, j = \frac{3}{2}$) and $n\bar{p}$ orbitals (with $\kappa = +1, j = \frac{1}{2}$) have different spatial distributions as a consequence of the dynamical and indirect effects of relativity, makes it essential to formulate the equations in terms of jj -coupling. Although relativistic ASF and CSF construction uses the same ideas as in nonrelativistic models, the details are different. For further insight, see [22, 30, 39].

There are several relativistic self-consistent field programs built on these lines. The program GRASP2K [21, 83] is the most recent development of [85–87]. The MCDFGME

program [88] is a development of [77, 78]. The flexible atomic code (FAC) is described in [89].

Finite matrix methods for atoms Here, we extend the equations of Sect. 23.4.2 to the many-body problem based on the effective Hamiltonian of Sect. 23.4.1. This leads to an energy functional of the form

$$E = E_0 + E_1, \quad (23.174)$$

where E_0 is the expected value of H_0 Eq. (23.76), and E_1 the expected value of H_1 for the finite basis many-body trial function. Simple variational arguments lead to matrix Dirac–Fock equations of the form

$$\mathbf{F}\mathbf{X} = \mathbf{E}\mathbf{S}\mathbf{X}. \quad (23.175)$$

In general, the Fock matrix \mathbf{F} is a sum of several matrices

$$\mathbf{F} = \mathbf{f} + \mathbf{g} + \mathbf{b}, \quad (23.176)$$

where, for each symmetry κ , \mathbf{f} can be partitioned into blocks

$$\mathbf{f}_{A\kappa} = \begin{pmatrix} \mathbf{V}_{\kappa}^{LL} & c\mathbf{\Pi}_{\kappa}^{LS} \\ c\mathbf{\Pi}_{\kappa}^{SL} & \mathbf{V}_{\kappa}^{SS} - 2mc^2\mathbf{S}_{\kappa}^{SS} \end{pmatrix}. \quad (23.177)$$

The matrix

$$\mathbf{g} = \begin{pmatrix} \mathbf{J}^{LL} - \mathbf{K}^{LL} & -\mathbf{K}^{LS} \\ -\mathbf{K}^{SL} & \mathbf{J}^{SS} - \mathbf{K}^{SS} \end{pmatrix} \quad (23.178)$$

is the matrix of the Coulomb repulsion part of the electron–electron interaction, and

$$\mathbf{b} = \begin{pmatrix} \mathbf{B}^{LL} & \mathbf{B}^{LS} \\ \mathbf{B}^{SL} & \mathbf{B}^{SS} \end{pmatrix} \quad (23.179)$$

is the matrix of the Breit interaction, modeling the magnetic interaction of electron currents.

Using superscripts T to label the L or S components and the notation \bar{T} to denote the complementary label: $\bar{T} = S$ when $T = L$ or $\bar{T} = L$ when $T = S$, then the direct Coulomb part \mathbf{J}_{κ}^{TT} has matrix elements

$$J_{\kappa pq}^{\text{TT}} = \sum_{\kappa'rs} (2j' + 1) \left(D_{\kappa'rs}^{\text{TT}} J_{\kappa pq, \kappa'rs}^{0, \text{TTTT}} + D_{\kappa'rs}^{\bar{\text{T}}\bar{\text{T}}} J_{\kappa pq, \kappa'rs}^{0, \text{TT}\bar{\text{T}}\bar{\text{T}}} \right), \quad (23.180)$$

whilst the exchange part $\mathbf{K}_{\kappa}^{\text{TT}'}$ has the form

$$K_{\kappa pq}^{\text{TT}'} = \sum_{\kappa'rs} \sum_{\nu} (2j' + 1) b_{\nu}(jj') D_{\kappa'rs}^{\text{TT}'} K_{\kappa pq, \kappa'rs}^{\nu, \text{TT}'\text{TT}'}, \quad (23.181)$$

where TT' denotes any combination of component matrix with elements

$$D_{\kappa pq}^{\text{TT}'} = c_{\kappa p}^{\text{T}*} c_{\kappa q}^{\text{T}'}, \quad (23.182)$$

where $c_{\kappa p}^{\text{T}}$ are the expansion coefficients. The Breit interaction matrices have a similar form

$$B_{\kappa pq}^{\text{TT}} = \sum_{\kappa'rs} \sum_{\nu} (2j' + 1) e_{\nu}(jj') D_{\kappa'rs}^{\bar{\text{T}}\bar{\text{T}}} K_{\kappa pq, \kappa'rs}^{\nu, \text{TT}\bar{\text{T}}\bar{\text{T}}}, \quad (23.183)$$

and

$$B_{\kappa pq}^{\bar{\text{T}}\bar{\text{T}}} = \sum_{\kappa'rs} \sum_{\nu} (2j' + 1) D_{\kappa'rs}^{\bar{\text{T}}\bar{\text{T}}} \times \left[d_{\nu}(\kappa\kappa') K_{\kappa pq, \kappa'rs}^{\nu, \bar{\text{T}}\bar{\text{T}}\bar{\text{T}}\bar{\text{T}}} + g_{\nu}(\kappa\kappa') M_{\kappa pq, \kappa'rs}^{\nu, \bar{\text{T}}\bar{\text{T}}\bar{\text{T}}\bar{\text{T}}} \right]. \quad (23.184)$$

The matrix elements are constructed from standard radial integrals

$$J_{\kappa pq, \kappa'rs}^{\nu, \text{TTT}'\text{T}'} = \int_0^{\infty} \int_0^{\infty} f_{\kappa p}^{\text{T}}(r_1) f_{\kappa q}^{\text{T}}(r_1) U_{\nu}(r_1, r_2) \times f_{\kappa'r}^{\text{T}'}(r_2) f_{\kappa's}^{\text{T}'}(r_2) dr_2 dr_1, \quad (23.185)$$

where

$$U_{\nu}(r_1, r_2) = \begin{cases} \frac{r_1^{\nu}}{r_2^{\nu+1}} & \text{for } r_1 < r_2, \\ \frac{r_2^{\nu}}{r_1^{\nu+1}} & \text{for } r_1 > r_2. \end{cases}$$

Similarly,

$$K_{\kappa pq, \kappa'rs}^{\nu, \text{TT}'\text{TT}'} = J_{\kappa p, \kappa'r, \kappa q, \kappa's}^{\nu, \text{TTT}'\text{T}'}, \quad (23.186)$$

and

$$M_{\kappa pq, \kappa'rs}^{\nu, \bar{\text{T}}\bar{\text{T}}\bar{\text{T}}\bar{\text{T}}} = \int_0^{\infty} \int_{r_1}^{\infty} f_{\kappa p}^{\text{T}}(r_1) f_{\kappa'r}^{\bar{\text{T}}}(r_1) U_{\nu}(r_1, r_2) \times f_{\kappa q}^{\bar{\text{T}}}(r_2) f_{\kappa's}^{\text{T}}(r_2) dr_2 dr_1. \quad (23.187)$$

Further details about the coefficients $b_{\nu}(jj')$, $e_{\nu}(jj')$, $d_{\nu}(\kappa\kappa')$, and $g_{\nu}(\kappa\kappa')$ may be found in [90].

This formalism has been implemented for closed shell atoms with both S-spinors and G-spinors [90]. The computation of radial integrals using S-spinors is discussed in [91, 92], and can be adapted with relative ease to G-spinor basis sets. Applications can be found in [90, 93–96], which deal with Dirac–Fock and Dirac–Fock–Breit calculations, many-body perturbation theory, and coupled-cluster schemes. Methods based on the approximation of radial functions with B-splines lead to similar matrix structures.

G-spinor basis sets provide the most promising technique for application to the electronic structure of molecules [97]. L-spinors underpin the RCCC (relativistic convergent close coupling) method for particle collision studies [53].

23.8.8 Electron Correlation

Methods of dealing with electron correlation for atoms have advanced greatly in the last few years; see Chap. 22 for a detailed account. The strategies being actively researched nonrelativistically are equally applicable to relativistic calculations. Codes such as GRASP2K [21, 83] are now able to use high-power multiprocessor systems, so that the user is able to employ trial ASFs composed of as many as 10^6 – 10^7 CSFs. The first step is to construct a *multireference wave function* (MR) using a RMCDHF model built with the most strongly interacting CSFs to represent the target states of interest, accounting for what is often termed *static correlation*. *Dynamic correlation* effects can then be modeled by the *active space* (AS) method; the orbital and CSF sets are expanded systematically, *layer by layer* [22, 82]. A new layer of correlation orbitals in the AS is constructed with a RMCDHF calculation keeping MR orbitals frozen. Single and double substitutions from the MR CSFs into this layer are then used to expand the CSF basis according to prescribed rules for a chosen correlation mechanism (valence-valence, core-valence or core-core). These independent calculations converge to partition correlation functions (PCF). Each PCF will have its own orbital set, so that PCF interactions require biorthogonal algorithms for their evaluation [98]. The full Hamiltonian matrix incorporating the PCFs can then be diagonalized in a relativistic configuration calculation (RCI).

This program structure has great flexibility; the layer-by-layer process allows the user to assess convergence in an unprecedented manner. The disadvantage is the explosive increase in problem dimensions. Current research focuses on the PCFI method (partition correlation function interaction) in which the results of separate PCF calculations are combined in a final RCI calculation of relatively small dimension. The final ASF are then available for calculating atomic properties: energy levels, splittings, radiative transitions, and other properties.

Many-body perturbation theory calculations and coupled-cluster calculations are not well suited to calculations with finite difference codes, because of the expense of calculating more than a limited orbital basis and all the matrix elements required. Calculations based on finite matrix methods enable this sort of calculation to be done more economically. Some justification for the use of finite matrix methods in relativistic many-body theory is given in [49].

23.8.9 Electron Self-Energy and Vacuum Polarization

The main programs, RMCDHF and RCI, of the GRASP2K package account for the major interactions between the atom's constituents. The RMCDHF program usually uses

the Dirac–Coulomb Hamiltonian, Sect. 23.4.1 to generate MR orbitals and correlation orbitals needed to populate the CSF sets. The configuration interaction program RCI adds the Breit interaction to the effective Hamiltonian, or the more complex complete transverse interaction if requested. In future, it should be possible to self-consistently treat the Breit operator, which captures the dominant magnetic interactions, in RMCDHF. This will slightly change the orbitals generated. The more complex transverse photon interaction, whose predictions vary little from those of the Breit interaction, can be handled perturbatively.

The next most important processes described by QED perturbation theory are the polarization of the vacuum by the nuclear charge distribution, and the electron self-energy, both of which are modeled as perturbations of the effective Hamiltonian in GRASP2K and other software. Here, it is the electron self-energy in a many-electron atom that is the most difficult to model, and most studies have relied on approximations adapting the results of elaborate calculations for one-electron atoms; see in particular Chap. 28 of this Handbook.

Vacuum polarization As shown by Eq. (23.49), the nuclear potential generates a current in the vacuum that is responsible for a short-range screening of the nuclear charge. This can be represented as a local perturbing potential that is easy to take into account in the RCI program [99–101].

Electron self-energy GRASP2K and similar programs model the electron self-energy correction as a diagonal contribution to the effective Hamiltonian matrix in the CSF basis of the form

$$H_{rr}^{\text{SE}} = \sum_A q_r(A) E_A^{\text{SE}}, \quad (23.188)$$

where $q_r(A)$ is the occupation number of subshell A in CSF r . No simple methods of direct evaluation of E_A^{SE} in a many-electron atom are currently available. Most programs use the expression

$$\frac{E_{n\kappa}^{\text{SE}}}{mc^2} = \frac{\alpha (\alpha Z)^4}{\pi n^3} F(\alpha Z), \quad (23.189)$$

for an electron in the $n\kappa$ subshell of a hydrogenic atom with atomic number Z ; $F(\alpha Z)$ is a smooth function of its argument, and *Mohr* [102] tabulated values for $1s, 2s, 2p_{1/2}, 2p_{3/2}$ states with point charge nuclei for $Z = 5, 10, 15, \dots, 110$. *Shabaev* et al. [103, Tables I–V] published results for a similar range of Z , with corrections for finite size nuclear charge distributions where appropriate, for $ns, np_{1/2}, np_{3/2}, nd_{3/2}$ and $nd_{5/2}$ states with $n \leq 5$.

A common approach is to interpolate to a value Z_{eff} for each orbital of the many-electron atom when calculating Eq. (23.188). Several prescriptions exist; GRASP2K

currently searches for the best overlap with a hydrogenic $n\kappa$ orbital to the corresponding spectroscopic MR orbital. *Shabaev et al.* [103] devised a more complex model operator approach, published as the QEDMOD program [104].

23.8.10 Radiative Transitions

The operator $j^\mu(x)A_\mu(x)$ that occurs in the interaction Hamiltonian Eq. (23.61) describes processes in which the number of photons present can increase or decrease by one. The Fock space operator may be written

$$H_{\text{int}} = \sum_{a,b} \sum_{\rho} \left[a_a^\dagger a_b q_\rho^\dagger M_{ab}^{(\rho)\dagger}(t) + a_a^\dagger a_b q_\rho M_{ab}^{(\rho)}(t) \right], \quad (23.190)$$

where the first set of terms in the sum represents emission of a photon in the mode labeled ρ and the second to absorption of a photon by the same initial state. The operators a_a and a_a^\dagger are *anticommuting* annihilation and creation operators of electrons, whilst q_ρ and q_ρ^\dagger are *commuting* annihilation and creation operators of photons. If ω denotes photon frequency, then

$$M_{ab}^{(\rho)\dagger}(t) = M_{ab}^{(\rho)} e^{i(E_a - E_b + \omega)t},$$

$$M_{ab}^{(\rho)}(t) = M_{ab}^{(\rho)} e^{i(E_a - E_b - \omega)t},$$

where

$$M_{ab}^{(\rho)} = \left(\frac{\omega}{\pi c} \right)^{1/2} \int \psi_a^\dagger(\mathbf{x}) [\Phi^{(\rho)}(\mathbf{x}) + c\boldsymbol{\alpha} \cdot \mathbf{A}^{(\rho)}(\mathbf{x})] \times \psi_b(\mathbf{x}) d^3x$$

is the transition amplitude. For a discussion of this expression, including the effect of gauge transformations on the computed amplitudes, the elimination of angular coordinates for atomic central field orbitals, and connection with the non-relativistic limit, see [13, 23, 73].

23.9 GRASP – Information and Software

Additions, updates and instructions on downloading and commissioning the GRASP programs will be found on the website <https://github.com/compas/grasp>. See also [106]

Abstract

All atoms except hydrogen are many-body systems, in which the interelectron interaction plays an important or even decisive role. The aim of this chapter is to describe a consistent method for calculating the structure of atoms and the characteristics of different atomic processes by applying perturbation theory to take into account the interelectron interaction. This method involves drawing a characteristic diagram based on the structure or process. This is then used to create an analytical expression to the lowest order in the interelectron interaction. Higher-order corrections are subsequently generated.

This technique was invented almost 70 years ago for quantum electrodynamics by *Feynman* [1] and then modified and adjusted for multiparticle systems by a number of authors [2, 3]. Its application to atomic structure and atomic processes required further modifications, which were initiated in the 1960s [4, 5]. The corresponding technique was successfully applied to the calculation of a wide variety of characteristics and processes in hun-

dreds of papers, a number of review articles, and several books [6]. The increasing amount of experimental data available has led to improved accuracy of this technique, so that it can be applied to current problems considering not only atoms and ions, both positive and negative [6–9], but also molecules [10], clusters [11], and so-called “big atoms” [12] – fullerenes and endohedrals [13].

The elements of the diagrammatic technique, which form a convenient and simple *language*, are given together with the rules for creating *sentences* using basic *words*. A kind of *dictionary* helps to translate diagrammatic *sentences* into analytical expressions suitable for calculations.

Keywords

photoionization cross section · spectroscopic factor · giant resonance · diagrammatic technique · single vacancy · electron correlation

An essential part of the program is to learn how the simplest approximation can be formed and then consistently improved. It is important to understand the mechanisms and processes connected with and responsible for higher-order perturbation theory terms that describe the corrections to the simplest approximation.

When the diagrammatic technique of many-body theory is used, it is unnecessary to be restricted to a finite number of lowest-order terms in the interelectron interaction. On the contrary, some infinite sequences may be taken into account. The sum of all many-body diagrams is completely equivalent to the many-particle Schrödinger equation. Therefore, taking all of them into account is just as complicated as solving the corresponding equation. Compared with other approaches, the diagrammatic technique can easily uncover hidden approximations and transparently demonstrate possible sources of corrections.

24.1 Diagrammatic Technique

24.1.1 Basic Elements

Each physical atomic process (a process with participation of a molecule, cluster, fullerene, or endohedral) involves an electronic interaction with a projectile or external field, in general time dependent, or a mutual interelectron interaction. By convention, the ground state of the atom (if it is not degenerate) is regarded as the vacuum state. Then the simplest process in this target is excitation of an electron to an unoccupied level, leaving behind a vacancy. The basic elements of a diagram are

where (a) a line with an arrow directed to the right represents an electron excited to a vacant level, (b) a line with an arrow directed to the left represents a vacancy, (c) a wavy line with a cross represents the static Coulomb interaction, (d) a wavy line represents the interelectron Coulomb interaction, (e) a dashed line represents interaction with a time-dependent external field, usually electromagnetic, and (f) a dot represents the very act of interaction.

The elements Eq. (24.1a, b, e, f) in combination can describe the following real or virtual basic processes

which represent (a) photon absorption by the vacuum with electron–vacancy pair creation, (b) electron excitation, and (c) vacancy excitation. Diagrams Eq. (24.2) depict processes as developing in time, shown increasing from left to right. A vacancy can be thought of as an antiparticle to the electron, moving backward in time. The time-reversal of processes Eq. (24.2) represent processes of photon emission due to annihilation of an electron–vacancy pair, vacancy transition, and electron inelastic scattering, respectively.

A static [for example, Coulomb Eq. (24.1c)] field can virtually create an electron–vacancy pair or affect the moving electron or vacancy, as shown in the following diagrams:

Just as for Eq. (24.2), diagrams Eq. (24.3) have their time-reversed counterparts.

Inclusion of interelectron interaction leads to a number of processes of which some examples are

Here, Eq. (24.4a) describes creation of two electron–vacancy pairs, Eq. (24.4b) represents the simplest picture of electron inelastic scattering, Eq. (24.4c) depicts vacancy decay with electron–vacancy pair creation, Eq. (24.4d) stands for electron–electron scattering, Eq. (24.4e) represents a process which can be called electron–vacancy annihilation and creation, while Eq. (24.4f) shows electron–vacancy scattering.

Just as for Eqs. (24.2) and (24.3), diagrams Eq. (24.5) have their time-reversed counterparts.

24.1.2 Construction Principles for Diagrams

The foundations of diagrammatic techniques are discussed in a number of books such as [14]. This chapter presents recipes for the construction and evaluation of diagrams corresponding to various atomic processes [15, 16].

The basic procedure is to connect the initial and final states of the system considered, drawn at the left and right-hand sides of the diagram, respectively, using appropriate elements from Eq. (24.1). In doing so, the following rules apply:

1. At each dot Eq. (24.1f), only three lines can meet: wavy (or dashed) and electron–vacancy.
2. A vacancy cannot be transformed into an electron or vice versa.
3. Electrons and vacancies can be created only pairwise from the vacuum.
4. Only linked diagrams are allowed, i.e., only those having no parts entirely disconnected from one another.

The simplest or initial approximation to a process is represented by a diagram that includes the lowest possible number of elements Eqs. (24.1)–(24.4). Higher-order corrections can be derived by including additional elements of interaction with the static field of the nucleus Eq. (24.1c) and between electrons and/or vacancies Eq. (24.1d).

As illustration of the method, consider the following three processes:

1. One-electron photoionization – the initial state is a photon while the simplest final state is an electron–vacancy pair.

They can be combined together giving the basic diagram Eq. (24.2a).

2. Elastic electron scattering – the initial and final states are single electrons. To describe the simplest scattering process, the interaction with the Coulomb field must be taken into account, leading to Eq. (24.3b). To account for inter-electron interaction, the simplest element

must be introduced. It is a modification of Eq. (24.4b) accounting for the interaction of an incoming electron with all target electrons individually, not altering their states. This is emphasized by the loop in which the same vacancy leaving the lower dot reenters it. The indistinguishability of all electrons as fermions is taken into account by permutation of the electron (vacancy) line ends, as illustrated in the following diagrams:

Diagram Eq. (24.6a) is obtained from Eq. (24.5) by permutation of the electron lines on one side of the interelectron interaction. Diagram (24.6b) is equivalent to Eq. (24.6a) but is simpler to draw.

3. Inelastic electron scattering – the initial state is a single electron. For the final state, we choose one with two electrons and, therefore, a single vacancy. The simplest diagram in this case is given by Eq. (24.4b).

To illustrate the description of the ground state characteristics, consider the contributions to the ground state energy of an atom. If this state is not degenerate, its potential energy is given by vacuum diagrams that have no free lines in the initial or final states. The simplest vacuum diagrams are

Higher-order corrections to all these diagrams can be obtained by adding elements such as a static external field Eq. (24.3) or interelectron interaction Eq. (24.4) without changing the initial and final states of the processes. The lowest-order processes are represented by Eqs. (24.2a), (24.5), (24.6), (24.4b), and (24.7). There are many corrections even in the next order of interaction, either with an external field or with electrons or vacancies. To illustrate, only one correction to each process will be presented:

1. Simple photoionization Eq. (24.2a) may be combined with Eqs. (24.4e) and (24.4f) to obtain

This describes the effect of the creation of another electron–vacancy pair, after annihilation of the first one formed by absorption of the initial photon.

2. Simple elastic electron scattering Eq. (24.5) can be combined with an extra interaction term Eq. (24.4f) between the incoming electron and the vacancy of the loop Eqs. (24.5) and (24.6b), to obtain

3. Simple inelastic electron scattering Eq. (24.4b) can also be combined with Eqs. (24.4e) and (24.4f), accounting for the interaction of an electron and vacancy created in the lowest-order process, to obtain

4. The ground state energy terms Eqs. (24.7b) and (24.7c) can be combined with Eq. (24.7) and the element Eq. (24.3c) of the interaction between the vacancy in the Eqs. (24.7b) and (24.7c) loops to obtain

Higher-order corrections can be constructed step by step by introducing further elements of interaction. In some cases, classes of diagrams may be taken into account up to infinite order by solving closed systems of integral or differential equations.

24.1.3 Correspondence Rules

These rules describe how to obtain an analytical expression corresponding to a given diagram. One starts by choosing a zero-order approximation, which for atoms can be that of independent electrons moving in the Coulomb field of an atomic nucleus. For nonatomic objects, e.g., molecules or clusters, other approximations are chosen as zero-order. Objects with

a nondegenerate ground state correspond to the vacuum. For atoms, the vacuum is a state with all completely occupied or closed subshells. Electron (vacancy) states are characterized in this case by the quantum numbers n, ℓ, m_ℓ , and $\sigma = \pm 1/2$, with good accuracy, as vacuum can be treated an atom with a semifilled shell. Such an atom is considered as constructed from two different types of electrons, called *up* and *down* electrons and denoted by their spin directions \uparrow and \downarrow [16].

The first correspondence rule is to substitute a matrix element for each interaction

$$\begin{aligned} \text{Diagram (24.2)} &\rightarrow \langle p|W|q \rangle, \\ \text{Diagram (24.3)} &\rightarrow \langle p|U|q \rangle, \\ \text{Diagram (24.4)} &\rightarrow \langle pt|V|qs \rangle, \end{aligned} \quad (24.12)$$

where W is the interaction potential of an electron with the external time-dependent field, U is the interaction potential of an electron (vacancy) with an external static field, for example that of the nucleus, and V is the Coulomb interelectron interaction. Each of the letters p, q, t, s represents a full set of n, ℓ, m_ℓ, σ quantum numbers. Vacancy states are below (and include) the highest occupied energy level, called the Fermi level, so that $p \leq F$. Electron states are above the Fermi level so that $q > F$. Thus, diagram Eq. (24.2a) is represented by $\langle p|W|q \rangle$ with $p \leq F$ and $q > F$.

Apart from initial and final states, each diagram can have sections, i.e., intervals between successive interactions. For instance, Eqs. (24.9) and (24.10) each have one section. Each section is represented by an inverse energy denominator ε_d^{-1} . It includes the sum over all vacancy energies $\sum_{\text{vac}} \varepsilon_i$ minus the sum of the electron energies $\sum_{\text{el}} \varepsilon_n$ to which the entrance energy E of the diagram (e.g., $\hbar\omega$ for a time-dependent field) must be added:

$$\varepsilon_d^{-1} = \left(\sum_{\text{vac}} \varepsilon_i - \sum_{\text{el}} \varepsilon_n + E \right)^{-1}. \quad (24.13)$$

The second correspondence rule is to identify sections and write down their energy denominators. After attributing to each electron (vacancy) line a letter, denoting its state, the analytical expression for a diagram is given by

$$\begin{aligned} &\text{Analytical Expression} \\ &= (\text{the product of all interaction matrix elements}) \\ &\times (\text{all energy denominators})^{-1} \\ &\times (-1)^L \text{ summed over all intermediate electron} \\ &\quad \text{and vacancy states,} \end{aligned} \quad (24.14)$$

where L is equal to the sum of the total number of vacancy lines and closed vacancy or electron–vacancy loops.

Although electrons are fermions, the summation in Eq. (24.14) has no additional restrictions caused by the Pauli

principle. It runs over all electron ($> F$) and vacancy ($\leq F$) states, including those where two or more electrons (or vacancies) are in the same state. The correspondence rules Eqs. (24.12), (24.13), and (24.14) can be illustrated by giving as examples the analytical expressions of two diagrams Eqs. (24.8) and (24.9).

Attributing letters denoting electron and vacancy states, diagram Eq. (24.8) becomes

According to Eqs. (24.12)–(24.14), the analytical formula

$$A_{if}(\omega) = \sum_{r>F, t \leq F} \frac{\langle t|W|r \rangle \langle ri|V|tf \rangle}{\varepsilon_t - \varepsilon_r + \omega} (-1)^{2+1} \quad (24.16)$$

is obtained. The symbol \sum includes summation over discrete levels and integration over a continuous spectrum. In Eq. (24.16), the intermediate state is $r > F, t \leq F$, and the diagram has two vacancies (t and i) and one loop rt . Integration must be performed over those states r that belong to the continuum.

Assigning letters denoting states, Eq. (24.9) appears as

where $p, q, p', r > F$, while $t \leq F$. According to Eq. (24.14),

$$\Delta E = \sum_{r, q > F; t \leq F} \frac{\langle pt|V|qr \rangle \langle qr|V|p't \rangle}{\varepsilon_t - \varepsilon_q - \varepsilon_r + \varepsilon_p} (-1)^{1+1}, \quad (24.18)$$

where the intermediate states are $q, r > F$ and $t \leq F$. It has one vacancy and one electron–vacancy loop rt .

An intermediate state in a diagram can be real or virtual. It is real if the energy conservation law can be fulfilled, i.e., if for some values of the section energy the following relation holds

$$E = \sum_{\text{el}} \varepsilon_n - \sum_{\text{vac}} \varepsilon_i. \quad (24.19)$$

If Eq. (24.19) can be fulfilled, a prescription for avoiding the singularity in Eq. (24.13) is to substitute the expression ε_d^{-1} by for Q , where

$$Q = \lim_{\eta \rightarrow 0} \left(E - \sum_{\text{el}} \varepsilon_n + \sum_{\text{vac}} \varepsilon_i + i\eta \right)^{-1}$$

$$= P \left(E - \sum_{\text{el}} \varepsilon_n + \sum_{\text{vac}} \varepsilon_i \right)^{-1} - i\pi \delta \left(E - \sum_{\text{el}} \varepsilon_n + \sum_{\text{vac}} \varepsilon_i \right), \quad (24.20)$$

for ε_d^{-1} . Here, P denotes that the principal value is to be taken on integration over intermediate state energies. The result of Eq. (24.20) can thus be complex.

An intermediate state is virtual if the energy conservation law in Eq. (24.19) is violated for all values of the section energy. In general, the bigger the virtuality, i.e., the difference $E - \sum_{\text{el}} \varepsilon_n + \sum_{\text{vac}} \varepsilon_i$, the smaller the contribution to the amplitude of the process.

24.1.4 Higher-Order Corrections and Summation of Sequences

An important feature of the diagrammatic technique is the convenience in constructing higher-order corrections and in the summation of infinite sequences of diagrams. According to Eq. (24.13), each new interaction line leads to an additional interaction matrix element, an extra energy denominator, and summation over new intermediate states.

An important example of infinite summation is that of determining the one-electron states. The interaction with the nucleus in atoms Eq. (24.3b) (or nuclei in multiatomic objects, e.g., molecules) and with atomic (or e.g., molecular) electrons Eqs. (24.5) and (24.6) is not small and must be taken into account nonperturbatively; i.e., these elements must be iterated infinitely. To simplify the drawing, only the element Eq. (24.5) is repeated, leading to the diagrammatic equation:

$$= \text{[Diagrammatic Equation (24.21)]} \quad (24.21)$$

Indeed, everything in the infinite sum that is in front of the dashed line repeats the infinite sum itself, thus leading to a closed equation of the form

$$\langle \tilde{p} | = \langle p | + \sum_{q>F} \langle \tilde{p} i | V | q i \rangle \frac{1}{-\varepsilon_q + \varepsilon_p} \langle q |. \quad (24.22)$$

The two interactions leading to Eq. (24.21) can be permuted, so that interaction 1 can be after interaction 2. This leads to extension of the sum to include states with $q \leq F$. As a result, the summation in Eq. (24.22) must be performed over all states q .

Interaction with the nucleus (nuclei in multiatomic objects) and the other electrons also affects the occupied (or vacancy) states i in Eq. (24.21), and, therefore, the latter must be modified by inserting the elements Eqs. (24.3b), (24.5), and (24.6) into them. Here again, the vacancy line in Eqs. (24.5) and (24.6) must be modified by including the corrections Eqs. (24.3b), (24.5), (24.6), and so on. Finally, the diagrammatic equation

$$= \text{[Diagrammatic Equation (24.23)]} \quad (24.23)$$

is obtained. The doubled line for i emphasizes that the vacancy wave function is determined by an equation similar to Eq. (24.21). The corresponding analytical equation looks like Eq. (24.22), but includes also the Coulomb interaction with the nucleus and the exchange interaction with other atomic electrons. The summation over q in this equation is extended over all q , not only $q > F$. Multiplying the corresponding equation by $(\hat{H}_0 - \varepsilon_p)$ from the right (atomic units are used in this chapter: $e = m_e = \hbar = 1$), where $\hat{H}_0 = -\nabla^2/2$, and using the completeness of the functions $\sum_q |q\rangle \langle q| = \delta(\mathbf{r} - \mathbf{r}')$, results in the equation

$$\left[-\frac{\nabla^2}{2} - \frac{Z}{r} + \sum_{i \leq F} \int \frac{d\mathbf{r}'}{|\mathbf{r}' - \mathbf{r}|} |\phi_i(\mathbf{r}')|^2 - \varepsilon_p \right] \phi_p(\mathbf{r}) = \sum_{i \leq F} \int \frac{d\mathbf{r}'}{|\mathbf{r}' - \mathbf{r}|} \phi_i^*(\mathbf{r}') \phi_p(\mathbf{r}') \phi_i(\mathbf{r}), \quad (24.24)$$

for the electron wave function $\phi_p(\mathbf{r})$ in an atom; Z/r is the nucleus Z Coulomb potential. Here, $\phi_i(\mathbf{r})$ are wave functions determined by equations similar to Eq. (24.24). For multiatomic objects, instead of Z/r another potential $U(\mathbf{r})$ appears in these equations, called the Hartree-Fock (HF) equations.

HF includes a part of interelectron interaction matrix elements, namely those given by Eqs. (24.5) and (24.6). The rest is called the residual interaction, and its inclusion leads beyond the HF frame, accounting for correlations.

When a perturbative approach is used, it is essential to define the zero-order approximation. In this chapter, and very

often in the literature, the Hartree–Fock approximation is used in this role. To simplify the drawing of diagrams, from now on single (rather than double) lines will represent electrons (vacancies), whose wave functions are determined in the HF approximation by Eq. (24.24). Obviously, in this case, elements Eqs. (24.3a), (24.5), and (24.6) should not be added to any other diagrams.

The procedure used in deriving Eqs. (24.21) and (24.23) is, in fact, more general. Let us separate all diagrams describing elastic scattering that do not include a single one-electron or one-vacancy state as intermediate. Depicting their total contribution by a square, the precise one-particle state is determined by an infinite sequence of iterative diagrams that can be summed, similarly to Eq. (24.21), by

$$\begin{aligned}
 & \text{Diagram with square } \hat{a} = \text{Diagram 1} + \text{Diagram 2} + \text{Diagram 3} + \dots \\
 & = \text{Diagram 1} + \text{Diagram 2}
 \end{aligned}
 \quad (24.25)$$

Here, the single line stands for an HF state. Using the correspondence rule Eq. (24.14), an analytical equation similar to the Schrödinger equation can be derived with the operator $\hat{\Sigma}$ playing the role of an external potential. The essential difference is, however, that this *potential* in principle depends upon the energy and state of the particle. The same kind of iterative procedure leading to Eq. (24.21) or (24.23) will be used several times in this chapter.

Other zero-order approximations can be chosen. But then diagrams with corrections of the type Eq. (24.3a) must be included, with the external static field potential equal to the difference between the HF and the chosen one.

To calculate the numerical value of a given diagram or a sequence of diagrams one needs to know, according to the description given above, the matrix elements of external fields and interelectron interactions obtained with the help of one-electron HF wave functions. The required calculational procedures are described in [17] and [18].

24.2 Calculation of Atomic Properties

24.2.1 Electron Correlations in Ground State Properties

A major advantage of the diagrammatic technique in many-body theory is that it is usually unnecessary to know the total wave function of the atom or other considered object. On the contrary, only actively participating electrons or vacancies appear in a diagram. The HF zero-order approximation

for one-electron and one-vacancy wave functions is used in what follows. All atomic characteristics and cross sections for atomic processes calculated with HF form the one-electron approximation. Everything beyond the HF frame, i.e., caused by residual interaction, is called correlation corrections or correlations. They can be calculated using the many-body perturbation theory (MBPT) [4], random phase approximation (RPA) [19], and random phase approximation with exchange (RPAE) [15] or its generalized version GRPAE [15–17].

The simplest diagrammatic expression for the correlation energy is given by the two diagrams

$$\text{Diagram (a)} \quad \text{Diagram (b)} \quad (24.26)$$

The analytical expression $\Delta E_{\text{corr}}^{(2)}$ for Eq. (24.26a) is

$$\Delta E_{\text{corr}}^{(2)} = \sum_{k,n>F;i,j\leq F} \frac{\langle ij|V|kn\rangle\langle kn|V|ij\rangle}{\varepsilon_i + \varepsilon_j - \varepsilon_k - \varepsilon_n}. \quad (24.27)$$

The analytical expression for Eq. (24.26b) differs from Eq. (24.27) by the sign and an exchange matrix element $\langle kn|V|ji\rangle$ instead of a direct $\langle kn|V|ij\rangle$ one. As concrete calculations show, the contribution Eq. (24.26) overestimates the correlation energy by $\approx 10\%$.

Diagrams Eq. (24.26) can also be used to describe the interaction potential of two atoms, designated A and B. Let the ki states belong to A and nj to B. At large distances R between the atoms, the contribution of Eq. (24.26b) is exponentially small. Because the vacancies i and j are located inside atoms A and B, respectively, the interelectron potential $V = |\mathbf{r}_A - \mathbf{r}_B + \mathbf{R}|^{-1}$ at large distances $R \gg R_{A,B}$ ($R_{A,B}$ are atomic radii) can be expanded as a series in powers of R^{-1} . The first term giving a nonvanishing contribution to Eq. (24.27) is $V \simeq R^{-3}[(\mathbf{r}_A \cdot \mathbf{r}_B) - 3(\mathbf{r}_A \cdot \mathbf{n})(\mathbf{r}_B \cdot \mathbf{n})]$, \mathbf{n} being the unit vector in the direction of \mathbf{R} . Substituted into Eq. (24.27), this potential leads to the expression

$$U(R) = -\frac{C_6}{R^6}, \quad (24.28)$$

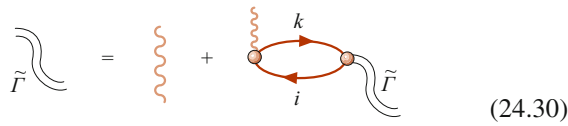

for the interatomic potential [20], where

$$C_6 \approx \sum_{k,n>F;i,j\leq F} \frac{|(i|\mathbf{r}|k)|^2|(j|\mathbf{r}|n)|^2}{(\varepsilon_i + \varepsilon_j - \varepsilon_k - \varepsilon_n)}. \quad (24.29)$$

Calculations [21] show that the inclusion of higher-order correlations is important for obtaining accurate values for ΔE_{corr}

and C_6 . However, to improve accuracy by taking into account the corrections to diagrams Eq. (24.26) requires considerable effort. Indeed, there are several types of corrections to Eq. (24.26) such as (i) screening of the Coulomb interelectron interaction by the electron–vacancy excitations, (ii) interaction between vacancies ij , (iii) interaction between electrons and vacancies $ki(nj)$ ($kj(ni)$), and (iv) interaction between electrons kn . Corrections to the HF field itself, which acts upon electrons k, n and vacancies i, j , are discussed in Sect. 24.2.3.

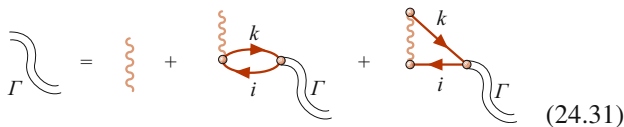

Screening of the Coulomb interelectron interaction is very important, and in many cases must be taken into account non-perturbatively. The simplest way to do this is to use RPA, which defines the effective interelectron interaction $\tilde{\Gamma}$ as a solution of an integral equation, shown diagrammatically by

$$\tilde{\Gamma} = V + V \tilde{\Gamma} \quad (24.30)$$

If V in Eq. (24.27) is replaced by $\tilde{\Gamma}$, an expression for ΔE_{corr} in RPA can be derived.

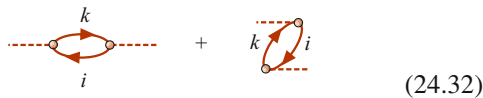

Exchange is very important in atoms and molecules, so diagram Eq. (24.30) can be modified to include this effect, thus leading to the effective interaction Γ in RPAE [15–17, 21]:

$$\Gamma = V + V \Gamma + V \Gamma \quad (24.31)$$

Replacing V in Eq. (24.27) by Γ gives a rather accurate expression for ΔE_{corr} in RPAE. Taking into account screening also affects the long-range interatomic interaction considerably by altering the constant C_6 in Eq. (24.28).

The ground state energy of an atom or molecule is modified by an external field. For a not too intense electromagnetic field, the simplest correction to the ground state energy is given by the diagrams

$$\quad + \quad \quad (24.32)$$

Considering a dipole external field, its interaction with the atomic electrons is given by $W = \sum_{i \leq F} \mathbf{E} \cdot \mathbf{r}_i$, \mathbf{E} being the strength of the field. The ground state energy shift is given by $\Delta E = -\alpha(\omega) E^2/2$, where $\alpha(\omega)$ is the dynamical dipole polarizability, and ω is the frequency of the field. According to Eq. (24.32), $\alpha(\omega)$ is determined by

$$\alpha(\omega) = \sum_{k>F; i \leq F} \frac{2|\langle i|z|k \rangle|^2 (\varepsilon_k - \varepsilon_i)}{(\varepsilon_k - \varepsilon_i)^2 - \omega^2}, \quad (24.33)$$

where z is a component of the vector \mathbf{r} .

RPAE corrections to $\alpha(\omega)$ are discussed in Sect. 24.2.5 in connection with the photoionization process.

Nondipole polarizabilities of other multipolarities can be obtained in the lowest order of interelectron interaction using Eq. (24.32) with a properly chosen interaction operator between the electromagnetic field and an electron, instead of $W = \sum_{i \leq F} \mathbf{E} \cdot \mathbf{r}_i$.

24.2.2 Characteristics of One-Particle States

A single vacancy or electron can propagate from one instant of interaction to another, as described to zero order by elements Eq. (24.1b) [or Eq. (24.1a)] with dots Eq. (24.1f) at the ends. For an atom, this line represents a HF one-particle state with a given angular momentum, spin, and total momentum. Accounting for virtual or real atomic excitations leads, for a vacancy, to a diagram similar to Eq. (24.25) but with oppositely directed arrows. Because the interaction with these excitations is usually much smaller than the energy distance between shells, in the sum over q only the term $q = i$, i being the considered vacancy state, need be taken into account. Interaction with the vacuum leaves the angular momentum, spin, and total momentum unaltered. It can, however, change the energy and lead to a finite lifetime for a vacancy state.

Analytically, the vacancy propagation in the HF approximation is described by the one-particle HF Green's function G^{HF} :

$$G_i^{\text{HF}}(E) = 1/(\varepsilon_i - E). \quad (24.34)$$

Solving Eq. (24.25) for a vacancy i with only Σ_{ii} terms included gives

$$G_i(E) = 1/[\varepsilon_i + \Sigma_{ii}(E) - E]. \quad (24.35)$$

The pole in $G(E)$, which determines the vacancy energy, is shifted from $E = \varepsilon_i$ to $E_i = \varepsilon_i + \Sigma_{ii}(E_i)$. The quantity $\Sigma_{ii}(E)$ is called the self-energy, and is, in general, a complex function of energy, its imaginary part determining the lifetime of the vacancy i . Near E_i , Eq. (24.35) can be written in the form

$$G_i(E) \approx F_i/[\varepsilon_i + \Sigma_{ii}(E_i) - E] = F_i/(E_i - E), \quad (24.36)$$

where

$$F_i = \left(1 - \frac{\partial \Sigma_{ii}(E)}{\partial E} \Big|_{E=E_i} \right)^{-1} \quad (24.37)$$

is called the *spectroscopic factor*. It characterizes the probability for more complicated configurations to be admixed into a single vacancy state i [15, 22].

An important problem is to calculate the self-energy part $\Sigma(E)$. The first nonzero contributions are

$$(24.38)$$

Specific calculations [16, 21] demonstrate that if the intermediate electron states n [in Eq. (24.38a)] and kn [in Eq. (24.38b)] are found in the field of vacancies jj' and $i'j$, the diagrams Eq. (24.38) are able to reproduce the values of the correlation energy shift with about 5% accuracy. For outer subshell vacancies, the contributions Eqs. (24.38a) and (24.38b) are almost equally important, to a large extent canceling each other. For example, Eq. (24.38a) shifts the outer 3p vacancy in Ar to lower binding energies by 0.1 Ry, while the contribution of Eq. (24.38b) is -0.074 Ry. The total value 0.026 Ry is small and close to the experimental one, which is 0.01 Ry. For inner vacancies, Eq. (24.38a) is dominant because the intermediate states in Eq. (24.38b) have large virtualities and are, therefore, small. The main contribution to the sum over j' comes from the term $j' = i' = i$, which gives for the energy shift of level i

$$\Delta\varepsilon_i = \Sigma_{ii}^{(2)}(\varepsilon_i) = \sum_{n>F; j \leq F} \frac{|\langle n|r^{-1}|j \rangle|^2}{\varepsilon_n - \varepsilon_j}. \quad (24.39)$$

The value of Eq. (24.39) is positive. Most important higher-order corrections will be included if V in Eq. (24.27) is replaced by Γ from Eq. (24.31).

The physical meaning of diagram Eq. (24.38a) is transparent: it accounts for configuration mixing of one vacancy i and two vacancies jj' – one-electron n states in the lowest order in the interelectron interaction. Diagram Eq. (24.38b) is not as transparent, and for $i = i'$, its intermediate state appears to violate the Pauli principle. However, as noted in connection with Eq. (24.14), the Pauli principle should not be considered as a restriction in constructing intermediate states.

Diagram Eq. (24.38a) and its exchange can have an imaginary part, which gives the probability of Auger decay $\gamma_i^{(A)}$, calculated to the lowest order in the interelectron interaction. For Eq. (24.38a), one has

$$\begin{aligned} \gamma_i^{(A)} &= \text{Im}[\Sigma_{ii}(E_i)] \\ &= 2\pi \sum_{j, j' \leq F; n > F} |\langle in|V|jj' \rangle|^2 \delta(\varepsilon_j + \varepsilon_{j'} - \varepsilon_n - \varepsilon_i). \end{aligned} \quad (24.40)$$

The width $\gamma_i^{(A)}$ is usually much smaller than $\text{Re}[\Sigma_{ii}(E_i)]$, but there are several exceptional cases with abnormally large Auger widths, among which the most impressive is the 4p-vacancy in Xe with its $\gamma_{4p} \approx 10$ eV.

Along with Auger, radiative decay of vacancies takes place. Its amplitude is presented by time reverse of Eq. (24.2b) diagram. The radiation width $\gamma_i^{(\nu)}$ in its HF approximation is given by equation

$$\gamma_i^{(\nu)HF} = \frac{1}{c^3} \sum_{i < j \leq F} \omega_{ji}^3 |\langle i|\mathbf{er}|j \rangle|^2, \quad (24.41)$$

where \mathbf{e} is the emitted photon polarization vector, $\omega_{ji} \equiv \varepsilon_j - \varepsilon_i$.

Higher-order corrections include those that are taken into account when V in Eq. (24.40) is replaced by Γ from Eq. (24.31). The others include jj' vacancy–vacancy interaction, the interaction between vacancies jj' and the electron n , and so on. As noted above, all of these can be obtained step by step by inserting the elements Eq. (24.4) into Eq. (24.38). To select the most important corrections, a physical idea and/or experience are necessary. For instance, if the energy transferred in the decay process $\Delta\varepsilon = \varepsilon_{j'} - \varepsilon_j$ is close to some threshold energies of atomic intermediate or outer shells, corrections that include virtual excitation of this shell must be taken into account.

The contribution to the spectroscopic factor from Eq. (24.38a) is given according to Eq. (24.37) by

$$F_i^{(2)} \equiv \left(1 + \sum_{j, j' \leq F; n > F} \frac{|\langle in|V|j'j \rangle|^2}{(\varepsilon_j + \varepsilon_{j'} - \varepsilon_n - \varepsilon_i)^2} \right)^{-1}. \quad (24.42)$$

Generally, for any Fermi particle, $F_i \leq 1$ [17] because there cannot be more than one particle in a given state. Note that the integrand in Eq. (24.42) is the lowest-order admixture of the $jj'n$ state to a pure one-vacancy state i . A small F value means strong mixing. For atoms, F_i is usually close to 1, but there are exceptions where F is small. For example, F_{5s} in Xe is about 0.33 [15].

The operator $\Sigma_{ij(n)}(\varepsilon)$ has nondiagonal matrix elements, which leads to admixture of other one-vacancy j or one-electron n states to the vacancy i . A measure of this admixture is given by the ratio $\Sigma_{ij(n)}(\varepsilon_i)/(\varepsilon_{j(n)} - \varepsilon_i)$.

In higher orders, decay processes more complex than those described by the imaginary part of Eq. (24.40) become possible. For example, this could be a two-electron Auger decay in which the transition energy is distributed between two outgoing electrons. An example of the lowest-order diagram for this process is

$$(24.43)$$

This is one of those diagrams that describe the mixing of a pure one-vacancy state with a quite complex configuration $jj_1j_2\varepsilon_1\varepsilon_2$.

24.2.3 Electron Scattering

Propagation of an electron in a discrete level or in a scattering state can be described in the same way as for a vacancy. The electron wave function is determined by Eq. (24.25). Using the correspondence rule Eq. (24.14), Eq. (24.25) can be expressed analytically in the form

$$\begin{aligned} & \left[-\frac{\nabla^2}{2} - \frac{Z}{r} + \sum_{i \leq F} \int \frac{d\mathbf{r}'}{|\mathbf{r}' - \mathbf{r}|} |\phi_i(\mathbf{r}')|^2 - \varepsilon \right] \psi_\varepsilon(\mathbf{r}) \\ &= \sum_{i \leq F} \int \frac{d\mathbf{r}'}{|\mathbf{r}' - \mathbf{r}|} \phi_i^*(\mathbf{r}') \psi_\varepsilon(\mathbf{r}') \phi_i(\mathbf{r}) \\ &+ \int \hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon) \psi_\varepsilon(\mathbf{r}') d\mathbf{r}'. \end{aligned} \quad (24.44)$$

The terms with the Coulomb interelectron interaction $|\mathbf{r}' - \mathbf{r}|^{-1}$ determine the Hartree–Fock self-consistent potential. The last term in Eq. (24.44) represents the nonlocal energy dependent polarization interaction of the continuous spectrum electron with the target atom. For HF wave functions for molecular targets, one has to substitute the proper multinuclear Coulomb potential for $-Z/r$ in Eq. (24.44). Although Eq. (24.44) resembles the ordinary Schrödinger equation, because of the energy dependence of the self-energy part $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$, it is not the same. Consequently, the wave function $\psi_\varepsilon(\mathbf{r})$, often called a Dyson orbital, must be normalized according to the condition

$$\langle \psi_{\varepsilon'} | \psi_\varepsilon \rangle = F_\varepsilon \delta(\varepsilon' - \varepsilon), \quad (24.45)$$

where

$$F_\varepsilon = \left[1 - \left(\varepsilon \left| \frac{\partial \hat{\Sigma}(\mathbf{r}, \mathbf{r}', E)}{\partial E} \right| \varepsilon \right) \Big|_{E=\varepsilon} \right]^{-1}. \quad (24.46)$$

The relation in Eq. (24.45) is different from that for ordinary wave functions by the factor $F_\varepsilon < 1$. In F_ε , the matrix element of the operator $\partial \hat{\Sigma}(\mathbf{r}, \mathbf{r}', E) / \partial E$ is calculated between states $\psi_\varepsilon(\mathbf{r})$. It is seen that F_ε is the same spectroscopic factor as determined by Eq. (24.37) but for a continuous spectrum or an excited electron state.

The object described by the wave function $\psi_\varepsilon(\mathbf{r})$ differs from an individual electron because it can be unstable, and its state is mixed with those of more complicated configurations, such as *two electrons* $k'k''$ – one vacancy j'' . This object is called a *quasi electron*.

Equation (24.44) also determines the energies of electrons in discrete levels that are shifted from their HF values. Con-

trary to the case of deep vacancies, it is impossible to predict the sign of the energy shift without detailed calculations.

For incoming electron energies ε higher than the target ionization threshold, the operator $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$ acquires an imaginary part, thus becoming an optical potential for the projectile. The additional elastic scattering phase shifts from their HF values can be expressed via matrix elements of $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$ between the wave functions $\phi_\varepsilon^*(\mathbf{r})$ and $\psi_\varepsilon(\mathbf{r})$; but to find numbers for these phase shifts, the self-energy part or polarization interaction $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$ must be calculated. It appears that the second-order projectile–target interactions

$$\text{a} \quad \text{b} \quad + \text{exchange terms} \quad (24.47)$$

provide a reasonably good approximation [10, 16, 21].

The expression for $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$ simplifies at distances far from the target. Only Eq. (24.47a) contributes in this region, while other terms are exponentially small. Expanding the Coulomb interelectron interactions in Eq. (24.47a) in powers of $r_1'/r_1 \ll 1$, $r_2'/r_2 \ll 1$ gives

$$\Sigma(\mathbf{r}, \mathbf{r}', \varepsilon) = -\delta(\mathbf{r} - \mathbf{r}') \frac{\alpha^{\text{HF}}(0)}{2r^4}, \quad r, r' \rightarrow \infty, \quad (24.48)$$

where $\alpha^{\text{HF}}(0)$ is the static ($\omega = 0$) dipole polarizability determined by Eq. (24.33).

Accounting for each additional interaction between the projectile and target increases the power of r in the denominator of Eq. (24.48). The interaction between target electrons is most important. By including this, the asymptotic expression in Eq. (24.48) is also modified, where instead of $\alpha^{\text{HF}}(0)$, the RPAE polarizability $\alpha^{\text{RPAE}}(0)$ appears. If the target–projectile interelectron interaction is taken into account to second order, as in Eq. (24.47), while all the rest is included exactly, the expression for $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$ for $r, r' \rightarrow \infty$ is still given by Eq. (24.48) but with the exact static polarizability.

Many experimental results for low energy electron scattering by noble gases, alkalis, and alkaline earths agree well with the calculations of elastic scattering phase shifts obtained by solving Eq. (24.44) in which $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$ is given by Eq. (24.47) with RPAE corrections taken into account. Total cross sections are reproduced with an accuracy as high as several percent, including the Ramsauer minimum region. This is illustrated in Fig. 24.1 for the $e^- + \text{Xe}$ case [16, 23]. This approximation is also reasonably good in describing the angular distributions. As the projectile energy ε increases, the contribution of Eq. (24.47) decreases rapidly.

The simplest amplitude of inelastic electron scattering is represented by the Eq. (24.4b) diagram. Higher-order correc-

Fig. 24.1 Electron–Xe atom elastic scattering cross section [16]. *Dark solid line*: including polarization interaction; *dashed line*: HF; *light solid line*: experiment

tions to it include additional interaction between electrons and between electrons and the vacancy in the final state, as well as corrections to all electron (vacancy) HF lines, such as Eq. (24.38). If one considers inelastic scattering, the situation becomes more simple, and the process becomes similar to photoionization (Sect. 24.2.6), with the operator of photon–electron interaction being substituted by $\frac{1}{q^2} \cdot \exp^{i\vec{q} \cdot \vec{r}}$, where \vec{q} is the linear momentum transferred from the projectile to target in the collision process [20].

The approach presented here also applies to other incoming particles, such as, for instance, positrons e^+ . The exchange between e^+ and target electrons must be omitted by discarding Eq. (24.6) and all but Eq. (24.47a) terms in the polarization interaction $\hat{\Sigma}(\mathbf{r}, \mathbf{r}', \varepsilon)$. The incoming positron in its intermediate state k' [see Eq. (24.47a)] interacts strongly with the virtually excited electron k'' , forming a positronium-like object. Corresponding diagrams are obtained by inserting elements Eq. (24.4d) for the e^+e^- interaction into Eq. (24.47a). Summation of the infinite sequence of such diagrams corresponds to substituting the product $\phi_{k'}(\mathbf{r}_1)\phi_{k''}(\mathbf{r}_2)$ in the intermediate state of Eq. (24.47a) by the exact e^+e^- wave function in the field of a target with a vacancy j . Such a program is very complicated, and a crude simplification has proven to be satisfactory. Only the positronium (Ps) binding is taken into account by subtracting its binding energy in the denominator of Eq. (24.13). This is equivalent to adding the Ps ionization potential I_{Ps} to ε in Eq. (24.47) [24]. It enhances the polarization interaction and leads to an interesting qualitative feature: the possibility of alteration of the sign of the interaction Eq. (24.47). Indeed, instead of $\alpha(0)$, the corresponding polarization expression Eq. (24.47) for e^+ -atom collision includes $\alpha(I_{Ps})$. For alkalis, the binding energy is less than I_{Ps} , and for the energy region $\omega > I_{Ps}$, the polarizability in Eq. (24.33) is negative, while $\alpha(0) > 0$. This leads to a repulsive polarization inter-

action, rather than the usual attractive one. This difference affects the cross section qualitatively [25].

Another, more complicated, approximation substitutes $\phi_{k'}(\mathbf{r}_1)\phi_{k''}(\mathbf{r}_2)$ by the product of the precise Ps wave function $\psi_{Ps}(|\mathbf{r}_1 - \mathbf{r}_2|)$ and the wave function of the free motion of the Ps center of gravity [26].

According to the diagrams Eq. (24.23), Eq. (24.44) describes the target with an additional electron. If the target is a neutral atom, the solution of Eq. (24.44) with discrete energy values describes negative ion states, both ground and excited ones.

Again, as in Sect. 24.2.2, diagrams Eq. (24.47) with RPAE corrections form a reasonably good starting point for calculating the negative ion binding energies, even in cases when this binding is comparatively small, as in alkaline earth negative ions [27]. The inclusion of only the outer shell polarizability (j is a vacancy in the outer shell) leads to overbinding of the additional electron forming the negative ion. Only the inclusion of screening due to inner shell excitations yields good agreement with experiment. For instance, measurements of Ca^- affinity [28] give about 20 meV, while the calculations without inner shell excitations give about 50 meV [27]. Their inclusion must reduce the theoretical value considerably.

24.2.4 Two-Electron and Two-Vacancy States

One can construct a diagrammatic equation for the wave function of a two-electron or a two-vacancy state by separating all diagrams describing two-electron (two-vacancy) scattering that do not include these states as intermediate, and denoting their total contribution by a circle. Then the exact two-electron (vacancy) state is determined by the infinite sequence of diagrams

$$\begin{aligned}
 \text{Diagram} &= \text{Diagram 1} + \text{Diagram 2} + \text{Diagram 3} + \dots \\
 &= \text{Diagram 4} + \text{Diagram 5} + \text{Diagram 6} + \dots
 \end{aligned}
 \tag{24.49}$$

The analytic equation for two electrons in an atom or any multiatomic system, interacting with each other can be written in the form

$$\begin{aligned}
 &(\hat{H}_1^{\text{HF}} + \hat{\Sigma}_1 + \hat{H}_2^{\text{HF}} + \hat{\Sigma}_2 + \hat{Q}\hat{\Pi}_{12} - \varepsilon) \\
 &\times \psi_{12}(\mathbf{r}_1 \cdot \mathbf{r}_2) = 0.
 \end{aligned}
 \tag{24.50}$$

Here, $\hat{H}_{1(2)}^{\text{HF}}$ is the HF part of the one-particle Hamiltonian in Eq. (24.24), $\hat{\Pi}_{12}$ is the effective interelectron interaction, and \hat{Q} is the projection operator

$$\hat{Q} \equiv (1 - n_1)(1 - n_2) - n_1 n_2 = 1 - n_1 - n_2, \quad (24.51)$$

with $n_{1(2)}$ being the Fermi step function, $n_{1(2)} = 1$ for $1(2) \leq F$, and $n_{1(2)} = 0$ for $1(2) > F$. The function $n_{1(2)}$ thus eliminates contributions of vacant states. The operator \hat{Q} takes into account the fact that propagation of two electrons (or, more precisely, quasi electrons due to the presence of $\hat{\Sigma}$) takes place in a system of other particles, which occupy all levels up to the Fermi level. The presence of \hat{Q} makes Eq. (24.50) essentially different from a simple two-electron Schrödinger equation: \hat{Q} requires that after each act of interaction described by $\hat{\Pi}_{12}$, both participants either remain electrons or become vacancies.

Diagrams Eq. (24.49) describe the states of two electrons outside the closed shell core, or electron scattering by an atom with one electron outside the closed shells. In general, $\hat{\Pi}_{12}$ is nonlocal, dependent upon ε , and can have an imaginary part. The lowest-order approximation to $\hat{\Pi}_{12}$ is $V = |\mathbf{r}_1 - \mathbf{r}_2|^{-1}$. Equation (24.50) must be solved in order to obtain, for example, the excitation spectrum of two electrons in atoms with two electrons outside closed subshells, such as Ca. Instead of V , the interaction Γ from Eq. (24.31) can be used, which would account for screening due to virtual excitation of inner shell electrons. For low-level two-electron excitations, the energy dependence of $\hat{\Pi}_{12}$ can be neglected.

The same type of equation can be obtained for two-vacancy states, describing their energies, decay widths, and structure due to configuration mixing with more complex states. For inner and intermediate shell vacancies in atoms, however, the corresponding corrections can be taken into account perturbatively, and the screening by outer shells is not essential. The admixture of outer shell excitation with inner vacancies is important, leading to so-called satellites of the main spectral lines.

The interaction between vacancies leads to correlated two-vacancy decay processes in which the energy is carried away by a single electron or photon. Some diagrams exemplifying these processes in the lowest possible order of interaction are

Even in this order, there are several diagrams that together give the amplitude of the correlation Auger Eq. (24.52a) and

radiative Eq. (24.52b) decay rates. For inner shells, a specific feature of such processes is that the released energy is about twice that for a single vacancy decay. Of course, in these cases, the decay probability is relatively small. It is not, however, necessarily much smaller than that of individual vacancies if the energies of the intermediate and initial states are close to each other.

The presence of residual two-body forces leads to effective multiparticle interactions. The simplest diagram presenting a three-electron interaction is given by

The role of multiparticle interactions in the atomic structure is far from being clear. Diagrams similar to Eq. (24.53) are important if it is of interest to calculate the energy levels of atoms with three or more electrons (or vacancies) outside of closed shells. This is a very complicated calculation because even two electrons in the Coulomb field of the nucleus are a difficult three-body problem.

24.2.5 Electron–Vacancy States

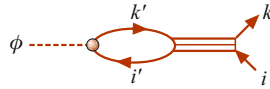

The one-electron–one-vacancy state is the simplest excitation of a closed shell system under the action of an external time-dependent field, represented by Eq. (24.2a). Beginning with the electrons and vacancies described in the HF approximation, the result of residual interactions leads to excitations of more complex states, including those with two or more electron–vacancy pairs. The interaction can also lead to a single electron–vacancy pair. Let us concentrate on the latter case and separate all diagrams describing electron–vacancy interaction that do not include these states as intermediate and denote them by a circle. Then the exact electron–vacancy state is determined by the infinite sequence of diagrams

Contrary to the electron–electron case in Sect. 24.2.4, the analytical expression corresponding to Eq. (24.54) cannot be

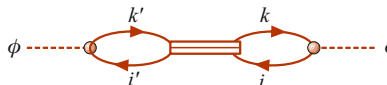

represented as a Schrödinger-type equation. Indeed, being symmetric under time reversal, Eq. (24.54) leads to an equation depending, unlike Eq. (24.50), upon the second power of the electron–vacancy energy ω . Note that R in Eq. (24.54) and \hat{T} in Eq. (24.49) are different.

It is necessary to solve Eq. (24.54) when calculating the photoabsorption amplitude, which can then be represented as

$$(24.55)$$

The amplitude for elastic photon scattering is also expressed via the exact electron–vacancy state, determined by (24.54) to be

$$(24.56)$$

The other case where it is necessary to solve Eq. (24.54) is the scattering of electrons, both elastic and inelastic, by atoms with a vacancy in their outer shell, such as halogens.

The simplest approximation to R is given by the Coulomb interaction to lowest order Eqs. (24.4e) and (24.4f). With such R , the sequence of diagrams Eq. (24.54) is the same as Eq. (24.31) and, thus, forms the RPAE, which is often used to describe photoionization and other atomic processes [15, 16]. Both terms Eqs. (24.4e) and (24.4f) contribute to the electron–vacancy in Eq. (24.54) only if the external field is spin independent, such as an ordinary photon. For a magnetic interaction, which is proportional to spin, the term Eq. (24.4e) does not contribute.

24.2.6 Photoionization in RPAE and Beyond

In RPAE, the photoionization amplitude $\langle k|D(\omega)|i\rangle$ is determined by solving an integral equation obtained from Eqs. (24.54) and (24.55) using the correspondence rule Eq. (24.14) [15, 16]

$$\begin{aligned} \langle k|D(\omega)|i\rangle &= \langle k|d|i\rangle \\ &+ \sum_{k'>F; i'\leq F} \left(\frac{\langle k'|D(\omega)|i'\rangle \langle ki'|V|ik' - k'i\rangle}{\omega - \varepsilon_{k'} + \varepsilon_{i'} + i\eta} \right. \\ &\quad \left. - \frac{\langle i'|D(\omega)|k'\rangle \langle kk'|V|ii' - i'i\rangle}{\omega + \varepsilon_{k'} - \varepsilon_{i'} - i\eta} \right), \end{aligned} \quad (24.57)$$

where d is the dipole operator describing the photon–electron interaction, and $V = |\mathbf{r}_1 - \mathbf{r}_2|^{-1}$. To obtain the RPAE photoionization cross section, the usual expression

in Eq. (24.19) must be multiplied by the square modulus of the ratio $\langle k|D(\omega)|i\rangle/\langle k|d|i\rangle$, with $\omega = \varepsilon_k + I_i$. The RPAE corrections described by the term in round brackets in Eq. (24.57) are very large for outer and intermediate electron shells. Through the sum over i' , if only terms with the same energies $\varepsilon_{i'} = \varepsilon_i$ are included, Eq. (24.57) accounts for intrashell correlations. By adding terms with $\varepsilon_{i'} \neq \varepsilon_i$, the effect of intershell correlations is taken into account.

One can obtain the radiative width in RPAE $\gamma_i^{(y)RPAE}$ from Eq. (24.41), substituting $\langle i|d|j\rangle$ by $\langle i|D(\omega_{ji})|j\rangle$.

For atoms, Eq. (24.57) has to be solved numerically but can be presented in a symbolical operator form that creates the possibility of qualitative analyses of its solutions

$$D(\omega) = d + D(\omega)\chi(\omega)U, \quad (24.58)$$

where U is a combination of the direct V_d and exchange V_e Coulomb interelectron potentials, $U = V_d - V_e$, $\chi(\omega) = \chi_1(\omega) + \chi_2(\omega)$, $\chi_1(\omega) = 1/(\omega - \omega' + i\eta)$, and $\chi_2(\omega) = -1/(\omega + \omega')$, with ω' being the excitation energy of the virtual electron–vacancy state. Thus, $\chi(\omega) = 2\omega'/(\omega^2 - \omega'^2 + i\eta)$. Using Γ from Eq. (24.31), one can present $D(\omega)$ as

$$D(\omega) = d + d\chi(\omega)\Gamma(\omega). \quad (24.59)$$

Equation (24.58) allows a rather simple, also symbolic, solution

$$D(\omega) = d/[1 - \chi(\omega)U]. \quad (24.60)$$

If the denominator in Eq. (24.60) has a solution Ω determined by the equation

$$1 - \chi(\Omega)U = 0, \quad (24.61)$$

at $\Omega > I$, where I is the atomic ionization potential, $\chi(\Omega) > 0$, then the cross section has a powerful maximum called a giant resonance with energy Ω .

A giant resonance is of collective nature in the sense that it appears to be due to coherent virtual excitation of all electrons of at least one considered multielectron subshell.

These intrashell correlations are most important for multielectron shells with large photoionization cross sections. Their inclusion leads to a quantitative description of the above-mentioned giant resonances – huge maxima in the photoionization cross sections. An example is the $4d^{10}$ photoionization cross section of Xe shown in Fig. 24.2 [16], where satisfactory agreement with experiment is demonstrated. In [16], one can find a number of examples of other Giant resonances.

It appears that all RPAE intrashell time-forward diagrams, such as that on the first line in Eq. (24.54), and the first term in brackets in Eq. (24.57) with $\varepsilon_{i'} = \varepsilon_i$, may be taken into account by the matrix element $\langle \tilde{k}|d|i\rangle$. This is the

Fig. 24.2 Photoabsorption in the vicinity of the $4d^{10}$ subshell threshold in Xe [8]. Solid line: RPAE; dashed line: experiment

one-electron approximation but with the function $\tilde{\phi}_k(r)$ calculated in the term-dependent HF approximation [15–18]. Term-dependency means that only the total angular momentum and spin and their projections for the electron–vacancy pair are conserved, being equal to that of the incoming photon. The individual values for the electron and vacancy angular momentum and spin are not considered to be good quantum numbers. Thus, the term-dependent HF includes a large fraction of RPAE correlations.

RPAE allows the calculation of interference resonances. To describe them, let us consider a situation in which the direct HF amplitude d_s is small, while there are other electrons with large photoionization amplitude D_b , $D_b(\omega) \gg d_s$. Then, from Eq. (24.58) one has

$$\begin{aligned} D_s(\omega) &\approx d_s + D_b(\omega)\chi(\omega)U_{bs} \\ &\approx D_b(\omega)\chi(\omega)U_{bs} \gg d_s, \end{aligned} \quad (24.62)$$

if the intertransition interaction U_{bs} is not too small. The enhancement of the photoionization amplitude described by Eq. (24.62) manifests itself as a resonance in the partial cross section of s electrons photoionization. Very often, the term $D_b(\omega)\chi(\omega)U_{bs}$ and d_s are of opposite sign, so that the total amplitude acquires two minima, along with an extra maximum, thus forming a rather complicated structure in the partial cross section, which was named *interference* or *correlation* resonance.

Usually, these resonances are manifestations of intershell correlations. These are taken into account if the sum over i' in Eq. (24.57) includes terms with $\varepsilon_{i'} \neq \varepsilon_i$. An example is the $5s^2$ subshell in Xe, which is strongly affected by the outer $5p^6$ and inner $4d^{10}$ neighboring electrons. Due to this interaction, the $5s^2$ cross section is completely altered, as illustrated in Fig. 24.3 [15, 16]. The RPAE results predict a qualitative feature of the experimental data, namely the formation of a maximum and two minima in the cross section. The second

Fig. 24.3 Photoionization of $5s^2$ electrons in Xe [8]. light brown solid line: RPAE with effects of $5p^6$ and $4d^{10}$ included; dotted line: $5s^2$ electrons only; grey solid line: with effect of $5p^6$ electrons; dark brown solid line: with effect of $4d^{10}$ electrons; black dashed line: experiment

minimum is not seen in Fig. 24.3, since it lies at considerably higher ω .

RPAE is able to describe a number of other effects, such as *giant autoionization* resonance (decay of a powerful discrete excitation into a continuum, with which the excitation interacts strongly), *continuous spectrum autoionization* (modification of a broad continuous spectrum excitation due to its strong interaction with a narrow continuum that occurs in negative ions [27]), and *quadrupole giant resonances* [29].

Above we concentrated on dipole giant resonances. Quadrupole amplitudes in RPAE are determined by an equation similar to Eq. (24.58):

$$Q(\omega) = q + Q(\omega)\chi(\omega)U, \quad (24.63)$$

where q is the quadrupole amplitude in HF approximation.

Giant quadrupole resonance was found in excitations of $4d^6$ electrons in Xe [30]. Its direct observation in photoabsorption is almost impossible, since the corresponding cross section is very small due to the inclusion of the extra factor $\alpha^2 = 1/c^2 \approx 10^{-4}$ as compared to the dipole cross section. However, the quadrupole amplitude leads to noticeable corrections to the angular distributions of photoelectrons where their relative contribution is considerably bigger [16].

Note that the amplitude of electron elastic scattering on an atom with a vacancy is expressed in RPAE via Γ given by Eq. (24.31) [31].

For the inner or deep intermediate shells, RPAE proves to be insufficient. First, screening of the Coulomb interaction between the outgoing or virtually excited electron and the vacancy [see Eq. (24.4f)] must be taken into account. This can be done by replacing V with Γ from Eq. (24.31). The ionization potential (or the energy of the vacancy i) must also be corrected, which requires inclusion of at least the contribution from the first term of Eq. (24.38). It has been demon-

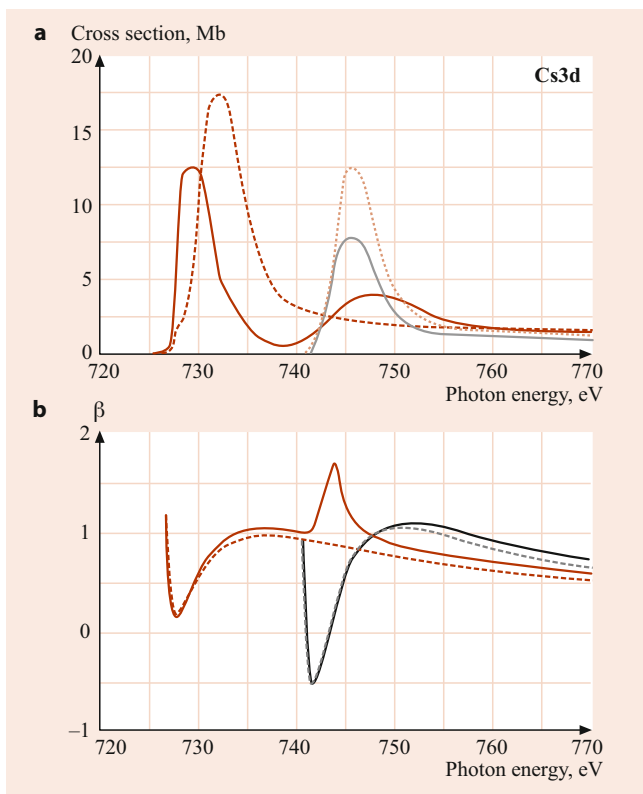

Fig. 24.4 Intradoublet resonance in $3d^{10}$ Cs. (a) Partial photoionization cross sections $\sigma_{5/2}$ (left peaks) and $\sigma_{3/2}$ (right peaks) [33]. Dashed curves represent the HF approximation. (b) Dipole angular anisotropy parameters $\beta_{5/2}$ and $\beta_{3/2}$. Solid red line: data for 5/2 with account of 3/2; dashed red line: data for 5/2 without account of 3/2; solid black line: data for 3/2 with account of 5/2; dashed black line: data for 3/2 without account of 5/2

strated [32] that the screening of the electron–vacancy interaction can be taken into account by calculating the wave function of the virtually excited or outgoing electron in the self-consistent HF field of an ion instead of that of a neutral atom. A method that uses only these one-particle wave functions in Eqs. (24.55) and (24.57) is called the generalized RPAE or GRPAE [16]. The use of this approximation improves the agreement with experiment near the intermediate shell thresholds considerably, decreasing the cross section value there and shifting its maximum to higher energies. GRPAE reveals *intradoublet resonances* that result from the interaction of electrons belonging to two components of the spin–orbit doublet, e.g., $3d_{3/2}$ and $3d_{5/2}$ in Xe, Cs, and Ba atoms [29, 33].

RPAE and GRPAE corrections do not only affect the cross sections but also the characteristics of the photoelectron angular distribution, i.e., dipole and nondipole angular anisotropy parameters [15, 21, 29]. As an example, Fig. 24.4a presents the partial cross sections [33], while Fig. 24.4b depicts the dipole anisotropy parameter β [29] for $3d_{5/2}$ and $3d_{3/2}$ electrons in Cs. The effect of intradoublet resonance – an additional maximum in the $3d_{5/2}$ cross section under the action of $3d_{3/2}$ electrons – can be seen clearly.

Figure 24.5 depicts the nondipole angular anisotropy parameter γ_{5s} for 5s electrons in Xe [34]. The parameter γ_{ns} (in Fig. 24.5, $n = 5$) is given by the simple formula [21]

$$\gamma_{ns}(\omega) = 6[|Q_{ns}(\omega)|/|D_{ns}(\omega)|] \cos(\Delta_q - \Delta_d), \quad (24.64)$$

where $Q_{ns}(D_{ns})$ are the RPAE (GRPAE) quadrupole (dipole) photoionization amplitudes, and $\Delta_q(\Delta_d)$ are their phases. Thus, $\gamma_{ns}(\omega)$ is sensitive to the presence of interference, dipole, and quadrupole resonances. The latter is presented by a small but noticeable maximum on the high energy slope of the huge maximum, caused by the presence of the giant dipole resonance. The variation of γ_{5s} near the 5s threshold is determined by the resonant behavior of $\cos(\Delta_q - \Delta_d)$, called *phase resonance* [29].

Close to inner shell thresholds, the Auger decay of a deep vacancy must be taken into account. Due to decay, the photoelectron instantly finds itself in the field of at least two vacancies instead of one, leading to considerable growth of the threshold cross section. Diagrammatically, the effect of decay may be described by

$$(24.65)$$

Here, the double line emphasizes that starting from the moment of decay; the photoelectron moves in the field $j_1 j_2$ of a double instead of a single i vacancy. For inner vacancies, this is a strong effect, which can lead even to recapture of the photoelectron into some of the discrete levels in the field of the double vacancy $j_1 j_2$. The instant change of the outgoing electron wave function due to rapid vacancy decay is called *postcollision*.

This effect in photoionization can be taken into account by the diagram Eq. (24.65) when the Auger electron is much faster than the photoelectron [35]. If their speed is of the same order, their mutual Coulomb repulsion must be accounted for, leading to additional alteration of energy and angular redistributions.

A photoelectron can excite or knock out another atomic electron. To lowest order in the residual interelectron interaction, this process can be represented by the diagrams Eqs. (24.66) and (24.67)

$$(24.66)$$

While the formation of an initial electron–vacancy ki_1 pair requires RPAE or GRPAE for its description, the sec-

Fig. 24.5 Nondipole anisotropy parameter $\gamma_{5s}(\omega)$ of $5s^2$ electrons in Xe [34]

ond step of Eq. (24.66a) can be reproduced reasonably well by the lowest-order term in V . It appears that process Eq. (24.66a) has a high probability of not too fast photoelectrons, changing the cross section [36] considerably for ionization by creating a vacancy i_1 . Comparatively simple diagrams

describe the photoionization process in which a more complicated state is created in the ion than a single vacancy, e.g., a state with two vacancies and one electron. Here, the double arrow indicates that the electron is in a discrete level n .

If one considers cases when n also belongs to a continuous spectrum, the diagrams (Eqs. (24.65)–(24.67)) present in the lowest order the amplitude of two-electron–one-photon ionization. Usually, the contribution of this process to the total photon absorption cross section is small, but it contains very important information on the role of interelectron correlations in atoms.

Diagrams (Eqs. (24.65)–(24.67)) present some corrections that mix electron–vacancy and two-electron–two-vacancy configurations. Each additional interaction line increases the number of possible physical processes considerably. With the growth of the number of particles actively participating in a process, the calculational difficulties increase enormously. However, this is not a shortcoming of the diagrammatic approach but a specific feature of more and more complex physical processes.

Most prominent are multielectron effects in photoionization of outer and intermediate subshells and close to the inner thresholds of intermediate and heavy atoms. However, even at very high, although nonrelativistic, energies, the role of correlations is important. For example, the ionization probability for a dipole satellite to a $l > 0$ level decreases with the photon energy; ω grows as $\approx \omega^{-7/2}$, which is much slower than for the main line itself: $\approx \omega^{-7/2-l}$. Correlations alter the asymptotic behavior of the cross section of all subshells with $l > 1$ that acquire a universal behavior $\approx \omega^{-9/2}$ instead of the HF value $\approx \omega^{-7/2-l}$ [37].

Note that inelastic scattering of any fast charge particle can be studied and described as mentioned above, similarly to photoionization if one substitutes the dipole operator d in Eq. (24.57) for $4\pi \exp(i\mathbf{q}\mathbf{r})/q^2$, where q is the momentum transferred from the projectile to the target [20]. Fast particle scattering as a tool to study a target’s structure has some advantages as compared to photoionization [38].

24.2.7 Photon Emission and Bremsstrahlung

The amplitude of photon emission in lowest order is given by the time-reversal of Eq. (24.2c):

This diagram represents ordinary Bremsstrahlung, i.e., a photon emission in the process of projectile deceleration in the field of the target. If the target has an internal structure like atoms, it can be really or virtually excited during the collision process. The simplest excitation means the creation of

an electron–vacancy pair. The annihilation of this pair results via the time-reversal of Eq. (24.2a) in photon emission. The process thus looks like

$$(24.69)$$

To obtain the total Bremsstrahlung amplitude, the terms in Eqs. (24.68) and (24.69) must be summed. The *polarization radiation* (PR) created by the mechanism Eq. (24.69) has a number of features that are different from the ordinary Bremsstrahlung (OB) represented by Eq. (24.68). The intensity is proportional to $1/M_p^2$ for OB, where M_p is the projectile mass, and the spectrum, at least for high ε_k , is proportional to $1/\omega$. On the other hand, the PR intensity is almost completely independent of M_p , and its frequency dependence is quite complex, being determined by the target polarizability $\alpha(\omega)$ [39]. PR is most important for frequencies ω of the order of and higher than the target's ionization potential. At sufficiently large distances and for neutral targets, PR starts to predominate over OB. Close to discrete excitations of the k' electron, the contribution Eq. (24.69) becomes resonantly enhanced.

Higher-order corrections are important in the PR amplitude. First, the Coulomb interaction V in Eq. (24.69) must be replaced by Γ from Eq. (24.31).

The analytical expression for the total Bremsstrahlung amplitude, including RPAE corrections to Eq. (24.69), is given by the expression

$$\begin{aligned} & \langle k|A(\omega)|k' \rangle \\ &= \langle k|d|k' \rangle + \sum_{k''>F; i \leq F} \langle ki|V|k'k'' \rangle \\ & \times \lim_{\eta \rightarrow +0} \frac{2(\varepsilon_{k''} - \varepsilon_i)}{\omega^2 - (\varepsilon_{k''} - \varepsilon_i)^2 + i\omega\eta} \langle i|D(\omega)|k'' \rangle. \end{aligned} \quad (24.70)$$

To derive the Bremsstrahlung spectrum, the usual general expression must be multiplied by the square modulus of the ratio $\langle k|A(\omega)|k' \rangle / \langle k|d|k' \rangle$. If the incoming electron is slow, corrections Eq. (24.47) also become important. The intermediate state in Eq. (24.47a) includes two electrons k' and k , and a vacancy i . The extent of the interaction between them could be considerable.

An important feature of PR is that it is nonzero even if the projectile is neutral but is able to polarize the target. For example, it leads to emission of continuous spectrum radiation in atom–atom collisions, whose intensity for frequencies of the order of the ionization potentials is close to that in electron–atom collisions.

The second and higher orders in the residual interaction involve processes that are more complicated than

Eq. (24.69), for instance those that include simultaneous photon emission and target excitation (ionization) [40, 41]. More general mechanisms of PR, other than those depicted in Eq. (24.69), are discussed in [42].

24.2.8 RPAE in the Magnetic Channel

Above, we considered the absorption and emission of pure electric photons that do not interact with the spin of electrons. So, the total spin of excitation is $S = 0$. Of interest is RPAE in the magnetic channel with $S = 1$. The respective channels do not mix if the spin of an electron (vacancy) in the system under consideration is a good quantum number. The $\text{RPAE}_{S=1}$ is obtained from Eq. (24.57) by the contribution of direct terms in the V matrix element only Eq. (24.4f) and discarding Eq. (24.4e). Thus, the $\text{RPAE}_{S=1}$ amplitude $\langle k|\mathbf{H}(\omega)|i \rangle$ is determined by the following equation

$$\begin{aligned} & \langle k|\mathbf{H}(\omega)|i \rangle \\ &= \langle k|\boldsymbol{\sigma}|i \rangle \\ & - \sum_{k'>F; i' \leq F} \left(\frac{\langle k'|\mathbf{H}(\omega)|i' \rangle \langle ki'|V|k'i \rangle}{\omega - \varepsilon_{k'} + \varepsilon_{i'} + i\eta} \right. \\ & \left. - \frac{\langle i'|\mathbf{H}(\omega)|k' \rangle \langle kk'|V|i'i \rangle}{\omega - \varepsilon_{k'} - \varepsilon_{i'} - i\eta} \right), \end{aligned} \quad (24.71)$$

where $\boldsymbol{\sigma}$ is the operator describing the interaction of an electron with the magnetic field. Just like Eq. (24.57), this equation can be presented in a symbolical operator form that creates the possibility of qualitative analyses of its solutions:

$$\mathbf{H}(\omega) = \vec{\boldsymbol{\sigma}} + \mathbf{H}(\omega)\chi(\omega)V_e, \quad (24.72)$$

where V_e is the exchange Coulomb interelectron potential Eq. (24.4f), $\chi(\omega) = \chi_1(\omega) + \chi_2(\omega)$, $\chi_1(\omega) = 1/(\omega - \omega' + i\eta)$, and $\chi_2(\omega) = 1/(\omega + \omega')$, with ω' being the excitation energy of the virtual electron–vacancy state in the $S = 1$ channel. Equation (24.72) allows a rather simple, also symbolic, solution

$$\mathbf{H}(\omega) = \vec{\boldsymbol{\sigma}} / [1 + \chi(\omega)V_e]. \quad (24.73)$$

Here, $\chi(\omega) = 2\omega'/(\omega^2 - \omega'^2)$. For $\omega < I_1$, where I_1 is the lowest possible excitation energy in the system under consideration, $\chi(\omega) < 0$, and according Eq. (24.73), the magnetic excitation enhances. If $[1 + \chi(0)V_e] < 0$, the system under consideration undergoes a phase transition, since $S = 1$ electron–vacancy pair creation proceeds without a supply of external energy. This is why open subshell systems have the maximum possible, compatible to the Pauli principle, spin, i.e., they obey the so-called Hund rule.

24.2.9 Consideration of “Big Atoms”

The theory presented can be applied to any many-body system. However, each object has some specific features. In the previous sections of this chapter, we concentrated on atoms. In addressing molecules, clusters, fullerenes, and endohedrals one can use two approaches. The first is “brutal force” or the first-principle approach. This approach employs the technique presented above where the action of all nuclei upon electrons is described by the potential $U(r)$

$$U(r) = - \sum_{\text{All nuclei } i} \frac{Z_i}{|r - \mathbf{R}_i|}, \quad (24.74)$$

where \mathbf{R}_i is the location of the i -th nucleus. One-electron wave functions must be calculated using the Eq. (24.74) expression for U instead of $-Z/r$, as in Eq. (24.57). Then all the techniques presented above can be applied directly. However, this is a difficult approach that requires solution of three-dimensional multicenter equations. For all but the simplest molecules, this approach is beyond the capabilities of modern computers. Simplifications are necessary to decrease the computational complexity for properties and processes in multiatomic formations.

However, the so-called “big atom” [12] or endohedral, which is a fullerene C_N stuffed by an atom A (denoted as $A@C_N$), permits essential simplification, making them only a little bit more complex than ordinary atoms. As one can read in a number of sources (e.g., [13]), a potential that acts upon an electron in an endohedral can be taken into account by adding to Eq. (24.57) $U_F(r)$, which is, e.g., a square well of depth U_0 , radius R_F , and width b . This allows one to describe *confinement resonances*, which are manifestations of resonances in reflection of the photoelectron wave by $U_F(r)$. This reflection strongly affects the encapsulated atom photoionization cross section. The Giant resonance of Xe 4d¹⁰ subshell, when Xe is caged in fullerene C_{60} , serves as an example. As a result the curve Fig. 24.2 is completely modified, as can be seen in Fig. 24.6 [43].

The fullerene electron shell is an object with a big polarizability [16]. This polarizability affects photon absorption in the polarizability maximum region. The treatment is essentially simplified in many cases, when, with good accuracy, one can consider $R_F \gg b$ and $R_F \gg r_a$, where r_a is the atom’s A radius. The effects of the static fullerene shell potential and its polarizability lead to *giant endohedral resonances*, prominent maxima in the inner atom photoionization cross section. This effect is illustrated by the cross section of the 5p subshell of endohedral Xe@ C_{60} depicted in Fig. 24.7 [44, 45].

The presence of a fullerene shell in $A@C_{60}$ opens up a number of new channels in endohedral processes as com-

Fig. 24.6 Photoionization cross section of 4d-electrons for the Xe free atom and Xe@ C_{60} in RPAE

pared to the atomic ones, e.g., in multielectron ionization and vacancy decay. In both of these channels, the interaction between atomic and fullerenes’ electrons is important. For example, the subvalent vacancies in noble gases decay only radiatively, since the decay energy is smaller than the outer electrons’ ionization potential. The presence of fullerenes’ electrons opens the Auger decay channel for subvalent vacancy [16, 38],

$$\gamma_{if}^{(A)A@C_N} = \gamma^{(\gamma)A} \frac{3}{8\pi} \left(\frac{c}{\omega_{if}} \right)^4 \frac{\sigma_{C_N}(\omega_{if})}{R_F^6}, \quad (24.75)$$

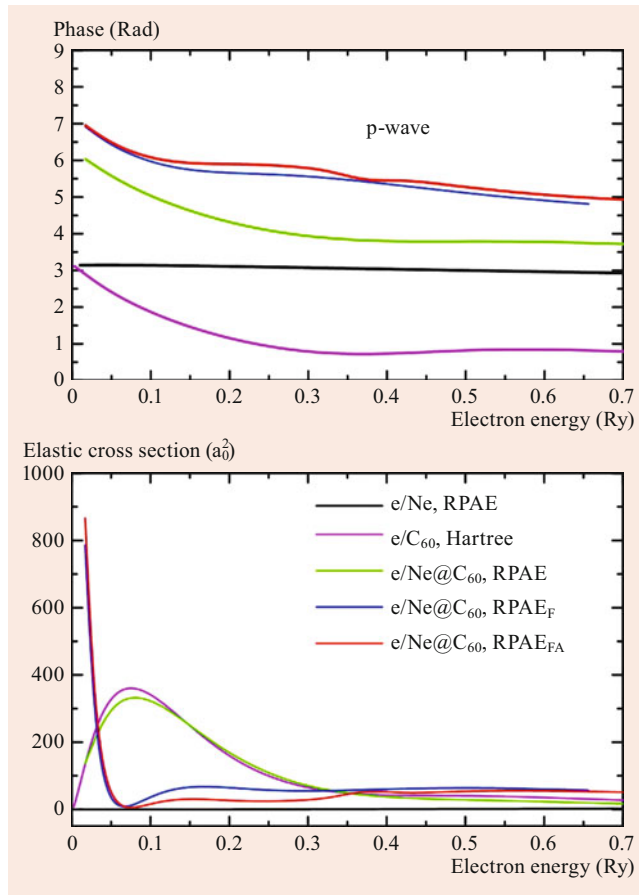

Fig. 24.8 Phases and cross sections of the p-wave contribution in electron collisions with $\text{Ne}@C_{60}$. Index F marks the inclusion of fullerenes' polarization potential, while FA denotes the mutual influence of Ne and C_{60} polarizations

where $\gamma_{if}^{(A)A@C_N}$ is the width of the noble gas endohedral subvalent i vacancy decay via electron transition $i \rightarrow j$ into the outer shell vacancy j , c is the speed of light, $\gamma^{(\gamma)A}$ is the pure atomic radiative decay probability, and $\sigma_{C_N}(\omega_{if})$ is the endohedrals photoionization cross section at frequency ω_{if} . The width in Eq. (24.75) increases by four to six orders of magnitude, as compared to $\gamma^{(\gamma)A}$.

The presence of A in $A@C_{60}$ strongly alters the low-energy $e^- + A@C_{60}$ cross section as compared to that of $e^- + C_{60}$, in spite of the fact that fullerene C_{60} is much bigger than the atom A . The quantum mechanical nature of this process is also reflected in a multitude of scattering resonances, maxima, and minima, including Ramsauer minimum in higher than $l = 0$ scattering waves, which is exemplified by Fig. 24.8 [46]. Of interest is the scattering $e^+ + A@C_{60}$ that differs from $e^- + A@C_{60}$ not only due to the lack of exchange but also due to effects of target polarization, which are different for $e^- + A@C_{60}$ and $e^+ + A@C_{60}$ processes [47].

24.3 Concluding Remarks

It is most convenient to apply diagrammatic techniques to closed shell objects whose ground state is nondegenerate. Degeneracy means that some of the energy denominators in Eq. (24.13) become zero with nonzero statistical weight. All such contributions must be summed to eliminate this degeneracy. This leads to strong mixing of some states. For example, the energy required for electron–vacancy transitions jn [see Eq. (24.38)] within an open shell is zero, thus leading to strong mixing of i and ijn states. If a pair with zero excitation energy has nonzero angular momentum, taking into account the mixing within such a pair destroys angular momentum as a characteristic of a one-vacancy state. This makes all calculations much more complicated, reflecting a specific feature of the degenerate physical system.

In using the diagrams and formulas presented above, it is essential that the interelectron and electron–nucleus interactions be purely potential. Inclusion of retardation and spin-dependence in the interparticle interaction makes the calculations much more complicated. These parts of the interaction appear as relativistic corrections. They are comparatively small in all but the heaviest atoms and can be taken into account perturbatively. Beyond lowest order, these additional interactions are strongly altered when virtual excitations of electron–vacancy pairs and the Coulomb interaction between them is taken into account. An example is given by the sequence of diagrams

The diagram shows a sequence of four terms representing different interaction paths. The first term is a simple scattering process with incoming momenta k_1 and k_2 and outgoing momenta k'_1 and k'_2 . The second term shows a loop interaction between the two particles. The third and fourth terms show more complex multi-loop interactions involving spin-dependent interactions (represented by heavy dashed lines) and electron–vacancy loops. The sequence is labeled (24.76).

where the heavy dashed line stands for the spin-dependent interelectron interaction. Note that here there are no electron–vacancy loops as in Eq. (24.38) because the Coulomb interaction is unable to affect the electron spin and thus to transfer spin excitations.

The same kind of diagrams describe the one-particle field acting upon an electron or vacancy due to the presence of spin–orbit interaction or weak interaction between electrons and the nucleus. For instance, the effective weak potential includes contributions from the sequence

The diagram shows a sequence of three terms representing interactions with a one-particle field. The first term is a simple scattering process with incoming momenta k_1 and k and outgoing momenta k' and k . The second and third terms show interactions with a field W_i (represented by a cross in a box) and include electron–vacancy loops. The sequence is labeled (24.77).

This is another example demonstrating how flexible and convenient the many-body approach is for considering different processes and interactions.

Abstract

This chapter outlines the theory of atomic photoionization and the dynamics of the photon–atom collision process. Those kinds of electron correlation that are most important in photoionization are emphasized, although many qualitative features can be understood within a central field model. The particle–hole type of electron correlations are discussed, as they are by far the most important for describing the single photoionization of atoms near ionization thresholds. Detailed reviews of atomic photoionization are presented in [1, 2] and [3]. Additional related aspects are well-described in two books [4, 5]. Also, reviews of experimental results for noble gas atom photoionization [6] and for metal atom photoionization [7] provide valuable information on the corresponding theoretical results. At the end of this chapter, some recent applications of the theory of atomic photoionization to few-photon ionization and to high-order harmonic generation are discussed.

25.1 General Considerations

25.1.1 The Interaction Hamiltonian

Consider an N -electron atom with nuclear charge Z . In the nonrelativistic approximation, it is described by the Hamiltonian

$$H = \sum_{i=1}^N \left(\frac{p_i^2}{2m} - \frac{Ze^2}{r_i} \right) + \sum_{i>j=1}^N \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (25.1)$$

The one-electron terms in brackets describe the kinetic and potential energy of each electron in the Coulomb field of the nucleus; the second set of terms describes the repulsive electrostatic potential energy between electron pairs. The interaction of this atom with external electromagnetic radiation is described by the additional terms obtained upon replacing \mathbf{p}_i by $\mathbf{p}_i + (|e|/c)\mathbf{A}(\mathbf{r}_i, t)$, where $\mathbf{A}(\mathbf{r}_i, t)$ is the vector po-

tential for the radiation. The interaction Hamiltonian is, thus,

$$H_{\text{int}} = \sum_{i=1}^N \left\{ \frac{+|e|}{2mc} [\mathbf{p}_i \cdot \mathbf{A}(\mathbf{r}_i, t) + \mathbf{A}(\mathbf{r}_i, t) \cdot \mathbf{p}_i] + \frac{e^2}{2mc^2} |\mathbf{A}(\mathbf{r}_i, t)|^2 \right\}. \quad (25.2)$$

Under the most common circumstance of single-photon ionization of an outer-subshell electron, the interaction Hamiltonian in Eq. (25.2) may be simplified considerably. First, the third term in Eq. (25.2) may be dropped, as it introduces two-photon processes (since it is of second order in \mathbf{A}). In any case, it is small compared with single-photon processes since it is of second order in the coupling constant $|e|/c$. Second, we choose the Coulomb gauge for \mathbf{A} , which fixes the divergence of \mathbf{A} as $\nabla \cdot \mathbf{A} = 0$; \mathbf{A} thus describes a transverse radiation field. Furthermore, \mathbf{p} and \mathbf{A} now commute, and, hence, the first and second terms in Eq. (25.2) may be combined. Third, we introduce the following form for \mathbf{A}

$$\mathbf{A}(\mathbf{r}_i, t) = \left(\frac{2\pi c^2 \hbar}{\omega V} \right)^{\frac{1}{2}} \hat{\boldsymbol{\epsilon}} e^{i(\mathbf{k} \cdot \mathbf{r}_i - \omega t)}. \quad (25.3)$$

This classical expression for \mathbf{A} may be shown [8] to give photoabsorption transition rates that are in agreement with those obtained using the quantum theory of radiation. Here, \mathbf{k} and ω are the wave vector and angular frequency of the incident radiation, $\hat{\boldsymbol{\epsilon}}$ is its polarization unit vector, and V is the spatial volume. Fourth, the *electric dipole* (E1) approximation, in which $\exp[i(\mathbf{k} \cdot \mathbf{r}_i)]$ is replaced by unity, is usually appropriate. The radii r_i of the atomic electrons are usually of order 1 Å. Thus, for $\lambda \gg 100$ Å, $|\mathbf{k} \cdot \mathbf{r}_i| \ll 1$. Now $\lambda \gg 100$ Å corresponds to photon energies $\hbar\omega \ll 124$ eV. For outer atomic subshells, most of the photoabsorption occurs for much smaller photon energies, thus validating the use of the E1 approximation. (This approximation cannot be used uncritically, however. For example, photoionization of excited atoms (which have large radii), photoionization of inner subshells (which requires the use of short wavelength radiation), and calculation of differential cross sections or other measurable quantities that are sensitive to the overlap of electric dipole and higher multipole amplitudes all require that the validity of the electric dipole approximation be checked.) The use of all of the above conventions and approximations allows the reduction of H_{int} in Eq. (25.2) to the simplified form

$$H_{\text{int}} = \frac{+|e|}{mc} \left(\frac{2\pi c^2 \hbar}{\omega V} \right)^{\frac{1}{2}} \sum_{i=1}^N \hat{\boldsymbol{\epsilon}} \cdot \mathbf{p}_i \exp(-i\omega t); \quad (25.4)$$

H_{int} thus has the form of a harmonically time-dependent perturbation. According to time-dependent perturbation theory, the photoionization cross section is proportional to the absolute square of the matrix element of Eq. (25.4) between

the initial and final electronic states described by the atomic Hamiltonian in Eq. (25.1). Atomic units, in which $|e| = m = \hbar = 1$, are used in what follows.

25.1.2 Alternative Forms for the Transition Matrix Element

The matrix element of Eq. (25.4) is proportional to the matrix element of the momentum operator $\sum_i \mathbf{p}_i$. Alternative expressions for this matrix element may be obtained from the following operator equations involving commutators of the exact atomic Hamiltonian in Eq. (25.1)

$$\sum_{i=1}^N \mathbf{p}_i = -i \left[\sum_{i=1}^N \mathbf{r}_i, H \right], \quad (25.5)$$

$$\left[\sum_{i=1}^N \mathbf{p}_i, H \right] = -i \sum_{i=1}^N \frac{\mathbf{Z} \mathbf{r}_i}{r_i^3}. \quad (25.6)$$

Matrix elements of Eqs. (25.5) and (25.6) between eigenstates $\langle \psi_0 |$ and $|\psi_f \rangle$ of H having energies E_0 and E_f , respectively, give

$$\langle \psi_0 | \sum_{i=1}^N \mathbf{p}_i | \psi_f \rangle = -i\omega \langle \psi_0 | \sum_{i=1}^N \mathbf{r}_i | \psi_f \rangle, \quad (25.7)$$

$$\langle \psi_0 | \sum_{i=1}^N \mathbf{p}_i | \psi_f \rangle = \frac{-i}{\omega} \langle \psi_0 | \sum_{i=1}^N \frac{\mathbf{Z} \mathbf{r}_i}{r_i^3} | \psi_f \rangle, \quad (25.8)$$

where $\omega = E_f - E_0$. Matrix elements of $\sum_{i=1}^N \mathbf{p}_i$, $\sum_{i=1}^N \mathbf{r}_i$, and $\sum_{i=1}^N \mathbf{Z} \mathbf{r}_i / r_i^3$ are known as the *velocity*, *length*, and *acceleration* forms of the E1 matrix element. Equality of the matrix elements in Eqs. (25.7) and (25.8) does not hold when approximate eigenstates of H are used [9]. In such a case, qualitative considerations may help to determine which form is most reliable. For example, the length form tends to emphasize the large r part of the approximate wave functions, the acceleration form tends to emphasize the small r part of the wave functions, and the velocity form tends to emphasize intermediate values of r .

If instead of employing approximate eigenstates of the exact H , one employs exact eigenstates of an approximate N -electron Hamiltonian, then inequality of the matrix elements in Eqs. (25.7) and (25.8) is a measure of the nonlocality of the potential in the approximate Hamiltonian [10–12]. The exchange part of the Hartree–Fock potential is an example of such a nonlocal potential. Nonlocal potentials are also implicitly introduced in configuration interaction calculations employing a finite number of configurations [10–12]. One may eliminate the ambiguity of which form of the E1 transition operator to use by requiring that the Schrödinger equation be gauge invariant. Only the length form is consistent with such gauge invariance [10–12].

However, equality of the alternative forms of the transition operator does not necessarily imply high accuracy. For example, they are exactly equal when one uses an approximate local potential to describe the N -electron atom, as in a central potential model, even though the accuracy is often poor. The length and velocity forms are also exactly equal in the random phase approximation with exchange (RPAE) [1, 3], which generally gives accurate cross sections for single photoionization of closed shell atoms. No general prescription exists, however, for ensuring that the length and velocity matrix elements are equal at each level of approximation to the N -electron Hamiltonian. However, if all corrections of a given order in interelectron interaction are taken into account, length and velocity matrix elements are equal [3].

25.1.3 Selection Rules for Electric Dipole Transitions

If one ignores relativistic interactions, then a general atomic photoionization process may be described in LS -coupling as follows

$$\mathcal{A}(L, S, M_L, M_S, \pi_{\mathcal{A}}) + \gamma(\pi_{\gamma}, \ell_{\gamma}, m_{\gamma}) \longrightarrow \mathcal{A}^+(\bar{L}\bar{S}\pi_{\mathcal{A}^+})\varepsilon\ell(L', S', M_{L'}, M_{S'}) . \quad (25.9)$$

Here, the atom \mathcal{A} is ionized by the photon γ to produce a photoelectron with kinetic energy ε and orbital angular momentum ℓ . The photoelectron is coupled to the ion \mathcal{A}^+ with total orbital and spin angular momenta L' and S' . In the electric dipole approximation, the photon may be regarded as having odd parity, i.e., $\pi_{\gamma} = -1$, and unit angular momentum, i.e., $\ell_{\gamma} = 1$. This is obvious from Eqs. (25.7) and (25.8), where the E1 operator is seen to be a vector operator. The component m_{γ} of the photon in the E1 approximation is ± 1 for right or left circularly polarized light and 0 for linearly polarized light. (The z axis is taken as $\hat{\mathbf{k}}$ in the case of circularly polarized light and as $\hat{\mathbf{e}}$ in the case of linearly polarized light, where \mathbf{k} and $\hat{\mathbf{e}}$ are defined in Eq. (25.3).) Angular momentum and parity selection rules for the E1 transition in Eq. (25.9) imply the following relations between the initial and final state quantum numbers

$$L' = L \oplus 1 = \bar{L} \oplus \ell , \quad (25.10)$$

$$M_{L'} = M_L + m_{\gamma} = M_{\bar{L}} + m_{\ell} , \quad (25.11)$$

$$S' = S = \bar{S} \oplus \frac{1}{2} , \quad (25.12)$$

$$M_{S'} = M_S = M_{\bar{S}} + m_s , \quad (25.13)$$

$$\pi_{\mathcal{A}}\pi_{\mathcal{A}^+} = (-1)^{\ell+1} . \quad (25.14)$$

Equation (25.14) follows from the parity $(-1)^{\ell}$ of the photoelectron. The direct sum symbol \oplus denotes the vector addition of \mathbf{A} and \mathbf{B} , i.e., $\mathbf{A} \oplus \mathbf{B} = \mathbf{A} + \mathbf{B}, \mathbf{A} + \mathbf{B} - 1, \dots, |\mathbf{A} - \mathbf{B}|$.

In Eq. (25.9), the quantum numbers $\alpha \equiv \bar{L}, \bar{S}, \pi_{\mathcal{A}^+}, \ell, L', S', M_{L'}, M_{S'}$ (plus any other quantum numbers needed to specify the state of the ion \mathcal{A}^+ uniquely) define a final state *channel*. All final states that differ only in the photoelectron energy ε belong to the same channel. The quantum numbers $L', S', M_{L'}, M_{S'}$, and $\pi_{\text{tot}} = (-1)^{\ell} \pi_{\mathcal{A}^+}$ are the only good quantum numbers for the final states. Thus, the Hamiltonian Eq. (25.1) mixes final state channels having the same angular momentum and parity quantum numbers but differing quantum numbers for the ion and the photoelectron; i.e., differing $\bar{L}, \bar{S}, \pi_{\mathcal{A}^+}$, and ℓ but the same $L', S', M_{L'}, M_{S'}$ and $(-1)^{\ell} \pi_{\mathcal{A}^+}$.

25.1.4 Boundary Conditions on the Final State Wave Function

Photoionization calculations obtain final state wave functions satisfying the asymptotic boundary condition that the photoelectron is ionized in channel α . This boundary condition is expressed as

$$\begin{aligned} & \psi_{\alpha E}^{-}(\mathbf{r}_1 s_1, \dots, \mathbf{r}_N s_N) \\ & \xrightarrow{r_N \rightarrow \infty} \theta_{\alpha}(\mathbf{r}_1 s_1, \dots, \hat{\mathbf{r}}_N s_N) \frac{1}{i(2\pi k_{\alpha})^{\frac{1}{2}}} \frac{1}{r_N} e^{i\Delta_{\alpha}} \\ & - \sum_{\alpha'} \theta_{\alpha'}(\mathbf{r}_1 s_1, \dots, \hat{\mathbf{r}}_N s_N) \frac{1}{i(2\pi k_{\alpha'})^{\frac{1}{2}}} \frac{1}{r_N} e^{-i\Delta_{\alpha'}} S_{\alpha'\alpha}^{\dagger} , \end{aligned} \quad (25.15)$$

where the phase appropriate for a Coulomb field is

$$\Delta_{\alpha} \equiv k_{\alpha} r_N - \frac{1}{2} \pi \ell_{\alpha} + \frac{1}{k_{\alpha}} \log 2k_{\alpha} r_N + \sigma_{\ell_{\alpha}} . \quad (25.16)$$

The minus superscript on the wave function in Eq. (25.15) indicates an *incoming wave* normalization; i.e., asymptotically $\psi_{\alpha E}^{-}$ has outgoing spherical Coulomb waves only in channel α , while there are incoming spherical Coulomb waves in all channels; $S_{\alpha'\alpha}^{\dagger}$ is the Hermitian conjugate of the S -matrix of scattering theory, θ_{α} indicates the coupled wave function of the ion and the angular and spin parts of the photoelectron wave function, k_{α} is the photoelectron momentum in channel α and ℓ_{α} is its orbital angular momentum, and $\sigma_{\ell_{\alpha}}$ in Eq. (25.16) is the Coulomb phase shift.

While one calculates channel functions $\psi_{\alpha E}^{-}$, experimentally one measures photoelectrons that asymptotically have well-defined linear momenta \mathbf{k}_{α} and well-defined spin states $m_{\frac{1}{2}}$, and ions in well-defined states $\bar{\alpha} \equiv \bar{L}\bar{S}M_{\bar{L}}M_{\bar{S}}$. The wave function appropriate for this experimental situation is related to the channel functions by uncoupling the ionic and electronic orbital and spin angular momenta and projecting the photoelectron angular momentum states $\ell_{\alpha}, m_{\alpha}$ onto the direction $\hat{\mathbf{k}}_{\alpha}$ by means of the spherical harmonic $Y_{\ell_{\alpha} m_{\alpha}}^*(k_{\alpha})$.

This relation is [2]

$$\begin{aligned} & \psi_{\bar{\alpha}k_\alpha}^-(\mathbf{r}_1s_1, \dots, \mathbf{r}_Ns_N) \\ &= \sum_{\ell_\alpha m_\alpha} \frac{i^{\ell_\alpha} \exp(-i\sigma_{\ell_\alpha})}{k_\alpha^{\frac{1}{2}}} Y_{\ell_\alpha m_\alpha}^*(\hat{\mathbf{k}}_\alpha) \\ & \times \sum_{LM_L SM_S} \langle \bar{L}M_{\bar{L}} \ell_\alpha m_\alpha | LM_L \rangle \\ & \times \langle \bar{S}M_{\bar{S}} \frac{1}{2} m_{\frac{1}{2}} | SM_S \rangle \psi_{\bar{\alpha}E}^-(\mathbf{r}_1s_1, \dots, \mathbf{r}_Ns_N), \end{aligned} \quad (25.17)$$

where the coefficients in brackets are Clebsch–Gordan coefficients. This wave function is normalized to a delta function in momentum space, i.e.,

$$\int (\psi_{\bar{\alpha}k_\alpha}^-)^\dagger \psi_{\bar{\alpha}'k_{\alpha'}}^- d^3\mathbf{r} = \delta_{\bar{\alpha}\bar{\alpha}'} \delta(\mathbf{k}_\alpha - \mathbf{k}_{\alpha'}). \quad (25.18)$$

The factors $i^{\ell_\alpha} \exp(-i\sigma_{\ell_\alpha}) k_\alpha^{-\frac{1}{2}}$ ensure that for large r_N , Eq. (25.17) represents a Coulomb wave (with momentum \mathbf{k}_α) times the ionic wave function for the state $\bar{\alpha}$ plus a sum of terms representing incoming spherical waves. Thus, only the ionic term $\bar{\alpha}$ has an outgoing wave. One uses the wave function in Eq. (25.17) to calculate the angular distribution of photoelectrons.

25.1.5 Photoionization Cross Sections

If one writes H_{int} in Eq. (25.4) as $H_{\text{int}}(t) = H_{\text{int}}(0) e^{-i\omega t}$, then from first-order time-dependent perturbation theory, the transition rate for the transition from an initial state with energy E_0 and wave function ψ_0 to a final state with total energy E_f and wave function $\psi_{\bar{\alpha}k_\alpha}^-$ is

$$\begin{aligned} dW_{k_\alpha} &= 2\pi |\langle \psi_0 | H_{\text{int}}(0) | \psi_{\bar{\alpha}k_\alpha}^- \rangle|^2 \\ & \times \delta(E_f - E_0 - \omega) k_\alpha^2 dk_\alpha d\Omega(\hat{\mathbf{k}}_\alpha). \end{aligned} \quad (25.19)$$

The delta function expresses energy conservation, and the last factors on the right-hand side are the phase space factors for the photoelectron. Dividing the transition rate by the incident photon current density c/V , integrating over dk_α , and inserting $H_{\text{int}}(0)$, the differential photoionization cross section is

$$\frac{d\sigma_{\bar{\alpha}}}{d\Omega} = \frac{4\pi^2}{c} \frac{k_\alpha}{\omega} \left| \hat{\boldsymbol{\epsilon}} \cdot \langle \psi_0 | \sum_{i=1}^N \mathbf{p}_i | \psi_{\bar{\alpha}k_\alpha}^- \rangle \right|^2. \quad (25.20)$$

Implicit in Eqs. (25.19) and (25.20) is an average over initial magnetic quantum numbers $M_{L_0} M_{S_0}$ and a sum over final magnetic quantum numbers $M_{\bar{L}} M_{\bar{S}} m_{\frac{1}{2}}$. The length form of Eq. (25.20) is obtained by replacing each \mathbf{p}_i by $\omega \mathbf{r}_i$ Eq. (25.7).

Substitution of the final state wave function Eq. (25.17) in Eq. (25.20) permits one to carry out the numerous summations over magnetic quantum numbers and obtain the form

$$\frac{d\sigma_{\bar{\alpha}}}{d\Omega} = \frac{\sigma_{\bar{\alpha}}}{4\pi} [1 + \beta P_2(\cos \theta)] \quad (25.21)$$

for the differential cross section [13]. Here, $\sigma_{\bar{\alpha}}$ is the partial cross section for leaving the ion in the state $\bar{\alpha}$, β is the asymmetry parameter [23], $P_2(\cos \theta) = \frac{3}{2} \cos^2 \theta - \frac{1}{2}$, and θ indicates the direction of the outgoing photoelectron with respect to the polarization vector $\hat{\boldsymbol{\epsilon}}$ of the incident light. The form of Eq. (25.21) follows in the electric dipole approximation from general symmetry principles, provided that the target atom is unpolarized [15]. The partial cross section is given in terms of reduced E1 matrix elements [14] involving the channel functions in Eq. (25.15) by

$$\sigma_{\bar{\alpha}} = \frac{4\pi^2}{3c} \omega [L]^{-1} \sum_{\ell_\alpha L'} \left| \langle \psi_0 | \left\| \sum_{i=1}^N r_i \right\|^{[1]} | \psi_{\bar{\alpha}E}^- \rangle \right|^2. \quad (25.22)$$

The β parameter has a much more complicated expression involving interference between different reduced dipole amplitudes [16, 23]. Thus, measurement of β provides information on the relative phases of the alternative final state channel wave functions, whereas the partial cross section in Eq. (25.22) does not. From the requirement that the differential cross section in Eq. (25.21) be positive, one can see that $-1 \leq \beta \leq +2$.

25.2 An Independent Electron Model

The many-body wave functions ψ_0 and $\psi_{\bar{\alpha}E}^-$ are usually expressed in terms of a basis of independent electron wave functions. Key qualitative features of photoionization cross sections can often be interpreted in terms of the overlaps of initial and final state one-electron radial wave functions [2, 14]. The simplest independent electron representation of the atom, the central potential model, proves useful for this purpose.

25.2.1 Central Potential Model

In the central potential (CP) model, the exact H in Eq. (25.1) is approximated by a sum of single-particle terms describing the independent motion of each electron in a central potential $V(r)$

$$H_{\text{CP}} = \sum_{i=1}^N \left[\frac{p_i^2}{2m} + V(r_i) \right]. \quad (25.23)$$

The potential $V(r)$ must describe the nuclear attraction and the electron–electron repulsion as well as possible and must satisfy the boundary condition

$$V(r) \xrightarrow{r \rightarrow 0} -Z/r \quad \text{and} \quad V(r) \xrightarrow{r \rightarrow \infty} -1/r \quad (25.24)$$

in the case of a neutral atom; H_{CP} is separable in spherical coordinates and its eigenstates can be written as Slater determinants of one-electron orbitals of the form $r^{-1}P_{n\ell}Y_{\ell m}(\Omega)$ for bound orbitals and of the form $r^{-1}P_{\varepsilon\ell}(r)Y_{\ell m}(\Omega)$ for continuum orbitals. The one-electron radial wave functions satisfy

$$\frac{d^2P_{\varepsilon\ell}(r)}{dr^2} + 2\left[\varepsilon - V(r) - \frac{\ell(\ell+1)}{2r^2}\right]P_{\varepsilon\ell}(r) = 0, \quad (25.25)$$

subject to the boundary condition $P_{\varepsilon\ell}(0) = 0$, and similarly for the discrete orbitals $P_{n\ell}(r)$. *Hermann* and *Skillman* [17] have tabulated a widely used central potential for each element in the periodic table, as well as radial wave functions for each occupied orbital in the ground state of each element.

25.2.2 High Energy Behavior

The hydrogen atom cross section, which is nonzero at threshold and decreases monotonically with increasing photon energy, serves as a model for inner-shell photoionization cross sections in the X-ray photon energy range. A sharp onset at threshold followed by a monotonic decrease above threshold is precisely the behavior seen in X-ray photoabsorption measurements. A simple hydrogenic approximation at high energies may be justified theoretically as follows: (1) Since a free electron cannot absorb a photon (because of kinematical considerations), at high photon energies one expects the more strongly bound inner electrons to be preferentially ionized as compared with the outer electrons. (2) Since the $P_{n\ell}(r)$ for an inner electron is concentrated in a very small range of r , one expects the integrand of the radial dipole matrix element to be negligible except for those values of r where $P_{n\ell}(r)$ is greatest. (3) Thus, it is only necessary to approximate the atomic potential locally, e.g., by means of a screened Coulomb potential

$$V_{n\ell}(r) = -\left(\frac{Z - s_{n\ell}}{r}\right) + V_{n\ell}^o \quad (25.26)$$

appropriate for the $n\ell$ orbital. Here, $s_{n\ell}$ is the *inner-screening* parameter, which accounts for the screening of the nuclear charge by the other atomic electrons, and $V_{n\ell}^o$ is the *outer-screening* parameter, which accounts for the lowering of the

$n\ell$ electrons' binding energy due to repulsion between the outer electrons and the photoelectron as the latter leaves the atom. The potential in Eq. (25.26) predicts hydrogen-like photoionization cross sections for inner-shell electrons with onsets determined by the outer-screening parameters $V_{n\ell}^o$.

The use of more accurate atomic central potentials in place of the screened hydrogenic potential in Eq. (25.26) generally enables one to obtain photoionization cross sections below the keV photon energy region to within 10% of the experimental results [18]. For $\ell > 0$, subshells and photon energies in the keV region and above, the independent particle model becomes increasingly inadequate owing to coupling with nearby ns -subshells, which generally have larger partial cross sections at high photon energies [19]. For high, but still nonrelativistic, photon energies, i.e., $\omega \ll mc^2$, the energy dependence of the cross section for the $n\ell$ subshell within the independent particle model is [20]

$$\sigma_{n\ell} \approx \omega^{-\ell-\frac{7}{2}}. \quad (25.27)$$

However, when interchannel interactions are taken into account, the asymptotic energy dependence for subshells having $\ell > 0$ becomes independent of ℓ [21]

$$\sigma_{n\ell} \approx \omega^{-\frac{9}{2}} (\ell > 0). \quad (25.28)$$

This result stems from coupling of the $\ell > 0$ photoionization channels with nearby s -subshell channels.

25.2.3 Near-Threshold Behavior

For photons in the vacuum ultra violet (VUV) energy region, i.e., near the outer-subshell ionization thresholds, the photoionization cross sections for subshells with $\ell \geq 1$ frequently have distinctly nonhydrogenic behavior [22, 24]. The cross section, instead of decreasing monotonically as for hydrogen, rises above threshold to a maximum (the so-called *delayed maximum* above threshold). Then it decreases to a minimum (the *Cooper minimum* [25, 26]) and rises to a second maximum. Finally, the cross section decreases monotonically at high energies in accordance with hydrogenic behavior. Such nonhydrogenic behavior may be interpreted as due either to an effective potential barrier or to a zero in the radial dipole matrix element. We examine each of these effects in turn. The *delayed maximum* above outer subshell ionization thresholds of heavy atoms (i.e., $Z \gtrsim 18$) is due to an *effective potential barrier* seen by $\ell = 2$ and $\ell = 3$ photoelectrons in the region of the outer edge of the atom Eq. (25.25). This effective potential lowers the probability of photoelectron escape until the photoelectrons have enough excess energy to surmount the barrier. Such behavior is nonhydrogenic. Furthermore, in cases where an inner subshell with $\ell = 2$ or 3

is being filled as Z increases (as in the transition metals, the lanthanides and the actinides) there is a double well potential. This double well has profound effects on the $3p$ -subshell spectra of the transition metals, the $4d$ -subshell spectra of the lanthanides, and the $5d$ -subshell spectra of the actinides, as well as on atoms with Z just below those of these series of elements [27, 28]. The potential barrier effects on the photoionization cross sections of these elements are often referred to as “giant dipole resonances”. In fact, to describe the $4d$ subshell, interaction of at least all $4d$ electrons has to be taken into account. The many-electron nature of “giant dipole resonances” is presented in Chap. 24 (also [1]).

Cross section minima arise due to a change in sign of the radial dipole transition matrix element in a particular channel [29, 30]. Rules for predicting their occurrence were developed in [25, 26]. Studies of their occurrence in photoionization from excited states [31], in high Z atoms [32], and in relativistic approximation [33] have been carried out. A proof has been given [34] that such minima do not occur in atomic hydrogen spectra. For other elements, there are further rules on when and how many minima may occur [35–37].

Often within such minima, one can observe the effects of weak interactions that are otherwise obscured. Relativistic and weak correlation effects on the asymmetry parameter β for s -subshells is a notable example [38]. Wang et al. [39] also emphasized that near such minima in the E1 amplitudes, one cannot ignore the effects of quadrupole and higher corrections to the differential cross section. Central potential model calculations [39] show that quadrupole corrections can be as large as 10% of the E1 cross section at such cross section minima, even for low photon energies. Particularly strong is the role of quadrupole effects in the so-called nondipole angular anisotropy parameters (e.g., [40]).

25.3 Particle–Hole Interaction Effects

The experimental photoionization cross sections for the outer subshells of the noble gases have played a prominent role in the development of the theory of photoionization for two reasons. These were among the first elements studied by experimentalists with synchrotron radiation beginning in the 1960s. Also, their closed-shell, spherically symmetric ground states simplified the theoretical analysis of their cross sections. The cross sections near the ionization thresholds can be understood in terms of interactions between the photoelectron, the residual ion, and the photon field that are called, in many-body theory language, *particle–hole* interactions (Chap. 24). These may be described as interactions in which two electrons either excite or de-excite each other out of or into their initial subshell locations in the unexcited atom. To analyze the effects of these interactions on the cross section, it is con-

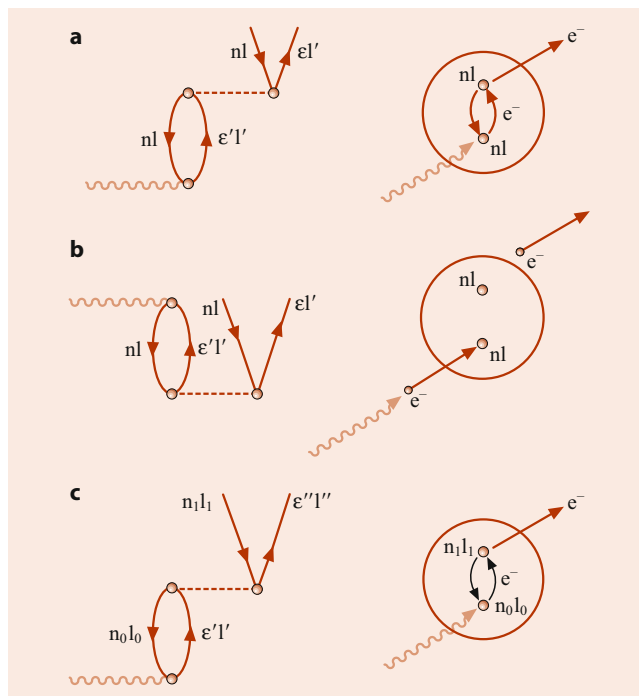

Fig. 25.1 MBPT diagrams (*left*) and scattering pictures (*right*) for three kinds of particle–hole interaction: (a) intrachannel scattering following photoabsorption; (b) photoabsorption by a virtual doubly excited state; (c) interchannel scattering following photoabsorption

venient to classify them into three categories: intrachannel, virtual double excitation, and interchannel. In many publications, however, another classification is used: intrasubshell and intersubshell correlations (Chap. 24). These alternative kinds of particle–hole interactions are illustrated in Fig. 25.1 using both many-body perturbation theory (MBPT) diagrams and more *physical* scattering pictures. We discuss each of these types of interaction in turn.

25.3.1 Intrachannel Interactions

The MBPT diagram for this interaction is shown on the left-hand side of Fig. 25.1a; on the right-hand side, a slightly more pictorial description of this interaction is shown. The wiggly line indicates a photon, which is absorbed by the atom in such a way that an electron is excited out of the nl subshell. During the escape of this excited electron, it collides or interacts with another electron from the same subshell in such a way that the second electron absorbs all the energy imparted to the atom by the photon; the first electron is de-excited back to its original location in the nl subshell. For closed-shell atoms, the photoionization process leads to a 1P_1 final state in which the intrachannel interaction is strongly repulsive. This interaction tends to broaden cross section maxima and push them to higher photon energies as compared with the results of central potential model calculations.

Intrachannel interaction effects are taken into account automatically when the correct Hartree–Fock (HF) basis set is employed, in which the photoelectron sees a net Coulomb field due to the residual ion and is coupled to the ion to form the appropriate total orbital L and spin S angular momenta [3]. Any other basis set requires explicit treatment of intrachannel interactions.

25.3.2 Virtual Double Excitations

The MBPT diagram for this type of interaction is shown on the left-hand side of Fig. 25.1b. Topologically, this diagram is the same as that on the left-hand side in Fig. 25.1a. In fact, the radial parts of the two matrix elements are identical; only the angular factors differ. A more pictorial description of this interaction is shown on the right-hand side of Fig. 25.1b. The ground state of the atom before photoabsorption is shown to have two electrons virtually excited out of the $n\ell$ subshell. In absorbing the photon, one of these electrons is de-excited to its original location in the $n\ell$ subshell, while the other electron is ionized. These virtual double excitations imply a more diffuse atom than in central-potential or HF models, with the effect that the overly repulsive intrachannel interactions are weakened, leading to cross sections for noble gas atoms that are in very good agreement with experiment with the exception that resonance features are not predicted. As an impressive example of strong intrachannel coupling serves the formation of so-called atomic giant resonance (Chap. 24, Fig. 24.2).

25.3.3 Interchannel Interactions

The interchannel interaction shown in Fig. 25.1c is important, particularly for s subshells. This interaction has the same form as the intrachannel interaction shown in Fig. 25.1a, except now when an electron is photoexcited out of the $n_0\ell_0$ subshell, it collides or interacts with an electron in a different subshell – the $n_1\ell_1$ subshell. This interaction causes the second electron to be ionized, and the first electron to fall back into its original location in the $n_0\ell_0$ subshell.

Interchannel interaction effects are usually very conspicuous features of photoionization cross sections. When the interacting channels have partial photoionization cross sections that differ greatly in magnitude, one finds that the calculated cross section for the weaker channel is completely dominated by its interaction with the stronger channel. A good example of interchannel (or intershell) interaction is the photoionization cross section of $5s$ subshell in Xe that is totally determined by $5s$ interaction with its many-electron neighboring $5p$ and $4d$ subshells (Chap. 24, Fig. 24.3). At the same time, it is often a safe approximation to ignore

the effect of weak channels on stronger channels. In addition, when the interacting channels have differing binding energies, their interchannel interactions lead to a resonance structure in the channel with lower binding energy (arising from its coupling to the Rydberg series in the channel with higher binding energy).

At high photon energies, s -subshell partial cross sections dominate over $\ell > 0$ subshell partial cross sections (Eqs. (25.27), (25.28)). Hence, interchannel interactions of $\ell > 0$ subshells with nearby s -subshells change independent particle model predictions significantly. In particular, as noted in Sect. 25.3.2, such interactions can drastically change the magnitudes of the $\ell > 0$ partial cross sections [19], as well as their asymptotic energy behavior [21].

25.3.4 Photoionization of Ar

An example of both the qualitative features exhibited by photoionization cross sections in the VUV energy region and of the ability of the theory to calculate photoionization cross reactions accurately is provided by photoionization of the $n = 3$ subshell of argon, i.e.,

First calculations of photoionization cross section of Ar $3p_6$ subshell with account of many-electron correlations was performed by *Amusia et al.* [41] in RPAE. Good agreement with experiment was achieved. Figure 25.2 shows the MBPT calculation of *Kelly and Simons* [42], which includes both intrachannel and interchannel interactions, as well as the effect of virtual double excitations. The cross section is in excellent agreement with experiment [43, 44], even to the extent of describing the resonance behavior due to discrete members of the $3s \rightarrow \epsilon p$ channel.

Figure 25.2 illustrates most of the features of photoionization cross sections described so far. First, the cross section rises to a delayed maximum just above the threshold because of the potential barrier seen by photoelectrons from the $3p$ subshell having $\ell = 2$. For photon energies in the range of 45–50 eV, the calculated cross section goes through a minimum because of a change in sign of the $3p \rightarrow \epsilon d$ radial dipole amplitude. The HFL and HFV calculations include the strongly repulsive intrachannel interactions in the 1P final-state channels and calculate the transition amplitude using the length (L) and velocity (V) form, respectively, for the electric dipole transition operator Eq. (25.7). With respect to the results of central potential model calculations, the HFL and HFV results have lower and broader maxima at higher energies. They also disagree with each other by a factor of 2! Inclusion of virtual double excitations results in length and

Fig. 25.2 Photoionization cross section for the 3p and 3s subshells of Ar. HFL and HFV indicate the length and velocity results obtained using HF orbitals calculated in a 1P_1 potential. Dot-dash and dashed lines represent the length and velocity results of the MBPT calculation of Kelly and Simons [42]. Only the four lowest $3s \rightarrow np$ resonances are shown; the series converges to the 3s threshold at 29.24 eV. Experimental results are those of Samson [43] above 37 eV and of Madden et al. [44] below 37 eV (after [42])

velocity results that agree to within 10% with each other and with experiment, except that the resonance structures are not reproduced. Finally, taking into account the interchannel interactions, one obtains the length and velocity form results shown in Fig. 25.2 by dash-dot and dashed curves, respectively. The agreement with experiment is excellent, and the observed resonances are well reproduced.

25.4 Theoretical Methods for Photoionization

25.4.1 Computational Methods

Most of the ab initio methods for the calculation of photoionization cross sections (e.g., the MBPT method [45], the close-coupling (CC) method [46], the R-matrix method [47, 48], the random phase approximation with exchange (RPAE) method [1, 3, 49], the relativistic RPAE method [50], the transition matrix method [51, 52], the multiconfiguration Hartree–Fock (MCHF) method [53–55], time-dependent multiconfiguration methods [56], etc.) have successfully calculated outer p -subshell photoionization cross sections of the noble gases by treating in their alternative ways the key interactions described above, i.e., the particle–hole interactions. In general, these methods all treat both intrachannel and interchannel interactions to infinite order and differ only in their treatment of ground state correlations. (The exception is MBPT, which often treats interchannel interactions between weak and strong channels only to first or second order.) These methods, therefore, stand in contrast to central potential model calculations, which do not treat any

of the particle–hole interactions, and single-channel term-dependent HF calculations, which treat only the intrachannel interactions. The key point is that selection of the interactions that are included in a particular calculation is more important than the method by which such interactions are handled.

Treatment of the photoionization of atoms other than the noble gases presents additional challenges for theory. For example, elements such as the alkaline earths, which have s^2 outer subshells, require careful treatment of electron pair excitations in both initial and final states. Open-shell atoms have many more ionization thresholds than do the noble gases. Treatment of the resultant rich resonance structures typically relies heavily on quantum defect theory [55] (Chap. 32). All the methods listed above can be used to treat elements other than the noble gases, but a method that has come to prominence because of the excellent results it obtains for both alkaline earth and open-shell atoms is the eigenchannel R-matrix method [57].

25.4.2 Other Interaction Effects

A number of interactions, not of the particle–hole type, lead to conspicuous effects in localized energy regions. When treating photoionization in such energy regions, one must be careful to choose a theoretical method that is appropriate. Among the interactions that may be important are the following:

Relativistic and spin-dependent interactions The fact that $j = \ell - \frac{1}{2}$ electrons are contracted more than $j = \ell + \frac{1}{2}$ electrons at small distances has an enormous effect on the location of cross section minima in heavy elements [18, 58]. It may explain the large differences observed in the profiles of a resonance decaying to final states that differ only in their fine structure quantum numbers [59]. Impressive effects in the photoionization cross section appear due to interaction not only between inner but also intermediate sublevels $\ell + \frac{1}{2}$ and $\ell - \frac{1}{2}$ [60].

Inner-shell vacancy rearrangement Inner-shell vacancies often result in a significant production of satellite structures in photoelectron spectra. Calculations for inner-subshell partial photoionization cross sections are often substantially larger than results of photoelectron measurements [61–63]. This difference is attributed to such satellite production that is often not treated in theoretical calculations, as well as to effect of inner-shell rearrangement, due to its ionization, upon the outgoing photoelectron [3, 49].

Polarization and relaxation effects Negative ion photodetachment cross sections often exhibit strong effects of core polarization near the threshold. These effects can be treated

semempirically, resulting in excellent agreement between theory and experiment [64]. Even for inner-shell photoionization cross sections of heavy elements, *ab initio* theories do not reproduce measurements near threshold without the inclusion of polarization and relaxation effects [65, 66].

An example The calculation of the energy dependence of the asymmetry parameter β for the $5s$ subshell of xenon requires the theoretical treatment of all of the above effects. In the absence of relativistic interactions, β for Xe $5s$ would have the energy-independent value of 2. Deviations of β from 2 are, therefore, an indication of the presence of these relativistic interactions. The greatest deviation of β from 2 occurs in the localized energy region where the partial photoionization cross section for the $5s$ subshell has a minimum. In this region, however, relativistic calculations show larger deviations from 2 than are observed experimentally. Inner-shell rearrangement and relaxation effects play an important role [67, 68] and must be included to achieve good agreement with experiment.

25.5 Related Photoionization Processes

One of the most intensively studied areas in atomic photoionization has been the *double photoionization of the helium atom*. Extensive sets of experimental measurements for the two electron angular distributions (i.e., the triply differential cross sections) have provided stringent tests for various theoretical models and their treatments of electron correlations. A number of excellent reviews of this field have been published recently [69–71].

Another intensively studied area has been the analysis and measurement of *nondipole effects in photoionization*, which were first observed in the X-ray region [72] but have been found to be significant even in the VUV photon energy region [73, 74]. In general, these effects stem from interference between electric quadrupole and the (usual) electric dipole transition amplitudes in differential cross sections (for a review, [75]). Besides asymmetries in the photoelectron angular distributions, nondipole effects also lead to new features for spin-resolved measurements [76, 77], and for the case of polarized atoms [78]. Nondipole effects have been predicted to be significant also in double photoionization of helium at relatively low photon energies [79]. In fact, the so-called “back-to-back” two-electron photoionization, predicted quite long ago [80] and experimentally observed recently [81], is entirely nondipole.

Finally, both experimental and theoretical *studies of ionic species* have flourished since the 1990s. In particular, photodetachment of negative ions near excited atomic thresholds provides an opportunity to study correlated, three-body Coulomb states unencumbered by Rydberg series. The ad-

vent of powerful computer workstations in the 1990s enabled theorists to carry out numerical calculations for such high, doubly excited states with spectroscopic accuracy. Following experiments for photodetachment of H^- with excitations of atomic levels in $H(n > 2)$, theorists developed propensity rules for identifying and characterizing the dominant photodetachment channels [82–84]. Experimental and theoretical [85–88] interest also focused on the negative alkali ions (e.g., Li^- and Na^-), which for low photon energies have outer electron detachment spectra grossly resembling that of H^- . However, the negative alkali spectra contain clear signatures of propensity-rule-forbidden states that become increasingly prominent as the atomic number increases (owing to the nonhydrogenic inner electron cores). A brief review of low-energy negative alkali photodetachment is given in [89]. Among the more general features brought to light by these studies is the mirroring of resonance profiles in alternative partial cross sections, which appears to be a very general phenomenon common to photodetachment and photoionization processes involving highly excited residual atoms or ions [90].

Recently, high-energy (K -shell) photodetachment of the negative ions Li^- and He^- (resulting in two-electron ionization) was studied both experimentally and theoretically [91, 92]. These studies represent the first results for inner-shell photodetachment. There is general agreement between theory and experiment well above the K edge, but the theoretical cross sections at the K edge are significantly higher than the experimental measurements. The latter discrepancy is now understood as arising from recapture of the low-energy detached electron following Auger decay of the inner-shell vacancy, which when taken into account theoretically has been shown to provide results that agree with experiment [93, 94]. Also, the first experimental data together with theoretical analyses were recently presented for photoionization of ground and metastable positive ions (O^+ and Sc^{++}) [95, 96]. With the advent of data for photoionization of positive ions it now becomes possible (using the principle of detailed balance) to make connections to data for electron–ion photo-recombination cross sections [96].

25.6 Applications to Other Processes

The detailed understanding of single-photon ionization processes in atoms described in this chapter have recently proved useful in interpreting more complex interactions of electromagnetic radiation with atoms. First, potential barrier effects, which are key features of single-photon ionization of the heavier rare gases, have been shown to also be key features of two and three-photon ionization processes in rare gases. Second, prominent features of the high-order harmonic generation (HHG) spectra of an atom have been

shown to stem from features of that atom's photoionization cross section. We discuss each of these two applications of the theory of atomic photoionization below.

25.6.1 Applications to Two and Three-Photon Ionization Processes

Potential barriers in the effective radial potential experienced by a photoexcited electron have been shown to result in dramatic, resonance-like effects in both two-photon ionization processes [97] and three-photon ionization processes [98] in rare gas atoms. In these two-photon and three-photon ionization processes, such potential barriers were found to affect not only the final state of the electron (as in ordinary photoionization), but also the intermediate-state electron wave packets corresponding to the absorption of one or two photons when the energy absorbed places the intermediate state wave packet in the energy vicinity of the effective potential barrier. These effects were illustrated for the generalized two and three-photon cross sections for ionization of Ar, Kr, and Xe within a single-active-electron, central-potential model [97, 98]. The results are relevant to experimental studies of nonlinear extreme ultraviolet and X-ray processes [99]. Numerous theoretical treatments of electron correlation effects relevant to few-photon ionization processes have been carried out (e.g., [100–103]). Interest in these theoretical treatments is likely to increase when experimental few-photon (nonlinear) ionization cross sections become available as a function of photon frequency.

25.6.2 Application to High-Order Harmonic Generation

The photoionization cross section of an atom has been found to have a direct connection to the high-order harmonic generation (HHG) spectrum of that atom, which is an unexpected relationship between linear and highly nonlinear interactions of an atom with electromagnetic radiation. The relation between the two processes may be understood by means of the quasi-classical interpretation of HHG as a three-step process [104–106] involving: (1) tunnel ionization of an electron in an atom by a strong low-frequency laser field; (2) propagation of the ionized electron in the (laser-dressed) continuum away from and back to the atomic ion by the oscillating laser field; and (3) recombination of the returning electron back to the atom ground state with emission of a harmonic photon. The approach that permits us to understand and describe atomic photoionization by a strong field, called “atomic antenna” was first suggested by *Kuchiev* [107]. It includes the above-mentioned steps (1) and (2). The three-step model suggests a phenomenological parametrization [108, 109] of

the HHG yield Y as the product of an electronic wave packet $W(E)$ (corresponding to the first two steps) and the field-free photorecombination cross section (PRCS) $\sigma(E)$

$$Y \propto W(E)\sigma(E), \quad E = E_\Omega - I_p, \quad (25.30)$$

where E is the energy of the recombining electron, E_Ω is the harmonic energy, and I_p is the target binding energy. This phenomenological parametrization has been confirmed by analysis of exactly solvable model systems [110–112]. The intensity of the harmonic radiation thus carries information on the PRCS of an electron whose momentum is directed along the linear polarization axis of the driving laser field.

Since the photorecombination process is the inverse to that for photoionization, the PRCS is directly related (through the principle of detailed balance) to the photoionization cross section for photon energy E_Ω . Thus, the form of the HHG spectrum replicates the shape of the photoionization cross section. Indeed, experimental and theoretical studies for the case of linearly polarized driving laser fields have shown that HHG spectra exhibit such key features of the corresponding photoionization cross sections as Cooper minima [110, 113] and potential barrier-induced (“giant dipole”) resonances [110, 114–116]. Extension of such studies to the case of two-dimensional driving laser waveforms has shown that this “HHG spectroscopy” can enable the extraction of not only photoionization cross sections but also the photoelectron angular distribution asymmetry parameters [117, 118].

25.7 Future Directions

A main new direction in photoionization is toward time-domain studies in the extreme ultraviolet (XUV) and X-ray regimes. First, advances in high-order harmonic generation have led to the production of isolated pulses of XUV light whose temporal width is measured in tens or hundreds of attoseconds [119]. The shortest such pulses have durations of only a few optical cycles so that (i) they have significant bandwidth, and (ii) the probability of photoionization depends on the phase of the electric field within the pulse envelope. Second, the construction of free-electron lasers (FELs) around the world has enabled studies of intense X-ray interactions with atoms (e.g., [120, 121]). Thus, inner-shell vacancy production and decay, satellite production, and multiple ionization phenomena are all being increasingly studied on timescales comparable to the durations of the FEL X-ray pulses, which are estimated to be on the order of tens of femtoseconds. Of essential importance are also studies of photoionization of fullerenes and endohedrals that represent ordinary atoms “stuffed” inside a fullerene shell, such as, e.g., C60 [122].

Anthony F. Starace Dr Starace earned his PhD from the University of Chicago (1971) and became George Holmes University Professor of Physics at the University of Nebraska (2001). His primary research interests were the interaction of intense laser light with atoms, especially single and multiphoton detachment and ionization processes. He was a Fellow of the American Physical Society and the American Association for the Advancement of Science. He passed away in 2019.

Abstract

The phenomenon of autoionization, or more particularly the autoionization state itself, is treated for the most part in this chapter as a bound state. The process is rigorously a part of the scattering continuum, but, due mostly to the work of *Feshbach* [1], a rigorous formulation can be es-

tablished whereby the main element of the theory can be made into a bound state problem with the scattering elements built around it. The major constituent of both these features is accomplished with projection operators. A brief description of the above elements of the theory, centered around projection operators, is the aim of this chapter [2], although some additional methods are discussed in Sect. 26.5. Another class of resonances, shape resonances, is also briefly discussed, because one of the additional methods, complex rotation, reveals both Feshbach and shape resonances.

projection operator · resonance parameter · Feshbach resonance · pseudopotential method · autoionization state

26.1 Introduction

26.1.1 Auger Effect

Autoionization falls within the general class of phenomena known as the Auger effect. In the Auger effect, an atomic system *seemingly* (Sect. 26.1.3) spontaneously decays into a partition of its constituent parts.

26.1.2 Autoionization, Autodetachment, and Radiative Decay

If the initial, composite system is neutral, or positively charged, and its constituent decay particles are an electron and the residual ion, then the process is called *autoionization*. If the original system is a negative ion, so that the residual heavy particle system is neutral, then the process is technically called *autodetachment*; for the most part, the physics and the mathematical treatment are the same.

It is also possible, before electron emission takes place, that the system will alternatively decay radiatively to an autoionization state of lower energy or a true bound state of the composite system. The latter process is called *radiative stabilization* (which is a basic part of dielectronic recombination (Chap. 59)).

26.1.3 Formation, Scattering, and Resonances

Autoionizing states are formed by scattering processes and photoabsorption. These are the inverses of the autoionization and photon emission processes by which they can decay. In the scattering process, formation of the autoionization state corresponds to a resonance in the scattering cross section (Chap. 49). Autoionization is the process that corresponds to the decay of the resonance. The decay of the resonance (autoionization) is then seen to be the last half of the resonant scattering process. Strictly speaking, therefore, the resonant or autoionization state, although it may be long lived, is not completely stationary, and that is the reason that the word *seemingly* was used to describe the Auger process. The compound system can also be formed by absorption of photons impinging on a bound state (usually the ground state) of the compound system, in which case the autoionization state shows up as a *line* in the absorption spectrum.

26.2 Projection Operator Formalism

In the energy domain where the Schrödinger equation (SE)

$$H\Psi = E\Psi \quad (26.1)$$

describes scattering, the wave function does not vanish at infinity, i.e.,

$$\lim_{r_i \rightarrow \infty} \Psi \neq 0, \quad (26.2)$$

where r_i is the radial coordinate of the i -th electron.

The basic idea of the projection operator formalism [1] is to define projection operators P and Q , which separate Ψ into scattering-like ($P\Psi$) and quadratically integrable ($Q\Psi$) parts

$$\Psi = P\Psi + Q\Psi. \quad (26.3)$$

Implicit in Eq. (26.3) are

$$\begin{aligned} \text{completeness} \quad & P + Q = 1, \\ \text{idempotency} \quad & P^2 = P, \quad Q^2 = Q, \\ \text{orthogonality} \quad & PQ = 0, \end{aligned} \quad (26.4)$$

and the asymptotic properties

$$\lim_{r_i \rightarrow \infty} \begin{cases} P\Psi = \lim_{r_i \rightarrow \infty} \Psi \\ Q\Psi = 0 \end{cases}. \quad (26.5)$$

26.2.1 Optical Potential

Straightforward manipulation of Eqs. (26.1) and (26.3) leads to an important relation between $Q\Psi$ and $P\Psi$

$$Q\Psi = (E - QHQ)^{-1} QHP\Psi. \quad (26.6)$$

From Eq. (26.6), a basic equation for $P\Psi$ (which, by virtue of Eq. (26.5), contains all the scattering information) emerges

$$(PHP + V_{\text{op}} - E)P\Psi = 0. \quad (26.7)$$

The most significant part of Eq. (26.7) is the optical potential V_{op} given by

$$V_{\text{op}} = PHQ(E - QHQ)^{-1} QHP; \quad (26.8)$$

V_{op} is a nonlocal potential; the most incisive way to give it meaning is to define the QHQ problem.

26.2.2 Expansion of V_{op} : The QHQ Problem

The following eigenvalue problem constitutes the heart of projection operator formalism

$$QHQ\Phi_n = \mathcal{E}_n\Phi_n. \quad (26.9)$$

For calculational purposes, it is best to recast Eq. (26.9) in the variational form

$$\delta \left(\frac{\langle \Phi QHQ\Phi \rangle}{\langle \Phi Q\Phi \rangle} \right) = 0. \quad (26.10)$$

This equation may yield a discrete plus a continuous spectrum in an energy domain where the SE has only a continuous spectrum. Moreover, if the Q operator is appropriately chosen, then the discrete eigenvalues \mathcal{E}_n are close to the desired class of many-body resonances, called variously Feshbach resonances, core-excited [3], or doubly excited states. In terms of these solutions, V_{op} has the expansion

$$V_{\text{op}} = \sum_n^{\wedge} PHQ|\Phi_n\rangle(E - \mathcal{E}_n)^{-1}\langle\Phi_n|QHP. \quad (26.11)$$

26.3 Forms of P and Q

26.3.1 The Feshbach Form

Projection operators are not unique. *Feshbach* [1] sketched a derivation of a *robust* projection operator for the general N -electron target system. Robust means that $Q\Phi$ is devoid

of open channels. The complete expression for P , including inelastic channels, was derived in [4]

$$P = \sum_{i=1}^{N+1} \left[\langle \psi(r^{(i)}) \rangle \cdot \langle \psi(r^{(i)}) \rangle + \sum_{\lambda_\alpha} \frac{v_\alpha(r_i) \cdot \psi(r^{(i)}) \langle v_\alpha(r_i) \cdot \psi(r^{(i)}) \rangle}{\lambda_\alpha - 1} \right], \quad (26.12)$$

where the prime on the second summation means that terms with $\lambda_\alpha = 1$ are to be omitted; r_i denotes the radial coordinate of electron i , and $r^{(i)}$ stands for the angular and spin coordinates of electron i plus all coordinates of the remaining N electrons. Thus, $r^{(i)}$ indicates the totality of all coordinates of the $(N + 1)$ electrons *except* the radial coordinate of the i -th electron r_i ; $\psi(r^{(i)})$ is the vector channel wave function in which the angular momentum and spin of the electron i are coupled to the target in state v ($v = 0, \dots, v_{\max}$). A component of a vector labels the inelastic channel, and dot products represent sums over channels. The Q operator is then made explicit by completeness: $Q = 1 - P$, Eq. (26.4).

The α -indexed quantities in Eq. (26.12) arise from exchange; they are the eigensolutions of the integral eigenvalue problem

$$v_\alpha(r_i) = \lambda_\alpha \langle \mathbf{K}(r_i|r_j) \cdot v_\alpha(r_j) \rangle_{r_j}. \quad (26.13)$$

Here, $\mathbf{K}(r_i|r_j)$ is a matrix with components

$$K_{\mu\nu}(r_i|r_j) \propto N \langle \psi_\mu(r^{(i)}) \psi_\nu(r^{(j)}) \rangle_{r^{(ij)}}, \quad (26.14)$$

and $r^{(ij)}$ indicates that all variables, except r_i and r_j , are integrated over. In the inelastic regime, therefore, the $[v_\alpha, \lambda_\alpha]$ are not associated with specific channels but rather with the totality of open channels. This means that every component of v_α is associated with all inelastic channels [4]. The v_α are orthogonal and can be normalized so that $\langle v_\alpha \cdot v_\beta \rangle = \delta_{\alpha\beta}$. The λ_α obey several sum rules [5], of which the most useful is

$$\sum_{\alpha=1}^{n_\lambda} (\lambda_\alpha)^{-1} = \sum_{v=0}^{v_{\max}} \langle K_{vv}(r|r) \rangle_r, \quad (26.15)$$

where n_λ is the number of eigenvalues of Eq. (26.13). The v_α can be accurately calculated by use of a variational principle [5]. A test of Eq. (26.15) for the lowest He⁻(²S) resonance, using Hylleraas functions to construct Q in the evaluation of QHQ , is shown in Table 26.1 [5], and results for the resonance position are compared in Table 26.2.

26.3.2 Reduction for the $N = 1$ Target

Explicit rigorous P and Q operators of the above type are only possible for $N = 1$ (i.e., hydrogenic) targets. In that case, spin can be easily eliminated by using spatially sym-

Table 26.1 Test of sum rule in Eq. (26.15) for the lowest He⁻(1s2s²2S) autodetachment state [5]. Projection operators are based on a 4 term Hylleraas ϕ_0 and the variational form of v_α given below. Values of other constants are given in [5]

$$\begin{aligned} \phi_0 &\propto (1 + C_1 r_1 + C_2 r_2 + C_{12} r_{12}) \exp(-\gamma_1 r_1 - \gamma_2 r_2) \\ &\quad + (1 \leftrightarrow 2) + (r_1 \leftrightarrow r_2), \\ v_\alpha &\propto (c_{11}^{(\alpha)} + c_{12}^{(\alpha)} r) \exp(-\gamma_1 r) + (c_{21}^{(\alpha)} + c_{22}^{(\alpha)} r) \exp(-\gamma_2 r), \end{aligned}$$

and the variational eigenvalues are [5]

$$\lambda_1 = 1.009453, \lambda_2 = 232.8540, \lambda_3 = 80.101.08, \lambda_4 = 4.817,341$$

Summation	Value (Ry ⁻¹)

metric or antisymmetric wave functions. In the elastic region, P and Q reduce to [12, 13]

$$P = P_1 + P_2 - P_1 P_2; \quad Q = 1 - P_1 - P_2 + P_1 P_2. \quad (26.16)$$

Here, the $P_i = \phi(r_i) \langle \phi(r_i) \rangle$ are purely spatial projectors. Forms for the inelastic continuum are easily generalized [11].

There have been many calculations of QHQ for two-electron systems ($N = 1$), starting with fundamental work of *O'Malley and Geltman* [11]. A small sample is given in Table 26.3. They are given for their historical importance, demonstrating for the first time the convergence of eigenvalues to well-defined values in the continuum. All eigenvalues

Table 26.3 Energies E_s of the He(2s2p¹P⁰) autoionization states below He⁺ ($n = 2$) threshold from the variational calculations of *O'Malley and Geltman* [11]. Units are Ry; N is the number of terms in the trial function

(below the $n = 2$ threshold, in this case) correspond to resonances.

26.3.3 Alternative Projection and Projection-Like Operators

Two alternative methods based on the idea of projection are available: quasi projectors and hole projection operators. Quasi projectors [14] relax the condition of idempotency but still maintain a discrete spectrum, which is in a one-to-one correspondence with resonances, with a predeterminable number of exceptions [2]. Hole projection operators have proven to be a more practical and effective approach [15]. The method uses one-particle (say, hydrogenic) orbitals, $\phi_n(q; \mathbf{r})$, to build holes via projectors, $[1 - \sum_n \phi_n] \langle \phi_n |$, operating on the $(N + 1)$ -particle wave function. The Rayleigh–Ritz functional is minimized with respect to the linear parameters in Φ , but it is maximized with respect to q , the nonlinear parameter in all the ϕ_n . In a model case, this *minimax* procedure was shown [15] to optimize the eigenvalues to describe resonance energies; many calculations since then [16] have verified the minimax criteria in many-electron systems. More recently, the technique was combined with complex rotation, so as to enable calculation of other resonant quantities [17]. Remarkably accurate results have been obtained.

Finally, hole projectors are ideally suited for inner-shell vacancy states of many-electron systems if high accuracy is required [2]. Effectively, this amounts to a reliable method for optimizing parameters of a hole orbital to be used in an Auger transition integral for filling such a vacancy, although that method has apparently never been used (Chap. 66).

26.4 Width, Shift, and Shape Parameter

26.4.1 Width and Shift

Here, one requires $P\Psi$ as well as $Q\Psi$. The former is obtained from a *nonresonant continuum*, defined as the scattering solution of

$$[P\mathcal{H}P + V_s^{(\text{nr})} - E]P\Psi_s^{(\text{nr})} = 0, \quad (26.17)$$

where the nonresonant potential,

$$V_s^{(\text{nr})} = V_{\text{op}} - PHQ\Phi_s \langle E - \mathcal{E}_s \rangle^{-1} \langle \Phi_s QHP, \quad (26.18)$$

excludes the resonant state s from the optical potential. In terms of $P\Psi_s^{(\text{nr})}$, whose phase shift, η_0 , is smooth in the vicinity of $E \approx \mathcal{E}_s$, a solution of the complete problem, Eq. (26.7), can be constructed [11] with a phase shift $\eta_0 + \eta_r$,

Fig. 26.1 Precision calculation of $\text{H}^- (1\text{S})$ resonance. *Solid curve*: $E + 1$ versus k^2 , where $E = \mathcal{E} + \Delta$, Eq. (26.20). k_F^2 is that value of k^2 at which $E + 1 = k^2$. *Dashed curve* is Γ versus k^2 from Eq. (26.21), and $\Gamma_F = \Gamma(k_F^2)$. Curves are from calculations of [18]; results are $E_F = 9.55735$ eV and $\Gamma_F = 0.0470605$ eV. Applying corrections, Eq. (26.31) finally gives $E_{\text{BW}} = E_F + O(10^{-6})$, $\Gamma_{\text{BW}} = 0.04717$ eV

where the additional phase shift

$$\eta_r = \arctan\left(\frac{\Gamma/2}{(\mathcal{E}_s + \Delta_s) - E}\right) \quad (26.19)$$

exhibits typical resonant behavior ($0 < \eta_r < \pi$). From Eq. (26.19), it is clear that the *true* position of the resonance is

$$E_s(E) = \mathcal{E}_s + \Delta_s(E). \quad (26.20)$$

The width Γ_s and shift Δ_s are given by [11]

$$\Gamma_s(E) = 2k |\langle \Psi_s^{(\text{nr})}(E) PHQ \Phi_s \rangle|^2, \quad (26.21)$$

$$\Delta_s(E) = \langle \Phi_s QHP G_P(E) PHQ \Phi_s \rangle, \quad (26.22)$$

where k is the scattering momentum (i.e., $k^2 = E - E_0$), and G_P is the Green's function associated with Eq. (26.17); G_P , whose asymptotic form is given in [2, 11], is the usual combination of regular and irregular solutions of Eq. (26.17).

Equation (26.20) is an implicit equation for the energy at which the resonance occurs. It can be solved graphically [18], and that energy defines the Feshbach resonant energy E_F , which differs (very slightly) from the Breit–Wigner energy (Sect. 26.4.3 and Fig. 26.1).

26.4.2 Shape Parameter

The shape of an isolated radiative transition between an autoionization state and some other state can be described by

Table 26.4 Comparison of high-precision calculations with the experiment for the resonance parameters of the He($1P^0$) resonances below the $n = 2$ threshold. For photoabsorption, the appropriate Rydberg constant is $R_M = R_\infty/(1 + m/M)$ [19]. The value used here is $R_M = 13.603833$ eV, and $E_0 = -79.0151$ eV [6]

Quantity	Units	Calculation ^a		Experiment	
		$s = 1$	$s = 2$	$s = 1$	$s = 2$
\mathcal{E}_s	Ry	-1.3857895	-1.194182

Γ	eV	0.0369 ^d	0.0001165	0.038 ± 0.004^b	
				0.038 ± 0.002^c	
q_s		-2.849 ^e	-4.606 ^e	-2.80 ± 0.25^b	
				-2.55 ± 0.16^c	

^a Bhatia and Temkin [19], except as noted; ^b Madden and Codling [20]; ^c Morgan and Ederer [21]; ^d Bhatia, Burke, and Temkin [22]; ^e Bhatia and Temkin [23]

Γ , E , and an additional parameter q_s , often called the shape parameter [24]. The ratio of transition probability (in, say, absorption from an initial state labeled i) through the resonant state to its nonresonant value, parametrized in its Fano form [24] on the left-hand side of Eq. (26.23), can be equated to its meaning in Feshbach terms on the right-hand side of Eq. (26.23)

$$\frac{(e_s + q_s)^2}{1 + e_s^2} = \frac{|\langle P\Psi + Q\Psi|T|i\rangle|^2}{|\langle P\Psi_s^{(nr)} + Q\Psi_s^{(nr)}|T|i\rangle|^2}, \quad (26.23)$$

where e_s is the scaled energy

$$e_s = (E - E_s)/(\Gamma_s/2), \quad (26.24)$$

and T is a radiative transition operator Eq. (26.25).

To analyze Eq. (26.23) in the Feshbach formalism, the key point [11] is to recognize that the bras on the right-hand side must include P , as well as Q parts of the respective wave functions, as is indicated in Eq. (26.23). That is because the T operator is a perturbation and not part of the dynamical problem. With T in length form

$$T \propto \sum_{j=1}^{N+1} z_j, \quad (26.25)$$

the right-hand side of Eq. (26.23) can be calculated by noting that $P\Psi_s$ and $P\Psi_s^{(nr)}$ can, in principle, be determined from Eqs. (26.7) and (26.17); $Q\Psi_s$ is then derived from $P\Psi_s$ using Eq. (26.6). However, $Q\Psi_s^{(nr)}$ excludes the s th term from the right-hand side of Eq. (26.6)

$$Q\Psi_s^{(nr)} = \sum_{n \neq s} \frac{\Phi_n \langle \Phi_n | QHP\Psi^{(nr)} \rangle}{E - \mathcal{E}_n}. \quad (26.26)$$

With use of these relations in the right-hand side of Eq. (26.23), an explicit formula for q_s was derived in [2];

it is given by

$$q_s = \frac{\langle \Phi_s | \tilde{Q} | T | i \rangle}{k \langle i | T | \Psi_s^{(nr)} \rangle \langle \Psi_s^{(nr)} | PHQ \Phi_s \rangle}, \quad (26.27)$$

where

$$\tilde{Q} = Q + QHPG_s + \sum_{n \neq s} \frac{QHPPG_s HQ | \Phi_n \rangle \langle \Phi_n |}{E - \mathcal{E}_n}. \quad (26.28)$$

Green's function G_s in Eq. (26.28) is the one associated with Eq. (26.17). It can be expanded in terms of the eigensolutions of Eq. (26.17), but its spectrum may have a discrete as well as continuous part, in which case,

$$G_s = \sum_{\nu}' \frac{P\Psi_{\nu}^{(nr)} \langle P\Psi_{\nu}^{(nr)} |}{E_s - E_{\nu}} + \frac{\wp}{\pi} \int \frac{P\Psi_s^{(nr)}(E') \langle P\Psi_s^{(nr)}(E') | \sqrt{E'} dE'}{E_s - E'}. \quad (26.29)$$

The sum over ν refers to the discrete part of the spectrum of Eq. (26.17) (if there is one), and \wp denotes a principal value integral over the continuum solutions. The latter are always assumed to be normalized as plane waves (not energy normalized) throughout this chapter.

Equation (26.27) is a nontrivial example of what can be done with the projection operator technique. Not only does it allow very accurate calculations ([17, 19] and footnote in Table 26.4), but it provides a theoretical incisiveness that far exceeds all previous resonance formalisms.

A formula for the resonant scattering cross section, which is of the same form as the left-hand side of Eq. (26.23), can be derived; however, in that case, the parameter corresponding to q_s is related to the nonresonant phase shift [25] and has no quantitative relationship to the above shape parameter (q_s).

26.4.3 Relation to Breit–Wigner Parameters

Inferring resonance parameters from experimental data is generally done by fitting to resonance formulae in which the resonance parameters are assumed to be energy independent. A phase shift, for example, would be inferred by assuming

$$\eta(E) = \delta_0(E) + \arctan\left(\frac{\Gamma_{\text{BW}}/2}{E_{\text{BW}} - E}\right). \quad (26.30)$$

The relation between the above Breit–Wigner parameters and those of the Feshbach theory was derived in lowest order by *Drachman* [26]

$$\begin{aligned} E_{\text{BW}} &= E_{\text{F}} - (1/4)\Gamma_{\text{F}}(d\Gamma_{\text{F}}/dE)_{E=E_{\text{F}}}, \\ \Gamma_{\text{BW}} &= \Gamma_{\text{F}}(1 + d\Delta_{\text{F}}/dE)_{E=E_{\text{F}}}, \\ \delta_0(E) &= \eta_0(E) - (1/2)d\Gamma_{\text{F}}/dE. \end{aligned} \quad (26.31)$$

So far these differences have been evaluated in only one precision calculation (for the lowest ^1S resonance in electron–hydrogen scattering) [18]. A précis is given in Fig. 26.1.

26.5 Other Computational Methods

We now briefly review two calculational methods used for basic applications in autoionization of few body systems: (a) complex rotation and (b) a pseudopotential method.

26.5.1 Complex Rotation Method

Complex rotation, which is based on a theorem of *Balslev* and *Combes* [27], has been extensively applied with great accuracy. Two additional basic systems to be mentioned here are H^- and Ps^- (Ps = positronium). In complex rotation, the particle distances are multiplied by a common phase factor

$$r_i \rightarrow r_i e^{i\theta}. \quad (26.32)$$

Under this replacement, the Hamiltonian undergoes the transformation

$$H \rightarrow T e^{-2i\theta} + V e^{-i\theta} \quad (26.33)$$

(only Coulomb interactions are assumed). A real variational wave function Φ is used (for the applications here, they are of Hylleraas form, multiplied by rotational harmonics of symmetric Euler angles of the desired angular momentum, parity, and spin [28]). The functional

$$[E] = \frac{\langle \Phi | H | \Phi \rangle}{\langle \Phi | \Phi \rangle} = \frac{\langle \Phi | T | \Phi \rangle e^{-2i\theta} + \langle \Phi | V | \Phi \rangle e^{-i\theta}}{\langle \Phi | \Phi \rangle} \quad (26.34)$$

is then evaluated. Minimization of Eq. (26.34) with respect to the linear parameters, for a given value of θ , is carried out in the usual way, but by virtue of the complex dependence on rotation angle, the matrix elements H_{ij} in the matrix eigenvalue equation

$$\det |H_{ij}(\theta) - E\Delta_{ij}| = 0 \quad (26.35)$$

are complex. Thus, the solution of Eq. (26.35) gives rise to complex eigenvalues $E_\lambda = E_\lambda(\theta)$. For a given λ , the optimum θ is the one for which $E_\lambda(\theta)$ is effectively stationary as a function of θ [29]. Note that no projection operators are used: the real part of E_λ corresponds to the Breit–Wigner (i.e., experimental) position of the resonance, and $\text{Im}(E_\lambda) = \Gamma_{\text{BW}}/2$, where Γ_{BW} corresponds to the Breit–Wigner width of the resonance. These parameters thus include the full Feshbach values plus corrections Eq. (26.31).

Using Hylleraas wave functions with up to 1230 terms in the complex rotation method, resonance parameters have been obtained for resonance states of H^- below the $n = 2$ and 3 thresholds of H , which compare very well with those obtained using the projection-operator, R-matrix, and close-coupling methods. Results for the $^1\text{D}^e$ states of H^- are given in Table 26.5. Similar calculations for Ps^- have been carried out [30]. The complex rotation method has been applied to the autoionization states of many different systems, including muonic systems [31], as well as to study the combined effect of electric field and spin–orbit interaction on resonance parameters [32].

The following are more recent very accurate results for Feshbach resonances using the complex-rotation method. They show that this method is a very powerful technique for uncovering not only Feshbach but also shape resonances, as well as exact bound states in the continuum.

Using Hylleraas type wave functions, *Lindroth* [35] calculated the resonance parameters for singlet and triplet S , P , D , and F states of He below $n = 2$ and 3 threshold of He^+ . Some of her results below $n = 2$ are given in Table 26.6.

Burgers et al. [36] also carried out a very extensive calculation (up to 24497 Sturmian functions) for parameters of resonance states of He below thresholds up to $n = 10$ of He^+ . They used perimetric coordinates introduced by *Coolidge* and *James* [37]. Their results for a few states below $n = 2$ are given in Table 26.6. The resonance parameters of some of the states obtained in these calculations are compared in Table 26.6 with those obtained by *Bhatia* and *Temkin* [19]. We use $R_\infty = 13.605826$ eV throughout.

Similar calculations have carried out by *Lindroth* [35] and *Burgers* et al. [36] to calculate resonance parameters for triplet states of He . Their results are given in Table 26.7 and compared with those obtained by *Bhatia* and *Temkin* [19].

Ho [38] has calculated resonances parameters in Ps^- below the $n = 2, 3, 4$, and 5 thresholds of Ps using Hylleraas

Table 26.5 Comparison of resonance parameters (in eV) obtained from different methods for calculating $^1D^e$ states in H^-

type wave functions. Ps^- is similar to H^- except that the proton in H is replaced by a positron. But for Ps^- the mass polarization term in the Hamiltonian becomes important and must be included. Ps^- results are approximately close to half of the values in H^- . Ho's results for the singlet and triplet S states are given in Table 26.8. Note that there is more than one state below the n -th state of Ps. He used 364 Hylleraas terms for singlet states and 455 terms for triplet states in the wave functions, respectively. It is seen that in He and Ps^- systems, the singlet resonances have lower energies than the triplet resonances. The parameters for these resonances (not shown here) have also been calculated by Papp et al. [39] by solving Faddeev–Merkuriev integral equations for three-body Coulombic systems by using Coulomb–Sturmian separable expansion approach. They found several new resonances in addition to those calculated by Ho [38].

Ho and Bhatia [40] have calculated resonance parameters for the $^3P^e$ states of Ps^- below the thresholds $n = 2, 3, 4, 5$, and 6 of Ps. The results are given in Table 26.9. These states can autoionize to orthopositronium of odd parity and an electron with angular momentum equal to one.

The autoionization states described above are compound states in which the incoming electron is, in fact, attached to an excited state of the target. These states are referred to as Feshbach resonances. However, there is another class of compound states that arise when an incoming electron is in effect caught in a potential barrier set up by the incoming electron interacting with the target atom or ion. These states are referred to as shape resonances. Shape resonances

occur above the energy necessary to excite the target. They are also allowed to decay by autoionization. Theoretically, the appearance of shape resonances is based on a theorem of *Balslev and Combes* [27].

Resonance parameters for odd parity $^{1,3}P$ states in Ps^- were calculated by *Bhatia and Ho* [42] using the complex-rotation method. Their results are given in Table 26.10. The lowest odd parity state was observed in Ps^- by using laser beams of 2285 and 2297 Å by *Michishio et al.* [43]. Their results for the energy and width agree with those given in Table 26.10 and also with the energy and width calculated by *Botero and Greene* [44].

26.5.2 Pseudopotential Method

The second method in this section is included for the reason that it represents a rather different idea for the calculation of autoionization rather than being a more elaborate application of methodologies that are already known, with results too numerous to be referenced here. The method, described as a pseudopotential approach, was introduced by *Martin et al.* [45]. An effective Hamiltonian H_{eff} is defined as

$$H_{eff} = H + MP, \quad (26.36)$$

where M is a scalar parameter (i.e., a number), which will be taken to be very large, multiplying the P operator,

Eq. (26.16). [Applications have thus far been restricted to one-electron targets and resonances below the $n = 3$ excited state.] In practice, one minimizes the expectation value of H_{eff} , i.e.,

$$\delta \left(\frac{\langle \Psi_v | H_{eff} | \Psi_v \rangle}{\langle \Psi_v | \Psi_v \rangle} \right) = 0, \quad (26.37)$$

using an arbitrary, quadratically integrable, variational function Ψ_v .

In order to understand the nature of the spectrum that arises from this variation, we imagine Ψ_v divided into its P and Q space components

$$\Psi_v = Q\Psi_v + P\Psi_v = \Psi_v^Q + \Psi_v^P. \quad (26.38)$$

The expectation value $\langle \Psi_v | H_{eff} | \Psi_v \rangle$ is written in matrix form as

$$\begin{aligned} & \langle \Psi_v | H_{eff} | \Psi_v \rangle \\ &= \left\langle \begin{pmatrix} \Psi_v^Q & \Psi_v^P \end{pmatrix} \begin{pmatrix} H_{QQ} & H_{QP} \\ H_{PQ} & H_{PP} + M \end{pmatrix} \begin{pmatrix} \Psi_v^Q \\ \Psi_v^P \end{pmatrix} \right\rangle. \end{aligned} \quad (26.39)$$

The eigenvalue problem resulting from Eq. (26.37) reduces to finding the eigenvalues of the determinant

$$\det \begin{pmatrix} \langle H_{QQ} \rangle - \lambda & \langle H_{QP} \rangle \\ \langle H_{PQ} \rangle & \langle H_{PP} \rangle + M - \lambda \end{pmatrix} = 0. \quad (26.40)$$

Note that only the bottom right-hand side component contains the term M . As a result, in the limit of large M , the eigenvalues, which can readily be solved for from Eq. (26.39), are

$$\lim_{M \rightarrow \text{large}} \lambda = \begin{cases} M + \langle H_{PP} \rangle \\ \langle H_{QQ} \rangle \end{cases}. \quad (26.41)$$

The lower eigenvalue is the desired Feshbach resonant energy $\mathcal{E}_F = \langle H_{QQ} \rangle$. The width is calculated from [with our normalization, Eq. (26.21)]

$$\Gamma = 2k |\langle \Psi_\lambda | H_{eff} | \chi_E \rangle|^2, \quad (26.42)$$

where χ_E is the solution of the exchange approximation

$$(H_{PP} - E)\chi_E = 0. \quad (26.43)$$

It is emphasized that this method only calculates the Feshbach energy; thus the shifts are not included. On the other hand, the method uses no projection operators in calculating the matrix elements of H , and only the matrix elements of P by itself occur. This is much easier than a standard QHQ calculation (Sect. 26.2.2).

In practice, the matrix in Eq. (26.39) will expand to an $N \times N$ matrix, where N is the number of linear parameters

Table 26.11 Resonance energies \mathcal{E}_F (Ry) and widths (eV) for 1P states of He below the $n = 2$ threshold (-1 Ry) of He^+

State	Martin et al. [45]		Lipsky and Conneely [46]		Bhatia and Temkin [19, 23]	
	Position	Width	Position	Width	Position	Width
1	-1.38400	0.0382	-1.37672	0.0341	-1.38579	0.0363
2	-1.19460	0.000146	-1.19312	0.000131	-1.19418	0.000106
3	-1.12752	0.000860	-1.12584	0.00727	-1.12772	0.0090

in Ψ_V , and (if one uses a Hylleraas form of Ψ_V , for example) the matrix in Eq. (26.39) will not overtly divide itself into the simple form of this heuristic exposition pictured in Eq. (26.39) or (26.40). Nevertheless, the conclusion holds; in detail, the eigenvalue spectrum will span a range of values with those below the threshold, appropriate to the P operator being used, corresponding to real resonances, and the largest eigenvalue will approach the value of M used in the specific calculation.

A sample of results for the $\text{He}(^1P)$ resonances below the $n = 2$ threshold of He^+ taken from [45], with some comparisons, is given in Table 26.11. Note that the value of \mathcal{E}_F of the second resonance in the Martin et al. [45] calculation is lower than the rigorous QHQ calculation [19]. It is believed that this may be due to the residual M dependence of H_{eff} .

26.5.3 Exact Bound States in Continuum

There is another class of “autoionization” states, which are states in the Coulomb limit: i.e., only Coulomb potentials in the Hamiltonian whose energy although in the continuum of the electron–atom scattering process are of symmetry different from a scattering state into which they might otherwise be allowed to decay. A prime example of such states is the $^3P^e$ state of H^- [47] whose energy (9.6669 eV) is lower than the $n = 2$ state of H (10.2044 eV). Such a state cannot decay by Coulomb forces to the ground state (1S) plus an outgoing electron; the outgoing electron would have to be a P-wave (to conserve angular momentum). However, in that case, the total parity of the electron plus the residual atom (singlet S) would be odd, whereas the parity of the initial system ($^3P^e$) is even! Such states have various consequences from a calculational point of view. (a) They can be calculated as ordinary bound states, e.g., using the Rayleigh-Ritz variational principle

$$\delta \left(\frac{\langle \Psi H \Psi \rangle}{\langle \Psi \Psi \rangle} \right) = 0. \quad (26.44)$$

Using an ansatz for Ψ with the correct quantum symmetry (in the $^3P^e$ case, such a function would be labeled $\Psi(2p3p^3P^e)$. (b) From the point of view of the projection operators’ formalism, such a state would correspond to a state with parameters for which $P = 0$ and $Q = 1$, and, thus, no projection operators are needed in doing the variational calculations. (c) From the point of view of complex rotation, one would

Table 26.12 $^3P^e$ shape resonances in Ps^- . Results are in eV relative to the ground state energy of $\text{Ps}^- = -0.5$ Ry

n	E (eV)	Γ (eV)
2	5.1103	7.35(−3)
4	6.3815	8.71(−4)
6	6.7842	5.44(−4)

find three things: first that the stationary value would occur at $\Theta = 0$; second that the $[E]$ from Eq. (26.34) would behave like an ordinary bound state, and third that the fact that $[E]$ is a real number (with no imaginary parts) implies that its width $\Gamma \propto \text{Im}[E] = 0$.

Ho and Bhatia [40] also calculated parameters for $^3P^e$ shape resonances of Ps^- above $n = 2, 4$, and 6. They are given in Table 26.12.

Accurate resonance parameters in two-electron systems H^- , He , and Li^+ have also been determined by using a hybrid theory of scattering [48] in which the short-range and the long-range correlations are included, and it is variationally correct. The complex rotation method has also been applied to calculate resonance parameters of the $^2\Pi_g$ shape resonance of N_2^- [49].

26.6 Related Topics

This chapter is necessarily of limited scope. Within the projection operator formalism, overlapping resonance theory [50] is discussed in Chap. 49.1.3.

Previous calculations [51] have shown that such effects, when present, can induce significant alteration of isolated resonance results. Other prominent items not included are stabilization methods [52] and hyperspherical coordinate methods [53, 54]. The latter methods have the appealing property of presenting energies as a function of the hyper-radius, $R = (\sum_i r_i^2)^{1/2}$, which look like potential energy curves of diatomic molecules as a function of the intermolecular separation, which is also usually denoted by R . The molecular structure analogy has also been used to uncover additional (approximate) symmetries with corresponding quantum labels [53, 54]. They thus have a global character not present in the foregoing methods. On a purely quantitative level, however, they are not generally as accurate as methods based on the projection operator or complex rotation formalism.

There are many other areas in which autoionization can play an important role, such as satellite line formation [55] and inner-shell ionization [56], to mention only a couple (Chap. 66 and [57]). In addition, significant application of the phenomena associated with autoionization to diagnostics of astrophysical [58] and fusion [59] plasmas, for example, shows that autoionization has considerable applied utility.

Anand K. Bhatia Dr Bhatia received his PhD in Theoretical Physics from the University of Maryland in 1963. Since then he has been at Goddard Space Flight Center. He has published a large number of papers on various topics in atomic and astrophysics: scattering of electrons and positrons from atoms, muonic fusion, polarizabilities of two-electron systems, Lamb shift, Rydberg states, excitation of ions, etc. He is a Fellow of the American Physical Society.

Aaron Temkin Dr Temkin is a research physicist (emeritus) at NASA/GSFC He has specialized (primarily) in scattering problems of electrons from atoms and molecules, and associated processes (autoionization, in particular). He received his PhD degree from the Massachusetts Institute of Technology in 1956, and has been at his present institution since 1960.

Abstract

The discussion in this chapter is restricted to Green's function techniques as applied to problems in atomic physics, specifically to the calculation of higher order (correlation, Breit, as well as radiative) corrections to energy levels, and also of transition amplitudes for radiative transitions of atoms which are gauge invariant (GI) at every level of approximation.

Green's function techniques were first applied to many-electron atoms in 1971 as specific instances of the use of field theory techniques in many-particle problems [1, 2]. They initially provided alternative derivations of known approximations such as the Hartree–Fock (HF) approximation and random phase approximation (RPA). The starting point for the derivations was a nonrelativistic (NR) field-theoretical effective Hamiltonian for the system, which involved the nucleus–electron potential and only Coulomb interactions between electrons.

field theory · Green's function · radiative transition · Dyson equation · Fourier transform · lepton charge · Coulomb exchange · Koopmans' theorem · MBPT calculation · radiative correction

27.1 Introduction

It subsequently became apparent that it was possible to formulate the problem more generally, with the full quantum electrodynamic (QED) Hamiltonian as a starting point [3, 4]. Thus, the theory contains both relativity, and virtual and real transverse photons, as well as the Coulomb interaction between the electrons. The relativistic (R) approximate equations, such as the Dirac–Fock (DF) and relativistic random phase approximation (RRPA) are the natural outcomes of the formalism, and the NR results can be viewed as approximations to these R cases. Moreover, the Green's function approach (GFA) now provides a means of carrying out programs involving systematic approximations of successively higher and higher accuracy. The GFA provides a framework which allows one to make corrections to results obtained in the DF approximation or in the coupled cluster approximation (CCA) and many-body perturbation theory (MBPT), including magnetic (Breit type) interactions [5, 6]. It ensures that there is neither double counting nor omission of contributions. For radiative transitions, the formalism allows for a systematic treatment of such effects which is gauge independent that at any given level of approximation [7–10]. (It should be noted that there is a subtle difference between gauge invariance and gauge independence. The first refers to the transition amplitude and the second to quantities which are directly observable experimentally.) Finally, the GFA is numerically implementable. Renormalization can be carried out for radiative corrections, resulting in finite and calculable expressions [11–13]. The integro-differential equations (i.e., the Dyson equations) needed to calculate energies or transition amplitudes in nontrivial approximations are also soluble [8, 9, 14].

In quantum field theory, Green's functions are defined in terms of vacuum expectation values of products of field operators. While this restriction can be relaxed, expecta-

tion values must still be taken for a nondegenerate state. As a practical matter, this requirement ultimately restricts one to consider atoms with electron numbers associated only with closed shells or subshells, and those with closed shells or subshells plus or minus one or two electrons. The corresponding Green's functions considered here are the two- and four-point functions for energy levels, and the three- and five-point functions for transition amplitudes (leading to oscillator strengths). The restriction in electron numbers is clearly not a severe one. It allows one to cover many atomic species.

Starting from relativistic QED, the electron field operator $\psi(\mathbf{r}, t)$ written in the Heisenberg picture, satisfies equal-time anticommutation relations

$$[\psi(\mathbf{r}, t), \psi(\mathbf{r}', t)] = [\psi^\dagger(\mathbf{r}, t), \psi^\dagger(\mathbf{r}', t)] = 0, \quad (27.1)$$

$$[\psi(\mathbf{r}, t), \psi^\dagger(\mathbf{r}', t)] = \delta^3(\mathbf{r} - \mathbf{r}'). \quad (27.2)$$

(Spinor labels are suppressed.)

The time-translation operator, acting on any Heisenberg operator $\mathcal{O}(\mathbf{r}, t) = \{\psi(\mathbf{r}, t), \psi^\dagger(\mathbf{r}, t), j_\mu(\mathbf{r}, t), \dots\}$, is

$$\mathcal{O}(\mathbf{r}, t) = e^{i\mathcal{H}t} \mathcal{O}(\mathbf{r}, 0) e^{-i\mathcal{H}t}, \quad (27.3)$$

where \mathcal{H} is the full QED Hamiltonian.

Notations and Definitions

For brevity, plainface numbers are used to denote both a coordinate and time, while boldface numbers denote a coordinate vector alone. For example,

$$\begin{aligned} 1 &\equiv (\mathbf{1}, t_1) \equiv (\mathbf{r}_1, t_1), \\ d^3\mathbf{1} &\equiv d^3\mathbf{r}_1, \\ d^4\mathbf{1} &\equiv d^3\mathbf{r}_1 dt_1. \end{aligned} \quad (27.4)$$

For radiative transitions, $\mathcal{M}_{fi}^{N'}(k_0)$ denotes the transition amplitude for the emission of a single photon of energy k_0 for an N' -electron atom from an initial energy $E_i^{N'}$ to a final energy $E_f^{N'}$, where

$$\mathcal{M}_{fi}^{N'}(k_0) \equiv (2\pi)^4 \delta(E_f^{N'} - E_i^{N'} - k_0) M_{fi}^{N'}(k_0). \quad (27.5)$$

The notation on the right-hand side of Eq. (27.5) is somewhat redundant, since k_0 is taken to be $k_0 = E_f^{N'} - E_i^{N'}$.

The current density operators at $t = 0$ are given respectively by

$$\begin{aligned} j_\mu(\mathbf{r}, 0) &= \begin{cases} \frac{1}{2} \int d^3\mathbf{1} d^3\mathbf{2} [\psi^\dagger(\mathbf{1}, 0), u_\mu^R(\mathbf{12}; \mathbf{r}) \psi(\mathbf{2}, 0)], & \text{for R} \\ \int d^3\mathbf{1} d^3\mathbf{2} \psi^\dagger(\mathbf{1}, 0) u_\mu^{NR}(\mathbf{12}; \mathbf{r}) \psi(\mathbf{2}, 0), & \text{for NR} \end{cases} \end{aligned} \quad (27.6)$$

with

$$\begin{aligned} u_\mu(\mathbf{12}; \mathbf{r}) &= \begin{cases} e\alpha_\mu \delta^3(\mathbf{1} - \mathbf{r}) \delta^3(\mathbf{2} - \mathbf{r}), & \text{for R} \\ e \left[1, \left(\frac{1}{2im} \right) (\nabla_2 - \nabla_1) \delta^3(\mathbf{1} - \mathbf{r}) \delta^3(\mathbf{2} - \mathbf{r}) \right], & \text{for NR} \end{cases} \end{aligned} \quad (27.7)$$

where $\alpha_\mu = (\boldsymbol{\alpha}, 1)$, and the components of $\boldsymbol{\alpha}$ are the usual Dirac matrices.

The corresponding charge operators are defined as

$$\mathcal{Q} = \begin{cases} \frac{1}{2} e \int d^3\mathbf{1} [\psi^\dagger(\mathbf{1}, 0), \psi(\mathbf{1}, 0)], & \text{for R} \\ e \int d^3\mathbf{1} \psi^\dagger(\mathbf{1}, 0) \psi(\mathbf{1}, 0), & \text{for NR} \end{cases}. \quad (27.8)$$

The transition amplitude for a photon of polarization four-vector $\epsilon^\mu(k)$, momentum \mathbf{k} , energy k_0 ($k_0 = |\mathbf{k}|$), and photon attachment point \mathbf{r} is

$$M_{fi}^{N'}(k_0) = \int d^3\mathbf{r} \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2k_0}} M_{fi}^{N'}(\mathbf{r}; k_0). \quad (27.9)$$

In terms of the current density operator, $M_{fi}^{N'}(\mathbf{r}; k_0)$ can be written as

$$\begin{aligned} M_{fi}^{N'}(\mathbf{r}; k_0) &= \left\langle f^{N'} \left| \epsilon^\mu(k) j_\mu(\mathbf{r}, 0) \right| i^{N'} \right\rangle \\ &\equiv \left\langle f^{N'} \left| j^k(\mathbf{r}, 0) \right| i^{N'} \right\rangle, \end{aligned} \quad (27.10)$$

where $|i^{N'}\rangle$ is a state of leptonic charge number N' , with N' corresponding to an atom of N' electrons, with total energy $E_n^{N'}$. The term *lepton charge* is used to refer to the charge of electrons and positrons.

In the dipole approximation, $e^{i\mathbf{k}\cdot\mathbf{r}} \approx 1$, $\epsilon^\mu j_\mu$ contains the quantity

$$\epsilon^\mu(k) u_\mu(\mathbf{12}; \mathbf{r}) \equiv \lambda_k(\mathbf{r}) \delta(\mathbf{1} - \mathbf{r}) \delta(\mathbf{2} - \mathbf{r}), \quad (27.11)$$

where, in the radiation gauge,

$$\lambda_k(\mathbf{r}) = \begin{cases} e\boldsymbol{\epsilon}(k) \cdot \boldsymbol{\alpha}, & \text{velocity form} \\ ie k_0 \boldsymbol{\epsilon}(k) \cdot \mathbf{r}, & \text{length form} \end{cases}. \quad (27.12)$$

27.2 The Two-Point Green's Function

The two-point Green's function, or one-body propagator [3, 4], for a system of lepton charge Ne is defined as the expectation value of a time-ordered product

$$G^N(1, 1') \equiv -i \langle 0^N | T [\psi(1) \psi^\dagger(1')] | 0^N \rangle, \quad (27.13)$$

where $|^N_0\rangle$ is the ground state of leptonic charge number N , with N corresponding to an atom with electron number N in a filled shell or subshell ($N = 2, 4, 8, \dots$).

The relative time $(t_1 - t'_1)$ Fourier transform of Eq. (27.13) yields the spectral representation of $G^N(\mathbf{1}, \mathbf{1}')$:

$$G^N_\omega = \sum_j \frac{|u^j\rangle\langle u^j|}{\omega - \varepsilon^j + i\eta} + \sum_\zeta \frac{|v^\zeta\rangle\langle v^\zeta|}{\omega - \varepsilon^\zeta + i\eta}, \quad \eta = 0^+, \quad (27.14)$$

where

$$G^N_\omega(\mathbf{1}, \mathbf{1}') \equiv \langle \mathbf{1} | G^N_\omega | \mathbf{1}' \rangle, \quad u^j(\mathbf{r}) \equiv \langle \mathbf{r} | u^j \rangle, \quad \text{etc.}, \quad (27.15)$$

and where the symbol \sum denotes a summation over discrete and integration over continuous states. The two terms in Eq. (27.14) are obtained by counting each time-ordering separately in Eq. (27.13), introducing a complete set of intermediate states and using the time translation operator Eq. (27.3). The functions $u^j(\mathbf{r})$ and $v^\zeta(\mathbf{r})$ are defined by

$$u^j(\mathbf{r}) \equiv \langle ^N_0 | \psi(\mathbf{r}, 0) | ^{N+1}_j \rangle, \\ \langle ^N_0 | \psi(\mathbf{r}, t) | ^{N+1}_j \rangle = e^{i(E^N_0 - E^{N+1}_j)t} u^j(\mathbf{r}), \quad (27.16)$$

and

$$v^\zeta(\mathbf{r}) \equiv \langle ^{N-1}_\zeta | \psi(\mathbf{r}, 0) | ^N_0 \rangle, \\ \langle ^{N-1}_\zeta | \psi(\mathbf{r}, t) | ^N_0 \rangle = e^{i(E^{N-1}_\zeta - E^N_0)t} v^\zeta(\mathbf{r}). \quad (27.17)$$

Here, $|^N_0\rangle$ is the ground state of an atom of lepton charge number N (corresponding to a nondegenerate state – a closed shell or subshell) of energy E^N_0 , $|^{N+1}_j\rangle$ an atomic state of total energy E^{N+1}_j and leptonic charge number $N + 1$, and $|^{N-1}_\zeta\rangle$ is the state of energy E^{N-1}_ζ and leptonic charge number $N - 1$. These several states satisfy the eigenvalue equations

$$\mathcal{H} |^N_0\rangle = E^N_0 |^N_0\rangle, \\ \mathcal{H} |^{N+1}_j\rangle = E^{N+1}_j |^{N+1}_j\rangle, \\ \mathcal{H} |^{N-1}_\zeta\rangle = E^{N-1}_\zeta |^{N-1}_\zeta\rangle. \quad (27.18)$$

The energy parameters ε^j and ε^ζ are defined by

$$\varepsilon^j \equiv E^{N+1}_j - E^N_0, \quad (27.19)$$

$$\varepsilon^\zeta \equiv E^N_0 - E^{N-1}_\zeta. \quad (27.20)$$

Equations (27.19) and (27.20) are generalizations of Koopman's theorem [15] (see Sect. 22.4.1). In the DF approximation, the state $|^{N+1}_j\rangle$ can be thought of as N effective particles

(electrons) making up the core, plus one valence electron, with energy label j . The atom can also be an isoelectronic ion with nuclear charge number Z . In this (DF) approximation, the state $|^{N-1}_\zeta\rangle$ is one of two possible types. It can have N independent electrons making up the core, with one of the core electrons missing, or equivalently the N electron core with one electron-hole, with energy label ζ . There is a finite number N of such hole states, which shall be labeled a . There are no other states in the NR (HF) case. In the R (DF) case, the second group of states $|^{N-1}_\zeta\rangle$ can also describe an atom with a core of N electrons, plus one positron. Its continuum energy label, will be taken as $\zeta = \bar{\ell}$. This energy will appear with a negative sign in Eq. (27.14).

The second step in leading to an explicit $G^N(1, 1')$ is the generation of a Dyson equation which it satisfies. In both the DF and HF approximations, the Dyson equation can be obtained through a successive series of steps [11]. Working in the Coulomb gauge (see Chap. 28), begin with the Coulomb interaction between electrons and neglect the exchange of transverse virtual photons. The Dyson equation for the resulting two-point function is then expanded as a power series in the electron-electron (ee) interaction

$$V_{\text{ee}} \equiv V = \frac{\alpha}{|\mathbf{x} - \mathbf{y}|}, \quad (27.21)$$

resulting in an infinite set of Feynman diagrams ($\alpha = e^2/4\pi$ in rationalized mks units). As a next approximation, consider only diagrams involving single Coulomb exchanges and their iterates (*ladders*). That is, set aside for later consideration nonladder Feynman diagrams of two or more Coulomb photons and their iterates (e.g., two crossed Coulomb photon lines). A summation of the infinite set of these remaining terms generates an equation for a propagator labeled $G^N_{\omega, \text{Coul}}$, which contains Coulomb radiative corrections in its kernel. Finally, modify the kernel by isolating these radiative corrections (self energy and vacuum polarization) by constructing a spectral representation of G^N_{ω} which mimics that for the usual QED propagator, which is a vacuum (rather than an N -lepton ground state) expectation value. This requires shifting the poles corresponding to core energies of the atom from the upper to the lower complex ω plane. The shifting of poles is accomplished by means of the equation

$$\frac{1}{x - i\eta} - \frac{1}{x + i\eta} = 2\pi i \delta(x), \quad (27.22)$$

which, when used to shift the poles of core electrons in the ω plane, gives

$$G^N_{\omega, \text{Coul}} = 2\pi i \sum_{a=1}^N |v^a\rangle\langle v^a| \delta(\omega - \varepsilon^a) + G^N_{\omega}{}^{00}. \quad (27.23)$$

It is the first term on the right-hand side of this equation which occurs in the kernel of Eq. (27.24) below and generates the DF approximation.

Some of the terms set aside in the course of this sequence of approximations are reconsidered in Sect. 27.5 to obtain more accurate energy results. What remains at the end of this sequence is an approximation to G_ω^N of Eq. (27.14), designated as $G_{\omega,DF}^N$, and which satisfies the self-consistent Dyson equation

$$G_{\omega,DF}^N = g_\omega + g_\omega \Sigma_{DF}^N G_{\omega,DF}^N, \quad (27.24)$$

where Σ_{DF}^N is the kernel defined in Eq. (27.27). For the R (DF) case,

$$g_\omega^{-1} = \omega - h^R(\mathbf{r}), \quad h^R(\mathbf{r}) = \boldsymbol{\alpha} \cdot \mathbf{p} + m\beta - \frac{Z\alpha}{r}, \quad (27.25)$$

and the corresponding h^{NR} , used in the HF case, is

$$h^{NR}(\mathbf{r}) = \frac{\mathbf{p}^2}{2m} - \frac{Z\alpha}{r}. \quad (27.26)$$

The function g_ω in Eq. (27.25) is the R or NR Coulomb Green's function. It is the solution of the corresponding inhomogeneous c-number Schrödinger or Dirac equation. It is a single-particle equation which has had a long history of specific treatments (see Chap. 9 and [16–19]). It is the semi-classical limit of the two-point propagator we consider here when only the c-number nuclear Coulomb potential is kept and all other (q-number) interactions are turned off.

In the DF and HF approximations in Eq. (27.14), we replace ε^j by $e_j > 0$, $|u^j\rangle$ by $|j\rangle$ (the valence energies and states of an atom with $N + 1$ electrons and a frozen relaxed core of N electrons), ε^ξ by $e_a > 0$, $|u^\xi\rangle$ by $|a\rangle$, for the N discrete electron core states, and ε^ζ by $e_{\bar{\ell}} < 0$, $|u^\zeta\rangle$ by $|\bar{\ell}\rangle$, for the continuum of negative energy states (which do not appear in the HF approximation). The kernel Σ_{DF}^N contains *only* core states $|a\rangle$, in *both* the DF and HF approximations, and is given by the sum over states

$$\begin{aligned} \langle m | \Sigma_{DF}^N | n \rangle &= \alpha \sum_{a=1}^N \int d^3\mathbf{x} d^3\mathbf{y} \frac{1}{|\mathbf{x} - \mathbf{y}|} \langle m | \mathbf{x} \rangle \langle a | \mathbf{y} \rangle \\ &\quad \times (\langle \mathbf{x} | n \rangle \langle \mathbf{y} | a \rangle - \langle \mathbf{x} | a \rangle \langle \mathbf{y} | n \rangle) \\ &\equiv \sum_{a=1}^N [{}^m_a | V |^n_a] \\ &\equiv \sum_{a=1}^N [{}^m_a | V |^n_a] \end{aligned} \quad (27.27)$$

for arbitrary states m and n . The first term in brackets is the Hartree term and the second is the electron exchange term

in the DF (HF) approximation. The DF (HF) equation is the homogeneous equation corresponding to the inhomogeneous Eq. (27.24). Thus,

$$(e_n - h - \Sigma_{DF}^N) | n \rangle = 0, \quad \langle n | n' \rangle = \delta_{nn'}. \quad (27.28)$$

The states $|n\rangle$ (valence, core, and negative energy states) are orthonormal and complete. In the coordinate basis, Eq. (27.28) takes the more familiar form

$$[e_n - h(\mathbf{x})] \langle \mathbf{x} | n \rangle - \langle \mathbf{x} | \Sigma_{DF}^N | n \rangle = 0, \quad (27.29)$$

where

$$\begin{aligned} \langle \mathbf{x} | \Sigma_{DF}^N | n \rangle &= \not\int_m \sum_{a=1}^N \langle \mathbf{x} | m \rangle [{}^m_a | V |^n_a] \\ &\equiv \sum_{a=1}^N [{}^x_a | V |^n_a] \\ &\equiv \int V_{DF}(\mathbf{x}, \mathbf{y}) d^3\mathbf{y} \langle \mathbf{y} | n \rangle. \end{aligned} \quad (27.30)$$

One can also generate equations corresponding to higher approximations than DF using the same approach. For example, one can obtain a Brueckner equation [20],

$$[e_n - h - \Sigma_{DF}^N - \Sigma_B^N(e_n)] | n \rangle = 0, \quad (27.31)$$

and the states now satisfy the orthonormality condition

$$\begin{aligned} \lim_{\omega \rightarrow e_n} \int d^3\mathbf{x} d^3\mathbf{y} \langle n | \mathbf{x} \rangle \langle \mathbf{y} | n' \rangle \\ \times \left(\frac{\{(\omega - e_n) \delta^3(\mathbf{x} - \mathbf{y}) - \langle \mathbf{x} | \{ \Sigma_B^N(\omega) - \Sigma_B^N(e_n) \} | \mathbf{y} \rangle\}}{\omega - e_n} \right) \\ = \delta_{nn'}, \end{aligned} \quad (27.32)$$

where the energy-dependent kernel $\Sigma_B(e_n)$ arises from irreducible Feynman diagrams involving two Coulomb photons. The kernel is given by

$$\begin{aligned} \langle m | \Sigma_B^N(e_n) | n \rangle &= \not\int_{a,i,j} \frac{1/2}{e_n + e_a - e_i - e_j} [{}^m_a | V |^i_j] [{}^i_j | V |^n_a] \\ &\quad + \not\int_{a,b,i} \frac{1/2}{e_n + e_i - e_a - e_b} [{}^m_i | V |^a_b] [{}^a_b | V |^n_i]. \end{aligned} \quad (27.33)$$

$\not\int$ involves summations over core states (a, b), and summation and integration over valence states (i, j). In perturbation theory, the lowest order contribution of $\Sigma_B(e_n)$ is an ee correlation term.

27.3 The Four-Point Green's Function

The four-point Green's function [4, 8, 11], or two-body propagator, is defined as

$$G^N(12, 1'2') \equiv -\langle 0^N | T[\psi(1)\psi^\dagger(1')\psi(2)\psi^\dagger(2')] | 0^N \rangle. \quad (27.34)$$

In order to avoid unnecessary complication, only simple ladders of $V_{ee} \equiv V$ are considered. There are 4! possible time orderings. Of these, there are four groups of four with $t_1, t_{1'} > t_2, t_{2'}$, $t_1, t_{1'} < t_2, t_{2'}$, $t_1, t_2 > t_{1'}, t_{2'}$, and $t_1, t_2 < t_{1'}, t_{2'}$, corresponding to the particle-hole (PH/HP) and the two-particle/two-hole (2P/2H) cases for the first eight and last eight time orderings, respectively. For each of these cases, introduce a total time and relative time variable defined by

$$\begin{aligned} T &= \frac{1}{2}(t_1 + t_{1'}), & T' &= \frac{1}{2}(t_2 + t_{2'}), \\ t &= t_1 - t_{1'}, & t' &= t_2 - t_{2'}, \end{aligned} \quad (27.35)$$

for the first eight cases (PH/HP) and

$$\begin{aligned} T &= \frac{1}{2}(t_1 + t_2), & T' &= \frac{1}{2}(t_{1'} + t_{2'}), \\ t &= t_1 - t_2, & t' &= t_{1'} - t_{2'}, \end{aligned} \quad (27.36)$$

for the last eight cases (2P/2H). For a particular set of eight time orderings, a time translation with respect to the relevant c.m. time t or t' , followed by a separate Fourier transformation for each case with respect to $T - T'$ (with integration variable $d\Omega$), yields contributions with poles in the separately defined Ω -planes at

$$\omega_{(ia)} = E_{(ia)}^N - E_0^N, \quad \text{for PH} \quad (27.37a)$$

$$-\omega_{(ia)} = E_0^N - E_{(ia)}^N, \quad \text{for HP} \quad (27.37b)$$

$$\omega_{(ij)} = E_{(ij)}^{N+2} - E_0^N, \quad \text{for 2P} \quad (27.38a)$$

$$\omega_{(ab)} = E_0^N - E_{(ab)}^{N-2}, \quad \text{for 2H}. \quad (27.38b)$$

Equations (27.37a), (27.37b) parallel Eqs. (27.19) and (27.20) as generalizations of Koopmans' theorem. The spectral representation is of a form similar to Eq. (27.14), with wave functions corresponding to Eqs. (27.16) and (27.17) given by

$$\begin{aligned} \chi_{(ia)}(11') &\equiv \langle \mathbf{1} | \chi_{(ia)}(t) | \mathbf{1}' \rangle e^{-i\omega_{(ia)}T} \\ &= \langle 0^N | T[\psi(1)\psi^\dagger(1')] | 0^N \rangle_{(ia)} \end{aligned} \quad (27.39)$$

for the PH/HP case and

$$\begin{aligned} \varphi_{(ij)}(12) &\equiv \langle \mathbf{1}\mathbf{2} | \varphi_{(ij)}(t) \rangle e^{-i\omega_{(ij)}T} \\ &= \langle 0^N | T[\psi(1)\psi(2)] | 0^N \rangle_{(ij)}^{N+2}, \end{aligned} \quad (27.40)$$

$$\begin{aligned} \gamma_{(ab)}(1'2') &\equiv \langle \mathbf{1}'\mathbf{2}' | \gamma_{(ab)}(t') \rangle e^{-i\omega_{(ab)}T'} \\ &= \langle 0^N | T[\psi(1')\psi(2')] | 0^N \rangle_{(ab)}^{N-2}, \end{aligned} \quad (27.41)$$

for the 2P and 2H cases, respectively. The antisymmetry under exchange follows from the definitions Eqs. (27.40) and (27.41):

$$\zeta_{(\tau)}(12) = -\zeta_{(\tau)}(21), \quad \zeta_{(\tau)} = \varphi_{(ij)}, \gamma_{(ab)}, \quad (27.42)$$

where it is understood that the suppressed spinor indices are interchanged as well as the coordinate and time variables.

The three amplitudes defined above satisfy Bethe-Salpeter (BS) equations. The PH/HP case is the analog of the positronium atom and the 2P case is analogous to He. For the case of Coulomb ladder exchanges, to which we have restricted ourselves, these BS equations can be reduced to simpler ones, with the relative time set equal to zero (the Salpeter equation [21]). The corresponding BS wave functions in the DF (HF) basis (rather than the coordinate basis), are for PH/HP,

$$\langle m | \bar{\chi}_{(ia)} | n \rangle \equiv \int d^3\mathbf{1} d^3\mathbf{1}' \langle m | \mathbf{1} \rangle \langle \mathbf{1} | \chi_{(ia)}(0) | \mathbf{1}' \rangle \langle \mathbf{1}' | n \rangle, \quad (27.43)$$

with $m = k$ and $n = c$, or $m = c$ and $n = k$, and for 2P/2H,

$$\langle mn | \bar{\zeta}_{(\tau)} \rangle \equiv \int d^3\mathbf{1} d^3\mathbf{2} \langle m | \mathbf{1} \rangle \langle n | \mathbf{2} \rangle \langle \mathbf{1}\mathbf{2} | \zeta_{(\tau)}(0) \rangle, \quad (27.44)$$

where $\zeta_{(\tau)} = \varphi_{(ij)}, \gamma_{(ab)}$. The states $|i\rangle, |j\rangle, |a\rangle, |b\rangle, |m\rangle$, and $|n\rangle$ label one-particle DF (HF) eigenkets and e_i, e_j, e_a, e_b, e_m , and e_n , the corresponding eigenvalues.

In the PH/HP case, the BS equation is

$$\begin{aligned} &-(\omega_{(ia)} - e_k + e_c) \langle i | \bar{\chi}_{(ia)} | a \rangle \\ &= \sum_j^k \left\{ \left[\begin{matrix} k \\ b \end{matrix} \middle| V \right| \begin{matrix} j \\ c \end{matrix} \right] \langle j | \bar{\chi}_{(ia)} | b \rangle + \left[\begin{matrix} k \\ j \end{matrix} \middle| V \right| \begin{matrix} b \\ c \end{matrix} \right] \langle b | \bar{\chi}_{(ia)} | j \rangle \right\}, \\ &(\omega_{(ia)} - e_c + e_k) \langle a | \bar{\chi}_{(ia)} | i \rangle \\ &= \sum_{j,b}^c \left\{ \left[\begin{matrix} c \\ b \end{matrix} \middle| V \right| \begin{matrix} j \\ k \end{matrix} \right] \langle j | \bar{\chi}_{(ia)} | b \rangle + \left[\begin{matrix} c \\ j \end{matrix} \middle| V \right| \begin{matrix} b \\ k \end{matrix} \right] \langle b | \bar{\chi}_{(ia)} | j \rangle \right\}. \end{aligned} \quad (27.45)$$

In the 2P/2H case, the coupled pairs of BS equations are

$$\begin{aligned} &-(\omega_{(\tau)} - e_c - e_d) \langle cd | \bar{\zeta}_{(\tau)} \rangle = \sum_{m>n}^c \left[\begin{matrix} c \\ d \end{matrix} \middle| V \right| \begin{matrix} m \\ n \end{matrix} \right] \langle mn | \bar{\zeta}_{(\tau)} \rangle, \\ &(\omega_{(\tau)} - e_k - e_\ell) \langle k\ell | \bar{\zeta}_{(\tau)} \rangle = \sum_{m>n}^k \left[\begin{matrix} k \\ \ell \end{matrix} \middle| V \right| \begin{matrix} m \\ n \end{matrix} \right] \langle mn | \bar{\zeta}_{(\tau)} \rangle, \end{aligned} \quad (27.46)$$

with m and n in these equations labeling either both core, or both valence states.

The wave functions also satisfy the additional conditions:

$$\langle c | \bar{\chi}_{(ia)} | d \rangle = \langle k | \bar{\chi}_{(ia)} | \ell \rangle = 0, \quad \text{PH/HP (no 2P/2H terms)} \quad (27.47)$$

$$\langle ck | \bar{\varphi}_{(ij)} \rangle = \langle ck | \bar{\gamma}_{(ab)} \rangle = 0, \quad \text{2P/2H (no PH/HP terms)} \quad (27.48)$$

The single indices a, b, c, d refer to core and i, j, k, ℓ to valence DF (HF) states. The BS wave functions satisfy the orthonormality conditions

$$\begin{aligned} \sum_{k,c} (\langle k | \bar{\chi}_{(ia)} | c \rangle \langle c | \bar{\chi}_{(ia)'} | k \rangle + \langle c | \bar{\chi}_{(ia)} | k \rangle \langle k | \bar{\chi}_{(ia)'} | c \rangle) \\ = \delta_{(ia)(ia)'} , \end{aligned} \quad (27.49)$$

for the PH/HP case, and

$$\begin{aligned} \pm \left(\sum_{c>d} \langle \bar{\xi}_{(\tau)} | cd \rangle \langle cd | \bar{\xi}_{(\tau)'} \rangle - \sum_{k>\ell} \langle \bar{\xi}_{(\tau)} | k\ell \rangle \langle k\ell | \bar{\xi}_{(\tau)'} \rangle \right) \\ = \delta_{(\tau)(\tau)'} , \end{aligned} \quad (27.50)$$

where $+$ ($-$) corresponds to the 2H(2P) case and $(\tau) = (ab)$ or (ij) .

The PH/HP case in the GFA, involving Coulomb ladders for the ee interaction, is just the R and NR RPA [2]. The labels c, d should also refer to antiparticles, but the contributions of the integrals from these terms to Eqs. (27.45) and (27.46) are negligible.

27.4 Radiative Transitions

For the majority of applications, one begins with the function $\Gamma^N(12; 3)$, the reducible three-point vertex:

$$\Gamma^N(12; 3) = -\langle \bar{0}^N | T[\psi(1)j^k(3)\psi^\dagger(2)] | \bar{0}^N \rangle . \quad (27.51)$$

The usual strategy is followed. The spectral representation serves to identify the functions of ultimate interest. (Energies are not relevant in this case.) One then generates Dyson equations in the chosen approximation by summing an infinite series of perturbation terms.

There are $3!$ time orderings in Eq. (27.51). As with the four-point function, not all of them are subsequently useful. The two useful cases are $t_1 > t_3 > t_2$, and $t_2 > t_3 > t_1$. To obtain a spectral representation for these two cases, one first carries out a time translation of t_3 , using the operator $\exp(i\mathcal{H}t_3)$ of Eq. (27.3), so that $t_1 \rightarrow \tau_1 = t_1 - t_3$, $t_2 \rightarrow \tau_2 = t_2 - t_3$. One then introduces complete sets of intermediate states. The functions defined in connection with the two-point function in Eqs. (27.16) and (27.17) will now appear, as well as the radiative transition amplitude, defined in Eq. (27.10). If one next carries out a separate time translation of τ_1 and τ_2 and Fourier-transforms the resulting expressions, one obtains

(with $\mathbf{3}$ replaced by \mathbf{r})

$$\begin{aligned} \Gamma^N(\mathbf{r}; \omega_1 \omega_2) \\ = \sum_{j\ell} \frac{|u^j\rangle M_{j\ell}^{N+1}(\mathbf{r}) \langle u^\ell|}{(\omega_1 - \varepsilon_j + i\eta)(\omega_2 - \varepsilon_\ell + i\eta)} \\ + \sum_{\xi\chi} \frac{|v^\xi\rangle M_{\xi\chi}^{N-1}(\mathbf{r}) \langle v^\chi|}{(\omega_1 - \varepsilon_\xi - i\eta)(\omega_2 - \varepsilon_\chi - i\eta)} + \dots \end{aligned} \quad (27.52)$$

We next define the three-point irreducible electron vertex Λ^N from the reducible vertex Γ^N (the electron legs in Γ^N are missing in Λ^N) as

$$\begin{aligned} \langle \mathbf{1} | \Gamma^N(\mathbf{r}; \omega_1 \omega_2) | \mathbf{2} \rangle \\ \equiv \int \int d^3\mathbf{1}' d^3\mathbf{2}' \langle \mathbf{1} | G_{\omega_1}^N | \mathbf{1}' \rangle \langle \mathbf{1}' | \Lambda^N(\mathbf{r}; \omega_1 \omega_2) | \mathbf{2}' \rangle \\ \times \langle \mathbf{2}' | G_{\omega_2}^N | \mathbf{2} \rangle , \end{aligned} \quad (27.53)$$

and pick out the residues of the ω_1 and ω_2 poles at specific energies ε_m and ε_n . [$\Lambda^N(\mathbf{r}; \omega_1 \omega_2)$ has no such poles.] With the equivalent of the DF(HF) approximation to the Dyson equations in Eq. (27.57) below, the corresponding kets form an orthonormal set, and scalar products are calculated with respect to $\langle m |$ and $| n \rangle$. The second term on the right-hand side of Eq. (27.52) refers to hole states and is of less interest than the first term describing 1P–1P transitions. From the first term, the transition matrix element in terms of Λ^N is

$$M_{fi}^{N+1}(\mathbf{r}; k_0) = \langle f | \Lambda^N(\mathbf{r}; e_f e_i) | i \rangle . \quad (27.54)$$

Generation of a Dyson Equation

The approximation of only Coulomb ladder ee interactions in the two-point Green's function produces an infinite set of Feynman diagrams to which one end of a single transverse photon line is attached in all possible ways. A resummation of these diagrams generates the $G_{\omega, \text{Coul}}^N$ functions, which are approximated by the DF (HF) propagators written in their spectral form. The scalar products leading to Eq. (27.54) can then be taken.

A further simplification results because of the Coulomb ladder approximation, which is the same as in the four-point Green's function case: the relative time can be set equal to zero, which corresponds to integrating over the relative frequency, $\omega = \omega_1 - \omega_2$. With the total frequency defined as $\Omega = \frac{1}{2}(\omega_1 + \omega_2)$, and the definitions

$$\begin{aligned} \bar{\Lambda}^N(\mathbf{r}, \Omega) &= \frac{1}{2\pi} \int d\omega \Lambda^N\left(\mathbf{r}; \omega + \frac{1}{2}\Omega, \omega - \frac{1}{2}\Omega\right) , \\ \langle m | \bar{\Lambda}^N(\Omega) | n \rangle &= \int d^3\mathbf{r} \frac{e^{ik\cdot\mathbf{r}}}{\sqrt{2k_0}} \langle m | \bar{\Lambda}^N(\mathbf{r}, \Omega) | n \rangle , \\ \Omega_{mn} &= e_n - e_m = k_0 , \end{aligned} \quad (27.55)$$

with a relation similar to Eq. (27.55) for the quantity $\lambda_k(\mathbf{r})$ defined in Eq. (27.11), i.e.,

$$\langle m|\lambda(k_0)|n\rangle = \int d^3\mathbf{r} \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2k_0}} \langle m|\lambda_k(\mathbf{r})|n\rangle, \quad (27.56)$$

the matrix elements in the DF (HF) basis are [14, 20]

$$\begin{aligned} & \langle m|\bar{\Lambda}^N(k_0)|n\rangle \\ &= \langle m|\lambda(k_0)|n\rangle \\ &+ \sum_{aj} \left\{ \frac{1}{e_a - e_j + k_0} \left[\begin{matrix} m \\ j \end{matrix} \middle| V \right| \begin{matrix} n \\ a \end{matrix} \right] \langle a|\bar{\Lambda}^N(k_0)|j\rangle \right. \\ &\left. + \frac{1}{e_a - e_j - k_0} \left[\begin{matrix} m \\ a \end{matrix} \middle| V \right| \begin{matrix} n \\ j \end{matrix} \right] \langle j|\bar{\Lambda}^N(k_0)|a\rangle \right\}. \quad (27.57) \end{aligned}$$

As discussed in Sect. 27.2, the label a should include not just hole states but also negative energy states, which have been neglected in Eq. (27.57). Note also that only PH or HP matrix elements appear on the right-hand side of Eq. (27.57). Therefore, a closed set of inhomogeneous linear algebraic equations for $\langle b|\bar{\Lambda}^N(k_0)|\ell\rangle$ and $\langle \ell|\bar{\Lambda}^N(k_0)|b\rangle$ results from setting $m = b$, $n = \ell$ or $m = \ell$, $n = b$, respectively, in Eq. (27.57). These equations can be solved numerically, and the resulting $\langle a|\bar{\Lambda}^N(k_0)|j\rangle$ and $\langle j|\bar{\Lambda}^N(k_0)|a\rangle$ substituted in Eq. (27.57) to obtain the final result

$$M_{\text{fi}}^{N+1}(k_0) \equiv \langle f|\bar{\Lambda}^N(k_0)|i\rangle. \quad (27.58)$$

An integro-differential equation form, which provides the option of choosing alternative numerical techniques [14], is obtained from Eq. (27.57), after some rearrangement and passage to a coordinate basis. Defining $m_{\text{fi}}(k_0)$ from $\lambda(k_0)$ in analogy with the definition of $M_{\text{fi}}^{N+1}(k_0)$ from $\bar{\Lambda}^N(k_0)$ in Eq. (27.58), one has

$$\begin{aligned} M_{\text{fi}}^{N+1}(k_0) &= m_{\text{fi}}(k_0) + \sum_a (\langle a|\lambda(k_0)|A^- \rangle \\ &+ \langle A^+|\lambda(k_0)|a\rangle), \quad (27.59) \end{aligned}$$

where

$$\begin{aligned} & [h(\mathbf{r}) \mp k_0 - e_a] \langle \mathbf{r}|A^\pm \rangle + \sum_a \left[\begin{matrix} r \\ a \end{matrix} \middle| V \right| \begin{matrix} A^\pm \\ a \end{matrix} \right] \\ &= - \sum_j \langle \mathbf{r}|j\rangle \langle j|[v_\pm + \mathcal{V}_\pm]|a\rangle, \quad (27.60) \end{aligned}$$

$$\langle j|v_+|a\rangle = \left[\begin{matrix} j \\ i \end{matrix} \middle| V \right| \begin{matrix} a \\ i \end{matrix} \right], \quad \langle j|v_-|a\rangle = \left[\begin{matrix} j \\ i \end{matrix} \middle| V \right| \begin{matrix} a \\ i \end{matrix} \right], \quad (27.61)$$

$$\langle j|\mathcal{V}_\pm|a\rangle = \sum_b \left\{ \left[\begin{matrix} j \\ b \end{matrix} \middle| V \right| \begin{matrix} a \\ B_\pm \end{matrix} \right] + \left[\begin{matrix} j \\ B_\mp \end{matrix} \middle| V \right| \begin{matrix} a \\ b \end{matrix} \right] \right\}. \quad (27.62)$$

The three-point Green's function, as can be seen from this summary, describes transition amplitudes for radiative transitions between two valence states of atoms with closed shells (subshells) plus one electron (the 1P case). In the Coulomb

ladder approximation, closely related to the DF equation, the photon vertex $\langle \mathbf{1}|\Lambda^N(\mathbf{r}; \omega_1\omega_2)|\mathbf{2}\rangle$ of Eq. (27.53), is nonlocal in space, rather than the local vertex $\langle \mathbf{1}|\lambda_k(\mathbf{r})|\mathbf{2}\rangle$ of Eq. (27.11) [as follows from the factor of $\delta^3(\mathbf{1}-\mathbf{r})\delta^3(\mathbf{2}-\mathbf{r})$]. The presence of these additional nonlocal contributions to $M_{\text{fi}}^{N+1}(k_0)$ is made apparent in Eq. (27.59). The $m_{\text{fi}}(k_0)$ term is the contribution of the local vertex. Of course, if one knew the *exact* $N+1$ electron wave functions and energies, only the local vertex would enter and a GI result would be obtained. However, the length and velocity versions of Eq. (27.12) are equal and GI even in the approximation just discussed [3, 7]. Gauge invariance is an *essential* constraint on radiative transition amplitudes. It has been proven for general gauges not only in the present approximation, but also in the ones discussed below [8, 10], all of them arising in the GFA. Since the effective potential in the DF (or HF) approximation is nonlocal, the effective current must also be nonlocal in order to maintain the GI.

The somewhat more complicated Dyson equation satisfied by the nonlocal vertex corresponding to the Brueckner approximation has also been generated [22], and put in a numerically implementable form.

An alternative approximation [3, 7] for transition matrix elements, proposed earlier [2] than the one just discussed, is based on the RPA [our PH/HP case, with wave function $\bar{\chi}_{(fa)}$ the solution of Eq. (27.45)]. Reference to Eqs. (27.6), (27.7), (27.10) and (27.11) gives immediately

$$M_{fa}^N(\mathbf{r}; \omega_{(fa)}) = -\lambda_k(\mathbf{r}) \langle \mathbf{r}|\bar{\chi}_{(fa)}|\mathbf{r}\rangle, \quad (27.63)$$

where $k_0 = k = \omega_{(fa)}$ and N corresponds to atoms with a closed shell or subshell of electrons.

Aside from being a different approximation to transition amplitudes than Eqs. (27.54), (27.63) covers a different set of cases than does Eq. (27.54), since the corresponding initial states i in Eq. (27.54) are restricted to core states a in Eq. (27.63). Thus, for example, the case $N=2$ in Eq. (27.54) can describe transitions between any two valence states of Li. The corresponding case for Eq. (27.63) is $N=4$, but only transitions to a higher level, originating in the 1s or 2s level of Li, can be described by the formalism.

Finally, we shall discuss radiative transitions [8] for 2P atoms (closed shell/subshell plus two valence electrons). The general case involves a five-point nonlocal vertex. However, in the ladder approximation, this reduces to transition matrix elements which contain combinations of DF, 2P BS wave functions, and three-point functions. The final expressions are

$$\begin{aligned} & M_{\text{fi}}^{N+2}(\mathbf{r}; k_0) \\ &= \langle \bar{\zeta}_{(fp)} | \left(\frac{\bar{\Lambda}^N(\mathbf{r}, k_0)}{k_0 - \Delta H} V - V \frac{\bar{\Lambda}^N(\mathbf{r}, k_0)}{k_0 - \Delta H} \right) | \bar{\zeta}_{(iq)} \rangle. \quad (27.64) \end{aligned}$$

The expressions appearing in this equation are, in more detail, in the DF basis:

$$\left\langle \begin{matrix} m \\ n \end{matrix} \middle| \frac{\bar{\Lambda}^N(\mathbf{r}, k_0)}{k_0 - \Delta H} \middle| \begin{matrix} q \\ s \end{matrix} \right\rangle \equiv \frac{\langle m | \bar{\Lambda}^N(\mathbf{r}, k_0) | q \rangle \delta_{ns}}{k_0 + e_q - e_m}, \quad (27.65)$$

where m, n, q, s label DF states (P or H), $|s^q\rangle \equiv |qs\rangle \equiv |q\rangle|s\rangle$; Eq. (27.65) serves to define ΔH , as a difference of two DF Hamiltonians, the argument \mathbf{r} of $\bar{\Lambda}$ refers to the electron which emits the photon, and

$$\langle {}^m_n | V | \bar{\xi}_{(\tau)} \rangle = \sum_{cd} \langle {}^m_n | V | c_d \rangle \langle c_d | \bar{\xi}_{(\tau)} \rangle + \sum_{k\ell} \langle {}^m_n | V | k_\ell \rangle \langle k_\ell | \bar{\xi}_{(\tau)} \rangle. \quad (27.66)$$

In Eq. (27.66) we used the fact that, in the DF basis, $|\bar{\xi}_{(\tau)}\rangle$ only has 2P or 2H components Eqs. (27.46), (27.48).

27.5 Radiative Corrections

This section summarizes radiative corrections for 1P/1H atoms, starting from the two-point Green's function. The Dyson equations are generated and solved perturbatively for the energy to order $\alpha^5 m$ (α^3 a.u.). The perturbation theory starts from the DF solution as the zero-order one.

As done for the three-point function in Sect. 27.4, the Dyson equation for radiative corrections involving a single transverse photon is generated by expanding the two-point propagator to all orders in the Coulomb ladder approximation, inserting a transverse virtual photon in all possible ways, and then resumming. The resulting integral equation [23] is quite complicated, containing even the three-point vertex in its inhomogeneous term, as well as a mass counter term to eliminate divergences. It is sufficient for the present purposes to expand these vertices through first order matrix elements of $V_{ee} \equiv V$, but to exclude matrix elements of type $\langle {}^m_n | V | a_n \rangle$ (where a is the label for core states), since these are already included in the DF approximation [see Eq. (27.27)].

Other radiative corrections are also generated, which include Coulomb photons. Two of these corrections, involving only such photons, have already been referred to in the text between Eqs. (27.21) and (27.23). Finally, to order $\alpha^5 m$, corrections involving two transverse photons must be included.

Systematic application of the pole-shifting process in Eq. (27.23) to the one- and two-transverse-photon and the Coulomb-photon expressions yields two types of terms: first, photon exchange (of one transverse photon or of two-photons of either kind, Coulomb or transverse) between core and valence states; and second, self-energy and vacuum polarization contributions. Among the photon exchange terms,

one can identify those contributions included in other approaches (at least for a few special cases, such as those arising from a single transverse photon interaction, and from two Coulomb interactions and Coulomb–Breit interactions with positive energy intermediate electron states). These are electron correlation terms which are included as part of a MBPT calculation [5], or one which involves consideration of an infinite subset of MBPT terms [6]. They need not be re-evaluated. The terms not covered by calculations of the type in [5, 6], which are of $O(m\alpha^5 c^2)$, involve retardation in Coulomb-transverse photon exchange, negative energy intermediate electron states for two Coulomb and Coulomb-transverse photon exchanges, two transverse photon exchange, self-energy and vacuum polarization terms, as well as anomalous magnetic moment corrections.

After lengthy calculation, one obtains final results in finite analytic form, which are numerically implementable. The results given below are obtained after further approximations. First, the remnants of the original integral equation are solved iteratively. Second, the self-energy terms are calculated in a joint expansion [24–26] in α and αZ , and are thus only valid for low Z in isoelectronic sequences. Finally, there are characteristic logarithmic terms generated by low virtual photon momenta in the self-energy contributions. A standard approach is to scale these with a factor of $(\alpha Z)^2$ to obtain Bethe log (BL) terms as constants independent of α , together with constant log (CL) terms of the form $\ln(\alpha Z)^2$. The BL terms are independent of Z for hydrogenic ions, and remain nearly so for other atoms. BL and CL terms are associated with both nuclear and ee Coulomb potentials. The ee CL terms arising from core and valence self-energy terms are canceled exactly by those coming from Coulomb and transverse photon exchange. Thus, the numerous and rather complicated corresponding ee BL terms, which also are *individually* small compared to their associated CL terms, should additionally almost cancel, and are therefore neglected.

One finally obtains (with all state labels denoting principal and orbital quantum numbers as well as spin indices: $n \equiv (n, \ell; m_s)$)

$$\Delta E(n, \ell) = Z |\langle \mathbf{0} | n \rangle|^2 F(n, \ell), \quad (27.67)$$

in a.u., where $\langle \mathbf{0} | n \rangle \equiv \langle \mathbf{0} | n, 0 \rangle$ is the s-state HF wave function at the origin of coordinates, and serves to define an effective (shielded) nuclear charge $Z_{n,\text{eff}}$:

$$\langle \mathbf{r} | n, \ell \rangle \equiv \Psi_{n,\ell}(\mathbf{r}), |\langle \mathbf{0} | n \rangle|^2 \equiv \frac{1}{\pi n^3} (Z_{n,\text{eff}} \alpha)^3. \quad (27.68)$$

(Just as in hydrogen, for which the final expressions for the radiative corrections require NR and not R wave functions and energies, so in this case we use HF (NR) and not DF (R) quantities.) $F(n, \ell)$ consists of a valence or hole contribution

$F_{v,h}$, a core term $F_{\text{core}}(n, \ell)$, and one due to photon exchange between electrons $F_{\text{ee}}(n, \ell)$:

$$F(n, \ell) = F_{v,h}(n, \ell) + F_{\text{core}}(n, \ell) + F_{\text{ee}}(n, \ell), \quad (27.69)$$

$$F_{v,h}(n, \ell) = \frac{4}{3} [N(Z)\delta_{\ell 0} + L(n\ell) + U_{v,h}^{\text{so}}(n\ell)], \quad (27.70)$$

$$F_{\text{core}}(n, \ell) = \frac{4}{3Z} [N(Z)\rho(n\ell) + L_{\text{core}}(n\ell) + U(n\ell) + U_{\text{core}}^{\text{so}}(n\ell)], \quad (27.71)$$

$$F_{\text{ee}}(n, \ell) = \frac{4}{3Z} [E(Z)K^C(n\ell) + K^L(n\ell)], \quad (27.72)$$

with $U_{v,h}^{\text{so}}(n\ell)$ and $U_{\text{core}}^{\text{so}}(n\ell)$ being the spin-orbit terms,

$$N(Z) = \ln \frac{1}{(Z\alpha)^2} + \frac{19}{30} + Z\alpha C_5, \quad (27.73)$$

$$C_5 = 3\pi \left(1 + \frac{11}{128} - \frac{1}{2} \ln 2 \right), \quad (27.74)$$

$$E(Z) = -\frac{7}{2} \ln \frac{1}{Z\alpha} + \frac{59}{20} - \frac{9}{8}\pi, \quad (27.75)$$

$$L(n\ell) = \frac{i/4\pi}{|\langle \mathbf{0} | n \rangle|^2} \langle n, \ell | \left[\mathbf{p} \cdot \mathcal{L}_B(n\ell) \frac{\mathbf{r}}{r^3} - \frac{\mathbf{r}}{r^3} \mathcal{L}_B(n\ell) \cdot \mathbf{p} \right] | n, \ell \rangle, \quad (27.76)$$

$$\mathcal{L}_B(n\ell) \equiv \ln \frac{Z^2}{2|e_n - H|}, \quad (27.77)$$

H the HF Hamiltonian, $e_n \equiv e(n\ell)$ the HF energy,

$$U_{v,h}^{\text{so}}(n\ell) = \frac{3/16\pi}{|\langle \mathbf{0} | n \rangle|^2} \langle n | \frac{1}{r^3} | n \rangle C_\ell, \quad (27.78)$$

where

$$C_\ell = \begin{cases} \ell & j = \ell + \frac{1}{2} \\ -(\ell + 1) & j = \ell - \frac{1}{2} \end{cases}, \quad (27.79)$$

$$\rho(n\ell) = \frac{i/4\pi}{|\langle \mathbf{0} | n \rangle|^2} \sum_a \sum_{jk} \left\{ \frac{(e_k - e_j)(e_a - 2e_k + e_j)}{e_a - e_j} \times \left[{}^n_a V | j \right] \langle j | \mathbf{r} | k \rangle \cdot \langle k | \mathbf{p} | a \rangle + \text{c.c.} \right\}, \quad (27.80)$$

$$L_{\text{core}}(n\ell) = \frac{i/4\pi}{|\langle \mathbf{0} | n \rangle|^2} \sum_a \sum_{jk} \left\{ \frac{(e_k - e_j)(e_a - 2e_k + e_j)}{e_a - e_j} \times \left[{}^n_a V | j \right] \ln \frac{Z^2}{2|e_a - e_k|} \langle j | \mathbf{r} | k \rangle \cdot \langle k | \mathbf{p} | a \rangle + \text{c.c.} \right\}, \quad (27.81)$$

$$U_{(1)}(n\ell) = \frac{1/2\pi}{|\langle \mathbf{0} | n \rangle|^2} \sum_a \left\{ \langle a | \mathbf{p}^2 | a \rangle \left[{}^n_a V | a \right] - \left[{}^n_{(a')} V | a \right] - \left(\left[{}^{(b')}_a V | a \right] + \text{c.c.} \right) \delta_{nb} \right\}, \quad (27.82)$$

$$U_{(2)}(n\ell) = \frac{i/2\pi}{|\langle \mathbf{0} | n \rangle|^2} \sum_a \sum_{k < q} \left\{ \frac{(2e_a - e_k - e_q)}{e_q - e_k} \left[{}^n_q V | k \right] \times \left(\ln \left| \frac{e_a - e_q}{e_a - e_k} \right| + 2 \right) \langle a | \mathbf{p} | q \rangle \cdot \langle k | \mathbf{p} | a \rangle + \text{c.c.} \right\}, \quad (27.83)$$

$$U_{\text{core}}^{\text{so}}(n\ell) = \frac{3/16\pi}{|\langle \mathbf{0} | n \rangle|^2} \sum_{aj} \left\{ \frac{\delta_{\ell a \ell_j}}{e_a - e_j} \left[{}^n_a V | j \right] \times \langle j | \frac{1}{r^3} | a \rangle C_\ell + \text{c.c.} \right\}, \quad (27.84)$$

$$K^C(n\ell) = \frac{1}{|\langle \mathbf{0} | n \rangle|^2} \sum_a \left[{}^n_a \delta^3(\mathbf{x} - \mathbf{y}) \right]_a, \quad (27.85)$$

$$K^L(n\ell) = \frac{7/2}{|\langle \mathbf{0} | n \rangle|^2} \sum_a \left[{}^n_a \frac{1}{4\pi} \nabla^2 \times \left(\frac{\ln(Z|\mathbf{x} - \mathbf{y}|) + \gamma}{|\mathbf{x} - \mathbf{y}|} \right) \right]_a, \quad (27.86)$$

where

$$U(n\ell) \equiv U_{(1)}(n\ell) + U_{(2)}(n\ell), \quad (27.87)$$

$$\langle \mathbf{r} | (a)' \rangle \equiv \frac{d}{dr} \langle \mathbf{r} | a \rangle, \quad (27.88)$$

and γ is the Euler–Mascheroni constant. As in Eq. (27.27), x refers to the top row and y to the bottom row in the two-row expression in Eq. (27.86).

$L(n\ell)$, which is associated with the valence electron and the nuclear Coulomb potential, has the form of a hydrogenic BL, except that it is calculated with HF wave functions and energies. $L_{\text{core}}(n\ell)$ comes from BL terms associated with core electrons.

The expressions appearing in Eqs. (27.80), (27.81), and (27.83) originate from the double commutator $[\mathbf{p} \cdot [\mathbf{p}, H]]$, which is then approximated by using the commutator $[\mathbf{r}, H] \approx i\mathbf{p}$. This is not an exact result because the ee exchange term in the HF potential is neglected. One thus obtains [13]

$$\langle m | [\mathbf{p} \cdot [\mathbf{p}, H]] | n \rangle \approx i(e_n - 2e_k + e_m)(e_k - e_n) \langle m | \mathbf{p} | k \rangle \cdot \langle k | \mathbf{r} | n \rangle. \quad (27.89)$$

A less accurate approximation is [12]

$$4\pi Z \delta^3(\mathbf{r}) \approx [\mathbf{p} \cdot [\mathbf{p}, H]]. \quad (27.90)$$

Using the left-hand side of this equation instead of the approximation Eq. (27.89) to the right-hand side would lead to only s-state a, j and p-state k contributions in Eq. (27.80) and alternative forms of Eqs. (27.81) and (27.83).

The major part of the contribution to the energy due to radiative corrections comes from $F_{v,h}(n, 0)$ (s-states), and

numerical tests indicate that the principal effect in this term comes from the renormalization of the electron density at the coordinate origin due to electron shielding. This reduction occurs because the shielded wave function is more spread out than the unshielded one. Thus, one can extend the above results semi-empirically to high Z (for which $F_{\text{core}}(n, \ell)$ and $F_{\text{ee}}(n, \ell)$ play a much smaller role because of their $1/Z$ dependence) by using the hydrogenic results [27] for high Z , i.e., replacing Z^4 for hydrogen by $Z(Z_{n,\text{eff}})^3$ for 1P/1H atoms (where $Z_{n,\text{eff}}$ is the shielded nuclear charge number, defined in Eq. (27.68), and Z is the unshielded nuclear charge number). The results obtained in this way are competitive with other evaluations of ΔE_n [28].

Finally, there is a correction to $F(n, \ell)$ for smaller Z when the integral equations for the self-energy and vacuum polarization contributions are solved more accurately than by iteration. These corrections play little role in s-state energies, but are somewhat more important in p-states for the hard core case (closed shells, $N = 2, 10$, etc.). They are expected to provide a much more significant contribution in the soft core case (closed *subshells*, $N = 4, 12$, etc.).

The correction is based on the simpler approximation given in Eq. (27.90) of the more accurate Eq. (27.89). It is given by

$$\delta F(n, \ell) = \frac{1}{Z \langle \mathbf{0} | n \rangle^2} \sum_a \sum_j^f \left\{ \frac{\left[\begin{smallmatrix} n \\ a \end{smallmatrix} | V \begin{smallmatrix} n \\ j \end{smallmatrix} \right]}{e_a - e_j} \left[\langle j | \mathcal{E} | a \rangle - Z \mathcal{F}_{\text{v,h}}^{(0)}(j | \mathbf{0} \rangle \langle \mathbf{0} | a \rangle \right] + \text{c.c.} \right\}, \quad (27.91)$$

where

$$\langle j | \mathcal{E} | a \rangle = Z \mathcal{F}_{\text{v,h}}^{(0)}(j | \mathbf{0} \rangle \langle \mathbf{0} | a \rangle + \sum_b \sum_k^f \left(\frac{\left[\begin{smallmatrix} j \\ b \end{smallmatrix} | V \begin{smallmatrix} a \\ k \end{smallmatrix} \right]}{e_b - e_k} \left[\langle k | \mathcal{E} | b \rangle + \text{c.c.} \right] \right), \quad (27.92)$$

$$\mathcal{F}_{\text{v,h}}^{(0)} = \frac{4}{3} \{ N(Z) + L \}. \quad (27.93)$$

The inhomogeneous term in Eq. (27.92) appears only for states $|j\rangle$ and $|a\rangle$ which are s-states. L in Eq. (27.93) is taken to be a constant, an approximation sufficient for the desired accuracy, and reflects the fact that $L(n, 0)$ for s-states is essentially constant as a function of radial quantum number,

and is approximately the same for hydrogen and the HF approximation.

In order to obtain the correction $\delta F(n, \ell)$ of Eq. (27.91), it is necessary first to solve the coupled inhomogeneous linear equations of Eq. (27.92). While the sum \sum_a over core states is always over a finite number of discrete states, the symbol \sum_j^f denotes an infinite sum over discrete bound valence states and an integral over the continuum of such states. Indeed, expressions of this type occur throughout the GFA. They can be dealt with by the use of finite basis techniques, for example the B-spline approach [29, 30].

Abstract

Theoretical issues in bound state quantum electrodynamics are discussed with emphasis on a unified derivation of radiative and recoil corrections with the use of Green functions.

Keywords

effective field theory · vacuum polarization · Lamb shift · order perturbation theory · Feynman gauge

28.1 Introduction

Quantum electrodynamics (QED) is now understood to be a component of the Standard Model, the theory which describes the strong, weak, and electromagnetic interactions in the framework of quantum field theory (QFT). It was historically the first QFT, describing the interactions of electrons and photons, consistently incorporating quantum mechanics

and relativity. Many of the seminal papers on the subject are collected in [1]. Corrections to the lowest order predictions of the theory are proportional to powers of α , the fine structure constant. However, difficulties are encountered with ultraviolet divergent integrals when setting up perturbation theory in this small ($\approx 1/137$) parameter, and while the first papers on QED date from 1928, the difficulties were not overcome until 1947 [2]. Once the modern renormalized form of QED was established, work on the perturbation expansion in α could proceed, and efforts by many researchers that continue to the present day have led to theoretical predictions of unparalleled accuracy for a number of systems. The hydrogen atom in particular plays a central role in QED tests, and the breaking of the Dirac degeneracy between the $2s$ and $2p_{1/2}$ states, the Lamb shift, will be discussed in some detail below. Along with the Lamb shift, corrections to the Dirac equation's prediction $g = 2$, first explained by *Schwinger* [3], are of central importance in QED. As bound state issues are emphasized here, we note only that this anomalous magnetic moment of the electron was first detected in hydrogen hyperfine splitting and Zeeman effect experiments, and that its present status is discussed in Chap. 29 "Tests of Fundamental Physics" in this volume along with a number of other extraordinarily high-precision tests of the theory.

It is the purpose of this chapter to discuss how the theory is applied to bound state problems. While almost every textbook on QFT describes the basic structure of QED, the applications given are usually to calculate scattering cross sections, the evaluation of one-loop radiative corrections, and the implementation of the renormalization program. The free electron propagator, which has a relatively simple form in momentum space, is used in the one-loop calculations. However, most of the precision tests of QED involve electrons that are bound, generally in a hydrogen-like atom. Even for the anomalous magnetic moment of the electron, which is calculated in terms of free Feynman diagrams, the electron is, in fact, bound in the constant magnetic field of a Penning trap [4]. While most QED effects require the evaluation of loop diagrams, these bound state calculations have rela-

tively unfamiliar features that will be concentrated on here. It is, of course, important to test free QED with scattering experiments at the highest possible energies. To a large degree these tests have now merged with tests of the Standard Model. Experiments, for example, on electron–positron annihilation into muon or tau pairs have to include both the photon and the Z boson in the intermediate state along with a unified treatment of radiative corrections [5].

The fact that QED is part of the Standard Model affects bound states in two notable ways. Because of the weak interactions, parity nonconserving transitions become possible through Z boson exchange, as discussed elsewhere in this volume. The strong interactions, which in principle describe the nucleus of the bound state in terms of QCD, cannot yet provide precise predictions for charge radii and other nuclear properties. This leads to limitations on predictions for atomic structure. In this case, if QED is understood well enough, and accurate experiments are available, atomic spectroscopy can be used to obtain information about nuclear properties. At the time of this writing a prominent example of this is the case of muonic hydrogen, where measurements imply a smaller proton size than had been expected [6].

The Lamb shift in hydrogen is smaller than the atomic unit of energy ($1 \text{ a.u.} = m_e c^2 \alpha^2$) by a factor α^3 , under one part per million (ppm). For almost all electromagnetically bound states such a tiny correction is negligible compared to the uncertainty in the energy when solving the many-electron Schrödinger equation, $H\psi = E\psi$, where

$$H \equiv \sum_i^N \left(\frac{\mathbf{p}_i^2}{2m} - \frac{Z\alpha\hbar c}{r_i} \right) + \sum_{i>j=1}^N \frac{\hbar c\alpha}{|\mathbf{r}_i - \mathbf{r}_j|} \quad (28.1)$$

$$\psi = \psi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N).$$

Solving for a particular bound state energy E_v this way we refer to as the Hamiltonian approach. For a single electron bound to any positively charged nucleus (which will be referred to as hydrogen for simplicity in what follows) this uncertainty is not present, and QED corrections are easily identified. For many-electron atoms, however, the electron–electron interaction term usually makes it too difficult to solve for E_v with the accuracy required to see such corrections. The techniques used to deal with the many-body problem are rather different from those used for QED corrections. While attempts to create a unified approach have been made [7], the most advanced atomic QED calculations have been carried out for hydrogen [8, 9]. To study QED in atoms with more than one electron accurate solutions to the structure problem are required, which are available for few electron atoms, particularly helium, and certain highly charged ions, as will be discussed below.

The Coulomb potential of the nucleus in Eq. (28.1),

$$V_C(r) \equiv -\frac{Z\alpha\hbar c}{r}, \quad (28.2)$$

is responsible for the dominant physics of binding. It is, thus, very useful to incorporate it into bound state QED calculations, which we will do here when we introduce Furry picture QED [10]. This is an example of an external field approximation [11]. Such approximations are very good for an electron in a classical electric or magnetic field, as a single electron has essentially no effect on the charge distributions and currents that create the external field. In an atom, the success of the Schrödinger equation shows that even a single nucleus effectively creates an external field. In this case, the fact that the nucleus is a single particle leads to observable corrections to the external field approximation. They are called recoil corrections, and if the nucleus is taken to have mass m_N , begin in order m/m_N . They vanish in the limit of infinite nuclear mass, which is called the nonrecoil limit.

The first QED treatments of recoil corrections were by *Salpeter* [12, 13], using the equation he had earlier derived with *Bethe* [14]. They formed a field theoretic function of the total energy of hydrogen E that had a pole at $E = E_v$, with recoil corrections identified as the difference of E_v with its nonrecoil limit.

This approach can also be used to calculate nonrecoil corrections in bound state QED, and the central purpose of this chapter is to show how this technique allows a unified treatment of both types of QED correction. The treatment also leads to a rigorous justification of the external field approximation for hydrogen.

Three central objects in the following are the electron propagator for one electron, the electron–nucleus propagator, and the many-electron propagator. While the terms propagator and Green function are basically synonymous, it is convenient to designate propagators as functions of time, and Green functions as time Fourier transforms depending on an energy E . We will show that the latter have poles when $E = E_v$ and develop perturbation theory for QED using this behavior. While QED has a Hamiltonian, the analysis that will be described here is based on the Green functions of the theory, and the approach is fundamentally different from the Hamiltonian approach. While for most bound state problems the Hamiltonian approach suffices, there are situations in which an approach grounded in field theory is absolutely necessary.

This chapter is organized as follows. In the next section free QED is set up in Coulomb gauge, and photon and electron propagators introduced. The perturbation expansion in the interaction picture is described, and the connection with Feynman gauge, which is particularly useful for calculating loop corrections, is shown.

In the next section, the Green functions for the free and bound electrons are formed as time Fourier transforms of the propagators, and the field theory based analog of Rayleigh–Schrödinger perturbation theory developed. The formulas for the one-loop electron self-energy and vacuum polarization

are derived and analyzed, and a short discussion of the two-loop Lamb shift is given.

In the following section, the approach is extended to electron–nucleus scattering, with emphasis placed on the emergence of the bound electron propagator in the limit of infinite nuclear mass. The perturbation theory for recoil corrections is described.

We then turn to the generalization of the method to many-electron atoms, and mention some applications of QED to highly charged many-electron ions. In the final section an alternative to the Bethe–Salpeter approach to recoil corrections is given, and remarks about nonrelativistic QED (NRQED) [15] are made.

28.2 Basic QED Formalism

In the following, we work in SI units, keeping all factors of c , \hbar , and ϵ_0 . The photon momentum \mathbf{q} is understood to be \hbar times the associated wavenumber \mathbf{k} . The electron and proton charges are denoted q_e and q_p . The elementary charge e is understood to be positive, so $q_e = -e$ and $q_p = e$. In calculations, we will replace e^2 with $4\pi\hbar c\epsilon_0\alpha$. The charge and mass of the nucleus are $q_N = Ze$ and m_N . Before treating bound states, we set up QED for free electrons. The electron field will be understood to describe either an electron or positron state, and the vacuum is the state with zero electrons, positrons, and photons, indicated by

$$\begin{aligned} b_s(\mathbf{p})|0\rangle &= 0 \\ d_s(\mathbf{p})|0\rangle &= 0 \\ a_\lambda(\mathbf{q})|0\rangle &= 0. \end{aligned} \quad (28.3)$$

The destruction operators above have creation operator counterparts, and the only cases in which photon operators do not commute, or electron operators do not anticommute, are

$$\begin{aligned} [a_{\lambda_1}(\mathbf{q}_1), a_{\lambda_2}^\dagger(\mathbf{q}_2)] &= (2\pi)^3 \delta_{\lambda_1\lambda_2} \delta^3(\mathbf{q}_1 - \mathbf{q}_2) \\ \{b_{s_1}(\mathbf{p}_1), b_{s_2}^\dagger(\mathbf{p}_2)\} &= \{d_{s_1}(\mathbf{p}_1), d_{s_2}^\dagger(\mathbf{p}_2)\} \\ &= (2\pi)^3 \delta_{s_1s_2} \delta^3(\mathbf{p}_1 - \mathbf{p}_2). \end{aligned} \quad (28.4)$$

The electron field operator is given by

$$\begin{aligned} \psi(\mathbf{x}, t) &= \int \frac{d\mathbf{p}}{(2\pi)^3} \sqrt{\frac{mc^2}{E_p\hbar^3}} \sum_s \left[e^{-ip\cdot x/\hbar} b_s(\mathbf{p}) u(\mathbf{p}, s) \right. \\ &\quad \left. + e^{ip\cdot x/\hbar} d^\dagger(\mathbf{p}) v(\mathbf{p}, s) \right], \end{aligned} \quad (28.5)$$

with $p\cdot x = E_p t - \mathbf{p}\cdot\mathbf{x}$, $E_p = \sqrt{(mc^2)^2 + c^2\mathbf{p}^2}$; $u(\mathbf{p}, s)$ and $v(\mathbf{p}, s)$ are Dirac spinors that form the projection operators

$$\Lambda_+(\mathbf{p}) \equiv \sum_s u(\mathbf{p}, s) \bar{u}(\mathbf{p}, s) = \frac{E_p \gamma_0 - c\boldsymbol{\gamma}\cdot\mathbf{p} + mc^2}{2E_p}$$

$$\Lambda_-(\mathbf{p}) \equiv \sum_s v(\mathbf{p}, s) \bar{v}(\mathbf{p}, s) = \frac{E_p \gamma_0 + c\boldsymbol{\gamma}\cdot\mathbf{p} - mc^2}{2E_p}. \quad (28.6)$$

The noncovariant normalization $u^\dagger(\mathbf{p}, s)u(\mathbf{p}, s') = \delta_{ss'}$, $v^\dagger(\mathbf{p}, s)v(\mathbf{p}, s') = \delta_{ss'}$ is used.

The charge density and current in terms of the electron field operators are

$$\begin{aligned} \rho(\mathbf{x}, t) &= \psi^\dagger(\mathbf{x}, t)\psi(\mathbf{x}, t) \\ \mathbf{j}(\mathbf{x}, t) &= \psi^\dagger(\mathbf{x}, t)\boldsymbol{\alpha}\psi(\mathbf{x}, t). \end{aligned} \quad (28.7)$$

Normal ordering of the operators, in which destruction operators are moved to the right and creation to the left, is left implicit. The free electron Hamiltonian is

$$H_0(t) = \int d\mathbf{x} \bar{\psi}(\mathbf{x}, t) [-i\hbar c\boldsymbol{\alpha}\cdot\nabla + mc^2\beta] \psi(\mathbf{x}, t); \quad (28.8)$$

H_0 without t dependence indicated refers to the operator in square brackets.

Turning to the quantization of the electromagnetic field, as we use Coulomb gauge,

$$\nabla\cdot\mathbf{A}(\mathbf{x}, t) = 0. \quad (28.9)$$

This gives a constraint when quantizing $\mathbf{A}(\mathbf{x}, t)$, so that only the physical degrees of freedom of photons need be dealt with, and the field operator is

$$\begin{aligned} \mathbf{A}(\mathbf{x}, t) &= \sqrt{\frac{1}{\hbar c\epsilon_0}} \sum_{\lambda=1}^2 \int \frac{d\mathbf{q}}{(2\pi)^3 \sqrt{2|\mathbf{q}|}} \\ &\quad \times \left[a(\lambda, \mathbf{q}) \hat{\epsilon}_\lambda(\hat{\mathbf{q}}) e^{-iq\cdot x/\hbar} + a^\dagger(\lambda, \mathbf{q}) \hat{\epsilon}_\lambda(\hat{\mathbf{q}}) e^{iq\cdot x/\hbar} \right]. \end{aligned} \quad (28.10)$$

The scalar potential, which is not quantized, is fixed by

$$\nabla^2\phi(\mathbf{x}, t) = -\frac{\rho(\mathbf{x}, t)}{\epsilon_0}, \quad (28.11)$$

and the Hamiltonian describing the electrostatic energy is

$$\begin{aligned} H_C(t) &= \frac{e^2}{8\pi\epsilon_0} \int d\mathbf{x} \int d\mathbf{y} \\ &\quad \times \frac{\psi^\dagger(\mathbf{x}, t)\psi(\mathbf{x}, t)\psi^\dagger(\mathbf{y}, t)\psi(\mathbf{y}, t)}{|\mathbf{x} - \mathbf{y}|}. \end{aligned} \quad (28.12)$$

If the negative energy summation is removed from ψ , this Hamiltonian can be used to organize atomic many-body perturbation theory (MBPT) calculations [16]. Historically,

although QED was developed first, the power of the diagrammatic approach was later applied to many-electron atoms starting with the work of *Kelly* [17].

The remaining part of the interaction Hamiltonian comes from the minimal coupling replacement $c\boldsymbol{\alpha} \cdot \mathbf{p} \rightarrow c\boldsymbol{\alpha} \cdot (\mathbf{p} - q_e \mathbf{A}(\mathbf{x}, t))$,

$$H_T(t) = -q_e c \int d\mathbf{x} \mathbf{A}(\mathbf{x}, t) \cdot \psi^\dagger(\mathbf{x}, t) \boldsymbol{\alpha} \psi(\mathbf{x}, t), \quad (28.13)$$

where the subscript T stands for transverse.

The sum of $H_C(t)$ and $H_T(t)$ is the interaction Hamiltonian $H_I(t)$ and enters perturbation theory through its role in the time evolution operator $U(t_2, t_1)$. After transforming from the Schrödinger to the interaction picture through

$$|\psi_I(t)\rangle = e^{iH_0(t)t/\hbar} |\psi_S(t)\rangle, \quad (28.14)$$

it is given by

$$\begin{aligned} U(t_2, t_1) &= 1 + \frac{1}{i\hbar} \int_{t_1}^{t_2} dt H_I(t) + \left(\frac{1}{i\hbar}\right)^2 \int_{t_1}^{t_2} dt \\ &\quad \times \int_{t_1}^t dt' H_I(t) H_I(t') + \dots \\ &= 1 + \frac{1}{i\hbar} \int_{t_1}^{t_2} dt H_I(t) + \frac{1}{2!} \left(\frac{1}{i\hbar}\right)^2 \int_{t_1}^{t_2} dt \\ &\quad \times \int_{t_1}^t dt' T(H_I(t) H_I(t')) + \dots \\ &= T\left(e^{\frac{1}{i\hbar} \int_{t_1}^{t_2} dt H_I(t)}\right). \end{aligned} \quad (28.15)$$

Of particular importance is its value for $t_1 = -\infty, t_2 = \infty$, denoted S , and the matrix elements, the S -matrix,

$$\begin{aligned} S &\equiv U(\infty, -\infty) \\ S_{fi} &= \langle f | S | i \rangle. \end{aligned} \quad (28.16)$$

When one encounters the vacuum expectation value of a product of operators, a theorem due to Wick allows one to rearrange it in terms of creation and annihilation operators multiplying factors of the electron and photon propagators,

$$S_F(x, y) \equiv -i \langle 0 | T(\psi(x, t) \bar{\psi}(y, t')) | 0 \rangle \quad (28.17)$$

and

$$D^{ij}(x, y) \equiv -i \langle 0 | T(A^i(\mathbf{x}, t) A^j(\mathbf{y}, t')) | 0 \rangle. \quad (28.18)$$

Their form in momentum space is relatively simple,

$$S_F(x, y) = \frac{1}{\hbar^3} \int \frac{d^4 p}{(2\pi)^4} \frac{e^{-ip \cdot (x-y)/\hbar}}{p_0 \gamma_0 - \vec{\gamma} \cdot \vec{p} - mc + i\epsilon}, \quad (28.19)$$

$$D^{ij}(x, y) = \frac{1}{\epsilon_0 \hbar c} \int \frac{d^4 q}{(2\pi)^4} e^{-iq \cdot (x-y)/\hbar} \frac{\left(\delta_{ij} - \frac{q_i q_j}{q^2}\right)}{q_0^2 - \mathbf{q}^2 + i\epsilon}; \quad (28.20)$$

$D^{ij}(x, y)$ is called the transverse photon propagator.

The compact form for $S_F(x, y)$ given above can be expanded into a form that separates positive and negative energy states,

$$\frac{1}{\not{p} - mc + i\epsilon} = \frac{\Lambda_+(\mathbf{p})}{p_0 - E_p/c + i\epsilon} + \frac{\Lambda_-(\mathbf{p})}{p_0 + E_p/c - i\epsilon}, \quad (28.21)$$

which will be used later.

If one wants the S -matrix for electron–electron scattering, for example, one chooses

$$\begin{aligned} |i\rangle &= b^\dagger(\mathbf{p}_1, s_1) b^\dagger(\mathbf{p}_2, s_2) |0\rangle \\ \langle f| &= \langle 0 | b(\mathbf{p}_3, s_3) b(\mathbf{p}_4, s_4) \end{aligned} \quad (28.22)$$

(the states are properly antisymmetrized because the operators anticommute) and applies Wick's theorem. This procedure is greatly facilitated by a set of rules introduced by Feynman; they can be learned quickly, and correct QED matrix elements can be set up in an automatic way.

Unless the initial and final states are identical, the first contribution to S_{fi} comes from the term linear in H_C . Another term with the same number of factors q_e comes from the quadratic term with two H_T 's. The latter involves a transverse photon propagator between the electrons. It is convenient to introduce a corresponding Coulomb photon propagator in order to rewrite the H_C term so that it also arises from a quadratic term. This can be done by including with D^{ij} another propagator, D^{00} . If one generalizes D^{ij} to $D^{\mu\nu}$, with $D^{0i} = D^{i0} = 0$ and

$$\begin{aligned} D^{00}(x, y) &= \frac{1}{\epsilon_0 \hbar c} \int \frac{d^4 q}{(2\pi)^4} e^{-iq \cdot (x-y)/\hbar} \frac{1}{q^2} \\ &= \frac{\delta(t-t')}{4\pi\epsilon_0 |\mathbf{x}-\mathbf{y}| c^2}, \end{aligned} \quad (28.23)$$

one reproduces S_{fi} by using

$$H_I(t) = q_e c \int d\mathbf{x} A^\mu(\mathbf{x}, t) \bar{\psi}(\mathbf{x}, t) \gamma^\mu \psi(\mathbf{x}, t) \quad (28.24)$$

and using the photon propagator in Coulomb gauge described above.

This simpler form for $H_I(t)$ comes at the apparent cost of the more complicated photon propagator just described, but the photon propagator is always encountered in the form $A_\mu(q)D^{\mu\nu}B_\nu(q)$. If one requires $q^\mu A_\mu = 0$ and $q^\mu B_\mu = 0$, a short calculation shows

$$\begin{aligned} \frac{A_0 B_0}{q^2} + \frac{q^2 \mathbf{A} \cdot \mathbf{B} - \mathbf{A} \cdot \mathbf{q} \mathbf{B} \cdot \mathbf{q}}{q^2(q_0^2 - q^2)} &= -\frac{A_0 B_0 - \mathbf{A} \cdot \mathbf{B}}{q_0^2 - q^2} \\ &= -\frac{A_\mu B_\nu g^{\mu\nu}}{q^2}, \end{aligned} \quad (28.25)$$

where we will suppress the $i\varepsilon$ in the following for brevity. Because of this one can use the simpler Feynman gauge propagator

$$D_F^{\mu\nu}(x, y) = \frac{1}{\hbar c \varepsilon_0} \int \frac{d^4 q}{(2\pi)^4} e^{-iq \cdot (x-y)/\hbar} \frac{-g^{\mu\nu}}{q^2}. \quad (28.26)$$

The requirement that $A^\mu q_\mu = B^\mu q_\mu = 0$ can be shown to be satisfied as long as a gauge invariant set of diagrams are evaluated together. In the following, we will use both gauges: Coulomb gauge is useful for recoil calculations and Feynman gauge for calculations involving loops with ultraviolet divergences.

In cases when a fixed external electromagnetic potential is present, one would decompose

$$A^\mu(x) \rightarrow A_{\text{ext}}^\mu(x) + A^\mu(x), \quad (28.27)$$

quantizing only the second term. This is the external field approximation [11]. The part of H_I involving the external field can then be grouped with $H_0(t)$ so that, restricting our attention to external fields constant in time,

$$\begin{aligned} H_0(t) = \int d\mathbf{x} \psi^\dagger(\mathbf{x}, t) [-i\hbar c \boldsymbol{\alpha} \cdot \nabla - q_e c \boldsymbol{\alpha} \cdot \mathbf{A}_{\text{ext}}(\mathbf{x}) \\ + mc^2 \beta + V(\mathbf{x})] \psi(\mathbf{x}, t), \end{aligned} \quad (28.28)$$

with $q_e A_{\text{ext}}^0(\mathbf{x}) = V(\mathbf{x})$. If the removal of the quantized part of H_I is carried out in this case, the interaction picture is referred to as the Furry picture [10]. This form of QED is extremely useful, as it builds in the dominant physics of binding, although at the cost of a more complicated electron propagator.

In Furry picture QED, the photon propagator is unchanged, but the electron propagator now depends on both \mathbf{x} and \mathbf{y} rather than only on their difference. We distinguish the free electron propagator $S_F(x, y)$ from the bound propagator by including a suffix V , and define the related Green function through

$$S_F^V(x, y) = \int \frac{dE}{2\pi} e^{-iE(t-t')/\hbar} G(E, \mathbf{x}, \mathbf{y}) \gamma_0. \quad (28.29)$$

When $V(\mathbf{r})$ is the Coulomb potential, we call $S_F^V(x, y)$ the Coulomb propagator, and $G(E, \mathbf{x}, \mathbf{y})$ the Coulomb Green function. In general, the Green function satisfies

$$[E - (H_0 + V(\mathbf{x}))]G(E, \mathbf{x}, \mathbf{y}) = \delta^3(\mathbf{x} - \mathbf{y}). \quad (28.30)$$

All information about the energy eigenvalues and eigenfunctions is contained in $G(E, \mathbf{x}, \mathbf{y})$. This is most clearly seen when it is represented as a spectral decomposition,

$$G(E, \mathbf{x}, \mathbf{y}) = \sum_m \frac{\psi_m(\mathbf{x}) \psi_m^\dagger(\mathbf{y})}{E - \varepsilon_m(1 - i\delta)}. \quad (28.31)$$

In this form, one identifies the eigenvalues ε_m as the position of simple poles of E , with the eigenvectors associated with the residue of the pole. (If there is a continuous distribution of energies, the pole is replaced with a branch cut.)

To isolate a particular pole $m = v$, we form the projection

$$G_{vv}(E) \equiv \int d\mathbf{x} \int d\mathbf{y} \psi_v^\dagger(\mathbf{x}) G(E, \mathbf{x}, \mathbf{y}) \psi_v(\mathbf{y}), \quad (28.32)$$

which collapses the sum over m in the spectral decomposition, giving

$$G_{vv}(E) = \frac{1}{E - \varepsilon_v}. \quad (28.33)$$

The related identities

$$\begin{aligned} \int d\mathbf{x} \psi_v^\dagger(\mathbf{x}) G(E, \mathbf{x}, \mathbf{y}) &= \frac{1}{E - \varepsilon_v} \psi_v^\dagger(\mathbf{y}) \\ \int d\mathbf{y} G(E, \mathbf{x}, \mathbf{y}) \psi_v(\mathbf{y}) &= \frac{1}{E - \varepsilon_v} \psi_v(\mathbf{x}) \end{aligned} \quad (28.34)$$

will also be used.

For the free case, we denote the Green function as $G_0(E, \mathbf{x}, \mathbf{y})$. It satisfies Eq. (28.30) with $V = 0$, and a useful representation of it is
